$$G_0(E, \mathbf{x}, \mathbf{y}) = \frac{1}{\hbar^3} \int \frac{d\mathbf{p}}{(2\pi)^3} \frac{e^{i\mathbf{p} \cdot (\mathbf{x}-\mathbf{y})/\hbar}}{E \gamma_0 - c \boldsymbol{\gamma} \cdot \mathbf{p} - mc^2 + i\varepsilon} \gamma_0. \quad (28.35)$$

The two functions are related by

$$\begin{aligned} G(E, \mathbf{x}, \mathbf{y}) &= G_0(E, \mathbf{x}, \mathbf{y}) \\ &+ \int d\mathbf{r} G_0(E, \mathbf{x}, \mathbf{r}) V(\mathbf{r}) G(E, \mathbf{r}, \mathbf{y}), \end{aligned} \quad (28.36)$$

which leads to the expansion

$$\begin{aligned}
 G(E, \mathbf{x}, \mathbf{y}) &= G_0(E, \mathbf{x}, \mathbf{y}) \\
 &+ \int d\mathbf{r}_1 G_0(E, \mathbf{x}, \mathbf{r}_1) V(\mathbf{r}_1) G_0(E, \mathbf{r}_1, \mathbf{y}) \\
 &+ \int d\mathbf{r}_1 \int d\mathbf{r}_2 G_0(E, \mathbf{x}, \mathbf{r}_1) V(\mathbf{r}_1) \\
 &\quad \times G_0(E, \mathbf{r}_1, \mathbf{r}_2) V(\mathbf{r}_2) G_0(E, \mathbf{r}_2, \mathbf{y}) + \dots
 \end{aligned} \tag{28.37}$$

A characteristic difficulty of the atomic bound state problem is that going to the next order in the expansion of $G(E, \mathbf{x}, \mathbf{y})$ does not always lead to additional powers of α . Each term is nominally of the same order, and in many cases, the series must be summed to all orders. However, the expansion remains very useful. One reason for this is that the ultraviolet divergences of QED are generally associated with the first and second terms of the expansion, and isolating them allows manipulations to simplify loop calculations. As those are carried out in momentum space, we will need the momentum space version of the expansion of Eq. (28.37),

$$\begin{aligned}
 G(E, \mathbf{p}, \mathbf{q}) \gamma_0 &= \hbar^3 \left[\frac{(2\pi)^3 \delta^3(\mathbf{p} - \mathbf{q})}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{p} - mc^2} \right. \\
 &+ \frac{1}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{p} - mc^2} \gamma_0 \frac{4\pi Z\alpha c}{|\mathbf{p} - \mathbf{q}|^2} \\
 &\times \frac{1}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{q} - mc^2} \\
 &+ \frac{1}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{p} - mc^2} \gamma_0 \int \frac{d\mathbf{k}}{(2\pi)^3} \\
 &\times \frac{4\pi Z\alpha c}{|\mathbf{p} - \mathbf{k}|^2} \frac{1}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{p} - mc^2} \\
 &\times \gamma_0 \frac{4\pi Z\alpha c}{|\mathbf{k} - \mathbf{q}|^2} \frac{1}{E\gamma_0 - c\boldsymbol{\gamma} \cdot \mathbf{q} - mc^2} + \dots \left. \right].
 \end{aligned} \tag{28.38}$$

An interesting feature of the Furry picture is the role of negative energy states for many electron atoms. For free electrons, the unitary transformation to the interaction picture is unambiguous, chosen to subtract H_I , and the spinors $u(\mathbf{p}, s)$ and $v(\mathbf{p}, s)$ that enter the electron field operator are also unique. For hydrogen, the solutions are solutions to the Dirac equation in a Coulomb field, which are also unambiguous. However, for many electron atoms, an extended Furry representation can be used in order to account for some portion of electron screening, and this can be done using any local potential $U(\mathbf{x})$. This extension involves introducing an additional interaction Hamiltonian,

$$H_I'(t) = - \int d\mathbf{x} U(\mathbf{x}) \psi^\dagger(\mathbf{x}, t) \psi(\mathbf{x}, t) \tag{28.39}$$

along with changing $V(\mathbf{x}) \rightarrow V(\mathbf{x}) + U(\mathbf{x})$ in Eq. (28.28), and will be used when we discuss many-electron calculations. The positive and negative energy solutions to the Dirac equation now depend on the choice of the screening potential. For the positive energy solutions, one then faces the same problem as in the Hamiltonian approach. Except for atoms with only a few electrons, the only practical way to even form a wave function is to assume that all electrons move in the same potential, so that a lowest order approximation of the wave function as a Slater determinant of occupied states can be formed. When the potential is modified to incorporate screening, a modification of the Furry picture leads to a replacement of the Coulomb potential with the screened potential, as will be discussed later. The associated negative energy states also depend on the potential, so that forming a general projection operator to remove them, a useful approximation in relativistic many body physics, is problematical.

28.3 Perturbation Theory with Green Functions

We now introduce the basic approach to calculating energy levels in QED, which is to form a function of an energy E that has poles at the eigenvalue E_v . We first generalize the lowest order electron propagator that we have been dealing with to its exact form. This is done by starting in Heisenberg representation, defining

$$S_2(x, y) = \langle 0 | T(\psi_H(x) \bar{\psi}_H(y)) | 0 \rangle, \tag{28.40}$$

sometimes referred to as the two-point function. We then define the associated Green function,

$$\begin{aligned}
 G_2(E, \mathbf{x}, \mathbf{y}) &= -\frac{i}{\hbar} \int dt e^{iEt/\hbar} \\
 &\times \langle 0 | T(\psi_H(\mathbf{x}, t) \bar{\psi}_H(\mathbf{y}, 0)) | 0 \rangle e^{-\varepsilon|t|/\hbar}.
 \end{aligned} \tag{28.41}$$

We have set $t' = 0$ and introduced a convergence factor with the understanding that the limit $\varepsilon \rightarrow 0$ is to be taken.

We next note that a positive energy state ψ_v that satisfies $H\psi_v = E_v\psi_v$ leads to a pole at $E = E_v$ once the integral over positive values of t is carried out. This is because for such values the operators are already time ordered, and a complete set of states can be inserted between them, so that

$$\begin{aligned}
 G_2(E, \mathbf{x}, \mathbf{y}) &= -\frac{i}{\hbar} \sum_m \int_0^\infty dt e^{-\varepsilon t/\hbar} e^{iEt/\hbar} \\
 &\times \langle 0 | \psi_H(\mathbf{x}, t) | m \rangle \langle m | \psi_H(\mathbf{y}, 0) | 0 \rangle
 \end{aligned}$$

$$= -\frac{i}{\hbar} \sum_m \int_0^\infty dt e^{it(E-E_m+i\epsilon)/\hbar} \times \langle 0 | \psi_H(\mathbf{x}, 0) | m \rangle \langle m | \bar{\psi}(y, 0) | 0 \rangle. \quad (28.42)$$

We have used

$$\psi_H(\mathbf{x}, t) = e^{iHt/\hbar} \psi_H(\mathbf{x}, 0) e^{-iHt/\hbar} \quad (28.43)$$

to remove the time dependence from the electron field operator. This makes it possible to carry out the t integration, so for a particular state v

$$G_2(E, \mathbf{x}, \mathbf{y}) \approx \frac{1}{E - E_v + i\epsilon}. \quad (28.44)$$

We now have a way of finding E_v through the analysis of $G_H(E, \mathbf{x}, \mathbf{y})$, an object that is well defined in field theory. Of course, determining E_v is tantamount to exactly solving QED, so in practice, some kind of perturbation expansion must be made. Going to interaction representation allows the expansion to be derived through expanding the time evolution operator. However, while Feynman diagrams can be used for the expansion, instead of generating S -matrix elements we will find modifications of the Green function involving double poles, and the energy shifts will be the factors multiplying them. An extremely thorough treatment of this approach is given by *Shabaev* in [18]. The basic idea follows by considering the second term in the Taylor expansion of

$$\frac{1}{E - \epsilon_v - \delta E_v} = \frac{1}{E - \epsilon_v} + \frac{\delta E_v}{(E - \epsilon_v)^2} + \dots \quad (28.45)$$

The third term in the expansion will give a term with a triple pole, and so on, but to generalize first-order Rayleigh–Schrödinger perturbation theory to field theory it suffices to find terms with double poles and identify the factor with δE_v . As emphasized by *Yennie* [19], this approach to QED perturbation theory allows one to examine a limited set of Feynman diagrams contributing to a Green function. To find the shift of a state $\psi_v(\mathbf{x})$ with energy ϵ_v , one projects out that state as described above Eq. (28.33), and reads off the energy shift from coefficients of $1/(E - \epsilon_v)^2$.

Transforming from the Heisenberg to the interaction representation is done by including a factor of $U(\infty, -\infty)$ in the two-point function and dividing by the vacuum expectation value,

$$S_2(x, y) = \frac{\langle 0 | T(U \psi(\mathbf{x}, t) \bar{\psi}(y, 0)) | 0 \rangle}{\langle 0 | U | 0 \rangle}. \quad (28.46)$$

The denominator term eliminates contributions involving disconnected diagrams. We have already shown in

Fig. 28.1 The Green function for one-loop self-energy

Eq. (28.33) that in lowest order, the projected Green function has a pole at the Dirac energies ϵ_v . In particular, the $2s$ and $2p_{1/2}$ are degenerate. The experimental measurement of the energy difference of the state by *Lamb and Retherford* [20] was an important impetus for developing methods to calculate δE_v .

The first nonvanishing term in the Taylor expansion when using Feynman gauge is from second order, as one needs at least a pair of photon fields to combine into a propagator. The six electron fields contract into three propagators in two topologies, the self-energy (SE) and vacuum polarization (VP). We start with the self-energy, shown in Fig. 28.1.

$$G_{SE}(E) = -\frac{i}{\hbar} \int \frac{dE}{2\pi} e^{iEt/\hbar} \left(\frac{q_e c}{\hbar} \right)^2 \int dx_2 \int dx_1 \times S_F^V(x, x_1) \gamma_\mu S_F^V(x_1, x_2) \gamma_\nu S_F^V(x_2, y) \times D_F^{\mu\nu}(x_1, x_2). \quad (28.47)$$

The “outside” propagators $S_F^V(x, x_1)$ and $S_F^V(x_2, y)$ are next replaced with integrals over the variables E_1 and E_3 of $G(E_1, \mathbf{x}, \mathbf{x}_1)$ and $G(E_3, \mathbf{x}_2, \mathbf{y})$ using Eq. (28.29), and represented as spectral decompositions as in Eq. (28.31). The interior Green function is written as an integral over E_2 of $G(E_2, \mathbf{x}_2, \mathbf{x}_1)$ and left in that form. We collapse the sums as described earlier. The integral over t involves only $S(x, x_1)$, and carrying it out gives a delta function that puts $E_1 = E$. The remaining integrals over t_1 and t_2 force $E_3 = E$ and $E_2 = E - cq_0$, and we have a double pole term,

$$G_{SE}(E)_{vv} = -\frac{1}{(E - \epsilon_v)^2} \frac{ie^2 c}{\epsilon_0 \hbar} \int dx dy \times \int \frac{d^4 q}{(2\pi)^4} \frac{e^{iq \cdot (x-y)/\hbar}}{q^2 + i\delta} \bar{\psi}_v(\mathbf{x}) \gamma_\mu \times G(E - cq_0, \mathbf{x}, \mathbf{y}) \gamma_0 \gamma^\mu \psi_v(\mathbf{y}). \quad (28.48)$$

The factor multiplying the double pole is identified with the self-energy part of the one-loop Lamb shift,

$$E_{SE}^{(2)} = -4\pi i \alpha c^2 \int dx dy \int \frac{d^4 q}{(2\pi)^4} \frac{e^{iq \cdot (x-y)/\hbar}}{q^2 + i\delta} \times \bar{\psi}_v(\mathbf{x}) \gamma_\mu G(\epsilon_v - cq_0, \mathbf{x}, \mathbf{y}) \gamma_0 \gamma^\mu \psi_v(\mathbf{y}), \quad (28.49)$$

where we have replaced E with ϵ_v in the numerator of G .

Because the integral over q is ultraviolet infinite, $E_{SE}^{(2)}$ is not defined as it stands. If the d^4q integral were Euclidean, the radial part of the integral would go as $q^3 dq$: the denominator at large q goes as q^3 , so it is nominally linearly divergent. Before meaningful results can be calculated, two steps are needed: regularization and renormalization. Regularization involves making the integral a finite quantity, for example by cutting the q integral off at a large momentum Λ . Renormalization then involves showing that terms that diverge when Λ goes to infinity have the effect of changing quantities like the electron mass and charge. In a renormalizable theory such as QED, a limited number of renormalizations lead to finite results, with residual terms depending on the regularization vanishing in the limit.

An important breakthrough made in QED, which had basically been stalled for years by these infinities, was the realization they were present for both free and bound electrons. To show this, it is useful to present the self-energy term in momentum space,

$$E_{SE}^{(2)} = -\frac{4\pi i \alpha c^2}{\hbar^6} \int \frac{d^4q}{(2\pi)^4} \frac{1}{q^2} \int \frac{d\mathbf{p}_2}{(2\pi)^3} \int \frac{d\mathbf{p}_1}{(2\pi)^3} \times \bar{\psi}_v(\mathbf{p}_2) \gamma_\mu G(\varepsilon_v - cq_0, \mathbf{p}_2 - \mathbf{q}, \mathbf{p}_1 - \mathbf{q}) \times \gamma_0 \gamma^\mu \psi_v(\mathbf{p}_1) \quad (28.50)$$

and examine the first two terms in the expansion of the Green function given in Eq. (28.38).

Introducing a four-vector $p = (\varepsilon_v/c, \mathbf{p})$, the first term, the “zero potential” or OP term, can be written as

$$E_{0P}^{(2)} = \frac{1}{\hbar^3} \int \frac{d\mathbf{p}}{(2\pi)^3} \bar{\psi}_v(\mathbf{p}) \Sigma(p) \psi_v(\mathbf{p}), \quad (28.51)$$

where

$$\Sigma(p) = -4\pi i \alpha \int \frac{d^4q}{(2\pi)^4} \frac{1}{q^2} \gamma_\mu \times \frac{(\varepsilon_v - cq_0) \gamma_0 - c \boldsymbol{\gamma} \cdot (\mathbf{p} - \mathbf{q}) + mc^2}{(q - p)^2 - m^2 c^2} \gamma^\mu, \quad (28.52)$$

and the identity

$$\frac{1}{\not{p} - mc} = \frac{\not{p} + mc}{p^2 - m^2 c^2} \quad (28.53)$$

has been used. (If, instead, Eq. (28.21) is used for the electron propagator, it can be shown that there is a linear divergence present in the two parts that cancels.) We proceed by combining the denominators using

$$\frac{1}{AB} = \int_0^1 dx \frac{1}{(Ax + B(1-x))^2} \quad (28.54)$$

and find

$$\Sigma(p) = -4\pi i \alpha c \int \frac{d^4q}{(2\pi)^4} \int_0^1 dx \times \frac{\gamma_\mu (\boldsymbol{\gamma} \cdot (\mathbf{p} - \mathbf{q}) + mc) \gamma^\mu}{[(q - xp)^2 - xm^2 c^2 (1 - (1-x)p^2/(mc)^2)]^2}. \quad (28.55)$$

In this form, it is not hard to see that the divergence is logarithmic: the linear divergence, associated with the factor q , vanishes by symmetry after transforming $q \rightarrow q + xp$.

A powerful technique to regulate these infinities is dimensional regularization [21], where $d^4q \rightarrow dq_0 d^r q$, with $r = 3 - \varepsilon$. With ε small but nonzero, the integrals above can be done after transforming to a Euclidean form through $q_0 \rightarrow iq_4$. After defining a constant $C \equiv (4\pi)^{\varepsilon/2} \Gamma(1 + \varepsilon/2)$ and then expanding the result to order ε^0 , one has

$$\Sigma(p) = \frac{\alpha}{\pi} \left(\frac{3C}{2\varepsilon} + 1 \right) mc^2 - \frac{\alpha}{2\pi} \left(\frac{C}{\varepsilon} + 1 \right) (c \not{p} - mc^2) - \frac{\alpha}{4\pi} \int dx \ln(1 - (1-x)p^2/(mc)^2) \times [mc^2(1+x) - (1-x)(c \not{p} - mc^2)]. \quad (28.56)$$

For an on-shell free electron, only the first term survives and is termed the second-order electron self-mass, $\delta m^{(2)}$. It has the effect of shifting the electron mass from m to $m + \delta m^{(2)}$. This is to be identified with the observed mass of the electron, so if we use the observed mass in propagators, a renormalization counterterm must be included in the interaction Hamiltonian.

For a bound electron, the counterterm also removes the divergent self-mass term. The realization that a renormalization process that accounted for the changed meaning of the mass of free electrons would remove a divergence of bound electrons was a crucial step in establishing the modern form of QED. However, a divergence still remains for hydrogen. It is also removed by another renormalization, but because of an identity associated with current conservation, also directly cancels with a divergence from another part of the self-energy, the one-potential (1P) term.

The 1P term comes from the second term in Eq. (28.37), which is represented by the vertex diagram shown in Fig. 28.3. If we now define the two four-vectors $p_1 = (\varepsilon_v/c, \mathbf{p}_1)$ and $p_2 = (\varepsilon_v/c, \mathbf{p}_2)$, this part of the self-energy is

$$E_{1P}^{(2)} = \frac{1}{\hbar^3} \int \frac{d\mathbf{p}_2}{(2\pi)^3} \frac{d\mathbf{p}_1}{(2\pi)^3} \bar{\psi}_v(\mathbf{p}_2) \Gamma_0(p_2, p_1) \times \psi_v(\mathbf{p}_1) \frac{4\pi Z \alpha c}{|\mathbf{p}_2 - \mathbf{p}_1|^2}, \quad (28.57)$$

with

$$\Gamma_\rho(p_2, p_1) = -4\pi i \alpha \int \frac{d^4 q}{(2\pi)^4} \frac{1}{q^2} \gamma^\mu \frac{1}{\not{p}_1 - \not{q} - mc} \times \gamma_\rho \frac{1}{\not{p}_2 - \not{q} - mc} \gamma^\mu. \quad (28.58)$$

As with $\Sigma(p)$, $\Gamma_\rho(p_2, p_1)$, the one-loop vertex, is a standard one-loop expression that can be evaluated independently of the bound state problem. When it is sandwiched between on-shell electron wave functions, it can be expressed in terms of two form factors,

$$\Gamma_\rho(p_2, p_1) = \gamma_\rho F_1(q^2) + F_2(q^2) \frac{i\sigma^{\rho\nu} q_\nu}{2mc}, \quad (28.59)$$

where $q = p_2 - p_1$. Note that $q^2 = -|p_2 - p_1|^2$. While we will concentrate on $F_1(q^2)$, we note that $F_2(q^2)$ goes to $\alpha/2\pi$ when q is small compared to mc , which is the case for atomic momenta. This gives a contribution to the leading order Lamb shift, and in the case of the external field being a magnetic field gives the Schwinger correction [3].

The $F_1(q^2)$ has two divergences, the first being the same kind of ultraviolet divergence that dimensional regularization controls, and the second an infrared divergence. Although there is no infrared divergence in $E_{1P}^{(2)}$, the requirement of being on shell induces one in $F_1(q^2)$. For small values of q , one has

$$F_1(q^2) = \frac{\alpha}{2\pi} \left(\frac{C}{\varepsilon} + 1 \right) + \frac{\alpha}{3\pi} \frac{q^2}{(mc)^2} \left(\ln \frac{mc^2}{\varepsilon} - \frac{3}{8} \right), \quad (28.60)$$

where ε is a lower cutoff energy used to regulate the infrared divergence. The ultraviolet divergence can be seen to cancel with the 0P term after using the Dirac equation.

After noting the cancelation of the ultraviolet divergences, while the calculation of this term can be carried out numerically, one can immediately determine important properties of the energy shift by considering the form given above. In particular, the term of order q^2 in F_1 , when put into $E_{1P}^{(2)}$, leads to a factor of the wave function at the origin squared, as the p_1 and p_2 integrations are decoupled and can be carried out separately. Using the nonrelativistic form, this leads to a logarithmic term

$$E_{1P}^{(2)} \approx \frac{mc^2 \alpha (Z\alpha)^4}{\pi n^3} \frac{4}{3} \ln \frac{mc^2}{\varepsilon}. \quad (28.61)$$

The factor multiplying $4/3 \ln mc^2/\varepsilon$ characterizes the basic size of the Lamb shift. Compared to the scale of Bohr energies, $mc^2(Z\alpha)^2$, the effect is suppressed by a factor $\alpha(Z\alpha)^2$; while less than a ppm effect at low Z , it can be of order of a percent at high Z , as will be discussed later.

If the replacement $\varepsilon \rightarrow m(Z\alpha)^2$ is made, the cutoff form factor term gives, for s-states,

$$\Delta E = \frac{mc^2 \alpha (Z\alpha)^4}{\pi n^3} \frac{4}{3} \ln(Z\alpha)^{-2}, \quad (28.62)$$

the largest contribution, at 1334.801 MHz, to the Lamb shift in hydrogen. As the measurement is about 1057 MHz, the constant term is also important. It involves energies less than the cutoff and is sensitive to atomic structure. It receives contributions from each term in the expansion of the propagator we have been using, but the sum of the terms, the Bethe logarithm, can be numerically evaluated to high precision [22].

While the lowest order contribution to the self-energy, of order $mc^2 \alpha (Z\alpha)^4$, is understood, it is corrected by powers of $Z\alpha$ along with logarithms of $Z\alpha$, referred to as binding corrections. While the difficulty of the calculations increases as the power increases, they have been carried out to the high orders described elsewhere. However, for high Z this approach breaks down, and a numerical calculation is needed. For this reason, we now turn to a discussion of these calculations. We note, however, the useful constraint of requiring that the numerical methods, which work at any value of Z (although the numerical difficulty increases as Z gets small), agree with the power series expansion at low Z .

While the program began in 1955 [23, 23], numerical control to high accuracy was only relatively recently achieved. To set the calculations up, one first carries out the dq integration and does the Wick rotation $q_0 \rightarrow iu/c$ in Eq. (28.49). Both the Coulomb Green function and the photon Green function are expanded in partial waves. Using spherical symmetry allows the four angle integrations to be done, leaving a sum over partial waves of a three-dimensional integral. The main difficulty for the numerical approach is the fact the summation over partial waves extends to infinity. The most accurate values have been presented in [25], where acceleration techniques are used to extrapolate the sum to infinity, after which the radial and energy integrals are done. Highly accurate results have been presented for the $n = 1$ and $n = 2$ states for all Z in [26]. In this case, the integrations are carried out before the partial wave expansion, but subtraction techniques, to be discussed below, are used to make the partial wave expansion converge very rapidly, so that fewer than 20 terms are needed [27].

All numerical approaches involve subtractions, which are done in a number of ways. We have already examined the first and second terms in Eq. (28.37). The finite terms left over after the ultraviolet divergent terms have been canceled can be accurately evaluated, so if we add and subtract $E_{0P}^{(2)} + E_{1P}^{(2)}$ from the one-loop self-energy but express the subtracted part in coordinate space, we have an ultraviolet finite coordinate space term to deal with called the many-potential (MP) term. It is called this since only the second-order and higher

terms in Eq. (28.37) remain after the subtraction. This approach was suggested by *Blundell and Snyderman* [28] and has been used extensively.

This procedure involves subtracting, using a shorthand notation for the second term in Eq. (28.37), $G_0 V G_0$. Originally, however, *Mohr* [29] instead subtracted a term $G_0 \bar{V} G_0$, where, undoing the shorthand notation,

$$G_0 \bar{V} G_0 = \frac{V(x_2) + V(x_1)}{2} \times \int d\mathbf{w} G_0(E, \mathbf{x}_2, \mathbf{w}) G_0(E, \mathbf{w}, \mathbf{x}_1). \quad (28.63)$$

The integral over \mathbf{w} can be carried out using

$$\begin{aligned} & \int d\mathbf{w} G_0(E, \mathbf{x}_2, \mathbf{w}) G_0(E, \mathbf{w}, \mathbf{x}_1) \\ &= \int d\mathbf{w} \sum_m \frac{\psi_m(\mathbf{x}_2) \psi_m^\dagger(\mathbf{w})}{E - \varepsilon_m} \sum_n \frac{\psi_n(\mathbf{w}) \psi_n^\dagger(\mathbf{x}_1)}{E - \varepsilon_n} \\ &= \sum_m \frac{\psi_m(\mathbf{x}_2) \psi_m^\dagger(\mathbf{x}_1)}{(E - E_m)^2} \\ &= -\frac{d}{dE} G_0(E, \mathbf{x}_2, \mathbf{x}_1), \end{aligned} \quad (28.64)$$

and a much simpler function results. This allowed the first accurate calculations of the self-energy for a range of Z [29]. The argument just given for two Green functions applies to the product of any number of them, resulting in successively higher derivatives of a single Green function. This was used in [27] to form the subtractions mentioned above.

A set of corrections to the self-energy arise when it is perturbed that illustrate other aspects of the Green function perturbation theory expansion [30–32]. These corrections must be evaluated, for example, when dealing with radiative corrections to the Zeeman effect. For laboratory magnetic fields, the energy shift of a bound electron in an atom, E_Z , need be treated only in first order. However, to include the effect of the one-loop self-energy (which in the nonrelativistic case is dominated by the Schwinger correction), one must treat the diagrams of both figures (Figs. 28.2 and 28.3). (For Fig. 28.2, the Green functions are understood to be $G(z, \mathbf{x}, \mathbf{y})$ rather than $G_0(z, \mathbf{x}, \mathbf{y})$, and the vertical photon line as the magnetic field rather than the Coulomb field of the proton.) The latter diagrams have four electron propagators. We recall that for the one-loop self-energy, one of the three propagators was not decomposed, and the other two gave a double pole.

The same arguments apply to Fig. 28.2, and one leaves both interior propagators unexpanded. For the diagrams of Fig. 28.3, one encounters terms involving $\Sigma(p)$, but with argument E not replaced with ε_v , sandwiched with various states. Because only one propagator is left “as is”, there is a triple pole at $E = \varepsilon_v$. The triple pole itself gives no new

Fig. 28.2 $G_0 V G_0$ contribution

Fig. 28.3 Green functions leading to derivative and perturbed orbital terms

energy shift, but there are two ways a residual double pole can be generated. The first comes from expanding

$$\Sigma(E) = \Sigma(\varepsilon_v) + (E - \varepsilon_v) \Sigma'(\varepsilon_v) + \dots \quad (28.65)$$

and is called the derivative term. The second comes from restricting one of the “outside” propagators so that $m \neq v$, which again leads to a double pole. (The excluded term is associated with a cross term in the Taylor expansion of $1/(E - \Sigma_{vv} - E_Z)$.) This is referred to as a perturbed orbital term, since one can form a state $|\tilde{v}\rangle$ and show that the term is $\Sigma_{v\tilde{v}}(\varepsilon_v) + \Sigma_{\tilde{v}v}(\varepsilon_v)$. If written as

$$\Delta E_{PO} = \sum_{m \neq v} \left[\frac{\langle v | \Sigma | m \rangle \langle m | V | v \rangle}{\varepsilon_m - \varepsilon_v} + \frac{\langle v | V | m \rangle \langle m | \Sigma | v \rangle}{\varepsilon_m - \varepsilon_v} \right], \quad (28.66)$$

the close relation of the term to second-order Rayleigh–Schrödinger perturbation theory is seen.

The self-energy term discussed above has both the electron and the photon propagate from the same initial point to the same final point. Another term in which the photon propagates from x_1 to x_2 , but the electron propagates from x_2 to the same point is present, called the vacuum polarization term. The diagram representing it is shown in Fig. 28.4. If one expands the electron propagator using Eq. (28.37), only terms with odd powers of V contribute. The term linear in V gives the bulk of the effect and is called the Uehling term. The exact calculation was considered in [33], where it was shown that a partial wave expansion can be formed of the difference of the full VP with the Uehling term. The resulting Wichmann–Kroll terms are quite small. The fact that the basic expression for vacuum polarization involves $G(E, \mathbf{x}_2, \mathbf{x}_2)$, which is very singular, was analyzed in [34]

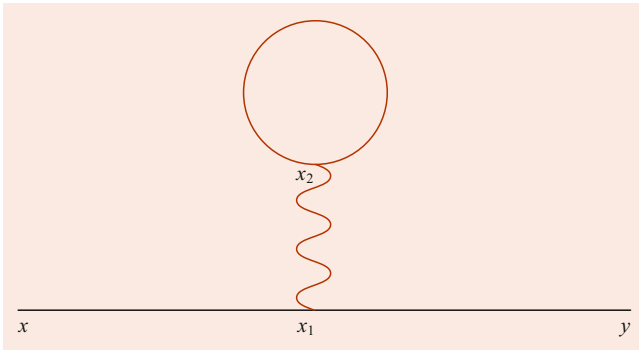

Fig. 28.4 Green function for vacuum polarization

using an alternative to dimensional regularization, Pauli–Villars regularization [35]. We present some details of the calculation, which illustrates charge renormalization.

Following the same steps as with the self-energy, we note that the energy of the photon line, cq_0 , is now forced to vanish, which allows the \mathbf{q} integration to be carried out, leading to a double pole with factor

$$E_{VP}^{(2)} = i\alpha\hbar c \int d\mathbf{x}_1 d\mathbf{x}_2 \frac{\bar{\psi}_v(\mathbf{x}_1)\gamma_0\gamma_\mu\psi_v(\mathbf{x}_1)}{|\mathbf{x}_1 - \mathbf{x}_2|} \times \int \frac{dz}{2\pi} \text{Tr}[\gamma^\mu G(z, \mathbf{x}_2, \mathbf{x}_2)\gamma_0]. \quad (28.67)$$

The $\mu = 0$ component of this then describes the Coulomb field of the charge density of the state v interacting with an electron looping from the point of interaction back to the same point.

Pauli and Villars [35] analyzed the ultraviolet infinities of one-loop vacuum polarization and showed that they could be regularized by introducing two similar expressions, but with the electron mass ($m \equiv M_0$) replaced by either M_1 or M_2 . If the two expressions are multiplied by the factors $(M_0^2 - M_2^2)/(M_2^2 - M_1^2)$ and $(M_1^2 - M_0^2)/(M_2^2 - M_1^2)$, respectively, and added to the original term, they showed the ultraviolet infinities were eliminated, and explicitly finite expressions could be analyzed. It is of interest to show how the calculation works for the case $M_1 = 20M_0$ and $M_2 = 30M_0$, even though they are understood to be taken to infinity after renormalization.

If one starts by considering the energy of a positive charge e in the Coulomb field of a fixed proton, one has $E_0(r) = \hbar c\alpha/r$. The effect of vacuum polarization on the energy breaks into two parts. One part is proportional to the lowest order energy,

$$E_1(r) = -\frac{2\alpha}{3\pi} \left[C_1 \ln \frac{M_1}{m} + C_2 \ln \frac{M_2}{m} \right] E_0(r) \equiv (Z_3 - 1)E_0(r). \quad (28.68)$$

For the Pauli–Villars masses chosen, $Z_3 = 1.004138$. Even though in the limit of infinite masses this so-called photon

renormalization constant is formally infinite, the smallness of α and the slow increase of the logarithm function make this formally infinite term close to 1 for the values chosen.

As with the electron mass renormalization, one must realize that this contribution is always present when two charges interact. If one could somehow suppress the effect of vacuum polarization, the effective elementary charge, which is called the bare charge e_0 , would be smaller. The effect of $E_1(r)$ is to renormalize e_0 to the observed charge e through $e = e_0\sqrt{Z_3}$. Alternatively, one can simply work with the observed charge and drop E_1 . In either case, the finite remainder is what of interest. The Uehling term is the term independent of C_1 and C_2 in

$$E_2(r) = -\frac{\alpha}{12\pi^2} E_0(r) \int_1^\infty dt \sqrt{t^2 - 1} \left(\frac{1}{t^2} + \frac{2}{t^4} \right) \times \left[e^{-2\frac{M_0 c}{\hbar} t r} + C_1 e^{-2\frac{M_1 c}{\hbar} t r} + C_2 e^{-2\frac{M_2 c}{\hbar} t r} \right]. \quad (28.69)$$

It plays a role in the Lamb shift, and by itself would act to make the $2s$ state more strongly bound than the $2p_{1/2}$ state. The other two terms are small and can be shown to vanish quadratically for large values of the masses M_1, M_2 .

Our using finite masses allows a central point about the renormalization program to be emphasized. As long as one works with renormalized quantities, finite calculations can be carried out. As shown in the example here, there is some dependence on the masses; however, there is little sensitivity to it, technically because of a quadratic falloff. A renormalizable theory in this picture should be thought of as insensitive to the high energy behavior: even if there is some new physics associated with the large momentum part of the loops, the predictions of a renormalizable theory like QED will change very little.

An important, relatively recent advance in exact calculations is in the two-loop Lamb shift. As with the one-loop case, both expansions in $Z\alpha$ and numerical treatments have been made. An example of a contribution is the overlapping loop diagram (Ov) shown in Fig. 28.5.

$$E_{SE}^{(4)}(\text{Ov}) = \alpha^2 c^4 \int \frac{d^4 q_1}{(2\pi)^4} \frac{d^4 q_2}{(2\pi)^4} \frac{1}{q_1^2} \frac{1}{q_2^2} \int d\mathbf{x} d\mathbf{z} d\mathbf{w} \times d\mathbf{y} \bar{\psi}_v(\mathbf{x})\gamma_\mu G(\varepsilon_v - cq_{10}, \mathbf{x}, \mathbf{z}) \times \gamma^\nu G(\varepsilon_v - cq_{10} - cq_{20}, \mathbf{z}, \mathbf{w}) \times \gamma^\mu G(\varepsilon_v - cq_{20}, \mathbf{w}, \mathbf{y})\gamma_\nu \psi_v(\mathbf{y}) e^{i\mathbf{q}\cdot(\mathbf{x}-\mathbf{y})/\hbar}. \quad (28.70)$$

A striking feature of the expansion in $Z\alpha$ was the discovery of a very large coefficient by Pachucki [36], who found

$$E_{SE}^{(4)} = \frac{mc^2\alpha^2(Z\alpha)^4}{\pi^2 n^3} [0.538941 - 21.55447(Z\alpha) + \dots] \quad (28.71)$$

Fig. 28.5 Representative two-loop Lamb shift diagram

This emphasizes the need for the numerical approach for even moderate values of Z , as the above function changes sign by $Z = 4$. A recent discussion of the present status of two-loop calculations can be found in [37].

28.4 Two-Particle Bound States

We have so far dealt with hydrogen using the external field approximation, with the only role of the nucleus being the creation of a static Coulomb potential. We now will treat the nucleus dynamically, so that we must deal with two-particle bound states. To firstly justify the approximation, and secondly set up a perturbation theory to evaluate corrections to it, specifically recoil corrections, we now generalize $G_2(E, \mathbf{x}, \mathbf{y})$ from Eq. (28.41) to

$$\begin{aligned} G_4(E, \mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2) &= -\frac{i}{\hbar} \int_{-\infty}^{\infty} dt e^{iEt/\hbar} \langle 0 | T(\psi_H(\mathbf{x}_1, t) \phi_H(\mathbf{x}_2, t) \\ &\quad \times \bar{\psi}_H(\mathbf{y}_1, 0) \bar{\phi}_H(\mathbf{y}_2, 0)) | 0 \rangle. \end{aligned} \quad (28.72)$$

Because the structure of the proton brings up issues not directly related to what we want to stress, it is convenient to treat it as a positive muon, so the field ϕ_H denotes that particle. No external field is now assumed, so the perturbation expansion will involve the free electron propagator, with mass denoted m_1 , and the free muon propagator, with mass denoted m_2 .

The argument given previously for $G_2(E, \mathbf{x}, \mathbf{y})$ showing that a pole is present carries through almost unchanged. The only difference is that to eliminate the time dependence from the product of the two operators one writes, after choosing $t > 0$ and inserting a complete set of states,

$$\begin{aligned} \langle 0 | \psi_H(\mathbf{x}_1, t) \phi_H(\mathbf{x}_2, t) | m \rangle &= \langle 0 | e^{iHt/\hbar} e^{-iHt/\hbar} \psi_H(\mathbf{x}_1, t) e^{iHt/\hbar} e^{-iHt/\hbar} \\ &\quad \times \phi_H(\mathbf{x}_2, t) e^{iHt/\hbar} e^{-iHt/\hbar} | m \rangle \\ &= \langle 0 | \psi_H(\mathbf{x}_1, 0) \phi_H(\mathbf{x}_2, 0) | m \rangle e^{-iE_m t/\hbar}. \end{aligned} \quad (28.73)$$

This argument can clearly be extended to a string of any number of operators, and the conclusion that a pole at $E = E_v$ is present is the same.

Fig. 28.6 Two-rung ladder diagram

We again begin by transforming to the interaction picture, but use Coulomb gauge rather than Feynman gauge. In lowest order,

$$\begin{aligned} \langle 0 | T(\psi(\mathbf{x}_1, t) \phi(\mathbf{x}_2, t) \bar{\psi}(\mathbf{y}_1, t') \bar{\phi}(\mathbf{y}_2, t')) | 0 \rangle \\ = -[S_F(\mathbf{x}_1, \mathbf{y}_1, t - t')]_1 [S_F(\mathbf{x}_2, \mathbf{y}_2, t - t')]_2, \end{aligned} \quad (28.74)$$

and we introduce a free propagator

$$\begin{aligned} S_0(\mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2, t - t')_{ab,cd} \\ = [S_F(\mathbf{x}_1, \mathbf{y}_1, t - t')]_{ab} [S_F(\mathbf{x}_2, \mathbf{y}_2, t - t')]_{cd}. \end{aligned} \quad (28.75)$$

Binding is associated with an infinite summation of Coulomb photon exchanges described by the function, now taking $t' = 0$,

$$\begin{aligned} S_L(\mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2, t)_{ab,cd} \\ = S_0(\mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2, t)_{ab,cd} \\ + \int d\mathbf{w}_1 d\mathbf{w}_2 dt_w S_0(\mathbf{x}_1, \mathbf{x}_2, \mathbf{w}_1, \mathbf{w}_2, t - t_w)_{ae,cf} \\ \cdot \gamma_{0eg} \gamma_{0fh} \frac{\alpha}{|\mathbf{w}_1 - \mathbf{w}_2|} S_L(\mathbf{w}_1, \mathbf{w}_2, \mathbf{y}_1, \mathbf{y}_2, t_w)_{gb,hd}. \end{aligned} \quad (28.76)$$

Expanding this leads to a set of terms whose Feynman diagrams look like a ladder, with the Coulomb interaction forming the rungs. A two-rung ladder is shown in Fig. 28.6.

Before analyzing S_L , it is useful to form the Green function of S_0 and analyze it. It is

$$\begin{aligned} G_0(E, \mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2) &= -\frac{i}{\hbar} \int_{-\infty}^{\infty} dt e^{iEt/\hbar} S_F^{(1)}(\mathbf{x}_1, t, \mathbf{y}_1, 0) S_F^{(2)}(\mathbf{x}_2, t, \mathbf{y}_2, 0) \\ &= -\frac{i}{\hbar} \int_{-\infty}^{\infty} dt \int \frac{dE_1}{2\pi} \int \frac{dE_2}{2\pi} e^{it(E-E_1-E_2)/\hbar} \\ &\quad \times [G_0(E_1, \mathbf{x}_1, \mathbf{y}_1) \gamma_0]_1 [G_0(E_2, \mathbf{x}_2, \mathbf{y}_2) \gamma_0]_2 \\ &= -i \int \frac{dE_1}{2\pi} [G_0(E_1, \mathbf{x}_1, \mathbf{y}_1) \gamma_0]_1 \\ &\quad \times [G_0(E - E_1, \mathbf{x}_2, \mathbf{y}_2) \gamma_0]_2. \end{aligned} \quad (28.77)$$

Using Eq. (28.35) and the decomposition given in Eq. (28.21) then gives

$$\begin{aligned}
G_0(E, \mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2) &= -i \frac{1}{\hbar^6} \int \frac{dE_1}{2\pi} \int \frac{d\mathbf{p}_1}{(2\pi)^3} e^{i\mathbf{p}_1 \cdot (\mathbf{x}_1 - \mathbf{y}_1)/\hbar} \int \frac{d\mathbf{p}_2}{(2\pi)^3} \\
&\times e^{i\mathbf{p}_2 \cdot (\mathbf{x}_2 - \mathbf{y}_2)/\hbar} \left[\frac{\Lambda_+(\mathbf{p}_1)}{E_1 - E_{p_1} + i\delta} + \frac{\Lambda_-(\mathbf{p}_1)}{E_1 + E_{p_1} - i\delta} \right]_1 \\
&\times \left[\frac{\Lambda_+(\mathbf{p}_2)}{E - E_1 - E_{p_2} + i\delta} + \frac{\Lambda_-(\mathbf{p}_2)}{E - E_1 + E_{p_2} - i\delta} \right]_2. \quad (28.78)
\end{aligned}$$

Finally, using the Cauchy residue theorem to carry out the E_1 integration gives

$$\begin{aligned}
G_0(E, \mathbf{x}_1, \mathbf{x}_2, \mathbf{y}_1, \mathbf{y}_2) &= -\frac{1}{\hbar^6} \int \frac{d\mathbf{p}_1}{(2\pi)^3} e^{i\mathbf{p}_1 \cdot (\mathbf{x}_1 - \mathbf{y}_1)/\hbar} \\
&\times \int \frac{d\mathbf{p}_2}{(2\pi)^3} e^{i\mathbf{p}_2 \cdot (\mathbf{x}_2 - \mathbf{y}_2)/\hbar} \frac{[\Lambda_+(\mathbf{p}_1)]_1 [\Lambda_+(\mathbf{p}_2)]_2}{E - E_{p_1} - E_{p_2} + i\delta} \\
&- \frac{[\Lambda_-(\mathbf{p}_1)]_1 [\Lambda_-(\mathbf{p}_2)]_2}{E + E_{p_1} + E_{p_2} - i\delta}. \quad (28.79)
\end{aligned}$$

The early calculations of recoil effects used this relatively complicated Green function. However, one has the freedom to work with simpler expressions, as long as the difference between the Green functions is accounted for in perturbation theory. The term with two factors of Λ_{--} is small and can be dropped. We further note that one can avoid the need to use the Cauchy residue theorem by the following manipulation. The Λ_{++} part of the muon propagator in Eq. (28.78) has a denominator that can be rewritten as

$$\begin{aligned}
&\frac{1}{E - E_1 - E_{p_2} + i\delta} \\
&= \left[\frac{1}{E - E_1 - E_{p_2} + i\delta} - \frac{1}{E - E_1 - E_{p_2} - i\delta} \right] \\
&+ \frac{1}{E - E_1 - E_{p_2} - i\delta} \\
&= -2\pi i \delta(E_1 - (E - E_{p_2})) + \frac{1}{E - E_1 - E_{p_2} - i\delta}. \quad (28.80)
\end{aligned}$$

This motivates using an approximation to the muon propagator,

$$\begin{aligned}
&[G_0(E - E_1, \mathbf{x}_2, \mathbf{y}_2)\gamma_0]_2 \\
&\rightarrow -2\pi i \delta(E_1 - \tilde{E}) \delta^3(\mathbf{x}_2 - \mathbf{y}_2) \left[\frac{1 + \gamma_0}{2} \right]_2, \quad (28.81)
\end{aligned}$$

where $\tilde{E} \equiv E - m_2 c^2$. The term not involving the delta function has been dropped because it has a pole that is on

the same side of the axis as the pole associated with the electron's positive projector term and, thus, fails to vanish only for the electron's negative energy projector, which gives a small result. For purposes of illustration, we have further approximated $E_{p_2} = m_2 c^2$ and $\Lambda_{++} = \frac{1 + \gamma_0}{2}$, the $m_2 \rightarrow \infty$ limit, although for practical calculations, it is useful to retain some parts of the muon propagator. When this approximation is made in the ladder diagrams, the muon propagators essentially drop out of the calculation; the position variables are all forced to all be at the same place, which we choose as the origin. If one creates the Green function of S_L from Eq. (28.76), approximating the muon line as just described, it now effectively depends only on the electron variables, and one can show it satisfies

$$\begin{aligned}
G_L(E, \mathbf{x}_1, \mathbf{y}_1) &= G_0(E, \mathbf{x}, \mathbf{y}) \gamma_0 \\
&+ \int d\mathbf{w} G_0(E, \mathbf{x}, \mathbf{w}) \gamma_0 \frac{\alpha \hbar c}{|\mathbf{w}|} G_L(E, \mathbf{w}, \mathbf{y}). \quad (28.82)
\end{aligned}$$

The muon positive energy projector $[(1 + \gamma_0)/2]_2$ is understood as a common factor. Outside of that factor, this equation is identical to that satisfied by the Coulomb Green function, leading to the expansion previous given in Eq. (28.37) when V is a Coulomb potential. However, we know that this Green function has poles at the Dirac eigenvalues, so although we started with free propagators, we now have an function of E that has poles at the nonrecoil values and can now start building in the effect of recoil.

Once we have a Green function that has bound state poles that approximate the full Green function, recoil corrections can be found in the way we described previously. Since now we can represent this approximated Green function as a spectral representation of the form in Eq. (28.31), although with the wave functions ψ_m we now have a muon component multiplied in, the goal (which involves some fairly complicated manipulations that we will not show here) is to set up an equation of the form

$$G_4 = G_L + G_L \delta K G_4, \quad (28.83)$$

where δK is formed from both pure "kernels", diagrams that cannot be split in two by a cut through the electron and muon lines (unlike Fig. 28.6) and the effect of simplifying the Green function. Approximating G_4 with G_L on the right-hand side can be seen to give a double pole, with an energy shift equal to the matrix element of δK .

An example of this kind of calculation applied to positronium hyperfine splitting is given in [38, 39]. The heart of the calculation involves the treatment of kernels with three exchanged photons in Coulomb gauge. The calculation was originally done by *Pachucki* [40], and while quite different

in many details, requires the evaluation of the same set of diagrams.

An important generalization of the Bethe–Salpeter approach is having the two bound particles being electrons in helium and accounting for the nucleus by using the Furry picture. This program was carried out by *Araki* [41] and *Sucher* [42]. As with recoil calculations, the basic step is consideration of an infinite ladder of Coulomb exchanges. In place of free propagators between the rungs, one has Coulomb Green functions. By carrying out approximations valid in the nonrelativistic limit one can form a Green function with poles at the nonrelativistic energies known from solving Eq. (28.1) for two electrons. As stressed earlier, because these lowest order energies can be determined with an accuracy far exceeding the level at which QED corrections enter, the study of these corrections is quite advanced. However, the present state-of-the-art calculations are carried out in the framework of NRQED, and we defer the discussion of helium to the concluding remarks.

28.5 Many-Electron Bound States

The incorporation of QED effects in many-electron bound states is a problem of fundamental interest, although as emphasized earlier, it must be possible to solve the Schrödinger equation with high accuracy. As a matter of principle, though, we now wish to show that the use of Green functions allows a QED approach to the many-electron problem. It now has to describe both radiative corrections and the exchange of photons between different electrons consistently.

An active subfield of QED is the study of highly charged ions, generally with two or more electrons remaining after the others have been stripped from a high Z atom. Relativistic and QED effects are enhanced in these ions, and a QED treatment is needed. In highly charged ions, the dominant effect on electrons is their attraction to the nucleus, and it can be shown that electron–electron interactions have a factor $1/Z$ and can be treated in perturbation theory. This can lead to situations where one can, indeed, study the larger QED effects relatively free of structure uncertainty, and the study of the spectra of some of these ions now provides tests of QED in intense Coulomb fields.

A treatment of the QED alternative to the Green function approach described here is afforded through S -matrix techniques [43, 44]. In these calculations, an adiabatic factor ε plays a central role. It is used to “turn off” H_I at large positive and negative times. An example of how it works for the sodium isoelectronic sequence is given in [45]. Here, we show some of the features of the Green function approach. To be specific we work with lithium-like ions and consider

a six-point Green function. One starts with

$$G_6(E, \mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3) = -\frac{i}{\hbar} \int_{-\infty}^{\infty} dt e^{iEt/\hbar} \langle 0 | T(\psi_H(\mathbf{x}_1, t) \psi_H(\mathbf{x}_2, t) \psi_H(\mathbf{x}_3, t) \times \bar{\psi}_H(\mathbf{y}_1, 0) \bar{\psi}_H(\mathbf{y}_2, 0) \bar{\psi}_H(\mathbf{y}_3, 0)) | 0 \rangle. \quad (28.84)$$

The formal treatment showing the presence of poles at $E = E_v$ is identical to the earlier discussion. To carry out calculations one uses the Furry or extended Furry picture, with either a Coulomb potential or some screened potential defining the states.

With many electrons present, these states are Slater determinants of occupied orbitals, and the starting point of QED calculations is the same as for MBPT calculations. The non-radiative QED terms, in fact, have a close relation to the MBPT expansion. For the example here, if considering the ground and first excited states, one would use

$$|V\rangle = b^\dagger_v b^\dagger_a b^\dagger_b |0\rangle, \quad (28.85)$$

with v being a $2s$, $2p_{1/2}$, or $2p_{3/2}$ state, and a and b the two spin states of the $1s$ state.

In lowest order, the energy should be the sum of the three energies of the populated states, in this case $\varepsilon_v + 2\varepsilon_a$. It actually takes a little work to show that the energies add, but the calculation is instructive. The lowest order Green function has three electron propagators, with associated integrals over E_1 , E_2 , and E_3 . The t integration then gives a delta function of $E - E_1 - E_2 - E_3$. Using it to eliminate E_3 , say, leaves an integral over E_1 and E_2 of the form

$$\int \frac{dE_1}{2\pi} \int \frac{dE_2}{2\pi} \frac{1}{E_1 - \varepsilon_a + i\delta} \frac{1}{E_2 - \varepsilon_b + i\delta} \times \frac{1}{E - E_1 - E_2 - \varepsilon_v + i\delta}. \quad (28.86)$$

Because the three states all have positive energy, the E_1 and E_2 integrations can be carried out with Cauchy’s residue theorem, giving the expected factor

$$\frac{1}{E - E_v - E_a - E_b}. \quad (28.87)$$

One can then proceed finding double poles to find the shift of the energy.

The self-energy and vacuum polarization terms enter in the same way as for hydrogen, with the other electrons as “spectators”. If the extended Furry picture is used, the Coulomb Green function cannot be used, and the Green function must be formed numerically. Unless the ion studied is

hydrogenic, one must account for the interaction between electrons. A perturbative treatment works well for highly charged ions that have a simple electronic structure, particularly ions with one valence electron and a filled core. In place of the helium treatment, where the Coulomb interaction between the electrons was treated to all orders, one calculates order by order, with diagrams roughly ordered by the number of photons present.

An example of how QED has been tested is provided by lithium-like bismuth. This is a case where QED calculations have been carried out [46, 47], and at the level of the one-loop Lamb shift, one can see that extra physics must be included. The accurate measurement required for QED effects to be studied was provided by measurements in the LLNL EBIT [48], where

$$E = 2788.139(39) \text{ eV} \quad (28.88)$$

was found for the $2p_{3/2} - 2s$ splitting.

Before including the Lamb shift, calculations not including it were carried out in a range of screening potentials. Despite starting off differently, inclusion of up to three-photon exchange diagrams led to a common answer of 2814.348 eV. As was mentioned above, the field theory treatment of photon exchange has an interesting relationship to MBPT. One photon exchange can be done in either Coulomb or Feynman gauge, with the latter being more convenient computationally. However, in Coulomb gauge, one can see that exchange of a Coulomb photon is exactly equivalent to first-order MBPT. Exchange of a transverse photon is again equivalent to the MBPT treatment of the Breit interaction, with retardation included. However, when two photons are exchanged between two electrons, one encounters diagrams of the form of Fig. 28.6, with the understanding that spectator electrons are present. When both photons are Coulomb photons, the same contour integral encountered in the recoil discussion arises. It is well defined, with the two positive energy projectors giving a standard second-order MBPT term, and the other part giving a small contribution. We stress this point because this is a case where the use of field theory automatically avoids a term that would arise if one included negative energy states in MBPT perturbation theory in a straightforward manner. In sums over states m and n , MBPT would appear to include terms with m positive and n negative energy, and those terms can have vanishing denominators. They do not occur in the field theory calculation because they have poles on the same side of the axis, and the contour integration can be chosen to avoid them, giving zero. The more complicated case of having two transverse photons is also of interest, having a history dating back to Breit's calculations of helium fine structure. The equation he used, named after him, suffers from problems similar to those just

discussed, in particular leading to a term apparently of the order of the fine structure that had to be artificially removed. The integration is more complicated in this case, but the end result is that the two transverse photon term that appeared to be of the order of fine structure is reduced by a factor of α . This aspect of QED in atomic physics is just as important as the Lamb shift, although it does not require renormalization.

Because of the high charge of this ion, radiative corrections are now a one percent effect. They are dominated by the one-loop Lamb shift, which has to be treated with the numerical methods described earlier. However, while it is of the correct size, different potentials give differing answers. This disparity is removed to a large extent by including a set of "screening" diagrams, similar to Figs. 28.2 and 28.3, but with the lower photon line connecting to another electron. After including these (along with the effect of the counterterm Eq. (28.39) on the self-energy if extended Furry picture is used), a unique answer of -26.308 eV is found, taking theory to 2788.040 eV. This differs only slightly from experiment and shows that QED works even in very intense Coulomb fields. However, the experiment has sufficient accuracy to show clearly that extra physics must be accounted for.

Two obvious sources of known physics can account for the remaining discrepancy, recoil corrections and the two-loop Lamb shift. Remarkably, even though the bismuth nucleus is quite heavy, sophisticated recoil corrections are needed before the actual two-loop Lamb shift can be treated. These will be described in Sect. 28.6. After their removal an effect expected to be dominated by the $2s$ two-loop Lamb shift remains. As with the one-loop Lamb shift, an expansion in $Z\alpha$ could not be expected to be reliable, and exact numerical calculations had to be carried out. The result is consistent with experiment. The present status of that large-scale effort is described in [37].

28.6 Recoil Corrections at High Z

The first recoil calculations were carried out in the context of the Bethe–Salpeter equation. They relied heavily on expanding in powers of $Z\alpha$. For highly charged ions, $Z\alpha$ is no longer a small parameter, so the calculation of recoil corrections in hydrogenic ions with high Z requires the consideration of an infinite set of kernels rather than just a few. The problem was treated by *Grotch* and *Pachucki* in [49], and Bethe–Salpeter type calculations were done in [50] and [51]. The combinatoric problems are considerable, but the simplicity of the final expressions that result suggests that a simpler approach is possible. Such an approach was, indeed, found by *Shabaev* [52], and we describe it here.

The simplest way to derive the leading effect of the finite mass of the nucleus can be found in the context of classi-

cal mechanics, where in a system with N_e light particles of mass m (the electrons) and a heavy particle of mass M (the nucleus), one considers the heavy particle's nonrelativistic kinetic energy,

$$T_N = \frac{\vec{P}_N^2}{2M}, \quad (28.89)$$

and evaluates it in the center of mass system. In that frame, one can eliminate T_N through

$$\vec{P}_N \rightarrow -\sum_{i=1}^{N_e} \vec{p}_i. \quad (28.90)$$

Adding this to the nonrelativistic kinetic energy of the electrons (the first term in Eq. (28.1)) gives a total kinetic energy

$$T_{\text{tot}} = \sum_{i=1}^{N_e} \frac{\vec{p}_i^2}{2m_r} + H_{\text{MP}}, \quad (28.91)$$

where $m_r = m/(1 + m/M)$ is the reduced mass, and

$$H_{\text{MP}} = \sum_{i \neq j} \frac{\vec{p}_i \cdot \vec{p}_j}{2M} \quad (28.92)$$

is the mass polarization Hamiltonian. When this classical argument is extended to nonrelativistic quantum mechanics, it incorporates recoil exactly. However, if one works in the approximation of keeping only m/M corrections, extending the classical argument described above to field theory allows recoil to be treated relativistically for both one and many-electron systems.

To generalize Eq. (28.90) to field theory, we first note that the electron momentum is now described as a single field operator,

$$\vec{p}_e = -i\hbar \int d^3x \psi^\dagger(x) \vec{\nabla} \psi(x). \quad (28.93)$$

We also must include the electromagnetic field with the nuclear momentum in the usual way, with Eq. (28.89) now becoming

$$T_N \rightarrow \frac{|\vec{P}_N + Ze\vec{A}(\vec{0}, t)|^2}{2M}. \quad (28.94)$$

The position of the nucleus is close to the origin, so \vec{A} is evaluated there. Now the operation of going to the center of mass frame replaces \vec{P}_N with the negative of Eq. (28.93),

$$\vec{P}_N \rightarrow -\vec{p}_e, \quad (28.95)$$

and we see that including the kinetic energy of the nucleus leads to three new interaction Hamiltonians, operators to be

added to \tilde{H}_I ,

$$H_R = H_R(CC) + H_R(CT) + H_R(TT), \quad (28.96)$$

with

$$H_R(CC) = -\frac{\hbar^2}{2M} \int d^3x \int d^3y \psi^\dagger(\vec{x}, t) \times \vec{\nabla}_x \psi(\vec{x}, t) \cdot \psi^\dagger(\vec{y}, t) \vec{\nabla}_y \psi(\vec{y}, t), \quad (28.97)$$

$$H_R(CT) = \frac{iZe\hbar}{M} \vec{A}(\vec{0}, t) \cdot \int d^3x \psi^\dagger(\vec{x}, t) \vec{\nabla}_x \psi(\vec{x}, t), \quad (28.98)$$

and

$$H_R(TT) = \frac{Z^2 e^2}{2M} \vec{A}(\vec{0}, t) \cdot \vec{A}(\vec{0}, t). \quad (28.99)$$

We note the similarity of $H_R(CC)$ with the Coulomb part of the QED Hamiltonian H_C , Eq. (28.12).

Treating the new interaction Hamiltonians then to first order will account for all m/M corrections to all order in $Z\alpha$. One can equally well extend the calculations to many-electron ions, although accounting for the electron–electron interaction requires including as many factors coming from the initial interaction Hamiltonian as are required for convergence.

28.7 Concluding Remarks

Precision QED is presently a quite active field, and we have touched on only a few topics. Conferences on the subject are frequent, with the biannual International Conference on Precision Atomic Physics being of note; the interested reader should be able to access the talks given at them through the internet. A particularly active field involves applications of NRQED, which has been developed to quite a high level by a number of researchers. In these recent works, dimensional regularization is used in conjunction with the Foldy–Wouthuysen transformation along with powerful numerical methods that allow treatment of Green functions involving more than one electron. Of particular note is the completion of the treatment of helium fine structure in [53] to order $mc^2\alpha^7$, which can be used to determine the fine structure constant. More recently, we note the very large-scale calculation of the properties of singlet helium in [54]. What we wish to emphasize in closing is that the basic framework of QED as the theory underpinning our understanding of all electromagnetically bound states is in some sense simple, despite the extreme complexity of present calculations. We have discussed the two basic propagators, that of the electron and the photon, and the interaction Hamiltonian $H_I(t)$ given

in Eq. (28.24), and an approach based on a Feynman diagram treatment of Green functions to calculate the energies of bound states. That is all that is needed to describe a vast array of systems, and when they are simple enough, agreement with experiment at the ppm level is routinely found from just a few basic assumptions.

Acknowledgements Donald Yennie was working on the basic idea of using the Green function approach of the Bethe–Salpeter equation for atoms with many electrons, in particular using a two-time formalism. His unpublished paper “Bethe–Salpeter Approach to Atomic Physics”, along with [19], shaped the treatment of QED given in this chapter.

Abstract

We describe recent developments in tests of quantum electrodynamics (QED), the theory of the interactions of matter with electromagnetic fields. The tests focus on consistency in the determination of parameters or constants within QED obtained via multiple independent means and, in particular, by comparisons of precision measurements with equivalently accurate theoretical calculations. The most precise tests rely on a combination of the spectroscopy of atomic hydrogen, g -factor measurements of a free electron as well as that of an electron bound in a hydrogen-like ion, and finally the mass determination of the ions through atom recoil experiments and mass spectrometry. These experiments determine the dimensionless

fine-structure constant and the mass of the electron to about ten significant digits, orders of magnitude better than any other description of nature. We also show that an international system of units (SI) based on fixed values of the Planck constant and the charge of the electron (in addition to the fixed value of the speed of light in vacuum) modifies the interpretation of some of these tests.

fundamental constants · quantum electrodynamics · g -factors · proton radius puzzle · hydrogen energy levels

29.1 Introduction

Tests of the fundamental laws of nature are crucial for the foundations of our knowledge of physics. The most precise theory is quantum electrodynamics (QED), which describes charged particles interacting with electromagnetic fields. It is a well-verified theory with uncertainties of observables approaching a few parts in 10^{13} for the g -factor of the electron. Our ability to test the theory is still improving with no sign of a breakdown. For example, Fig. 29.1 shows that over the past 100 years the relative uncertainty of the dimensionless fine-structure constant α has seen an exponential improvement by eight orders of magnitude to a 2014 relative uncertainty of 2×10^{-10} . In some cases, the precision of the tests is now limited by our understanding of another fundamental theory, namely quantum chromodynamics (QCD). For example, nuclear-structure effects limit the comparison between theory and experiment for the hyperfine structure of hydrogen.

On May 20, 2019 the International System of Units (SI) [2] was redefined based on fixing the values of fundamental constants that appear naturally in the laws of physics. This continues a trend started in 1983 when the speed of light

Fig. 29.1 Fractional uncertainty of the fine-structure constant α over the past 100 years, starting in 1916 with the introduction of α by A. Sommerfeld [1]

in vacuum, c , was fixed [3]. Now the reduced Planck constant \hbar , electron charge e , the Boltzmann constant k , and the Avogadro constant N_A have also been fixed. Although the laws of nature are independent of the definitions of the units, the transition to the revised SI does change our perspective on the tests.

This chapter reviews comparisons between theory and experiment that test our understanding of laws of nature. The focus is on quantitative tests of QED through measurements of hydrogen energy levels, the g -factors of the electron and hydrogen-like ions, and atom recoil energies from photon interactions. These measurements determine the fine-structure constant α , the electron mass m_e , and atomic masses, and demonstrate consistency of the theory. It is worth noting that the dimensionless constant $\alpha \equiv e^2/(4\pi\epsilon_0\hbar c)$ is much less than one, where ϵ_0 is the electric constant or permittivity of vacuum. Recent reviews that cover topics in this chapter are given in [4, 5]. Our values of inexactly-known fundamental constants are the 2014 CODATA recommended values [5], unless otherwise noted.

29.2 Consistency of Fundamental Physics

The most precise tests of quantum electrodynamics are intertwined with the determination of the fine-structure constant, electron mass, and masses of atoms. In fact, the measure-

ments are determinations of transition frequencies in hydrogen, spin-flip and cyclotron frequencies of the free and bound electron in a magnetic field, as well as atom recoil energies. They are compared to theoretical expressions for these observables, which, generally, are functions of fundamental constants.

For a hydrogen atom at rest, the energy of state i is

$$E_i = (m_p + m_e)c^2 - \frac{1}{2}m_e c^2 \alpha^2 \left\{ \frac{1}{n_i^2} + \dots \right\}, \quad (29.1)$$

where m_p is the mass of the proton, and n_i is the principal quantum number of state i . It will be convenient to use the Hartree energy $E_h = m_e c^2 \alpha^2$. The dots in this theoretical expression indicate corrections that are small compared to the leading term. Examples are contributions that are higher-order in α , of order of the electron–proton mass ratio m_e/m_p , and of order of the ratio of the root-mean-square (rms) proton charge radius to the Bohr radius r_p/a_0 . Equation (29.1) also sets the mass of the hydrogen atom in state i , that is, $m(\text{H}_i) = E_i/c^2$.

Many (angular) transition frequencies

$$\omega = \frac{E_j - E_i}{\hbar} \quad (29.2)$$

have been measured over the decades. They primarily determine the Hartree energy E_h (or equivalently the Rydberg constant R_∞ .) Often the experiments, such as those measuring the energy differences between two S states, involve two-photon transitions where ω is replaced by 2ω . A second class of transitions relevant for our purposes is that where the contribution from the Bohr energies, proportional to $1/n^2$, cancels. An example is the Lamb shift between the $2P_{1/2}$ and $2S_{1/2}$ states. In this case, the transition frequencies are proportional to a higher power in α than α^2 .

The frequency measurements provide a first example of the change in perspective introduced by the revised SI. In particular, in precise spectroscopy, photon frequencies ω are measured from which energy differences $\hbar\omega$ are inferred. In the SI in which \hbar is not exact, this inference leads to relatively inaccurate energies in units of joules. In the revised SI, there is no loss of accuracy in this conversion.

The second ingredient for our tests of QED is a measurement of the anomaly a_e of the g -factor of the free electron placed in a homogeneous magnetic field \vec{B} [6]. The electron undergoes cyclotron motion with angular frequency

$$\omega_c = 2 \frac{\mu_B}{\hbar} B \quad (29.3)$$

and spin-flip transitions with frequency

$$\omega_s = |g_e| \frac{\mu_B}{\hbar} B, \quad (29.4)$$

where $\mu_B = e\hbar/(2m_e)$ is the Bohr magneton, and the electron g -factor is $g_e = -2[1 + a_e(\alpha, \dots)]$. The anomaly is then extracted from a direct measurement of the difference of the spin-flip and cyclotron frequencies, $\omega_s - \omega_c$ and a measurement of ω_c . That is,

$$\left. \frac{\omega_s - \omega_c}{\omega_c} \right|_{\text{exp}} = a_e(\alpha, \dots) = \frac{1}{2} \frac{\alpha}{\pi} + \dots \quad (29.5)$$

The \dots indicate small corrections of higher order in α . Additional corrections are proportional to the mass ratio m_e/m_μ for vacuum polarization corrections from virtual muon loops, for example.

The hydrogen spectroscopy is, thus, a means to determine $m_e c^2 \alpha^2 / \hbar$ (or equivalently $m_e c \alpha^2$), while g -factor measurements of the free electron determine α . Together, the two experiments thus specify α and m_e . This, however, does not constitute a test of a fundamental theory. It only determines values of the constants. The required additional input is achieved with atom recoil measurements.

The recoil energy of a neutral atom X of mass $m(X)$ initially at rest after absorption of a photon from a laser beam with angular frequency ω_1 and subsequent (resonant) emission of a photon into a laser beam with a slightly-smaller frequency ω_2 propagating in the opposite direction is

$$E_{\text{rec}} = \hbar(\omega_1 - \omega_2) = \frac{(2\hbar k)^2}{2m(X)} + \dots, \quad (29.6)$$

where the average momentum of the photons is $\hbar k$, $k = \omega/c$ and $\omega = (\omega_1 + \omega_2)/2$. The \dots represent small corrections mainly due to the difference in momentum of the photons in the two laser beams. (In actual realizations, many photons are scattered from the atom in order to improve accuracy.)

Photon frequencies and their differences can be measured more accurately than any of the other parameters in Eq. (29.6). Thus, we restate this equation as

$$\left. \frac{\omega^2}{(\omega_1 - \omega_2)} \right|_{\text{exp}} = \frac{1}{2} \frac{m(X)c^2}{\hbar} + \dots \quad (29.7)$$

Hence, recoil measurements determine mass $m(X)$ in the revised SI as both c and \hbar are exactly defined. In the old SI, \hbar was not exact, and the experiment only measured $m(X)/\hbar$.

A measurement of atomic mass does not immediately help in testing fundamental theory. We can complete the story, illustrated in Fig. 29.2, by determining the atom-to-electron mass ratio $m(X)/m_e$ and, thus, find an independent value for the electron mass. To date this occurs in a two-step process. First, mass spectrometry of atomic ions [7, 8] measures mass ratios of low-charge-state ions of atoms X and Y . The mass ratio of the corresponding neutral atom is then accurately inferred by accounting for the appropriate number of electron masses and ionization energies.

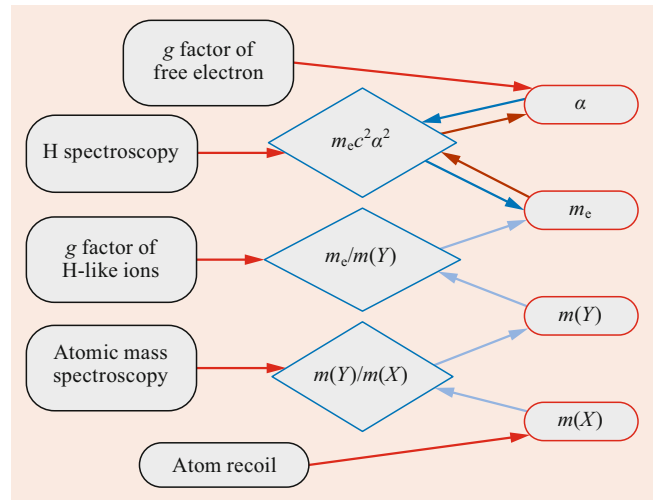

Fig. 29.2 Flow diagram for tests of QED based on the revised SI. Black boxes on the left-hand side correspond to the five precision experiments used to determine four fundamental constants in red boxes on the right-hand side. Arrows describe one-way connections from experiments to the constants. The constants are the fine-structure constant α , the electron mass m_e , and masses of various atoms, $m(X)$ and $m(Y)$. Most experiments only measure products or ratios of the fundamental constants shown as blue diamonds. For example, atomic mass spectrometry only determines ratios of atomic masses. The relations among α , m_e , and $m_e c^2 \alpha^2$ can be traversed in either direction

Second, g -factor measurements of the electron bound in a hydrogen-like ion Y^{q+} determine mass ratios $m(Y^{q+})/m_e$ through spin-flip and cyclotron frequency ratios of the ion in a magnetic field and the relationship

$$\left. \frac{\omega_s(Y^{q+})}{\omega_c(Y^{q+})} \right|_{\text{exp}} = -\frac{1}{2q} \frac{m(Y^{q+})}{m_e} g_Y(\alpha, \dots). \quad (29.8)$$

Here, $q = Z_Y - 1$, Z_Y is the charge number of the nucleus of the ion, and the theoretical (negative) g -factor g_Y can be calculated with sufficient accuracy. The ratio $m(Y)/m_e$ is then inferred as in mass spectrometry measurements. It may seem surprising that g_Y can be calculated accurately. The key is that $g_Y \approx -2$ to lowest order in Dirac theory, and, therefore, corrections need not be computed as accurately as for the anomaly of a free electron.

This indirect approach to obtain $m(X)/m_e$ is needed as recoil experiments use atoms for which hydrogen-like g -factor measurements are not available. Moreover, mass differences between ionization stages of an atom, including those due to the binding energy of the electrons, can only be accurately accounted for in small- Z_Y ions.

The change in units from the old to the revised SI is also reflected in our understanding of mass. Figure 29.3 shows the contributions to and uncertainties of the mass of the ground-state hydrogen atom, $m(\text{H})$, in the SI unit of mass (kg) and in the atomic mass unit (amu) $m_u = m(^{12}\text{C})/12$, one twelfth of the mass of a ^{12}C atom. Clearly, the mass of the proton

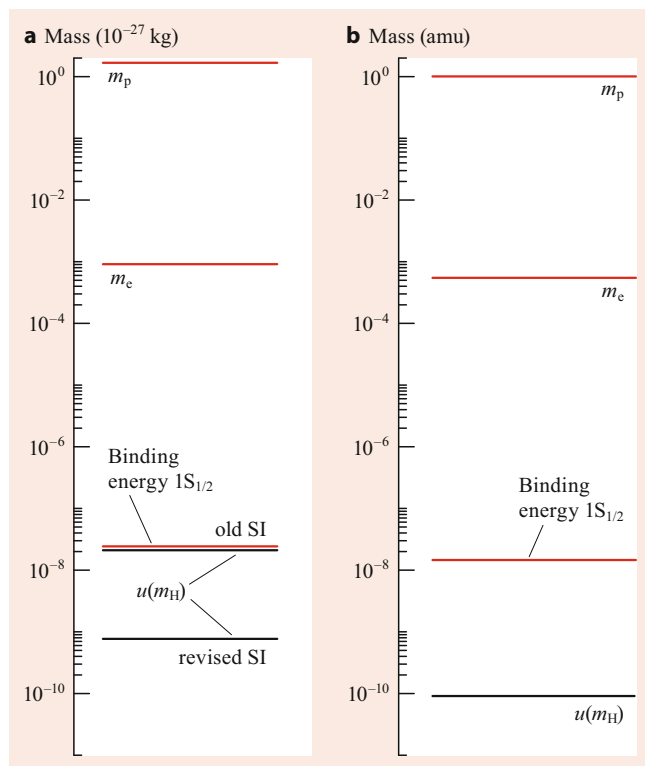

Fig. 29.3 Contributions to the mass of a $1S_{1/2}$ hydrogen atom, $m(\text{H})$, in kilograms (a) and atomic mass units (b) on a logarithmic scale. From top to bottom, the red lines in each panel correspond to the mass of the proton, electron, and the absolute value of the binding energy (divided by c^2), respectively. In (a), the black horizontal lines are the uncertainties of the hydrogen mass, $u(m_{\text{H}})$, in the old and revised SI. The black line in (b) shows $u(m_{\text{H}})$ in atomic mass units

is by far the largest contribution and, in fact, its uncertainty fully determines the uncertainty in both units of mass. Nevertheless, in units of m_{u} , the hydrogen mass is known with ten significant digits as it can be relatively easily compared to the mass of a carbon atom. This has not changed in the redefinition. We also observe that in the old SI, the uncertainty of $m(\text{H})$ in kg nearly coincides with the contribution from the binding energy. With the redefinition, the uncertainty of $m(\text{H})$ in kg has improved by more than an order of magnitude to 1 part in 10^9 and is mainly limited by our ability to measure the fine-structure constant. This follows from expressing the hydrogen mass in terms of the atomic mass unit and that of the electron, i.e.,

$$m(\text{H}) = \frac{m(\text{H})}{m_{\text{u}}} \frac{m_{\text{u}}}{m_{\text{e}}} m_{\text{e}} = A_{\text{r}}(\text{H}) \frac{1}{A_{\text{r}}(\text{e})} \left[\frac{E_{\text{h}}}{\hbar} \right] \frac{1}{\alpha^2} \frac{\hbar}{c^2},$$

where $A_{\text{r}}(X) \equiv m(X)/m_{\text{u}}$, and we used the definition of the Hartree energy to rewrite the dependence on the electron mass. The relative uncertainties in $A_{\text{r}}(\text{H})$, $A_{\text{r}}(\text{e})$, and E_{h} are currently smaller than that of α .

In summary, we have described five experiments that determine four quantities. This is an overdetermined data set and

checks for consistency. To date these checks are good to parts in 10^{10} and confirm the theory at this level. We stress, however, that the tests of fundamental theory are more wide ranging than suggested by the limited number of measurements. They include at least two implicit assumptions that are worth mentioning. The first is energy conservation and leads to the fact that the frequency of an emitted or absorbed photon equals the frequency difference of energy levels of the atom. A second assumption is that particles have a wave-like nature as well or, more precisely, that the momentum p of a massive particle or massless photon is inversely proportional to its reduced wavelength λ . In fact, $p = \hbar k$, where $k = 1/\lambda$ is the photon wavenumber. This relation combined with energy-momentum conservation underpins the atom recoil experiments.

29.3 Topics in This Review

The description of tests of QED in the previous section needs to be refined to include the role of small corrections and their parameters. For example, in hydrogen spectroscopy, the mass and charge radius of the proton must be considered. In g -factor measurements and hydrogen spectroscopy, virtual vacuum polarization loops containing the heavier muon and tau leptons, as well as quarks, lead to additional mass dependencies. The next sections summarize how these dependencies arise.

We only consider a subset of tests of QED. Some of the omitted topics are the spectroscopy of positronium, QED of highly-charged simple ions, Delbrück scattering of photons by nuclei, and helium fine structure. Positronium would suffer less from corrections due to hadronic effects. The theory, however, is more difficult due to the absence of a small parameter, such as the electron-to-proton mass ratio. Highly-charged ions are a means of studying strong field effects near their nucleus. Photon scattering by nuclei can create virtual lepton pairs in a domain beyond the Compton scattering process. The helium measurements are an independent means of determining the fine-structure constant. Some of these topics are covered in other chapters of this book. Although these topics may be considered equally important, our attention in this chapter is focused on the most precise tests of QED.

The remainder of this article has the following structure. Section 29.4 summarizes the required QED theory for the g -factor of the free electron and our ability to extract α . Section 29.5 then describes mass measurements by atom recoil experiments and mass-ratio measurements by atomic mass spectrometry for the heavier atoms. Mass-ratio determinations $m(Y)/m_{\text{e}}$ for light atoms are discussed in Sect. 29.6. The section also summarizes the theory of the electron g -factor in hydrogen-like ions. Combined, Sects. 29.5 and 29.6 lead to the most-accurate value for m_{e} . We finish with a discussion of QED theory for the hydrogen atom in Sect. 29.7.

29.4 Electron g -Factor Anomaly

The theoretical expression for the anomaly of the electron $a_e(\text{th})$ may be written as

$$a_e(\text{th}) = a_e(\text{QED}) + a_e(\text{weak}) + a_e(\text{had}) , \quad (29.9)$$

where the terms denoted by “QED”, “weak”, and “had” account for the purely quantum electrodynamic, predominantly electroweak, and predominantly hadronic (that is, strong interaction) contributions to a_e , respectively. The QED contribution may be written as

$$a_e(\text{QED}) = \sum_{n=1}^{\infty} C_e^{(2n)} \left(\frac{\alpha}{\pi}\right)^n , \quad (29.10)$$

where index n corresponds to contributions with n virtual photons. Here, $n > 5$ contributions can be neglected, and

$$C_e^{(2n)} = A_1^{(2n)} + A_2^{(2n)}(x_{e\mu}) + A_2^{(2n)}(x_{e\tau}) + \dots , \quad (29.11)$$

with coefficients $A_1^{(2n)}$ and functions $A_2^{(2n)}(x)$ evaluated at $x = x_{eX} \equiv m_e/m_X \ll 1$ for lepton $X = \mu$ or τ . For $n > 1$, the coefficients $A_1^{(2n)}$ include vacuum-polarization corrections with virtual electron/positron pairs, while $A_2^{(2n)}(x)$ are vacuum-polarization corrections due to heavier leptons. For $x \rightarrow 0$, we have $A_2^{(4)}(x) = x^2/45 + \mathcal{O}(x^4)$ and $A_2^{(6)}(x) = x^2(b_0 + b_1 \ln x) + \mathcal{O}(x^4)$ with $b_0 = 0.593274\dots$ and $b_1 = 23/135$ [9, 10]. The $\mathcal{O}(x^4)$ contributions are known and included in the calculations but not reproduced here. The functions $A_2^{(8)}(x)$ and $A_2^{(10)}(x)$ are also $\mathcal{O}(x^2)$ for small x but are not reproduced here [11, 12]. Currently, vacuum-polarization corrections for the free-electron anomaly that depend on two lepton mass ratios can be neglected. Table 29.1 lists the relevant coefficients as used in the 2014 CODATA adjustment. Uncertainties in parenthesis here and elsewhere are combined one-standard-deviation statistical and systematic uncertainties. Additional references to the

Table 29.1 Coefficients for the QED contributions to the electron anomaly. The coefficients $A_1^{(2n)}$ and functions $A_2^{(2n)}(x)$, evaluated at $x = x_{e\mu} \equiv m_e/m_\mu$ and $x_{e\tau} \equiv m_e/m_\tau$ for the muon and tau leptons, respectively, are listed with two significant digits for ease of comparison; summed values $C_e^{(2n)}$, based on the 2014 CODATA adjustment, are listed as accurately as needed for the tests described in this article. Missing values indicate that their contribution to the electron anomaly is negligible

Fig. 29.4 Fractional absolute values of the contributions to the theoretical g -factor anomaly of the free electron. QED contributions are due to the mass-independent $A_1^{(2n)}$ (black markers), to the muon-dependent $A_2^{(2n)}(x_{e\mu})$ (red markers), and to the tau-dependent $A_2^{(2n)}(x_{e\tau})$ (blue markers) corrections, respectively. Contributions due to the weak and hadronic interactions are also shown. The horizontal orange line shows the relative uncertainty in the determination of $a_e(\text{th})$. The graph is based on the 2014 CODATA value for the fine-structure constant

original literature can be found in the paper on the adjustment. It is worth noting that since 2014 the coefficient $A_1^{(8)}$ has been evaluated virtually exactly in a tremendous effort described in [13], while $A_2^{(10)}$ has been updated, shifting its value [14].

The electroweak contribution is

$$a_e(\text{weak}) = 0.02973(23) \times 10^{-12} \quad (29.12)$$

and is calculated as discussed in the 1998 CODATA adjustment but with the 2014 values of the Fermi coupling constant $G_F/(\hbar c)^3$ and the weak mixing angle θ_W [15]. The total hadronic contribution is

$$a_e(\text{had}) = 1.734(15) \times 10^{-12} \quad (29.13)$$

and is a sum of multiple vacuum-polarization contributions.

Figure 29.4 shows a graphical representation of contributions to the electron anomaly. The QED corrections decrease roughly exponentially in size with order n for both mass-independent and dependent contributions. Contributions from virtual loops containing τ leptons are currently negligible. Weak and hadronic contributions are more important. The theoretical uncertainty of the anomaly (absent any uncertainty in the fine-structure constant) is dominated by two contributions: the mass-independent $n = 5$ QED correction and the hadronic contribution. In fact, it is given by

$$u[a_e(\text{th})] = 0.037 \times 10^{-12} = 0.32 \times 10^{-10} a_e \quad (29.14)$$

and is significantly smaller than the uncertainty of the most-accurate experimental value of $2.4 \times 10^{-10} a_e$ [6]. Consequently, the relative uncertainty of the fine-structure constant is essentially the same as the experimental relative uncertainty. That is, equating the theoretical expression of a_e (th) and the experimental value yields

$$\alpha^{-1}(a_e) = 137.035999160(33) \quad [2.4 \times 10^{-10}]. \quad (29.15)$$

The number in square brackets is the relative uncertainty of the fine-structure constant, $u_r(\alpha) = u(\alpha)/\alpha$.

29.5 Atom Recoil Experiments and Mass Spectrometry

Atom recoil experiments are performed with the heavier alkali-metal atoms, ^{87}Rb and ^{133}Cs . These atoms have easily accessible atomic transitions in the optical frequency domain, with excited states that only decay back to the ground state and can, thus, be brought to a near standstill by laser cooling techniques. For the 2014 CODATA adjustment, the most accurate measurement relied on the ^{87}Rb isotope [16] and gave

$$\frac{m(^{87}\text{Rb})}{\hbar} = 1,368,480,428.9(1.7) \text{ m}^{-2} \text{ s} \quad [1.2 \times 10^{-9}]. \quad (29.16)$$

In the revised SI with a fixed reduced Planck constant, this translates into an equally accurate measurement of $m(^{87}\text{Rb})$ in kg. A 2018 value for $m(^{133}\text{Cs})/\hbar$ for atomic cesium with a three times smaller relative uncertainty is reported in [17].

In mass spectrometry, the most accurate measurements compare the mass of two or more low-charge-state ions. Over the years, these measurements have been performed for most stable and unstable atoms in the periodic table. After accounting for the mass of the electrons and binding energies, mass data for neutral atoms were collated in [18, 19] in the atomic mass unit m_u . For ^{87}Rb and ^{28}Si , this 2012 database gives

$$A_r(^{87}\text{Rb}) = \frac{m(^{87}\text{Rb})}{m_u} = 86.9091805319(65) \quad [7.5 \times 10^{-11}], \quad (29.17)$$

and

$$A_r(^{28}\text{Si}) = 27.97692653465(44) \quad [1.6 \times 10^{-11}], \quad (29.18)$$

respectively, which have a much smaller relative uncertainty than that for masses determined by atom recoil measurements. The improved 2016 evaluation can be found in [7, 20].

In any case, from this recoil measurement, we calculate

$$m(^{12}\text{C}) = m(^{87}\text{Rb}) \times \frac{12}{A_r(^{87}\text{Rb})} \quad (29.19)$$

in kg in the revised SI to determine $m(^{12}\text{C})$ with a relative uncertainty of 1.2×10^{-9} through error propagation. Similarly, relationships can be used for the mass of ^{28}Si .

29.6 Mass-Ratio Measurements Using the g -Factor of Hydrogen-Like Ions

Measurements of the spin-flip and cyclotron frequencies of ground-state hydrogen-like atomic ions in a homogeneous magnetic field are currently the most accurate means to determine atom-to-electron mass ratios. This method relies on the ability of theorists to calculate the g -factor of the bound electron accurately. This approach is competitive as long as the trapped ion is relatively light. Accounting for the electron removal energies of ions becomes prohibitively hard for heavy atoms. Similarly, computing the g -factor within the framework of relativistic QED bound-state theory is more complex for heavier hydrogen-like ions as corrections with higher powers in $Z\alpha$ are more important. For nuclei with zero nuclear spin, the mass ratio follows from rearranging Eq. (29.8) to

$$\frac{m(Y^{q+})}{m_e} = -2q \frac{1}{g_Y(\alpha, \dots)} \frac{\omega_s(Y^{q+})}{\omega_c(Y^{q+})} \Big|_{\text{exp}} \quad (29.20)$$

and

$$\frac{m(Y)}{m_e} = \frac{m(Y^{q+})}{m_e} + q - \sum_{m=0}^{q-1} \frac{E_1(Y^{m+})}{m_e c^2}, \quad (29.21)$$

where $E_1(Y^{m+})$ is the positive ionization energy of ion Y^{m+} , and we recall that $q = Z_Y - 1$.

A broad program involving researchers from a number of European laboratories has measured spin-flip and cyclotron frequency ratios and calculated the g -factor for different ions, most notably $^{12}\text{C}^{5+}$ and $^{28}\text{Si}^{13+}$. The measurements themselves were performed at the Max-Planck Institut für Kernphysik (MPIK), Heidelberg, Germany. Recently reported values are [21, 22]

$$\frac{\omega_s(^{12}\text{C}^{5+})}{\omega_c(^{12}\text{C}^{5+})} = 4376.21050087(12) \quad [2.8 \times 10^{-11}], \quad (29.22)$$

and [23]

$$\frac{\omega_s(^{28}\text{Si}^{13+})}{\omega_c(^{28}\text{Si}^{13+})} = 3912.86606484(19) \quad [4.8 \times 10^{-11}]. \quad (29.23)$$

These two frequency ratios are correlated with a correlation coefficient $r = 0.347$ mainly due to image charge corrections [24]. The authors of [24] also slightly reassessed the values given in the original references. The reassessed values are quoted here.

Fig. 29.5 Ionization energies (a) and their uncertainties (b) of the six charge states $^{12}\text{C}^{m+}$ of carbon-12 expressed in units of $m_e c^2$. Notice the large difference in scale between the two panels. In practice, ionization energies, E_I , are reported in units of hc . The unit conversion of the energies and their uncertainties is based on the identity $E/(m_e c^2) = \alpha^2/(2R_\infty) \times E/(hc)$, where R_∞ is the Rydberg constant, and we observe that $\alpha^2/(2R_\infty)$, with a relative uncertainty of 5×10^{-10} , does not increase the uncertainty of the E_I

The theoretical electron g -factors for $^{12}\text{C}^{5+}$ and $^{28}\text{Si}^{13+}$ have a relative uncertainty of 1.3×10^{-11} and 8.5×10^{-10} , respectively, as explained in the next section. Hence, the relative uncertainty for the mass ratio m_{Yq+}/m_e is 3.0×10^{-11} and 8.5×10^{-10} for these two ions, respectively. Next, we use Eq. (29.21) to determine the neutral atom to electron mass ratio. Figure 29.5 shows the ionization energies and their uncertainties for all charge states of ^{12}C in units of $m_e c^2$. We observe that, as expected, the ionization energy increases with charge state, but that, possibly surprisingly, the ionization energy with the largest uncertainty by far is that for the singly charged carbon ion. The ionization energies are added to give the electron removal energy $\Delta E_B = 1.0569819(18) \times 10^{-3} m_e c^2$ from ^{12}C to $^{12}\text{C}^{5+}$.

We combine the results of Sects. 29.5 and 29.6 to find the values

$$\frac{m(^{12}\text{C})}{m_e} = 21,874.66183428(66) \quad [3.0 \times 10^{-11}]$$

and

$$\begin{aligned} \frac{m_e}{\hbar} &= \frac{m_e}{m(^{12}\text{C})} \frac{m(^{12}\text{C})}{m(^{87}\text{Rb})} \frac{m(^{87}\text{Rb})}{\hbar} \\ &= 8.637992726(11) \times 10^3 \text{ m}^{-2} \text{ s} \quad [1.2 \times 10^{-9}]. \end{aligned} \quad (29.24)$$

We observe that the removal energy ΔE_B has a measurable effect on the mass of the carbon-12 atom but that the uncertainty of m_e/\hbar is currently limited by the atom recoil

experiment. An evaluation of m_e/\hbar based on ^{28}Si data gives a consistent value with only a slightly larger uncertainty. The two values can be combined to find more accurate values for $m(^{12}\text{C})/m_e$ and m_e/\hbar as long as the strong correlations between the uncertainties of the g -factor, as well as those of the frequency ratio ω_s/ω_c , are taken into account. With the 2018 atom recoil experiments with ^{133}Cs [17], the uncertainty of m_e/\hbar has improved by a factor of 3.

29.6.1 Theory for the g -Factor of Hydrogen-Like Ions

We summarize the contributions to the theoretical description of the electron g -factor of ground S -state hydrogen-like ions. The main contributions to the g -factor can be categorized as

$$g_Y = g_D + \Delta g_{\text{rad}} + \Delta g_{\text{rec}} + \Delta g_{\text{ns}} + \dots, \quad (29.25)$$

where g_D is the Dirac (relativistic) value, and Δg_{rad} , Δg_{rec} , and Δg_{ns} are due to radiative, recoil, and nuclear size corrections, respectively. Other corrections, indicated by the dots, are negligible at this time. Numerical results for the various contributions are summarized in Table 29.2 for $^{12}\text{C}^{5+}$ and Table 29.3 for $^{28}\text{Si}^{13+}$.

The Dirac value is known exactly [25] from the Dirac equation for an electron in the field of a fixed point charge of magnitude Ze , where, for clarity, we omit subscript Y on Z for the remainder of this section. Its value is

$$g_D = -\frac{2}{3} \left[1 + 2\sqrt{1 - (Z\alpha)^2} \right], \quad (29.26)$$

with an uncertainty that is solely due to the uncertainty in α . Radiative corrections may be written as

$$\Delta g_{\text{rad}} = -2 \sum_{n=1} C_e^{(2n)}(Z\alpha) \left(\frac{\alpha}{\pi} \right)^n, \quad (29.27)$$

where the functions $C_e^{(2n)}(x)$ are evaluated at $x = Z\alpha$, correspond to contributions with n virtual photons, and are slowly varying functions of x . They are related to the coefficients for the free electron $C_e^{(2n)}$, defined in Sect. 29.4, by

$$\lim_{x \rightarrow 0} C_e^{(2n)}(x) = C_e^{(2n)}. \quad (29.28)$$

The function $C_e^{(2)}(x)$ is computed as the sum of three contributions. The first contribution is a self-energy correction given by

$$\begin{aligned} C_{e,\text{SE}}^{(2)}(x) &= \frac{1}{2} \left\{ 1 + \frac{1}{6} x^2 + x^4 \left[\frac{32}{9} \ln(x^{-2}) + \frac{247}{216} \right. \right. \\ &\quad \left. \left. - \frac{8}{9} \ln k_0 - \frac{8}{3} \ln k_3 \right] + x^5 R_{\text{SE}}(x) \right\}, \end{aligned} \quad (29.29)$$

where $\ln k_0 = 2.984128556$ and $\ln k_3 = 3.272806545$. Values for the remainder function $R_{SE}(x)$ are based on extrapolations from numerical calculations at high Z . In particular, $R_{SE}(6\alpha) = 22.160(10)$ and $R_{SE}(14\alpha) = 20.999(2)$ based on the 2014 CODATA adjustment. In 2017, the values for $R_{SE}(x)$ were significantly improved [26].

The second and third contributions to $C_e^{(2)}(x)$ are two lowest-order vacuum-polarization corrections [27]. In the second “wave function” correction, the vacuum polarization loop modifies the interaction between the bound electron and the Coulomb field of the nucleus, and in the third “potential” correction, the loop modifies the interaction between the bound electron and the external magnetic field. The sum of the one-photon vacuum polarization contributions are

$$C_{e,VP}^{(2)}(6\alpha) = -0.000001832142(12), \quad (29.30)$$

and

$$C_{e,VP}^{(2)}(14\alpha) = -0.0000505452(11), \quad (29.31)$$

for $^{12}\text{C}^{5+}$ and $^{28}\text{Si}^{13+}$, respectively.

The $n = 2$ two-photon correction for the ground S -state is [28, 29]

$$\begin{aligned} C_e^{(4)}(x) &= \left(1 + \frac{x^2}{6}\right) C_e^{(4)} \\ &+ x^4 \left[\frac{14}{9} \ln(x^{-2}) + \frac{991,343}{155,520} - \frac{2}{9} \ln k_0 - \frac{4}{3} \ln k_3 \right. \\ &+ \left. \frac{679\pi^2}{12,960} - \frac{1441\pi^2}{720} \ln 2 + \frac{1441}{480} \zeta(3) \right] + \mathcal{O}(x^5) \\ &= \begin{cases} -0.3285778(23) & \text{for } x = 6\alpha \\ -0.32917(15) & \text{for } x = 14\alpha \end{cases}, \end{aligned} \quad (29.32)$$

where $\zeta(z)$ is the Riemann zeta function. The quoted uncertainty is an estimate of uncalculated higher-order contributions given by [28]

$$u[C_e^{(4)}(x)] = 2 |x^5 C_e^{(4)} R_{SE}(x)|. \quad (29.33)$$

Since the remainder function differs only by about one percent for carbon and silicon, the main Z (or x) dependence of the uncertainty is given by x^5 , and we assume that the uncertainty of the two-photon correction is completely correlated for the two ions. The authors of [30, 31] calculated some of the two-loop vacuum polarization diagrams of order x^5 and found them to be on the order of the uncertainty in Eq. (29.32). The authors of [32] computed an additional light-by-light contribution to $C_e^{(4)}(x)$, which shifts its value within its uncertainty. It is not included here.

The leading binding correction to $C_e^{(2n)}(x)$ is

$$C_e^{(2n)}(x) = \left(1 + \frac{x^2}{6} + \dots\right) C_e^{(2n)}, \quad (29.34)$$

for any n . This surprising result was derived in [33, 34], and for $n = 1$ and 2 it is evident from Eqs. (29.29) and (29.32). As the uncertainty due to uncalculated higher-order terms is negligible we use $C_e^{(2n)}(x) \rightarrow (1 + x^2/6)C_e^{(2n)}$ for the three, four, and five ($n = 3, 4,$ and 5) photon contributions with an uncertainty solely determined by the uncertainty of $C_e^{(2n)}$ in Table 29.1.

The corrections g_D and Δg_{rad} are based on the assumption that nuclei have an infinite mass. The recoil correction to the g -factor associated with a finite mass is

$$\Delta g_{\text{rec}} = \Delta g_{\text{rec}}^{(0)} + \Delta g_{\text{rec}}^{(2)}, \quad (29.35)$$

corresponding to terms that are zero-order and first-order in α/π , respectively. For $\Delta g_{\text{rec}}^{(0)}$, we have

$$\begin{aligned} \Delta g_{\text{rec}}^{(0)} &= \left\{ -(Z\alpha)^2 + \frac{(Z\alpha)^4}{3[1 + \sqrt{1 - (Z\alpha)^2}]^2} - (Z\alpha)^5 P(Z\alpha) \right\} \\ &\times \frac{m_e}{m_N} + (1 + Z)(Z\alpha)^2 \left(\frac{m_e}{m_N} \right)^2, \end{aligned} \quad (29.36)$$

where m_N is the mass of the nucleus. Mass ratios, based on the 2014 adjustment values of the constants, are $m_e/m(^{12}\text{C}^{6+}) = 0.0000457275\dots$ and $m_e/m(^{28}\text{Si}^{14+}) = 0.0000196136\dots$. The authors of [35] evaluated the function $P(x)$ numerically for a discrete set of $x < 1$, with the result $P(6\alpha) = 10.49395(1)$ for hydrogenic carbon. For silicon, we use the interpolated value $P(14\alpha) = 7.16223(1)$. For $\Delta g_{\text{rec}}^{(2)}$, we have

$$\Delta g_{\text{rec}}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^2}{3} \frac{m_e}{m_N}. \quad (29.37)$$

The uncertainty in $\Delta g_{\text{rec}}^{(2)}$ is negligible compared to that of $\Delta g_{\text{rad}}^{(2)}$.

Finally, the finite size of the nucleus leads to a small correction to the g -factor given by [36]

$$\Delta g_{\text{ns}} = -\frac{8}{3} (Z\alpha)^4 \left(\frac{r_N}{\lambda_C} \right)^2 + \dots, \quad (29.38)$$

where r_N is the nuclear rms charge radius, and $\lambda_C = \hbar/(m_e c)$ is the reduced Compton wavelength of the electron. The authors of [37] calculated additional corrections but gave numerical values for Δg_{ns} based on early r_N values. We incorporate their corrections using an $(r_N)^2$ scaling and the updated $r_N = 2.4703(22)$ fm and $r_N = 3.1223(24)$ fm for ^{12}C and ^{28}Si , respectively [38].

The theoretical value for the g -factor of the electron in hydrogen-like carbon 12 or silicon 28 is the sum of the individual contributions discussed above and summarized in Tables 29.2 and 29.3. For each contribution the tables also list the uncertainty. For both ions the uncertainty is dominated by

Table 29.2 Theoretical contributions and total value for the g -factor of hydrogenic carbon 12 based on the 2014 CODATA recommended values of the constants and corresponding theory. The total g -factor has a relative uncertainty of 1.3×10^{-11}

that of the two-photon $n = 2$ correction $\Delta g^{(4)}$. The relative uncertainties of the $^{12}\text{C}^{5+}$ and $^{28}\text{Si}^{13+}$ values are 1.3×10^{-11} and 8.5×10^{-10} , respectively, sufficient for the purpose of determining competitive atom-to-electron mass ratios. Finally, the two g -factors have a correlation coefficient $r = 0.79$.

29.7 Hydrogen Atom Energy levels

Measurements of the hydrogen energy levels are currently the most precise way to determine the Hartree energy divided by the reduced Planck constant or, equivalently, the Rydberg constant. The measurements also help determine α and the proton charge radius. The eigenstates are labeled by $n\ell_j$, where $n = 1, 2, \dots$ is the principal quantum number, $\ell = 0, 1, \dots, n-1$ is the nonrelativistic angular momentum quantum number, and j is the total angular momentum quantum number. Their energies are denoted by $E(n\ell_j)$ and, following the usual convention, we use S, P, D, \dots to denote $\ell = 0, 1, 2, \dots$ states. Our discussion will omit hyperfine effects from coupling of the electron to the magnetic and other moments of the proton, as at 2014 accuracy levels they can easily be accounted for.

The world's best-known optical transition frequency is that for the $1S_{1/2}-2S_{1/2}$ Lyman-alpha line of hydrogen, which has been obtained by an experimental group in Garching, Germany [39, 40]. They quote

$$\omega_H(1S_{1/2}-2S_{1/2}) = 2\pi \times 2,466,061,413,187,035(10) \text{ rad/s} \quad [4.2 \times 10^{-15}]$$

or

$$\nu_H(1S_{1/2}-2S_{1/2}) = 2,466,061,413,187,035(10) \text{ Hz}$$

in 2011 and

$$\omega_H(1S_{1/2}-2S_{1/2}) = 2\pi \times 2,466,061,413,187,018(11) \text{ rad/s} \quad [4.4 \times 10^{-15}]$$

or

$$\nu_H(1S_{1/2}-2S_{1/2}) = 2,466,061,413,187,018(11) \text{ Hz}$$

in 2013. The two values are correlated with a correlation coefficient $r = 0.707$ [41].

The frequency of this Lyman-alpha line is known to almost 15 significant digits. The analytical, theoretical determination of this transition frequency, which in its simplest description by Bohr equals $3E_h/(8h)$, is equally impressive, although less accurate. It has 13 contributions ranging from the Dirac eigenvalue, QED corrections with one or more virtual photons and lepton-antilepton pairs, as well as nuclear size and recoil effects. Figure 29.6a gives a visual representation of the size and uncertainties of these contributions. We postpone the discussion of the name for and mathematical form of each of the corrections until Sect. 29.7.1. The sizes of the contributions vary by orders of magnitude, although size is not necessarily an indication of its uncertainty. The uncertainty of both the Dirac energy and the correction due to the proton charge radius are the largest at ≈ 10 kHz and reflect the uncertainty of constants E_h/\hbar and r_p , respectively. The largest theoretical uncertainties are in the two-photon and three-photon corrections and reflect uncomputed terms. (The individual uncertainties of the Dirac energy and correction due to the proton charge radius are large compared to that of the experimental $1S_{1/2}-2S_{1/2}$ transition frequency. As a result the uncertainties are highly correlated with a correlation coefficient very close to one.)

The $2P_{1/2}-2S_{1/2}$ transition, or Lamb shift, is equally important, because the Dirac or Bohr energies cancel, and the dominant contribution by far is the self-energy correction, a QED correction where the bound electron emits and absorbs a virtual photon. It is of order $\alpha^3 E_h$ as seen in Sect. 29.7.1. The energy contributions to this transition are shown in Fig. 29.6b, while the two best measurements of this transition frequency are

$$\nu_H(2P_{1/2}-2S_{1/2}) = 1,057,845.0(9.0) \text{ kHz} \quad [8.5 \times 10^{-6}]$$

Fig. 29.6 Absolute value of the 13 contributions (gray bars) and their uncertainty (red and orange bars) to the hydrogen $1S_{1/2}-2S_{1/2}$ (a) and $2P_{1/2}-2S_{1/2}$ (b) transition frequencies on a logarithmic scale. The values are sorted by the size of the contribution. The label next to each contribution is defined in the text. The uncertainty of a contribution is either fully due to the uncertainty of constants within QED theory, here the Hartree frequency, E_h/\hbar , and proton charge radius (orange bars), or by the estimated value of missing or uncomputed terms (red bars). The two transition frequencies have been measured to 10 and 9 kHz, respectively

and

$$\nu_H(2P_{1/2}-2S_{1/2}) = 1,057,862(20) \text{ kHz} \quad [1.9 \times 10^{-5}],$$

from research groups at Harvard University [42] and the University of Sussex [43], respectively. The theoretical value for this transition from the 2014 CODATA least-squares adjustment is

$$\nu_H(2P_{1/2}-2S_{1/2}) = 1,057,843.7(2.1) \text{ kHz} \quad [2.0 \times 10^{-6}]$$

and is in agreement with the experiments. The largest contribution to the theoretical uncertainty is due to the uncertainty

in the proton charge radius, while uncertainties from uncomputed terms in the two-photon and three-photon corrections are much smaller than the experimental uncertainty.

In a naive least-squares adjustment that includes only these two transitions, the Lyman-alpha line and Lamb shift determine (relatively inaccurate) values for α and m_e . Data on other transitions and the measurements discussed in the previous sections significantly decrease their uncertainties, constrain the value for the proton charge radius, and check for consistency. Indeed, the focus has shifted to complementary transitions in H [44, 45] and measurements on and theory of muonic-hydrogen with the goal of resolving the discrepancies in the determination of the charge radius of the proton. In the 2014, CODATA adjustment muonic-hydrogen data was not included.

29.7.1 Theory for the Hydrogen Energy Levels

Theoretical values for hydrogen energy levels as for the bound-electron g -factor are determined by the Dirac eigenvalue, QED effects such as self-energy and vacuum polarization, and proton size and motion or recoil effects. Theoretical energies of different states are correlated. For example, for S-states, uncalculated contributions are primarily of the form of an unknown constant divided by n^3 . This is taken into account by using covariances between levels in addition to the uncertainties of the individual levels. Hence, we distinguish between components of uncertainty that are proportional to $1/n^3$ and those that are uncorrelated, where necessary. They are denoted by u_0 and u_n , respectively.

We now consider each of the contributions to the energy in turn, as well as explain how to combine the uncertainties of the contributions. Table 29.4 gives a list of the contributions, their size both in terms of fundamental constants, as well as order-of-magnitude numerical values for the $1S_{1/2}-2S_{1/2}$ transition.

Dirac Eigenvalue

The energy of an electron in a static Coulomb field with charge Ze with infinite mass is predominantly determined by the relativistic Dirac eigenvalue

$$E_D = f(n, \kappa) m_e c^2, \quad (29.39)$$

where

$$f(n, \kappa) = \left[1 + \frac{(Z\alpha)^2}{(n - \delta)^2} \right]^{-1/2}, \quad (29.40)$$

with defect $\delta = |\kappa| - \sqrt{\kappa^2 - (Z\alpha)^2}$ and κ is the angular momentum-parity quantum number ($\kappa = -1, 1, -2, 2, -3$ for $S_{1/2}, P_{1/2}, P_{3/2}, D_{3/2},$ and $D_{5/2}$ -states, respectively). States

Table 29.4 List of contributions and their main dependence on fundamental constants to the hydrogen transition frequencies ordered by appearance in the text. The first two columns give the section in Sec. 29.7.1 in which the contribution is described in detail and the name of the contribution, respectively. The fundamental-constant dependence of a contribution in the third column is given in terms of the Hartree energy $E_h = m_e c^2 \alpha^2$ and four dimensionless variables with values small compared to one: the fine-structure constant α , the proton charge radius divided by the reduced Compton wavelength r_p/λ_C , and the mass ratios m_e/m_μ and m_e/m_p . The last column gives the order of magnitude of each of the contributions in Hz for the $1S_{1/2}-2S_{1/2}$ transition

	Contribution	Scaling	Δ/h (Hz)
<i>a</i>	Dirac energy	E_h	10^{15}
<i>b</i>	Relativistic recoil	$(m_e/m_p)\alpha^3 E_h$	10^6
<i>c</i>	Nuclear polarizability	–	10^2
<i>d</i>	Self-energy	$\alpha^3 E_h$	10^{10}
<i>e</i>	Vacuum polarization	$\alpha^3 E_h$	10^8
<i>e</i>	Muon vacuum polarization	$(m_e/m_\mu)^2 \alpha^3 E_h$	10^4
<i>e</i>	Hadronic vacuum pol.	–	10^3
<i>f</i>	Two-photon	$\alpha^4 E_h$	10^6
<i>g</i>	Three-photon	$\alpha^5 E_h$	10^3
<i>h</i>	Nuclear size	$(r_p/\lambda_C)^2 \alpha^2 E_h$	10^6
<i>i</i>	Nucl. size on SE & VP	$(r_p/\lambda_C)^2 \alpha^4 E_h$	10^2
<i>j</i>	Radiative recoil	$(m_e/m_p)\alpha^4 E_h$	10^4
<i>k</i>	Nuclear self-energy	$(m_e/m_p)^2 \alpha^3 E_h$	10^3

with the same n and $j = |\kappa| - 1/2$ have degenerate eigenvalues. Finally, $\ell = |\kappa + 1/2| - 1/2$, and we retain the atomic number Z in the equations in order to classify the various contributions to the energies.

Corrections to the Dirac eigenvalue that approximately take into account the finite mass of the proton m_p are included in a more general expression for atomic energy levels. That is, we replace Eq. (29.39) by [46, 47]

$$E_M = M c^2 + \left\{ f(n, \kappa) - 1 - \frac{1}{2} [f(n, \kappa) - 1]^2 \frac{m_r}{M} + \frac{1}{2} \frac{1 - \delta_{\ell 0}}{\kappa(2\ell + 1)} \frac{(Z\alpha)^4 m_r^2}{n^3 m_p^2} + \dots \right\} m_r c^2, \quad (29.41)$$

where $M = m_e + m_p$ and $m_r = m_e m_p / (m_e + m_p)$ is the reduced mass. Note that in this equation, the energy of $nS_{1/2}$ -states differs from that of $nP_{1/2}$ -states.

Relativistic Recoil

The leading relativistic-recoil correction, to lowest order in $Z\alpha$ and all orders in m_e/m_p , is [47, 48]

$$E_S = \frac{m_r^3}{m_e^2 m_p} \frac{(Z\alpha)^5}{\pi n^3} m_e c^2 \times \left\{ \frac{1}{3} \delta_{\ell 0} \ln(Z\alpha)^{-2} - \frac{8}{3} \ln k_0(n, \ell) - \frac{1}{9} \delta_{\ell 0} - \frac{7}{3} a_n - \frac{2}{m_p^2 - m_e^2} \delta_{\ell 0} \left[m_p^2 \ln\left(\frac{m_e}{m_r}\right) - m_e^2 \ln\left(\frac{m_p}{m_r}\right) \right] \right\}, \quad (29.42)$$

Table 29.5 Values of the Bethe logarithms $\ln k_0(n, \ell)$. Missing entries correspond to states for which no experimental measurements are available

<i>n</i>	S	P	D
1	2.984128556		
2	2.811769893	−0.030016709	
3	2.767663612		
4	2.749811840	−0.041954895	−0.006740939
6	2.735664207		−0.008147204
8	2.730267261		−0.008785043
12			−0.009342954

where $a_n = -2 \ln(2/n) - 2 + 1/n - 2 \sum_{i=1}^n (1/i)$ for $\ell = 0$ and $a_n = 1/[\ell(\ell+1)(2\ell+1)]$ otherwise. Values for the Bethe logarithms $\ln k_0(n, \ell)$ are given in Table 29.5.

Additional contributions to lowest order in the mass ratio and of higher order in $Z\alpha$ are

$$E_R = \frac{m_e}{m_p} \frac{(Z\alpha)^6}{n^3} m_e c^2 [D_{60} + D_{72} Z\alpha \ln^2(Z\alpha)^{-2} + \dots], \quad (29.43)$$

where $D_{60} = 4 \ln 2 - 7/2$ for $\ell = 0$ and $D_{60} = 2[3 - \ell(\ell+1)/n^2]/[(2\ell-1)(2\ell+1)(2\ell+3)]$ otherwise. Finally, $D_{72} = -11/(60\pi) \delta_{\ell 0}$. Recently, the coefficients D_{71} and D_{70} have been computed [49, 50], where, in particular, the D_{71} was found to be surprisingly large. In [49], the nuclear-size correction to $E_S + E_R$ was also computed.

The uncertainty in the relativistic recoil correction $E_S + E_R$ is

$$[0.1\delta_{\ell 0} + 0.01(1 - \delta_{\ell 0})] E_R. \quad (29.44)$$

Covariances follow from the $1/n^3$ scaling of the uncertainty.

Nuclear Polarizability

For the energy correction due to the nuclear polarizability in hydrogen, we use

$$E_P(\text{H}) = -0.070(13) h \frac{\delta_{\ell 0}}{n^3} \text{kHz}. \quad (29.45)$$

The effect is neglected for states of higher ℓ .

Self-Energy

The one-photon self-energy of an electron bound to a stationary point nucleus is

$$E_{SE}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^4}{n^3} F(Z\alpha) m_e c^2, \quad (29.46)$$

where the function

$$F(x) = A_{41} \ln(x^{-2}) + A_{40} + A_{50} x + A_{62} x^2 \ln^2(x^{-2}) + A_{61} x^2 \ln(x^{-2}) + G_{SE}(x) x^2, \quad (29.47)$$

with $A_{41} = 4/3 \delta_{\ell 0}$, and $A_{40} = -(4/3) \ln k_0(n, \ell) + 10/9$ for $\ell = 0$ and $-(4/3) \ln k_0(n, \ell) - 1/[2\kappa(2\ell + 1)]$ otherwise. Next, $A_{50} = (139/32 - 2 \ln 2)\pi \delta_{\ell 0}$, $A_{62} = -\delta_{\ell 0}$, and

$$A_{61} = \left[4 \left(1 + \frac{1}{2} + \dots + \frac{1}{n} \right) + \frac{28}{3} \ln 2 - 4 \ln n - \frac{601}{180} - \frac{77}{45n^2} \right] \delta_{\ell 0} + \frac{n^2 - 1}{n^2} \left(\frac{2}{15} + \frac{1}{3} \delta_{j\frac{1}{2}} \right) \delta_{\ell 1}, \\ + \frac{[96n^2 - 32\ell(\ell + 1)](1 - \delta_{\ell 0})}{3n^2(2\ell - 1)(2\ell)(2\ell + 1)(2\ell + 2)(2\ell + 3)}.$$

Values for $G_{SE}(\alpha)$ in Eq. (29.47) are listed in Table 29.6. The uncertainty of the self-energy contribution is due to the uncertainty of $G_{SE}(\alpha)$ listed in the table and is taken to be type u_n . See [51] for details.

Following convention, $F(Z\alpha)$ is multiplied by the factor $(m_r/m_e)^3$, except the magnetic moment term $-1/[2\kappa(2\ell + 1)]$ in A_{40} , which is instead multiplied by the factor $(m_r/m_e)^2$, and the argument $(Z\alpha)^{-2}$ of the logarithms is replaced by $(m_e/m_r)(Z\alpha)^{-2}$.

Vacuum Polarization

The stationary point nucleus second-order vacuum-polarization level shift is

$$E_{VP}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^4}{n^3} H(Z\alpha) m_e c^2, \quad (29.48)$$

where $H(x) = H^{(1)}(x) + H^{(R)}(x)$ with

$$H^{(1)}(x) = V_{40} + V_{50}x + V_{61}x^2 \ln(x^{-2}) + G_{VP}^{(1)}(x)x^2,$$

with $V_{40} = -4/15 \delta_{\ell 0}$, $V_{50} = 5\pi/48 \delta_{\ell 0}$, and $V_{61} = -2/15 \delta_{\ell 0}$. Values of $G_{VP}^{(1)}(\alpha)$ are given in Table 29.7. Moreover, $H^{(R)}(x) = G_{VP}^{(R)}(x)x^2$ with

$$G_{VP}^{(R)}(x) = \frac{19}{45} - \frac{\pi^2}{27} + \left(\frac{1}{16} - \frac{31\pi^2}{2880} \right) \pi x + \dots, \quad (29.49)$$

for $\ell = 0$ and zero otherwise. Higher-order terms are negligible. We multiply Eq. (29.48) by $(m_r/m_e)^3$ and include a factor of (m_e/m_r) in the argument of the logarithm of the term proportional to V_{61} .

Vacuum polarization from $\mu^+\mu^-$ pairs is

$$E_{\mu VP}^{(2)} = \frac{\alpha}{\pi} \frac{(Z\alpha)^4}{n^3} \left[-\frac{4}{15} \delta_{\ell 0} \right] \left(\frac{m_e}{m_\mu} \right)^2 \left(\frac{m_r}{m_e} \right)^3 m_e c^2 + \dots, \quad (29.50)$$

while the hadronic vacuum polarization is given by

$$E_{had VP}^{(2)} = 0.671(15) E_{\mu VP}^{(2)}. \quad (29.51)$$

Uncertainties are of type u_0 . The muonic and hadronic vacuum-polarization contributions are negligible for higher- ℓ -states.

Two-Photon Corrections

The two-photon correction is

$$E^{(4)} = \left(\frac{\alpha}{\pi} \right)^2 \frac{(Z\alpha)^4}{n^3} m_e c^2 F^{(4)}(Z\alpha), \quad (29.52)$$

where

$$F^{(4)}(x) = B_{40} + B_{50}x + B_{63}x^2 \ln^3(x^{-2}) \\ + B_{62}x^2 \ln^2(x^{-2}) + B_{61}x^2 \ln(x^{-2}) + B_{60}x^2 \\ + B_{72}x^3 \ln^2(x^{-2}) + B_{71}x^3 \ln(x^{-2}) + \dots,$$

with

$$B_{40} = \left[\frac{3\pi^2}{2} \ln 2 - \frac{10\pi^2}{27} - \frac{2179}{648} - \frac{9}{4} \zeta(3) \right] \delta_{\ell 0} \\ + \left[\frac{\pi^2 \ln 2}{2} - \frac{\pi^2}{12} - \frac{197}{144} - \frac{3\zeta(3)}{4} \right] \frac{1 - \delta_{\ell 0}}{\kappa(2\ell + 1)},$$

$B_{50} = -21.55447(13) \delta_{\ell 0}$, $B_{63} = -8/27 \delta_{\ell 0}$, and

$$B_{62} = \frac{16}{9} \left[\frac{71}{60} - \ln 2 + \psi(n) + \gamma - \ln n - \frac{1}{n} + \frac{1}{4n^2} \right] \delta_{\ell 0} \\ + \frac{4}{27} \frac{n^2 - 1}{n^2} \delta_{\ell 1},$$

with Euler's constant γ and Psi function $\psi(z)$.

Values and uncertainties for B_{61} and B_{60} are listed in Tables 29.8 and 29.9, respectively. For the S-state values, the first number in parentheses for B_{60} is the state-dependent uncertainty $u_n(B_{60})$, while the second number in parentheses is the state-independent uncertainty $u_0(B_{60})$. It is worth noting that recently [32] computed an additional light-by-light correction to B_{61} for S-states. It only shifts this coefficient within its current uncertainty.

For S-states, the next term B_{72} is state independent, but its value is not known. The B_{71} coefficient is state dependent, although only the difference

$$\Delta B_{71}(nS) = B_{71}(nS) - B_{71}(1S) = \pi \left(\frac{427}{36} - \frac{16}{3} \ln 2 \right) \\ \times \left[\frac{3}{4} - \frac{1}{n} + \frac{1}{4n^2} + \psi(n) + \gamma - \ln n \right] + \dots$$

is known with a relative uncertainty $u_n(\Delta B_{71}) = 0.5 \Delta B_{71}$. For our calculations, we use $B_{71}(1S) = 0$.

As with the one-photon correction, the two-photon correction is multiplied by the reduced-mass factor $(m_r/m_e)^3$, except the magnetic moment term proportional to $1/[\kappa(2\ell + 1)]$ in B_{40} , which is multiplied by the factor $(m_r/m_e)^2$, and the argument $(Z\alpha)^{-2}$ of the logarithms is replaced by $(m_e/m_r)(Z\alpha)^{-2}$.

Three-Photon Corrections

The three-photon contribution in powers of $Z\alpha$ is

$$E^{(6)} = \left(\frac{\alpha}{\pi}\right)^3 \frac{(Z\alpha)^4}{n^3} m_e c^2 [C_{40} + C_{50}(Z\alpha) + C_{63}(Z\alpha)^2 \ln^3(Z\alpha)^{-2} + \dots]. \tag{29.53}$$

The leading term C_{40} is

$$C_{40} = \left[-\frac{568 a_4}{9} + \frac{85 \zeta(5)}{24} - \frac{121 \pi^2 \zeta(3)}{72} - \frac{84,071 \zeta(3)}{2304} - \frac{71 \ln^4 2}{27} - \frac{239 \pi^2 \ln^2 2}{135} + \frac{4787 \pi^2 \ln 2}{108} + \frac{1591 \pi^4}{3240} - \frac{252,251 \pi^2}{9720} + \frac{679,441}{93,312} \right] \delta_{\ell 0}$$

$$+ \left[-\frac{100 a_4}{3} + \frac{215 \zeta(5)}{24} - \frac{83 \pi^2 \zeta(3)}{72} - \frac{139 \zeta(3)}{18} - \frac{25 \ln^4 2}{18} + \frac{25 \pi^2 \ln^2 2}{18} + \frac{298 \pi^2 \ln 2}{9} + \frac{239 \pi^4}{2160} - \frac{17,101 \pi^2}{810} - \frac{28,259}{5184} \right] \frac{1 - \delta_{\ell 0}}{\kappa(2\ell + 1)},$$

where $a_4 = \sum_{n=1}^{\infty} 1/(2^n n^4) = 0.517479061\dots$ Only partial results for C_{50} have been obtained [52, 53]. We use $C_{50} = 0$ with uncertainty $u_0(C_{50}) = 30\delta_{\ell 0}$. Finally, we use $C_{63} = 0$ and $u_n(C_{63}) = 1$ for this unknown coefficient. Recently, *Karshenboim* and *Ivanov* [54] determined several of these coefficients. The dominant effect of the finite mass of the nucleus is taken into account by multiplying the term proportional to $\delta_{\ell 0}$ by the reduced-mass factor $(m_r/m_e)^3$ and the term proportional to $1/[\kappa(2\ell + 1)]$, the magnetic mo-

ment term, by the factor $(m_r/m_e)^2$. The contribution from four photons is expected to be negligible at the level of uncertainty of current interest.

Finite Nuclear Size

For S-states, the leading and next-order correction to the level shift due to the finite size of the nucleus is given by

$$E_{\text{NS}} = \mathcal{E}_{\text{NS}} \left\{ 1 - C_\eta \frac{m_r}{m_e} \frac{r_p}{\lambda_C} Z\alpha - \left[\ln \left(\frac{m_r}{m_e} \frac{r_p}{\lambda_C} \frac{Z\alpha}{n} \right) + \psi(n) + \gamma - \frac{(5n+9)(n-1)}{4n^2} - C_\theta \right] (Z\alpha)^2 \right\}, \quad (29.54)$$

where

$$\mathcal{E}_{\text{NS}} = \frac{2}{3} \left(\frac{m_r}{m_e} \right)^3 \frac{(Z\alpha)^2}{n^3} m_e c^2 \left(\frac{Z\alpha r_p}{\lambda_C} \right)^2. \quad (29.55)$$

The coefficients C_η and C_θ are constants that depend on the charge distribution in the nucleus with values $C_\eta = 1.7(1)$ and $C_\theta = 0.47(4)$ for hydrogen.

For the $P_{1/2}$ -states in hydrogen, the leading term is

$$E_{\text{NS}} = \mathcal{E}_{\text{NS}} \frac{(Z\alpha)^2 (n^2 - 1)}{4n^2}. \quad (29.56)$$

For $P_{3/2}$ -states and higher- ℓ -states, the nuclear-size contribution is negligible.

Nuclear-Size Correction to Self-Energy and Vacuum Polarization

For the lowest-order self-energy and vacuum polarization, the correction due to the finite size of the nucleus is

$$E_{\text{NSE}} = \left(4 \ln 2 - \frac{23}{4} \right) \alpha (Z\alpha) \mathcal{E}_{\text{NS}} \delta_{\ell 0}, \quad (29.57)$$

and

$$E_{\text{NVP}} = \frac{3}{4} \alpha (Z\alpha) \mathcal{E}_{\text{NS}} \delta_{\ell 0}, \quad (29.58)$$

respectively.

Radiative-Recoil Corrections

Corrections for radiative-recoil effects are

$$E_{\text{RR}} = \frac{m_r^3}{m_e^2 m_p} \frac{\alpha (Z\alpha)^5}{\pi^2 n^3} m_e c^2 \delta_{\ell 0} \times \left[6 \zeta(3) - 2 \pi^2 \ln 2 + \frac{35 \pi^2}{36} - \frac{448}{27} + \frac{2}{3} \pi (Z\alpha) \ln^2 (Z\alpha)^{-2} + d_{61} (Z\alpha) \ln (Z\alpha)^{-2} + \dots \right]. \quad (29.59)$$

The uncertainty is controlled by the unknown coefficient d_{61} inside the square brackets. We use $d_{61} = 0$, $u_0(d_{61}) = 10$, and $u_n(d_{61}) = 1$. Corrections for higher- ℓ -states are negligible.

Nucleus Self-Energy

The nucleus self-energy correction for S-states of hydrogen is

$$E_{\text{SEN}} = \frac{4Z^2 \alpha (Z\alpha)^4 m_r^3}{3\pi n^3 m_p^2} c^2 \times \left[\ln \left(\frac{m_p}{m_r (Z\alpha)^2} \right) \delta_{\ell 0} - \ln k_0(n, \ell) \right], \quad (29.60)$$

with an uncertainty u_0 given by Eq. (29.60), with the factor in the square brackets replaced by 0.5. For higher- ℓ -states, the correction is negligible.

Total energy and uncertainty: the energy $E(n\ell_j)$ of a level is the sum of the contributions listed above. Uncertainties in the energy due to the fundamental constants, i.e., α , $m_e c^2$, etc., are taken into account through a least-squares adjustment. Uncertainties in the theory, i.e., from estimates of missing and uncomputed terms in the contributions, are taken into account with an energy correction $\delta(n\ell_j)$, with an uncertainty that is the rms sum of the uncertainties of the individual contributions

$$u^2[\delta(n\ell_j)] = \sum_i [u_{0i}^2(n\ell_j) + u_{ni}^2(n\ell_j)], \quad (29.61)$$

where $u_{0i}(n\ell_j)$ and $u_{ni}(n\ell_j)$ are the components of uncertainty u_0 and u_n of contribution i . Covariances of the δ s are

$$u[\delta(n_1\ell_j), \delta(n_2\ell_j)] = \sum_i u_{0i}(n_2\ell_j) u_{0i}(n_1\ell_j). \quad (29.62)$$

The corrections $\delta(n\ell_j)$, their uncertainties, and covariances are input data in the least-squares adjustment. A value for $\delta(n\ell_j)$ returned by the adjustment that lies outside its uncertainty indicates either an underestimate of the value of uncomputed terms in the contributions or a role for unexpected physics beyond QED. No such discrepancies have been found.

Abstract

Fundamental constants play an important role in modern physics, being landmarks that designate different areas. We call them constants, however, as long as we only consider minor variations with the cosmological time/space scale, their constancy is an experimental fact rather than a basic theoretical principle. Modern theories unifying gravity with electromagnetic, weak, and strong interactions, or even the developing quantum gravity itself, often suggest such variations.

Many parameters that we call *fundamental constants*, such as the electron charge and mass (Chap. 1 and [1]), are actually not truly fundamental constants but effective parameters that are affected by renormalization or the presence of matter [2, 3]. Living in a changing universe we cannot expect that matter will affect these parameters the same way during any given cosmological epoch. An example is the inflationary model of the universe, which states that in a very early epoch, the universe experienced a phase transition, which, in particular, changed a vacuum average of the so-called Higgs field, which determines the electron mass. The latter was zero before this transition and reached a value close or equal to the present value after the transition.

The problem of variations of constants has many facets, and here we discuss aspects related to atomic clocks and precision frequency measurements. Other related topics may be found in [4, 5].

years; (ii) one has to be able to interpret the result in terms of fundamental constants. The latter is a strong requirement for a cross comparison of different results.

The measurements that may be performed the most accurately are frequency measurements, and thus, frequency standards or atomic clocks will be involved in most of the laboratory searches.

With the introduction of laser cooling, ion trapping, frequency comb technology, atomic interferometry, and quantum entanglement, frequency metrology has shown great progress in the past two decades and will continue to do so for some time. The constraints on the variations of the fundamental constants obtained in this manner for the present epoch are now more stringent than those from other methods (astrophysics, geochemistry), when these are extrapolated under the assumption of a linear drift in time. Laboratory experiments on frequency comparisons allow for checks of reproducibility, a very clear interpretation of the final results, and a transparent evaluation procedure, making them less susceptible to systematic errors.

The most advanced atomic clocks are discussed in Sect. 30.1. They are realized with many-electron atoms, and their frequency cannot be interpreted in terms of fundamental constants. However, a much simpler problem needs to be solved: to interpret their variation in terms of fundamental constants. This idea is discussed in Sect. 30.2. The current laboratory constraints on the variations of the fundamental constants are summarized in Sect. 30.3.

30.1 Atomic Clocks and Frequency Standards

Frequency standards are important tools for precision measurements and serve various purposes that, in turn, have different requirements that must be satisfied. In particular, it is not necessary for a practical frequency standard to reproduce a frequency that is related to a certain atomic transition, although it may be expressed in terms of it. A well-known example is the hydrogen maser, where the frequency is affected by the wall shifts, which may vary with time [6]. For the study of time variations of fundamental constants, it is necessary to use standards similar to a primary caesium clock. In this case, any deviation of its frequency from the unperturbed atomic transition frequency should be known (within a known uncertainty) because this is a necessary requirement for being a *primary* standard.

From the point of view of fundamental physics, the hydrogen maser is an artefact quite similar, in a sense, to the prototype of the kilogram held at the Bureau International des Poids et Mesures (BIPM) in Paris. Both artefacts are somehow related to fundamental constants (e.g., the mass of the prototype can be expressed in terms of the nucleon masses and their number), but they also have a kind of resid-

ual classical-physics flexibility, which allows their properties to change. In contrast, standards similar to the caesium clock have a frequency (or other property) that is determined by a certain natural constant, which is not flexible, being of pure quantum origin. It may change only if the fundamental constants are changing.

In Sect. 30.3, the results obtained with the most advanced microwave and optical frequency standards are discussed. The former include the ones based on caesium and rubidium fountains, while the latter deal with precision spectroscopy with atomic beams using two-photon excitation, with laser-cooled ions in traps and atoms in optical lattices.

30.1.1 Caesium Atomic Fountain

Caesium clocks are the most accurate primary standards for time and frequency [7]. The hyperfine splitting frequency between the $F = 3$ and $F = 4$ levels of the $^2S_{1/2}$ ground state of the ^{133}Cs atom at 9.192 GHz has been used for the definition of the SI second since 1967. In a so-called caesium fountain [8] (Fig. 30.1), a dilute cloud of laser cooled caesium atoms at a temperature of about $1\ \mu\text{K}$ is launched upwards to initiate a free parabolic flight with an apogee at about 1 m above the cooling zone. A microwave cavity is mounted near the lower endpoints of the parabola and is traversed by the atoms twice – once during ascent and once during descent – so that Ramsey’s method of interrogation with separated oscillatory fields [6] can be realized. The total interrogation

Fig. 30.1 Schematic of an atomic fountain clock

time being on the order of 0.5 s, a resonance linewidth of 1 Hz is achieved, about a factor of 100 narrower than in devices using a thermal atomic beam from an oven. Selection and detection of the hyperfine state is performed via optical pumping and laser-induced resonance fluorescence. In a carefully controlled setup, a relative uncertainty in the low 1×10^{-16} range can be reached in the realization of the resonance frequency of the unperturbed Cs atom. The averaging time that is required to reach this level of uncertainty is in the range of 10^4 to 10^5 s. One limiting effect that contributes to the systematic uncertainty of the caesium fountain is the frequency shift due to cold collisions between the atoms. In this respect, a fountain frequency standard based on the ground state hyperfine frequency of the ^{87}Rb atom at about 6.835 GHz is more favorable, since its collisional shift is lower by more than a factor of 50 for the same atomic density. While the caesium frequency is fixed by definition in the SI system, the ^{87}Rb frequency has been measured repeatedly and is one of the recommended secondary realizations of the second [9]. While a number of optical frequency standards have been evaluated with lower uncertainty, the realization of the caesium standards remains the base of international time and frequency measurements. A number of them, realized independently in numerous national metrological laboratories, are regularly compared via satellite time and frequency transfer to a fractional uncertainty of a few 10^{-16} . At such a level of accuracy, the effects of general relativity should be carefully taken into account. From the gravitational potential of the Earth, a correction of 1×10^{-16} will appear due to a displacement of the clocks by 1 m in the vertical direction.

30.1.2 Trapped Ions

An alternative to interrogating atoms in free flight, and a possibility to obtain practically unlimited interaction time, is to store them in a trap. Ions are well suited because charged particles can be trapped in radio frequency ion traps (Paul traps [10], Chap. 79) that provide confinement around a field-free saddle point of an electric quadrupole potential. This ensures that the internal level structure is only minimally perturbed by the trap. Combined with laser cooling it is possible to reach the Lamb–Dicke regime, i.e., localization within a volume whose extension is smaller than the wavelength of the spectroscopic transition, leading to an elimination of the linear Doppler shift. A single ion, trapped in an ultrahigh vacuum is highly isolated from external perturbations, permitting excellent control of systematic frequency shifts [11]. The use of the much higher optical reference frequency allows one to obtain a stability that is superior to microwave frequency standards, although only a single ion is used to obtain the steering signal for the reference oscillator.

Fig. 30.2 Double-resonance scheme applied in single-ion-trap frequency standards

A number of possible optical reference transitions with natural linewidths of the order of 1 Hz or below are available in different ions. Most ions of interest possess a level scheme where two transitions, a dipole-allowed transition and a forbidden reference transition of the optical clock, can be driven with two lasers from the ground state (Fig. 30.2). The dipole transition is used for laser cooling and for the optical detection of the ion via its resonance fluorescence. If the clock laser excites the ion to the metastable upper level of the reference transition, the fluorescence is interrupted, and every single excitation of the reference transition can thus be detected with unit efficiency as a dark period in the fluorescence signal.

Different types of forbidden reference transitions are investigated [12]: ions with a single valence electron and $s_{1/2}$ ground state possess metastable d levels that couple to the ground state via electric quadrupole (E2) radiation. This level scheme is found in Ca^+ , Sr^+ , Yb^+ [13] and Hg^+ [14, 15]. In Yb^+ , the lowest excited level is an f state, coupled to the ground state only by an electric octupole (E3) transition [16]. In ions with two valence electrons, like Al^+ and In^+ , the total electronic angular momentum couples to 0 in the $^1\text{S}_0$ ground and $^3\text{P}_0$ lowest excited state. The vanishing angular momentum and high intrinsic symmetry of these states makes them less susceptible to level shifts induced by external fields. Hyperfine coupling with a nuclear spin mixes the P_0 and P_1 levels and induces a weak electric dipole transition between $^3\text{P}_0$ and $^1\text{S}_0$.

The absolute transition frequencies of several trapped ion optical frequency standards have been measured with an uncertainty that is essentially limited by the Cs reference (Table 30.1). Frequency standards based on $^{27}\text{Al}^+$ and $^{171}\text{Yb}^+$ have been evaluated with relative systematic uncertainties in the 10^{-18} range [12]. A distinctive feature of the Al^+ system is that it does not rely on direct laser cooling of the ion, because Al^+ does not possess a cooling transition at a technically convenient wavelength. Instead, the ion is cooled sympathetically via the Coulomb interaction by a laser-cooled ion of Be^+ or Ca^+ in the same trap. The two ions form a quasi molecule with joint motional degrees of freedom. Laser excitation of motional sidebands is used to transfer information about the internal state of the Al^+ ion

to a joint motional mode and onwards to an internal state of the coolant ion, where it can be read out via fluorescence detection. Such quantum logic protocols make it possible to perform precision spectroscopy on ions that cannot be directly laser cooled.

The double resonance technique with the observation of dark periods in the fluorescence signal can also be employed if the reference transition is in the microwave domain, and a number of accurate measurements of hyperfine structure intervals in trapped ions have been performed. In particular, the HFS interval in $^{171}\text{Yb}^+$ has been measured several times [17–19] and can be used to obtain constraints on temporal variations.

30.1.3 Laser-Cooled Neutral Atoms

Optical frequency standards have been developed with laser-cooled neutral atoms, most notably of the alkaline-earth elements that possess narrow intercombination transitions and the $J = 0 \rightarrow 0$ transitions discussed for ions above. The atoms are collected and cooled in a magneto-optical trap. They may then be released and interrogated as free atoms by a sequence of laser pulses to realize a frequency-sensitive Ramsey–Bordé atom interferometer [20]. Of these systems, the one based on the $^1\text{S}_0 \rightarrow ^3\text{P}_1$ intercombination line of ^{40}Ca at 657 nm has reached the lowest relative uncertainty so far (about 2×10^{-14}) [21, 22]. Limiting factors in the un-

certainty of these standards are the residual linear Doppler effect and phase front curvature of the laser beams that excite the ballistically expanding atom cloud. For an optical frequency standard of high precision, it is, therefore, necessary to confine the atoms in an optical lattice, i.e., in the array of interference maxima produced by several intersecting, red-detuned laser beams [23, 24]. The wavelength of the trapping laser can be chosen such that the light shift it produces in the ground and excited state of the reference transition are equal, and, therefore, it does not induce a shift of the reference frequency (Fig. 30.3). Such a so-called “magic” wavelength can be estimated with reasonable accuracy theoretically and later on verified experimentally. This approach is presently applied to the very narrow (mHz natural linewidth) $^1\text{S}_0 \rightarrow ^3\text{P}_0$ transitions in neutral strontium, ytterbium, and mercury [12]. As in the case of trapped ions, absolute transition frequencies of several so-called lattice clocks with neutral atoms have been measured with an uncertainty that is essentially limited by the Cs reference (Table 30.1), and systems based on Sr and Yb have been evaluated with relative systematic uncertainties in the 10^{-18} range.

30.1.4 Two-Photon Transitions and Doppler-Free Spectroscopy

The linear Doppler shift of an absorption resonance can also be avoided if a two-photon excitation is induced by two counterpropagating laser beams. A prominent example that has been studied with high precision is the two-photon excitation of the $1s \rightarrow 2s$ transition in atomic hydrogen. The precise measurement of this frequency is of importance for the determination of the Rydberg constant and as a test of quantum electrodynamics (QED). Hydrogen atoms are cooled by collisions in a cryogenic nozzle and interact with a standing laser wave of 243 nm wavelength inside a resonator. Since the atoms are not as cold as in laser-cooled samples, a correction for the second-order Doppler effect is performed. The laser excitation is interrupted periodically, and the excited atoms are detected in a time-resolved manner so that their velocity can be examined. The experiments on absolute frequency measurement were carried out at the Max-Planck-Institut für Quantenoptik, which is not a national metrological institute and does not possess its own primary caesium standard. The problem of the lack of such a standard was resolved by use of a transportable caesium fountain [25] from the Observatoire de Paris and comparing their hydrogen transition frequency with the caesium reference at PTB via a 920 km fiber link [26]. An accuracy of about 4×10^{-15} has been obtained.

Fig. 30.3 Light shift of the $^1\text{S}_0$ ground state and $^3\text{P}_0$ first excited state of Sr as a function of wavelength. At the ‘magic’ wavelength of 813 nm both levels are shifted equally. Sr atoms in an optical lattice at this wavelength do not show a frequency shift for the $^1\text{S}_0 \rightarrow ^3\text{P}_0$ transition. Equivalent conditions can be found for reference transitions in other atoms

Fig. 30.4 Frequency comb generated from femtosecond laser pulses

30.1.5 Optical Frequency Measurements

An essential tool for the measurement of optical frequencies with respect to a Cs clock in the microwave range is the so-called femtosecond laser frequency comb generator [27]. Briefly, a mode-locked femtosecond laser produces, in the frequency domain, a comb of equally spaced optical frequencies f_n (Fig. 30.4) that can be written as $f_n = n f_r + f_{\text{ceo}}$ (with $f_{\text{ceo}} < f_r$), where f_r is the pulse repetition rate of the laser, the mode number n is a large integer (of order 10^5), and f_{ceo} (carrier-envelope-offset) is a shift of the whole comb that is produced by group velocity dispersion in the laser. The repetition rate f_r can easily be measured with a fast photodiode. In order to determine f_{ceo} , the comb is broadened in a non-linear medium, so that it covers at least one octave. Now, the second harmonic of mode n from the *red* wing of the spectrum, at frequency $2(n f_r + f_{\text{ceo}})$, can be mixed with mode $2n$ from the *blue* wing, at frequency $2n f_r + f_{\text{ceo}}$, and f_{ceo} is obtained as a difference frequency. In this way, the precise relation between the two microwave frequencies f_r and f_{ceo} , and the numerous optical frequencies f_n , is known. The setup can now be used for an absolute optical frequency measurement by referencing f_r and f_{ceo} to a microwave standard and recording the beat note between the optical frequency f_o to be measured and the closest comb frequency f_n . Vice versa, the setup may work as an optical clockwork, for example, by adjusting f_{ceo} to zero and by stabilizing one comb line f_n to f_o , so that f_r is now an exact subharmonic to order n of f_o . The precision of these transfer schemes has been investigated and was found to be so high that it will not limit the performance of optical clocks for the foreseeable future.

Since the most precise optical frequency standards are now more stable and reproducible than primary caesium clocks, it is important to be able to measure the ratio of two

Table 30.1 Accurately measured atomic transition frequencies and their fractional uncertainty ([9, 12] and references therein). These transitions have been used in evaluations of temporal variation of fundamental constants

Atom, transition	f (GHz)	u_r (10^{-15})	Ref.
H, Opt	2,466,061	14	[25, 26]
Al ⁺ , Opt	1,121,015	0.6	
Sr, Opt	429,228	0.4	
Rb, HFS	6.835	0.3

optical transition frequencies without the use of a microwave reference. A frequency comb generator can be configured for this task, for example by referencing the optical beat notes and f_{ceo} to f_r . In this way, the dimensionless optical frequency ratio $f_1/f_2 = (n_1 + f_{o1}/f_r + f_{\text{ceo}}/f_r)/(n_2 + f_{o2}/f_r + f_{\text{ceo}}/f_r)$ can be measured to an accuracy that is only limited by the optical frequency standards. A number of such measurements have been performed. They will provide essential consistency checks for the developing system of optical frequency standards and build the basis for the most stringent laboratory tests for changes of the fine structure constant.

30.1.6 Limitations on Frequency Variations

A variety of frequency standards described above have been successfully developed and their accuracy has been improved dramatically. This progress, as a consequence, has led to certain constraints on the possible variations of the fundamental constants. Considering frequency variations, one has to have in mind that not only the numerical value but also the unit may vary. For this reason, one needs to deal with dimensionless quantities, which are unit independent. During the last decade, a number of transition frequencies were measured in the corresponding SI unit, the hertz (Table 30.1). These-dimensional results are actually related to dimensionless quantities since a frequency measurement in SI is a measurement with respect to the caesium hyperfine interval

$$\{f\} = 9,192,631,770 \frac{f}{f_{\text{HFS}}(\text{Cs})}, \quad (30.1)$$

where $\{f\}$ stands for the numerical value of the frequency f . (Most absolute frequency measurements have been realized as a direct comparison with a primary caesium standard.) In Sect. 30.3, in order to simplify notation, this symbol for the numerical value is dropped.

30.2 Atomic Spectra and Their Dependence on the Fundamental Constants

30.2.1 The Spectrum of Hydrogen and Nonrelativistic Atoms

The hydrogen atom is the simplest atom, and one can easily calculate the leading contribution to different kinds of transitions in its spectrum, such as the gross, fine, and hyperfine structure. The scaling behavior of these contributions with the values of the Rydberg constant R_∞ , the fine structure constant α , and the magnetic moments of proton and Bohr magneton is clear. The results for some typical hydrogenic transitions are

$$\begin{aligned} f(2p \rightarrow 1s) &\simeq \frac{3}{4} c R_\infty, \\ f(2p_{3/2} - 2p_{1/2}) &\simeq \frac{1}{16} \alpha^2 c R_\infty, \\ f_{\text{HFS}}(1s) &\simeq \frac{16}{3} \alpha^2 \frac{\mu_p}{\mu_B} c R_\infty. \end{aligned} \quad (30.2)$$

In the nonrelativistic approximation, the basic frequencies and the fine and hyperfine structure intervals of all atomic spectra have a similar dependence on the fundamental constants in Eq. (30.2)

$$\begin{aligned} f_{\text{gross structure}} &\propto c R_\infty, \\ f_{\text{fine structure}} &\propto \alpha^2 c R_\infty, \\ f_{\text{HFS}} &\propto \alpha^2 \frac{\mu}{\mu_B} c R_\infty, \end{aligned} \quad (30.3)$$

where μ stands for the nuclear magnetic moment. The presence of a few electrons and a nuclear charge of $Z \neq 1$ makes theory more complicated and introduces certain multiplicative numbers but involves no new parameters. The importance of this scaling for a search for the variations of the atomic constants was first pointed out in [28] and was applied to astrophysical data.

Similar results may be presented for molecular transitions (electronic, vibrational, rotational, and hyperfine) [29]

$$\begin{aligned} f_{\text{electronic}} &\propto c R_\infty, \\ f_{\text{vibrational}} &\propto (m_e/M)^{1/2} c R_\infty, \\ f_{\text{rotational}} &\propto (m_e/M) c R_\infty. \end{aligned} \quad (30.4)$$

Up to now, no laboratory measurement with molecules has been performed at a level of accuracy that is competitive with atomic transitions (e.g., Sect. 30.3.3). However, they have widely been used in a search for variations of constants in astrophysical observations (e.g., [30]).

Table 30.2 Magnetic moments and relativistic corrections for atoms involved in microwave standards. The relativistic sensitivity κ is defined in Sec. 30.2.3. Here, μ is an actual value of the nuclear magnetic moment, μ_N is the nuclear magneton, and μ_S stands for the Schmidt value of the nuclear magnetic moment; the nucleon g factors are $g_p/2 \simeq 2.79$ and $g_n/2 \simeq -1.91$

Z	Atom	μ/μ_N	μ_S/μ_N	μ/μ_S	κ
37	^{87}Rb	2.75	$g_p/2 + 1$	0.74	0.34
55	^{133}Cs	2.58	$7/18(10 - g_p)$	1.50	0.83
70	$^{171}\text{Yb}^+$	0.49	$-g_n/6$	0.77	1.5

30.2.2 Hyperfine Structure and the Schmidt Model

The atomic hyperfine structure

$$f_{\text{NR}}(\text{HFS}) = \text{const.} \alpha^2 \frac{\mu}{\mu_B} c R_\infty \quad (30.5)$$

involves nuclear magnetic moments μ , which are different for different nuclei; thus, a comparison of the constraints on the variations of nuclear magnetic moments has a reduced value. To compare them, one may apply the Schmidt model [2, 3, 31], which predicts all the magnetic moments of nuclei with an odd number of nucleons (odd value of atomic number A) in terms of the proton and neutron g -factors, g_p , and g_n , respectively, and the nuclear magneton only. Unfortunately, the uncertainty of the calculation within the Schmidt model is quite high (usually from 10 to 50%). The Schmidt model, being a kind of *ab initio* model, only allows for improvements that, unfortunately, involve more effective phenomenological parameters. This would not really improve the situation but return us to the case where there are too many possibly varying independent parameters. A comparison of the Schmidt values to the actual data is presented for caesium, rubidium, and ytterbium in Table 30.2. The measurements of the hyperfine intervals in those atoms supply us with the constraints on the variation of the nuclear magnetic moments.

30.2.3 Atomic Spectra: Relativistic Corrections

A theory based on the leading nonrelativistic approximation may not be accurate enough. Any atomic frequency can be presented as

$$f = f_{\text{NR}} F_{\text{rel}}(\alpha), \quad (30.6)$$

where the first (nonrelativistic) factor is determined by a scaling similar to the hydrogenic transitions in Eq. (30.3). The second factor stands for relativistic corrections that vanish at $\alpha = 0$; and thus, $F_{\text{rel}}(0) = 1$.

The importance of relativistic corrections for the hyperfine structure was first emphasized in [32]. Relativistic

many-body calculations for various transitions were performed in [33–38]. A typical accuracy is about 10%. Some results are summarized in Tables 30.2 and 30.3, where we list the relative sensitivity of the relativistic factors F_{rel} to changes in α ,

$$\kappa = \frac{\partial \ln F_{\text{rel}}}{\partial \ln \alpha}. \quad (30.7)$$

Note that the relativistic corrections in heavy atoms are proportional to $(Z\alpha)^2$ because of the singularity of relativistic operators. Due to this, the corrections rapidly increase with the nuclear charge Z .

The signs and magnitudes of κ are explained by a simple estimate of the relativistic correction. For example, an approximate expression for the relativistic correction factor for the hyperfine structure (Casimir factor) of an s -wave electron in an alkali-like atom is [32]

$$F_{\text{rel}}(\alpha) = \frac{1}{\sqrt{1 - (Z\alpha)^2}} \frac{1}{1 - (4/3)(Z\alpha)^2}.$$

The related integral for the matrix element of the hyperfine interaction rapidly converges in a vicinity of the nucleus, on the distance about a_B/Z , where a_B is the Bohr radius. The wave function of a valence electron at such distance is proportional to the Coulomb wave function with zero energy since the energy of valence electron is negligible there, and nuclear charge is not screened. That allows one to perform an analytical calculation.

A similar rough estimation for the energy levels may be performed for the gross structure

$$E = -\frac{(Z_a\alpha)^2 mc^2}{2n_*^2} \left(1 + \frac{(Z\alpha)^2}{n_*} \frac{1}{j + 1/2} \right). \quad (30.8)$$

Here, j is the electron angular momentum, n_* is the effective value of the principle quantum number (which determines the nonrelativistic energy of the electron), and Z_a is the charge *seen* by the valence electron – it is 1 for neutral atoms, 2 for singly charged ions, etc. This equation tells us that κ , for the excitation of the electron from the orbital j to the orbital j' , has a different sign for $j > j'$ and $j < j'$. The difference of sign between the sensitivities of the ytterbium and mercury transitions in Table 30.3 reflects the fact that in Yb^+ , a 6s-electron is excited to the empty 5d-shell, while in Hg^+ , a hole is created in the filled 5d-shell if the electron is excited to the 6s-shell.

Usually, the sensitivity is roughly of order of unity (Table 30.3). However, it may happen that it is greatly enhanced. One can rewrite the definition in Eq. (30.7) as

$$\kappa = \frac{\partial \ln(f/f_{\text{NR}})}{\partial \ln \alpha} = -\frac{\partial \ln f_{\text{NR}}}{\partial \ln \alpha} + \frac{1}{f} \frac{\partial f}{\partial \ln \alpha}. \quad (30.9)$$

Table 30.3 The frequencies of different transitions in neutral atoms and ions, applied or tried for precision spectroscopy, and their sensitivity to variations in α due to relativistic corrections

Atom, transition	κ
H, 1s – 2s	0.00
^{40}Ca , $^1\text{S}_0 - ^3\text{P}_1$	0.02
^{87}Sr , $^1\text{S}_0 - ^3\text{P}_0$	0.06
^{88}Sr , $^1\text{S}_0 - ^3\text{P}_0$	0.06
^{111}Cd , $^1\text{S}_0 - ^3\text{P}_0$	0.23
^{171}Yb , $^1\text{S}_0 - ^3\text{P}_0$	0.31
^{174}Yb , $^1\text{S}_0 - ^3\text{P}_0$	0.31
^{199}Hg , $^1\text{S}_0 - ^3\text{P}_0$	0.81
$^{27}\text{Al}^+$, $^1\text{S}_0 - ^3\text{P}_0$	0.01
$^{40}\text{Ca}^+$, $\text{S}_{1/2} - \text{D}_{5/2}$	0.15
$^{88}\text{Sr}^+$, $\text{S}_{1/2} - \text{D}_{5/2}$	0.43
$^{115}\text{In}^+$, $^1\text{S}_0 - ^3\text{P}_0$	0.18
$^{171}\text{Yb}^+$, $^2\text{S}_{1/2} - ^2\text{D}_{3/2}$	1.0
$^{171}\text{Yb}^+$, $\text{S}_{1/2} - \text{F}_{7/2}$	–6.0
$^{199}\text{Hg}^+$, $^2\text{S}_{1/2} - ^2\text{D}_{5/2}$	–2.9

The first term here is a standard one, while the second term may be enhanced if the frequency f is very small. In other words, if a certain frequency is a difference between two transitions that have different nonrelativistic quantum numbers (which means that the value of f_{NR} is not small) and has a [very] small value ($f \ll f_{\text{NR}}$), it may be enhanced. A small eventual value of the frequency means that there is an accidental cancelation between the nonrelativistic contribution and the relativistic correction, which depends differently on α . An example of such a transition is the one between two nearly degenerate states $4f^{10}5d6s$ and $4f^95d^26s$ in atomic dysprosium. The presence of a strong enhancement $\kappa \simeq 5.7 \times 10^8$ there was pointed out in [38]. The dysprosium transition was studied in [39, 40].

30.3 Laboratory Constraints on Temporal Variations of Fundamental Constants

Logarithmic derivatives in Eq. (30.7) appear since we are looking for a variation of the constants in relative units. In other words, we are interested in a determination of, e.g., $\Delta\alpha/\alpha\Delta t$, while the input data of interest are related to $\Delta f/f\Delta t$. Their relation takes the form

$$\frac{\partial \ln f}{\partial t} = \frac{\partial \ln f_{\text{NR}}}{\partial t} + \kappa \frac{\partial \ln \alpha}{\partial t}. \quad (30.10)$$

If one compares transitions of the same type – gross structure, fine structure – the first term cancels.

Fig. 30.5 Frequency variations versus their sensitivity κ following Eq. (30.11)

30.3.1 Constraints from Absolute and Relative Optical Measurements

Absolute frequency measurements offer the possibility to compare a number of optical transitions with frequencies f_{NR} , which scale as cR_{∞} , with the caesium hyperfine structure. One can rewrite Eq. (30.10) as

$$\frac{\partial \ln f_{\text{opt}}}{\partial t} = \frac{\partial \ln cR_{\infty}}{\partial t} + \kappa \frac{\partial \ln \alpha}{\partial t}, \quad (30.11)$$

where dimensional quantities, such as frequency and the Rydberg constant, are stated in SI units in Eq. (30.1). This equation may be used in different ways. For example, in Fig. 30.5, we plot experimental data for $\partial \ln f_{\text{opt}}/\partial t$ as a function of the sensitivity κ and derive a model-independent constraint on the variation of the fine structure constant and the numerical value of the Rydberg frequency cR_{∞} in the SI unit of hertz. The latter is of great metrological importance, being related to a common drift of optical clocks with respect to a caesium clock, i.e., to the definition of the SI second. The SI definition of the meter is impractical and so, in practice, the optical wavelengths of reference lines calibrated against the caesium standard are used to determine the SI meter [9].

Equation (30.11) allows us a simple graphic interpretation (Fig. 30.5). The data around $\kappa = 0$ are those, whose frequencies are well described by nonrelativistic formulas and have a low sensitivity to α variation.

A direct comparison of two optical frequencies allows us a model-independent constraint on a variation of the fine structure constant α , which for relative optical measurements is given by

$$\frac{d \ln(f_1/f_2)}{dt} = \frac{(\kappa_1 - \kappa_2)d \ln \alpha}{dt}. \quad (30.12)$$

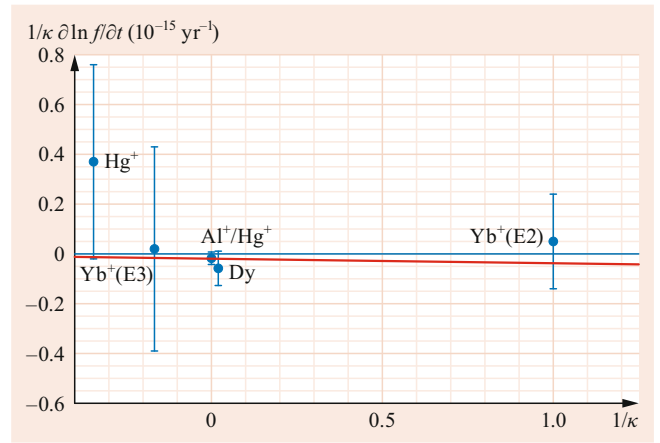

Fig. 30.6 Frequency variations versus their sensitivity κ following Eq. (30.14): value of $\partial \ln f_{\text{opt}}/\partial t/\kappa$ as function of $1/\kappa$

Progress with relative optical frequency measurements [14, 15], comparing the transitions in a mercury ion and an ion of aluminum, delivers the constraints on α variation

$$\frac{\partial \ln \alpha}{\partial t} = (-1.7 \pm 2.5) \times 10^{-17} \text{yr}^{-1}. \quad (30.13)$$

This relative-measurement result, which contributes the dominant constraint on the α variation, cannot be presented in such a plot as in Fig. 30.5 since the disappearance of the cR_{∞} term makes the result equivalent to the result for an infinite value of the overall sensitivity in the terms of Eq. (30.11).

There is an alternative equation,

$$\frac{1}{\kappa} \frac{\partial \ln f_{\text{opt}}}{\partial t} = \frac{1}{\kappa} \frac{\partial \ln cR_{\infty}}{\partial t} + \frac{\partial \ln \alpha}{\partial t}, \quad (30.14)$$

which can be applied for a graphic presentation. In Fig. 30.6, the intercept at $1/\kappa = 0$ is the α constraint, while the slope reflects the variation of cR_{∞} .

To plot all the data we have to use a two-dimensional plot (see below). The constraints on the variations of α and cR_{∞} are correlated, and the standard uncertainty ellipse, defined as

$$\sum_i \frac{1}{u_i^2} \left(\frac{\partial \ln f_i}{\partial t} - \frac{\partial \ln R_{\infty}}{\partial t} - \kappa_i \frac{\partial \ln \alpha}{\partial t} \right)^2 = 1 + \chi_{\text{min}}^2,$$

is presented in Fig. 30.7. Here, we sum over all available data: $\partial(\ln f_i)/\partial t$ is the central value of the observed drift rate, u_i its 1σ uncertainty, and χ_{min}^2 the minimized χ^2 of the fit. The results of the fit are presented in Table 30.4.

The progress in the constraint on the time variation of the fine structure constant and of the numerical value of the Rydberg constant is summarized in Table 30.5.

Fig. 30.7 Constraints on the time variations of the fine structure constant α and the numerical value of the Rydberg constant (from [41])

Table 30.4 Model-independent laboratory constraints on the possible time variations of natural constants [41, 42]

X	$\partial \ln X / \partial t$
α	$-0.022(22) \times 10^{-15} \text{ yr}^{-1}$
$\{cR_\infty\}$	$-0.01(14) \times 10^{-15} \text{ yr}^{-1}$
$\mu_{\text{Cs}}/\mu_{\text{B}}$	$0.07(16) \times 10^{-15} \text{ yr}^{-1}$
$\mu_{\text{Rb}}/\mu_{\text{Cs}}$	$-0.15(9) \times 10^{-15} \text{ yr}^{-1}$
$\mu_{\text{Yb}}/\mu_{\text{Cs}}$	$(3 \pm 3) \times 10^{-14} \text{ yr}^{-1}$

Table 30.5 Progress in constraining a possible time variation of the fundamental constants: the results of 2004 (following [43, 44]), 2008 (following [45]), and of 2014 using data summarized in [42] but following [43, 44] (see [41] for details). Here, ρ is the correlation coefficient $\rho(\partial \ln \alpha / \partial t, \partial \ln \{R_\infty\} / \partial t)$

Year	$\partial \ln \alpha / \partial t$ (10^{-15} yr^{-1})	$\partial \ln \{R_\infty\} / \partial t$ (10^{-15} yr^{-1})	ρ
2004	$-0.4(2.0)$	$-1.5(3.2)$	0.13
2008	$-0.018(23)$	$0.20(37)$	0.17
2014	$-0.022(22)$	$-0.01(14)$	0.08

The numerical value of the Rydberg constant, from the point of view of fundamental physics, can be expressed in terms of the caesium hyperfine interval in atomic units, and its variation may be expressed in terms of the variations of α and $\mu_{\text{Cs}}/\mu_{\text{B}}$. A constraint for the latter is presented in Table 30.4. Because of that, there is also an alternative parameterization applied for the 2D constraint. It is based on the relation

$$\frac{\partial \ln cR_\infty}{\partial t} = \frac{\partial \ln(\mu_{\text{Cs}}/\mu_{\text{e}})}{\partial t} + (\kappa + 2.83) \frac{\partial \ln \alpha}{\partial t}. \quad (30.15)$$

To compare the results of two equivalent evaluations one has to remember the correlations in the results for the fitting parameters (Table 30.5). The correlation is unimportant for the central values but affects the uncertainty of the outcome.

We have also to mention a ‘nonclock’ constraint on the α variation obtained from the study of the dysprosium atom on a determination of the splitting between the $4f^{10}5d\ 6s$ and $4f^95d^2\ 6s$ states. The most recent Dy constraint is [40]

$$\frac{\partial \ln(\alpha)}{\partial t} = (-0.6 \pm 0.7) \times 10^{-16} \text{ yr}^{-1}.$$

30.3.2 Constraints from Microwave Clocks

A model-independent comparison of different HFS transitions is not simple because their nonrelativistic contributions f_{NR} are not the same but involve different magnetic moments. Applying Eq. (30.15) to experimental data, one can obtain constraints on the relative variations of the magnetic moments of Rb, Cs, and Yb (Table 30.4).

30.3.3 A Model-Independent Constraint on the Variation of the Electron-to-Proton Mass Ratio from Molecular Spectroscopy

Vibrational and rotational spectroscopy of molecules provide direct access to transition frequencies that depend on the electronic to nuclear mass ratio. Precision measurements have been performed with two-photon Ramsey spectroscopy of a rovibrational transition in a supersonic beam of SF_6 . A relative uncertainty of 2.8×10^{-14} has been obtained for the transition frequency at 28.4 THz, and from a sequence of measurements against a primary Cs clock spanning about 2 years, a limit on the temporal variation of the proton to electron mass ratio has been derived [46]

$$\frac{\partial \ln(m_{\text{p}}/m_{\text{e}})}{\partial t} = (-3.8 \pm 5.6) \times 10^{-14} \text{ yr}^{-1}.$$

This result makes use of the more stringent limit on a variation of the Cs magnetic moment, obtaining essentially a model-independent constraint on a change of $m_{\text{p}}/m_{\text{e}}$.

30.3.4 Other Model-Dependent Constraints

In order to gain information on constants more fundamental than the nuclear magnetic moments, any further evaluation of the experimental data should consider the model. Here, we apply the Schmidt model, which is far from perfect. It is an *ab initio* model, but its accuracy for any individual case is unclear. The model-dependent constraints obtained by exploiting the Schmidt model are summarized in Table 30.6.

The nucleon g factors, in turn, depend on a dimensionless fundamental constant $m_{\text{q}}/\Lambda_{\text{QCD}}$, where m_{q} is the quark mass, and Λ_{QCD} is the quantum chromodynamic (QCD) scale. A study of this dependence may supply us with deep

Table 30.6 Model-dependent laboratory constraints on possible time variations of fundamental constants. The uncertainties here do not include uncertainties from the application of the Schmidt model

X	$\partial \ln X / \partial t$
m_e/m_p	$-0.02(16) \times 10^{-15} \text{ yr}^{-1}$
μ_p/μ_e	$-0.08(16) \times 10^{-15} \text{ yr}^{-1}$
g_p	$-0.07(5) \times 10^{-15} \text{ yr}^{-1}$
g_n	$(3 \pm 3) \times 10^{-14} \text{ yr}^{-1}$

insight into the possible variations of the more fundamental properties of Nature (see [33, 34] for details). This approach is promising, but its accuracy needs to be better understood. Following the model suggested in [47, 48], the constraint on the variation of the proton-to-electron mass ratio reads [42]

$$\frac{\partial \ln(m_p/m_e)}{\partial t} = (-0.5 \pm 1.6) \times 10^{-16} \text{ yr}^{-1}.$$

30.4 Summary

The results collected in Tables 30.4 and 30.6 are competitive with or even more sensitive than data from other searches and have a more reliable interpretation. The results from astrophysical searches and the study of the samarium resonance from Oklo data (e.g., [4, 5]) possess sensitivity over extended time scales; however, they are more difficult to interpret. We have, for example, not assumed any hierarchy in variation rates or that some constants stay fixed while others vary, as it is done in the study of the position of the Oklo resonance. The evaluation presented here is transparent, and any particular calculation or measurement can be checked. In contrast, the astrophysical data show significant results only after an intensive statistical evaluation.

The laboratory searches involving atomic clocks have definitely shown progress, and a further increase in the accuracy of these clocks can be expected, as well as an increase in the number of different kinds of frequency standards (e.g., optical Sr, Sr⁺, Yb, Yb⁺, Hg standards are being tried). Systems of enhanced sensitivity have been identified, for example in highly charged ions [49], and experiments for their study are under development. An optical clock based on a nuclear transition in Th-229 is also under consideration [50, 51]. Such a clock would offer different sensitivity to systematic effects, as well as to variations of different fundamental constants [52].

Laboratory searches are not necessarily limited to experiments with metrological accuracy. An example of a high-sensitivity search with a relatively low accuracy is the study of the dysprosium atom for a determination of the splitting between the 4f¹⁰5d 6s and 4f⁹5d²6s states, which offers a great sensitivity value of $\kappa \simeq 5.7 \times 10^8$ [38].

Variations of constants on the cosmological time scale can be expected, but the magnitude, as well as other details, are

unclear. Because of a broad range of options there is a need for the development of as many different searches as possible, and the laboratory search for variations is an attractive opportunity to open up a way that could lead to new physics.

Precision frequency measurements with or without the use of clocks are the most accurate among the other measurements. They are used not only to constrain the variation of the values of the constants but also on some other possible effects of new physics, ranging from the violation of Lorentz invariance to modified fundamental theories, opening a window of opportunities for new physics [49].

Savely G. Karshenboim Dr Savely G. Karshenboim graduated in 1983 from St. Petersburg (then Leningrad) State University, from where he also received his PhD (1992) and DSc (1999). He was with D.I. Mendeleev Institute for Metrology, Max-Planck-Institut für Quantenoptik (Garching), and Pulkovo Observatory. He is currently with Ludwig-Maximilians-Universität München. His scientific interests include precision physics of simple atoms, quantum electrodynamics, determination of fundamental constants, and the search for their variations.

Victor Flambaum Dr Victor Flambaum is a Professor of Physics and holds a Chair of Theoretical Physics. PhD, DSc from the Institute of Nuclear Physics, Novosibirsk, Russia. He has about 400 publications in atomic, nuclear, particle, solid state, statistical physics, general relativity and astrophysics including works on violation of fundamental symmetries (parity, time reversal, Lorentz), test of unification theories, temporal and spatial variation of fundamental constants from Big Bang to present, many-body theory and high precision atomic calculations, as well as statistical theory of finite chaotic Fermi systems and enhancement of weak interactions.

Ekkehard Peik Dr Ekkehard Peik is Head of the Time and Frequency Department at PTB in Braunschweig. His research interests are in the fields of optical clocks with laser-cooled and trapped ions, precision laser spectroscopy, the low-energy nuclear isomer of Th-229, the metrology of time and frequency, and tests of fundamental physics with atomic clocks.

Searches for New Particles Including Dark Matter with Atomic, Molecular, and Optical Systems

scales. The nature of these effects depends on the specific particles and their nongravitational interactions. In this chapter, we give a brief overview of how atomic, molecular, and optical systems can be used to search for new particles. To illustrate the basic principles behind these methods, we focus on the simplest class of particles, namely new spinless bosons.

Abstract

The “standard model” of physics has been successful in explaining most physical processes and phenomena that we see around us. However, despite the great success of the standard model, there remain a number of unresolved puzzles within the model, as well as questions about the self-consistency of the framework. Additionally, various independent astrophysical and cosmological observations contradicting the predictions of the standard model have been accumulating over the course of the past century. Many of these puzzles and unexpected observations can be elegantly explained by postulating the existence of at least one new particle or field outside of the present standard model.

New particles can manifest their effects in many settings, ranging from effects on subatomic to galactic length

The “standard model” of particle physics at present provides the most fundamental framework for understanding the basic building blocks of matter and describing various known interactions between these building blocks. The standard model does incredibly well in describing physical processes and phenomena that take place over a very broad range of energies and length scales, from explaining the binding of the constituents of atoms to understanding the formation and evolution of stars.

However, numerous astrophysical and cosmological observations that cannot be explained by the standard model have been accumulating over the course of the past century. Observations of stellar orbits about the galactic center from as early as the 1930s indicate the presence of a nonbaryonic matter component that is traditionally termed “dark matter” (this nonbaryonic matter component does not appreciably emit or absorb electromagnetic radiation) [1]. Further astrophysical evidence for dark matter comes from measurements of angular fluctuations in the cosmic microwave background spectrum [2] and the need for nonbaryonic matter to explain the observed structure formation in our universe [1]. Additionally, distance and redshift measurements of supernovae show that the expansion of the universe is accelerating, indicating that the universe is being pushed apart by a repulsive

force associated with a “dark energy” component [3]. These dark components (which are naturally explained by postulating the existence of at least one new particle or field) overwhelmingly dominate the observed matter-energy content of our universe, with ordinary baryonic matter making up only a small fraction of the total content [2].

Another profound mystery is the observed predominance of matter over antimatter in our universe—the problem of baryogenesis. The standard model contains the necessary ingredients to produce ever slightly more matter than antimatter; however, the observed predominance of matter over antimatter in our universe is much larger than can be accommodated within the standard model [4]. One of the key ingredients for baryogenesis is CP violation, which is the violation of the product of the charge parity ($C =$ exchange of particles and antiparticles) and parity ($P =$ inversion of spatial coordinates) symmetries. Additional sources of CP violation necessary to explain baryogenesis may come from new particles possessing CP -violating interactions with ordinary matter. Intriguingly, practically no CP violation has been observed in strong processes in the standard model (compared with the relatively large amount of CP violation in weak processes). This puzzling observation—termed the “strong CP problem”—is most elegantly explained by postulating the existence of a new low-mass feebly-interacting spinless boson called the axion [5].

In order to corroborate or refute models that claim to explain the above problems and observations via putative new particles, one needs experimental probes for such particles. New particles may arise in several different settings:

- (1) As mediators of new interactions between particles or bodies (Sect. 31.2)
- (2) Produced in laboratories or colliders (Sect. 31.3)
- (3) Produced in stars and astrophysical processes (Sect. 31.4)
- (4) Constitute the observed dark matter or dark energy (Sect. 31.5).

Atomic, molecular, and optical systems lie at the heart of some of the highest precision measurements currently available. Optical clocks, which measure transition frequencies in atoms and ions, have demonstrated a fractional precision at the level $\approx 10^{-18}$ [6, 7]. Optical magnetometers, which measure magnetic fields using atoms, have demonstrated a magnetic field sensitivity at the level $\approx 10^{-15}$ T Hz $^{-1/2}$ [8]. Laser interferometers (which have directly detected gravitational waves) have demonstrated an equivalent sensitivity to length fluctuations at the level $\approx 10^{-23}$ Hz $^{-1/2}$ [9].

Can these extraordinary levels of precision and sensitivity be leveraged to search for new particles? The answer to this question is in the affirmative. Indeed, new particles arising in all types of settings described above can be sought for with experiments using atomic, molecular, and optical systems. In this chapter, we present a brief overview of how this can

be done, focusing mainly on new spinless bosons (which are the simplest possibility from the theoretical point of view) to help illustrate the basic principles behind the methods. We begin by presenting the simplest possible nongravitational interactions of spinless bosons with ordinary matter (Sect. 31.1). We then explain how atomic, molecular, and optical systems can be used to search for spinless bosons possessing nongravitational interactions in a broad variety of settings (Sects. 31.2–31.5). Unless explicitly stated otherwise, we adopt the natural units $\hbar = c = 1$ in this chapter.

31.1 Nongravitational Interactions of Spinless Bosons

The possible nongravitational interactions of spinless bosons can be broadly distinguished on the basis of the parity symmetry (behavior under the inversion of spatial coordinates). The most relevant scalar-type (even-parity) interactions of a spinless boson ϕ with ordinary matter are:

$$\mathcal{L}_{\text{scalar}}^{\text{lin.}} = \frac{g_{\gamma}^s}{4} \phi F_{\mu\nu} F^{\mu\nu} - \phi \sum_{\psi} g_{\psi}^s \bar{\psi} \psi, \quad (31.1)$$

$$\mathcal{L}_{\text{scalar}}^{\text{quad.}} = \frac{h_{\gamma}^s}{4} \phi^2 F_{\mu\nu} F^{\mu\nu} - \phi^2 \sum_{\psi} h_{\psi}^s \bar{\psi} \psi, \quad (31.2)$$

where the first term represents the interaction of the spinless boson with the electromagnetic field tensor F , and the second term represents the interaction of the spinless boson with a fermion field ψ , with $\bar{\psi} = \psi^{\dagger} \gamma^0$ the Dirac adjoint. Here, $g_{\gamma,\psi}^s$ and $h_{\gamma,\psi}^s$ are parameters that determine the relevant nongravitational interaction strengths.

The most relevant pseudoscalar-type (odd-parity) interactions of a spinless boson ϕ with ordinary matter are:

$$\begin{aligned} \mathcal{L}_{\text{pseudoscalar}} = & \frac{g_{\gamma}^p}{4} \phi F_{\mu\nu} \tilde{F}^{\mu\nu} + \frac{g_{\mathcal{G}}^p}{4} \phi G_{\mu\nu} \tilde{G}^{\mu\nu} \\ & - i \phi \sum_{\psi} g_{\psi}^p \bar{\psi} \gamma_5 \psi, \end{aligned} \quad (31.3)$$

where the first term represents the interaction of the spinless boson with the electromagnetic field tensor F , with \tilde{F} the dual field tensor, the second term represents the interaction of the spinless boson with the gluonic field tensor G , and the third term represents the interaction of the spinless boson with a fermion field ψ . Here, $g_{\gamma,g,\psi}^p$ are parameters that determine the relevant nongravitational interaction strengths.

31.2 New Forces

In the presence of the nongravitational interactions in Eqs. (31.1)–(31.3), new forces can be mediated between particles or bodies via the exchange of spinless boson(s). The

simplest possibility involves the exchange of a single boson between two fermions in the presence of the linear-in- ϕ interactions in the last terms of Eqs. (31.1) and (31.3). In this case, there are three distinct potentials that arise from the permutation of the two vertex types. In the nonrelativistic limit, these potentials take the following form [10, 11]:

$$V_{ss}(\mathbf{r}) = -g_1^s g_2^s \frac{e^{-m_\phi r}}{4\pi r}, \quad (31.4)$$

$$V_{ps}(\mathbf{r}) = +g_1^p g_2^s \boldsymbol{\sigma}_1 \cdot \hat{\mathbf{r}} \left(\frac{1}{r^2} + \frac{m_\phi}{r} \right) \frac{e^{-m_\phi r}}{8\pi m_1}, \quad (31.5)$$

$$V_{pp}(\mathbf{r}) = -\frac{g_1^p g_2^p}{4} \left\{ \boldsymbol{\sigma}_1 \cdot \boldsymbol{\sigma}_2 \left[\frac{1}{r^3} + \frac{m_\phi}{r^2} + \frac{4\pi}{3} \delta(\mathbf{r}) \right] - (\boldsymbol{\sigma}_1 \cdot \hat{\mathbf{r}})(\boldsymbol{\sigma}_2 \cdot \hat{\mathbf{r}}) \left[\frac{3}{r^3} + \frac{3m_\phi}{r^2} + \frac{m_\phi^2}{r} \right] \right\} \times \frac{e^{-m_\phi r}}{4\pi m_1 m_2}. \quad (31.6)$$

Here, m_ϕ is the mass of the exchanged boson, $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$ denote the Pauli spin matrix vectors of the two fermions, $\hat{\mathbf{r}}$ is the unit vector directed from fermion 2 to fermion 1, and r is the distance between the two fermions. In Eq. (31.5), the cross term (obtained by permuting the particle indices $1 \leftrightarrow 2$) is implicit.

Other relatively common potentials include the potential mediated by the exchange of a single boson between two bodies with nonzero electromagnetic energies in the presence of the linear-in- ϕ interaction in the first term of Eq. (31.1) [12], the potential mediated by the exchange of a pair of bosons between two fermions in the presence of the quadratic-in- ϕ interactions in the last term of Eq. (31.2) [13], and the potential mediated by the exchange of a pair of fermions (including neutrinos) between two particles [14]. In the limit when the mass of the exchanged particles is small, these potentials scale as $V(r) \propto 1/r$, $V(r) \propto 1/r^3$ and $V(r) \propto 1/r^5$, respectively.

31.2.1 Macroscopic-Scale Experiments

When the condition $m_\phi \ll 1/r$ is satisfied, the potentials in Eqs. (31.4)–(31.6) can be treated as long-range (since the exponential terms reduce to $e^{-m_\phi r} \approx 1$ when $m_\phi r \ll 1$). Experiments performed on macroscopic length scales provide an excellent way of probing these new interactions. These types of experiments employ a massive body, such as the Sun, Earth, Moon, or a massive object in the laboratory, which functions as the source of new bosons. In order to detect effects associated with the anomalous interactions mediated by these bosons, a high-precision detector is required. Various methods can be used to search for new spin-independent forces in macroscopic-scale experiments:

- (1) Torsion pendula to search for anomalous torques [17–20]
- (2) Atom interferometers to search for anomalous accelerations [21, 24]
- (3) Atomic clocks and other spectroscopy-based measurements to search for anomalous frequency shifts [12, 25, 26].

The first two types of methods involve measurements of vector quantities, namely differences of torques and accelerations, respectively, of two different test bodies, while the third method involves measuring a scalar quantity, namely the difference in the ratio of two transition frequencies at two different distances from a massive body. We mention that lunar laser ranging measurements can also be used to search for spin-independent anomalous interactions [27].

Various methods can be used to search for new spin-dependent forces in macroscopic-scale experiments:

- (4) Torsion pendula to search for anomalous torques [28, 29]
- (5) Magnetometers to search for anomalous spin-precession effects [30–38].

Current limits from macroscopic-scale experiments on several types of nongravitational interactions of spinless bosons are shown in Figs. 31.1–31.3.

31.2.2 Atomic-Scale Experiments

Compared with the macroscopic-scale experiments discussed in Sect. 31.2.1, the condition $m_\phi \ll 1/r$ holds up to much larger boson masses when a boson is exchanged between the constituents of an atom or molecule. This is because the interparticle separations between the constituents of atomic systems are much smaller than the length scales in macroscopic-scale experiments. Thus, phenomena originating on atomic and subatomic length scales are generally much more sensitive to bosons with larger masses. Various atomic-scale phenomena can be used to search for new forces:

- (1) Comparison of measured and predicted spectra of atoms, molecules and ions to search for new parity-conserving forces [14, 40, 44–49]
- (2) Comparison of measured and predicted parity-violating observables in atoms and molecules to search for new parity-violating forces [50]
- (3) Measurements of permanent electric dipole moments in atoms and molecules to search for new parity and time-reversal-invariance-violating forces [39, 51].

There is an important difference between atomic-scale and macroscopic-scale experiments in the regime of a large boson mass, $m_\phi \gg 1/r$. Macroscopic-scale experiments lose

Fig. 31.1 Limits on the linear scalar interaction of a spinless boson ϕ with the photon, as defined in the first term of Eq. (31.1). The region in *green* corresponds to constraints from light-shining-through-a-wall experiments [15, 16]. The region in *blue* corresponds to constraints from macroscopic-scale experiments that search for new forces [12, 17–21]. The region in *red* corresponds to constraints from atomic spectroscopy measurements that search for the effects of a relic coherently oscillating field $\phi = \phi_0 \cos(m_\phi t)$, which saturates the local cold dark matter (DM) content [22, 23]

Fig. 31.2 Limits on the P, T -violating scalar-pseudoscalar nucleon-electron interaction mediated by a spinless boson ϕ , as given in Eq. (31.5) (which arises from the last terms of Eqs. (31.1) and (31.3)). The region in *blue* corresponds to constraints from macroscopic-scale experiments that search for new forces [28–30, 37, 38]. The region in *magenta* corresponds to constraints from atomic and molecular electric dipole moment experiments [39]

sensitivity to new forces exponentially quickly when the boson mass becomes large, because the interaction becomes contact-like, and so the very heavy boson cannot propagate between the source body and detector. In atomic-scale phe-

Fig. 31.3 Limits on the linear pseudoscalar interaction of a spinless boson ϕ with nucleons, as defined in the last term of Eq. (31.3). The region in *blue* corresponds to constraints from a macroscopic-scale experiment that searches for new forces [31]. The region in *magenta* corresponds to constraints from molecular hydrogen spectroscopy measurements and comparison with theory [40]. The region in *red* corresponds to constraints from magnetometry measurements that search for the effects of a relic coherently oscillating field $\phi = \phi_0 \cos(m_\phi t)$, which saturates the local cold dark matter (DM) content [41]. The region in *light gray* corresponds to astrophysical constraints pertaining to supernova energy-loss bounds [42, 43]

nomena, however, there is always a finite probability for two constituent particles to be located very close to each other, and so these types of experiments lose sensitivity to new forces much more slowly (at a power-law rate) when the boson mass becomes large. Current limits from atomic-scale experiments on several types of nongravitational interactions of spinless bosons are shown in Figs. 31.2 and 31.3.

31.3 Laboratory Sources

In the presence of the nongravitational interactions in the first terms of Eqs. (31.1) and (31.3), spinless bosons may interconvert with photons. Several different types of methods can be used to exploit this possible interconversion:

(1) “Light-shining-through-a-wall” experiments [15, 16, 52, 53]. The basic idea here is to shine a powerful laser into a region of strong magnetic field. Some of the laser photons will convert into spinless bosons (provided that the energy of these photons is not less than the rest-mass energy of the spinless boson), which then pass through a wall that is impenetrable to photons (but not to the spinless bosons). A second strong magnetic field is applied on the other side of this wall in order to reconvert some of the transmitted spinless bosons back into photons for detection. In principle, it is not necessary for all of the incident laser photons to be blocked by the

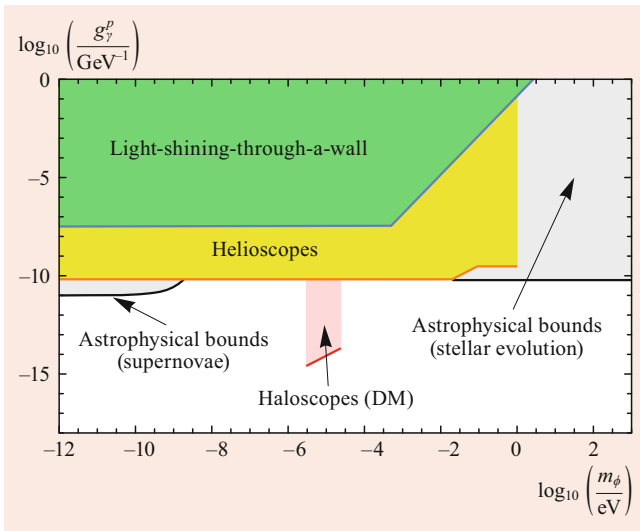

Fig. 31.4 Limits on the linear pseudoscalar interaction of a spinless boson ϕ with the photon, as defined in the first term of Eq. (31.3). The region in *green* corresponds to constraints from “light-shining-through-a-wall” experiments [15, 16]. The region in *yellow* corresponds to constraints from helioscope experiments that search for bosons emitted from the Sun [59, 60]. The region in *red* corresponds to constraints from haloscope experiments that search for the conversion of galactic dark matter (DM) bosons into photons [61, 62]. The regions in *light gray* correspond to astrophysical constraints pertaining to stellar evolution and supernova energy-loss bounds [42, 43]

wall. A tiny fraction of incident photons can be transmitted through the wall, so that an atomic or molecular transition can be resonantly induced involving the interference of photon and spinless-boson-induced amplitudes (assuming there exists a nongravitational interaction between the spinless boson and electron) [54].

(2) Experiments to search for vacuum birefringence and dichroism [55–58]. The basic idea in these types of experiments is to shine a polarized laser into a region of strong magnetic field. Vacuum birefringence involves different indices of refraction for light polarized parallel and perpendicular to an applied magnetic field and is caused by virtual spinless bosons. Dichroism involves different absorptivities for light of different polarizations in an applied magnetic field and is caused by the production of real spinless bosons.

Although electric fields could also be used in these experiments, in practice it is much easier to generate a stronger magnetic field (in terms of the equivalent electromagnetic energy density) in the laboratory. An advantage of producing spinless bosons in the laboratory is that the energies of these bosons are fixed by energy conservation, so resonance techniques can be applied without having to scan over an *a priori* unknown range of boson energies. Current limits from laboratory source experiments on several types of nongravitational interactions of spinless bosons are shown in Figs. 31.1 and 31.4.

31.4 Astrophysical Sources

In the presence of the nongravitational interactions in Eqs. (31.1)–(31.3), spinless bosons can be produced and subsequently emitted from the hot interiors of active stars (such as the Sun) and dead stars (such as white dwarfs), as well as in supernovae explosions. Excessive emission of spinless bosons from astrophysical sources would contradict observations and corresponding standard-model calculations, providing strong constraints on possible nongravitational interactions of spinless bosons (Figs. 31.3–31.6) [42, 43]. If spinless bosons are emitted from the nearest star (the Sun), then it also becomes feasible to search for these particles in terrestrial experiments.

Spinless bosons emitted from the Sun can be detected using helioscope experiments, which seek to exploit the interconversion of spinless bosons with photons in a strong applied magnetic field [59, 60, 63–65]. Helioscope experiments are somewhat similar to the “light-shining-through-a-wall” experiments discussed in Sect. 31.3, except that the source of spinless bosons in helioscope experiments is provided by nature. The nature of the spinless boson sources in these two types of experiments is very different, however. In a “light-shining-through-a-wall” experiment, the energy of the spinless bosons depends on the frequency of the laser source used and can, thus, be altered. Additionally, since lasers

Fig. 31.5 Limits on the linear pseudoscalar interaction of a spinless boson ϕ with gluons, as defined in the second term of Eq. (31.3). The region in *red* corresponds to constraints from magnetometry measurements that search for the effects of a relic coherently oscillating field $\phi = \phi_0 \cos(m_\phi t)$, which saturates the local cold dark matter (DM) content [41]. The region in *light gray* corresponds to astrophysical constraints pertaining to supernova energy-loss bounds [77]. The region in *dark gray* corresponds to astrophysical constraints pertaining to big bang nucleosynthesis (BBN) measurements, assuming that spinless bosons saturate the DM content [78–80]

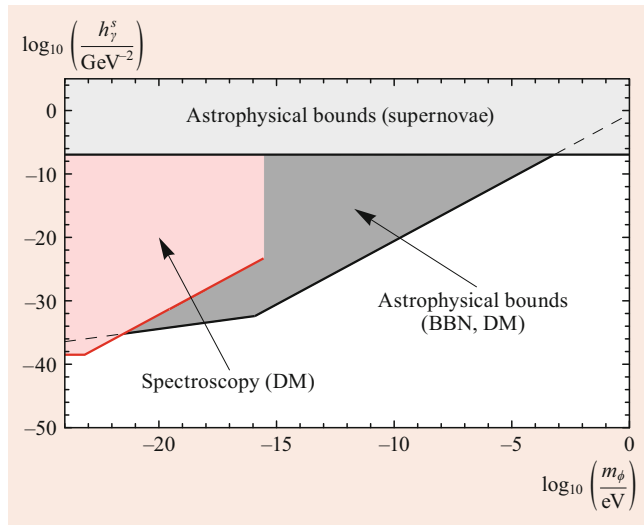

Fig. 31.6 Limits on the quadratic scalar interaction of a spinless boson ϕ with the photon, as defined in the first term of Eq. (31.2). The region in *red* corresponds to constraints from atomic spectroscopy measurements that search for the effects of a relic coherently oscillating field $\phi = \phi_0 \cos(m_\phi t)$, which saturates the local cold dark matter (DM) content [79, 90]. The region in *light gray* corresponds to astrophysical constraints pertaining to supernova energy-loss bounds [13]. The region in *dark gray* corresponds to astrophysical constraints pertaining to big bang nucleosynthesis (BBN) measurements, assuming that spinless bosons saturate the DM content [79]

are practically monochromatic sources of light, the resulting energy spectrum of spinless bosons is likewise sharply peaked in these types of laboratory experiments. On the other hand, in a helioscope experiment, the energies of the spinless bosons are determined by the core temperature of the Sun (≈ 1 keV), and the energy spectrum of the bosons is relatively broad. Current limits from solar source experiments on one type of nongravitational interaction of a spinless boson are shown in Fig. 31.4.

31.5 Cosmological Sources

Low-mass (sub-eV) spinless bosons can be produced efficiently via nonthermal production mechanisms (which impart practically no kinetic energy to the bosons), such as “vacuum misalignment” in the early universe [66], and subsequently form a coherently oscillating classical field: $\phi = \phi_0 \cos(\omega t)$, with the angular frequency of oscillation given by $\omega \approx m_\phi c^2 / \hbar$, where m_ϕ is the boson mass, c is the speed of light, and \hbar is the reduced Planck constant. The classical nature of this field arises due to the large number of low-mass bosons per reduced de Broglie volume. The oscillating bosonic field carries the energy density $\rho_\phi \approx m_\phi^2 \phi_0^2 / 2$, which may saturate the local cold dark matter (DM) energy density $\rho_{\text{DM}}^{\text{local}} \approx 0.4 \text{ GeV}/\text{cm}^3$ [67]. If these bosons comprise all of the DM, then the requirement that the boson de

Broglie wavelength does not exceed the DM halo size of the smallest dwarf galaxies gives the lower boson mass bound $m_\phi \gtrsim 10^{-22} \text{ eV}$.

A variety of atomic, molecular, and optical experiments can be used to search for oscillating DM fields. The specific detection methods crucially depend on the particular nongravitational interactions between the bosonic DM and ordinary matter that are probed. In this section, we give a brief overview of the main types of detection methods for oscillating bosonic fields. We note that similar detection strategies can also be implemented to search for bosonic fields that form “clump-like” DM, except in this case, a network of detectors is required to unambiguously confirm the passage of such DM clumps [68–72]. Additionally, spinless bosonic fields with certain self-interactions are conjectured in “chameleonic” models of dark energy [73] and may be sought for with atom interferometry techniques [74, 75].

31.5.1 Haloscope Experiments

In the presence of the nongravitational interaction in the first term of Eq. (31.3), spinless bosons may interconvert with photons. Spinless bosons that make up (part of) the galactic DM can be detected using haloscope experiments, which aim to convert galactic DM bosons into photons in the presence of a strong applied magnetic field inside a microwave cavity [61–63, 76]. Haloscope experiments are examples of “resonance-type” experiments, since the resonant frequency of a cavity mode must match the boson’s energy, $h\nu_{\text{mode}} \approx m_\phi c^2$. Although resonance-type experiments are sensitive to very feeble nongravitational interactions, the drawback of these types of experiments is that the boson mass (and hence energy) are not known *a priori*, meaning that these types of experiments have to scan over a very large range of frequencies in order to find a narrow resonance. Indeed, galactic bosonic DM in the vicinity of the Solar System is expected to have a root-mean-square velocity of $v_{\text{rms}} \approx 300 \text{ km/s}$, giving the oscillating galactic bosonic field the finite coherence time: $\tau_{\text{coh}} \approx 2\pi / m_\phi v_{\text{rms}}^2 \approx 2\pi \times 10^6 / m_\phi$, which is equivalent to a relative width of $\Delta\omega / \omega \approx 10^{-6}$. Current limits from haloscope experiments on one type of nongravitational interaction of a spinless boson are shown in Fig. 31.4.

31.5.2 Spin-Precession Experiments

In the presence of the nongravitational interactions in the last two terms of Eq. (31.3), bosonic DM fields can induce a number of time-varying spin-dependent effects. In particular, the second term in Eq. (31.3) gives rise to time-varying electric dipole moments of nucleons [81] and atoms and molecules [82], with the angular frequency of oscilla-

tion governed by the boson mass. The last term in Eq. (31.3) gives rise to anomalous time-varying spin-precession effects due to the motion of Earth through an apparent time-varying *pseudo*-magnetic field [77, 82, 83]. Various types of methods can be used to search for time-varying spin-dependent effects:

- (1) Atomic magnetometers and ultracold neutrons to search for time-varying anomalous spin-precession effects [41, 80, 82, 83]
- (2) Torsion pendula to search for time-varying anomalous torques [80, 82, 83]
- (3) Nuclear-magnetic-resonance techniques to search for the resonant build-up of transverse magnetization [77, 84, 85]
- (4) Resonant conversion of galactic DM bosons into photons in a magnetized material [86–89].

In the case of time-varying electric dipole moments, which can be sought for with methods (1) and (3), it is necessary to apply an electric field in the experiment. In the case of methods (1)–(3), the observables scale only to the first power of the underlying interaction constant. This is a particularly attractive feature of these types of methods, compared with the methods discussed in Sects. 31.2–31.5.1, where the observables scale either to the second or fourth power in a small interaction constant. Current limits from spin-precession experiments on several types of nongravitational interactions of spinless bosons are shown in Figs. 31.3 and 31.5.

31.5.3 Time-Varying Physical Constants

In the presence of the nongravitational interactions in Eqs. (31.1) and (31.2), bosonic DM fields can induce “apparent” variations in the physical constants [70, 79, 91]. One particularly powerful class of measurements to search for these apparent oscillations in the physical constants involve high-precision comparisons of atomic and molecular transition frequencies [22, 23, 70, 79, 90, 91], which were previously used to search for “slow temporal drifts” in the physical constants [92], Chap. 30. The basic idea of clock-comparison experiments is to compare two transition frequencies with different sensitivities to variations in the physical constants. For example, in the atomic units $\hbar = e = m_e = 1$, an atomic optical transition frequency scales as $\omega_{\text{opt}} \propto F_{\text{rel}}^{\text{opt}}(Z\alpha)$, while an atomic hyperfine transition frequency scales as $\omega_{\text{hf}} \propto [\alpha^2 F_{\text{rel}}^{\text{hf}}(Z\alpha)](m_e/m_N)\mu$, where F_{rel} are relativistic factors (which generally increase rapidly with the nuclear charge Z), and μ is the nuclear magnetic dipole moment. A summary of calculated sensitivity coefficients for various atomic, molecular, and nuclear transitions can be found in [92], Chap. 30.

Instead of comparing two transition frequencies, it is also possible to compare a transition frequency against a reference frequency determined by the length of an optical cavity or an interferometer arm, or to compare two (different) cavities or arms [70, 93, 94]. In this case, the reference frequency scales roughly as $\omega_{\text{ref}} \propto 1/L \propto 1/a_B$ if the solid length is allowed to vary freely, while the reference frequency is practically independent of the physical constants for a “fixed” length where fluctuations in the arm length are deliberately shielded. The sensitivity coefficients for laser/maser interferometry experiments depend on the specific configuration and mode of operation and were calculated in [70, 93, 94]. Like some of the methods discussed in Sect. 31.5.2 to search for time-varying spin-dependent effects, the observables in the types of experiments discussed in this section also have the attractive feature of scaling to the first power of the underlying interaction constant. Current limits on several types of nongravitational interactions of spinless bosons from experiments that search for apparent oscillations in the physical constants are shown in Figs. 31.1 and 31.6.

Victor Flambaum Professor Victor Flambaum received his PhD and DSc from the Institute of Nuclear Physics, Novosibirsk, Russia. He has about 400 publications in atomic, nuclear, particle, solid state, statistical physics, general relativity and astrophysics, including works on the violation of fundamental symmetries, tests of unification theories, temporal and spatial variation of fundamental constants from the Big Bang to the present, many-body theory, and high-precision atomic calculations.

Yevgeny Stadnik Dr Yevgeny Stadnik completed his PhD at the University of New South Wales, Australia. He was a Humboldt Research Fellow at the Johannes Gutenberg University of Mainz, Germany, and a Kavli Fellow and Assistant Professor at Kavli IPMU within the University of Tokyo, Japan. Yevgeny is currently a DECRA Fellow at the University of Sydney, Australia. His research interests include the manifestations and phenomenology of dark matter in low-energy atomic and astrophysical phenomena.

Abstract

While the Standard Model (SM) of particle physics has been very successful in describing as well as predicting numerous phenomena, it provides no insight into the nature of dark matter and dark energy. Moreover, SM is not consistent with the present observable Universe, which has a glaring imbalance of matter and antimatter. Despite decades of effort, all attempts to unify gravity with other fundamental interactions remain unsuccessful.

The advances in atomic, molecular, and optical (AMO) precision measurements, coupled with improved theoretical description, enabled new tests of fundamental physics. Revolutionary developments led to the extraordinary precision now reached by atomic clocks, other spectroscopy

measurements, atomic magnetometers, laser and atom interferometers, and other precision AMO experiments. These advances bring forth a question: Do our current laws of fundamental physics hold at the level of experimental precision?

Modern physics is based on a number of cornerstone principles such as Lorentz invariance, universality of free fall, local position invariance, constancy of fundamental constants, etc. However, in many theories beyond the Standard Model (BSM), these principles no longer hold, and discovery of their violation will be a first glimpse into the nature of BSM physics. AMO studies aimed to search for new physics beyond SM and to test the fundamental physics postulates are the subject of this chapter. This entire topic was recently reviewed in detail in [1]. In this chapter, we briefly discuss AMO studies in parity nonconservation, time-reversal violation including electric dipole moments, tests of the *CPT* theorem, tests of general relativity, and the search of the violation of local Lorentz invariance. The tests of quantum electrodynamics (QED), constraints on variations of fundamental constants, and searches for new particles, including dark matter, are discussed in other chapters.

32.1 Parity Nonconserving Effects in Atoms

Under the parity transformation P , the position vector \mathbf{r} transforms to $-\mathbf{r}$, which corresponds to mirror reflection and 180° rotation. Until 1957, the invariance of the laws of

physics under the process of parity inversion was assumed to hold. The concept of this invariance has its origin in atomic physics, where Laporte introduced it to explain certain aspects of the iron spectrum. The underlying theory of atomic structure, quantum electrodynamics, is an example of a theory that has this invariance. In 1956, it was suggested by *Lee* and *Yang* [2] that weak interaction processes are not invariant under parity inversion, and the parity violation in nuclear β -decay was discovered by *Wu* et al. [3].

Zeldovich [4] discussed a possibility of observing parity nonconservation (PNC) in atoms but estimated the effect to be too small to be observed. The parity violation in atoms leads to a nonzero amplitude for atomic transitions otherwise forbidden by the parity selection rule, such as the $6s-7s$ transition in cesium. In 1974, the *Bouchiats* [5] showed that these effects in heavy atoms with a nuclear charge Z were enhanced by approximately a factor of Z^3 .

In 1978, the first P -violating signal in an atom was observed in bismuth [6]. Parity violation was observed in other atoms, including lead [7], thallium [8, 9], cesium [10, 11], and ytterbium [12, 13]. Atomic parity violation has been discussed in detail in a number of reviews, most recently in [1, 14, 15]. The goals of high-precision atomic PNC studies are to search for new physics beyond the Standard Model by accurate determination of the weak charge and to probe hadronic parity violation.

In the Standard Model, atomic PNC arises from weak interactions mediated by a Z boson. The contact contribution to the SM Hamiltonian density is given by [16]

$$H_{\text{PV}} = \frac{G_{\text{F}}}{\sqrt{2}} \sum_q \left(C_q^{(1)} \bar{e} \gamma_\mu \gamma_5 e \bar{q} \gamma^\mu q + C_q^{(2)} \bar{e} \gamma_\mu e \bar{q} \gamma^\mu \gamma_5 q \right), \quad (32.1)$$

where q and e are field operators for quarks and electrons, respectively, sum q is over all quark flavors, γ_μ are Dirac matrices, and γ_5 is the Dirac matrix associated with pseudo scalars. The Fermi constant $G_{\text{F}} = 2.22 \times 10^{-14}$ a.u. quantifies the strength of the weak interactions. In Eq. (32.1), the first term describes a coupling of the electron axial-vector current to the quark vector current, $V_q A_e$, parameterized by the constant $C_q^{(1)}$. The second term describes a coupling of the electron vector current to the quark axial-vector current, $A_q V_e$. The $V_q A_e$ term dominates, because all the quarks contribute coherently. The $A_q V_e$ term contributes to the PNC effects that depend on nuclear spin.

For the description of the atomic PNC, it is convenient to combine $C_q^{(i)}$ ($i = 1, 2$) quantities into the corresponding constants for protons and neutrons [17]

$$\begin{aligned} C_p^{(1)} &= 2C_u^{(1)} + C_d^{(1)} = \frac{1}{2}(1 - 4 \sin^2 \theta_{\text{W}}), \\ C_n^{(1)} &= C_u^{(1)} + 2C_d^{(1)} = -\frac{1}{2}, \\ C_p^{(2)} &= -C_n^{(2)} = g_A C_p^{(1)}, \end{aligned}$$

where u and d refer to up and down quarks, θ_{W} is the weak mixing angle, and $g_A \approx 1.26$. We use a nucleon subscript N in expressions for the nucleon vector V_N or axial-vector A_N currents below. Substituting the value of the weak mixing angle, $\sin^2 \theta_{\text{W}} = 0.23122(4)$ [18] (M_Z value) into the equation above shows that atomic PNC is dominated by the neutron contribution.

Other contributions to atomic PNC are discussed in the next sections.

32.1.1 Nuclear-Spin-Independent PNC Effects

Because the nucleon current $V_N A_e$ in the first term of Eq. (32.1) is of vector nature, one can introduce a conserved charge, the nuclear *weak charge* Q_{W}

$$Q_{\text{W}} = 2ZC_p^{(1)} + 2NC_n^{(1)} = Z(1 - 4 \sin^2 \theta_{\text{W}}) - N. \quad (32.2)$$

Here, Z is the number of protons and N the number of neutrons. This is the lowest-order $Q_{\text{W}} \approx -N$ value, which is modified by SM radiative corrections at a level of a few percent [16, 18].

Assuming that the nucleon motion is nonrelativistic and averaging over nucleon distribution, the $V_N A_e$ contribution to H_{PV} reduces to the effective electron-sector weak Hamiltonian,

$$H_{\text{W}} = \frac{G_{\text{F}}}{\sqrt{8}} Q_{\text{W}} \rho(r) \gamma_5, \quad (32.3)$$

where $\rho(r)$ is a nuclear density. The expression above neglects the difference between the proton and the neutron distribution. It is accounted for by a so-called ‘‘neutron skin’’ correction. The neutron skin is defined as the difference between the root-mean-square radii of neutron and proton distributions [19]. It is small, 0.2% for the Cs $6s-7s$ PNC amplitude, increasing for heavier atoms [20].

Due to the smallness of the G_{F} , the matrix elements of the H_{W} are exceptionally small. For example, PNC matrix element in Cs is $\approx 10^{-11}$ a.u., while allowed electric-dipole matrix elements are typically on the order of an atomic unit (ea_0 , where e is the electric charge, and a_0 is the Bohr radius). The PNC interaction due to the exchange of Z between two atomic electrons is much smaller than the electron-nucleon Z exchange. The correction due to weak $e-e$ processes in Cs is only 0.03% [20], significantly below both experimental and theoretical uncertainties.

32.1.2 Nuclear-Spin-Dependent PNC Effects

The nuclear spin-dependent PNC effects, contributing in open-shell atoms with nuclear spin $I \neq 0$, are described by

the effective interactions in the electron sector [1]

$$H_{\text{NSD}} = \frac{G_{\text{F}}}{\sqrt{2}}(\eta_{\text{axial}} + \eta_{\text{NAM}} + \eta_{\text{hf}})(\boldsymbol{\alpha} \cdot \mathbf{I})\rho(r), \quad (32.4)$$

where $\boldsymbol{\alpha}$ is the velocity operator ($\alpha_i = \gamma_0 \gamma^i$) for atomic electrons. The first term is associated with the $A_N V_e$ term of H_{PV} given by Eq. (32.1). The second term arises from the anapole moment contribution, which generally dominates for heavy atoms. It is described in more detail below. The third term describes a combined effect of the hyperfine interactions and the Z-boson exchange interaction from the $V_N A_e$ term of H_{PV} . The corresponding parameter η_{hf} was calculated for transitions of experimental interest by *Johnson, Safronova, and Safronova* [21]. Another nuclear spin-dependent PNC effect was pointed out and evaluated for cases of experimental interest in [22]: nuclei with spin $I \leq 1$ have a weak quadrupole moment leading to a tensor weak interaction that mixes states of opposite parity for atomic levels with total angular momentum difference $\Delta J \leq 2$.

Nonzero nuclear multipolar electric (EJ) and magnetic (MJ) moments, such as charge ($E0$), magnetic dipole moment ($M1$), electric quadrupole moment ($E2$), etc., are all even under the parity transformation and T -reversal. Weak interactions inside the nucleus result in additional parity-odd nuclear moments. The nuclear anapole moment \mathbf{a} is such a leading parity-odd, time-reversal even nuclear moment [23]. For a current density distribution $\mathbf{J}(r)$, the anapole moment is given by

$$\mathbf{a} = -\pi \int d^3r r^2 \mathbf{J}(r). \quad (32.5)$$

The electromagnetic coupling of atomic electrons to the nuclear anapole moment is given by $\boldsymbol{\alpha} \cdot \mathbf{A}$, where $\mathbf{A} = \mathbf{a}\delta(\mathbf{r})$ is the corresponding vector potential. Just as in the case of the nuclear magnetic moment, \mathbf{a} is proportional to the nuclear spin. The anapole moment is related to the parameter η_{NAM} of Eq. (32.4) by

$$\mathbf{a} = \frac{G_{\text{F}}}{|e|\sqrt{2}} \eta_{\text{NAM}} \mathbf{I}. \quad (32.6)$$

The nonzero nuclear anapole moment was observed for the first time in the Cs PNC experiment [11], providing insight into hadronic weak interactions, as discussed in Sect. 32.1.3.

32.1.3 PNC in Cesium and Implications for Particle and Hadronic Physics

The most accurate PNC measurement was carried out in Cs [11]. Cs has a single electron outside a closed xenon-like core with 54 electrons. This is the simplest electronic

structure among all atoms for which the PNC effects were measured, allowing for accurate theoretical calculations of the PNC amplitude, required for the analysis of the experiment. In the text below, we omit the core electrons in the electronic level designations and only list the state of the valence electron.

The PNC transition in cesium that has been studied is $6s \rightarrow 7s$, which is forbidden by parity selection rules, i.e., the electric-dipole matrix element $\langle 7s|D|6s\rangle = 0$. This transition becomes weakly allowed due to PNC effects, which mixes the $6s$ and the $7s$ states with the opposite parity np states. The ^{133}Cs nucleus has 78 neutrons and 55 protons, its nuclear spin is $I = 7/2$. The total angular momentum of atomic ns $J = 1/2$ states is then $F = 3$ or $F = 4$. Both of the transitions,

$$6s(F=4) \rightarrow 7s(F=3)$$

and

$$6s(F=3) \rightarrow 7s(F=4),$$

have been measured, allowing the isolation of PNC effects that depend on the spin of the nucleus. The Boulder experiment [11] used the Stark interference method, applying the external electric field \mathbf{E} to provide an additional admixture of the np states. This induces an electric-dipole transition with a transition amplitude proportional to \mathbf{E} and a vector transition polarizability β (which is determined separately). The $6s$ – $7s$ transition is then excited with a 540 nm elliptically polarized laser light to get a nonzero interference between the Stark-induced amplitude and the parity-violating amplitude E_{PV} . The ratio of the two amplitudes is measured, using reversals of the electric fields, changes in magnetic substates, and in laser polarization to further isolate the PNC effect. The final results for both $6s$ – $7s$ transitions were reported to be

$$\text{Im} \frac{E_{\text{PV}}^{\text{exp}}}{\beta} = \begin{cases} -1.6349(80) & F=4 \rightarrow 3 \\ -1.5576(77) & F=3 \rightarrow 4 \end{cases} \quad (32.7)$$

in units of mV/cm.

Nuclear spin-independent part

The *average* of these values, combined with the value of β , gives *spin-independent* PNC amplitude, accurate to 0.35%. The value of the weak charge can be extracted from this averaged value using

$$E_{\text{PV}}^{\text{exp}} = k_{\text{PV}} Q_{\text{W}}, \quad (32.8)$$

where k_{PV} is the theoretical value of the PNC amplitude in terms of Q_{W} . Such a calculation in Cs with a subpercent accuracy was an extremely formidable task. The major

theoretical effort involved a very accurate treatment of the many-body Coulomb correlations, requiring both implementation of the coupled-cluster method and the fourth-order many-body perturbation theory, accomplished in [20, 24]. Their k_{PV} value, calculated with 0.27% uncertainty is the result of the most accurate and complicated PNC computation in heavy atoms accomplished to date. In addition, the small corrections due to the Breit interaction, radiative QED effects, and the neutron skin had to be calculated at this level of accuracy, which required the work of several groups. These calculations are reviewed by *Derevianko* and *Porsev* [14]. The resulting value of the weak charge

$$Q_w(^{133}\text{Cs}) = -73.16(29)[20], \quad (32.9)$$

where the first error is experimental and the second theoretical [20, 24], in agreement with the SM value [18]. Recent reevaluation of small Coulomb correlation corrections, contributions of the core, and highly excited states [25], raised the theoretical uncertainty to 0.5%, slightly shifting the value of k_{PV} but maintaining agreement with the SM. Theoretical effort to resolve the issue of the accuracy of the highly excited terms is currently in progress.

The Cs experiment, combined with theoretical calculations, provides the most accurate low-energy test of the SM electroweak sector. In combination with particle physics experiments, atomic PNC demonstrated the 3% “running” (i.e., dependence on the four-momentum transfer Q) of the electroweak interactions across five orders of energy values. This result is illustrated in Fig. 32.1 from [1] (adapted from [26]), which shows the Cs atomic parity violation (APV) result together with values from particle physics experiments.

Fig. 32.1 Running of the weak mixing angle with momentum transfer Q . The solid red curve is the SM prediction. The Cs APV result is supplemented with data from particle physics experiments: E158, Møller [electron–electron] scattering; Q-weak, PNC electron–proton scattering, ν -DIS, deep inelastic scattering; LEP and SLAC results. The colored area comes from one of the “new physics” scenarios [26]: a dark boson of mass 50 MeV. From [1] (adapted from [26])

Fig. 32.2 Illustration of the nucleon–nucleon interaction, mediated by a meson exchange

Atomic PNC studies are sensitive to extra Z bosons, setting limits on such particles with TeV masses, with limits only recently improved at the Large Hadron Collider [18]. APV is also uniquely sensitive to some “dark forces” [26], with the limits on the 50 MeV dark boson shown in Fig. 32.1. The AMO searches for new particles, including dark matter, are further discussed in Chap. 31.

Nuclear spin-dependent part

Next, we discuss the analysis of the Cs result in terms of the spin-dependent PNC effects. The *difference* of the values for two transitions in Eq. (32.7), $0.077(11)$ mV/cm, combined with the value of β , gives the *spin-dependent* PNC amplitude, accurate to 15%. To extract the value of the anapole moment, the theoretical calculation of the nuclear spin-dependent amplitude E_{PV}^{NSD} is needed, just as in the case of the spin-independent part, only using the H_{NSD} Hamiltonian (32.4), along with the calculations of η_{axial} and η_{hf} ; E_{PV}^{NSD} was calculated in [27] using the linearized coupled-cluster approach with 1% uncertainty, much exceeding the experimental accuracy.

The nuclear anapole moment arises due to nucleon–nucleon interaction, mediated by a meson (π , ω , ρ) exchange illustrated in Fig. 32.2, where one of the nucleon–meson vertexes is strong and another is weak and P -violating. Therefore, the experimental PNC result combined with the theoretical value of the spin-dependent PNC amplitude can be used to probe weak hadronic interactions. Such an analysis, carried out in [28], yielded the values of the weak meson–nucleon couplings in disagreement with other constraints. More recent limits on the values of the weak meson–nucleon couplings are given in [29], but the discrepancy remains unsolved, complicated by the difficulty in the required nuclear calculation [28]. More experiments, including anapole moment measurements in other atoms or molecules are required to solve this long-standing puzzle.

32.1.4 Current PNC Experiments

The Yb PNC experiment (ongoing in Mainz, Germany) recently reported the measurements of atomic parity violation, made on a chain of ytterbium isotopes with mass numbers $A = 170, 172, 174$, and 176 [13]. The PNC effect in

Yb is approximately 100 times larger than that of Cs. The advantage of the experiment with several isotopes is the potential of carrying out the analysis without the need for high-precision calculations, not currently feasible for the Yb PNC amplitude. Experiments with Dy, which has nearly-degenerate states of opposite parity, are being carried out by the same group. While PNC in Dy was not previously observed [30], it should be within the sensitivity of the new experiment.

An experiment to remeasure PNC in the $6s-7s$ transition of Cs is underway in Purdue, using new two-pathway coherent control technique [31]. An Fr PNC experiment is being pursued at TRIUMF in Vancouver [32], which is complicated by the requirement that it be performed at a facility capable of producing needed radioactive isotopes. Measurements in a chain of Fr isotopes are planned, with the main goal of measuring nuclear anapole moments. The TRIUMF collaboration plans to measure PNC in both optical $7s-8s$ and ground state hyperfine transitions. Experiments to measure spin-dependent PNC effects in molecules are underway at Yale [33].

32.2 Electric Dipole Moments and Related Phenomena

In this section, we continue with the discussion of the P -violating effects but consider phenomena that are also odd under the time reversal (T). Such searches probe the energy scales well above 1 TeV in particle theory models such as supersymmetry, considered to be natural extensions of the SM. Thus, the AMO studies of P, T -violating effects are of particular significance for particle physics. Numerous detailed reviews of this topic are available in the literature (e.g. [1, 34, 35] and references therein). Here, we discuss the most recent results.

The combined symmetry of charge conjugation C , parity transformation P , and time reversal T , i.e., CPT , is preserved in quantum field theory. Therefore, the violation of T implies the violation of CP . Tests of CPT invariance are discussed in Sect. 32.3. The question of CP -violation is directly related to the problem of baryon asymmetry, observed dominance of matter over the antimatter in our Universe. CP violation is required to generate baryon asymmetry [36], but CP violation in the Standard Model is by far too small to account for it. Therefore, there must be other sources of CP violation leading to the effects already well within the precision of the experiments described in this chapter. As a result, AMO searches for CP -violating effects have a particularly high potential of discovering new physics.

A permanent electric dipole moment (EDM) of a particle, d , along its spin s violates both P and T . The Hamiltonian describing the EDM interaction with an electric field E is

given by

$$H_{\text{EDM}} = -d \cdot E. \quad (32.10)$$

While it would seem that EDMs of electrons and nucleons will simply lead to observable effects (i.e., shifts in energy levels) in atoms and molecules, this issue turns out to be more complicated. According to Schiff's theorem [37], there is no energy shift resulting from constituent particles' EDMs when an E -field is applied to a neutral system, assuming nonrelativistic point particles in an electrostatic potential. This means that the other parts of the atomic system rearrange to completely screen the external E -field felt by the charged particle, otherwise it will experience a net acceleration. A number of effects (finite nuclear size, relativistic effects, magnetic interactions, and others) allow to evade the Schiff's theorem leading to potentially observable experimental signals.

In atoms and molecules, P, T -violating effects arise from EDMs of electrons, protons, and neutrons, P, T -violating electron–nucleon interactions and P, T -violating nucleon–nucleon interactions. Different atoms and molecules have various sensitivities to these effects, but one may divide them into two groups: paramagnetic (with unpaired electron spins) and diamagnetic (with closed electron shells but nonzero nuclear spin). The first group is the most sensitive to the electron EDM (eEDM) and one type of electron–nucleus interaction. The second is the most sensitive to EDMs of nucleons, purely hadronic (nucleon–nucleon) interactions, and other types of electron–nucleon interactions.

32.2.1 Experiments with Paramagnetic Systems

The relativistic motion of a bound electron in a heavy atom can lead to energy shifts due to eEDM that are larger than a shift for the free electron, i.e., EDM effects are enhanced in some atoms and molecules. For example, the EDM of a Tl atom is

$$d(^{205}\text{Tl}) = K d_e \approx 573 d_e,$$

where K is the enhancement factor calculated theoretically using a hybrid approach that combines configuration interaction and a linearized coupled cluster method [38] with a 3% accuracy. This enhancement makes measurement of EDM in heavy atoms and molecules containing heavy atoms particularly attractive. Measurement of the EDM of ^{205}Tl atom [39] placed the bound on the electron EDM $d_e < 1.6 \times 10^{-27} e \text{ cm}$. This limit was improved by the YbF molecular experiment to $d_e < 1.05 \times 10^{-27} e \text{ cm}$ [40]. The current best limit on eEDM comes from the ACME experiment with ThO molecules [41]; $d_e < 8.7 \times 10^{-29} e \text{ cm}$ with 90% confidence.

The valence electrons in some molecules, such as ThO, can experience exceptionally large intramolecular effective electric field E_{eff} , on the order of 100 GV/cm. If an electron has an EDM, such enormous field (which can not be achieved in the lab) leads to an enhanced energy shift $-d_e E_{\text{eff}}$, making these molecules particularly attractive for EDM searches. Unlike atoms, the ThO molecule can also be fully polarized applying an ≈ 100 V/cm external electric field. For the Ω -doublet $H^3\Delta_1$ electronic state in ThO, the effective field was calculated to be ≈ 80 GV/cm, with an uncertainty of about 10–20% ([42, 43] and references therein). The use of the Ω -doublet states is particularly advantageous as they provide for “internal comagnetometry”, which allows for the reversal of the EDM interaction without changing any lab fields, minimizing the systematic effects. The $H^3\Delta_1$ state has an additional advantage of the unusually small magnetic moment, which reduces the systematic effect due to spurious magnetic fields.

To measure d_e , ACME performed a spin precession measurement on pulses of $^{232}\text{Th}^{16}\text{O}$ molecules from a cryogenic buffer gas beam source, which has the advantages of a low internal temperature, high flux, and low forward velocity in comparison with conventional molecular beam sources.

Besides the electron EDM, ThO is also sensitive to the pseudoscalar electron–scalar nucleon T -violating interaction, quantified by the coupling C_S . This effect would lead to an additional frequency shift, $-W_S C_S$, where W_S is calculated theoretically [42, 43]. The electron EDM limit above assumes $C_S = 0$. Setting $d_e = 0$ yields $C_S < 6 \times 10^{-9}$ [41].

In 2017, an electron EDM result from a new experiment at JILA with HfF^+ molecular ions was reported [44]. *Cairncross* et al. used a rotating electric field ($E \approx 20$ V/cm) to trap and fully polarize Ω -doublet levels of a metastable $^3\Delta_1$ state. Combining the experimental result with the calculated value $E_{\text{eff}} \approx 23$ GV/cm [45, 46], this experiment gives $d_e < 13 \times 10^{-29}$ e cm at a 90% confidence level or $C_S < 14 \times 10^{-9}$. A combination of ThO and HfF^+ values may be used to improve the constraints further due to different relative sensitivities of the two experiments to d_e and C_S .

Improvements in ACME [47], HfF^+ , and YbF experiments are underway, and significant improvements in accuracy are expected. *Kozryev* and *Hutzler* [48] recently proposed using polyatomic paramagnetic molecules, which can be laser cooled and have a level structure favorable for electron EDM measurements.

32.2.2 Experiments with Diamagnetic Systems

The Hg EDM search at the University of Washington [49, 50] is the most sensitive EDM experiment with a diamagnetic system. Because ^{199}Hg has a closed-shell 1S_0 electronic ground state and nuclear spin $I = 1/2$, the EDM must point

along the nuclear spin axis. The nuclear spins are polarized by optical pumping with a resonant laser beam. When spin-polarized ^{199}Hg atoms are immersed in electric and magnetic fields, the Larmor frequency is given by

$$h\nu_L = 2|\mu B \pm dE|, \quad (32.11)$$

where μ and d are magnetic and electric dipole moments, and \pm sign denotes parallel (antiparallel) fields. The $d \neq 0$ EDM experimental signature would be a Larmor frequency change correlated with the electric field when \mathbf{E} is reversed relative to \mathbf{B} . Hg atoms are contained in four nominally identical high-density vapor cells. The inner cells have strong, equal, and opposite \mathbf{E} fields along the \mathbf{B} -field axis, while the outer cells have $\mathbf{E} = 0$ to cancel fluctuations not only in the average value of \mathbf{B} but also in its first-order gradient. With 252 daily runs, the experiment was sensitive to the PT -violating energy shift of $\Delta E/h < 20$ pHz. The final result for the Hg EDM was [49]

$$d_{\text{Hg}} = (2.20 \pm 2.75_{\text{stat}} \pm 1.48_{\text{sys}}) \times 10^{-30} e \text{ cm},$$

with a 95% confidence limit of

$$d_{\text{Hg}} < 7.4 \times 10^{-30} e \text{ cm}.$$

Theoretical interpretation of this limit in terms of the Schiff moment \mathbf{S}_{Hg} , which is the leading-order P , T -violating nuclear moment not completely screened by the electron cloud, gives

$$|\mathbf{S}_{\text{Hg}}| < 3 \times 10^{-13} e \text{ fm}^3,$$

where results of several theoretical calculations were averaged to provide

$$d_{\text{Hg}} = -2.4 \times 10^{-4} \mathbf{S}_{\text{Hg}}/\text{fm}^2.$$

Further limits on neutron EDM and proton EDM were derived from the corresponding contributions to \mathbf{S}_{Hg} in a random-phase approximation calculation with core polarization [51]

$$d_{\text{Hg}} = (1.9 d_n + 0.2 d_p) \text{ fm}^2.$$

The resulting limits are $d_n < 1.6 \times 10^{-26}$ e cm and $d_p < 2.0 \times 10^{-25}$ e cm, where the other terms were assumed to be zero, and 30% uncertainty was assigned to the d_p contribution. The ^{199}Hg experiment also set the best limits on the combined chromo-EDM of the up and down quarks, the observable QCD θ -parameter, $\bar{\theta}_{\text{QCD}} < 1.5 \times 10^{-10}$, and hadronic T -odd, P -odd couplings, pseudoscalar-scalar and tensor-tensor semileptonic couplings.

Other experiments with diamagnetic systems were carried out with ^{129}Xe [52], ^{225}Ra atoms [53] and ^{205}TlF molecules [54]. The groups at Yale, Columbia, and the University of Massachusetts are constructing a new experiment (CeN-TREX) to measure the Schiff moment of ^{205}Tl using a cryogenic beam of TlF molecules. A review of other new EDM experiments is given in [1].

32.2.3 Impact on Particle Physics

Calculations of the size of the relevant T , P -violating parameters were made for a wide range of theoretical models, in particular those that include supersymmetry (SUSY) that is broken near the electroweak scale. Attractive features of such theories include predictions of superpartner particles with mass $M_{\text{SUSY}} \approx M_Z \approx 0.1 \text{ TeV}$ that provide potential dark matter candidates, a solution to the problem of the stabilization of the Higgs mass against radiative corrections, extra sources of CP -violation to resolve the matter-antimatter asymmetry, etc. These theories predict EDMs that are already well within the experimental reach and improving EDM sensitivity by 1–2 orders of magnitude will either yield a discovery or conclusively rule out many SUSY models. Even in the scenarios when primary contribution to EDMs comes from the two-loop diagrams, the electron EDM and quark chromo-EDM limits correspond to lower bounds of $\approx 2\text{--}4 \text{ TeV}$ on the masses of the lighter SUSY particles, if $\delta_{\text{SUSY}} \approx 1$ [1, 55]. For these types of SUSY particles, this is well beyond the direct reach of the Large Hadron Collider [18]. EDM experiments also set limits on models with extra scalar fields, analogous to the Higgs boson [34], also exceeding LHC bounds.

32.3 Tests of the CPT Symmetry

Current laws of physics are believed to be invariant under the CPT transformation. However, CPT symmetry breaking may arise in physics beyond the Standard Model, such as string theories [56]. The CPT invariance ensures the same masses and magnetic moments of particles and corresponding antiparticles [57, 58]. Therefore, comparisons of particle/antiparticle properties test CPT symmetry. Such experiments were recently reviewed in [1, 59–61]. We only provide a brief summary of the most recent results of the CPT tests with antihydrogen ($\bar{\text{H}}$), antiprotons \bar{p} , and antiprotonic helium $\bar{p}\text{He}^+$. Antihydrogen experiments at CERN aimed at CPT and gravity tests include ATRAP, ALPHA, ASACUSA, AEGIS, and GBAR.

Recently, the ALPHA experiment performed a laser-spectroscopic measurement of the $1S\text{--}2S$ transition fre-

quency of antihydrogen using two-photon laser excitation with 243 nm light [62], which was a long-standing goal of the antihydrogen experiments. A comparison of this result with the $1S\text{--}2S$ frequency in hydrogen provided a test of with CPT invariance at a relative precision of 2×10^{-10} . In 2017, an observation of the hyperfine spectrum of antihydrogen was reported [63], finding a ground-state hyperfine splitting in $\bar{\text{H}}$ to be $1420.4 \pm 0.5 \text{ MHz}$. This result is consistent with a corresponding value in atomic hydrogen at the level of four parts in 10^4 .

ALPHA collaboration reported an experimental limit on the charge Qe of antihydrogen, in which e is the elementary charge, to be $|Q| < 0.71$ parts per billion (one standard deviation) [64]. This measurement constrained the relative difference between the positron and elementary charge at a level of about one part per billion (ppb), assuming charge superposition and using the best measured value of the antiproton charge [18].

Another focus of the antihydrogen experiments (GBAR, AEGIS, and ALPHA) is testing whether antimatter is affected by gravity in the same way as matter. Weakness of the gravitational interaction requires such direct laboratory tests to be conducted with neutral particles, making antihydrogen the best available system. These tests are complicated by the need for increased production of cold antihydrogen, requiring new cooling techniques [65, 66].

The goal of the Baryon Antibaryon Symmetry Experiment (BASE) is precise comparisons of the fundamental properties of antiprotons and protons for tests of CPT [67]. This experiment carries out measurements with single trapped particles.

In 2017, BASE collaboration reported a parts-per-billion measurement of the antiproton magnetic moment [68] using an advanced cryogenic multi-Penning trap system. This experiment used a particle with an effective temperature of 300 K for magnetic field measurements and a cold particle at 0.12 K for spin transition spectroscopy, reporting the value of $\mu_{\bar{p}} = 2.792\,847\,3441(42)\mu_N$, where μ_N is the nuclear magnetic moment (at the 68% confidence level). A measurement of the proton magnetic moment at the 0.3 ppb level was reported by the same team [69]. A comparison of the $\mu_{\bar{p}}$ with the new proton value $\mu_p = 2.792\,847\,344\,62(82)\mu_N$ constrains CPT -violating effects. In the future, BASE collaboration proposes to use quantum-logic technologies to further advance the CPT tests. They plan to sympathetically cool and probe the (anti)proton using a coupling to an atomic “qubit” ion trapped in its vicinity via the Coulomb interaction. This technique has a potential to enable the proton and antiproton magnetic moment measurements at the parts per trillion level [69].

The BASE collaboration also compared the charge-to-mass proton and antiproton ratios using high-precision cy-

clotron frequency comparisons carried out in a Penning-trap system, establishing a limit [70]

$$\frac{(q/m)_{\bar{p}}}{(q/m)_p} - 1 = 1(69) \times 10^{-12}.$$

Single-photon spectroscopy of antiprotonic helium, $\bar{p}\text{He}^+$, which consists of an α -particle, an electron, and an antiproton, was performed in [71]. Combining their experimental result with the high-precision calculations of the relevant transition frequencies [72], yielded a value of $m_{\bar{p}}/m_e = 1836.152\,673\,4(15)$ [71]. This value agrees with the CODATA proton to electron mass ratio [73] at a level of 0.8 ppb. A recent review of “magnetometry” CPT tests, which do not require antimatter is given in [74].

A number of very recent CPT tests described above mark a turning point from proof-of-principle experiments to high-precision metrology and CPT comparisons, with prospects for significant improvements in a near future.

32.4 Lorentz Symmetry Tests

Local Lorentz invariance (LLI) is the cornerstone of modern physics: the outcome of any local nongravitational experiment is independent of the orientation and the velocity of the (freely falling) apparatus. In the SM field theory, the Lorentz invariance and the CPT invariance, discussed in Sect. 32.3, are closely related. However, one may be violated but not the other in some BSM frameworks, which is a subject of recent debates (e.g. [75] and references therein).

Current LLI tests span almost all fields of physics as separate violations of LLI are possible for all particles. The resulting limits and references are compiled in the *Data Tables for Lorentz and CPT Violation* [76]. A scaling argument is used to provide some guidance to the Lorentz symmetry violation (LV) searches: one may expect the LV effects to be suppressed by some power of the ratio R between the electroweak scale and the natural (Planck) energy scale for strings: $R = m_{\text{ew}}/M_{\text{Pl}} = 2 \times 10^{-17}$ [56] or electron mass to Planck scale 4×10^{-23} [77]. The LV tests in the electron sector are just at the $R = 1$ boundary, while some limits for other particles have already surpassed it. This presents a particular attraction of the LV tests: any verified positive signal will be an unambiguous sign of the new physics.

Lorentz violation tests are analyzed in the context of an effective field theory known as the Standard Model extension (SME) [78]. The AMO LV tests include experiments with atomic clocks [79], other precision spectroscopy measurements [80], magnetometers [81, 82], rotating optical and microwave resonators [83–85], quantum-information trapped-ion technologies [86], and quartz oscillators [87]. In this section, we highlight the most recent AMO results; a detailed review is given in [1].

In minimal SME, a general expression for the quadratic Hermitian Lagrangian density in the presence of Lorentz violation describing a single spin-1/2 Dirac fermion of mass m is given by [88]

$$\mathcal{L} = \frac{1}{2} i c \bar{\psi} \Gamma_\nu \overleftrightarrow{\partial}^\nu \psi - M c^2 \bar{\psi} \psi, \quad (32.12)$$

where ψ is a four-component Dirac spinor,

$$f \overleftrightarrow{\partial}^\nu g = f \partial^\nu g - g \partial^\nu f, \quad (32.13)$$

$$M = m + a_\mu \gamma^\mu + b_\mu \gamma_5 \gamma^\mu + \frac{1}{2} H_{\mu\nu} \sigma^{\mu\nu},$$

and

$$\Gamma_\nu = \gamma_\nu + c_{\mu\nu} \gamma_\nu + d_{\mu\nu} \gamma_5 \gamma_\nu + e_\nu + i \gamma_5 f_\nu + \frac{1}{2} g_{\lambda\mu\nu} \sigma_{\lambda\mu}. \quad (32.14)$$

The first terms in the expressions for M and Γ_ν are from the SM Lagrangian. The coefficients in Eq. (32.13) have dimensions of mass, while the coefficients in Eq. (32.14) are dimensionless. Lorentz violation is parameterized by the coefficients b_μ , $c_{\mu\nu}$, $d_{\mu\nu}$, e_μ , f_μ , $g_{\lambda\mu\nu}$, and $H_{\mu\nu}$. The field operators in Eqs. (32.13), (32.14) containing the coefficients $c_{\mu\nu}$, $d_{\mu\nu}$, and $H_{\mu\nu}$ are even under CPT , and the remaining ones are odd under CPT . Therefore, the results of the CPT experiments discussed in Sect. 32.3 can also be parameterized by SME. AMO experiments may be interpreted as Lorentz-invariance tests for the photon, electron, proton and neutron, and their combinations, with photon contributions appearing in all atomic experiments.

32.4.1 Electron–Photon Sector of SME

Atomic LV experiments in the electron–photon sector [80, 86] use the different sensitivities of various energy levels to the hypothetical Lorentz violation. The quantization axis is set by the direction of the magnetic field, and the energy difference of two atomic levels with different LV sensitivities is monitored during the Earth’s rotation and motion around the Sun. No additional rotation of the experiment is required. The resulting data are combined with the theoretical calculations of the relevant LV-violating matrix elements and are analyzed to extract the SME coefficients. The SME coefficients are frame-dependent but have unique values in the specified frame. Generally, one uses the Sun centered celestial-equatorial frame (SCCEF) for the analysis of the experiments [89], indicated by the coordinate indexes T , X , Y , and Z . The experiment below set limits on the coefficient of the $c_{\mu\nu}$ tensor, which has nine components that need to be experimentally determined: parity-even c_{TT} and c_{JK}

and parity-odd c_{TJ} , where $J, K = X, Y, Z$. The elements c_{JK} describe the rotational effects and have a leading order time-modulation period related to the sidereal day (12-h and 24-h modulation), while the c_{TJ} and c_{TT} describe the boost effects of the laboratory frame and have a leading order time-modulation period related to the sidereal year. Therefore, the terms c_{TJ} are suppressed in comparison to c_{JK} by a ratio of the Earth's orbital velocity to the speed of light $\beta_{\oplus} \approx 10^{-4}$. The c_{TT} term is suppressed by $\beta_{\oplus}^2 \approx 10^{-8}$.

The LV effect on the bound electronic states is described by the Hamiltonian [80, 88]

$$\delta H = -\left(C_0^{(0)} - \frac{2U}{3c^2}c_{00}\right)\frac{\mathbf{p}^2}{2m_e} - \frac{1}{6m_e}C_0^{(2)}T_0^{(2)}, \quad (32.15)$$

where \mathbf{p} is the momentum of a bound electron, and $T_0^{(2)} = \mathbf{p}^2 - 3p_z^2$ in nonrelativistic approximation. Interpretation of the LV experiments requires theoretical calculations of the expectation values of these operators for the states of interest. The second term in the parentheses gives the leading order gravitational redshift anomaly in terms of the Newtonian potential U . The parameters $C_0^{(0)}$ and $C_0^{(2)}$ are elements of the $c_{\mu\nu}$ tensor in the laboratory frame defined by Eq. (32.14)

$$C_0^{(0)} = c_{00} + (2/3)c_{jj}, \quad (32.16)$$

$$C_0^{(2)} = c_{jj} + (2/3)c_{33}, \quad (32.17)$$

where $j = 1, 2, 3$. The other $C_i^{(2)}$ components do not contribute to the energy shift of bound states.

Fig. 32.3 Rotation of the quantization axis of the experiment with respect to the Sun as the Earth rotates. A magnetic field (B) is applied vertically in the laboratory frame to define the eigenstates of the system. As the Earth rotates with an angular frequency given by $\omega_{\oplus} = 2\pi/(23.93 \text{ h})$, the orientation of the magnetic field and, consequently, that of the electron wave packet (as shown in the inset in terms of probability envelopes) changes with respect to the Sun's rest frame. The angle χ is the colatitude of the experiment. From [86]

The formalism above also applies to the LV violation in the nuclei, but the expectation values of the \mathbf{p}^2 and $T_0^{(2)}$ operators for the nuclear states determine the sensitivity.

Here, we describe LV tests with Dy [80] and Ca^+ [86], performed using very different techniques. Both experiments only involve isotopes with zero nuclear spin making them insensitive to nuclear LV effects.

Dy has two opposite parity states with leading configurations $[\text{Xe}]4f^{10}5d6s$ $J = 10$ (state A) and $[\text{Xe}]4f^95d^26s$ $J = 10$ (state B) that are nearly degenerate. The $\Delta E = E_A - E_B$ energy difference is highly sensitive to the LV effects and can be measured directly by driving an electric-dipole transition between the states A and B with a radio-frequency (rf) field. The sign of the frequency shift is opposite for ^{162}Dy and ^{164}Dy allowing to reduce systematic effects. Repeated frequency measurements over the span of 2 years allowed to constrain eight of the nine elements of the $c_{\mu\nu}$ tensor, limiting Lorentz violation for electrons at the level of 10^{-17} for the c_{JK} components and improving bounds on gravitational redshift anomalies for electrons [90] by two orders of magnitude, to 10^{-8} .

In the $^{40}\text{Ca}^+$ trapped ion experiment, the LV-dependent energy difference of the two Zeeman substates of the $^2D_{5/2}$ manifold was monitored for 23 h [86]. A pair of $^{40}\text{Ca}^+$ ions was trapped in a linear Paul trap, with an applied static magnetic field pointed up defining the quantization axis (i.e., a z axis of the lab frame). The direction of this magnetic field changes with respect to the Sun as the Earth rotates resulting in a rotation of the experiment as illustrated in Fig. 32.3.

Using the theoretical calculation of the matrix elements of the $T_0^{(2)}$ operator for the ${}^2D_{5/2}$ atomic state, the energy difference $\Delta E = E_{m_J=5/2} - E_{m_J=1/2}$ of these two Zeeman levels induced by Lorentz violation is given by

$$\frac{\Delta E}{h} = [-4.45(9) \times 10^{15} \text{ Hz}] \times C_0^{(2)}. \quad (32.18)$$

This experiment was not sensitive to the scalar $C_0^{(0)}$ coefficient of Eq. (32.15).

The main problem of such LV experiments is the effect of the magnetic field noise, which causes frequency shifts. The Ca^+ experiment used quantum-information inspired techniques to create a decoherence-free two-ion product state, shown in Fig. 32.3, that is insensitive to magnetic field fluctuations to first order.

Pruttivarasin et al. [86] noted that electron and photon sector Lorentz violation can not be separated in the LV experiments involving atomic energy levels as LV violation in the photon sector affects the Coulomb potential. Therefore, the experimental results may be interpreted in terms of either photon or electron LV violation described via $c'_{\mu\nu} = c_{\mu\nu} + k_{\mu\nu}/2$, where two terms refer to the electron and photon LV, respectively. The Ca^+ experiment improved the limits to the c'_{JK} coefficients of the LV-violation in the electron–photon sector by a factor of 100.

The LV tests with Yb^+ octupole clock state, $4f^{13}6s^2 F_{7/2}$, and highly-charged ions proposed in [91, 92] promise another five orders of magnitude improvements in LV tests in the electron sector. *Harabati* et al. [93] proposed measuring transition energies of rare-earth ions doped in crystalline lattices, which can be highly sensitive to the electron SME parameters.

LLI tests in the photon sector were carried out with rotating optical and microwave resonators [83–85].

32.4.2 Proton and Neutron Sectors of SME

Wolf et al. [79] used a cold Cs atomic clock, which is also the primary frequency standard defining the second, to test nucleon LLI. The Cs atomic clock operates on the

$$|F = 3, m_F = 0\rangle \leftrightarrow |F = 4, m_F = 0\rangle \quad (32.19)$$

hyperfine transition at 9.2 GHz, where $\mathbf{F} = \mathbf{J} + \mathbf{I}$ is the total angular momentum, and m_F is a corresponding magnetic quantum number. This transition is insensitive to either Lorentz violation or first-order magnetic field effects. To test Lorentz symmetry, a combination of the clock transition above and two other transitions, which are LV sensitive,

was monitored

$$|F = 3, m_F = 3\rangle \leftrightarrow |F = 4, m_F = 3\rangle, \quad (32.20)$$

$$|F = 3, m_F = -3\rangle \leftrightarrow |F = 4, m_F = -3\rangle. \quad (32.21)$$

To suppress the magnetic field fluctuations to the first order, they used a combined observable

$$\nu_c = \nu_{+3} + \nu_{-3} - 2\nu_0, \quad (32.22)$$

where ν_0 , ν_{+3} , and ν_{-3} are frequencies of (32.19), (32.20), and (32.21) transitions.

The combined observable is not sensitive to the Lorentz-violating tensor component from the electron sector but is sensitive to the nuclear (mostly proton) LV violation since the ${}^{133}\text{Cs}$ nucleus has one unpaired proton. The Cs clock experiment set the limits for SME parameters for the proton at the 10^{-21} – 10^{-25} level. Recent reanalysis of the Cs experiment [94] placed improved bounds on the LV for the proton and neutron.

Some of the most stringent clock-comparison tests of LLI [81, 95] were carried out using the self-compensating spin-exchange relaxation-free (SERF) comagnetometry scheme.

The experiment of [95] was performed with K and ${}^3\text{He}$ coupled via spin-exchange collisions with the magnetic field along the z -direction tuned to the compensation point where the K- ${}^3\text{He}$ SERF comagnetometer is insensitive to magnetic fields but highly sensitive to anomalous interactions that do not scale with the magnetic moments. The orientation of the apparatus was alternated between North–South or East–West every 22 s over the course of many days to test the LV effects. The results of this experiment probed neutron couplings to SME background fields (b_μ) at energy scales $\approx 10^{-25}$ eV [95]. Recent work [96] analyzed the Coulomb interactions between the constituent particles of atoms and nuclei, and used comagnetometer experiments [81] to establish that the speed of light is isotropic to a part in 10^{28} .

A related experiment [81] used a ${}^{21}\text{Ne}$ -Rb-K SERF comagnetometer with an order of magnitude better shot-noise-limited sensitivity to LLI violations. Moreover, this experiment probed tensor anisotropies in addition to the vector ones since the nuclear spin of ${}^{21}\text{Ne}$ is $I = 3/2$. To further control the gyro-compass effect, a version of this experiment is being carried out at the South Pole for further improvement of precision.

A different scheme was used by [82] to test LV in the neutron sector with ${}^3\text{He}$ and ${}^{129}\text{Xe}$ atoms. We note a following discussion in the literature [97, 98] regarding this experiment. A novel approach to LLI tests in the matter sector was proposed and demonstrated by *Goryachev* et al. [99] using quartz bulk acoustic-wave oscillators.

32.5 AMO Tests of General Relativity

32.5.1 Tests of the Einstein Equivalence Principle

According to the weak equivalence principle (WEP) the trajectory of a freely falling body is independent of its internal structure and composition. All bodies in a common gravitational field fall with the same acceleration, which is referred to as the universality of free fall (UFF). The equivalence principle implies that all forms of matter-energy respond to gravity in the same way, which may not be the case for most theories aimed at unifying all four fundamental interactions, such as string theories [100]. Therefore, WEP may be violated at small but measurable levels [101]. General tests of gravity including the EEP tests are reviewed in [100]. A review of the WEP tests and future proposals, including torsion-balance experiments, free-fall experiments, and measurement of relative motions of celestial bodies (for example, lunar laser ranging) is given in [102]. We briefly review best classical WEP limits before discussing quantum-based AMO tests of the WEP.

If the WEP is violated, the gravitational mass of a body, m_g , is not equal to its inertial mass, m_1 , and the acceleration a of a body in a gravitational field g is given by

$$a = \frac{m_g}{m_1} g .$$

The violation of the WEP is generally quantified by the Eötvös ratio η

$$\eta = 2 \left| \frac{a_1 - a_2}{a_1 + a_2} \right| , \quad (32.23)$$

where a_1 , a_2 are the accelerations of the two falling bodies, which differ in their composition. The strictest WEP laboratory Earth-based constraints (at a 10^{-13} level) is from the “Eöt-Wash” torsion-balance experiments, which compare differential accelerations of beryllium-aluminum and beryllium-titanium test-body pairs [103, 104]. The lunar laser-ranging experiments provided similar limits [105, 106]. A significant improvement in probing WEP is expected to come from space-based missions. MicroSCOPE is an ongoing Centre National d’Études Spatiales (CNES)/European Space Agency (ESA) gravity-research minisatellite mission [107]. Its first results have already yielded improved limits

$$\eta = (-1 \pm 27) \times 10^{-15}$$

at a 2σ confidence level.

Recent progress in control of the ultracold atoms started the field of the weak-equivalence tests with quantum matter using atom interferometers (AI) to directly compare the

phase shifts of two different types of matter waves without the use of classical gravimeters [108, 109]. The sensitivity of atom interferometers to WEP violations increases linearly with the momentum difference between the two matter waves and quadratically with the time of free fall. Therefore, increasing either of these parameters improves the sensitivity of the AI WEP tests, with an ultimate goal of the space-based tests.

A proof-of-principle AI quantum tests of the universality of free fall were performed at the 10^{-8} – 10^{-9} level [110, 111]. A scheme to compensate the effects of gravity gradients that pose a major challenge for high-precision tests of the WEP with atom interferometry was proposed recently [112]. Implementation of this scheme by *Overstreet* et al. [113] demonstrated that one can bring down the systematic effects due to the gravity gradients in WEP tests to one part in 10^{14} , making future AI tests eventually competitive with tests employing macroscopic masses. *Hartwig* et al. [114] proposed a long baseline (with over 10 m of free fall) AI test of WEP with Rb and Yb, estimated to reach 7×10^{-13} accuracy in the Eötvös ratio.

We note that using quantum matter for gravity tests provides the opportunity to perform qualitatively different (from the classical) WEP tests using “test masses” with a definite spin for a search of the spin-gravity coupling effects. An experiment to study the possible influence of entanglement between two test masses on the universality of free fall was proposed [115].

A number of quantum WEP tests in microgravity are being pursued with the promise of greatly increased precision of the current quantum WEP tests. In 2017, the QUANTUS collaboration [116] conducted the successful MAIUS 1 (matter-wave interferometry in microgravity) experiment aboard a sounding rocket at an altitude of up to 243 km above the Earth’s surface, conducting ≈ 100 discrete matter-wave experiments during the 6-min experimental phase of this flight.

32.5.2 Other AMO Tests of Gravity

Tests of gravity with antimatter were briefly discussed in Sect. 32.3. A number of AMO gravity tests are related to searches for exotic forces. Atomic spectroscopy was used to search for Yukawa-type fifth-forces [117] by studying the behavior of atomic transition frequencies at varying distances away from massive bodies. A search for subgravitational forces on atoms from a miniature source mass was carried out in [118].

An intriguing possibility was proposed in [119]: a realization of the gravitational Aharonov–Bohm effect by

measuring phase shifts with an atom interferometer due to a gravitational potential U in the absence of a gravitational force.

Asenbaum et al. [120] measured a phase shift in an atom interferometer due to spacetime curvature across its wave function. In this experiment, interfering atomic wave packets were separated by a macroscopic (up to 16 cm) distance to study the interplay of recoil effects and gravitational curvature from a nearby Pb source mass.

32.5.3 Detection of Gravitational Waves

In 2015, the Advanced LIGO detected the gravitational waves (GW) for the first time [121], starting the field of gravitational-wave astronomy. However, the detection capability of such terrestrial detectors is limited to GWs with frequencies above ≈ 10 Hz by seismic and Newtonian noise [122]. The detection of the gravitational waves at lower frequencies will significantly increase the number and mass range of potentially observed GW sources, allow for longer observation of the inspiralling binary stars before the merger, and may improve the chances of detecting relic GWs from the early evolution of the Universe [123]. This is the goal of space-based laser interferometry detectors such as the Laser Interferometer Space Antenna (LISA) [124] and TianQin [125].

Rapid progress of matter-wave interferometry and atomic clocks opens other approaches to gravitational wave detection, with a number of proposals for both terrestrial and space-based detectors ([126–129] and references therein).

The Matter wave-laser based Interferometer Gravitation Antenna (MIGA) is a hybrid atom-laser detector in the 100 mHz–1 Hz frequency range [126]. MIGA will employ several atom interferometers simultaneously interrogated by the resonant mode of an optical cavity, with a cavity length of 200 m. It is the first very long baseline atom interferometry instrument, now under construction, to be located in dedicated tunnels, 500 m underground in France.

Hogan and Kasevich [127] proposed a space-based GW detector with light-pulse AIs separated by a long baseline (over 100 000 km), capable of detecting GWs in the 0.1-mHz to 1-Hz frequency band, requiring only two satellites and potentially exceeding the sensitivity of proposed the LISA detector. AI GW detector that can operate in a resonant detection mode and can switch between the broadband and narrowband detection modes to increase sensitivity was proposed in [128]. Geiger [130] reviewed the perspective of using AI for GW detection in the mHz to about 10 Hz frequency band. Kolkowitz et al. [129] proposed to use atomic optical lattice clocks (rather than atom interferometers) for a sensitive, narrowband GW space-based detector in a two-satellite configuration.

Mid-band Atomic Gravitational Wave Interferometric Sensor (MAGIS) collaboration assessed the technical feasibility of a satellite mission based on precision atomic sensors (involving both AI and atomic clocks) with laser-cooled atomic Sr [131]. MAGIS is expected to be sensitive to GWs of the 0.03 to 3 Hz observation band, intermediate between the LISA and advanced LIGO ranges, and also suited for performing dark matter searches.

Marianna Safronova Marianna Safronova is Professor of Physics at the University of Delaware. Her research interests include the study of fundamental symmetries and the search for physics beyond the standard model of elementary particles and fundamental interactions, the development of high-precision methodologies for calculating atomic properties and exploring their applications, atomic clocks, ultracold atoms and quantum information, long-range interactions, superheavy atoms, highly-charged ions, atomic anions, and other topics.

Part C
Molecules

Part C begins with a discussion of molecular structure from a theoretical/computational perspective using the Born–Oppenheimer approximation as the point of departure. The key role that symmetry considerations play in organizing and simplifying our knowledge of molecular dynamics and spectra is described. The theory of radiative transition probabilities, which determine the intensities of spectral lines, for the rotationally resolved spectra of certain model molecular systems is summarized. The ways in which molecular photodissociation is studied in the gas phase are outlined. The results presented are particularly relevant to the investigation of combustion and atmospheric reactions. Modern experimental techniques allow the detailed motions of the atomic constituents of a molecule to be resolved as

a function of time. A brief description of the basic ideas behind these techniques is given, with an emphasis on gas phase molecules in collision-free conditions. The semiclassical and quantal approaches to nonreactive scattering are outlined. Various quantitative approaches toward a description of the rates of gas phase chemical reactions are presented and then evaluated for their reliability and range of application. Ionic reactions in the gas phase are also considered. Clusters, which are important in many atmospheric and industrial processes, are arranged into six general categories, and then the physics and chemistry common to each category is described. The most important spectroscopic techniques used to study the properties of molecules are presented in detail.

Abstract

Molecular structure is a reflection of the Born–Oppenheimer separation of electronic and nuclear motion, which is in turn a consequence of the large difference between the electron and nuclear masses. One consequence of

this separation is the concept of a potential energy surface for nuclear motion created by the faster moving electrons. Corollaries include equilibrium structures, transition states, and reaction paths which are the foundation of the description of molecular structure and reactivity. However the Born–Oppenheimer approximation is not uniformly applicable and its breakdown results in perturbations in molecular spectra, radiationless decay, and nonadiabatic chemical reactions.

There are many issues that can be addressed in a discussion of molecular structure, including the structure and bonding of individual classes of molecules, computational and/or experimental techniques used to determine or infer molecular structure, the accuracy of those methods, etc. In an effort to provide a broad view of the essential aspects of molecular structure, this Chapter considers issues in molecular structure from a theoretical/computational perspective using the Born–Oppenheimer approximation as the point of origin. Rather than providing a compendium of results, this chapter will explain how issues in molecular structure are investigated and how the questions that can be addressed reflect the available methodology. Even with these restrictions the scope of this topic remains enormous and precludes a detailed presentation of any one issue. Thus the abbreviated discussions in this work are supplemented by ample references to the literature.

Several aspects of potential energy surfaces and their relation to molecular structure will be considered: (i) the electronic structure techniques used to determine a single point on a potential energy surface, and the interactions that couple the electronic states in question, (ii) the local properties of potential energy surfaces, in particular equilibrium structures and rovibrational levels that provide the link to experimental inferences concerning molecular structure, (iii) global chemistry deduced from potential energy surfaces including reaction mechanisms and reaction paths and (iv) phenomena resulting from the nonadiabatic interactions that couple potential energy surfaces.

33.1 Concepts**33.1.1 Nonadiabatic Ansatz:
Born–Oppenheimer Approximation****Basic Quantities**

The total Hamiltonian for electronic and nuclear motion in the space fixed coordinate frame, in atomic units, is

$$H^{\text{eN}}(\mathbf{r}, \mathbf{R}) = \sum_{\alpha=1}^N \frac{-1}{2M_{\alpha}} \nabla_{\alpha}^2 + H^{\text{e}}(\mathbf{r}; \mathbf{R}) \\ \equiv T^{\text{nuc}} + H^{\text{e}}(\mathbf{r}; \mathbf{R}), \quad (33.1)$$

where \mathbf{R} denotes the $3N$ nuclear coordinates, with $\mathbf{R} = (\mathbf{R}_1, \mathbf{R}_2, \dots, \mathbf{R}_N)$, $\mathbf{R}_i = (X_i, Y_i, Z_i)$, \mathbf{r} denotes the $3M$ electronic coordinates using similar conventions, T^{nuc} is the nuclear kinetic energy operator and $H^{\text{e}}(\mathbf{r}, \mathbf{R})$ is the total electronic Hamiltonian taken as

$$H^{\text{e}}(\mathbf{r}; \mathbf{R}) = H^0(\mathbf{r}; \mathbf{R}) + H^{\text{rel}}(\mathbf{r}; \mathbf{R}). \quad (33.2)$$

Here $H^0(\mathbf{r}; \mathbf{R})$ is the nonrelativistic Born–Oppenheimer Hamiltonian

$$H^0(\mathbf{r}; \mathbf{R}) = -\frac{1}{2} \sum_{i=1}^M \nabla_i^2 - \sum_{K,i} \frac{Z_K}{|\mathbf{R}_K - \mathbf{r}_i|} \\ + \frac{1}{2} \sum_{i \neq j}^M \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} + \frac{1}{2} \sum_{K \neq L}^N \frac{Z_K Z_L}{|\mathbf{R}_K - \mathbf{R}_L|}, \quad (33.3)$$

and $H^{\text{rel}}(\mathbf{r}; \mathbf{R})$ is the relativistic contribution to the electronic Hamiltonian, for light atoms conventionally treated within the Breit–Pauli approximation [1] and discussed further in Sect. 33.3.2. Note that in Eq. (33.3) the nuclear kinetic energy is absent, so that only the \mathbf{r}_i are dynamical variables in Eqs. (33.2) and (33.3). Using the Born–Huang approach [2] to the Born–Oppenheimer approximation, the total wave function $\Psi_L^{\text{eN}}(\mathbf{r}, \mathbf{R})$ is expanded in a basis of electronic states, $\Psi_I^{\text{e}}(\mathbf{r}; \mathbf{R})$. The total wave function for the system thus has the form

$$\Psi_L^{\text{eN}}(\mathbf{r}, \mathbf{R}) = \sum_I \Psi_I^{\text{e}}(\mathbf{r}; \mathbf{R}) \beta_I^L(\mathbf{R}). \quad (33.4)$$

Equation (33.4) is valid for any complete set of electronic states depending parametrically on nuclear coordinates. The parametrical dependence of $\Psi_I^{\text{e}}(\mathbf{r}; \mathbf{R})$ on \mathbf{R} , denoted by the semicolon, reflects the fact that the \mathbf{R} are not dynamical variables in Eqs. (33.2) and (33.3). As a practical matter it is necessary to make a particular choice of $\Psi_I^{\text{e}}(\mathbf{r}; \mathbf{R})$ in order to limit the size of the expansion in electronic states. An adiabatic electronic state is an eigenfunction of $H^{\text{e}}(\mathbf{r}; \mathbf{R})$ for fixed \mathbf{R} . A particularly useful choice of adiabatic state, denoted by $\Psi_I^0(\mathbf{r}; \mathbf{R})$, employs $H^0(\mathbf{r}; \mathbf{R})$ rather than the full $H^{\text{e}}(\mathbf{r}, \mathbf{R})$. These electronic wave functions satisfy

$$H^0(\mathbf{r}; \mathbf{R}) \Psi_I^0(\mathbf{r}; \mathbf{R}) = E_I^0(\mathbf{R}) \Psi_I^0(\mathbf{r}; \mathbf{R}). \quad (33.5)$$

The $\Psi_I^0(\mathbf{r}; \mathbf{R})$ are determined up to a geometry dependent phase. This phase is usually chosen such that the $\Psi_I^0(\mathbf{r}; \mathbf{R})$ are real. This assumption is acceptable except in the situation where there is a conical intersection on the potential energy surface in question. In that case, the real-valued $\Psi_I^0(\mathbf{r}; \mathbf{R})$ changes sign when a closed loop surrounding the conical intersection point is traversed, that is, $\Psi_I^0(\mathbf{r}; \mathbf{R})$ is not single-valued [3]. This geometric or *Berry* [4] phase condition has consequences in such phenomena as the dynamic Jahn–Teller effect [5, 6] but will not be addressed in detail in this review.

As a consequence of the parametric dependence of $\Psi_I^0(\mathbf{r}; \mathbf{R})$ on \mathbf{R} , $E_I^0(\mathbf{R})$ becomes a function of \mathbf{R} and is referred to as the nonrelativistic Born–Oppenheimer potential energy surface for reasons discussed below. Approaches based on Eq. (33.5) are most appropriate for molecular systems with only light atoms. However with the use of pseudopotential techniques [7], formally equivalent approaches can be developed for heavier systems (Sect. 33.3.2).

Inserting Eq. (33.4) into the time independent Schrödinger equation $[H^{\text{eN}}(\mathbf{r}; \mathbf{R}) - E] \Psi^{\text{eN}}(\mathbf{r}; \mathbf{R}) = 0$ and taking the inner product with the electronic basis state $\Psi_I^0(\mathbf{r}; \mathbf{R})$ gives the following system of coupled equations for the rovibronic functions $\beta_I^L(\mathbf{R})$ [8, 9]:

$$[T^{\text{nuc}} + E_I^0(\mathbf{R}) - E] \beta_I(\mathbf{R}) \\ = - \sum_J \left(\tilde{K}^{IJ}(\mathbf{R}) + H_{IJ}^{\text{BP}}(\mathbf{R}) \right. \\ \left. - \sum_{\alpha=1}^N \left\{ \frac{1}{2M_{\alpha}} [f_{\alpha}^{IJ}(\mathbf{R}) \cdot \nabla_{\alpha} + \nabla_{\alpha} \cdot f_{\alpha}^{IJ}(\mathbf{R})] \right\} \right) \beta_J(\mathbf{R}), \quad (33.6)$$

where the state label L on β_I^L has been suppressed, and

$$f_{\alpha}^{IJ}(\mathbf{R}) \equiv [f_{X_{\alpha}}^{IJ}(\mathbf{R}), f_{Y_{\alpha}}^{IJ}(\mathbf{R}), f_{Z_{\alpha}}^{IJ}(\mathbf{R})], \quad (33.7)$$

$$\tilde{K}^{JI}(\mathbf{R}) = \sum_{W,\alpha} \frac{1}{2M_{\alpha}} \tilde{k}_{W_{\alpha} W_{\alpha}}^{JI}(\mathbf{R}), \quad (33.8)$$

$$f_{W_\alpha}^{JJ}(\mathbf{R}) = \left\langle \Psi_J^0(\mathbf{r}; \mathbf{R}) \left| \frac{\partial}{\partial W_\alpha} \Psi_I^0(\mathbf{r}; \mathbf{R}) \right. \right\rangle_{\mathbf{r}}, \quad (33.9)$$

$$\tilde{k}_{W_\alpha W_\beta}^{JJ} = \left\langle \frac{\partial}{\partial W_\alpha} \Psi_J^0(\mathbf{r}; \mathbf{R}) \left| \frac{\partial}{\partial W_\beta} \Psi_I^0(\mathbf{r}; \mathbf{R}) \right. \right\rangle_{\mathbf{r}}, \quad (33.10)$$

with $W = X, Y, Z, \alpha = 1 \cdots N$. The subscript \mathbf{r} on the matrix elements in Eqs. (33.9)–(33.10) denotes integration over all electronic coordinates and the final ∇_α in Eq. (33.6) acts on both $f_\alpha^{IJ}(\mathbf{R})$ and $\beta_J(\mathbf{R})$. While this representation may not be optimal for a treatment of the nuclear dynamics, since it employs a space fixed frame representation, it is adequate for the present development as it clearly displays the origins of the Born–Oppenheimer approximation and its breakdown.

Modifications to the Nonrelativistic Born–Oppenheimer Potential Energy Surface

When the interstate couplings on the right-hand side of Eq. (33.6) can be neglected, the nuclear motion is governed by the effective potential given by $V^I(\mathbf{R}) \equiv E_I^c(\mathbf{R}) + \tilde{K}^{II}(\mathbf{R}) \equiv E_I^0(\mathbf{R}) + H_{II}^{\text{BP}}(\mathbf{R}) + \tilde{K}^{II}(\mathbf{R})$ and the Born–Oppenheimer approximation is valid. Here it is assumed that $f_\alpha^{II}(\mathbf{R}) = 0$, a sufficient condition for which is that the $\Psi_I^0(\mathbf{r}; \mathbf{R})$ are chosen real-valued [see discussion following Eq. (33.5)]. $E_I^0(\mathbf{R})$ is generally the principal \mathbf{R} -dependent contribution to $V^I(\mathbf{R})$. $H_{II}^{\text{BP}}(\mathbf{R})$ is referred to as the relativistic contribution to the nonrelativistic Born–Oppenheimer potential energy surface and is discussed further in Sect. 33.3.2. The contribution $\tilde{K}^{II}(\mathbf{R})$ is referred to as the adiabatic correction. Unlike $E_I^0(\mathbf{R})$ and $H_{II}^{\text{BP}}(\mathbf{R})$, which are independent of mass, $\tilde{K}^{II}(\mathbf{R})$ is mass dependent Eqs. (33.8) and (33.10). It has been computed from first principles [10–12] and inferred from experiments [13, 14] principally for diatomic systems.

33.1.2 Born–Oppenheimer Potential Energy Surfaces and Their Topology

$E_I^0(\mathbf{R})$ is the main focus of this chapter. There have been several recent reviews of ground state ($I = 1$) potential energy surfaces [15, 16].

Equilibrium structures (stable or metastable species) represent local minima on $E_I^0(\mathbf{R})$, that is $g_{W_\alpha}^I(\mathbf{R}) \equiv \partial E_I^0(\mathbf{R}) / \partial W_\alpha = 0$ for all W_α at $\mathbf{R} = \mathbf{R}^e$. There may be several equilibrium structures for a given set of nuclei; for example the atoms H, C and N form stable molecules HCN and HNC. Saddle points or transition states, extrema on $E_I^0(\mathbf{R})$ with one negative eigenvalue of the Hessian matrix $\mathbf{F}^I(\mathbf{R})$, whose elements are defined by $F_{W_\alpha W_\beta}^I(\mathbf{R}) \equiv \partial^2 E_I^0(\mathbf{R}) / \partial W_\alpha \partial W_\beta$, represent mountain passes separating the various equilibrium structures and the asymptotes – values of \mathbf{R} corresponding to isolated molecular fragments. This situation is illustrated in Fig. 33.1.

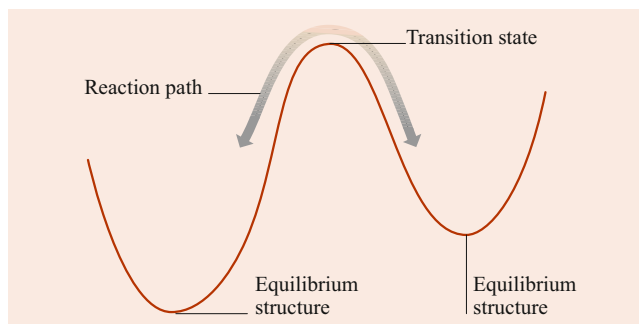

Fig. 33.1 Schematic representation of a transition state and reaction path connecting two minima

Reaction paths [17] connect the asymptotes, minima, and saddle points. They can best be defined as the steepest descent paths from a transition state structure down to local minima [17], although methods for walking uphill (shallowest ascent path) [18] also exist. Unlike equilibrium structures and saddle points which are independent of the choice of coordinate system used to represent \mathbf{R} , the reaction path is coordinate system dependent. The intrinsic reaction coordinate [17], the reaction coordinate in mass weighted cartesian coordinates $\mathbf{R}_i \rightarrow \mathbf{R}_i M_i$, is most frequently used (Sect. 33.4.4)

These features of the potential energy surfaces and their determination will be discussed further below. Their determination consists of two parts: (i) the level of treatment, i.e., the electronic structure technique used to determine $E_I^0(\mathbf{R})$ and (ii) the characterization of the features of $E_I^0(\mathbf{R})$, i.e., minima, saddle points, and reaction paths [19, 20] at the level of treatment chosen. In this chapter, only fully ab initio levels of treatment are considered [21, 22].

33.1.3 Classification of Interstate Couplings: Adiabatic and Diabatic Bases

Intersurface couplings, shown on the right-hand side of Eq. (33.6), result in the breakdown of the single potential energy surface Born–Oppenheimer approximation. Within the Born–Huang ansatz such a nonadiabatic process is interpreted in terms of motion on more than one Born–Oppenheimer potential energy surface [8]. From Eq. (33.6), it is seen that there are three types of matrix elements coupling the electronic states, $\tilde{K}^{IJ}(\mathbf{R})$, $H^{\text{BP}IJ}(\mathbf{R})$ and $f^{IJ}(\mathbf{R})$. Two of these couplings, $\tilde{K}^{IJ}(\mathbf{R})$ and $f^{IJ}(\mathbf{R})$ arise from the nuclear kinetic energy operator T^{nuc} , while the third coupling arises from the Breit–Pauli interaction H^{BP} . This classification of the intersurface interactions is a consequence of the choice of the adiabatic electronic states through Eq. (33.5). Other choices of $\Psi_I^0(\mathbf{r}; \mathbf{R})$, most notably the diabatic electronic states [23–27], are possible.

In the adiabatic state basis, $H^0(\mathbf{r}; \mathbf{R})$ is diagonal and in the absence of relativistic effects, intersurface couplings

originate exclusively from the derivative coupling terms in Eqs. (33.9) and (33.10). The diabatic basis seeks to *transfer* the intersurface coupling from these derivative operators to a potential term analogous in form to $H_{IJ}^{\text{BP}}(\mathbf{R})$. The diabatic basis, $\Psi_I^{0-d}(\mathbf{r}; \mathbf{R})$, is a unitary transformation of the adiabatic electronic basis, defined such that [24]

$$f_{R_\alpha}^{JJ,d} \equiv \left\langle \Psi_I^{0-d}(\mathbf{r}; \mathbf{R}) \left| \frac{\partial}{\partial R_\alpha} \Psi_I^{0-d}(\mathbf{r}; \mathbf{R}) \right. \right\rangle_r = 0, \quad (33.11)$$

where R_α is an internal coordinate. For polyatomic systems ($N > 2$), rigorous diabatic bases do not exist [27] and approximate diabatic bases are sought [27–30]. A discussion of this issue can be found in [31].

33.1.4 Surfaces of Intersection of Potential Energy Surfaces

The intersurface couplings are most effective in promoting a nonadiabatic process when $|V^I(\mathbf{R}) - V^J(\mathbf{R})|$ is small for some J on the right-hand side of Eq. (33.6), so that

$$\begin{aligned} E_I^e(\mathbf{R}) + \tilde{K}^{II}(\mathbf{R}) - [E_J^e(\mathbf{R}) + \tilde{K}^{JJ}(\mathbf{R})] \\ \equiv \Delta E_{IJ}^0(\mathbf{R}) + \Delta E_{IJ}^{\text{BP}}(\mathbf{R}) + \Delta K_{IJ}(\mathbf{R}) \end{aligned} \quad (33.12)$$

is small. Here

$$\Delta E_{IJ}^0(\mathbf{R}) \equiv E_I^0(\mathbf{R}) - E_J^0(\mathbf{R}), \quad (33.13)$$

$$\Delta K_{IJ}(\mathbf{R}) \equiv \tilde{K}^{II}(\mathbf{R}) - \tilde{K}^{JJ}(\mathbf{R}), \quad (33.14)$$

$$\Delta E_{IJ}^{\text{BP}}(\mathbf{R}) \equiv H_{II}^{\text{BP}}(\mathbf{R}) - H_{JJ}^{\text{BP}}(\mathbf{R}). \quad (33.15)$$

Since in general $\Delta K_{IJ}(\mathbf{R})$ is quite small, and for the low atomic number systems considered here H_{II}^{BP} is itself small, we are led to consider regions of nuclear coordinate space for which the magnitude of $\Delta E_{IJ}^0(\mathbf{R})$ is small, referred to as avoided intersections when $\Delta E_{IJ}^0(\mathbf{R}) \neq 0$ and as conical and Renner-type [32] intersections when $\Delta E_{IJ}^0(\mathbf{R}) = 0$. The set of \mathbf{R} for which $\Delta E_{IJ}^0(\mathbf{R}) = 0$, the noncrossing rule, was first discussed in 1929 by *von Neumann* and *Wigner* [33]. The rule states that for diatomic systems, crossings between two potential energy curves of the same symmetry are not possible (actually, are extremely rare), whereas for polyatomic systems, potential energy surface intersections are allowed. Mathematically the noncrossing rule is expressed in terms of the dimensions of a surface, the surface of intersection, on which a set of conditions can be satisfied [3, 34]. For electronic states of the same symmetry (neglecting electron spin degeneracy), the dimension of the surface of conical intersection is $K - 2$, where K is the number of internal nuclear degrees of freedom. For states of different spin symmetry, the dimension of the surface of intersection is $K - 1$.

33.2 Characterization of Potential Energy Surfaces

This section is concerned with the determination of the approximate solution of Eq. (33.5). For this purpose it is frequently convenient to re-express $H^0(\mathbf{r}; \mathbf{R})$ in second quantized [35] form as

$$H^0(\mathbf{r}; \mathbf{R}) = \sum_{i,j} h_{ij} a_i^\dagger a_j + \frac{1}{2} \sum_{i,j,k,l} (il|jk) a_i^\dagger a_j^\dagger a_k a_l, \quad (33.16)$$

where h_{ij} and $(il|jk)$ are standard abbreviations [36] for the one electron (kinetic energy and nuclear–electron attraction) and two electron (electron–electron repulsion) integrals respectively, and a_i^\dagger and a_i are the fermion creation and destruction operators. The integrals and the creation and destruction operators are defined in terms of a basis of one electron functions, usually molecular spin-orbitals $\phi_i \gamma_i$, $\gamma_i = \alpha$ or β . Thus

$$\begin{aligned} h_{ij}(\mathbf{R}) = \langle \phi_i(\mathbf{r}_k) \gamma_i | -\frac{1}{2} \nabla_k^2 \\ - \sum_K \frac{Z_K}{|\mathbf{R}_K - \mathbf{r}_k|} | \phi_j(\mathbf{r}_k) \gamma_j \rangle_{\mathbf{r}_k} \end{aligned} \quad (33.17)$$

$$\begin{aligned} (ij|kl) = \left\langle \phi_i(\mathbf{r}_m) \gamma_i \phi_j(\mathbf{r}_m) \gamma_j \left| \frac{1}{|\mathbf{r}_m - \mathbf{r}_n|} \right. \right. \\ \left. \left. \times \left| \phi_k(\mathbf{r}_n) \gamma_k \phi_l(\mathbf{r}_n) \gamma_l \right. \right\rangle_{\mathbf{r}_m, \mathbf{r}_n}. \end{aligned} \quad (33.18)$$

Equation (33.18) is referred to as the Mulliken notation [37] for a two-electron integral. It differs from the frequently used [36] bra-ket representation $\langle ij|kl \rangle = \langle ik|jl \rangle$. The molecular orbitals $\phi_i(\mathbf{r}_j; \mathbf{R})$ are in turn expanded in terms of a basis set of atom-centered functions [38], $\chi(\mathbf{r}_j; \mathbf{R})$, with $\phi_i(\mathbf{r}_j; \mathbf{R}) = \sum_{P=1}^L \chi_P(\mathbf{r}_j; \mathbf{R}) T_{P,i}(\mathbf{R})$. Note that here we have distinguished between a spin-orbital $\phi_i(\mathbf{r}_j; \mathbf{R}) \gamma_i$ and a molecular orbital $\phi_i(\mathbf{r}_j; \mathbf{R})$, but we will follow the usual convention of allowing the functions in Eqs. (33.17) and (33.18) to be molecular orbitals or spin-orbitals with the use being clear from the context.

Since $H^0(\mathbf{r}; \mathbf{R})$ is independent of electron spin, it can also be written in terms of the \tilde{E}_{pq} , spin-averaged excitation operators [39], where $\tilde{E}_{pq} = \sum_\gamma a_{p\gamma}^\dagger a_{q\gamma}$, p, q label orbitals and $\gamma = \alpha, \beta$ so that

$$H^0(\mathbf{r}; \mathbf{R}) = \sum_{i,j} h_{ij} \tilde{E}_{ij} + \frac{1}{2} \sum_{i,j,k,l} (ij|kl) \tilde{E}_{ij} \tilde{E}_{kl} - \delta_{jk} \tilde{E}_{il}. \quad (33.19)$$

The \tilde{E}_{pq} satisfy $[\tilde{E}_{ij}, \tilde{E}_{kl}] = \tilde{E}_{il} \delta_{jk} - \tilde{E}_{kj} \delta_{il}$ as a consequence of the commutation relations for the a_i^\dagger and a_i and are generators of the unitary group [40], (Chap. 4). This observation

allows the powerful machinery of the unitary group to be applied to the evaluation of $E_I^0(\mathbf{R})$ [41] (Sect. 33.1.2).

The determination of $E_I^0(\mathbf{R})$ involves two steps; (i) the determination of the molecular orbitals $\phi_i(\mathbf{r}_j; \mathbf{R})$, and (ii) sometimes simultaneously, the determination of the approximate wave function $\Psi_I^0(\mathbf{r}; \mathbf{R})$.

Wave functions discussed in this section are constructed from functions that are antisymmetrized products of spin-orbitals $\phi_i(\mathbf{r}_j; \mathbf{R})\gamma_i$

$$\Psi_I^0(\mathbf{r}; \mathbf{R}) = \mathcal{A} \prod_{i=1}^M \phi_i(\mathbf{r}_j; \mathbf{R})\gamma_i, \quad (33.20)$$

where $\gamma_i = \alpha$ or β . The antisymmetrizer \mathcal{A} is required to take into account the Fermi statistics of the electrons. The wave function in Eq. (33.20) is referred to as a Slater determinant and is an eigenfunction of M_z , the z -component of total electron spin. A linear combination of Slater determinants that is also an eigenfunction of S^2 is referred to as a configuration state function (CSF) [42]. Equation (33.20) corresponds to a particular distribution of electrons in the orbitals $\phi_i(\mathbf{r}_j; \mathbf{R})$. This distribution is referred to as an electron configuration.

In principle, it is possible to learn everything about the topology of a potential energy surface from the pointwise evaluation of $E_I^0(\mathbf{R})$. In practice however, the determination of topological features, including location of equilibrium structures, saddle points and reaction paths, characterization of quadratic and anharmonic force fields [43], and even the evaluation of derivative couplings [44], has benefitted immensely from techniques in which the energy gradient $\mathbf{g}^I(\mathbf{R})$ or higher derivatives are determined directly from knowledge of the wave function at the \mathbf{R} in question. These analytic derivative techniques, i.e., techniques that do not use divided difference differentiation, have been actively developed since their first introduction [45].

The techniques most commonly used to calculate $E_I^0(\mathbf{R})$ and its derivatives are described below.

33.2.1 The Self-Consistent Field (SCF) Method

The SCF Energy

In this most basic treatment, the electronic wave function $\Psi_I^{0-\text{SCF}}$ is taken as a single Slater determinant or a single CSF. The spin-orbitals are determined to give an extremum of the energy functional $\langle \Psi_I^{0-\text{SCF}}(\mathbf{r}; \mathbf{R}) | H^0(\mathbf{r}; \mathbf{R}) | \Psi_I^{0-\text{SCF}}(\mathbf{r}; \mathbf{R}) \rangle_r$. This gives rise to the self-consistent field conditions. For restricted closed shell wave functions [46], defined by the conditions

$$\Psi_I^{0-\text{RSCF}}(\mathbf{r}; \mathbf{R}) = \mathcal{A} \prod_{i=1}^L \phi_{2i}(\mathbf{r}_{2i}; \mathbf{R})\alpha\phi_{2i+1}(\mathbf{r}_{2i+1}; \mathbf{R})\beta \quad (33.21)$$

with $\phi_{2i}(\mathbf{r}_j; \mathbf{R}) = \phi_{2i-1}(\mathbf{r}_j; \mathbf{R})$, $i = 1, \dots, L$ and $2L = M$, the SCF equations are

$$\varepsilon_{ri} = h_{ri} + \sum_{j \in \{j_{\text{occ}}\}} 2(ir|jj) - (ij|rj) = 0 \quad (33.22)$$

for ϕ_i , ϕ_r occupied and virtual orbitals, respectively. Here, occupied orbitals j_{occ} are those occurring in the orbital product in Eq. (33.21), and the remainder of the orbitals are referred to as virtual orbitals. The solution to Eq. (33.22) is referred to as the canonical SCF solution, provided the orbitals satisfy the SCF equations

$$F\phi_i = \lambda_i\phi_i, \quad (33.23)$$

where the Fock operator F is defined by $F_{ri} = \varepsilon_{ri}$ and $\lambda_i = \varepsilon_{ii}$. The corresponding electronic energy is $E_I^0(\mathbf{R}) \equiv E_I^{0-\text{SCF}}(\mathbf{R}) = \sum_{j \in \{j_{\text{occ}}\}} (\varepsilon_{jj} + h_{jj})$.

SCF Energy Derivatives

The derivative of $E_I^{0-\text{SCF}}(\mathbf{R})$ can be expanded through third order using analytic gradient techniques [47, 48], and through fourth order using divided differences and more recently using analytic derivative techniques [43]. The ability to evaluate the energy derivatives or force field through fourth order is important in the determination of vibrational properties of molecules, as discussed in Sect. 33.4.2.

Direct SCF

The range of molecular systems accessible to treatment at the SCF level has been expanded considerably by the introduction of the direct SCF methods [49]. In this method, none of the two-electron integrals in the χ basis ($pq|rs$) are stored during the iterative solution of Eqs. (33.22) and (33.23). Since the number of such integrals grows as $L^4/8$, direct SCF procedures avoid the L^4 -storage bottleneck, enabling SCF wave functions to be determined for systems with more than 100 atoms and basis sets with more than 1000 functions. (If all the $L^4/8$ integrals were stored on disk this basis would require ≈ 1000 gigabytes).

33.2.2 Electron Correlation: Wave Function Based Methods

Wave functions more accurate than SCF wave functions are obtained by including the effects of electron correlation. The correlation energy is defined as $E_I^{\text{corr}}(\mathbf{R}) \equiv E_I^0(\mathbf{R}) - E_I^{0-\text{SCF}}(\mathbf{R})$. Methods for the determination of $E_I^{\text{corr}}(\mathbf{R})$ are commonly classified as single reference or multireference methods. In single reference methods, an SCF wave function $\Psi_I^{0-\text{SCF}}(\mathbf{r}; \mathbf{R})$ given by Eq. (33.20) is improved. In multireference methods, the starting point is the space spanned by

a set of terms like Eq. (33.20). This space is referred to as the reference space and the functions in the space as the reference configurations. Sometimes the molecular orbitals $\phi(\mathbf{r}_i; \mathbf{R})$ for the reference space are the SCF orbitals of a single reference configuration calculation, but more often the $\phi(\mathbf{r}_i; \mathbf{R})$ are chosen to satisfy multiconfigurational self-consistent field (MCSCF) equations [50–53].

Single Reference Methods

Second Order Møller–Plesset Perturbation Theory (MP2)

In this approach [54], the solutions of the SCF equations are used to determine $E_I^0(\mathbf{R})$ to second order as

$$E_I^{0\text{-MP2}}(\mathbf{R}) = E_I^{0\text{-SCF}}(\mathbf{R}) - \frac{1}{4} \sum_{a,b,i,j} \frac{(ab||ij)^2}{\lambda_a + \lambda_b - \lambda_i - \lambda_j}, \quad (33.24)$$

where i, j denote occupied orbitals, a, b denote virtual orbitals, and

$$(ab||ij) = (ai|bj) - (aj|bi) = \langle ab|ij \rangle - \langle ab|ji \rangle.$$

Both gradients of $E_I^{0\text{-MP2}}(\mathbf{R})$ and direct implementations of MP2 [37, 55] are currently available. Higher order perturbation theories, also in common use, are discussed in the context of coupled cluster methods which are considered next.

Coupled Cluster Method

Perhaps the most reliable method currently available for characterizing near equilibrium properties of moderately sized molecules is the coupled cluster approach [56–60] (Chap. 5). In this approach, the exact wave function is written as a unitary transformation of a reference wave function $\Phi_0(\mathbf{r}; \mathbf{R})$ [usually, but not necessarily, the SCF wave function $\Phi_0(\mathbf{r}; \mathbf{R}) = \Psi_I^{0\text{-SCF}}(\mathbf{r}; \mathbf{R})$],

$$\Psi_I^{0\text{-CC}} = \exp(T)\Phi_0. \quad (33.25)$$

where T is an excitation operator defined as

$$T = \sum_p T_p; \quad (33.26)$$

with

$$T_p = \frac{1}{p!^2} \sum_{i,j,k,\dots,a,b,c} t_{ijk\dots}^{abc\dots} a_a^\dagger a_b^\dagger a_c^\dagger a_i a_j a_k, \quad (33.27)$$

where i, j, k denote occupied orbitals in Φ_0 and a, b, c denote virtual orbitals. Thus

$$\Psi_I^{0\text{-CC}} = \Phi_0 + \sum_{i,a} t_i^a \Phi_i^a + \frac{1}{4} \sum_{i,j,a,b} t_{ij}^{ab} \Phi_{ij}^{ab} + \dots, \quad (33.28)$$

where Φ_i^a, Φ_{ij}^{ab} are single and double excitations from Φ_0 , and it is the amplitudes t that must be determined. Wave functions of the form in Eqs. (33.25)–(33.28) have the important property referred to as size consistency [60] or size extensivity [59]. Consider N noninteracting helium atoms. The electronic wave function for the i th helium atom in the natural orbital basis [61] can be written as $\Psi_i = [1 + T_2(i)]\phi_0(i)$, so that the N atom electronic wave function becomes

$$\Psi = \prod_i \Psi_i = \prod_i [1 + T_2(i)]\Phi_0 = \left[\exp \sum_i T_2(i) \right] \Phi_0 = \exp(T_2)\Phi_0 \quad (33.29)$$

Thus this exponential type of solution scales properly with the number of particles.

To obtain the amplitudes t , define $H_N = H^0 - \langle \Phi_0 | H^0 | \Phi_0 \rangle, E_I^{0\text{-CC}} = \Delta E_I^{0\text{-CC}} + \langle \Phi_0 | H^0 | \Phi_0 \rangle \equiv \Delta E_I^{0\text{-CC}} + E_I^{0-0}, P = |\Phi_0\rangle\langle\Phi_0|$ and $Q = 1 - P$. Then, inserting Eqs. (33.25)–(33.28) into Eq. (33.5) gives the energy Eq. (33.30) and amplitude Eq. (33.31) equations, which define the coupled cluster approach:

$$\Delta E_I^{0\text{-CC}} = \langle \Phi_0 | \tilde{H}_N | \Phi_0 \rangle, \quad (33.30)$$

$$\langle \Phi_{ijk\dots}^{abc\dots} | \tilde{H}_N | \Phi_0 \rangle = 0 \text{ for all } \Phi_{ijk\dots}^{abc\dots}, \quad (33.31)$$

where

$$\begin{aligned} \tilde{H}_N &= \exp(-T)H_N \exp(T) \\ &= -E_I^{0-0} + \exp(-T)H^0 \exp(T). \end{aligned} \quad (33.32)$$

To appreciate the nature of these equations, consider the approximation $T = T_2$ constructed from SCF orbitals [36, 59], referred to as the coupled cluster doubles (CCD) level. At this level the energy equation becomes

$$\begin{aligned} E_I^{0\text{-CCD}} &= \langle \Phi_0 | \exp(-T_2)H^0 \exp(T_2) | \Phi_0 \rangle \\ &= \langle \Phi_0 | H^0 T_2 | \Phi_0 \rangle + E_I^{0-0} \\ &= E_I^{0-0} + \frac{1}{4} \sum_{i,j,r,s} \Phi_0 H^0 a_i^\dagger a_s^\dagger a_i a_j \Phi_0 t_{ij}^{rs} \\ &= E_I^{0-0} + \frac{1}{4} \sum_{i,j,r,s} (rs||ij) t_{ij}^{rs} \end{aligned} \quad (33.33)$$

for i, j occupied and r, s virtual orbitals. The amplitude equations become

$$\begin{aligned} &\langle \Phi_{ij}^{rs} | \exp(-T_2)H^0 \exp(T_2) | \Phi_0 \rangle \\ &= \langle \Phi_{ij}^{rs} | \left(1 - T_2 + \frac{1}{2} T_2^2 \right) H^0 \left(1 + T_2 + \frac{1}{2} T_2^2 \right) | \Phi_0 \rangle \\ &= 0 \end{aligned} \quad (33.34)$$

which reduces (after considerable commutator algebra) [36] to

$$\begin{aligned}
 & (\lambda_r + \lambda_s - \lambda_i - \lambda_j)t_{ij}^{rs} \\
 &= -(rs||ij) - \sum_{p>q} (rs||pq)t_{ij}^{pq} - \sum_{k>l} (kl||ij)t_{kl}^{rs} \\
 &+ \sum_{k,p} [(ks||jp)t_{ik}^{rp} - (kr||jp)t_{ik}^{sp} \\
 &- (ks||ip)t_{jk}^{rp} + (kr||ip)t_{jk}^{sp}] \\
 &- \sum_{k>l;p>q} (kl||pq) \left[t_{ij}^{pq} t_{kl}^{rs} - 2(t_{ij}^{rp} t_{kl}^{sq} + t_{ij}^{sq} t_{kl}^{rp}) \right. \\
 &\left. - 2(t_{ik}^{rs} t_{jl}^{pq} + t_{ik}^{pq} t_{jl}^{rs}) + 4(t_{ik}^{rp} t_{jl}^{sq} + t_{ik}^{sq} t_{jl}^{rp}) \right]. \quad (33.35)
 \end{aligned}$$

The solution to Eq. (33.35) is obtained iteratively. The first iteration gives $t_{ij}^{rs} = -(rs||ij)/(\lambda_r + \lambda_s - \lambda_i - \lambda_j)$, which when inserted into Eq. (33.33) gives Eq. (33.24), i.e., the MP2 result. If the quadratic terms in Eq. (33.35) are neglected, then the second iteration gives the third order Møller–Plesset (MP3) result [36]. The result of iterating Eq. (33.35) to convergence gives the CCD result.

Of the levels of coupled cluster treatments in current use, those including T_1 , T_2 , T_3 , and T_4 in Eq. (33.25) provide the most reliable results [62–66].

Multireference Methods

Single reference methods provide probably the most powerful tools for treating near-equilibrium properties of ground electronic state systems. In other instances, such as the study of electronically excited states, determination of global potential energy surfaces and for systems with multiple open shells such as diradicals, multireference techniques are found to be extremely useful. In the multireference techniques discussed below, the wave function is written as

$$\Psi_I^{0-\text{MRF}}(\mathbf{r}; \mathbf{R}) = \sum_{\alpha} c_{\alpha}^I \psi_{\alpha}(\mathbf{r}; \mathbf{R}) \quad (33.36)$$

where $\psi_{\alpha}(\mathbf{r}; \mathbf{R})$ is a CSF. This expansion is usually referred to as a configuration interaction (CI) expansion, and the coefficients $c^I(\mathbf{R})$ are referred to as CI coefficients [42]. Since Eq. (33.36) does not involve the exponential ansatz, it is not automatically size extensive. In the description of these wave functions, it is useful to generalize the notion of occupied and virtual orbitals to inactive, active, and virtual orbitals, where, referring to the CSF's defining the reference space, inactive orbitals are fully occupied in all CSFs, virtual orbitals are not occupied in any CSF and the active orbitals are (partially) occupied in at least one CSF.

Most multireference techniques begin with the determination of a multiconfigurational self-consistent field (MCSCF) wave function or state averaged MCSCF(SA-MCSCF) wave

function [50–53, 67]. This approach is capable of describing the internal or static correlation energy, the part of the correlation energy that leads to sizeable separation of two electrons in a pair, and near-degeneracy effects. A particularly robust type of MCSCF wave function, the complete active space (CAS) [68–70] wave function, includes in Eq. (33.36) all CSFs arising from the distribution of the available electrons among the active orbitals. Note that a CAS wave function is size consistent.

The remaining part of the correlation energy, the dynamic correlation, describes the two-electron cusp, i.e., the regions of space for which two electrons experience the singularity in the Coulomb potential. Empirically, it has been shown [71] that wave functions capable of providing chemically accurate descriptions of the dynamic correlation can be obtained by augmenting the MCSCF or reference wave function with all CSFs that differ by at most two molecular orbitals, double excitations Eq. (33.28) from those of the reference space. Such wave functions are generally referred to as multireference single and double excitation configuration interaction (MR-SDCI) wave functions. First (second) order wave functions [72] include all single (single and double) excitations relative to a CAS reference space.

Multiconfigurational Self-Consistent Field (MCSCF)

Theory

In the MCSCF approximation, a wave function $\Psi_I^{0-\text{MCSCF}}(\mathbf{r}; \mathbf{R}) = \sum_{\alpha} c_{\alpha}^I \psi_{\alpha}(\mathbf{r}; \mathbf{R})$ of the form in Eq. (33.36) is to be determined. In this procedure, both the molecular orbitals $\phi(\mathbf{r}; \mathbf{R})$ and $c^I(\mathbf{R})$ are determined from the requirement that

$$\begin{aligned}
 E_I^{0-\text{MCSCF}} \\
 = \langle \Psi_I^{0-\text{MCSCF}}(\mathbf{r}; \mathbf{R}) | H^0 | \Psi_I^{0-\text{MCSCF}}(\mathbf{r}; \mathbf{R}) \rangle_r, \quad (33.37)
 \end{aligned}$$

be a minimum. In a popular variant, the state averaged MCSCF (SA-MCSCF) [50–53] procedure, the average energy functional

$$\begin{aligned}
 E^{0-\text{SA-MCSCF}} = \sum_{I=2}^K w_I \langle \Psi_I^{0-\text{MCSCF}}(\mathbf{r}; \mathbf{R}) | H^0 | \\
 \times \Psi_I^{0-\text{MCSCF}}(\mathbf{r}; \mathbf{R}) \rangle_r, \quad (33.38)
 \end{aligned}$$

where the weight vector $\mathbf{w} = (w_1, w_2, \dots, w_K)$ has only positive elements, is minimized. This procedure should be compared with the multireference CI approach described below in which a predetermined set of molecular orbitals is used.

The optimum molecular orbitals and CI coefficients can be written as unitary transformations of an initial set of such quantities, i.e.,

$$\Psi_I^{0-\text{MCSCF}} = \exp(\gamma) \exp(\Delta) \Phi_I^0, \quad (33.39)$$

where

$$\boldsymbol{\gamma} = \sum_{i,s} \gamma_{s,i} a_s^\dagger a_i, \quad \Delta = \sum_{n,l} \Delta_{l,n} |\Phi_l^0\rangle \langle \Phi_n^0|, \quad (33.40)$$

and $\boldsymbol{\gamma}$, Δ are general anti-Hermitian matrices. Since $m_{i,j} = -m_{j,i} \equiv m_{ij}$ for $\mathbf{m} = \boldsymbol{\gamma}$, Δ , the upper triangle of \mathbf{m} forms a vector $\vec{\mathbf{m}}$ that enumerates the independent parameters of \mathbf{m} . The MCSCF or SA-MCSCF equations can be succinctly formulated by inserting Eq. (33.39) into Eq. (33.37) or Eq. (33.38), expanding the commutators to second order and requiring $\partial E / \partial m_{ij} = 0$ [36]. The result provides a system of Newton–Raphson equations that can be solved iteratively for the $\boldsymbol{\gamma}$, Δ [52, 53, 67, 73].

Multireference Configuration Interaction Theory: The MR-SDCI Method

In multireference configuration interaction theory, the wave function is again of the form $\Psi_I^{0-\text{MRCI}}(\mathbf{r}; \mathbf{R}) = \sum_{\alpha} c_{\alpha}^I(\mathbf{R}) \psi_{\alpha}(\mathbf{r}; \mathbf{R})$, but now CSFs involving the large space of virtual orbitals are included. In this approach the CI coefficients are found for a predetermined set of molecular orbitals. The CSF expansions at the MR-SDCI level become quite large (1–10 million CSFs is routine), and even larger expansions are tractable using specialized methods. The c^I satisfy the usual matrix equation

$$(\mathbf{H}^0 - E_I^0) \mathbf{c}^I = 0, \quad (33.41)$$

where

$$\begin{aligned} H_{\alpha\beta}^0 &= \langle \psi_{\alpha} | H^0 | \psi_{\beta} \rangle \\ &= \sum_{i,j} A_{ij}^{\alpha\beta} h_{ij} + \sum_{i,j,k,l} A_{ijkl}^{\alpha\beta} (ij|kl). \end{aligned} \quad (33.42)$$

It is the computationally elegant solution of Eq. (33.41) for large expansions that is the essence of modern MR-SDCI methods.

Because of the large dimension of the CSF space, it is not possible (or even desirable) to find all the solutions of Eq. (33.41). The few lowest eigenstates and eigenvalues can be found [74] using an iterative direct CI procedure [75] in which a subspace is generated sequentially from the residual defined at the k th iteration by

$$\sigma_{\mu}^{(k)} = \sum_{\nu} (H_{\mu\nu}^0 - E^{(k-1)} \delta_{\mu\nu}) c_{\nu}^{(k-1)}, \quad (33.43)$$

where for simplicity of notation, the state index I is suppressed. The computationally demanding step in this procedure is the efficient evaluation of the $A_{ijkl}^{\alpha\beta} = \langle \psi_{\alpha} | \tilde{E}_{ij} \tilde{E}_{kl} - \delta_{jk} \tilde{E}_{il} | \psi_{\beta} \rangle$. Key to the efficiency of this evaluation is the factorization formally achieved by

$$\langle \psi_{\alpha} | \tilde{E}_{ij} \tilde{E}_{kl} | \psi_{\beta} \rangle = \sum_m \langle \psi_{\alpha} | \tilde{E}_{ij} | \psi_m \rangle \langle \psi_m | \tilde{E}_{kl} | \psi_{\beta} \rangle. \quad (33.44)$$

Using unitary group techniques, this apparently intractable summation can be used to express the $A_{ijkl}^{\mu\nu}$ as a simple finite product [76].

Contracted CI and Complete Active Space Perturbation Theory (CASPT2)

The direct approach outlined above makes treatment of large MR-SDCI expansions possible. However, as the size of the reference space grows, the CSF space in the MR-SDCI expansion may become intractably large, particularly if the full second-order wave function is used. To avoid this bottleneck, the reference CSFs may be selected from the active space, and perturbation theory may be used to select CSFs involving orbitals in the virtual space [42]. The use of selection procedures complicates the implementation of *direct* techniques although recently progress in selected direct CI procedures has been reported [77–79]. Alternatively, new techniques have been developed that avoid this selection procedure. In these approaches, the MCSCF wave function itself is used as the reference wave function for CI or perturbation theory techniques. The use of a reference wave function rather than a reference space considerably reduces the size of the CSF space to be handled. In this approach, one of the principal computational complications is that the excited functions are not necessarily mutually orthogonal. Two computational procedures currently in wide use, known as contracted CI [80–83] and CASPT2 [84, 85], are based on this approach.

The CASPT2 method is a computationally efficient variant of second order perturbation theory in which the reference wave function is a CAS-MCSCF wave function and thus may itself contain tens of thousands of CSFs. In this case the full multireference CI problem would be intractable owing to the large space of double excitations. A similar approach is adopted in the contracted CI method, in that the excitations are defined in terms of a general MCSCF reference wave function $\Psi_I^{0-\text{MRF}}$ rather than the reference space as in the MR-SDCI methods described above.

33.2.3 Electron Correlation: Density Functional Theory

The approaches in Sect. 33.1.1 and 33.1.2 can be referred to as wave function based approaches in the sense that determination of $E_I^0(\mathbf{R})$ is accompanied by the determination of the corresponding electronic wave function $\Psi_I^0(\mathbf{r}; \mathbf{R})$. An alternative approach is known as density functional theory (DFT) [86]. The ultimate goal of DFT is the determination of total densities and energies without the determination of wave functions, as in the Thomas–Fermi approximation. DFT is based on the Hohenberg–Kohn Theorem [87], which states that the total electronic density can be considered

to be the independent variable in a multi-electron theory (Chap. 21). Computationally viable approaches exploit the Kohn and Sham formulation [88], which introduces molecular orbitals as an intermediate device.

The essential features of the Kohn–Sham (KS) theory [86] are as follows [89]. Assume that the real N -electron system for a particular arrangement of the nuclei \mathbf{R} has a total electron density $\rho(\mathbf{r}; \mathbf{R})$. Consider a system of N independent noninteracting electrons subject to a one-body potential V_0 with total density $\rho^0(\mathbf{r}; \mathbf{R})$ such that $\rho(\mathbf{r}; \mathbf{R}) = \rho^0(\mathbf{r}; \mathbf{R})$. The corresponding independent particle orbitals, the Kohn–Sham orbitals $\phi_i^{\text{KS}}(\mathbf{r}_j; \mathbf{R})$, satisfy a Hartree–Fock-like equation

$$\left(-\frac{1}{2}\nabla^2 + V_0 - \varepsilon_i\right)\phi_i^{\text{KS}} = 0 \quad (33.45)$$

with

$$\rho^0(\mathbf{r}; \mathbf{R}) = \sum_i |\phi_i^{\text{KS}}|^2. \quad (33.46)$$

The relation between the energy of the ideal system and that of the true system $E^{0\text{-DFT}}(\mathbf{R})$ is obtained from the adiabatic connection formula [89].

In order to determine $E^{0\text{-DFT}}(\mathbf{R})$, functions ϕ_i^{KS} are required, which in turn means that V_0 , the Kohn–Sham noninteracting one-body potential, must be determined. V_0 is written as Eq. (33.3)

$$V_0 = V_{e\text{-N}} + V_{\text{Coul}} + V_{\text{xc}} \quad (33.47)$$

where V_{Coul} is the Coulomb interaction corresponding to the electron density, $V_{e\text{-N}}$ is the electron–nuclear attraction interaction and V_{xc} is the exchange–correlation density. The effect of Eq. (33.47) is to isolate from V_0 the straightforward contributions V_{Coul} and $V_{e\text{-N}}$, and transfers our ignorance to the remaining portion V_{xc} . Although, by the Hohenberg–Kohn theorem V_{xc} must exist, its determination remains the challenge of modern density functional theory, which currently uses approximate functional forms. These approximate treatments of V_{xc} are quite useful in practice, and for large systems, DFT offers a promising alternative to wave function based methods.

Through Eq. (33.45), the KS approach is formally similar to SCF theory, although the Kohn–Sham theory is in principle exact. This formal similarity is exploited in the evaluation of the derivative $E^{0\text{-DFT}}(\mathbf{R})$ [90].

33.2.4 Weakly Interacting Systems

When attempting to describe weak chemical interactions such as van der Waals or dispersion forces, the techniques

outlined in Sect. 33.2.2 must be modified somewhat. These modifications arise from the finiteness, and hence incompleteness, of the basis (the set χ) used to describe the molecular orbitals. Assume that the interaction of two molecules A and B is to be determined. Consider the description of molecule A as the distance between A and B decreases from infinity. The atom centered basis functions on molecule B augment those on molecule A , lowering its energy, independent of any physical interaction. This computational artifact serves to overestimate the interaction energy, and is known as the basis set superposition error [91, 92]. In chemically bonded systems where interaction energies are large, it is of negligible importance. However in weakly bonded systems for which the interaction energies may be on the order of 10 to 100 cm^{-1} , the basis set superposition error can be significant.

The basis set superposition error can be reduced by the counterpoise correction [93, 94]. In this approach, the interaction energy is evaluated directly as

$$E_I^{0\text{-int}}(\mathbf{R}) = E_I^0(\mathbf{R}) - [E_I^{0\text{-}A}(\mathbf{R}) + E_I^{0\text{-}B}(\mathbf{R})], \quad (33.48)$$

where $E_I^{0\text{-}A}(\mathbf{R})$ and $E_I^{0\text{-}B}(\mathbf{R})$, the energies of A and B respectively, are evaluated in the full basis.

33.3 Intersurface Interactions: Perturbations

The existence of interstate interactions can lead to *unexpected* shifts in spectral lines as well as predissociation of the states themselves [95]. These situations are illustrated in Fig. 33.2a,b which present the 1, 2, 3 $^3\Pi_g$ potential energy curves for Al_2 and the corresponding derivative couplings $f^{IJ}(\mathbf{R})$ respectively. The derivative couplings were evaluated using the method described in Sect. 33.3.1. In this molecule, derivative couplings between the 2, 3 $^3\Pi_g$ states are responsible for the perturbations in the vibrational levels of the bound 2, 3 $^3\Pi_g$ states. Derivative couplings of these states with the 1 $^3\Pi_g$ state causes predissociation of all levels in the 2, 3 $^3\Pi_g$ manifold [96].

Sect. 33.1 describes two classes of interstate matrix elements that can lead to these nonadiabatic phenomena, the derivative coupling matrix elements in Eqs. (33.7)–(33.10) and H_{IJ}^{rel} , which is usually treated for low Z systems within the Breit–Pauli approximation. An illustration of a nonadiabatic process induced by H^{rel} is provided in Sect. 33.5. A key issue in the treatment of the electronic structure aspects of these phenomena is the reliable evaluation of the interstate matrix elements. The interstate interactions are usually of most interest in regions of nuclear coordinate space far removed from the equilibrium nuclear configuration. Thus it is desirable to evaluate these interactions using multireference CI wave functions which (Sect. 33.1) are well suited

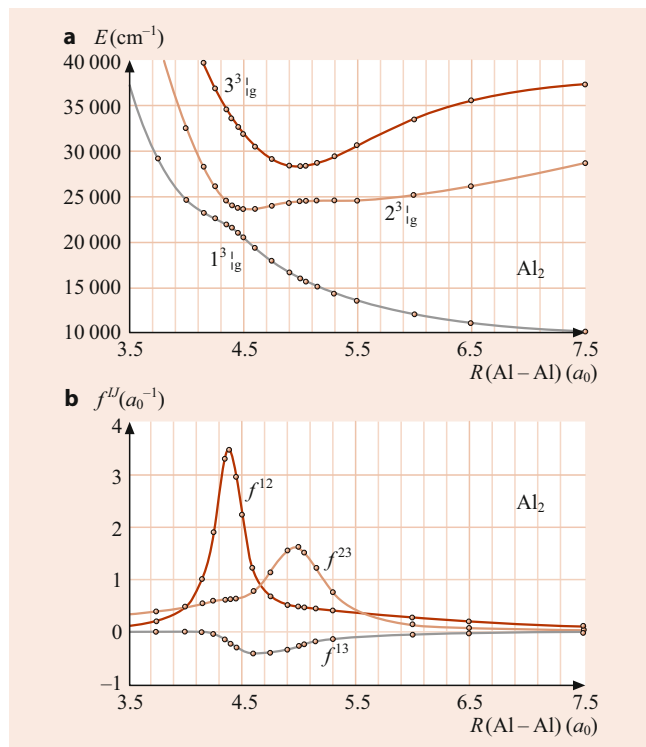

Fig. 33.2 (a) Adiabatic potential energy curves for the 1, 2, 3³Π_g states of Al₂ from [96]. (b) Derivative couplings $F^{IJ}(\mathbf{R})$ for $(I, J) = 1, 3^3\Pi_g$ and $2, 3^3\Pi_g$ from [96]

for use in these regions of coordinate space. The evaluation of nonadiabatic interactions, based on SA-MCSCF/CI wave functions, is discussed below.

33.3.1 Derivative Couplings

From Eqs. (33.9)–(33.11), two classes of matrix elements are required, $\tilde{k}_{W_\alpha W_\beta}^{II}(\mathbf{R})$ and $f_{W_\alpha}^{II}(\mathbf{R})$. In fact, techniques to evaluate both of these exist [44]. However, it is common to approximate $\tilde{k}_{W_\alpha W_\beta}^{II}(\mathbf{R})$ by

$$\begin{aligned} \tilde{k}_{W_\alpha W_\beta}^{II}(\mathbf{R}) &= \sum_M \left\langle \frac{\partial}{\partial W_\alpha} \Psi_J^0(\mathbf{r}; \mathbf{R}) \middle| \Psi_M^0(\mathbf{r}; \mathbf{R}) \right\rangle_r \\ &\quad \times \left\langle \Psi_M^0(\mathbf{r}; \mathbf{R}) \middle| \frac{\partial}{\partial W_\beta} \Psi_I^0(\mathbf{r}; \mathbf{R}) \right\rangle_r \\ &= \sum_M f_{W_\alpha}^{MJ} f_{W_\beta}^{MI}. \end{aligned} \quad (33.49)$$

with the (in principle infinite) summation over states truncated to reflect only the states explicitly treated in the nonadiabatic dynamics. Thus it is sufficient to discuss the determination of $f_{W_\alpha}^{II}(\mathbf{R})$.

The use of analytic derivative theory [97, 98] greatly improves the computational efficiency of evaluating $f_{W_\alpha}^{II}(\mathbf{R})$

relative to the earlier divided difference techniques [99]. The key ideas are given below. In this presentation, the standard, real-valued normalization is used. Additional contributions owing to the geometric phase, if required, must be evaluated separately as they do not follow from the electronic Schrödinger equation at a single point [100].

Differentiation of the $\Psi_J^0(\mathbf{r}; \mathbf{R})$ defined in Eq. (33.36) gives:

$$\begin{aligned} \frac{\partial}{\partial W_\alpha} \Psi_I^0(\mathbf{r}; \mathbf{R}) &= \sum_\lambda \left\{ \left[\frac{\partial}{\partial W_\alpha} c_\lambda^I(\mathbf{R}) \right] \psi_\lambda(\mathbf{r}; \mathbf{R}) \right. \\ &\quad \left. + c_\lambda^I(\mathbf{R}) \left[\frac{\partial}{\partial W_\alpha} \psi_\lambda(\mathbf{r}; \mathbf{R}) \right] \right\}. \end{aligned} \quad (33.50)$$

Thus $f_{W_\alpha}^{II}(\mathbf{R})$, consists of two terms

$$f_{W_\alpha}^{II}(\mathbf{R}) = {}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R}) + {}^{\text{CSF}} f_{W_\alpha}^{II}(\mathbf{R}), \quad (33.51)$$

where the CI contribution is given by

$${}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R}) = \sum_\lambda c_\lambda^J(\mathbf{R}) \left[\frac{\partial}{\partial W_\alpha} c_\lambda^I(\mathbf{R}) \right], \quad (33.52)$$

and the CSF contribution has the form

$$\begin{aligned} {}^{\text{CSF}} f_{W_\alpha}^{II}(\mathbf{R}) &= \sum_{\lambda, \mu} c_\lambda^J(\mathbf{R}) \left\langle \psi_\lambda(\mathbf{r}; \mathbf{R}) \middle| \frac{\partial}{\partial W_\alpha} \psi_\mu^I(\mathbf{r}; \mathbf{R}) \right\rangle_r c_\mu^I(\mathbf{R}). \end{aligned} \quad (33.53)$$

Evaluation of ${}^{\text{CSF}} f_{W_\alpha}^{II}(\mathbf{R})$ is straightforward using analytical derivative techniques [101], so that the remainder of the discussion focusses on ${}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R})$. From Eq. (33.52), it would appear that the derivative of the CI coefficients $\partial/\partial W_\alpha c_\lambda^I(\mathbf{R}) \equiv V_{W_\alpha, \lambda}^I(\mathbf{R})$ would be required to evaluate ${}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R})$. This is quite costly and is in fact not necessary, since only the projection onto the state $\Psi_J^0(\mathbf{r}; \mathbf{R})$ is required. Equation (33.52) for ${}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R})$ can be recast in a form similar to that of $\mathbf{g}^I(\mathbf{R})$. This transformation of Eq. (33.52) enables the explicit determination of $V_{W_\alpha}^I(\mathbf{R})$ to be avoided, and is the key to the efficient use of analytic gradient techniques in the evaluation of $\mathbf{f}^{II}(\mathbf{R})$.

Differentiating Eq. (33.41) with respect to W_α gives

$$\begin{aligned} [\mathbf{H}^0 - E_I^0(\mathbf{R})] V_{W_\alpha}^I(\mathbf{R}) &= - \left\{ \frac{\partial}{\partial W_\alpha} [\mathbf{H}^0 - E_I^0(\mathbf{R})] \right\} \mathbf{c}^I(\mathbf{R}). \end{aligned} \quad (33.54)$$

Taking the inner product of Eq. (33.54) with $\mathbf{c}^J(\mathbf{R})$ gives

$${}^{\text{CI}} f_{W_\alpha}^{II}(\mathbf{R}) \equiv \mathbf{c}^J(\mathbf{R})^\dagger V_{W_\alpha}^I(\mathbf{R}) \quad (33.55)$$

$$= \Delta E_{IJ}^0(\mathbf{R})^{-1} \mathbf{c}^J(\mathbf{R})^\dagger \frac{\partial \mathbf{H}^0(\mathbf{R})}{\partial W_\alpha} \mathbf{c}^I(\mathbf{R}) \quad (33.56)$$

$$\equiv \Delta E_{IJ}^0(\mathbf{R})^{-1} h_{W_\alpha}^{II}(\mathbf{R}). \quad (33.57)$$

Observe that Eq. (33.56) and Eq. (33.57) are not the Hellmann–Feynman theorem [101, 102] (Chap. 55), to which they bear a formal resemblance, since it is not the Hamiltonian operator $H^0(\mathbf{r}; \mathbf{R})$ but rather the Hamiltonian matrix $\mathbf{H}^0(\mathbf{R})$ that is being differentiated. Since the energy gradient has the form [44]

$$\frac{\partial}{\partial W_\alpha} E_I^0(\mathbf{R}) = \mathbf{c}^I(\mathbf{R})^\dagger \frac{\partial \mathbf{H}^0(\mathbf{R})}{\partial W_\alpha} \mathbf{c}^I(\mathbf{R}), \quad (33.58)$$

its relation to $\text{CI}f_{W_\alpha}^{JI}(\mathbf{R})$ is clear. This identification is the key step in the evaluation of $\text{CI}f_{W_\alpha}^{JI}(\mathbf{R})$ using analytic gradient techniques [97, 98].

33.3.2 Breit–Pauli Interactions

For light systems, it is possible to introduce relativistic effects using the Breit–Pauli approximation [1], in which the four component Dirac description of a single electron is replaced by a two component (α, β) description. The $H^e(\mathbf{r}; \mathbf{R})$ becomes [1, 103]

$$H^e(\mathbf{r}; \mathbf{R}) = H^0(\mathbf{r}; \mathbf{R}) + H^{\text{rel}}(\mathbf{r}; \mathbf{R}), \quad (33.59)$$

where, in parallel with Eqs. (33.4)–(33.13) for the atomic case, the relativistic correction $H^{\text{rel}} = \sum_{k=1}^3 H^k(\mathbf{r}; \mathbf{R})$ can be divided into spin-dependent (SD) and spin-independent (SI) parts, plus an external field interaction term H^{ext} . These are given by

$$H^1 = H^{\text{SD}} \equiv H^{\text{so}} + H^{\text{soo}} + H^{\text{ss}}, \quad (33.60)$$

$$H^2 = H^{\text{SI}} \equiv H^{\text{mass}} + H^{\text{D}} + H^{\text{ssc}} + H^{\text{oo}}, \quad (33.61)$$

$$H^3 = H^{\text{ext}}, \quad (33.62)$$

where, in atomic units,

$$H^{\text{so}} = \frac{\alpha^2}{2} \sum_{K,i} \frac{Z_K(\mathbf{r}_i - \mathbf{R}_K) \times \mathbf{p}_i \cdot \mathbf{s}_i}{|\mathbf{r}_i - \mathbf{R}_K|^3}, \quad (33.63)$$

$$H^{\text{soo}} = -\frac{\alpha^2}{2} \sum_{i \neq j} \frac{\mathbf{r}_{ij} \times \mathbf{p}_i \cdot (\mathbf{s}_i + 2\mathbf{s}_j)}{|\mathbf{r}_{ij}|^3}, \quad (33.64)$$

$$H^{\text{ss}} = \alpha^2 \sum_{i < j} \left[\frac{\mathbf{s}_i \cdot \mathbf{s}_j}{|\mathbf{r}_{ij}|^3} - \frac{3(\mathbf{r}_{ij} \cdot \mathbf{s}_i)(\mathbf{r}_{ij} \cdot \mathbf{s}_j)}{|\mathbf{r}_{ij}|^5} \right], \quad (33.65)$$

$$H^{\text{mass}} = -\frac{\alpha^2}{8} \sum_i p_i^4, \quad (33.66)$$

$$H^{\text{D}} = -\frac{\alpha^2}{8} \left[\sum_{K,i} Z_K \nabla_i^2 |\mathbf{r}_i - \mathbf{R}_K|^{-1} - \sum_{i \neq j} \nabla_i^2 |\mathbf{r}_{ij}|^{-1} \right], \quad (33.67)$$

$$H^{\text{ssc}} = -\frac{8\pi\alpha^2}{3} \sum_{i < j} (\mathbf{s}_i \cdot \mathbf{s}_j) \delta(\mathbf{r}_{ij}), \quad (33.68)$$

$$H^{\text{oo}} = -\frac{\alpha^2}{4} \left(\sum_{j \neq i} \frac{\mathbf{p}_i \cdot \mathbf{p}_j}{|\mathbf{r}_{ij}|} - \frac{\mathbf{r}_{ij} \cdot [\mathbf{r}_{ij} \cdot \mathbf{p}_j] \mathbf{p}_i}{|\mathbf{r}_{ij}|^3} \right), \quad (33.69)$$

$$H^{\text{ext}} = \frac{\alpha^2}{2} \sum_i \mathbf{E}(\mathbf{r}_i) \times \mathbf{p}_i \cdot \mathbf{s}_i + \frac{i\alpha^2}{4} \sum_i \mathbf{E}(\mathbf{r}_i) \cdot \mathbf{p}_i + 2\mu \sum_i \mathcal{H}(\mathbf{r}_i) \cdot \mathbf{s}_i, \quad (33.70)$$

$\mathbf{E}(\mathbf{r})$ and $\mathcal{H}(\mathbf{r})$ are electric and magnetic fields, and $\mu = e\hbar/(2m_e)$ is the Bohr magneton. The physical significance of these terms is discussed in Chap. 22.1. One of the most important consequences of these relativistic effects is that total electron spin is no longer a good quantum number as it is in $H^0(\mathbf{r}; \mathbf{R})$. The term H^{SD} couple states corresponding to distinct eigenvalues of S^2 and lead to the nonadiabatic effects that are the subject of this section.

The Breit–Pauli approximation is most useful for light atoms, but the approximation breaks down when Z becomes large [104–106]. One of the principal effects omitted in a treatment which includes only H^{SD} is the relativistic contraction of the molecular orbitals [107] due to the mass-velocity operator (H^{mass}), an effect whose importance increases with Z . Several approaches exist which attempt to correct this situation while retaining the spirit and simplifications of the Breit–Pauli approximation. The first of these is the relativistic effective core potential (ECP) approximation [108–111]. In this approach, the results of an atomic Dirac–Fock calculation [112] are used to replace innermost or core electrons of a given atom with (i) an effective one electron potential that modifies the electron–nuclear attraction term in H^0 and (ii) an effective one electron spin-orbit operator, so that

$$H^e(\mathbf{r}; \mathbf{R}) \rightarrow H^{e-\text{ECP}}(\mathbf{r}; \mathbf{R}) = H^{0-\text{ECP}}(\mathbf{r}; \mathbf{R}) + H^{\text{so}-\text{ECP}}(\mathbf{r}; \mathbf{R}). \quad (33.71)$$

The formal similarity between $H^{e-\text{ECP}}$ and $H^e(\mathbf{r}; \mathbf{R})$ results in a similar phenomenological interpretation of relativistically induced nonadiabatic processes. Applications of this approach have been reviewed [107, 113].

A second approach includes all electrons explicitly, and uses H^{SD} as defined above. The relativistic contraction of the core electrons is included by using a variational one-component spin-free approximation [114, 115] to the no-pair Hamiltonian [116] at the orbital optimization stage. The variational nature of the approximation provides advantages over the use of the H^{mass} term. Applications of this approach to the spectra of CuH and NiH have been reported [117, 118].

In order to evaluate $H_{IJ}^{\text{SD}}(\mathbf{R})$, it is necessary to specify the molecular orbitals to be used to construct the $\Psi_I^0(\mathbf{r}; \mathbf{R})$. The choice of molecular orbitals is dictated by the following considerations. Matrix elements of H^{SD} between different states

are required. The molecular orbitals appropriate for one state may not be appropriate for the description of the second state. Two approaches are available to handle this situation. In one approach, distinct sets of (mutually nonorthogonal) molecular orbitals are used to describe each state [119]. This permits a more compact description of the spaces in question. However in this case one is required to evaluate the matrix element of a two electron operator H^{soo} and/or H^{ss} in a nonorthogonal molecular orbital basis, an imposing computational task. This significantly limits the size of the CSF space which is tractable. The alternative approach is to use a common orthonormal basis balanced between the two spaces in question, and to use larger CSF spaces [120–122]. The use of a common orthonormal basis decreases significantly the computational effort required to evaluate the matrix elements. A symbolic matrix element method [123] has been applied to H^{SD} , as described in the review [124].

33.3.3 Surfaces of Intersection

The preceding subsections have considered what must be calculated in order to characterize an electronically nonadiabatic process. As noted in Sect. 33.1, it is also necessary to consider where in nuclear coordinate space electronic nonadiabaticity is important. Nonadiabatic processes are important in regions of close approach of the potential energy surfaces with regions of surface intersections being of pre-eminent interest. Until recently, these surfaces of intersection were determined by indirect methods, i.e., the potential energy surfaces were characterized, and then the surface of intersection was determined. This made the determination of these surfaces of intersection a computationally daunting task. However, computational advances have made it possible to determine these surfaces of intersection directly, i.e., without prior determination of the individual potential energy surfaces. This point is discussed next.

A point on the surface of conical intersection of two states of the same symmetry, subject to a set of geometric equality constraints of the form $C_i(\mathbf{R}) = 0$, $i = 1, \dots, m$, is determined from the Newton–Raphson equations [125]

$$-\begin{pmatrix} \mathbf{Q}^{IJ}(\mathbf{R}, \boldsymbol{\xi}, \boldsymbol{\lambda}) & \mathbf{g}^{IJ}(\mathbf{R}) & \mathbf{h}^{IJ}(\mathbf{R}) & \mathbf{k}(\mathbf{R}) \\ \mathbf{g}^{IJ}(\mathbf{R})^\dagger & 0 & 0 & \mathbf{0} \\ \mathbf{h}^{IJ}(\mathbf{R})^\dagger & 0 & 0 & \mathbf{0} \\ \mathbf{k}(\mathbf{R})^\dagger & \mathbf{0}^\dagger & \mathbf{0}^\dagger & \mathbf{0} \end{pmatrix} \begin{pmatrix} \delta \mathbf{R} \\ \delta \xi_1 \\ \delta \xi_2 \\ \delta \boldsymbol{\lambda} \end{pmatrix} = \begin{pmatrix} \mathbf{g}^I(\mathbf{R}) + \xi_1 \mathbf{g}^{IJ}(\mathbf{R}) + \xi_2 \mathbf{h}^{IJ}(\mathbf{R}) + \sum_{i=1}^m \lambda_i \mathbf{k}^i(\mathbf{R}) \\ \Delta E_{IJ}(\mathbf{R}) \\ 0 \\ \mathbf{C}(\mathbf{R}) \end{pmatrix} \quad (33.72)$$

where $\delta \mathbf{R} = \mathbf{R}' - \mathbf{R}$, $\delta \boldsymbol{\lambda} = \boldsymbol{\lambda}' - \boldsymbol{\lambda}$, $\delta \boldsymbol{\xi} = \boldsymbol{\xi}' - \boldsymbol{\xi}$, $\mathbf{g}_\alpha^{IJ}(\mathbf{R}) \equiv \partial \Delta E_{IJ}(\mathbf{R}) / \partial R_\alpha$, $\mathbf{k}_\alpha^i(\mathbf{R}) \equiv \partial C_i(\mathbf{R}) / \partial R_\alpha$, $\mathbf{h}_\alpha^{IJ}(\mathbf{R}) \equiv \mathbf{c}^{I\dagger}(\mathbf{R}) \mathbf{H}^0(\mathbf{R}) / \partial R_\alpha \mathbf{c}^J(\mathbf{R})$, $\boldsymbol{\xi}$ and $\boldsymbol{\lambda}$ are Lagrange multipliers, and $\mathbf{Q}^{IJ}(\mathbf{R}, \boldsymbol{\xi}, \boldsymbol{\lambda})$ is a matrix of second derivatives [125]. For two states of different symmetry, the analogue of Eq. (33.72) is used with the terms related to ξ_2 omitted [126]. The excellent performance of this algorithm has been documented [125, 127].

Equations (33.72) can be motivated as follows. \mathbf{R}^c is sought so that $E_I^0(\mathbf{R})$ is minimized subject to the constraints $E_I^0(\mathbf{R}) = E_J^0(\mathbf{R})$ and $\mathbf{C}(\mathbf{R}) = 0$. The key is to impose the first of these constraints, noting that at each step in the Newton–Raphson procedure, $\mathbf{c}^I(\mathbf{R})$ and $\mathbf{c}^J(\mathbf{R})$ are eigenvectors. Equation (33.72) are the Newton–Raphson equations corresponding to the Lagrangian function [128]

$$L_{IJ}(\mathbf{R}, \boldsymbol{\xi}, \boldsymbol{\lambda}) = E_I(\mathbf{R}) + \xi_1 \Delta E_{IJ}(\mathbf{R}) + \xi_2 H_{IJ}(\mathbf{R}) + \sum_{k=1}^M \lambda_k C_k(\mathbf{R}), \quad (33.73)$$

provided that the gradient of $H_{IJ}^0(\mathbf{R})$ is interpreted as a change in $\mathbf{H}^0(\mathbf{R})$ within the subspace spanned by $\mathbf{c}^I(\mathbf{R})$ and $\mathbf{c}^J(\mathbf{R})$. This can be derived from quasidegenerate perturbation theory and understood as follows. Assume for convenience that $m = 0$, i.e., there are no geometrical constraints.

Consider an \mathbf{R} for which Eq. (33.72) is not satisfied. The 2×2 matrix $\mathbf{H}(\mathbf{R})$ with matrix elements $H_{KL}(\mathbf{R})$, $K, L \in \{I, J\}$ becomes at $\mathbf{R} + \delta \mathbf{R}$

$$\mathbf{H}_{IJ}(\mathbf{R} + \delta \mathbf{R}) = \mathbf{c}^{I\dagger}(\mathbf{R}) \left(\mathbf{H}(\mathbf{R}) + \sum_\alpha \frac{\partial \mathbf{H}(\mathbf{R})}{\partial R_\alpha} \delta R_\alpha \right) \mathbf{c}^J(\mathbf{R}), \quad (33.74)$$

$\mathbf{H}(\mathbf{R})$ is diagonal but nondegenerate at \mathbf{R} , i.e.,

$$\mathbf{H}(\mathbf{R}) = \begin{pmatrix} E_I^0(\mathbf{R}) - E_J^0(\mathbf{R}) & 0 \\ 0 & 0 \end{pmatrix}. \quad (33.75)$$

From Eq. (33.74) at $\mathbf{R}^c = \mathbf{R} + \delta \mathbf{R}$, $\mathbf{H}(\mathbf{R}^c)$ becomes, to first order, ignoring an irrelevant uniform shift of the diagonal elements,

$$\mathbf{H}(\mathbf{R}^c) = \begin{pmatrix} \Delta E_{IJ}(\mathbf{R}) + \mathbf{g}^{IJ\dagger} \cdot \delta \mathbf{R} & \mathbf{h}^{IJ\dagger} \cdot \delta \mathbf{R} \\ \mathbf{h}^{IJ\dagger} \cdot \delta \mathbf{R} & 0 \end{pmatrix}. \quad (33.76)$$

Thus Eq. (33.72) is seen to be the requirement that $\mathbf{H}(\mathbf{R}^c)$ has degenerate eigenvalues, with eigenvectors $\mathbf{c}^I(\mathbf{R})$ and $\mathbf{c}^J(\mathbf{R})$. When Eq. (33.72) have been solved, $\mathbf{H}_{IJ}(\mathbf{R}^c)$ is diagonal and degenerate, $E_I(\mathbf{R}^c)$ has been minimized, and $\mathbf{g}^I(\mathbf{R}^c) = 0$, except along directions contained in the two

dimensional subspace spanned by $\mathbf{g}^{IJ}(\mathbf{R}^c)$ and $\mathbf{h}^{IJ}(\mathbf{R}^c)$. From Eq. (33.76), it is these two directions which lift the degeneracy of $\mathbf{H}(\mathbf{R}^c)$. Equation (33.72) is also relevant to the reaction path in a nonadiabatic process as discussed in Sect. 33.4. A discussion of these points from an alternative perspective has been presented by Radazos et al. [129].

A solution to Eq. (33.72) is referred to as a conical intersection, although rigorously degenerate states cannot be obtained from a numerical procedure. If required, the existence of a conical intersection can be rigorously established by showing that the adiabatic wave functions undergo a change of sign when transported around a closed loop containing \mathbf{R}^c in the plane defined by $\mathbf{g}^{IJ}(\mathbf{R}^c)$ and $\mathbf{h}^{IJ}(\mathbf{R}^c)$. This is the geometric or Berry phase criterion [130, 131]. It has been explicitly demonstrated for a conical intersection in O_3 by Ruedenberg and coworkers [132].

33.4 Nuclear Motion

33.4.1 General Considerations

The determination of the rovibrational spectrum of polyatomic systems from first principles is a problem of primary importance since it allows the determination of molecular forces and structure from spectral data. In the adiabatic case, the solution of Eq. (33.6)

$$[T^{\text{nuc}}(\mathbf{R}) + E_I^0(\mathbf{Q}) - E_K] \beta_K(\mathbf{R}) = 0 \quad (33.77)$$

is sought, where \mathbf{Q} denotes a set of internal nuclear coordinates. The reliability of the solution of Eq. (33.77) reflects the accuracy of the Born–Oppenheimer potential energy surface $E_I^0(\mathbf{Q})$ appearing in that equation. The methods for determining $E_I^0(\mathbf{Q})$ were discussed in Sect. 33.2. Conversely, the determination of the E_K from spectroscopic measurements can be used to infer information concerning $E_I^0(\mathbf{Q})$. In either case, the accurate solution of Eq. (33.77) is requisite and this section is concerned with its solution.

The operator in Eq. (33.77) has a continuous spectrum since T^{nuc} includes translations of the nuclear center of mass (cm). An operator with a discrete spectrum is obtained by replacing the Hamiltonian in Eq. (33.77) with one in which the translation of the nuclear c.m. has been eliminated by transforming to the c.m. frame. In the center of mass frame, Eq. (33.77) has the general form [133]

$$[T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}) + T^{\text{vib}}(\mathbf{Q}) + E_I^0(\mathbf{Q}) - E_K] \beta(\boldsymbol{\Omega}, \mathbf{Q}) = 0, \quad (33.78)$$

where $\boldsymbol{\Omega}$ are three rotational coordinates and T^{vr} and T^{vib} are the rotational and vibrational kinetic energy operators. In $T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q})$ all the complexity associated with the coupling of nuclear and electronic angular momentum is buried. The

determination of the appropriate form for Eq. (33.78) is by no means straightforward [134, 135], and treatment of the effects of multiple angular momentum is a complex problem in angular momentum algebra.

In diatomic systems, the vibrational problem involves only one internal coordinate and is straightforward. Angular momentum coupling is usually treated using Hund's case (a), (b), etc., or an intermediate case approach [95] with Van Vleck's reversed angular momentum commutation relations being helpful in analyzing the coupled angular momentum problem [134].

Polyatomic systems introduce new complications, since in addition to the increased dimensionality of the vibrational problem, internal and rotational coordinates interconvert for colinear arrangements of the nuclei; this is particularly relevant in triatomic systems. In addition, since the $C_{\infty v}$ point group has doubly degenerate representations at collinear geometries, electronic state degeneracies may arise (the Renner–Teller effect) [32, 136, 137], further complicating the analysis. Techniques associated with the description of triatomic systems involving coupled angular momentum and electronic degeneracy are illustrated in Sect. 33.4.3.

More generally, Eq. (33.78) can be rewritten as

$$[T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}^e) + T^{\text{vib}}(\mathbf{Q}) + E_I^{\text{sep}}(\mathbf{Q}) - E_K] \beta(\mathbf{R}) = -\Delta T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}) \beta(\mathbf{R}) - \Delta E_I^0(\mathbf{Q}), \quad (33.79)$$

where

$$\Delta T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}) \equiv T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}) - T^{\text{vr}}(\boldsymbol{\Omega}, \mathbf{Q}^e), \quad (33.80)$$

$$\Delta E_I^0(\mathbf{Q}) \equiv E_I^0(\mathbf{Q}) - E_I^{\text{sep}}(\mathbf{Q}), \quad (33.81)$$

\mathbf{Q}^e is an equilibrium structure, and $E_I^{\text{sep}}(\mathbf{Q})$ is a separable function of the normal coordinates. In this case, the solution to the left-hand side of Eq. (33.79) can be factorized into a rotational part and a vibrational part [138] according to

$$\psi_I^J = \sum_K k_K^J D_{K0}^J(\theta, \chi) \prod_i \alpha_i(Q_i) \quad (33.82)$$

where D_{K0}^J is a symmetric top wave function [139], and $\alpha_i(Q_i)$ is a pure vibrational wave function, e.g., harmonic oscillator function, for the i th internal normal coordinate. It is in this approximation that the notion of a molecule rotating and vibrating about a fixed molecular structure is achieved. In this case, E_K is just the sum of the pure rotational and vibrational energies. These rigid rotator–vibrator solutions then form the basis for the inclusion of the effects of the right-hand side using, for example, perturbation theory [140]. They can also be used as a basis for a nonperturbative treatment (Sect. 33.4.2).

The classic treatments of Eq. (33.77) [141–144] have been periodically revisited [134, 145]. In these investigations, the contributions of electronic angular momentum to

this Hamiltonian were frequently suppressed [144] so that these treatments are appropriate to totally symmetric electronic states. *Van Vleck* [134] has shown how the effects of electronic angular momentum can be incorporated into these treatments.

For nonlinear polyatomic systems, the Hamiltonian in Eq. (33.78) can be transformed to the Eckart or body fixed frame in which the reference axis is a body fixed axis oriented along the principal moments of inertia [146], although other choices of the body fixed axes are possible [147]. The principal moments of inertia represent the eigenvectors of the inertial tensor matrix I_{ij} , $i, j = x, y, z$, where [144]

$$I_{xx} = \sum_i M_i (\mathbf{R}_i^e \cdot \mathbf{R}_i^e - X_i^e X_i^e), \quad (33.83)$$

$$I_{xy} = - \sum_i M_i (X_i^e Y_i^e), \quad (33.84)$$

and cyclic permutations, and \mathbf{R}^e denotes an equilibrium structure. The Hamiltonian determined by this procedure is referred to as the Watson Hamiltonian [145], and is widely used in discussing the rovibrational spectrum of nonlinear polyatomic molecules in singlet electronic states. Treatments of the Watson Hamiltonian are mentioned in Sect. 33.4.2. For linear molecules, an alternative treatment is required since there is one fewer overall rotational coordinate and one more internal coordinate [138].

33.4.2 Rotational-Vibrational Structure

Various approaches to the solution of Eq. (33.79) exist. The principal issues, which are interrelated, are (i) the range of nuclear configurations over which $E_l^0(\mathbf{Q})$ is known, (ii) the coordinate system used to express the internal coordinates, and (iii) particularly in larger systems, the number of modes or internal coordinates retained in the calculations (Sect. 33.4.3). With regard to point (i), two approaches are currently in use. The force field method uses a power series expansion of $E_l^0(\mathbf{Q})$ about $E_l^0(\mathbf{Q}^e)$, that is (using the Einstein summation convention)

$$E_l^0(\mathbf{Q}) = E_l^0(\mathbf{Q}^e) + \frac{1}{2} \frac{\partial^2 E_l^0(\mathbf{Q}^e)}{\partial Q_i \partial Q_j} \Delta Q_i \Delta Q_j + \frac{1}{6} \frac{\partial^3 E_l^0(\mathbf{Q}^e)}{\partial Q_i \partial Q_j \partial Q_k} \Delta Q_i \Delta Q_j \Delta Q_k \quad (33.85)$$

together with perturbation theory to determine spectroscopic constants. In this approach, the force fields [the partial derivatives in Eq. (33.85)] are usually evaluated directly with the aid of analytic gradient techniques (Sect. 33.2). Since the expansion of $E_l^0(\mathbf{Q})$ is truncated, the results are not independent of the coordinate system used. For example,

significant differences in the description of Fermi-resonance parameters [148, 149] in rectilinear and curvilinear coordinates [150] have been reported.

Alternatively, $E_l^0(\mathbf{Q})$ can be represented by a grid of points around \mathbf{Q}^e . In the most reliable calculations reported to date, $E_l^0(\mathbf{Q})$ is determined using the coupled cluster techniques discussed in Sect. 33.2. Then Eq. (33.79) can be solved in a basis analogous to ψ_l^J in Eq. (33.82). This approach is frequently referred to as the vibrational CI problem [151]. The reliability of the results depends to a considerable extent on the basis functions and coordinate system used to describe the problem. Considerable success has been reported for a technique in which the Watson Hamiltonian and harmonic oscillator functions are used to solve Eq. (33.79) [151, 152].

33.4.3 Coupling of Electronic and Rotational Angular Momentum in Weakly Interacting

An understanding of the molecular structure of the weakly bound compounds of noble gas atoms and diatomic molecules provides important insights into the nature of chemical bonding. The inference of structural data from spectroscopic observations is an important aspect of this problem. In this subsection, a theoretical framework for understanding the spectroscopy of these systems is outlined as an illustration of the methods used to treat coupling of electronic and nuclear angular momentum in weakly interacting triatomic molecular systems. Detailed discussion of this class of problems can be found in [153–155].

As an example, consider the rovibronic structure of a noble gas-diatom complex Rg-AB , in either its $^1\Sigma^+$ or $^1\Pi$ states (which may be closely spaced). Note that degeneracy of the $^1\Pi$ state will only persist for collinear geometries of the triatom system. The rovibrational wave functions can be expanded in a product basis of functions describing (i) the rovibronic structure of AB and (ii) the relative motion (vibrational and end-over-end rotation) of Rg and AB . Since total angular momentum J and its space fixed projections M are good quantum numbers, the rovibronic wave function can be expanded as

$$\Psi^{JM} = \frac{1}{R} \sum_{vj\Omega l \varepsilon} C_{j\Omega l \varepsilon}^{JM}(R) |\psi_{\text{Rg}}\rangle |v_{Ij}\rangle |Ij \Omega \varepsilon, l; JM\rangle, \quad (33.86)$$

where ψ_{Rg} is the ground state wave function for the noble gas atom, l denotes the angular momentum associated with the end-over-end motion, and v, j, ε and I denote respectively the vibrational, angular momentum (electronic + rotational), e/f symmetry index and state label of the electronic state

of the AB molecule in Hund's case (a) basis. The angular momentum coupling algebra noted above is reflected in the definition of $|Ij\Omega\varepsilon, l; JM\rangle$, which is

$$|Ij\Omega\varepsilon, l; JM\rangle = \sum_{m_j m_l} \langle j m_j l m_l | JM \rangle Y_{lm_l}(\theta, \phi) \psi_{Ij m_j \Omega \varepsilon}(\beta, \alpha), \quad (33.87)$$

where θ, ϕ and β, α are the polar and azimuthal angles for the line connecting the noble gas atom to the center of mass of the diatom and the diatom axis, respectively, and $\langle \dots | \dots \rangle$ is a Clebsch–Gordan coefficient [156] (Chap. 2). The $\psi_{Ij m_j \Omega \varepsilon}$ are defined in turn by [95]

$$\begin{aligned} \psi_{Ij m_j \Omega \varepsilon} &= \left(\frac{2J+1}{8\pi} \right)^{1/2} \\ &\times [D_{m_j, \Omega}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda^+(\Sigma)\rangle \\ &+ \varepsilon D_{m_j, -\Omega}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda^-(-\Sigma)\rangle] \end{aligned} \quad (33.88)$$

or

$$\psi_{Ij m_j \Omega \varepsilon} = \left(\frac{2J+1}{4\pi} \right)^{1/2} D_{m_j, 0}^j(\alpha, \beta, 0)^* |I^{2S+1}\Lambda(\Sigma)\rangle \quad (33.89)$$

when $\Lambda = \Sigma = 0$, where the electronic state has term symbol $I^{2S+1}\Lambda$ with $\Omega = \Lambda + \Sigma$.

The $C^{JM}(\mathbf{R})$ satisfy the usual close coupled equations [157, 158] Chap. 49.1.1

$$\left[\left(\frac{-1}{2\mu} \frac{d^2}{dR^2} + \frac{l(l+1)}{2\mu R^2} \right) \mathbf{I} - \frac{\mathbf{k}^2}{2\mu} + V(r) \right] C^{JM}(r) = 0, \quad (33.90)$$

where $l(l+1)$ and $\mathbf{k}^2/2\mu$ designate the diagonal matrices of orbital angular momentum and asymptotic net scattering energy of individual channels. $V(R)$ represents the matrix elements of $H^e(\mathbf{r}; \mathbf{R})$ in the vibronic basis defined in Eqs. (33.86)–(33.89). It is built from terms of the form

$$\begin{aligned} &\langle Y_{lm} D_{m_j \Omega}^{j*} v_{Ij} | \langle \psi_{Rg} I^{2S+1}\Lambda | H^e(\mathbf{r}; \mathbf{R}) \\ &\times | \psi_{Rg} I^{2S'+1}\Lambda' \rangle_r | v_{I'j'} Y_{l'm'} D_{m'_j \Omega'}^{j'*} \rangle \\ &\equiv \langle Y_{lm} D_{m_j \Omega}^{j*} v_{Ij} | H_{II'}^e(R, \tilde{\beta}, r) | Y_{l'm'} D_{m'_j \Omega'}^{j'*} v_{I'j'} \rangle. \end{aligned} \quad (33.91)$$

The angle $\tilde{\beta}$ is the polar angle of the diatom with respect to the atom-diatom axis. The angular integrations on the right-hand side of Eq. (33.91) are accomplished by expanding the angular dependence of $H_{II'}^e$ in d -matrices and using angular momentum coupling algebra [158]. $H_{II'}^e$ gives the interaction potential of the ground state noble gas atom and the

$I^{2S+1}\Lambda$ state of AB . It represents the potential coupling in the diabatic basis $\psi_{Rg} | I^{2S+1}\Lambda \rangle$. These matrix elements are derived from the corresponding adiabatic potential energy surfaces, determined using the techniques of Sect. 33.2. Since the van der Waals interaction is weak, the counterpoised method discussed in Sect. 33.2.4 should be used. When only one electronic state of a given symmetry is involved (point group C_s in the case of a triatom), the adiabatic and diabatic potentials are taken as equal. This is the case if, for example, only the $^1\Pi$ state of AB is considered. When more than one electronic state of a given symmetry is involved, for example, when both $^1\Pi$ and $^1\Sigma^+$ electronic states of AB are included, the adiabatic potentials are used to determine the diabatic state potentials using an approximate adiabatic \rightarrow diabatic state transformation [159, 160].

The solution to Eq. (33.90) can be obtained by either variational methods or by direct integration [153]. Results for Ar-OH [161], Ar-BH [155], and Ar-CH [162], based on potential energy surfaces determined from multireference contracted CI wave functions, are encouraging. In these studies, the r -dependence of the potential energy surfaces was neglected.

33.4.4 Reaction Path

The rovibrational spectrum reflects the molecular structure in the vicinity of an equilibrium structure of the molecule. However a chemical reaction samples a much broader range of molecular structures. The evolution of molecular structure can be characterized by the reaction path, which represents a minimum energy path along the potential energy surface connecting the reactants and products. The reaction path Hamiltonian [163, 164] enables dynamical aspects of a chemical reaction to be inferred from a characterization of the reaction path.

The reaction path $\mathbf{R}(s)$ on potential energy surface $E_I^0(\mathbf{R})$ is the curve in mass weighted Cartesian coordinates given parametrically in terms of the arc length s and is defined as that solution to the differential equation

$$\frac{d\mathbf{R}}{ds} = \mathbf{g}^I / \sqrt{\mathbf{g}^{I\dagger} \mathbf{g}^I} \equiv \mathbf{R}'(s) \quad (33.92)$$

which approaches the saddle point from below [17, 165], where the arc length is given by

$$ds^2 = \sum_{i=1}^N dR_i^2. \quad (33.93)$$

At each point s , $\mathbf{R}(s)$ represents the molecular structure in terms of $3N$ mass weighted Cartesian coordinates. (In this subsection, the notation suppresses the difference between Cartesian and mass weighted Cartesian coordinates.)

The reaction path can be obtained by integrating Eq. (33.92). Integration begins at the saddle point along the direction of the single negative eigenvalue of \mathbf{F}^I , which is related to the reaction path curvature $d\mathbf{R}^2/ds^2$, by

$$\frac{d\mathbf{R}^2}{ds^2} \equiv \frac{d\mathbf{R}'}{ds} = \frac{[\mathbf{F}^I \mathbf{R}' - (\mathbf{R}'^\dagger \mathbf{F}^I \mathbf{R}') \mathbf{R}']}{\sqrt{\mathbf{g}^{I\dagger} \mathbf{g}^I}}. \quad (33.94)$$

Thus integration of Eq. (33.92) gives the steepest descent path from the saddle point. This integration requires, in principle, only knowledge of the energy gradient, $\mathbf{g}^I(\mathbf{R})$, which is readily available using analytic gradient techniques (see Sect. 33.2). This approach works quite well when the reaction path is used only to investigate the topology of a potential energy surface. However if quantities such as the curvature are desired, procedures that follow the reaction path more closely are required. Such procedures require higher derivatives of the energy, as fully discussed in [165].

In a nonadiabatic process, the reaction path necessarily involves more than one potential energy surface. In the case of nonadiabatic reactions involving avoided intersections, the reaction path is difficult to define since the propensity for an intersurface transition spreads out over a range of nuclear coordinates. However, for nonadiabatic reactions that proceed through a surface of intersection of two potential energy surfaces, the reaction path passes through the minimum energy point on the surface of intersection of the two potential energy surfaces [166]. An example of such a process is provided in Sect. 33.5. The minimum energy point on the surface of intersection satisfies Eq. (33.72) with no geometric constraints. For a spin-forbidden reaction, the solution of Eq. (33.72) yields $\mathbf{g}^I \mathbf{R} + \xi_1 \mathbf{g}^{IJ}(\mathbf{R}) = 0$, so that $\mathbf{g}^I(\mathbf{R}) = \xi_1/(1 + \xi_1) \mathbf{g}^J(\mathbf{R})$, i.e., the gradients on the two surfaces are either parallel or anti-parallel depending on the value of ξ_1 . The relationship between the gradients in the vicinity of an intersection of two states of the same symmetry is not as simple. The wave functions are not differentiable at a point of intersection. In the vicinity of the point of intersection, the condition $\mathbf{g}^I(\mathbf{R}) + \xi_1 \mathbf{g}^{IJ}(\mathbf{R}) + \xi_2 \mathbf{h}^{IJ}(\mathbf{R}) \approx 0$ holds, so that $\mathbf{g}^I(\mathbf{R})$ and $\mathbf{g}^J(\mathbf{R})$ will not be simply related. Finally, note that the adiabatic correction, defined in Sect. 33.1, is large (and positive) in the vicinity of the conical intersection, so that the nuclear wave function exhibits a node at this point.

33.5 Reaction Mechanisms: A Spin-Forbidden Chemical Reaction

This section presents an example to illustrate how the ideas outlined in the preceding sections can be used to obtain a mechanistic description of a chemical reaction which could

not be deduced on intuitive grounds. Considered here is the ground state reaction

which is of considerable importance in the chemistry of planetary atmospheres [167, 168] and hydrocarbon flames, having been suggested as the initial step in the production of prompt or Fenimore NO [168–171]. However, because the reaction is spin-forbidden, its importance has been questioned.

The reaction will be interpreted in terms of the intermediate complex model [172, 173]. In this model, the reaction can occur despite a small probability for intersystem crossing by repeatedly traversing the $2A''$ – $4A''$ surface of intersection. The repeated traversals result from a local minimum on the $2A''$ potential energy surface. This mechanism is operative for the spin-forbidden oxygen quenching reactions [172, 173]

which are important in the chemistry of the atmosphere.

To demonstrate the feasibility of reaction Eq. (33.95) as an intermediate complex assisted chemical reaction it is necessary to (i) determine the energetically relevant portion of the doublet-quartet surface of intersection, (ii) determine the spin-orbit interaction coupling the doublet and quartet surfaces, (iii) characterize a local minimum on the doublet surface from which the surface of intersection is accessible, (iv) characterize a path from the reactant channel to this region, and (v) determine the exit channel path on the quartet surface. The results of electronic structure calculations at the MR-CI level, addressing these points [174–178] are summarized below.

Local Extrema on the $2A''$ – $4A''$ Surface of Intersection

Points in the $2A''$ – $4A''$ surface of intersection were determined from the solution to Eq. (33.72) [126, 174]. The minimum energy point on the surface of intersection, labelled $C_{\text{mex}}^{C_{2v}}$, has approximate C_{2v} symmetry, and is shown in Fig. 33.3. It is the region of this crossing point that must be accessed from the doublet surface.

The Spin-Orbit Interaction

In the double group corresponding to C_s symmetry, the $4A''$ and $2A''$ wave functions each carry degenerate ir-

Fig. 33.3 Key bond distances in Å for (a) $R_{\min}^{\text{dative}}(\text{CH}) = 1.082$, $R_{\min}^{\text{dative}}(\text{CN}^1) = 1.340$, $R_{\min}^{\text{dative}}(\text{N}^1\text{N}^2) = 1.143$; (b) $R_{\min}^{\text{C}_{2v}}(\text{CH}) = 1.071$, $R_{\min}^{\text{C}_{2v}}(\text{CN}^1) = 1.311$; $R_{\min}^{\text{C}_{2v}}(\text{N}^1\text{N}^2) = 1.735$; $R_{\text{mex}}^{\text{C}_{2v}}(\text{CH}) = 1.076$, $R_{\text{mex}}^{\text{C}_{2v}}(\text{CN}^1) = 1.3$, $R_{\text{mex}}^{\text{C}_{2v}}(\text{N}^1\text{N}^2) = 2.221$; (c) $R_{\text{TS}}^c(\text{CH}) = 1.093$, $R_{\text{TS}}^c(\text{CN}^1) = 1.515$, $R_{\text{TS}}^c(\text{N}^1\text{N}^2) = 1.214$. The notation is as defined in Sect. 33.5. The dashed line in structure (c) indicates that H is out of the plane of the paper. (a), (b) after [124], (c) after [177]

reducible representations, Kramer's doublets [179]. The following pairs of nonrelativistic zeroth-order wave functions can be used to span these degenerate representations (i) $\Psi^0[2A''(\frac{1}{2})]$, $\Psi^0[2A''(-\frac{1}{2})]$, (ii) $i\Psi^0[4A''(\frac{1}{2})]$, $i\Psi^0[4A''(-\frac{1}{2})]$, and (iii) $i\Psi^0[4A''(\frac{3}{2})]$, $i\Psi^0[4A''(-\frac{3}{2})]$, where the M_s value has been given parenthetically. In this case, all nonvanishing matrix elements connecting the components of the $4A''$ and $2A''$ states can be expressed in terms of the single real-valued matrix element [139]

$$H^{\text{so}}(4A'', 2A'') \equiv \langle i\Psi^0[4A''(\frac{3}{2})] | H^{\text{so}} | \Psi^0[2A''(\frac{1}{2})] \rangle, \quad (33.98)$$

which was found to be $\approx 12.5 \text{ cm}^{-1}$ [126, 174] in the vicinity of the minimum energy crossing point determined above.

Local Extrema on the $2A''$ Potential Energy Surface

Two local minima on the $2A''$ potential energy surface have been found [174–176]. The local minimum configuration labeled C_{\min}^{dative} pictured in Fig. 33.3 represents a datively bonded structure in which N_2 donates a pair of electrons to the empty $\text{CH}(1\pi)$ orbital. This can be thought of as a reactant channel structure, since the N–N and C–H bond lengths are similar to those in the isolated molecules. This point on the $2A''$ potential energy surface is stable by 20.2 kcal/mol relative to the doublet asymptote in the reactant channel. The second minimum on the $2A''$ potential energy surface is also pictured in Fig. 33.3 and is seen to have C_{2v} symmetry. This configuration point, denoted $C_{\min}^{\text{C}_{2v}}$, is stable by 22.3 kcal/mol relative to the doublet asymptote in the reactant channel.

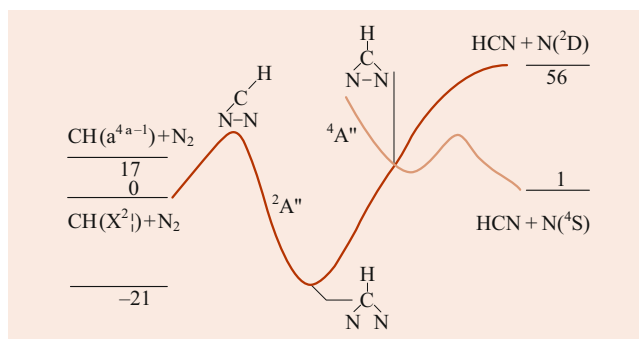

Fig. 33.4 Reaction path for $\text{CH}(X^2\Pi) + \text{N}_2(X^1\Sigma_g^+) \rightarrow \text{HCN}(X^1\Sigma^+) + \text{N}(^4\text{S})$ after [177]. Energy scale, which is approximate, is in kcal/mol

Note that $C_{\min}^{\text{C}_{2v}}$ and $C_{\text{mex}}^{\text{C}_{2v}}$ differ only in the length of the N–N bond.

Reaction Path

From the above data it might appear that both the $C_{\min}^{\text{C}_{2v}}$ and C_{\min}^{dative} structures are involved in the mechanism of reaction Eq. (33.95). However, the energy of the transition state connecting these two minima is quite large [176], so that the reaction path avoids C_{\min}^{dative} [177]. The true reaction path involves $C_{\min}^{\text{C}_{2v}}$, $C_{\text{mex}}^{\text{C}_{2v}}$, and a reactant channel transition state C_{TS}^c that connects $C_{\min}^{\text{C}_{2v}}$ and the reactant channel species $\text{CH} + \text{N}_2$. C_{TS}^c is also pictured in Fig. 33.3. It involves the nonplanar cis-approach of HC to N_2 [177]. The total reaction path is presented in Fig. 33.4 [178]. Note that following intersystem crossing, the system encounters a final transition state before proceeding to the spin-forbidden products.

From this qualitative analysis, a bimodal picture of the reaction of ground state CH with N_2 emerges. $\text{CH}(^2\Pi)$ can be removed by either (i) forming a complex C_{\min}^{dative} which is stabilized by a third body collision or (ii) forming the spin-forbidden products with the reaction mechanism indicated in Fig. 33.4. This mechanism has been deduced entirely from the computational results cited above. The key computational findings responsible for this mechanism are (i) the existence and geometrical relationship between $C_{\min}^{\text{C}_{2v}}$ and $C_{\text{mex}}^{\text{C}_{2v}}$, (ii) the large barrier separating C_{\min}^{dative} and $C_{\min}^{\text{C}_{2v}}$, and (iii) the entrance channel path across C_{TS}^c to $C_{\min}^{\text{C}_{2v}}$.

Since there is apparently no or little barrier to forming C_{\min}^{dative} [176], at low temperatures CH will be removed exclusively by this process at a rate with a small or negative temperature dependence, indicating a barrierless reaction. At higher temperatures, the rate constant is expected to exhibit a more usual Arrhenius type behavior as the spin-forbidden channel can be accessed [180]. These expectations are consistent with previous low temperature measurements [168, 181] and high temperature shock tube results [171, 182, 183]. The above reaction path for the spin-forbidden reaction has been used in a two internal coordinate model for reaction Eq. (33.95) [180] that also supports the proposed description of this reaction.

33.6 Recent Developments

Added by Mark M. Cassar

If the motion of nuclei within a molecule causes more than one Born–Oppenheimer potential energy surface to intersect, then nonadiabatic transitions become an essential process in molecular dynamics. These transitions are at the heart of many biological processes, such as light harvesting by plants [184, 185], which depends on electronic excitation transfer, and a host of processes in the upper atmosphere. In recent years, it has become apparent that conical intersections (see Sect. 33.3.3 for a definition) of two states of the same symmetry are a fundamental element of electronically nonadiabatic phenomena [186]. As an example, conical intersections can facilitate transitions from upper to lower electronic states. Transitions of this nature provide efficient pathways to lower electronic states, and are thus amenable to experimental study (e.g., through dissociation products of photoexcitation [187]).

Although points of conical intersection, which are not individual but form seams, can be located in a straightforward manner, finding points of minimum energy has proved more difficult. This difficulty has been attributed to the erratic behavior of the parameters used in the search algorithm. This seemingly intrinsic problem which would preclude extrapolation – a consequence of the singular nature of the intersection itself – has been avoided through the use of extrapolatable functions [188]. This recent work introduces functions that vary smoothly (i.e., are well-behaved) as one moves along the intersection seam, and hence allow the use of extrapolation techniques.

The study of conical intersections has also been extended to include three-state intersections and first-order relativistic effects. Accidental conical intersections (i.e., those not required by symmetry arguments) of three states of the same symmetry, which may provide an efficient mechanism for radiationless decay, have been shown to exist [189]. Spin-orbit effects are essential for the proper description of the nuclear dynamics in molecules containing an odd number of electrons [190]. The topography of conical intersections changes in this case, requiring the development of new algorithms [191].

Abstract

Molecules are aggregates of two or more nuclei bound by at least one electron. The nuclei of most stable molecules can be imagined to be points in a more or less rigid body whose relative positions are constrained by an electronic bonding potential. This potential depends strongly upon the electronic state, as described in Chap. 33. Most of this discussion is about stable molecules in their electronic ground state. The high/symmetry molecules CF_4 and SF_6 are discussed in Sect. 34.5 and compared to C_{60} or “Buckyball”, a recently discovered case of the highest 3-D symmetry. Section 34.6 introduced molecules with excited or “loose”= parts.

angular momentum · rigid rotor · body frame · tunneling rate · molecular rotation

34.1 Dynamics and Spectra of Molecular Rotors

Motions that stretch or compress the bonds are called *vibrational* motions and give rise to spectral resonances in the infrared region of the spectrum. Typical fundamental vibrational quanta (ν_0) lie between 80 cm^{-1} (the lowest GeBr_4 mode) and 3020 cm^{-1} (the highest CH_4 mode). (A 1000 cm^{-1} wave has a wavelength of $10\text{ }\mu\text{m}$ and a frequency defined by the speed of light: 29.9792458 THz .) Vibrational amplitudes are usually tiny since zero-point motions or vibrations involving one or two quanta ($\nu = 0, 1, 2, \dots$) are constrained by the steep bonding potential to less than a few percent of the bond lengths, but high overtones may lead to dissociation, i.e., molecular breakup.

The overall rotation of molecules in free space is unconstrained and gives rise to far-infrared or microwave

pure rotational transitions or sidebands on top of vibrational spectra. Typical rotational quanta ($2B$) lie between 0.18 cm^{-1} (5.4 GHz) for SF_6 and 10.6 cm^{-1} for CH_4 . Individual molecules are free to rotate or translate as a whole while undergoing tiny but usually rapid vibrations. Vibrating molecules may be thought of as tumbling collections of masses held together by “springs” (the electronic vibrational potential or force field) and are called semirigid rotors. The coupling of rotational and vibrational motion is called rovibrational coupling and includes centrifugal and Coriolis coupling, which will be introduced in Sect. 34.6.

This discussion of molecular dynamics and spectra mainly involves the molecular rotation and properties of rotationally excited molecules, particularly those with high rotational quantum number $J = 10\text{--}200$. However, the discussion also applies to molecules in excited vibrational states, and even certain cases of molecules in excited electronic states. The analysis of vibronic (vibrational-electronic), rovibrational (rotation-vibration), or rovibronic (all three) types of excitation can be very complicated [1–5] and is beyond the scope of this chapter, but these problems can also benefit from the elementary considerations to be introduced here.

34.1.1 Rigid Rotors

As a first approximation, and for the purposes of discussing basic molecular dynamics and spectra, one may ignore vibrations and model stable molecules as “stick-and-ball” structures or rigid rotors. Then the Hamiltonian has just three terms

$$H = AJ_x^2 + BJ_y^2 + CJ_z^2. \quad (34.1)$$

Here, $\{J_x, J_y, J_z\}$ are rotational angular momentum operators, and the rotational constants are half the inverses of the principal moments of inertia I_α of the body

$$A = \frac{1}{2I_x}, \quad B = \frac{1}{2I_y}, \quad C = \frac{1}{2I_z}. \quad (34.2)$$

This simple form follows if the J -coordinate system is assumed fixed to the rotor’s body and aligned to its principal axes, an elementary body, or Eckart frame.

Many molecules, and particularly all diatomic molecules, have two of the three rotational constants equal, say, $A = B$. Such rotors are called symmetric tops, and their Hamiltonian involves the usual total angular momentum squared $\mathbf{J} \cdot \mathbf{J}$ with one other body z -axial component J_z , in the form

$$\begin{aligned} H &= BJ_x^2 + BJ_y^2 + CJ_z^2 \\ &= BJ_x^2 + BJ_y^2 + BJ_z^2 + (C - B)J_z^2 \\ &= B\mathbf{J} \cdot \mathbf{J} + (C - B)J_z^2. \end{aligned} \quad (34.3)$$

This gives a simple formula for the symmetric top rotational energy levels in terms of the quantum numbers J for the total angular momentum and K for the body z -component

$$E(J, K) = BJ(J + 1) + (C - B)K^2. \quad (34.4)$$

However, this eigenvalue formula may be a little too simple, since it hides the structure of the eigenstates or eigenfunctions. Indeed, the full Schrödinger angular differential equation based upon the Hamiltonian in Eq. (34.1) is more lengthy. Note that H is written in a rotating body $\bar{x}, \bar{y}, \bar{z}$ coordinate frame moving relative to a star-fixed or laboratory frame.

34.1.2 Molecular States Inside and Out

Rotor angular momentum eigenfunctions can be expressed as continuous linear combinations of rotor angular position states $|\alpha\beta\gamma\rangle$ defined by Euler angles of the lab azimuth α , the polar angle β of body \bar{z} -axis, and the body azimuth, “gauge twist”, γ . The eigenfunctions are

$$\begin{aligned} \left| \begin{matrix} J \\ MK \end{matrix} \right\rangle &= \frac{\sqrt{2J + 1}}{8\pi^2} \int_0^{2\pi} d\alpha \int_0^\pi \sin\beta d\beta \\ &\quad \times \int_0^{2\pi} d\gamma D_{MK}^J{}^*(\alpha\beta\gamma) |\alpha\beta\gamma\rangle. \end{aligned} \quad (34.5)$$

Here, the rotor wave functions $D_{MK}^J{}^*$ are just the conjugates of the Wigner rotation matrices described in Sect. 34.3.1, and row and column indices M and K , respectively, are the lab and body z -components of angular momentum [6, 7]. It may surprise atomic physicists that polyatomic molecular angular momentum states have two kinds of polar quantum numbers. In addition to the usual lab component of momentum M associated with the lab coordinate α (usually α and β are labeled ϑ and φ), there is a body component K associated with the Euler coordinate γ , the body azimuthal angle of the lab z -axis relative to the body \bar{z} -axis.

The physics of atomic or diatomic angular momentum states has no internal or “body” structure, so the quantum number K is always zero. Unless one sets $K = 0$, the energy formula in Eq. (34.4) blows up for a point particle because z -inertia for a point is zero, and C is infinite. Also, the dimension of the angular momentum state multiplet of a given J is larger than the usual $(2J + 1)$ found in atomic or diatomic molecular physics. In polyatomic rotors, the number of states for each J is $(2J + 1)^2$, since both quantum numbers M and K range between $-J$ and $+J$. Also surprising, and this is a more pleasant surprise, is that the molecular rotor wave functions contain, as a special ($K = 0$) case, all

the usual atomic spherical harmonics Y_m^ℓ complete with correct normalization and phase, since

$$\sqrt{4\pi}Y_m^\ell(\vartheta, \varphi) = D_{m0}^{\ell*}(\varphi, \vartheta) \sqrt{2\ell + 1}. \quad (34.6)$$

This is part of a powerful symmetry principle: group representations are quantum wave functions, and symmetry analysis is an extension of Fourier analysis of plane e^{ikx} waves for cyclic C_n group translations as in Fourier's original work and holds for any group of symmetry operations. The usual Fourier coefficients are replaced by the D functions in the rotational Fourier transforms embodied by Eq. (34.5).

Molecular rotational analysis displays another important but little known aspect of symmetry analysis in general. For every group of symmetry operations, such as the external lab-based rotations familiar to atomic physics, there is an independent dual group of internal or body-based operations. The external symmetry of the environment or laboratory is independent of the internal symmetry of the molecular body, and all the operations of one commute with all those of the other. The molecular rotation group is thus written as an outer product $R(3)_{\text{LAB}} \otimes R(3)_{\text{BODY}}$ of the external and internal parts, and the degeneracy associated with this group's representations for a single J is $(2J + 1)^2$ as mentioned above. It is a special \otimes -product, however, since the J -number is shared.

The inversion or parity operator $\mathbf{I}(\mathbf{r} \rightarrow -\mathbf{r})$ can be defined to be the same for both lab and body frames. Including \mathbf{I} with the rotational group $R(3)$ gives the orthogonal group $O(3) = R(3) \otimes \{\mathbf{1}, \mathbf{I}\}$. If parity is conserved (e.g., no weak neutral currents), the fundamental molecular orthogonal group is $O(3)_{\text{LAB}} \otimes O(3)_{\text{BODY}}$.

How this symmetry breaks down and which levels split depends upon both the perturbative laboratory environment and

the internal molecular structure. A spherical top Hamiltonian is Eq. (34.1) with $A = B = C$. This has a full $O(3)_{\text{BODY}}$ (spherical) symmetry since it is just $B\mathbf{J} \cdot \mathbf{J}$. Given that the rotor is in an $O(3)_{\text{LAB}}$ laboratory (empty space), the original symmetry $O(3)_{\text{LAB}} \otimes O(3)_{\text{BODY}}$ remains intact, and the $(2J + 1)^2$ degeneracy is to be expected. However, a symmetric rotor in a lab vacuum has its internal symmetry broken down to $O(2)_{\text{BODY}}$ if $A = B \neq C$, and the energies given by Eq. (34.4) consist of internal quantum singlets for $K = 0$ and $\pm K$ doublets for $K \neq 0$. But each of these levels still has a lab degeneracy of $(2J + 1)$ if $O(3)_{\text{LAB}}$ is still in effect. So the $(2J + 1)^2$ level degeneracies are each split into multiplets of degeneracy $(2J + 1)$ and $2(2J + 1)$ for $K = 0$ and $K \neq 0$, respectively. The resulting levels are often labeled $\Sigma, \Pi, \Delta, \Phi, \Gamma, \dots$ in a somewhat inappropriate analogy with the atomic s, p, d, f, g, \dots labels of Bohr model electronic orbitals.

Only by perturbing the lab environment can one reduce the $O(3)_{\text{LAB}}$ symmetry and split the M degeneracies. For example, a uniform electric field would reduce the $O(3)_{\text{LAB}}$ to an $O(2)_{\text{LAB}}$, giving Stark splittings that consist of external quantum singlets for $M = 0$ and $\pm M$ doublets for $M \neq 0$. A uniform magnetic field would reduce the $O(3)_{\text{LAB}}$ to an $R(2)_{\text{LAB}}$, giving Zeeman splittings into external quantum singlets for each M . The analogy between atomic external field splitting and internal molecular rotational structure splitting is sometimes a useful one and will be used later.

34.1.3 Rigid Asymmetric Rotor Eigensolutions and Dynamics

The general case for the rigid rotor Hamiltonian in Eq. (34.1) has three unequal principal moments of inertia ($A \neq B \neq C$).

Fig. 34.1 $J = 10$ eigenvalue plot for symmetric rigid rotors ($A = 0.2, C = 0.6 \text{ cm}^{-1}, A < B < C$). Prolate and oblate RE surfaces are shown

Fig. 34.2 $J = 10$ rotational energy surface and related level spectrum for an asymmetric rigid rotator ($A = 0.2$, $B = 0.4$, $C = 0.6 \text{ cm}^{-1}$)

This is called the rigid asymmetric top Hamiltonian and provides a first approximation for modeling the rotation of low-symmetry molecules, such as H_2O . Also, a number of properties of its eigensolutions are shared by more complicated systems. The dynamics of an asymmetric top is quite remarkable, as demonstrated by tossing a tennis racquet in

the air, flat side up. The corresponding quantum behavior of such a molecule is also nontrivial.

Given the total angular momentum J , one may construct a $(2J + 1)$ -dimensional matrix representation of H using standard matrix elements of the angular momentum operators J_x , J_y , and J_z , as given in Chap. 2. The H matrix

connects states with $(2J + 1)$ -different body quantum numbers K ($-J \leq K \leq J$), but the matrix is independent of the lab quantum numbers M , so there are $(2J + 1)$ identical H matrices; one for each value of the lab quantum number M .

A plot of the 21 eigenvalues of Eq. (34.1) for $J = 10$ is shown in Fig. 34.1. Here, the constants are set to $A = 0.2 \text{ cm}^{-1}$ and $C = 0.6 \text{ cm}^{-1}$, while B is varied between $B = A$, which corresponds to a prolate symmetric top (an elongated cylindrical object) and $B = C$, which corresponds to an oblate symmetric top (a flattened cylindrical object or discus). For all B -values between those of A and C , the object is asymmetric.

The left-hand end ($A = B = 0.2 \text{ cm}^{-1}$, $C = 0.6 \text{ cm}^{-1}$) of the plot in Fig. 34.1 corresponds to a prolate symmetric top. The symmetric top level spectrum is given by Eq. (34.4). It consists of a lowest singlet state corresponding to $K = 0$ and an ascending quadratic ladder of doublets corresponding to $K = \pm 1, \pm 2, \dots, \pm J$. The right-hand end ($A = 0.2 \text{ cm}^{-1}$, $B = C = 0.6 \text{ cm}^{-1}$) of the plot corresponds to an oblate symmetric top with a descending quadratic ladder of levels, the $K = 0$ level being highest. Also, the internal K -axis of quantization switches from the body \bar{z} -axis for ($A = B = 0.2 \text{ cm}^{-1}$, $C = 0.6 \text{ cm}^{-1}$) to the body x -axis for ($A = 0.2 \text{ cm}^{-1}$, $B = C = 0.6 \text{ cm}^{-1}$). The lab M -degeneracy is invisible here but exists nevertheless.

For intermediate values of B , one has an asymmetric top level structure and, strictly speaking, no single axis of quantization. As a result, the eigenlevel spectrum is quite different. A detailed display of asymmetric top levels for the case ($A = 0.2 \text{ cm}^{-1}$, $B = 0.4 \text{ cm}^{-1}$, $C = 0.6 \text{ cm}^{-1}$) is given at the bottom of Fig. 34.2. They are shown to correspond to the semiclassical orbits discussed in Sect. 34.2. This example is the most asymmetric top, since parameter B has a value midway between the symmetric top limits of $B = A$ and $B = C$.

The twenty-one $J = 10$ asymmetric top levels are arranged into roughly ten asymmetry doublets and one singlet that resemble the symmetric top levels, except that the doublets are split by varying amounts, and the singlet is isolated from the other levels in the middle of the band instead of being crowded at the top or bottom. The doublet splittings are magnified in circles drawn next to the levels, and these indicate that the splitting decreases quasi exponentially with each doublet's separation from the central singlet.

An asymmetric doublet splitting is also called a superfine structure and can be viewed as the result of a dynamic tunneling process in a semiclassical model of rotation [8–10]. Such a model clarifies the classical-quantum correspondence for polyatomic rovibrational dynamics in general. It can also help to derive simple approximations for eigenvalues and eigenvectors.

34.2 Rotational Energy Surfaces and Semiclassical Rotational Dynamics

A semiclassical model of molecular rotation can be based upon what is called a rotational energy surface (RES) [7–14]. Examples of RES for an asymmetric top are shown in the previous Fig. 34.2 and for prolate and oblate symmetric tops in Fig. 34.1. Each surface is a radial plot of the classical energy derived from the Hamiltonian in Eq. (34.1) as a function of the polar direction of the classical angular momentum \mathbf{J} -vector in the “body” frame. The magnitude $|\mathbf{J}|$ of \mathbf{J} is fixed for each surface. Note that the \mathbf{J} -vector in the “lab” frame is a classical constant of the motion if there are no external perturbations. However, \mathbf{J} may gyrate considerably in the moving body frame, but its magnitude $|\mathbf{J}|$ stays the same in all frames for free rotation.

The RES differs from what is called a CE or constant energy surface, which is obtained by simply plotting $E = H = \text{const}$ in \mathbf{J} -space using Eq. (34.1). A rigid rotor CE surface is an ellipsoid covering a range of $|\mathbf{J}|$ -values at a single energy. A RES, on the other hand, is a spherical harmonic plot at a single $|\mathbf{J}|$ -value for a range of energies, so it is better for spectroscopic studies of fine structure, since one value of the rotational quantum number J corresponds to a multiplet of energy levels or transitions. The RES also shows loci of high and low energy rotations. Also, it has roughly the same shape as the body it represents, i.e., an RES is long in directions that its molecule is long (but vice versa for CE surfaces).

For a freely rotating molecule, the laboratory components of the classical total angular momentum \mathbf{J} are constant. If one chooses to let \mathbf{J} define the lab z -axis, then the direction of the \mathbf{J} -vector in the body frame is given by polar and body azimuthal coordinates β and γ , which are the second and third Euler angles, respectively. (It is conventional to use the negatives $-\beta$ and $-\gamma$ as polar coordinates, but this will not be necessary here.) Then the body components of the \mathbf{J} -vector are written

$$\begin{aligned} J_x &= |\mathbf{J}| \sin \beta \cos \gamma, & J_y &= |\mathbf{J}| \sin \beta \sin \gamma, \\ J_z &= |\mathbf{J}| \cos \beta. \end{aligned} \quad (34.7)$$

Here, the magnitude of the quantum value $|\mathbf{J}| = \sqrt{J(J+1)} \cong J + \frac{1}{2}$.

Substituting this into the Hamiltonian in Eq. (34.1) gives an expression for the general rigid rotor RES radius in polar coordinates

$$\begin{aligned} E(\beta, \gamma) &= \langle H \rangle \\ &= J(J+1) \\ &\quad \times [\sin^2 \beta (A \cos^2 \gamma + B \sin^2 \gamma) + C \cos^2 \beta]. \end{aligned} \quad (34.8)$$

The prolate symmetric top ($A = B < C$) expression is independent of azimuthal angle γ ,

$$E(\beta) = \langle H \rangle = J(J+1)[B + (C-B)\cos^2\beta]. \quad (34.9)$$

The three-dimensional plots of these expressions are shown in Figs. 34.1 and 34.2.

The RES has topography lines of constant energy ($E = \text{const}$) that are the intersection of the RES (constant $|J|$) with spheres of constant energy. The topography lines are allowed classical paths of the angular momentum J -vector in the body frame, since these paths conserve both energy and momentum.

The trajectories in these figures are special ones. They are the quantizing trajectories for total angular momentum $J = 10$. For the prolate symmetric top, the quantizing trajectories have integral values for the body z -component K of angular momentum. Using a Dirac vector model, angular momentum vectors trace out a cone of altitude K and slant height $|J| = \sqrt{J(J+1)}$. Quantizing polar angles are given by

$$\begin{aligned} \Theta_K^J &= \cos^{-1} \frac{K}{\sqrt{J(J+1)}} \\ (K &= J, J-1, \dots, -J). \end{aligned} \quad (34.10)$$

These are the latitude angles of the paths on the RES in Fig. 34.1 for $K = 10, 9, 8, \dots, -10$. (For the oblate RES, the angles are relative to the x -axis.) If $\beta = (\Theta_K^J)$ is substituted into the symmetric top RES in Eq. (34.9), the result is

$$E(\Theta_K^J) = J(J+1)B + (C-B)K^2, \quad (34.11)$$

which is precisely the symmetric top eigenvalue in Eq. (34.4). The quantizing paths are circles lying at the intersections of the Dirac angular momentum cones and the RES. Angle (Θ_K^J) is a measure of the angular momentum uncertainty ΔJ_x or ΔJ_y transverse to the z -axis of quantization. Clearly, $K = \pm J$ states have minimum uncertainty.

For the asymmetric top, the classical paths (which conserve both $|J|$ and E) fall into one of two types. First, there are those pairs of equal-energy orbits that go around the hills on the plus or minus end of the body z -axis and correspond to the $\pm K$ pairs of levels in the upper half of the level spectrum drawn in Fig. 34.2. Then there are the pairs of levels belonging to the equal-energy orbits in either of the two valleys surrounding the body x -axis, associated with the pairs of levels in the lower half of the level spectrum. Different eigensolutions occupy different geography.

The upper pairs of paths are seen to be distorted versions of the prolate top orbits seen on the left-hand side of Fig. 34.1, while the lower pairs are distorted versions of the oblate top orbits seen on the right-hand side of Fig. 34.1. The distortion makes J_z deviate from a constant K -value and corresponds to K -mixing in the quantum states. This also shows that one needs to consider more than one axis of quan-

tization; the prolate-like paths are based on the z -axis, while the oblate-like paths belong to the body x -axis.

The two types of orbits, x and y , are separated by a so-called separatrix curve crossing containing saddle points on either side of the body y -axis. In the example shown in Fig. 34.2, the separatrix is associated with a single level that separates the upper and lower energy doublets. The doublets that are closer to the separatrix level are split more than those farther away. Apart from the splitting, the energy levels can be obtained by generalized Bohr quantization of the classical paths on the RES. The quantization condition is,

$$\oint J_z d\gamma = K \oint J_z d\gamma = K, \quad (34.12a)$$

where

$$J_z = \sqrt{\frac{J(J+1)(C\cos^2\gamma + B\sin^2\gamma) - E}{(C\cos^2\gamma + B\sin^2\gamma) - A}} \quad (34.12b)$$

follows from Eqs. (34.7) and (34.8). The resulting E_K -values are obtained by iteration.

The doublet or superfine splitting is a quantum effect that may be associated with tunneling between orbits that would have had equal energies E_K in the purely classical or semiclassical model. Approximate tunneling rates are integrals over the saddle point between each pair of equal-energy quantizing paths. The K -th rate, or amplitude, is

$$S_K = \nu_K e^{-P_K}, \quad (34.13)$$

where

$$\begin{aligned} P_K &= i \int_{\gamma^-}^{\gamma^+} d\gamma \\ &\times \sqrt{\frac{J(J+1)(C\cos^2\gamma + B\sin^2\gamma) - E_K}{(C\cos^2\gamma + B\sin^2\gamma) - A}} \end{aligned} \quad (34.14)$$

is the saddle path integral between the points of closest approach, γ^+ and γ^- , and ν_K is the classical precession frequency or quantum level spacing around energy level E_K . Since there are two tunneling paths, amplitude S_K is doubled in a tunneling Hamiltonian matrix for the K -th semiclassical doublet of z and $-z = \bar{z}$ paths,

$$\langle H \rangle_K = \begin{pmatrix} E_K & 2S_K \\ 2S_K & E_K \end{pmatrix} \begin{pmatrix} |z\rangle \\ |\bar{z}\rangle \end{pmatrix}. \quad (34.15)$$

The resulting tunneling energy eigensolutions are given in Table 34.1.

Table 34.1 Tunneling energy eigensolutions

Eigenvectors	$ z\rangle$	$ \bar{z}\rangle$	Eigenvalues
$ A\rangle$	1	1	$E^A(K) = E_K + 2S_K$
$ B\rangle$	1	-1	$E^B(K) = E_K - 2S_K$

A - or B -states correspond to symmetric and antisymmetric combinations of waves localized on the two semiclassical paths. Rotational symmetry is considered in Sect. 34.3.

The total doublet splitting is $4S_K$ and decreases exponentially with the saddle point integral in Eq. (34.14). Superfine A – B splittings in Fig. 34.2 range from several GHz near the separatrix to only 26 kHz for the highest- K doublets at the band edges.

Meanwhile, the typical interdoublet level spacing or classical precessional frequency is about 150 GHz for the $J = 10$ levels shown in Fig. 34.2. This K -level spacing is called rotational fine structure splitting and is present in the symmetric top case, as well. (Superfine splitting of the symmetric top doublets is exactly zero, since they have $O(2)_{\text{BODY}}$ symmetry if $A = B$ or $B = C$ and tunneling amplitudes cancel.)

Classical precession of \mathbf{J} in the body frame follows a “left-hand” rule quite like what meteorologists use to determine Northern Hemisphere cyclonic rotation. A left “thumbs-down” or “low” has anticlockwise precession, as does an oblate rotor valley, but a prolate RES “high” supports clockwise motion just like a weather “high”.

Finally, consider the spacing between adjacent J -levels, which is called rotational structure, in a spectrum. This spacing is

$$E(J, K) - E(J - 1, K) = 2BJ, \quad (34.16)$$

according to the symmetric top energy formulas in Eq. (34.4). For this example, $2BJ$ is about 10 cm^{-1} or 300 GHz. It corresponds to the actual rotation frequency of the body. It is the only kind of rotational dynamics or spectrum that is possible for a simple diatomic rotor. However, a diatomic molecule may have internal electronic or nuclear spin rotation which gives an additional fine structure, as discussed later [1, 6, 15].

To summarize, polyatomic molecules can be expected to exhibit all three types of rotational motion and spectra. Noted above were three types of motion (from faster to slower): *rotational*, *precessional*, and *precessional tunneling*. These were related to three kinds of spectral structure (from coarser to finer spectra): *rotational* structure, *fine* structure, and *superfine structure*, respectively. Again, this neglects internal rotational and spin effects that can have abnormally strong rotational resonance coupling due to the superfine structure [9, 16]. Examples of this are discussed further along in this chapter.

34.3 Symmetry of Molecular Rotors

Molecular rotational symmetry is most easily introduced using examples of rigid rotors. Molecular rotor structures may have more or less internal molecular symmetry depending on how their nuclei are positioned relative to one another in the

body frame. A molecule’s rotational symmetry is described by one of the elementary rotational point symmetry groups. These are the n -fold axial cyclic groups C_n and polygonal dihedral groups D_n ($n = 1, 2, \dots$), the tetrahedral group T , the cubic-octahedral group O , or the icosahedral group Y . All other point groups, such as C_{nv} , T_d , and O_h , are one of these in combination with the inversion operation $\mathbf{I}(\mathbf{r} \rightarrow -\mathbf{r})$. Each of these groups consists of operations that leave at least one point (origin) of a structure fixed while mapping identical atoms or nuclei into each other in such a way that the structure ends up looking the same as it did before the operation. The point groups map onto subgroups of the nuclear permutation groups [17].

In other words, molecular symmetry is based upon one of the most fundamental (and mysterious!) properties of atomic physics: the absolute identity of all atoms or, more precisely, nuclei of a given atomic number Z and mass number A . It is the identity of the so-called “elementary” electronic and nucleonic constituent particles that underlies the symmetry.

A quite mysterious axiom of modern physics is the Pauli principle that states: *All half-integer spin particles are antisymmetrized with every other one of their kind in the universe.* The Pauli–Fermi antisymmetry and related Bose–Einstein symmetrization principle determine much of molecular symmetry and dynamics just as the Pauli exclusion principle is fundamental to atomic and molecular electronic structure.

34.3.1 Asymmetric Rotor Symmetry Analysis

For an asymmetric rigid rotor, any rotation that interchanges x -, y -, or z -axes of the body cannot possibly be a symmetry, since all three axes are assumed to have different inertial constants. This restricts one to consider only 180° rotations about the body axes, and these are the elements of the rotor groups C_2 and D_2 .

The two symmetry types for C_2 are even (denoted A or 0_2) and odd (denoted B or 1_2) with respect to a 180° rotation. For D_2 , which is just $C_2 \otimes C_2$, the four symmetry types are even-even (denoted A_1), even-odd (denoted A_2), odd-even (denoted B_1), and odd-odd (denoted B_2) with respect to 180° rotations about the y and x -axes, respectively. (The z -symmetry is determined by a product of the other two since $\mathbf{R}_z = \mathbf{R}_x \mathbf{R}_y$.) This is summarized in the character Tables 34.2 and 34.3.

The rotational energy surface for the rigid rotor shown in Fig. 34.2 is invariant under 180° rotations about each of the three body axes. Therefore, its Hamiltonian symmetry is

Table 34.2 Character table for symmetry group C_2

C_2	1	\mathbf{R}
A	1	1
B	1	–1

Table 34.3 Character table for symmetry group D_2

D_2	1	R_x	R_y	R_z
A_1	1	1	1	1
A_2	1	-1	1	-1
B_1	1	1	-1	-1
B_2	1	-1	-1	1

D_2 , and its quantum eigenlevels must correspond to one of the four types listed under D_2 in Table 34.3. The D_2 symmetry labels are called rotational (or, in general, rovibronic) species of the molecular state. The species label the symmetry of a quantum wave function associated with a pair of C_2 symmetric semiclassical paths.

The classical J -paths come in D_2 symmetric pairs, but each individual classical J -path on the rigid rotor RES has a C_2 symmetry that is a subgroup of D_2 . Each path in the valley around the x -axis is invariant under just the 180° rotation around the x -axis. This is $C_2(x)$ symmetry. The other member of its pair that goes around the negative x -axis also has this local $C_2(x)$ symmetry. The combined pair of paths has the full D_2 symmetry, but classical mechanics does not permit occupation of two separate paths. Such co-occupation is a completely quantum effect.

Similarly, each individual J -path on the hill around the z -axis is invariant under just the 180° rotation around the z -axis, so it has $C_2(z)$ symmetry as does the equivalent path around the negative z -axis. Only the separatrix has the full D_2 symmetry, since its pairs are linked up on the y -axis to form the boundary between the x and z paths. No J -paths encircle the unstable y -axis since it is a saddle point.

Fig. 34.3 Tables of correlations between D_2 symmetry species and the even (O_2) and odd (I_2) symmetric species of subgroups (a) $C_2(x)$, (b) $C_2(y)$, and (c) $C_2(z)$

Each classical J -path near the x or z -axes belongs to a particular K -value through semiclassical quantization conditions in Eqs. (34.12a) and (34.12b). Depending upon whether the K -value is even (denoted by O_2) or odd (denoted by I_2), the corresponding K -doublet will be correlated with a pair of D_2 species as shown in the columns of the correlation tables in Fig. 34.3. These three correlation tables give the axial 180° rotational symmetry of each D_2 species for rotation near each body axis x , y , and z , respectively, but only the stable rotation axes x and z support stable path doublets for this Hamiltonian in Eq. (34.1).

For example, consider $K = 10$ paths, which lie lowest in the x -axis valleys. Since $K = 10$ is even (O_2), it is correlated with an A_1 and B_1 superfine doublet (see the O_2 column of the $C_2(x)$ table). On the high end near the z -axis hilltop, $K = 10$ gives rise to an A_1 and B_2 doublet (see the O_2 column of the $C_2(z)$ table). All the doublets in Fig. 34.2 may be assigned in this way.

34.4 Tetrahedral-Octahedral Rotational Dynamics and Spectra

The highest symmetry rigid rotor is the *spherical top* for which the three inertial constants are equal ($A = B = C$). As was previously mentioned the spherical top Hamiltonian

$$H = B \mathbf{J} \cdot \mathbf{J}$$

has full $R(3)_{\text{LAB}} \otimes R(3)_{\text{BODY}}$ symmetry. Inversion parity symmetry is $O(3)_{\text{LAB}} \otimes O(3)_{\text{BODY}}$. In any case, the J -levels

are $(2J + 1)^2$ -fold degenerate. The resulting $BJ(J + 1)$ energy expression is the first approximation for molecules that have regular polyhedral symmetry of, for example, a tetrahedron (CF_4), cube (C_6H_6), octahedron (SF_6), dodecahedron or icosahedron ($\text{C}_{20}\text{H}_{20}$, $\text{B}_{12}\text{H}_{12}$, or C_{60}) [18, 19] discussed in later sections. Rigid regular polyhedra have isotropic or equal inertial constants and rotate just like they were perfectly spherical distributions of mass.

No molecule can really have spherical $O(3)_{\text{BODY}}$ symmetry since even molecules of the highest symmetry are made of a finite number of nuclear mass points. Evidence of octahedral or tetrahedral symmetry shows up in fine structure splittings analogous to those for asymmetric tops. However, spherical top fine structure is due to symmetry breaking caused by anisotropic or tensor rotational distortion, and so they are called semirigid rotors.

34.4.1 Semirigid Octahedral Rotors and Centrifugal Tensor Hamiltonians

The lowest-order tensor centrifugal distortion perturbation has the same form for both tetrahedral and octahedral molecules. It is simply a sum of fourth powers of angular momentum operators given in the third term of

$$H = B|J|^2 + D|J|^4 + 10t_{044} \times \left[J_x^4 + J_y^4 + J_z^4 - (3/5)J^4 \right]. \quad (34.17)$$

The first two terms are the scalar rotor energy and the scalar centrifugal energy. The tensor term includes the scalar $(3/5)J^4$ to preserve the center of gravity of the tensor level splitting. *Hecht* [20] first used this type of semirigid rotor Hamiltonian in the study of methane (CH_4) spectra.

The scalar terms do not reduce the symmetry or split the levels, but the tensor (t_{044}) term breaks the molecular symmetry from $O(3)_{\text{LAB}} \otimes O(3)_{\text{BODY}}$ to a lower symmetry subgroup $O(3)_{\text{LAB}} \otimes T_d_{\text{BODY}}$, or $O(3)_{\text{LAB}} \otimes O_h_{\text{BODY}}$ and splits the $(2J + 1)^2$ -fold degeneracy into intricate fine structure patterns that are analogous to cubic crystal field splitting of atomic orbitals. The first calculations of the tensor spectrum were done by direct numerical diagonalization [20–23]. As a result, many subtle symmetry properties were missed. Semiclassical analysis [24], described in the following sections, exposes these properties.

34.4.2 Octahedral and Tetrahedral Rotational Energy Surfaces

By substituting in Eq. (34.7) and plotting the energy as a function of body polar angles β and γ one obtains a rotational energy (RE) surface, two views of which are shown

in Fig. 34.4. Here, the tensor term is exaggerated in order to exhibit the topography clearly. (In $(n = 0)$ SF_6 , the t_{044} coefficient is only about 5.44 Hz, while the rotational constant is $B = 0.09 \text{ cm}^{-1}$. The t_{244} coefficient of $(n = 1)$ SF_6 is much greater.)

A positive tensor coefficient ($t_{044} > 0$) gives an octahedral-shaped RES, as shown in Fig. 34.4. This is appropriate for octahedral molecules since they are the least susceptible to distortion by rotations around the x , y , and z -axes containing the strong radial bonds. Thus, rotational energy is highest for a \mathbf{J} -vector near one of six body axes $(\pm 1, 0, 0)$, $(0, \pm 1, 0)$, or $(0, 0, \pm 1)$, i.e., one of the six RES hills in Fig. 34.4.

However, if the \mathbf{J} -vector is set in any of the eight interaxial directions $(\pm 1, \pm 1, \pm 1)$, the centrifugal force will bend the weaker angular bonds more easily, raise the molecular inertia, and lower the rotational energy to that of one of the eight valleys on the RES in Fig. 34.4.

A negative tensor coefficient ($t_{044} < 0$) gives a cubic shaped RES. Usually, this is appropriate for cubic and tetrahedral molecules since they are most susceptible to distortion by rotations around the x , y , and z -axes that lie between the strong radial bonds on the cubic diagonals. Instead of six hills and eight valleys, one finds six valleys and eight hills on the cubic RES. Both freon CF_4 and cubane C_8H_8 are examples of this type of topology.

It should be noted that a semirigid tetrahedral rotor may have the same form of rotational Hamiltonian and RES as a cubic rotor. The four tetrahedral atomic sites are in the same directions as four of the eight cubic sites. The other four cubic sites form an inverted tetrahedron of the same shape.

If only tetrahedral symmetry was required, the Hamiltonian might have third-order terms like $J_x J_y J_z$. However, such terms do not have the time-reversal symmetry that makes energy the same for \mathbf{J} and $-\mathbf{J}$, so that rotational sense does not matter. So simple rotor RES have inversion symmetry even if their molecules do not. Compound rotors containing spins or other rotors may have “lopsided” pairs of RES as shown in Sect. 34.6.

34.4.3 Octahedral and Tetrahedral Rotational Fine Structure

An example of rotational fine structure for angular momentum quantum number $J = 30$ is shown in Fig. 34.4. The levels consist mainly of clusters of levels belonging to the octahedral symmetry species A_1 , A_2 , E , T_1 , or T_2 . The characters of these species are the following Table 34.4. (The tetrahedral T_d group has a similar table where T_1 and T_2 are often labeled F_1 and F_2 .)

The first column gives the dimension or degeneracy of each species: A_1 and A_2 are singlets, E is a doublet, and T_1 and T_2 are triplets. These species form two clusters (A_1, T_1, T_2, A_2)

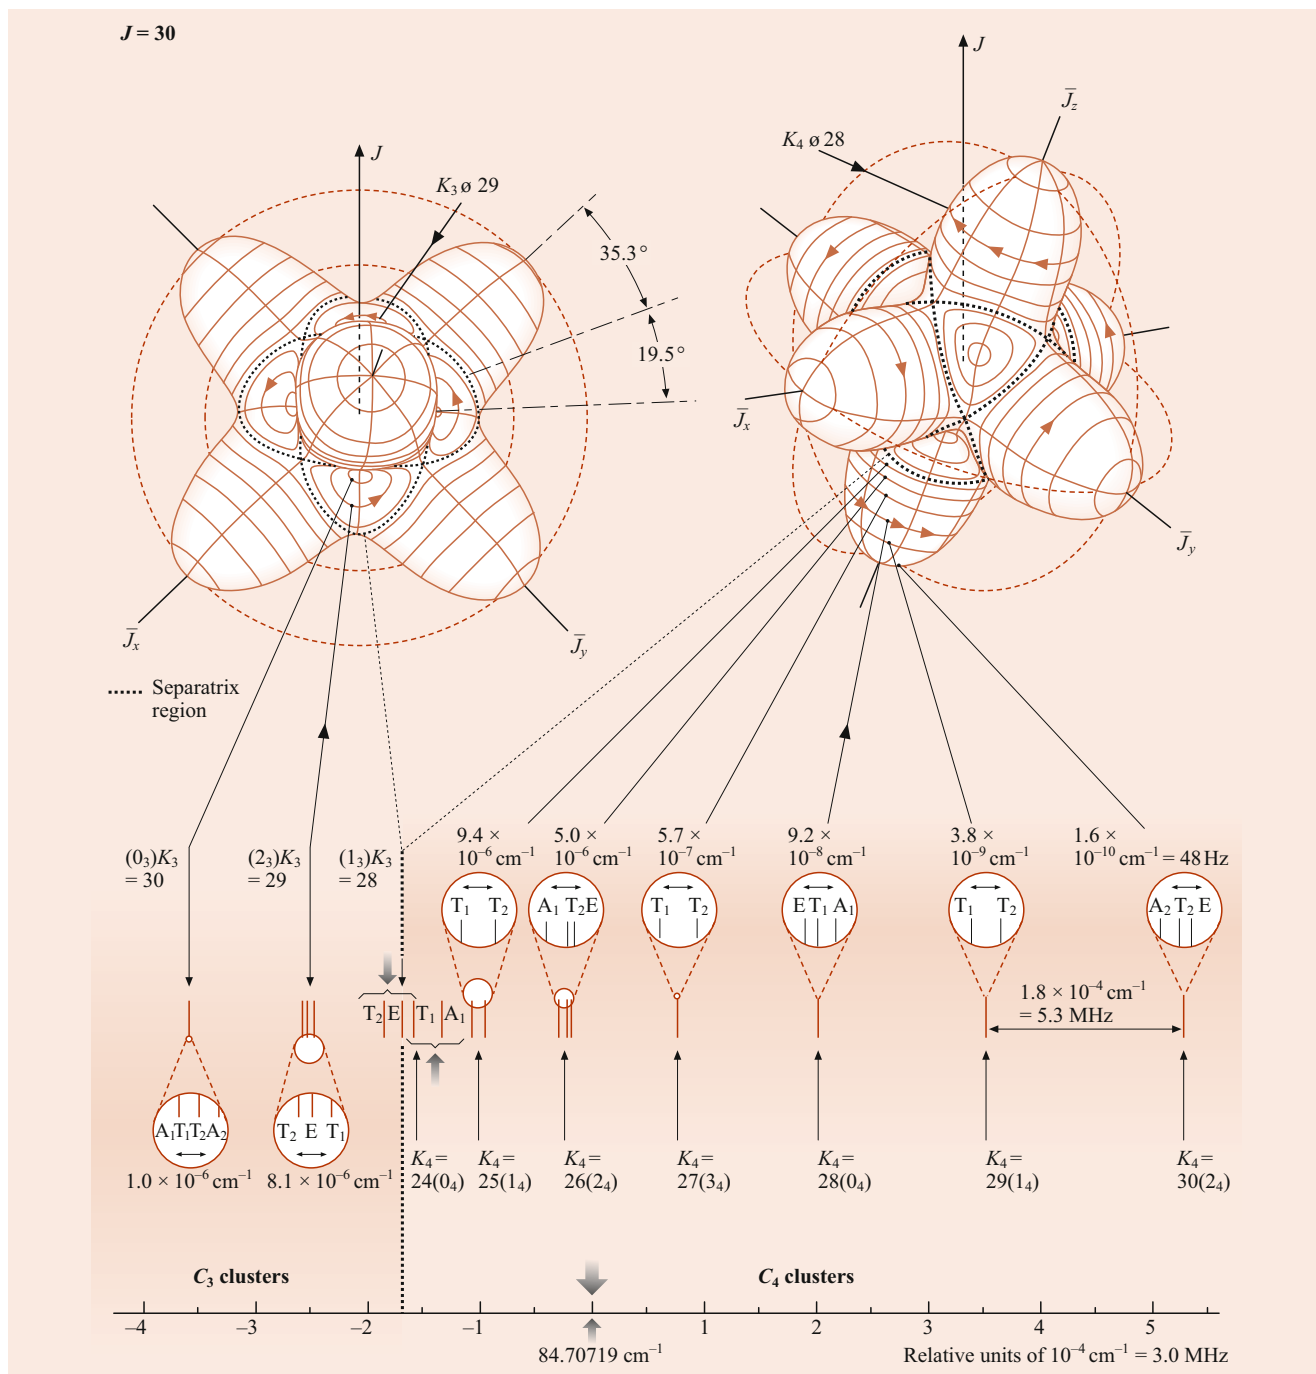

Fig. 34.4 $J = 10$ rotational energy surface related level spectrum for a semirigid octahedral or tetrahedral rotor

Table 34.4 Character table for symmetry group O

O	0°	120°	180°	90°	180°
A_1	1	1	1	1	1
A_2	1	1	1	-1	-1
E	2	-1	2	0	0
T_1	3	0	-1	1	-1
T_2	3	0	-1	-1	1

and (T_2, E, T_1) on the low end of the spectrum and six clusters (T_1, T_2) , (A_2, T_2, E) , (T_1, T_2) , (E, T_1, A_1) , (T_1, T_2) , and (A_2, T_2, E) on the upper part of the spectrum. (Right-hand side of Fig. 34.4.) Note that the total dimension or (near) degeneracy for each of the two lower clusters is eight: $(1 + 3 + 3 + 1)$ and $(3 + 2 + 3)$, while the upper clusters each have a sixfold (near) degeneracy: $(3 + 3)$, $(1 + 3 + 2)$, etc.

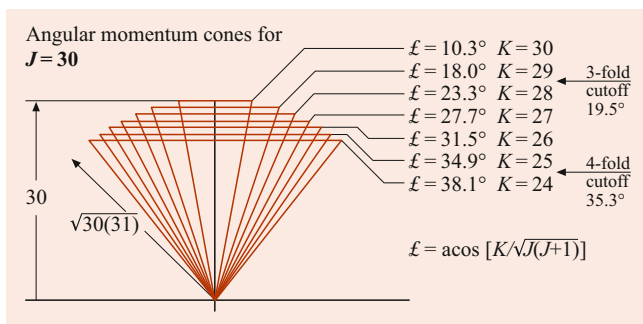

Fig. 34.5 $J = 30$ angular momentum cone half angles and octahedral cutoffs

Each of the two lower eightfold clusters can be associated with a semiclassical quantizing path in an RES valley as shown in Fig. 34.4. The eightfold dimension or (near) degeneracy occurs because each quantizing path is repeated eight times; once in each of the eight identical valleys. Similarly, the sixfold cluster dimension $((3 + 3), (1 + 3 + 2), \dots \text{etc.})$ occurs because there are six identical hills, and each quantizing path is repeated six times around the surface.

The majority of the paths lie on the hills because the hills are bigger than the valleys. The hills subtend a half angle of 35.3° to the separatrix, while the valleys only have 19.5° . To estimate the number of paths or clusters in hills or valleys, one may calculate the angular momentum cone angles for $J = 30$ using Eq. (34.10). The results are displayed in Fig. 34.5. The result is consistent with the spectrum

in Fig. 34.4. Only the two highest K -values of $K = 30$ and 29 have cones small enough to fit in the valleys, while the six states of $K = 30, 29, 28, 27, 26,$ and 25 can fit onto the hills.

The angular momentum cone formula also provides an estimate for each level cluster energy. The estimates become more accurate as K increases (approaching J) so the uncertainty angle decreases. Higher- K paths are more nearly circular and, therefore, more nearly correspond to symmetric top quantum states of pure K . The paths on octahedral RES are more nearly circular for a given K than are those on the asymmetric top RES, and so one can better approximate octahedral rotor states with those of a symmetric top.

34.4.4 Octahedral Superfine Structure

The octahedral RES has many more local hills and valleys and corresponding types of semiclassical paths than are found on the rigid asymmetric top RES. The tunneling between multiple paths gives an octahedral superfine structure that is more complicated than the asymmetric top doublets. Still, the same symmetry correlations and tunneling mechanics apply.

First, the octahedral symmetry must be correlated with the local symmetry of the paths on the hills and in the valleys. The hill paths have a C_4 symmetry, while the valley paths have a local C_3 symmetry. This is seen most clearly for the low- K paths near the separatrix that are less circular. The C_3

Fig. 34.6 Tables of correlations between 0 symmetry species and the cyclic axial symmetry species (K_p means $K \bmod p$) of subgroups (a) C_3 , (b) C_2 , and (c) C_4

and C_4 correlations are given in Fig. 34.6 with corresponding sketches of molecular rotation for each type of path.

To find the octahedral species associated with a $K_3 = 30$ path in a C_3 valley one notes that 30 is 0 modulo 3. Hence, the desired species are found in the 0_3 column of the C_3 correlation table. One finds (A_1, A_2, T_1, T_2) , and this is what appears (not necessarily in that order) on the extreme lower left-hand side of Fig. 34.4. Similarly, the species (A_2, E, T_2) for a $K_4 = 30$ path on top of a C_4 hill are found in the 2_4 column of the C_4 correlation table since 30 is 2 modulo 4, and these appear on the other side of Fig. 34.4. Similarly, clusters (T_1, T_2) for $K_4 = 29$ and (A_1, E, T_1) for $K_4 = 28$ follow.

A multiple path tunneling calculation analogous to the one for rigid rotors can be applied to approximate octahedral superfine splittings. Consider the cluster (A_1, E, T_1) for $K_4 = 28$, for example. One may label six C_4 -symmetric paths located on octahedral vertices on opposite sides of the $\pm x$ -, $\pm y$ -, and $\pm z$ -axes as on the right-hand side of matrix H in Eq. (34.18), which is the tunneling matrix between the six paths

$$\langle H \rangle_{K_4=28} = \begin{pmatrix} H & 0 & S & S & S & S \\ 0 & H & S & S & S & S \\ S & S & H & 0 & S & S \\ S & S & 0 & H & S & S \\ S & S & S & S & H & 0 \\ S & S & S & S & 0 & H \end{pmatrix} \begin{matrix} |x\rangle \\ |\bar{x}\rangle \\ |y\rangle \\ |\bar{y}\rangle \\ |z\rangle \\ |\bar{z}\rangle \end{matrix} \quad (34.18)$$

Here, the tunneling amplitude S is assumed between nearest neighbor octahedral vertices but is assumed to be zero between antipodal vertices. The eigenvectors and eigenvalues for this matrix are given in Table 34.5. K -cone polar uncertainty angles for $J = 30$ are listed in Fig. 34.5.

This predicts that the triplet (T_1) level should fall between the singlet (A_1) and the doublet (E) levels, and the singlet-triplet spacing ($4S$) should be twice the splitting ($-2S$) between the triplet and doublet. This 2:1 ratio is observed in the (E, T_1, A_1) and (A_2, T_2, E) clusters, which can be resolved and in numerical calculation as well [20–23].

The tunneling amplitudes can be calculated by a separatrix path integral analogous to the asymmetric top formula in Eq. (34.13) [10, 11]. As shown in Fig. 34.4, the tunneling rates or superfine splittings near the separatrix are ≈ 1 MHz, which is only slightly slower than the classical precessional

frequency. However, as K approaches J on the hilltops, the tunneling rate slows quasi exponentially to ≈ 3 mHz, that is by a factor of about 10^{-9} .

34.5 High-Resolution Rovibrational Structure

A display of spectral hierarchy for higher and higher resolution is shown in Fig. 34.7 for the 630 cm^{-1} or $16\text{ }\mu\text{m}$ bands of CF_4 [18, 19, 24, 25]. This summarizes the possible rovibrational spectral structures and places them in a larger context. The ν_4 resonance in part (a) corresponds to a dipole active $n_4 = 0 \rightarrow 1$ vibrational transition and is just one of many vibrational structures to study. The $P(54)$ sideband resonance in part (b) corresponds to a $(J = 54) \rightarrow (J - 1)$ rotational transition, and is just one of hundreds of rotational structures to study within the ν_4 bands.

Each band is like a Russian doll; it contains structure within structure within structure down to the resolution of few tens of Hz. Examples of rotational fine and superfine structures described in Sect. 34.4 are shown in Fig. 34.7c,d, but even more resolution is needed to see the hyperfine structure in Fig. 34.7e [26]. Such extreme resolution was reached with a CO_2 saturation absorption spectrometer [27, 28]. The $10\text{ }\mu\text{m}$ bands of SF_6 and SiF_4 have been studied in this manner, the latter being similar to CF_4 [26].

34.5.1 Tetrahedral Nuclear Hyperfine Structure

High-resolution spectral studies of SiF_4 showed unanticipated effects involving the four fluorine nuclear spin and magnetic moments giving rise to associated hyperfine states. First, and this was well known, the Pauli principle restricts the nuclear spin multiplicity associated with each of the rotational symmetry species in much the same way that atomic $L - S$ coupled states ^{2S+1}L have certain spin multiplicities $(2S + 1)$ allowed for a given orbital L species involving two or more equivalent electrons. Secondly, and this was not so well known, since superfine splittings can easily be tiny, different spin species can end up close enough that hyperfine interactions, however small, can cause strongly resonant mixing of the normally inviolate species. Finally, one gets to witness a pure and simple form of spontaneous symmetry breaking in which otherwise equivalent nuclei fall into different subsets due to quantum rotor dynamics.

Connecting nuclear spin to rotational species is done by correlating the full permutation symmetry (S_n for XY_n molecules) with the full molecular rotation and parity symmetry [$O(3)_{\text{LAB}} \otimes T_{d\text{BODY}}$ for CF_4 molecules or $O(3)_{\text{LAB}} \otimes O_{h\text{BODY}}$ and for SF_6]. For four spin-1/2 nuclei, the Pauli principle allows a total spin of $I = 2$ having multiplicity of five ($2I + 1 = 5$) for (J^+, A_2) or (J^-, A_1) species, but ex-

cludes (J^-, A_2) or (J^+, A_1) species altogether. Pauli allowed spin for (J^+, T_1) or (J^-, T_2) species is $I = 1$ with a multiplicity of three, but there are no allowed (J^+, T_2) or (J^-, T_1) species. Finally, both (J^+, E) and (J^-, E) belong to singlet spin $I = 0$ and are singlet partners to an inversion doublet. (None of the other species can have both + and – parity.)

The E inversion doublet is analogous to the doublet in NH_3 that is responsible for the ammonia maser. However, NH_3 inversion is not feasible in CF_4 or SiF_4 , and so the splitting of the E doublet in these molecules is due to hyperfine resonance [29] and analyzed by unitary symmetry [9, 16] given below and in later sections.

The Pauli analysis gives the number of hyperfine lines that each species would exhibit if it were isolated and resolved, as shown in the center of Fig. 34.7e. The rotational singlets A_1 and A_2 give five lines each, the rotational triplets T_1 and T_2 are spin triplets, and the rotational doublet E is a spin singlet but an inversion doublet. If the hyperfine structure of a given species A_1 , A_2 , T_1 , T_2 , or E is not resolved, then their line heights are proportional to their total spin weights of 5, 5, 3, 3, and 2, respectively.

If the unresolved species are clustered, then the total spin weights of each will add to give a characteristic cluster line height. The line heights of the C_4 clusters (T_1 , T_2), (A_2 , T_2 , E), (T_1 , T_2), (E , T_1 , A_1) are 6, 10, 6, 10, respectively. The line heights of the C_3 clusters (A_1 , T_1 , T_2 , A_2), (T_1 , E , T_2), (T_1 , E , T_2) are 16, 8, 8, respectively. This is roughly what is seen in the $P(54)$ spectrum in Fig. 34.7c.

34.5.2 Superhyperfine Structure and Spontaneous Symmetry Breaking

Superfine cluster splittings ($2S$, $4S$, etc.) are proportional to the J -precessional tunneling or “tumbling” rates between equivalent C_3 or C_4 symmetry axes that decrease with increasing K_3 or K_4 . At some point the superfine splittings decrease to less than the hyperfine splittings that are meanwhile actually increasing with K . The resulting collision of superfine and hyperfine structure has been called superhyperfine structure or Case 2 clusters. The following is a rough sketch of the phenomenology of this very complex spectra, using the results of Pfister [26].

As long as the tunneling rates are a megahertz or more, the nuclear spins will tend to average over spherical top motion. The spins couple into states of good total nuclear spin I , which, in turn, couple weakly with the overall angular momentum and with well-defined rovibrational species A_1 , A_2 , T_1 , T_2 , or E as described above. The resulting coupling is called Case 1. It is analogous to LS -coupling in atoms.

Stick figures for two examples of spectra observed by Pfister [26] are shown in Fig. 34.8a,b. The first Case 1 cluster, shown in Fig. 34.8a, is a C_4 type (0_4) cluster (A_1 , T_1 , E), which was solved in Table 34.6. The other Case 1 cluster, shown in Fig. 34.8b, is a C_3 type ($\pm 1_3$) cluster (T_1 , E , T_2) (recall C_3 correlations in Fig. 34.3). They are similar to the corresponding sketches shown in Fig. 34.7e. One notable difference is that the inversion doublet shows little or no splitting in the (A_1 , T_1 , E) cluster but does split in the (T_1 , E , T_2) cluster.

When the tunneling rates fall below 10 or 20 kHz, the angular momentum could remain near a particular C_3 or C_4 symmetry axis for a time that is longer than the nuclear spin precession rates. Spin precession rates and the corre-

Table 34.6 Hyperfine spin states

$I_z = 2$	$I_z = 1$	$I_z = 0$	$I_z = -1$	$I_z = -2$
		$\begin{array}{c} \uparrow \uparrow \\ \downarrow \downarrow \end{array}$		
		$\begin{array}{c} \uparrow\downarrow \uparrow\downarrow\rangle \\ \downarrow\uparrow \downarrow\uparrow\rangle \end{array}$		
	$ \uparrow\downarrow \uparrow\uparrow\rangle$	$ \downarrow\downarrow \uparrow\uparrow\rangle$	$ \downarrow\downarrow \uparrow\downarrow\rangle$	
$ \uparrow\uparrow \uparrow\uparrow\rangle$	$ \uparrow\uparrow \uparrow\downarrow\rangle$	$ \uparrow\uparrow \downarrow\downarrow\rangle$	$ \uparrow\downarrow \downarrow\downarrow\rangle$	$ \downarrow\downarrow \downarrow\downarrow\rangle$

sponding hyperfine splittings are on the order of 50 kHz, and increasing with K . Hence, there would be plenty of time for each of the nuclear spins to align or antialign with the C_3 or C_4 symmetry axes of rotation. The resulting coupling is called Case 2 coupling, and the resulting spectrum resembles that of an NMR scan of the nuclei with the magnetic field provided by the molecule itself through its own body frame rotation.

If SiF_4 rotates uniformly about one C_4 symmetry axis, then all four F nuclei occupy equivalent positions that are the same distance on average from the rotation axis and experience the same local magnetic fields. The molecule is like a paired diatomic F_2 - F_2 rotor with each one symmetrized or antisymmetrized so as to make the whole state symmetric. Table 34.6 shows the spin-1/2 base states listed horizontally by total projection I_z of nuclear spins on the C_4 axis. Horizontal arrays ($\uparrow\downarrow$) of spins denote symmetric states, while vertical arrays ($\uparrow\downarrow$) denote antisymmetric spin states.

The hyperfine energy is approximately proportional to the projection I_z . The resulting spectrum is a (1, 2, 4, 2, 1)-degenerate pyramid of equally spaced lines as shown in Fig. 34.8c. Four spin-1/2 states without symmetry restrictions would give the standard binomial (1, 4, 6, 4, 1)-degeneracy seen in NMR spectra.

If the molecule settles upon C_3 symmetry axes of rotation, the situation is markedly different. The four nuclei no

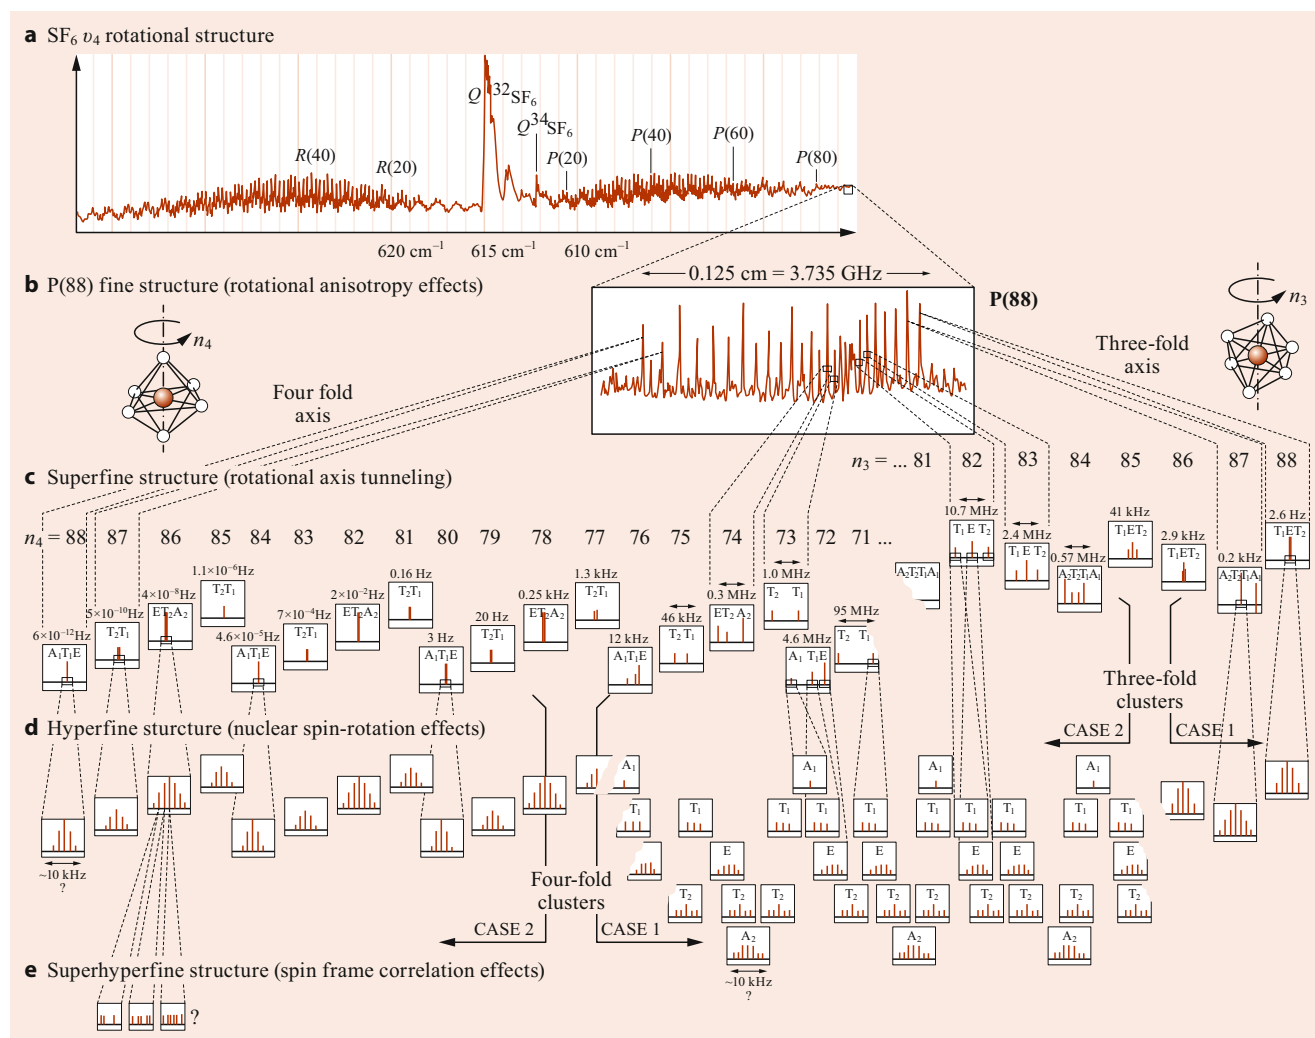

Fig. 34.9 SF₆ 16 μm ν₄ P(88) spectral clusters for C₄-axis rotation on the left and C₃-axis on the right

longer occupy equivalent positions. One nucleus sits on the rotation axis, while the other three nuclei occupy equivalent positions that are off the axis. The off-axis nuclei experience a different local magnetic field than the single on-axis nucleus (Fig. 34.8d). From the spectrum, it appears that the spin-up to spin-down energy difference is much greater for the lone on-axis nucleus than it is for the three equatorial nuclei. The spin states for the three equatorial nuclei form an energy quartet of spin states. The lone on-axis nucleus has an energy doublet with a large splitting, so together the four nuclei give a doublet of quartets as shown in Fig. 34.8d.

If the off-axis nuclei had experienced the greatest splitting, then the spectrum could have been a quartet of doublets instead of a doublet of quartets. Such affects also appear in the superhyperfine structure of SF₆ analyzed below. For either of these molecules, it is remarkable how different the rovibrational “chemical shifts” can become for equivalent symmetry sites. The result is a microscopic example of spontaneous symmetry breaking.

34.5.3 Large Spherical Top Molecules: Cubic-Octahedral Symmetry Effects

The most common high-symmetry molecules belong to either the tetrahedral T_d or cubic-octahedral O or O_h groups. The T_d group of order 24 matches order ${}^{\circ}S_4 = 4!$ of CF₄ nuclear permutation. O_h symmetry is more complicated. The octahedral O_h molecule SF₆ has F-spin-1/2 permutation symmetry S_6 of order $6! = 720$, 15 times larger than O_h . This allows O_h species to be correlated with a supercluster of S_6 symmetries that define nuclear spin hyperfine multiplets just as each C₄ or C₃ subgroup species correlate in Fig. 34.6 with a cluster of O_h symmetries.

Bordé et al. [27, 28, 30] first resolved hyperfine structure in 10 μm ν₃ bands of SF₆. Figure 34.9 displays 16 μm ν₄ bands [31] with focus on P(88) fine structures in Fig. 34.9b that contain superfine clusters in Fig. 34.9c, which in turn have hyperfine (Fig. 34.9d) and superhyperfine structure (Fig. 34.9e). Like SF₄ spectra in Fig. 34.7, SF₆ ν₄P(N)-

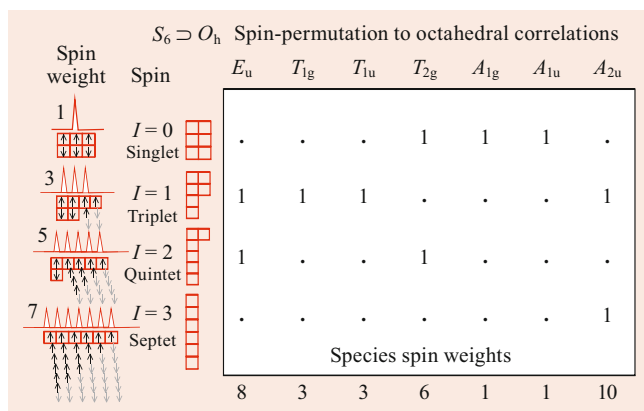

Fig. 34.10 SF_6 states of nuclear spin $I = 0-3$ correlated with O_h symmetry species listed on top

cluster bands avoid $P(N \pm 1)$ neighbours, while SF_6 $\nu_3P(N)$ -bands are crowded together by having lower scalar Coriolis splitting factors ($\xi_3 < \xi_4$) or greater tensor cluster splitting factors ($\tau_3 > \tau_4$) [29, 32, 33].

In either case, asymmetry correlation is done in Fig. 34.10 between O_h subgroup species $\{A_g, \dots, T_{2u}\}$ and supergroup S_6 species labeled by six-box spin-1/2 Young tableaux of 1 or 2 rows. Pauli-Fermi antisymmetry matches each spin tableau to its conjugate spatial tableau of 1 or 2 columns. Each matched pair belongs to a total nuclear spin of $I = 0$ (singlet state), $I = 1$ (triplet), $I = 2$ (quintet), or $I = 3$ (septet). This is correlated with one or more of the seven allowed O_h subgroup species $\{E_u, T_{1g}, T_{1u}, T_{2g}, A_{1g}, A_{1u}, A_{2u}\}$, and three species E_g, T_{2u} and A_{2g} are forbidden. They would be allowed if the F-spin were greater than 1/2. If the F-spin is less, i.e., zero, then only A_{1g} is allowed.

Case 1 hyperfine SF_6 spectra are sketched in the center and lower right-hand side boxes of Fig. 34.9d,e, as was done for CF_4 in Fig. 34.7d,e. Case 1 has greater superfine cluster splitting between O_h species than spin multiplet splitting within them as seen by comparing these boxes to Fig. 34.10.

The lowest A_2 boxes hold an ($I = 1$) triplet and ($I = 3$) septet for spin weight 10 below A_{2u} in Fig. 34.10. Above that lie T_{2g} boxes with an ($I = 0$) singlet and ($I = 2$) quintet (weight 6), E_u with an ($I = 1$) triplet and ($I = 2$) quintet (weight 8), T_{1g} or T_{1u} triplet boxes, and finally A_{1g} or A_{1u} singlets.

To form an SF_6 molecule requires considerable spontaneous symmetry breaking to make six F atoms, free to undergo (at the very least) $6!$ permutations and settle into O symmetry around a sulfur atom that has only 24 permutations. (A full $O_h \subset S_6$ correlation valid for any Fermi or Bose XY_6 octahedral molecule is given in [32]) Thus, SF_6 spectra in Fig. 34.9 involves a more severe symmetry downfall than that of CF_4 in Fig. 34.7.

This kind of downfall amounts to a breakdown of Herzberg's rule concerning rovibronic spin species [2, 3]:

transitions between species are very strictly forbidden since the nuclear moments are so very slight. In other words, if subkilohertz interactions are negligible between states separated by MHz or GHz, then resonant mixing of different species is unlikely.

However, it was only found later how symmetric molecules have tight level clusters that force subkilohertz near-degeneracy such as 6×10^{-12} Hz for the A_1T_1E cluster $n_4 = 88$ in Fig. 34.9c. Here, the exponential die-off of intracluster tunneling causes Case 2 superhyperfine mixing of species in the range from $n_4 = 88$ down to about $n_4 = 78$ where subkilohertz splitting begins. Also, on the right-hand side of Fig. 34.9c, the C_3 clusters labeled by $n_3 = 88$ and 87 may also fall into Case 2.

When O_h species levels such as the A_2T_2E cluster $n_4 = 86 = 2 \pmod{4}$ in Fig. 34.9c are crushed together, the corresponding energies and states mix and reorganize as shown in Fig. 34.11. With $O \subset S_6$ symmetry of Case 1, all 6 O -axes $\{x\bar{x}y\bar{y}z\bar{z}\}$ are equivalent. The three cluster levels are labeled by O_h symmetry species A_{2u} (lowest J -tunneling energy: $H - 4S$), T_g (middle: H), E_u (highest: $H + 2S$), and the six-box S_6 tableaux correlated by Fig. 34.10 columns A_{2u}, T_{2g} , and E_u . The columns match each O_h to one or two spin multiplets. A_{2u} is the winner with the highest hyperfine weight of 10: ($I = 3$)-septet + ($I = 1$)-triplet that gives a Bordé A_{2u} spectra like the one shown in the lower right-hand side of Fig. 34.11. (Note that the Bordé spectral curve is a derivative of the seven peaks. Ideally, seven zeroes of that curve precisely locate septet peaks.) The middle Case 1 T_{2g} has the lowest spin weight of 6: ($I = 2$)-quintet + ($I = 0$)-singlet with an easily read Bordé spectrum of 5 peaks and central peak doubled. The top E_u has a spin weight of 8: ($I = 2$)-quintet + ($I = 1$)-triplet with a more confusing Bordé spectrum, possibly due to onset of Case 2 mixing that happens if ATE splitting S is approaching that of hyperfine multiplets.

When the 6-axis J -tunneling rate S goes to zero, the SF_6 becomes stuck to rotating on single-axis pair $\{z\bar{z}\}$. So four F-atoms rotate around the equator, while the other two take up a more sedate residence at North (z) and South ($-\bar{z}$) poles. Such restrictions of freedom or symmetry breaking is indicated symbolically by literally breaking the six-box tableaux of S_6 into four-box and two-box pairs labeling subgroups of $S_4 \otimes S_2$ or $D_4 \otimes C_2$. Each orbit tableau is Fermi-matched to a conjugate spin tableau (Fig. 34.10) as shown in Case 2 level side of Fig. 34.11.

The whirling four-box nuclei enjoy greater spin-rotation coupling than their sedate two-box cohorts. To flip one of their four spins from \downarrow to \uparrow takes more energy than to flip a two-box spin. (The Bordé spectra in Fig. 34.11 indicate about four times more.) So raising $\downarrow\downarrow\downarrow\downarrow$ to $\uparrow\uparrow\uparrow\uparrow$ costs the entire width of superhyperfine pattern, while raising $\downarrow\downarrow$ to $\uparrow\uparrow$ costs only a triplet width. The scalar paired two-box spins $\uparrow\downarrow$ and four-box spins $\uparrow\uparrow\downarrow\downarrow$ are invariants.

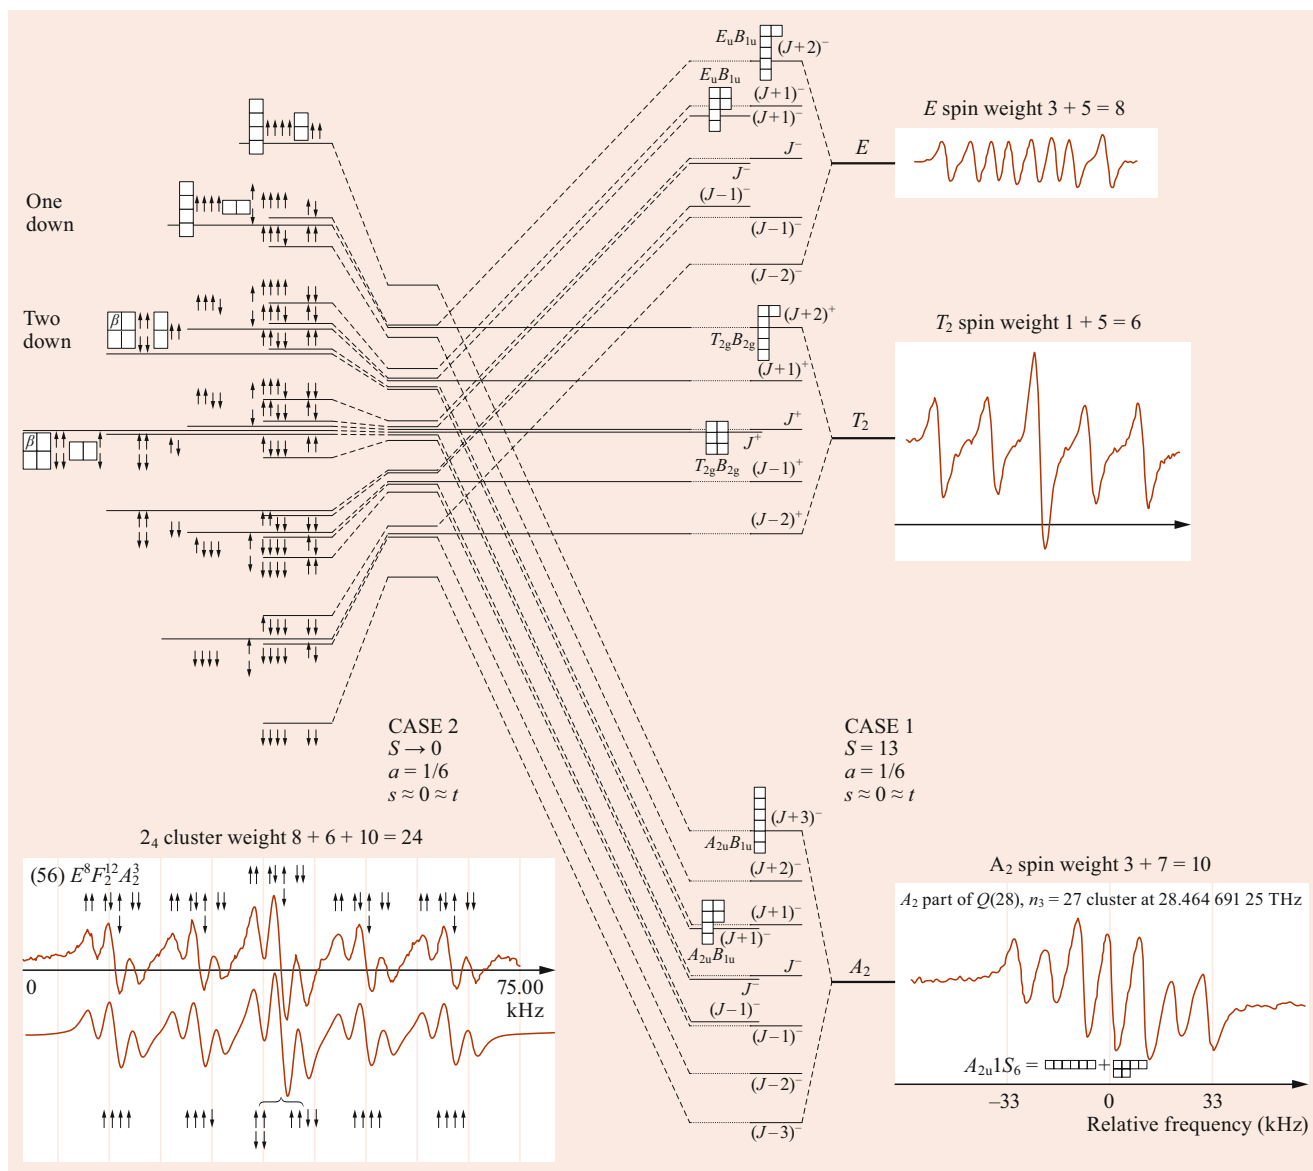

Fig. 34.11 Case 1 $S_6 \supset O\{A_1 T_2 E\}$ levels mix to become Case 2 $C_{4v} \otimes C_{2h}$ superhyperfine levels [9, 33]

34.5.4 Icosahedral Spherical Top Molecules: Extreme Spin Symmetry Effects

Until the recent discovery of fullerenes and the structure of virus capsids, molecules with the highest icosahedral symmetry were thought to be rare or nonexistent in nature [34, 35]. With the discovery of Buckminsterfullerenes (Buckyballs) C_{60} with molecular point symmetry Y_h or I_h , one expects extreme dynamical symmetry effects. It helps to compare Y_h -symmetric C_{60} to the O_h -symmetric SF_6 first by their symmetry-allowed rotation Hamiltonians of lowest rank [36–38]

an extreme example of symmetry breaking effects, consider the Buckminsterfullerene or Buckyball molecule C_{60} , which has the highest possible molecular point symmetry

Y_h . A semiclassical approach to rotational symmetry and dynamics is useful here since the rotational quantum constant is so small for the fullerenes (for C_{60} $2B = 0.0056 \text{ cm}^{-1}$ or 168 MHz) [36–40].

$$\begin{aligned} \mathbf{H}_{SF_6}^{\text{Rot}} = & B_{SF_6} \mathbf{J}^2 \\ & + t_{044} \left[\sqrt{\frac{7}{12}} \mathbf{T}_0^{(4)} + \sqrt{\frac{5}{24}} (\mathbf{T}_{+4}^{(4)} + \mathbf{T}_{-4}^{(4)}) \right] + \dots \end{aligned} \quad (34.19a)$$

$$\begin{aligned} \mathbf{H}_{C_{60}}^{\text{Rot}} = & B_{C_{60}} \mathbf{J}^2 \\ & + t_{066} \left[\sqrt{\frac{11}{25}} \mathbf{T}_0^{(6)} + \sqrt{\frac{7}{25}} (\mathbf{T}_{+5}^{(6)} + \mathbf{T}_{-5}^{(6)}) \right] + \dots \end{aligned} \quad (34.19b)$$

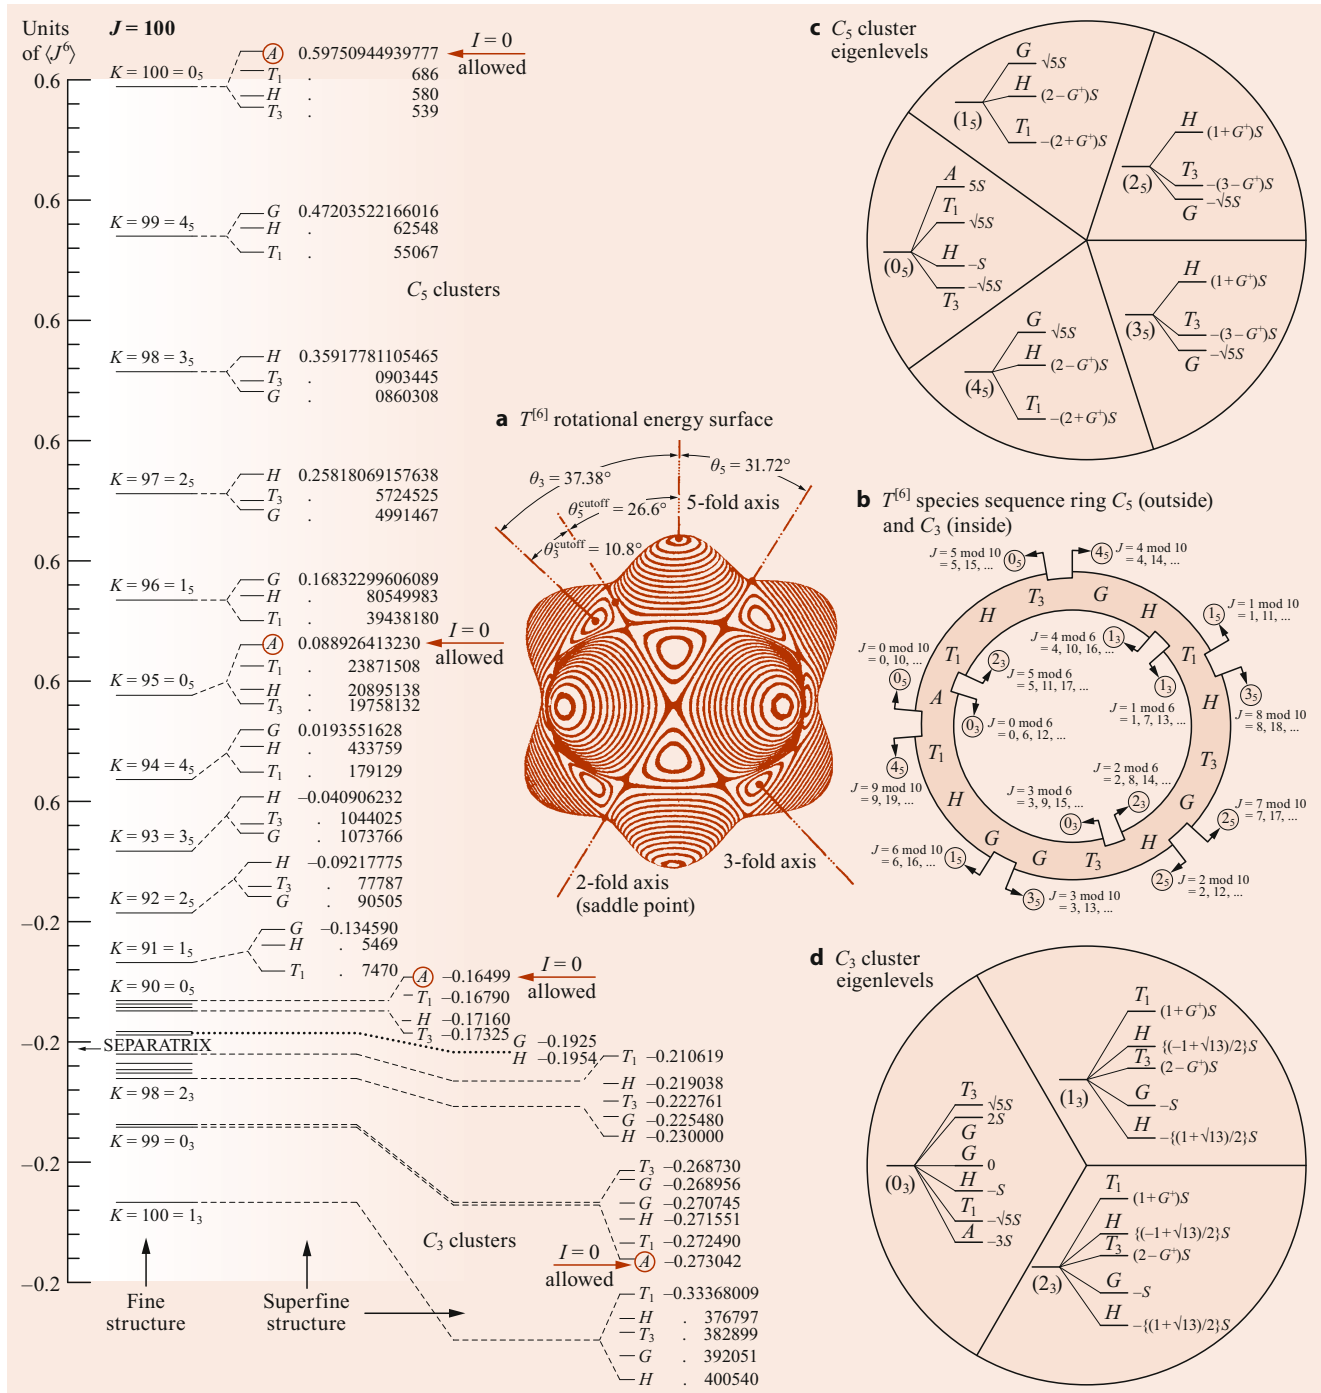

Fig. 34.12 $J = 100$ Y_h -symmetry sublevels. $^{12}\text{C}_{60}$ allows only the 4 A-species. $^{13}\text{C}_{60}$ allows all. (a) $T^{[6]}$ RES of 26.6° C_5 hills or 10.8° C_3 valleys hold (b, c) many C_5 levels, and (d) few C_3 levels

Both have large rotor inertia I and a small rotor constant $B = \frac{1}{2I}$. (For C_{60} : $2B = 0.0056 \text{ cm}^{-1}$ or 168 MHz . For SF_6 : $2B = 0.091 \text{ cm}^{-1}$) [39, 40]. Both use Wigner–Eckart form for tensor matrix elements,

$$\langle J' | \mathbf{T}_q^{(k)} | J \rangle = C_{qKK'}^{JJ'} (J || k || J); \quad (34.19c)$$

$J = 30$ eigenvalues of $\mathbf{H}_{\text{SF}_6}^{\text{Rot}}$ in Fig. 34.4 are to be compared to $J = 100$ -values of $\mathbf{H}_{\text{C}_{60}}^{\text{Rot}}$ in Fig. 34.12. Six C_4 hills of $\mathbf{H}_{\text{SF}_6}^{\text{Rot}}$ RES (rotational energy surface) compare to 12 C_5 hills on $\mathbf{H}_{\text{C}_{60}}^{\text{Rot}}$ RES, and 8 C_3 valleys of $\mathbf{H}_{\text{SF}_6}^{\text{Rot}}$ RES compare to 20 C_3 valleys on $\mathbf{H}_{\text{C}_{60}}^{\text{Rot}}$ RES. The C_3 cut-off angle $\theta_3^{\text{cut-off}} = 10.8^\circ$ for $\mathbf{H}_{\text{C}_{60}}^{\text{Rot}}$ is half of 19.5° for $\mathbf{H}_{\text{SF}_6}^{\text{Rot}}$. So the huge $J = 100$ man-

ifold has room for only two C_3 clusters. A first comparison of SF_6 and $^{13}C_{60}$ assumes fluorine, and ^{13}C nuclei causes no hyperfine splitting. (Here, we ignore Fig. 34.11 and assume that C_{60} rotates slowly with ^{13}C magnetic moments too weak to observe.) Just as order is maintained in a sequence of SF_6 species between C_3 valleys and C_4 hills in Fig. 34.4, so also is the order of $^{13}C_{60}$ symmetry species maintained as C_3 valley clusters morph into C_5 hill clusters on either side of the separatrix in Fig. 34.12b.

While SF_6 or $^{13}C_{60}$ level sequence is maintained, their intra and intercluster level *spacing* is not. The C_3 valley intra-cluster level *spacing* in Fig. 34.12c is quite different from the C_5 hill intracluster level *spacing* in Fig. 34.12d, and similarly for SF_6 cluster level eigenvalues in Table 34.5. Intracluster (superfine)eigenvalues have a quasi exponential tunneling “sneak” factor S , which was first defined for the asymmetric rotor by Eq. (34.13). It depends on local angular momentum m_n of each C_n cluster and J -momentum cone polar angle $\Theta_{m_n}^J$ as diagrammed in Fig. 34.5.

$$\Theta_{m_n}^J = \arccos \frac{m_n}{\sqrt{J(J+1)}}. \quad (34.20)$$

Asymmetric-rotor eigenvalues in Table 34.1 and CF_4 or SF_6 eigenvalues in Table 34.5 have numerical rationality and contrast with the rationality of C_{60} Golden ratios ($G^+ = (1 + \sqrt{5})/2$ and $\sqrt{13}$) of superfine eigenvalues in Fig. 34.12c,d. Rational frequencies give Poincaré periodicity, while irrational ones give quasi periodicity.

However, the discussion of the similarity of SF_6 and $^{13}C_{60}$ ends when the hyperfine structure of the latter overwhelms that of the former. This is revealed in the following section.

34.5.5 $^{12}C_{60}$ versus $^{13}C_{60}$: a World of Difference in Spin- $\frac{1}{2}$ Hyperfine Spectroscopy

SF_6 has one stable F-isotope. C_{60} chooses from two stable C isotopes: $^{12}C_{60}$ (spin 0) of 98.9% abundance or $^{13}C_{60}$ (spin- $\frac{1}{2}$) at 1.1%. ^{12}C spectroscopy is simpler than that of ^{13}C . (The ^{14}C spin-0 isotope is even trickier, with its 5707-year half-life β -decay into ^{14}N .) It helps to compare purely bosonic $^{12}C_{60}$ with purely fermionic $^{13}C_{60}$. In between are many mixed $^{12}C_n^{13}C_{60-n}$ isotopomers. The first $^{12}C_{59}^{13}C$ is 33% likely and is an extreme example of isotopic symmetry breaking [41]. A *single extra neutron* reduces the very highest 3-D point symmetry Y_h (120 operators) down to a lowly C_h (one planar reflection) [42, 43].

After comparing levels of SF_6 and $^{13}C_{60}$ above one should also compare SF_6 ($J = 30$) levels in Fig. 34.4 to *allowed* $^{12}C_{60}$ ($J = 100$) levels in Fig. 34.12. Only *four* of its 201 levels are Bose-allowed A -species: $K = n_5 = 100$, $K = n_5 =$

95, $K = n_5 = 90$, and finally $K = n_5 = 99$, in the second to lowest cluster in the C_3 valley. The upper three are $K = 0 \pmod{5} = 0_5$ waves orbiting C_5 hills. $K = n_3 = 99$ is the only 0-mod-3 wave in the tiny C_3 valley of the RES and, thus, the valley’s only $^{12}C_{60}$ -allowed level in Fig. 34.12.

Clearly, $^{12}C_{60}$ has a very sparse fine structure. This helps spectroscopists to assign lines and determine $^{12}C_{60}$ constants that will approximate those of $^{13}C_{60}$. (If $^{12}C_{60}$ has molecular weight of 720 atomic units, then $^{13}C_{60}$ weights in around 780.) Recently (as this article was being written), the very first J -resolved $^{12}C_{60}$ spectra was observed in its 8.4 μm_2 bands by Jun Ye’s group at JILA [44] that pioneered direct frequency comb spectroscopy. In this work, they used cavity-enhanced comb spectroscopy along with buffer gas cooling. [45, 46] This followed 27 years of failed attempts by other labs around the world. Now it suggests that a “Mt. Everest” of molecular spectroscopy, namely the $^{13}C_{60}$ spin-monster, might be attainable.

There is both good and bad news concerning this. The good news: Fermi-symmetric $^{13}C_{60}$ has only ten times as many rotating spin- $\frac{1}{2}$ nuclei as SF_6 . The bad news is that the factor-of-10 lies in exponents!

So, $^{13}C_{60}$ has about 2^{60} hyperfine states or about 1.15×10^{18} spin states distributed among its ten species [32], as listed in Fig. 34.13. That is in contrast to Bose-symmetric $^{12}C_{60}$, which has only a handful of A -states in each J -multiplet. Yet a single neutron entering $^{12}C_{60}$ to form $^{12}C_{59}^{13}C$ causes many of the excluded levels to arise under lower C_h symmetry labels.

SF_6 spin weights $\{8, 3, 3, 6, 1, 1, 10\}$ in $O_h \subset S_6$ correlation of Fig. 34.10 fit a sum identity of O_h irrep dimension

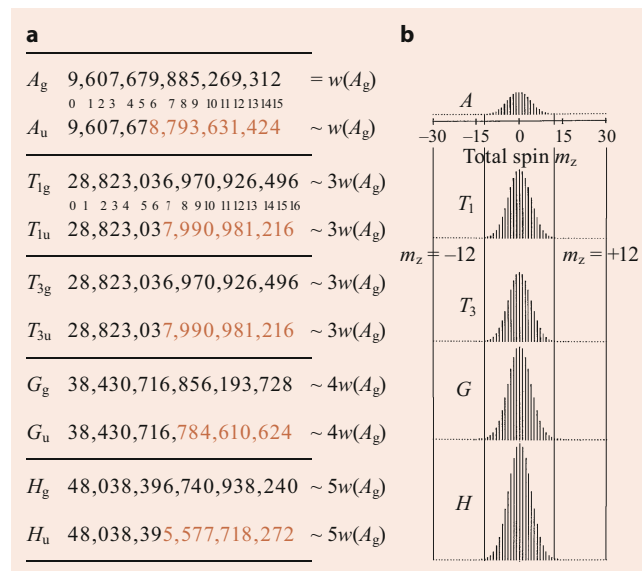

Fig. 34.13 (a) Total spin weights and (b) m_z -distributions for $Y_h \subset S_{60}$ symmetry species

(ℓ^μ) times each of its spin weights. This equals its total spin dimension $2^6 = 64$.

$$\begin{aligned}
 & 8\ell^{E_u} + 3\ell^{T_{1u}} + 3\ell^{T_{1g}} + 6\ell^{T_{2g}} + 1\ell^{A_{1g}} + 1\ell^{A_{1u}} + 10\ell^{A_{2u}} \\
 &= 16 + 9 + 9 + 18 + 1 + 1 + 10 \\
 &= 64 = 2^6.
 \end{aligned}
 \tag{34.21}$$

A similar identity uses products of $U(2)$ spin- $\frac{1}{2}$ dimensions $(2S + 1)$ with irreps of group S_6 whose tableaux match $U(2)$ tableaux that belong to each total spin $S = 3, 2, 1, 0$ made by six spin- $\frac{1}{2}$ nuclei.

$$\begin{aligned}
 2^6 &= \ell_{U(2)} + \ell_{S_6} + \ell_{U(2)} + \ell_{S_6} \\
 &+ \ell_{U(2)} + \ell_{S_6} + \ell_{U(2)} + \ell_{S_6} \\
 &= (2S + 1 = 7) \cdot 1 + (2S + 1 = 5) \cdot 5 \\
 &+ (2S + 1 = 3) \cdot 9 + (2S + 1 = 1) \cdot 5.
 \end{aligned}
 \tag{34.22}$$

Tableau hook-length formulas give the irrep dimension for S_n and for $U(m)$ ([15, p. 65]).

$$\begin{aligned}
 \ell_{S_{15}} &= \frac{15!}{\text{hooklength product:}} \begin{array}{|c|c|c|c|c|} \hline 8 & 7 & 5 & 3 & 1 \\ \hline 7 & 5 & 3 & 1 & \\ \hline 5 & 3 & 1 & & \\ \hline 2 & 1 & & & \\ \hline \end{array} \tag{34.23a}
 \end{aligned}$$

$$\begin{aligned}
 \ell_{U_5} &= \frac{\text{integer product:}}{\text{hooklength product:}} \begin{array}{|c|c|c|c|c|} \hline 5 & 6 & 7 & 8 & 9 \\ \hline 4 & 5 & 6 & 7 & \\ \hline 3 & 4 & 5 & & \\ \hline 2 & 3 & & & \\ \hline \end{array} \begin{array}{|c|c|c|c|c|} \hline 8 & 7 & 5 & 3 & 1 \\ \hline 7 & 5 & 3 & 1 & \\ \hline 5 & 3 & 1 & & \\ \hline 2 & 1 & & & \\ \hline \end{array} \tag{34.23b}
 \end{aligned}$$

The *hook length* h of a tableau box is the number n_r of boxes to its right plus the number n_b below it plus one for itself, that is, $h = n_r + n_b + 1$. The numerator for S_n formula in Eq. (34.23a) is $n!$ (here $n = 15$). The denominator has exactly n -boxes with one hook length for each particle. The same denominator applies to $U(m)$ irrep dimension and Eq. (34.23b) for an n -particle- m -state system (here $m = 5$), but the numerator fills the same tableau frame with a matrix whose corner diagonal is (m, m, m, \dots) , and $\pm 1^{\text{st}}$ off-diagonals are $\pm(m \pm 1, m \pm 1, m \pm 1, \dots)$, $\pm 2^{\text{nd}}$ off-diagonals are $\pm(m \pm 2, m \pm 2, m \pm 2, \dots)$, etc.

The Eqs. (34.23a) and (34.23b) fractions always yield a positive integer if the desired representation exists and

zero otherwise; $U(2)$ fractions ($m = 2$) derive factors $\ell_{S_6}^{[\mu]} = \{1, 5, 9, 5\}$ in Eq. (34.21).

$$\begin{aligned}
 \ell_{S_6}^{[\mu]} &= \{1, 5, 9, 5\} \\
 &= \left\{ \ell_{O_h}^{A_{2u}}, \ell_{O_h}^{E_u} + \ell_{O_h}^{T_{2g}}, \ell_{O_h}^{A_{2u}} + \ell_{O_h}^{E_u} + \ell_{O_h}^{T_{1g}} + \ell_{O_h}^{T_{1u}}, \right. \\
 &\quad \left. \ell_{O_h}^{A_{2g}} + \ell_{O_h}^{A_{1u}} + \ell_{O_h}^{T_{2g}} \right\}.
 \end{aligned}
 \tag{34.24}$$

This is consistent with Eqs. (34.22), (34.23a), and (34.23b), and the $O_h \subset S_6$ correlation table in Fig. 34.10, if we recall that each Fermi spin tableau has to be the *transpose* of its rotor tableau in order to make the Fermi-Dirac-Pauli distribution a totally antisymmetric spin-rotor state. The hook-length formulae structure in Eqs. (34.23a) and (34.23b) shows that a tableau has the same dimensions as its transpose for both S_n and $U(m)$.

As powerful as tableau formulae are, they do not quite prepare us for the huge tableau dimensions and correlations associated with $^{13}C_{60}$ and its permutation symmetry S_{60} containing its icosahedral symmetry subgroup $Y_h \subset S_{60}$. The analogous spin weights in Fig. 34.13 for a $Y_h \subset S_{60}$ correlation are truly enormous numbers when compared to the analogous $O_h \subset S_6$ numbers in Fig. 34.10. Most C_{60} spin states have no Y or Y_h symmetry. Applying all 60 Y operators to a typical state generally gives 60 orthogonal spin states spanning 60-by-60 *regular representation* and reducing to $1A \oplus 3T_1 \oplus 3T_3 \oplus 4G \oplus 5H$ that obeys its group order sum relation.

$$\begin{aligned}
 \circ Y &= (\ell^A)^2 + (\ell^{T_1})^2 + (\ell^{T_3})^2 + (\ell^G)^2 + (\ell^H)^2 \\
 &= 1^2 + 3^2 + 3^2 + 4^2 + 5^2 = 60.
 \end{aligned}
 \tag{34.25}$$

So Y_h species weights in Fig. 34.13 are (to one part in 10^6) proportional to the irrep dimension. Thus, the approximate weight ratios are $(A : T_1 : T_3 : G : H) = (1 : 3 : 3 : 4 : 5)$ with relatively tiny ratio variations between odd (u) and even (g) parity species. However, as Fig. 34.13 shows, the arithmetic variations are in the billions! This is in contrast to SF_6 , where the u and g ratios of O_h species differ markedly and even leave the three species A_{2g} , E_g , and T_{2u} with *zero* weight.

Plots of species weight versus spin z -component ($-30 \leq m_z \leq 30$) are shown in Fig. 34.13b. The height of each vertical line is proportional to the number of a given species $A, T_1, T_3, G,$ or H that have the m_z -value that line represents. Each species has its tallest line at $m_z = 0$ and then falls quasi exponentially on either side. They become too small to plot for m_z -values outside the interval $(-12 \leq m_z \leq +12)$ and thereafter are just lines of dots. The dots for scalar icosahedral A-species at extreme values of $m_z = +30$ or $m_z = -30$ are lines of height $\ell^{[60,0]} = 1$ for the S_{60} tableaux below.

The S_{60} dimension $\ell^{[30,30]}$ for this zero-spin tableau is given by applying Eq. (34.23a)

$$\begin{aligned} \ell^{[30,30]} &= \frac{60 \cdot 59 \cdot 58 \cdot 57 \cdots 2 \cdot 1}{31 \cdot 30 \cdot 29 \cdot 28 \cdots 3 \cdot 2} = \frac{60!}{(31!)(30!)} \\ &= 3.8149865020923 \cdot 10^{15}. \end{aligned} \quad (34.28)$$

That number of zero- m_z states is apportioned by ratios 1 : 3 : 3 : 4 : 5 ($\pm 0.0001\%$) to species A , T_1 , T_3 , G , and H , respectively (the exact ratio calculation is tricky and required an erratum [42, 43]). If ever the resulting panoply of $^{13}\text{C}_{60}$ superhyperfine spectra is observed, it will dwarf that of SF_6 in Figs. 34.9 and 34.10. A plot comparing $J = 100$ superfine levels of $^{13}\text{C}_{60}$ to those of $^{12}\text{C}_{60}$ in Fig. 34.12 only begins to relate to SF_6 levels in Fig. 34.4. An attempt to relate spectra of $^{13}\text{C}_{60}$ to $^{12}\text{C}_{60}$ is sketched by Fig. 34.14 as a highly speculative P(50) prognostication where only two A-singlet $^{12}\text{C}_{60}$ lines exist while $^{13}\text{C}_{60}$ has seven large clusters. The $(K = 50)0_5(AT_1HT_3)$ cluster is a Case 1 guess for superfine structure of astronomical numbers of hyperfine lines. The resolution assignment of such super-hyper-spectra will require a wealth of future technology and theory.

34.6 Composite Rotors and Multiple RES

So far, the discussion has focused on Hamiltonians and involved functions of even multipolarity, i.e., constant ($k = 0$), quadratic or quadrupole ($k = 2$), quartic or hexadecapole ($k = 4$), while ignoring functions that are linear-dipole ($k = 1$) or cubic-octupole ($k = 3$), for reasons of time-reversal symmetry. However, for composite “rotor-rotors” any multipolarity is possible, and the dipole is of primary utility.

A composite rotor is one composed of two or more objects with more or less independent angular momenta. This could be a molecule with attached methyl (CH_3) “gyro” or “pinwheel” subrotors, a system of considerable biological interest. It could be a molecule with a vibration or “phonon” excitation that couples strongly to rotation. Also, any nuclear or electronic spin with significant coupling may be regarded as an elementary subrotor. The classical analogy is a spacecraft with gyro(s) on board.

A rotor-rotor Hamiltonian has the following general interaction form

$$H_{\text{rotor } R+S} = H_{\text{rotor } R} + H_{\text{rotor } S} + V_{RS}. \quad (34.29)$$

A useful approximation assumes that the rotor_S gyro is fastened to the frame of rotor_R so the interaction V_{RS} becomes a constraint, does no work, and is thus assumed to be

zero. An asymmetric top with body-fixed spin is the following modified version of Eq. (34.1)

$$\begin{aligned} H_{R+S(\text{Body-fixed})} &= AR_x^2 + BR_y^2 + CR_z^2 + H_{\text{rotor } S} \\ &+ (\approx 0). \end{aligned} \quad (34.30a)$$

The system total angular momentum is a conserved vector $\mathbf{J} = \mathbf{R} + \mathbf{S}$ in the lab frame and a conserved magnitude $|\mathbf{J}|$ in the rotor-R body frame. So we use $\mathbf{R} = \mathbf{J} - \mathbf{S}$ in place of \mathbf{R} ,

$$\begin{aligned} H_{R,S(\text{fixed})} &= A(\mathbf{J}_x - \mathbf{S}_x)^2 + B(\mathbf{J}_y - \mathbf{S}_y)^2 \\ &+ C(\mathbf{J}_z - \mathbf{S}_z)^2 + H_{\text{rotor } S} \\ &= A\mathbf{J}_x^2 + B\mathbf{J}_y^2 + C\mathbf{J}_z^2 - 2A\mathbf{J}_x\mathbf{S}_x \\ &- 2B\mathbf{J}_y\mathbf{S}_y - 2C\mathbf{J}_z\mathbf{S}_z + H'_{\text{rotor } S}. \end{aligned} \quad (34.30b)$$

Gyro-spin components S_a are treated at first as constant classical parameters S_a ,

$$\begin{aligned} H_{R,S(\text{fixed})} &= \text{const } 1 - 2AS_x\mathbf{J}_x - 2BS_y\mathbf{J}_y - 2CS_z\mathbf{J}_z \\ &+ A\mathbf{J}_x^2 + B\mathbf{J}_y^2 + C\mathbf{J}_z^2 \\ &= M_0T_0^0 + \sum_d D_dT_d^1 + \sum_q Q_qT_q^2. \end{aligned} \quad (34.30c)$$

This is a simple Hamiltonian *multipole tensor operator expansion* having here just a monopole T_0^0 term, three dipole T_a^1 terms, and two quadrupole T_q^2 terms shown in Fig. 34.15.

Fig. 34.15 The six lowest-order RES components needed to describe rigid gyro rotors

Each is a radial plot of a spherical harmonic function $Y_q^k(\varphi, \vartheta)$ representing a tensor operator T_q^k

$$T_0^0 = \frac{J_x^2 + J_y^2 + J_z^2}{3} \quad (34.31a)$$

$$T_x^1 = J_x = \frac{T_{+1}^1 + T_{-1}^1}{\sqrt{2}}$$

$$T_y^1 = J_y = \frac{T_{+1}^1 - T_{-1}^1}{i\sqrt{2}}$$

$$T_z^1 = J_z = T_0^1 \quad (34.31b)$$

$$T_{zz}^2 = \frac{2J_z^2 - J_x^2 - J_y^2}{2} = T_0^2$$

$$T_{x^2-y^2}^2 = J_x^2 - J_y^2 = \frac{2(T_2^2 - T_{-2}^2)}{\sqrt{6}}. \quad (34.31c)$$

The constant coefficients or *moments* indicate the strength of each multipole symmetry,

$$M_0 = A + B + C + 3H'_{\text{rotor } S} \quad (34.32a)$$

$$D_x = -2AS_x,$$

$$D_y = -2BS_y,$$

$$D_z = -2CS_z \quad (34.32b)$$

$$Q_{zz} = (2C - A - B)/6$$

$$Q_{x^2-y^2} = (A - B)/2, \quad (34.32c)$$

The scalar monopole RES in Eq. (34.32a) is a sphere, while vector dipole RES in Eq. (34.32b) are bispheres pointing along Cartesian axes, and the RES in Eq. (34.32c) resemble quadrupole antenna patterns. Also, Fig. 34.15a–c plots the six s, p, and d Bohr–Schrödinger orbitals that are analogs for the six octahedral J -tunneling states listed in Table 34.5.

The asymmetric and symmetric rotor Hamiltonians in Eqs. (34.1) and (34.2) are combinations of a monopole in Eq. (34.31a), which by itself makes a spherical rotor, and varying amounts of the two quadrupole terms in Eq. (34.31c) to give the rigid rotor RES pictured previously in Figs. 34.1 and 34.2. Both Q coefficients in Eq. (34.32c) are zero for a spherical top ($A = B = C$), but only one is zero for a symmetric top ($A = B$).

Combining monopole in Eq. (34.31a) with dipole terms in Eq. (34.31b) gives a gyro-rotor Hamiltonian in Eq. (34.30b) for a spherical rotor ($A = B = C$) that has the following form

$$H = \text{const} + BJ^2 - g\mu S \cdot J \quad (34.33)$$

(where: $-g\mu = 2A = 2B = 2C$);

H resembles a dipole potential $-m \cdot B$ for a magnetic moment $m = gJ$ that precesses clockwise around a lab-fixed magnetic field $B = \mu S$. (The PE is least for J along S .)

Here, the Hamiltonian in Eq. (34.33) is a simple example of Coriolis rotational energy. It is least for J along S , where

Fig. 34.16 The spherical gyro-rotor RES is a cardioid of revolution around gyro spin S

$|R| = |J - S|$ is least, and rotor kinetic energy BR^2 is least. (Magnitudes $|J|$ and $|S|$ are constant here.) The spherical rotor-gyro RES in Fig. 34.16 is minimum along the body-axis $+S$ and maximum along $-S$, where BR^2 is greatest.

As is the case for the rigid solid rotors in Figs. 34.1 and 34.2, the RES energy topography lines determine the precession J -paths in the body frame, wherein gyro- S is fixed in Fig. 34.16. The left-hand rule gives J -precession sense in the body S -frame, i.e., all J precess *anti*-clockwise relative to the “low” on the $+S$ -axis, or clockwise relative to the “high” on the $-S$ -axis. In the lab, S precess clockwise around a fixed J .

Gyro-RES differ from solid rotor RES, which have two opposite “high” and/or two opposite “lows” separated by saddle fixed points where the precessional flow direction reverses, as can be seen in Fig. 34.2. The gyro-RES in Fig. 34.16 has no saddle fixed points and only one “high” and one direction of flow with the same harmonic precession frequency for all J -vectors between the high $+S$ and low $-S$ -axes. This is because the spectrum of the gyro-rotor Hamiltonian in Eq. (34.33) is *harmonic* or *linear* in the momentum quanta K ,

$$\langle \frac{J}{K} | H | \frac{J}{K} \rangle = \text{const.} + BJ(J+1) - 2BK. \quad (34.34)$$

In contrast, even the symmetric rigid rotor spectrum in Eq. (34.4) is *quadratic* in K . Other rotors shown in Figs. 34.2 and 34.4 have levels that are quite nonlinear.

34.6.1 3-D-Rotor and 2-D-Oscillator Analogy

Linear levels belong to harmonic *oscillators*, not rotors, but the gyro-rotor’s linear spectrum highlights a 160-year-old analogy of 3-D rotor motion to 2-D vibration. *Stokes* [47]

described 2-D electric vibration or *optical polarization*, by a 3-D vector that became known as the Stokes vector \mathbf{S} and labeled appropriately by the letter \mathbf{S} . (Now we say \mathbf{S} labels “spin”.) Stokes’ spin uses *Hamilton quaternions* [48, 49] re-done 80 years later as *Pauli spinor* σ_μ components [50] of a general 2-D Hermitian operator H ,

$$H = \begin{pmatrix} A & B - iC \\ B + iC & D \end{pmatrix} \\ = \frac{A+D}{2}\sigma_0 + \frac{A-D}{2}\sigma_A + B\sigma_B + C\sigma_C, \quad (34.35)$$

where

$$\sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_A = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \\ \sigma_B = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_C = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}.$$

Our labels A (“asymmetric-diagonal”), B (“bilateral-balanced”), and C (“circular-Coriolis”) are mnemonic alternatives to Pauli’s z , x , and y , respectively. The 2-D Hamiltonian has the $\mathbf{S} \cdot \mathbf{J}$ form of the Coriolis coupling in Eq. (34.33).

$$H = S_0\mathbf{1} + S_A J_A + S_B J_B + S_C J_C \\ = S_0 J_0 + \vec{S} \cdot \mathbf{J}, \quad (34.36)$$

where

$$J_0 = \mathbf{1}, \quad J_A = \frac{\sigma_A}{2}, \quad J_B = \frac{\sigma_B}{2}, \quad J_C = \frac{\sigma_C}{2},$$

and

$$S_0 = (A+D)/2, \quad S_A = (A-D), \quad S_B = 2B, \\ S_C = 2C.$$

The 2-D–3-D analogy is helped by using elementary oscillator ladder $a^\dagger a$ operators in Eq. (34.37),

$$\mathbf{J}_0 = N = a_1^\dagger a_1 + a_2^\dagger a_2, \quad \mathbf{J}_A = \frac{1}{2}(a_1^\dagger a_1 - a_2^\dagger a_2), \\ \mathbf{J}_B = \frac{1}{2}(a_1^\dagger a_2 + a_2^\dagger a_1), \quad \mathbf{J}_C = \frac{-i}{2}(a_1^\dagger a_2 - a_2^\dagger a_1), \quad (34.37)$$

where

$$a_1^\dagger a_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad a_1^\dagger a_2 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \\ a_2^\dagger a_1 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \quad a_2^\dagger a_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

This is a Jordan–Schwinger map of 2-D oscillation to 3-D rotation [51–53].

This easily gives Schwinger’s 3-D angular momentum raising-lowering operators $\mathbf{J}_+ = \mathbf{J}_B + i\mathbf{J}_C = a_1^\dagger a_2$ and $\mathbf{J}_- = \mathbf{J}_B - i\mathbf{J}_C = a_2^\dagger a_1$, where two dimensions 1 and 2 are spin-up ($+\hbar/2$) and spin-down ($-\hbar/2$) instead of the x - and y -polarized states envisioned by Stokes.

The angular 3-D ladder operation is replaced by a simpler 2-D oscillator operation

$$\mathbf{J}_+ |n_1 n_2\rangle = a_1^\dagger a_2 |n_1 n_2\rangle \\ = \sqrt{n_1 + 1} \sqrt{n_2} |n_1 + 1, n_2 - 1\rangle, \\ \mathbf{J}_- |n_1 n_2\rangle = a_2^\dagger a_1 |n_1 n_2\rangle \\ = \sqrt{n_1} \sqrt{n_2 + 1} |n_1 - 1, n_2 + 1\rangle. \quad (34.38)$$

2-D oscillator states are labeled by the *total* number $N = (n_1 + n_2)$ of quanta and the *net* quantum population $\Delta N = (n_1 - n_2)$. 3-D angular momentum states $|J_K^J\rangle$ are similarly labeled by the total momentum $J = N/2 = (n_1 + n_2)/2$ and z -component $K = \Delta N/2 = (n_1 - n_2)/2$, just half (or $\hbar/2$) of N and ΔN ,

$$|n_1, n_2\rangle = \frac{(a_1^\dagger)^{n_1} (a_2^\dagger)^{n_2}}{\sqrt{n_1! n_2!}} |0, 0\rangle = \\ |J_K^J\rangle = \frac{(a_1^\dagger)^{J+K} (a_2^\dagger)^{J-K}}{\sqrt{(J+K)!(J-K)!}} |0, 0\rangle, \quad (34.39)$$

where

$$n_1 = J + K, \quad n_2 = J - K.$$

From this, *Schwinger* [52] rederived the Wigner matrices $D_{MK}^J(\alpha\beta\gamma)$ appearing in Eqs. (34.5) and (34.6) and the Clebsch–Gordan $C_{qKK'}^{kJJ'}$ coefficient or Wigner–Eckart tensor relation. This helps clarify RES approximation such as Eqs. (34.10) and (34.11) that use (J, K) -cone levels on RES,

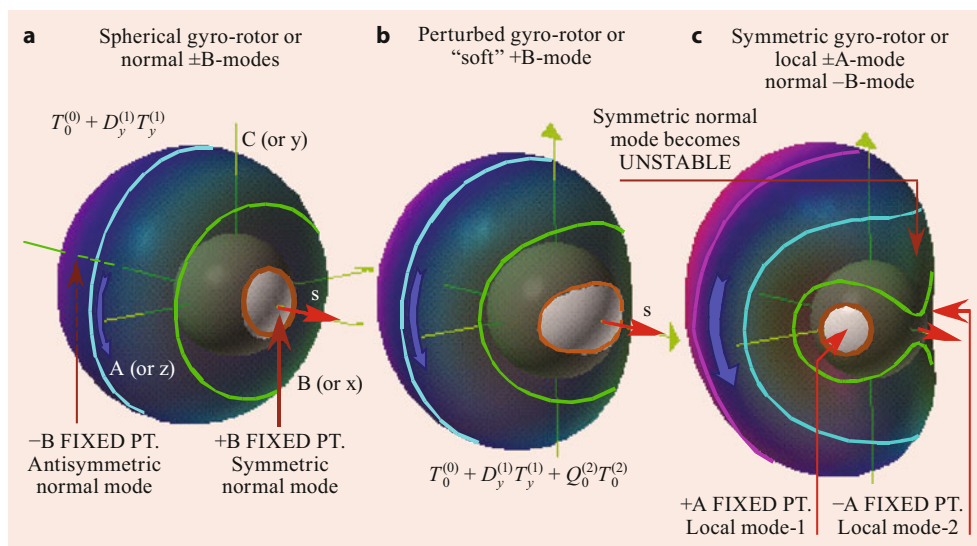

$$\left\langle \begin{matrix} J' \\ K' \end{matrix} \middle| T_q^k \middle| \begin{matrix} J \\ K \end{matrix} \right\rangle = C_{qKK'}^{kJJ'} \langle J' || k || J \rangle \\ \approx C_{0KK}^{kJJ} \langle J || k || J \rangle \approx D_{JK}^J(\Theta_K^J).$$

34.6.2 Gyro-Rotors and 2-D-Local Mode Analogy

The 2-D–3-D analogy provides insight into NMR spin [54], laser quasi spin (Rabi-rotation) [55], rovibrational dynamics [56, 57], and the local mode formation [58, 59]. It also has computational value. Part of this involves relating single 2-D-oscillator (Stokes model) to a model of two 1-D oscillators with coordinates $x_1 = x$ and $x_2 = y$.

Two identical side-by-side oscillators have bilateral or B -symmetry, and a H_B Hamiltonian commutes with both σ_B ($a + 45^\circ$ mirror reflection of axes $\pm x \rightleftharpoons \pm y$) and with $-\sigma_B$ ($a - 45^\circ$ mirror reflection of axes $\mp x \rightleftharpoons \pm y$) both of which

Fig. 34.17 A spherical gyro-rotor becomes an asymmetric gyro-rotor by adding T_0^2

interchange oscillators. This means that to first order the Hamiltonian is $H_B = 2B\sigma_B$, i.e., a gyro-rotor T_x^1 with S along the B -axis, as shown in Fig. 34.17. (Added T_0^0 affects eigenvalues but not states.)

Eigenvectors of H_B are the symmetric and antisymmetric normal modes that belong to the fixed points on the S -vector or $\pm B$ -axes of the Stokes space. If instead, the S -vector lies on the A -axis, the Hamiltonian is an asymmetric diagonal $H_A = 2A\sigma_A$ matrix. From Eq. (34.35), we can see that the operator σ_A reflects y into $-y$ but leaves x alone, so eigenvectors of H_A are localized on the x -oscillator or the y -oscillator, but not both. Such motions are local modes but are not modes of H_B , which does not commute with H_A .

Hamiltonian H_B precesses a J vector from the $+A$ -axis (local x -mode) around to the $-C$ -axis to the $-A$ (local y -mode), then to the $+C$ -axis, and then home to $+A$. The J -path is the largest equator of Fig. 34.17a. The $\pm C$ -axes are what Stokes would label circular polarization chirality, right and left, respectively. In a B -beat, $\pm C$ belong to resonant transitions where one vibrator's phase is 90° ahead and pumping up the other.

Simple mode beat transfer dynamics is disrupted by adding anharmonic T_0^2 or $T_{\pm 2}^2$ terms to existing B -symmetry terms T_x^1 and T_0^0 , as shown in Fig. 34.17b,c.

In molecular rotation theory, the T_0^2 terms along with T_0^0 make the initial unperturbed Hamiltonian in Eq. (34.3) of a symmetric top, and gyro terms T_q^1 are viewed as perturbations. For vibration theory, the latter make up a normal-mode Hamiltonian, and the former T_0^2 term is viewed as an anharmonic perturbation.

The effect of T_0^2 , seen in Fig. 34.17c, is to replace the stable fixed point $+B$ (representing the (+)-normal mode) by a saddle point as B bifurcates (splits) into a pair of fixed points that head toward the $\pm A$ -axes. So one normal mode dies and begets two stable local modes, wherein one mass

may keep its energy without losing it to the other through the usual B -beating process. (The A -modes become anharmonically detuned.)

Pairs of classical modes that each localize energy on one side of an RES in Fig. 34.17 are analogous to asymmetric top $\pm K$ -precession pairs in Fig. 34.2. However, one must consider more than the classical aspects of RES pictures. Quantum-tunneling Hamiltonians such as Eq. (34.15) give a superfine doublet for each trajectory pair with (\pm)-combination eigenstates (Table 34.1), and they occupy both paths just as each gyro-spin doublet would have J both up and down the A -axis in a quantum picture.

34.6.3 Multiple Gyro-Rotor RES and Rotational Energy Eigensurfaces (REES)

Just as quantum rotor theory allows J to occupy multiple paths, so also may J occupy multiple RES. In this way gyro-rotors differ from the analogous J precession around a lab-fixed B field or around the body-fixed S of a classical gyro. By allowing the S to be a quantum entity, the possibility arises for distribution over multiple RES [60, 61]. A simple quantum theory of S allows both $+S$ and $-S$ at once. The RES for each is plotted one on top of the other, as in Fig. 34.18a, while component RES are shown in Fig. 34.18b for $+S$ and in Fig. 34.18c for $-S$. An energy sphere is shown intersecting an RES pair for an asymmetric gyro-rotor. If the spin S is set to zero, the pair of RES collapse to a rigid asymmetric top RES shown in Fig. 34.2 having angular inversion (time-reversal $J \rightarrow -J$) and reflection symmetry. The composite RES in Fig. 34.18a has inversion symmetry but lacks reflection symmetry. Its parts in Fig. 34.18b,c have neither symmetry due to their body-fixed gyro-spins $\pm S$.

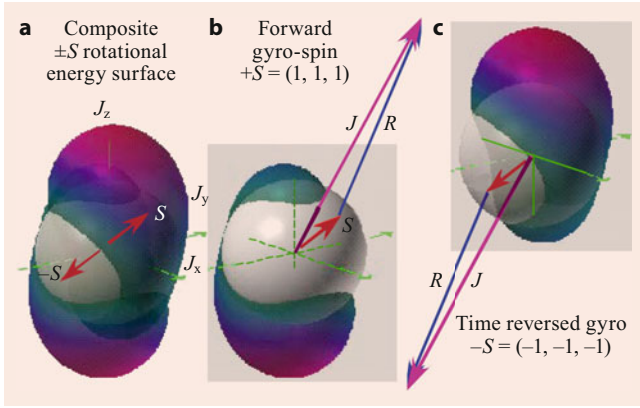

Fig. 34.18 Asymmetric gyro-rotor RES (classical body-fixed spin case); (a) composite $\pm S$; (b) forward spin $\pm S$; (c) reversed spin $-S$

Gyro-rotor Hamiltonians in Eq. (34.40) allow tunneling or mixing of multiple RES. A two-state spin- $1/2$ gyro-spin model has a 2-by-2 Hamiltonian matrix and two-base RES.

$$H_{\text{gyro}} = M_0 \mathbf{J} \cdot \mathbf{J} + D_x S_x J_x + D_y S_y J_y + D_z S_z J_z + Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2, \quad (34.40)$$

As in Eq. (34.7), \mathbf{J} is approximated by classical vector components in the body frame.

$$J_x = |J| \sin \beta \cos \gamma, \quad J_y = |J| \sin \beta \sin \gamma, \quad J_z = |J| \cos \beta. \quad (34.41a)$$

However, the gyro-spin S uses its quantum representation $S = |S|\sigma/2 = \sqrt{3}\sigma/2$ from Eq. (34.34)

$$\begin{aligned} \langle H_{\text{gyro}} \rangle &= M_0 J^2 + Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2 \\ &\quad + D_x |S| \|\sigma_x J_x + D_y |S| \|\sigma_y J_y + D_z |S| \|\sigma_z J_z \\ &= \begin{pmatrix} h(J) + D_z |S| \|J_z & |S| \|(D_x J_x - iD_y J_y) \\ |S| \|(D_x J_x + iD_y J_y) & h(J) - D_z |S| \|J_z \end{pmatrix} \\ &= \begin{pmatrix} h(J) + d_z \cos \beta & (d_x \cos \gamma - id_y \sin \gamma) \\ & \times \sin \beta \\ (d_x \cos \gamma + id_y \sin \gamma) & h(J) - d_z \cos \beta \\ & \times \sin \beta \end{pmatrix}, \end{aligned} \quad (34.41b)$$

where

$$h(J) = M_0 J^2 + Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2,$$

and

$$d_\mu = D_\mu |S| |J|. \quad (34.41c)$$

The semiclassical H_{gyro} makes spin expectation in $\langle S \rangle$ to precess around an angular velocity crank vector Ω with the

following \mathbf{J} -dependent body frame components

$$\Omega_x = d_x \sin \beta \cos \gamma, \quad \Omega_y = d_y \sin \beta \sin \gamma, \quad \Omega_z = d_z \cos \beta. \quad (34.41d)$$

The quantum REES shown in Fig. 34.19 results from substituting quantum spin $S = \frac{1}{2}\sigma$ matrices $\frac{1}{2}\sigma_x$, $\frac{1}{2}\sigma_y$, or $\frac{1}{2}\sigma_z$ for each algebraic Hamiltonian factor S_x , S_y , S_z of Eq. (34.40) to make a matrix Hamiltonian in Eq. (34.41a)–(34.41d) that is then diagonalized. The resulting pair of eigenvalues are plotted to make a pair of REES functions of polar body frame angles β and γ . In comparing the classical composite RES in Fig. 34.18a or Fig. 34.20 with the quantum REES in Fig. 34.19 one may note that they have similar shapes in regions where classical $\pm J$ -surfaces of Fig. 34.20 are well

Fig. 34.19 Quantum gyro-rotor REES views based on eigenvalues of Eqs. (34.41a)–(34.41d) with $S = \sigma/2$

Fig. 34.20 Classical gyro-rotor c-RES views of Fig. 34.18a based on Eq. (34.40)

separated. Wherever the classical RES cross the quantum REES differ most differently due to their intersurface resonance.

Each REES resembles a wrapped symmetric top RES that is most perturbed at points where the two classical RES cross the RES pair intersection along the horizontal x -axis (in figure plane) becomes an REES avoided crossing. The RES pair intersection along the y -axis (out of figure plane) becomes an REES *diabolical* point so-named after a toy top called a diabolo. A current term for such a dual-cone singularity is *Dirac point*.

Near-crossing RES are the rotational equivalent of near-crossing vibrational-potential (VES) employed in treatments of Jahn–Teller effects [62, 63]. The classical, semiclassical, and quantum theory for such loosely bound or fluxional systems is a rapidly growing subfield of atomic, molecular, and optical physics.

34.6.4 Multi-Quantum CF_4 Rovibrational Polyads and REES Visualization

Molecular quantum data comes first in the form of spectral line frequencies that are correlated with theory derived from Hamiltonian energy operator eigenvalues or differences thereof. Second comes a much larger dataset that includes spectral transition rates and intensities that are correlated with eigenvector matrices or density operators. As more AMOP phenomena become available researchers are trying to understand this deluge of data and find ways to visualize it. Section 34.4 provides a theory for level clustering of octahedral and tetrahedral molecules and shows a way to visualize underlying eigenstates using rotational energy surfaces (RES).

A possibility for visualizing ever more complex spectral phenomena involves rovibronic energy eigenvalue surfaces (REES) introduced in Sect. 34.6.3. An example involves the $\text{CF}_4\nu_3/2\nu_4$ rovibrational polyad. It begins with a plot versus the total angular momentum $J = 0$ –70 in Fig. 34.21 of level cluster bands found in this polyad as calculated by Boudon et al. [64, 65].

The plot uses squares (\square) as boundary points containing C_4 -level clusters such as are shown in Fig. 34.4 (right) and C_4 in Fig. 34.6c. Triangular points (\triangle) mark bands of C_3 -clusters shown in Fig. 34.4 (left) and C_3 -correlated in Fig. 34.6a.

Figure 34.21 also has C_2 -cluster regions marked by diamond (\diamond) points where C_2 -correlated species in Fig. 34.6 (centre) might appear. These are rare in O_h or T_d as the RES have saddle points at the C_2 -axes as in Fig. 34.4 so they are unstable. The asymmetric rotor in Fig. 34.2 is a prime example of an RES with unstable $C_2 \pm y$ -saddle points.

Fig. 34.21 CF_4 Molecular rovibrational level clusters for $\nu_3/2\nu_4$ polyad $J = 0$ to $J = 70$. Adapted from Boudon [64]. Energy units are 1 kayser (1 cm^{-1})

However, overtone and combination resonances give rise to the larger clusters that have lower local symmetry of C_2 and C_1 (no symmetry). The $\nu_3/2\nu_4$ REES for ($J = 57$)-states has five of its nine shells showing in Fig. 34.22 [66].

The innermost and lowest REES shell is nearly spherical at the scale of Fig. 34.22 and corresponds to the lowest cluster levels in Fig. 34.21 that come up if expanded, and would reveal usual ordering C_3 -below- C_4 separated by C_2 saddle as in Fig. 34.4. The shell above that has a cubic (as opposed to octahedral) shape with inverted ordering C_4 -below- C_3 clearly shown by levels in the next-to-lowest $J = 57$ cluster bunch in Fig. 34.21.

The three highest REES shells shown in Fig. 34.22 involve a level-cluster mashup in the middle of Fig. 34.21. A pair of shells form diabolical points on C_2 -axes and avoided-crossing pairs of orbits on both C_3 - and C_4 -axes. Above that

Fig. 34.22 CF_4 Molecular ($J = 57$) REES-1-to-5 for $\nu_3/2\nu_4$ polyad levels plotted in Fig. 34.21 (adapted from [66])

is an extraordinary REES shell with 24 C_1 orbits indicated by arrows emerging from their groups. This fifth shell also supports many C_3 orbits, a few C_4 orbits, and a bizarre saddle shape on the C_2 -axes.

The 24-cluster of C_1 orbits belongs to species correlation $O_1 \uparrow O = A_1 \oplus A_2 \oplus E \oplus T_1 \oplus T_2$ of a regular representation of the isomorphic groups $S_4 \approx T_d \approx O$ that now uses the identity subgroup $C_1 = \{1\}$. The relevant C_1 , C_2 , C_3 , and C_4 correlation tables are matched to corresponding cluster orbits in Fig. 34.22, while each of the 24 C_1 orbits lack rotational symmetry, they each do maintain a local reflection symmetry $C_v = \{1, \sigma_v\}$. At much higher J one should expect to find O_h clusters of 48 species levels, indeed, a majority of them in analogy to the majority of regular S_{60} spin states of unit S_1 symmetry in the correlation table of Fig. 34.13.

Abstract

This chapter summarizes the theory of radiative transition probabilities or intensities for rotationally-resolved (high-resolution) molecular spectra. A combined treatment of diatomic, linear, symmetric-top, and asymmetric-top molecules is based on angular momentum relations. Generality and symmetry relations are emphasized. The *energy-intensity* model is founded in a rotating-frame basis-set expansion of the wave functions, Hamiltonians, and transition operators. The intensities of the various rotational branches are calculated from a small number of transition-moment matrix elements, whose relative values can be assumed from the supposed nature of the transition, or inferred by fitting experimental intensities.

Keywords

wave function · angular momentum · diatomic molecule · transition moment · transition matrix element

35.1 Overview

35.1.1 Intensity Versus Line-Position Spectroscopy

The fact that atoms and molecules absorb and emit radiation with propensities that vary with wavelength is the origin of the field called spectroscopy. The relatively sharp intensity maxima are interpreted as corresponding to transitions between discrete states or energy levels. The frequencies or energies of these transitions are used as the primary source of information about the internal structure of the atom or molecule. Line positions can be measured with very high precision (1 ppm or better). Excellent calibration standards have been developed. The quality of these experimental data has attracted extensive analytical and theoretical effort.

Sophisticated parametrized models have been developed in which the smallest shifts from the expected line positions can be used to identify perturbations or other subtle effects.

For molecules, knowledge of the strengths of these transitions is far less well developed. One reason is that quantitative experimental data on rotationally-resolved absorption cross sections and emission intensities are much rarer and the experiments themselves are much more difficult to calibrate. Few measurements claim a precision better than 1% and agreement within 10% of measurements in different laboratories is typically viewed as good. This situation is undesirable because most applications of molecular spectroscopy are in fact measurements of intensity. In many cases the strengths of absorptions or emissions are used to infer gas composition, temperature, time evolution, or other environmental conditions. In other examples the actual absorption and emission is the primary interest. Among the most important of these are atmospheric absorption of solar radiation and the greenhouse effect.

35.2 Molecular Wave Functions in the Rotating Frame

35.2.1 Symmetries of the Exact Wave Function

The exact total wave function for any isolated molecule with well-defined energy and total angular momentum can be expressed in a basis-set expansion over configurations with well-defined internal quantum numbers,

$$\Phi_{\text{exact}} = \Phi_{\text{trans}} \sum_{\alpha\beta\gamma\delta\epsilon} C_{\alpha\beta\gamma\delta\epsilon} \Phi_{\text{rot}}^{\alpha} \Phi_{\text{vib}}^{\beta} \Phi_{\text{elec}}^{\gamma} \Phi_{\text{espin}}^{\delta} \Phi_{\text{nsin}}^{\epsilon} \quad (35.1)$$

In principle, the coefficients $C_{\alpha\beta\gamma\delta\epsilon}$ can be found only by diagonalizing the exact Hamiltonian. In practice one attempts to find a sufficiently good approximation, containing only a few terms, with coefficients chosen by diagonalizing an approximate or model Hamiltonian. This is the basis of the energy–intensity model developed in Sect. 35.3. As discussed by *Longuet-Higgins* [1] and *Bunker* [2], there are only six true symmetries of the exact Hamiltonian of an isolated molecule:

1. translation of the center of mass;
2. permutation of electrons;
3. permutation of identical nuclei;
4. time reversal or momentum reversal;
5. inversion of all particles through the center of mass;
6. rotation about space-fixed axes.

Of these, only the symmetries numbered 5 and 6 give quantum numbers (parity and the total angular momentum F) that are both rigorous and useful spectroscopic labels of the states of the molecule. The other symmetries are convenient for simplifying the description of the molecular wave function, for the evaluation of relations between matrix elements, and for classification of molecular states according to approximate symmetries.

The first symmetry, translation of the center of mass, allows the choice of a coordinate system referenced to the center of mass, and suppression of the portion of the wave function describing motion through space (as long as the molecule does not dissociate).

Symmetry number 2, exchange of electrons, does not directly provide any labels or quantum numbers, since the Fermi–Dirac statistics of electrons require that all wave functions must be antisymmetric. However, it provides considerable information about the probable electronic states since it controls whether molecular orbitals can be doubly or only singly occupied. For most (low- Z) molecules, each state will have a nearly well-defined value of electron spin: singlet or triplet for example. Admixture of other spin values usually can be treated as a perturbation. These points will be elaborated in Sects. 35.4.4 and 35.7.4.

Permutation of identical nuclei, symmetry number 3, also gives an identical quantum number to all the states of the molecule (± 1 depending on the character of the permutation and on whether nuclei with integral or half-integral spin are being permuted). It supplies little direct information about the energy separations between the states of the molecule. On the other hand, many molecules have identical nuclei in geometrically or dynamically equivalent positions. The existence of spatial symmetry, for nonplanar molecules, is really the same thing as permutational symmetry. Consequently, nuclear permutation, combined with inversion (symmetry number 5), is the basis for naming the states according to the approximate spatial symmetry group of the molecular frame and vibrational motion. These concepts will be explored in Sect. 35.4.3.

Symmetry number 4, time reversal, is both subtle and simple. In the absence of external magnetic fields the Hamiltonian for a molecule will contain only even combinations of angular momentum operators, e.g., $F_{\alpha}F_{\beta}$, $F_{\alpha}L_{\beta}$, or $F_{\alpha}S_{\beta}$. Thus changing the signs of all the angular momenta should result in an equivalent wave function. This will require that matrix elements retain the same absolute value when the angular quantum numbers are reversed, leading in general to complex conjugation [3].

Spatial inversion, symmetry number 5, is always an allowed operation for any molecule, even if it appears to lack internal inversion symmetry. This operation can be considered as a symmetry of the spherically-symmetric laboratory

in which the molecule resides. If the molecule is linear, triatomic, rigid with a plane of symmetry, or is nonrigid with accessible vibrational or tunneling modes that correspond to plane reflections, inversion symmetry divides the states of the molecule into two classes, called parities. Perturbations can occur only between states of the same parity. For optical transitions, the change in parity of the states must match the parity of the operator. Otherwise, reflection of the molecule in a plane will interchange inconvertible optical isomers. Such optical isomers are energetically degenerate, so in all cases, inversion through the center of mass remains a valid symmetry of the rotating molecule. However, the separation of the states into two kinds does not provide any selection rules. The two parity classes are perfectly degenerate, thus there is always an allowed level with the correct parity either for perturbations or for optical transitions.

35.2.2 Rotation Matrices

The final symmetry, rotation about the center of mass, restricts the discussion to states with well-defined laboratory angular momentum, and to re-expression of the exact wave function by changing variables from *laboratory* coordinates to *body-fixed* or internal coordinates, and introducing the Euler angles relating these two coordinate systems,

$$\Phi_{\text{exact}}^{F,M_F}(\text{lab}) = \sum_{K_F} \Phi_{\text{rot}}^{F,M_F K_F}(\text{Euler angles}) \times \Phi_{\text{vesn}}^{(F,K_F)}(\text{internal, spins}). \quad (35.2)$$

Here F is the total angular momentum of the molecule, including vibrational, mechanical-rotation, electron-orbital, electron-spin, and nuclear-spin contributions. M_F and K_F are the projections of F in the laboratory and body-fixed frames, respectively. In the majority of cases, the magnitude of nuclear hyperfine interactions is sufficiently small that its influence can be ignored when analyzing wave functions and computing energies. Thus the quantum numbers J , M_J , and K_J , or just J , M , and K can be used.

Explanation is postponed of how the body-fixed frame is to be selected, but for any choice, the wave function for rotation of the entire molecule can be expressed using a rotation matrix [4, 5]

$$\Phi_{\text{rot}}^{F,M_F K_F}(\text{Euler angles}) = \left(\frac{(2F+1)}{8\pi^2} \right)^{1/2} D_{M_F K_F}^{*F}(\phi, \theta, \chi). \quad (35.3)$$

For diatomics, Zare [5] suggests multiplying by $(2\pi)^{1/2}$ and setting $\chi = 0$. The internal wave function for the vibrational, electronic, electron-spin, and nuclear-spin degrees of free-

dom (thus the label (vesn)) can be thought of as the partial summation

$$\Phi_{\text{vesn}}^{(F,K_F)}(\text{internal, spins}) = \sum_{\beta\gamma\delta\epsilon} C_{(FK_F)\beta\gamma\delta\epsilon} \Phi_{\text{vib}}^\beta \Phi_{\text{elec}}^\gamma \Phi_{\text{espin}}^\delta \Phi_{\text{nsin}}^\epsilon, \quad (35.4)$$

expressed in the internal or rotated coordinate system. Note that the FK_F designation is only a parametric label. The rotational wave function has been absorbed into the rotation matrix.

35.2.3 Transformation of Ordinary Objects into the Rotating Frame

The assumption of rotational symmetry allows re-expression of matrix elements between total wave functions as a sum of matrix elements between internal wave functions. For example, the tensor operator $T^{(L)}$ belonging to the L representation of the rotation group, can be written in the rotating frame as [5–8]

$$T_p^{(L)}(\text{lab}) = \sum_q D_{pq}^{*L}(\phi\theta\chi) T_q^{(L)}(\text{body}), \quad (35.5)$$

and can be used to evaluate matrix elements that might represent radiative transitions

$$\begin{aligned} & \langle \psi^{F',M_F'+p} | T_p^{(L)}(\text{lab}) | \Phi^{F'',M_F''} \rangle \\ &= \left(\frac{(2F''+1)}{(2F'+1)} \right)^{1/2} \langle F''M_F'', Lp | F'M_F''+p \rangle \\ & \times \sum_{qK_F''} \langle F''K_F'', Lq | F'K_F''+q \rangle \\ & \times \langle \psi_{\text{vesn}}^{(F',K_F'+q)} | T_q^{(L)}(\text{body}) | \Phi_{\text{vesn}}^{(F'',K_F'')} \rangle, \end{aligned} \quad (35.6)$$

where $\langle F''M_F'', Lp | F'M_F''+p \rangle$ and $\langle F''K_F'', Lq | F'K_F''+q \rangle$ are Clebsch–Gordan coefficients that vanish if $|F'-F''| > L$, $|M_F''+p| > F'$, or $|K_F''+q| > F'$.

This transformation forms the basis for the derivation of rotational branch strengths (Sect. 35.7.2) and for the description of electron motions that are weakly coupled to the molecular frame (Sect. 35.7.4).

35.3 The Energy–Intensity Model

35.3.1 States, Levels, and Components

The previous section introduced the concept of representing the wave function of a molecule as a product of five simpler wave functions:

$$\psi \approx \psi_{\text{elec}} \psi_{\text{vib}} \psi_{\text{rot}} \psi_{\text{espin}} \psi_{\text{nsin}}. \quad (35.7)$$

This construction yields a similar separation of the Hamiltonian,

$$H \approx H_{\text{elec}} + H_{\text{vib}} + H_{\text{rot-fs}} + H_{\text{hf}}, \quad (35.8)$$

and representations of the energies as sums of contributions,

$$E \approx T_e + G_v + F_c(J), \quad (35.9)$$

and absorption or emission transition strengths as products,

$$I \approx I_{\text{elec}} I_{\text{vib}} I_{\text{rot-fs}} I_{\text{hf}}. \quad (35.10)$$

Whatever theoretical arguments might favor such a separation, the real impetus is the empirical observation that most molecular absorption and emission spectra exhibit recognizable patterns arising from the dissimilar magnitudes of the energies associated with these five degrees of freedom. Separation of the wave function and the Hamiltonian into these four or five contributions facilitates the assignment of molecular spectra, in addition to suggesting models with parameters that can be adjusted to quantitatively represent the observed spectra.

Most states of molecules are dominated by a single set of electronic and vibrational quantum numbers. Electronic states are often well separated. With each electronic state is associated a potential energy surface, the energy at the minimum being labeled T_e . Motion of nuclei within this potential generates various levels corresponding to different vibrational quantum numbers, following regular patterns or progressions in energy, summarized by a small number of parameters called vibrational frequencies. The quantity G_v represents the energy of the vibrational level above the potential minimum. For each vibrational level, a progression of rotational levels is expected. For linear molecules in electronic states without electronic angular momentum (i.e., $^1\Sigma$ states) the rotational energies are also reproduced by a few rotational constants.

For more complicated molecules and electronic states, i.e., most cases, there are multiple energetically distinct levels with the same value of J (in addition to the $2J + 1$ orientational degeneracy of each level). These multiple levels all share the same nominal quantum numbers (additional analysis may subdivide them into parity or permutational symmetry types). These sublevels are called *components* with energies expressed by the notation $F_c(J)$. The quantity N_c , the number of components expected, reflects the assignment of the nature of the vibronic state. For linear molecules there is a limited number of components corresponding to the various orientations of electron spin and orbital angular momentum. For example, a $^2\Pi$ electronic state will have four components for each value of J (except for $J = 1/2$, where there are only two components). For nonlinear molecules the number of components increases with J , proportional to $2J + 1$, corresponding to various possible projections of the total angular momentum onto the tumbling molecular frame.

The conclusion of this analysis is that a basis set be chosen, over which a model rotational and fine-structure Hamiltonian can be expressed. The wave functions then become vectors of numbers. A priori, only the form of the matrix elements and their dependence on J and body-frame projection (K or Ω) are known. Little is known in advance about how strong the interactions are in any given molecule. Thus one tends to write the Hamiltonian with parameters that are to be determined by fitting the observed energy levels.

Similarly, the choice of the basis sets for the upper and lower states specifies the overall form of the matrix of transition moments between the basis functions. The transition can be chosen to be of a simple standard form, for example, parallel or perpendicular, with only one unknown parameter representing the overall strength of the transition. Alternatively, the transition matrix elements can be considered to be independently adjustable, within the symmetry restrictions that are required (time reversal) or assumed (spatial symmetry).

35.3.2 The Basis Set and Matrix Hamiltonian

For linear molecules it is convenient to choose a basis set labeled by the projections of orbital and spin angular momenta in the body-frame coordinate system, represented symbolically by

$$|\Lambda\Sigma; JM\Omega\rangle = \left(\frac{(2J+1)}{8\pi^2}\right)^{1/2} D_{M\Omega}^{*J} |\Lambda\Sigma\rangle, \quad (35.11)$$

where $\Omega = \Lambda + \Sigma$. This is called the Hund's case (a) basis set, which is an accurate representation in a single term if the body-frame angular momenta are nearly conserved. This is true if the spin-orbit interaction is larger than the separation between rotational levels. Under all circumstances, this basis set facilitates construction of the matrix Hamiltonian and representation of sources of transition probability [9].

One parametrization for the spin-rotation Hamiltonian is provided by *Brown et al.* [10–12]:

$$\begin{aligned} H_{\text{spin-rot}} = & T_e + G_v + B_v N^2 - D_v N^4 \\ & + \frac{1}{2} [A_v + A_{D_v} N^2, L_z S_z]_+ \\ & + (\gamma_v + \gamma_{D_v} N^2) N \cdot S \\ & + \frac{1}{3} [\lambda_v + \lambda_{D_v} N^2, 3S_z^2 - S^2]_+ \\ & + \eta_v L_z S_z \left[S_z^2 - \frac{1}{5} (3S^2 - 1) \right] \\ & - \frac{1}{4} [o_v + o_{D_v} N^2, \Lambda_+^2 S_-^2 + \Lambda_-^2 S_+^2]_+ \\ & + \frac{1}{4} [p_v + p_{D_v} N^2, \Lambda_+^2 S_- N_- + \Lambda_-^2 S_+ N_+]_+ \\ & + \frac{1}{4} [q_v + q_{D_v} N^2, \Lambda_+^2 N_-^2 + \Lambda_-^2 N_+^2]_+, \end{aligned} \quad (35.12)$$

where $[x, y]_+$ is the anticommutator ($xy + yx$), and $N = J - S$. Zare et al. [13] provide an alternative parametrization, with different interpretations of the *spectroscopic constants* (B, D, A, γ, λ , etc.) because they multiply different symbolic operators. One significant difference is that Zare et al. use the *mechanical angular momentum* $R = J - L - S$ as the expansion operator, rather than N , which might be called the *spinless angular momentum*. These differences mean that care must be taken in attempting to construct simulated spectra from published constants. In spite of much discussion in the literature, there is little theoretical foundation for preferring one parametrization over another, as long as the observed levels are accurately fit. In a number of cases naive assumptions about the origin of certain types of interactions have been overturned. For example, the spin-spin interaction, represented by the constant λ , is often dominated by level shifts due to off-diagonal spin-orbit perturbations [14].

For polyatomic molecules, a suitable basis set for expansion can be chosen to have a similar form [8, 15, 16]

$$|l\Lambda\Sigma; JMK\rangle = \left(\frac{(2J+1)}{8\pi^2}\right)^{1/2} D_{MK}^{*J} |l\Lambda\Sigma\rangle, \quad (35.13)$$

where Λ and Σ represent the projections of the electron-orbital (L) and spin (S) angular momenta, and l represents the projection of the vibrational angular momentum (p for degenerate vibrational modes). This is the symmetric top basis set. Generalizing the work of Watson [17, 18], the parametrized Hamiltonian might be written in a form such as

$$\begin{aligned} H_{\text{rot}} = \sum h_{\xi\eta\theta l}^{\alpha\beta\gamma\delta\epsilon} & \left\{ (J^2)^\alpha (J_z)^{2\beta} (J_+^{2\gamma} + J_-^{2\gamma}) \right. \\ & \times (\mathbf{J} \cdot \mathbf{p})^\delta (\mathbf{J} \cdot \mathbf{L})^\epsilon (\mathbf{J} \cdot \mathbf{S})^\zeta \\ & \left. \times (\mathbf{p} \cdot \mathbf{L})^\eta (\mathbf{p} \cdot \mathbf{S})^\theta (\mathbf{L} \cdot \mathbf{S})^l \right\}, \end{aligned} \quad (35.14)$$

where the $\{\}$ indicates that an appropriately symmetric combination be constructed with anticommutators.

For both linear and nonlinear molecules, it is convenient to use the Wang transformation [19] to combine basis functions with opposite sense of rotation: for diatomics

$$\frac{1}{\sqrt{2}} [|l\Lambda, \Sigma; J, M, \Omega\rangle \pm |l\Lambda, -\Sigma; J, M, -\Omega\rangle]; \quad (35.15)$$

and for polyatomics

$$\frac{1}{\sqrt{2}} [|l, \Lambda, \Sigma; J, M, K\rangle \pm |l, -\Lambda, -\Sigma; J, M, -K\rangle]. \quad (35.16)$$

For diatomic molecules, these combinations can be assigned the parity $\pm(-1)^{J+S+s}$, where $s = 1$ for Σ^- states, and 0 otherwise [13, 20]. For symmetric top molecules, each term

is to be accompanied by the appropriate hidden nuclear-spin basis function [8, 21].

For asymmetric top molecules, the Wang transformation divides the basis functions into four symmetry classes E^\pm and O^\pm according to the combining sign and whether K is even or odd. The eigenstates are often labeled by two projection quantum numbers called K_{-1} and K_1 . Assuming that $A \geq B \geq C$, the asymmetry parameter

$$\kappa = \frac{(2B - A - C)}{(A - C)} \quad (35.17)$$

ranges from -1 for a prolate symmetric top ($B = C$) to 1 for an oblate symmetric top ($B = A$). A, B , and C are the rotational constants, or reciprocals of the moments of inertia, about the three principal top axes. Each asymmetric top level can be correlated with specific symmetric top levels (i.e., K -values) in the two limits. The prolate limiting K -value is called K_{-1} and the oblate limit is called K_1 (i.e., $\kappa = \pm 1$). Note that the symmetric-top principal axes rotate by 90° during this correlation. The eigenstates are given additional symmetry names (ee, eo, oe, oo) according to whether K_{-1} and K_1 are even or odd. Papousek and Aliiev [18] discuss the relations between the (E^\pm, O^\pm) and (ee, eo, oe, oo) labeling schemes.

35.3.3 Fitting Experimental Energies

Having chosen a basis set and model Hamiltonian for both the upper and lower levels, the observed transition energies can be used to infer the numerical values of the constants that best fit the spectrum. The following quotation provides a good description of the process:

The calculational procedure logically divides into three steps: (1) The matrix elements of the upper and lower state Hamiltonians are calculated for each J value using initial values of the adjustable molecular constants; (2) both Hamiltonians are numerically diagonalized and the resulting sets of eigenvalues are used to construct a set of calculated line positions; and (3) from a least-squares fit of the calculated to the observed line positions, an improved set of molecular constants is generated. This nonlinear least-squares procedure is repeated until a satisfactory set of molecular constants is obtained.

This quotation is taken from the article by Zare et al. [13] in which they describe the basis for the LINFIT computer program, one of the first to accomplish direct extraction of constants from diatomic spectral line positions based on numerically diagonalized Hamiltonians.

35.3.4 The Transition Moment Matrix

Diagonalization of the model Hamiltonians for the upper and lower states yields vector wave functions that can be used for calculating matrix elements, especially those needed to eval-

uate radiative transition probabilities. The wave functions for diatomic molecules have the form

$$\begin{aligned}\psi'_{J'M'\Omega'} &= \sum_{\Lambda'\Sigma'} b_{\Lambda'\Sigma'}^{J'\Omega'} |\Lambda'\Sigma'; J'M'\Omega'\rangle, \\ \Phi''_{J''M''\Omega''} &= \sum_{\Lambda''\Sigma''} a_{\Lambda''\Sigma''}^{J''\Omega''} |\Lambda''\Sigma''; J''M''\Omega''\rangle.\end{aligned}\quad (35.18)$$

Section 35.2.3 expresses matrix elements of laboratory-frame operators in terms of matrix elements in the rotating body-fixed frame. Terms of the form

$$\mu_{K'K''} = \langle \psi^{(J'K')} | T_q^{(L)}(\text{body}) | \Phi^{(J''K'')} \rangle \theta(-q) \quad (35.19)$$

need to be evaluated. These terms are multiplied by zero if $K' \neq K'' + q$. In the diatomic basis set these become

$$\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = \langle \Lambda'\Sigma' | T_q^{(L)}(\text{body}) | \Lambda''\Sigma'' \rangle \theta(-q), \quad (35.20)$$

where $\theta(-q)$ is a phase factor described in Sect. 35.7.2. Only a few of these matrix elements are independent and nonzero. For electric dipole transitions ($L = 1$), time-reversal and inversion-symmetry can be used to establish the relation

$$\mu_{-\Omega' - \Omega''} = \eta(-1)^{\Omega' - \Omega''} \mu_{\Omega' \Omega''}. \quad (35.21)$$

The sign of $\eta = \pm 1$ is determined by the overall character of the electronic transition, and is related to the classification of levels into e - and f -parity types and to the determination of which components are involved in the rotational branches (P , Q , and R). These concepts are elaborated in Sect. 35.4.

35.3.5 Fitting Experimental Intensities

For allowed transitions in linear molecules and symmetric tops, only one independent parameter is normally expected in the transition moment matrix. Thus no additional information is available from fitting the experimental rotational branch strengths (assuming the energy–intensity model is adequate). In diatomic molecules, the intensities of different vibrational bands can be used to infer the internuclear-distance dependence of the electronic transition moment (for example, see *Luque and Crosley* [22]).

For forbidden transitions and allowed transitions in asymmetric tops, more than one independent parameter is expected. The intensity of a single given rotational line can be expressed in the form

$$I^{\text{line}} = \left| \sum_{K'K''} \mu_{K'K''} Z_{K'K''}(\text{line}) \right|^2, \quad (35.22)$$

where $Z_{K'K''}(\text{line})$ can be calculated in advance from the energies (wave functions) and quantum numbers alone, using the formulas in Sect. 35.7.2. Nonlinear least-squares fitting can be used to derive the best intensity parameters [23–26], analysis of which can help characterize the nature of the transition, and identify the sources of transition probability.

35.4 Selection Rules

35.4.1 Symmetry Types

Selection rules are guidelines for identifying which transitions are expected to be strong and which are expected to be weak. These rules are based on classifying rovibronic levels into labeled symmetry types. Some symmetry distinctions are effectively exact: such as total angular momentum F , or laboratory-inversion parity. Others are approximate, derived from estimates that certain matrix elements are expected to be much larger than others. The most important of these are based on electron spin (for light molecules) and geometrical point-group symmetry (for relatively rigid polyatomics). In actual fact, no transition is completely forbidden. The multipole nature of electromagnetic radiation (electric-dipole, magnetic-dipole, electric-quadrupole, etc.) implies that any change in angular momentum or parity is possible in principle. Practical interest emphasizes identification of the origin of the strongest source of transition probability, and estimation of the strengths of the weak transitions relative to the stronger ones. The result is a collection of *propensity rules* using *selection rules* as tools of estimation.

Basis functions for expansion of the wave functions for the upper and lower states were chosen in Sect. 35.3.2. The first step in the symmetry classification of rovibronic levels consists of identifying various linear combinations of basis functions that block-diagonalize the exact or approximate Hamiltonians. Symmetry-type names are then assigned to these linear combinations based on the value of F or J and knowledge of the symmetry properties of the underlying vibrational and electronic states. Thus each eigenfunction or rovibronic level consists of an expansion over only one of the kinds of linear combination, and the level can be assigned a specific symmetry type.

Similarly, the basis-set expansion leads to a matrix representation of the possible transitions. Spin- and spatial-symmetry arguments establish relationships between these transition matrix elements, and provide estimates of which are much smaller than the others. Each combination of upper- and lower-state symmetry types results in a specific pattern of rotational branches. The most important patterns are ΔJ even (Q -branches) or odd (P - and R -branches), and intensity alternation for consecutive values of J (nuclear spin statistics).

35.4.2 Rotational Branches and Parity

The symmetry of time or momentum reversal implies that changing the signs of all the angular momenta should result in an equivalent wave function. For example, the phase con-

vention

$$\begin{aligned} & \Phi_{\text{vesn}}^{(F,-K_F)} \text{ (internal, spins)} \\ & = (-1)^{-F+K_F} \Phi_{\text{vesn}}^{*(F,K_F)} \text{ (internal, -spins)} \end{aligned} \quad (35.23)$$

can be chosen to establish that the relative phases of matrix elements of the Hamiltonian can be taken as

$$\begin{aligned} & \left\langle D_{M_F-K_F}^{*F} \Phi_{\text{vesn}}^{(F,-K_F)} \middle| H \middle| D_{M_F-K_F}^{*F} \Phi_{\text{vesn}}^{(F,-K_F)} \right\rangle \\ & = \left\langle D_{M_F K_F}^{*F} \Phi_{\text{vesn}}^{(F,K_F)} \middle| H \middle| D_{M_F K_F}^{*F} \Phi_{\text{vesn}}^{(F,K_F)} \right\rangle^* . \end{aligned} \quad (35.24)$$

The formula for matrix elements of optical transition operators can also be reanalyzed,

$$\begin{aligned} & \langle \psi^{F',M_F'+p} | T_p^{(L)} \text{ (lab)} | \Phi^{F'',M_F''} \rangle \\ & = \left[\frac{(2F''+1)}{(2F'+1)} \right]^{1/2} \langle F'' M_F'', Lp | F' M_F' + p \rangle \\ & \times \frac{1}{2} \sum_{qK''} \langle F'' K_F'', Lq | F' K_F' + q \rangle \\ & \times \left\{ \left\langle \psi_{\text{vesn}}^{(F',K_F'+q)} \middle| T_q^{(L)} \text{ (body)} \middle| \Phi_{\text{vesn}}^{(F'',K_F'')} \right\rangle \right. \\ & \quad + (-1)^{F'+L-F''} \\ & \quad \left. \times \left\langle \psi_{\text{vesn}}^{(F',-K_F'-q)} \middle| T_{-q}^{(L)} \text{ (body)} \middle| \Phi_{\text{vesn}}^{(F'',-K_F'')} \right\rangle \right\} , \end{aligned} \quad (35.25)$$

to establish that all contributions are purely real or purely imaginary [27]. Since such transition matrix elements will be used as absolute squares, they can be treated as if they were purely real.

Parity classification of molecular states according to inversion through the center of mass is important for establishing which transitions are electric-dipole allowed and which states can perturb each other. As discussed by Larsson [4], such classification is not without subtlety and opportunity for confusion. Inversion of the laboratory spatial coordinates (i_{sp} , also called E^* [2]) is equivalent to a reflection σ of the molecule-fixed electronic and nuclear coordinates in an arbitrary plane followed by rotation of the molecular frame by 180° about an axis through the origin and perpendicular to the reflection plane (if F is half-integral special care must be taken about the sense of rotation). It follows that

$$\begin{aligned} & i_{\text{sp}} \Phi_{\text{exact}}^{F,M_F} \text{ (lab)} \\ & = E^* \Phi_{\text{exact}}^{F,M_F} \text{ (lab)} \\ & = \eta(-1)^{F-\gamma} \Phi_{\text{exact}}^{F,M_F} \text{ (lab)} \\ & = \left[\frac{(2F+1)}{8\pi^2} \right]^{1/2} \\ & \times \sum_{K_F} (-1)^{F-K_F} D_{M_F-K_F}^{*F} \sigma_{xz} \Phi_{\text{vesn}}^{(F,K_F)} \end{aligned} \quad (35.26)$$

and

$$\sigma_{xz} \Phi_{\text{vesn}}^{(F,K_F)} = \eta(-1)^{K_F-\gamma} \Phi_{\text{vesn}}^{(F,-K_F)} , \quad (35.27)$$

where $\gamma = 0$ or $1/2$ for integral or half-integral F , respectively, and η is the parity label for the state, having values of ± 1 . In linear molecules, levels with $\eta = +1$ are called e -levels while those with $\eta = -1$ are called f -levels [28, 29].

Inversion symmetry can be combined with time reversal to establish that all matrix elements of the Hamiltonian can be taken to be real [27]. The wave function can also be expressed in the form of the Wang transformation [19], uniting the $\pm K_F$ components,

$$\begin{aligned} \Phi_{\text{exact}}^{F,M_F} \text{ (lab)} & = \left(\frac{(2F+1)}{8\pi^2} \right)^{1/2} \\ & \times \sum_{K_F \geq 0} [D_{M_F K_F}^{*F} \Phi_{\text{vesn}}^{(F,K_F)} \eta(-1)^{-K_F+\gamma} D_{M_F -K_F}^{*F} \sigma_{xz} \Phi_{\text{vesn}}^{(F,K_F)}] \\ & \times [2(1 + \delta_{K_F 0})]^{-1/2} . \end{aligned} \quad (35.28)$$

If the molecule is rigid and has a plane of symmetry, or is nonrigid with accessible vibrational or tunneling modes that correspond to plane reflections, inversion symmetry divides the states of the molecule into two classes, according to the sign of η . Perturbations can occur only for $\Delta F = 0$ and $\eta' \eta'' = +1$. For optical transitions, the change in parity of the states must match the parity of the operator. Odd operators (e.g., electric-dipole) require $\eta' \eta'' (-1)^{\Delta F} = -1$. Even operators (e.g., magnetic-dipole and electric-quadrupole) require $\eta' \eta'' (-1)^{\Delta F} = +1$.

35.4.3 Nuclear Spin, Spatial Symmetry, and Statistics

For most molecules, the coupling of nuclear spin with the electron-spin, electron-orbital, and frame-rotational angular momenta is sufficiently weak that treatment of the energetics of hyperfine interactions can be postponed. The first-order effect of nuclear spin is that rovibronic wave functions for molecules containing identical nuclei must be combined with appropriate nuclear spin wave functions in order to obtain the necessary Fermi–Dirac or Bose–Einstein nuclear permutation symmetry. For many molecules, there exist combinations of nuclear permutations that correspond to combinations of frame rotations, laboratory inversions, and feasible vibrational motions (the rotational wave function makes a contribution because renumbering the nuclei requires a reanalysis of the Euler angles). For rigid molecules, these permutations (possibly including inversion) can be used to generate the point symmetry group of the molecule. For

fluxional molecules, with multiple energetically equivalent nuclear configurations, a rather large *molecular symmetry group* can result, one that may not correspond to any ordinary point group [1, 2].

In the discussion immediately following, consider the case of N occurrences of one kind of nucleus, the others being unique (e.g., PD_3). The treatment can easily be extended to the case of multiple kinds of identical nuclei (e.g., C_2H_6). The exact wave function can be rearranged into a sum over products of the form

$$\Phi_{\text{exact}} = \sum_{a,b} \Phi_{\text{rves}}^{(a)} \Phi_{\text{nspin}}^{(b)}, \quad (35.29)$$

where $\Phi_{\text{rves}}^{(a)}$ is a rovibronic wave function belonging to the $\Gamma(a)$ representation of the symmetric group S_N of permutations over N objects, and $\Phi_{\text{nspin}}^{(b)}$ is a nuclear spin wave function, belonging to the $\Gamma(b)$ representation of S_N . In order to obtain the correct permutation symmetries for the overall wave function, the only terms that can appear in this sum are those for which the direct product $\Gamma(a) \otimes \Gamma(b)$ contains the symmetric or antisymmetric representation, for bosons or fermions, respectively.

Assumption of negligible hyperfine interactions allows evaluation of matrix elements of the form

$$\begin{aligned} & \langle \Phi_{\text{rves}}^{(c)} \Phi_{\text{nspin}}^{(d)} | H | \Phi_{\text{rves}}^{(a)} \Phi_{\text{nspin}}^{(b)} \rangle \\ &= \langle \Phi_{\text{rves}}^{(c)} | H | \Phi_{\text{rves}}^{(a)} \rangle \langle \Phi_{\text{nspin}}^{(d)} | \Phi_{\text{nspin}}^{(b)} \rangle, \end{aligned} \quad (35.30)$$

which vanishes unless $\Gamma(a) = \Gamma(c)$ and $\Gamma(b) = \Gamma(d)$. Thus the nearly-exact wave function can be written as a sum over products where the rovibronic and nuclear-spin factors correspond to basis functions from single known representations:

$$\Phi_{\text{exact}} \approx \sum_{a,b} \Phi_{\text{rves}}^{(a)} \Phi_{\text{nspin}}^{(b)}, \quad (35.31)$$

with $\Gamma(a) = \Gamma_{\text{rves}}$ and $\Gamma(b) = \Gamma_{\text{nspin}}$. This divides the states of the molecule into a number of noninteracting symmetry classes, labeled by the representations of the symmetric group. In the absence of hyperfine interactions, optical transitions are possible only within a certain symmetry class.

Thus the existence of spatial or dynamical symmetry implies that each rovibronic wave function transforms according to a particular representation of a subgroup of the permutation-inversion group (called CNPI by *Bunker* [2]). Each representation includes only specific values of nuclear spin, corresponding to the permutational properties of the nuclear spin wave functions. The most important effect of this analysis is to assign statistical weights or relative intensities to the different symmetry types. For example, the symmetry group for NH_3 is D_{3h} (including umbrella inversion), with representations A'_1 , A'_2 , A''_1 , A''_2 , E' , and E'' . The A'_1 and A'_1

representations must be combined with the (nonexistent) antisymmetric spin function, yielding a statistical weight of 0. Similarly, A'_2 and A''_2 combine with the symmetric $I = 3/2$ spin function, with a statistical weight of 4 (i.e., $2I + 1$). E' and E'' combine with the nonsymmetric $I = 1/2$ spin functions, with a statistical weight of 2. This material is discussed from various viewpoints in numerous articles and text books, of which only a few can be cited here [1, 2, 8, 18, 21, 30–36]. See Chap. 34 for additional details and examples.

Although this analysis appears rather complicated, the selection rules that result are actually the same, at least in simple cases, as the ones that are derivable from simpler ideas. For example, for a ${}^1\Sigma_g^+$ lower state, even J levels are permutation symmetric and have parity $+1$, while odd J levels are permutation antisymmetric and have parity -1 . For a ${}^1\Sigma_u^+$ upper state, even J levels are permutation antisymmetric and have parity $+1$, while odd J levels are permutation symmetric and have parity -1 . Both the parity selection rule and permutation-symmetry selection rule independently require that $\Delta J = \pm 1$ for electric-dipole transitions. Similarly, that the permanent dipole moment of a symmetric-top molecule must lie along the body-fixed axis replicates the $\Delta K = 0$ selection rule for pure-rotation transitions provided by permutational symmetry arguments. This means that when simulating absorption and emission spectra, the nuclear-spin wave function can usually be ignored. The intensity alternation imposed by spin-statistics can be represented by multiplying each wave function by the appropriate factor, for example, 0 or $[(2I + 1)/(2i + 1)^N]^{1/2}$, where I is the total nuclear spin, and i is the spin of one of the N equivalent nuclei.

Group theory remains vital for understanding the relative strengths of vibrational transitions in polyatomics (see *Cotton* [37], for example, and Sect. 35.6.2) and becomes very interesting as interaction between vibration and rotation increases. For the purposes of this discussion, the most important issue is identification of which transition-moment matrix elements $\mu_{K'K''}$ vanish and which are related by symmetry.

35.4.4 Electron Orbital and Spin Angular Momenta

For all molecules, the strongest transitions tend to be those that conserve electron spin. The zero-order transition-moment matrix is diagonal both in total spin and in spin-projection onto the body-frame axis. In the $|\Lambda\Sigma\rangle$ basis set for linear molecules this is expressed by

$$\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = \mu_{\Lambda'\Lambda''} \delta_{\Sigma'\Sigma''}. \quad (35.32)$$

The transition-moment tensor operator $T_q^{(L)}$ (body) can connect basis functions that differ in Λ by at most L . Allowed

electric-dipole transitions thus satisfy

$$\mu_{\Lambda'\Lambda''} = 0, \quad \text{for } |\Lambda' - \Lambda''| > 1. \quad (35.33)$$

In the usual case that the upper and lower states each consist of only a single value of $|\Lambda|$, there is only one independent, nonzero, matrix element $\mu_{|\Lambda'|,|\Lambda''|}$ with

$$\mu_{-|\Lambda'|,-|\Lambda''|} = \eta(-1)^{|\Lambda'|-|\Lambda''|} \mu_{|\Lambda'|,|\Lambda''|}. \quad (35.34)$$

See Sect. 35.8 for a discussion of spin-forbidden and orbitally-forbidden transitions. Similar arguments and phase relationships can be developed for polyatomic molecules with nonzero electron spin or degenerate vibrational or electronic states.

35.5 Absorption Cross Sections and Radiative Lifetimes

35.5.1 Radiation Relations

Among the most important radiation relations is the connection between the absorption cross section and the rate of spontaneous emission. *Einstein* [38] introduced his A and B coefficients to describe the rates of absorption and emission of radiation of a collection of two-level atoms or molecules in equilibrium with a radiation field at the same temperature. The discussion here follows that of *Condon and Shortley* [39], *Penner* [40], *Thorne* [41], and *Steinfeld* [42] (with corrections). Also see Chaps. 11, 18, 72 of this Handbook. The number of absorption events per unit volume per unit time is written as

$$N_l B_{lu} \rho(\nu). \quad (35.35)$$

While the rate of emission is

$$N_u B_{ul} \rho(\nu) + N_u A_{ul}. \quad (35.36)$$

In thermal equilibrium, the radiative energy density is given by the Planck blackbody law

$$\rho(\nu) = \left(\frac{8\pi h \nu^3}{c^3} \right) (e^{h\nu/kT} - 1)^{-1}, \quad (35.37)$$

and the ground and excited state densities satisfy a Boltzmann relationship,

$$\frac{N_u}{N_l} = \left(\frac{g_u}{g_l} \right) e^{-h\nu/kT}, \quad (35.38)$$

where g_u and g_l are the degeneracies of the upper and lower states. The requirement that the rates of absorption and emission must be equal leads to the relations

$$A_{ul} = \left(\frac{8\pi h \nu^3}{c^3} \right) B_{ul} = \left(\frac{8\pi h \nu^3}{c^3} \right) \left(\frac{g_l}{g_u} \right) B_{lu}. \quad (35.39)$$

Numerical values of the B coefficients can be derived from the optical absorption cross section, and thus

$$\begin{aligned} A_{ul} &= \left(\frac{8\pi \nu^2}{c^2} \right) \left(\frac{g_l}{g_u} \right) \int \sigma_{\text{abs}}(\nu) d\nu \\ &= \left(\frac{8\pi \nu^2}{c^2} \right) \int \sigma_{\text{se}}(\nu) d\nu. \end{aligned} \quad (35.40)$$

Finally, the expression for the absorption oscillator strength is

$$\begin{aligned} f_{\text{abs}} &= (4\pi\epsilon_0) \left(\frac{mc^3}{8\pi^2 \nu^2 e^2} \right) \left(\frac{g_u}{g_l} \right) A_{ul} \\ &= (4\pi\epsilon_0) \left(\frac{mc}{\pi e^2} \right) \int \sigma_{\text{abs}}(\nu) d\nu. \end{aligned} \quad (35.41)$$

The emission oscillator strength is simply related to that for absorption: $f_{\text{em}} = -(g_l/g_u) f_{\text{abs}}$. The oscillator strength offers considerable advantages as a means of reporting and comparing the strengths of radiative transitions. It is dimensionless, obeys the simple sum rule (for electric-dipole transitions)

$$\sum_u f_{ul} = \text{number of electrons}, \quad (35.42)$$

and is directly derivable from an experimental absorption cross section even before the assignment of the upper level has been determined (i.e., before its degeneracy is known).

35.5.2 Transition Moments

In many cases, the intention is to construct model quantum mechanical wave functions for the two states involved in the transition under study. In addition, ab initio electronic wave functions and matrix elements may be available (see Chap. 33). Quantum mechanics suggests the following expression for the Einstein A coefficient (see Sect. 12.6.1)

$$A_{ul} = \left(\frac{64\pi^4 \nu^3}{3hc^3} \right) \left(\frac{1}{4\pi\epsilon_0} \right) \left(\frac{1}{g_u} \right) \sum_{u',l'',p} |\langle \psi_{u'} | e r_p | \psi_{l''} \rangle|^2. \quad (35.43)$$

The summation is over all three optical polarization directions p (i.e., r_p runs over x , y , and z in the lab frame), all degenerate components l'' of the lower state (i.e., g_l of them), and all degenerate components u' of the upper state (i.e., g_u of them). This triple sum is also called the *line strength* S_{ul} . Division by the upper-level degeneracy corrects for the fact that the transitions should be averaged rather than summed over the initial levels.

In practice, choosing the appropriate degeneracy to divide by is a question of some ambiguity. For atoms, it is sufficient to understand how the individual matrix elements and

the line strength were calculated. For example, *Bethe* and *Salpeter* [43] use a degeneracy of $(2L + 1)$ for Schrödinger wave functions for the hydrogen atom, and $(2J + 1)$ for Dirac wave functions.

For molecules with internal angular momentum, i.e., everything other than $^1\Sigma$ states of linear molecules, the situation is much more complicated. For electric-dipole allowed transitions in light molecules, ab initio transition moments are calculated in a body-fixed coordinate system, ignoring spin, and not summed over anything.

For diatomic molecules, following the work of *Whiting* et al. [44, 45], the transition probability from a single upper-state component ($J'c'$) to a single lower-state component ($J''c''$) is written as

$$A_{J'c'J''c''} = \left(\frac{64\pi^4\nu^3}{3hc^3} \right) \left(\frac{1}{4\pi\epsilon_0} \right) \times \left(\frac{1}{2J'+1} \right) q_{v'v''} |R_e|^2 S_{J'J''}^{c'c''}. \quad (35.44)$$

In this formula $q_{v'v''} |R_e|^2$ represents the rotationless contribution to the transition moment, symbolically represented as a product of a vibrational overlap ($q_{v'v''}$, i.e., a Franck–Condon factor) and an electronic-only component $|R_e|^2$ (Sect. 35.6.1). All of the rotational complexity is absorbed into the rotational-branch strength factor $S_{J'J''}^{c'c''}$ (Sects. 35.7.2 and 35.7.3). The issue to be addressed here is how to divide numerical factors between $|R_e|^2$ and $S_{J'J''}^{c'c''}$. One approach is to construct an estimate for the rotationless transition probability

$$A_{v'v''} = \left(\frac{1}{N'_c} \right) \sum_{c'J''c''} A_{J'c'J''c''}, \quad (35.45)$$

where N'_c is the number of internal spin-orbit components of the upper state. *Whiting* et al. suggest that $S_{J'J''}^{c'c''}$ be normalized such that for spin-allowed transitions

$$\sum_{c'J''c''} S_{J'J''}^{c'c''} = (2 - \delta_{0,\Lambda'}\delta_{0,\Lambda''})(2S + 1)(2J' + 1). \quad (35.46)$$

The first factor is 1 for Σ – Σ transitions, and 2 for all others. The final factor is replaced by $(2J'' + 1)$ if the sum is over J' instead of J'' . For spin-forbidden transitions the following is a plausible extension of this sum rule,

$$\sum_{c'J''c''} S_{J'J''}^{c'c''} = \max(N'_c, N''_c)(2J' + 1). \quad (35.47)$$

Section 35.7.3 provides a corresponding sum rule for polyatomic molecules. This normalization yields

$$A_{v'v''} = \left(\frac{64\pi^4\nu^3}{3hc^3} \right) \left(\frac{1}{4\pi\epsilon_0} \right) \left(\frac{\max(N'_c, N''_c)}{N'_c} \right) q_{v'v''} |R_e|^2 \quad (35.48)$$

and for spin-allowed transitions, the simple spin-free expressions for the electronic transition moments

$$|R_e|^2 = |\langle \Lambda | e_z | \Lambda \rangle|^2 \quad (35.49)$$

for parallel transitions and

$$|R_e|^2 = \left| \langle \Lambda + 1 | e \frac{1}{\sqrt{2}}(x + iy) | \Lambda \rangle \right|^2 \quad (35.50)$$

for perpendicular transitions.

35.6 Vibrational Band Strengths

35.6.1 Franck–Condon Factors

The Born–Oppenheimer separation of electron and nuclear motion suggests that during an optical transition between different electronic states the nuclei should change neither their position nor momentum. This concept was developed from semiclassical arguments by *Franck* [46] and justified quantum mechanically by *Condon* [47]. Following *Herzberg* [48] and *Steinfeld* [42] the vibronic transition moment can be written as

$$\begin{aligned} \mu_{v'v''} &= \langle \psi'_e \psi'_{v'} | \mu | \psi''_e \psi''_{v''} \rangle, \\ &= \int dR \psi'_{v'}(R) \psi''_{v''}(R) \\ &\quad \times \int dr \psi'_e(r, R) \psi''_e(r, R) \mu(r, R), \\ &= \int dR \psi'_{v'}(R) \psi''_{v''}(R) \mu(R). \end{aligned} \quad (35.51)$$

If the R -dependence of $\mu(R)$ is sufficiently weak, it can be factored out to obtain

$$\mu_{v'v''} = R_e \int dR \psi'_{v'}(R) \psi''_{v''}(R), \quad (35.52)$$

where R_e is called the electronic transition moment. The transition probability is proportional to the square of the above, which is usually written as

$$I \approx q_{v'v''} R_e^2, \quad (35.53)$$

where

$$q_{v'v''} = \left| \int dR \psi'_{v'}(R) \psi''_{v''}(R) \right|^2, \quad (35.54)$$

the square of the overlap between initial and final vibrational wave functions, is called the Franck–Condon factor.

The Franck–Condon factors satisfy the sum rule

$$\sum_{v'} q_{v'v''} = \sum_{v''} q_{v'v''} = 1 \quad (35.55)$$

provided the summations include the continuum vibrational wave functions above the dissociation limits. The Franck–Condon approach also can be used to calculate intensities and cross sections for bound–free [49] and free–free [50] emission and absorption.

In some cases the variation of $\mu(R)$ is significant. Calculation of the effect on the intensities can usually be handled by the *r*-centroid method in which the expression

$$\bar{r}_{v'v''} = \frac{\langle \psi'_{v'} | R | \psi''_{v''} \rangle}{\langle \psi'_{v'} | \psi''_{v''} \rangle} \quad (35.56)$$

is used to calculate an effective internuclear distance for the transition. The transition strength is then proportional to $q_{v'v''} |\mu(\bar{r}_{v'v''})|^2$. An advantage of this formulation is that the vibrational overlaps can be calculated from energy information only, before the transition moment function is known and before the transition strengths are investigated experimentally. The quantitative accuracy of the *r*-centroid method for transition moments that are not linear in the internuclear distance, has been addressed by a considerable literature, which has been summarized by *McCallum* [51].

A second complication arises from the fact that the vibrational wave functions themselves depend parametrically on the rotational angular momentum. Calculation of rotationally-dependent Franck–Condon factors is described by *Dwivedi* et al. [52] who also discuss the *r*-centroid method.

35.6.2 Vibrational Transitions

Vibrational transitions derive their strength from the variation of the *permanent* dipole moment of the molecule as a function of geometry or internuclear coordinates. As described by several authors [31, 32, 34, 53] one can expand the dipole moment as a power series in the internal-Cartesian or normal-mode coordinates

$$M_{xyz}(Q) = M_{xyz}^0 + \sum_i \left(\frac{\partial M_{xyz}}{\partial Q_i} \right) Q_i + \dots \quad (35.57)$$

and calculate intensities from a formula like

$$I \approx \left| \langle \psi_{v'_1} \psi_{v'_2} \dots | M(Q) | \psi_{v''_1} \psi_{v''_2} \dots \rangle \right|^2. \quad (35.58)$$

For homonuclear diatomic molecules, the dipole moment vanishes identically, so there is no rovibrational spectrum. The dipole moment for heteronuclear diatomics is often close to linear in the internuclear distance. The harmonic oscillator model suggests that transitions with $\Delta v = \pm 1$ are the strongest, with intensities approximated by

$$I_{v+1,v} \approx \left| \frac{dM}{dR} \right|^2 (v+1). \quad (35.59)$$

Overtone bands, i.e., with $|\Delta v| > 1$, are observed, as dramatically illustrated by the $\Delta v = 4, 5$ emissions from the OH radical observed from the Earth's night sky [54].

For polyatomic molecules, overtone and combination bands are often quite strong. The presence or absence of which is used to establish the symmetries of the vibrational modes. In general, it is difficult to construct quantitative vibrational intensity formulas with only a few parameters that can be inferred experimentally.

35.7 Rotational Branch Strengths

35.7.1 Branch Structure and Transition Type

The overall rotational structure of a molecular transition is determined by the relative values and phases of the body-frame transition-moment matrix elements, the relative values and phases of coefficients in the expansion of the upper-state and lower-state component wave functions over the angular-momentum-projection basis functions, the energy separations between the components, and the relative values and phases of the vector-coupling coefficients. In simple cases, each lower component might be connected to only a single upper component (Hund's case (b) or symmetric tops), or $\Delta J = \pm 1$ (*P*- and *R*-branches) may dominate over $\Delta J = 0$ (*Q*-branches).

For diatomic molecules, symmetry arguments are used to divide the components into the two parity classes *e* and *f*. For electric dipole transitions, the selection rules from Sect. 35.4.2 imply that

$$\begin{aligned} (N'_e N''_e + N'_f N''_f) & \quad P\text{- and } R\text{-branches} \\ (N'_e N''_f + N'_f N''_e) & \quad Q\text{-branches} \end{aligned} \quad (35.60)$$

are expected, where N_e and N_f indicate the number of components of each parity class (N_e and N_f differ by no more than one). Rotational branches are labeled with the notation $\Delta^R \Delta J_{c'c''}$, using symbols *P* for -1 , *Q* for 0 , and *R* for $+1$. ΔR indicates the *apparent* change in mechanical rotational angular momentum (i.e., energy) (see Hund's case (b) in Sect. 35.7.4) and ΔJ indicates the *actual* change (i.e., quantum mechanical). The labels *c'c''* indicate the components involved. Thus a ${}^P Q_{21}$ branch is expected to be *red shaded* ($\Delta R = -1$) with $\Delta J = 0$ involving the second component of the upper state and the first (lowest) component of the lower state. The notation ${}^P Q_{21}(J)$ (or sometimes ${}^P Q_{21}(R = N)$ for Σ lower states) identifies an individual rotational line and specifies the rotational quantum number of the lower state involved in the transition. If the upper- and lower-state component numbers are the same, one of them may be dropped. Thus P_{22} is sometimes written as P_2 .

For symmetric top molecules, the rotational branches are labeled ΔJ_K (e.g., P_1). For asymmetric tops, the branches are labeled by $\Delta J_{\Delta K_{-1}, \Delta K_1}$, where K_{-1} and K_1 are the prolate- and oblate-limit angular momenta projections (described in Sect. 35.3.2).

The transition dipole moment commonly lies parallel or perpendicular to the body-frame axis. In the former case, $\mu_{K'K''}$ vanishes for $K' \neq K''$, and in the latter for $K' = K''$. Thus parallel bands correspond to $\Delta K = 0$ transitions, while perpendicular bands have $\Delta K = \pm 1$. As enforced by the vector-coupling coefficients or Hönl–London factors described below, for low values of K (e.g., diatomics), $\Delta K = 0$ implies strong $\Delta J = \pm 1$ (P and R) branches and weak $\Delta J = 0$ (Q) branches. On the other hand, $\Delta K = \pm 1$ leads to Q -branches that are approximately twice as strong as either the P - or R -branches.

35.7.2 Hönl–London Factors

The matrix model Hamiltonians for the upper and lower states have been diagonalized, yielding the wave functions

$$\psi_{c'}^{J'M'} = \sum_{K'} b_{J'c'}^{K'} \left(\frac{(2J'+1)}{8\pi^2} \right)^{1/2} D_{M'K'}^{*J'}(\text{lab}) \chi_{K'}(\text{body}) \quad (35.61)$$

and

$$\Phi_{c''}^{J''M''} = \sum_{K''} a_{J''c''}^{K''} \left(\frac{(2J''+1)}{8\pi^2} \right)^{1/2} D_{M''K''}^{*J''}(\text{lab}) \xi_{K''}(\text{body}). \quad (35.62)$$

In these expressions, the designations K' and K'' are slightly symbolic. They represent the body-frame projection of the total angular momentum and also a running index over basis functions. For complicated cases, more than one basis function can have a given value of K .

Following Sect. 35.2.3, the rotational branch strength is then written as

$$\begin{aligned} S_{J',J''}^{c',c''} &= \sum_{pM'M''} |\langle \psi_{c'}^{J'M'} | T_p^{(L)}(\text{lab}) | \Phi_{c''}^{J''M''} \rangle|^2 \\ &= (2J''+1) \left| \sum_{q'K'K''} b_{J'c'}^{*K'} a_{J''c''}^{K''} \langle \chi_{K'} | T_q^{(L)}(\text{body}) | \xi_{K''} \rangle \right. \\ &\quad \left. \times \langle J''K'', Lq | J'K' \rangle \right|^2 \end{aligned} \quad (35.63)$$

or

$$S_{J',J''}^{c',c''} = \left| \sum_{K'K''} b_{J'c'}^{*K'} a_{J''c''}^{K''} \mu_{K'K''} \zeta(J', K', J'', K'') \right|^2, \quad (35.64)$$

where

$$\mu_{K'K''} = \langle \chi_{K'} | T_q^{(L)}(\text{body}) | \xi_{K''} \rangle \theta(K'' - K') \quad (35.65)$$

is the body-frame transition-moment matrix introduced in Sect. 35.3.4, with relative values that are hypothesized based on interpretation of the nature of the transition, calculated from ab initio wave functions, or inferred by fitting the observed rotational branch strengths. The Clebsch–Gordan expression

$$\begin{aligned} \zeta(J', K', J'', K'') &= (2J''+1)^{1/2} \langle J''K'', LK' - K'' | J'K' \rangle \\ &\quad \times \theta(K'' - K') \theta(J' - J'') \end{aligned} \quad (35.66)$$

represents the transformation of the radiation field from the laboratory-frame to the body-frame, also related to the *direction cosines* used by many authors. The additional phase factors

$$\theta(k) = \text{sgn}(k) = \begin{cases} +1 & k \geq 0 \\ -1 & k < 0 \end{cases} \quad (35.67)$$

have been included here to make the signs and symmetry relations of $\mu_{K'K''}$ and $\zeta(J', K', J'', K'')$ agree with those already in use [9, 44, 55, 56]. They are related to the choice of the leading signs when T_+ and T_- are expressed as $\pm(T_x + iT_y)$ and $\pm(T_x - iT_y)$. Their inclusion has no effect for spin-allowed transitions with only one source of transition probability, e.g., purely parallel or perpendicular.

In the usual case of electric-dipole (or magnetic-dipole) radiation (i.e., $L = 1$), ζ^2 is the well-known Hönl–London factor [57]. $\zeta(J', K', J'', K'')$ is a real, signed quantity: negative for $\Delta J \Delta K > 0$; or $\Delta J = \Delta K = 0$ and $K < 0$; otherwise positive [9].

Setting $L = 2$ provides intensity formulas for electric-quadrupole [58], Raman [59], and two-photon [60, 61] transitions. Additional Rayleigh-like terms can appear for $K' = K'' \neq 0$. Halpern et al. [61] also give formulas for three-photon transitions in diatomics, expressed in terms of Clebsch–Gordan coefficients with $L = 3$ and $L = 1$ (for $|\Delta\Omega| \leq 1$).

35.7.3 Sum Rules

The orthonormality relations for component eigenvectors

$$\sum_{c'} b_{J'c'}^{*K'} b_{J'c'}^K = \delta_{K',K}, \quad (35.68)$$

$$\sum_{c''} a_{J''c''}^{*K''} a_{J''c''}^K = \delta_{K'',K} \quad (35.69)$$

can be used to construct the sum rule

$$\sum_{c'c''} S_{J'J''}^{c'c''} = \sum_{K'K''} |\mu_{K'K''} \zeta(J', K', J'', K'')|^2. \quad (35.70)$$

Finally, the orthonormality relations of the Clebsch–Gordan coefficients result in

$$\sum_{J'c'c''} S_{J'J''}^{c'c''} = (2J'' + 1) \sum_{K'K''} |\mu_{K'K''}|^2, \quad (35.71)$$

$$\sum_{J''c'c''} S_{J'J''}^{c'c''} = (2J' + 1) \sum_{K'K''} |\mu_{K'K''}|^2. \quad (35.72)$$

As discussed in Sect. 35.5.2, it is convenient to have the $\mu_{K'K''}$ matrix elements consist of numbers that represent the nature of the transition but not its strength, the latter being expressed by the *vibrational* ($q_{v'v''}$) and *electronic* (R_e) contributions. Following Sect. 35.5.2, for diatomic molecules, the *orientational* part $\mu_{K'K''}$ is taken to have a fixed sum rule

$$\sum_{K'K''} |\mu_{K'K''}|^2 = \max(N'_c, N''_c), \quad (35.73)$$

where N'_c is the number of components (K' values, or basis functions) for the upper state, and N''_c is the number of components in the lower state. For polyatomic molecules, the sum rule can be written as

$$(2J + 1)^2 (\mu_a^2 + \mu_b^2 + \mu_c^2) \max(N'_c, N''_c), \quad (35.74)$$

where

$$\mu_a^2 + \mu_b^2 + \mu_c^2 = |\mu_+|^2 + |\mu_-|^2 + |\mu_0|^2 = 1 \quad (35.75)$$

and N'_c and N''_c are the numbers of spin-electronic-vibrational components in the upper and lower states, respectively. Also see *Whiting* et al. [44, 45] and *Brown* et al. [7].

35.7.4 Hund's Cases

In diatomic molecules, several limiting cases are useful as short-hand or first-approximation concepts for classification of energy levels and rotational branch strengths. These are called the *Hund's cases* [62–64]. They are distinguished by the extent to which the electron orbital and spin angular momenta are rigidly attached to the tumbling molecular frame, i.e., whether Λ , Σ , and S are good quantum numbers. Hund's cases are discussed in many journal articles and in every textbook dealing with the rotational structure of diatomic spectra. An appealing recent description is provided by *Nikitin* and *Zare* [65].

In most works, the emphasis has been on finding a favorable zero-order approximation for perturbation expansion

of energy levels. The advance of precision measurement of transition energies and the availability of sophisticated parametrical matrix models and fast computers on which to realize them, has reduced the importance of Hund's cases for actual computations. In particular, the need to derive and implement numerous explicit energy and intensity formulas leads to unfortunate transcription errors. Nevertheless, they remain of value for qualitative and pedagogical understanding, especially for estimates of the relative intensities of rotational branches.

Hund's case (a) describes the situation in which Λ and Σ are separately well-defined. This is a common case in which the separation between electronic states, i.e., different values of $|\Lambda|$, is larger than the spin-orbit interaction, which in turn, is larger than the separation between rotational levels. At low J , there are $(2S + 1)$ pairs of nearly-degenerate energy levels separated from each other by the spin orbit constant: $E \approx A\Lambda\Sigma + BJ(J + 1)$. The wave functions are of the form

$$\begin{aligned} \psi_{\Omega\pm}^{JM} &= \frac{1}{\sqrt{2}} \left(\frac{(2J + 1)}{8\pi^2} \right)^{1/2} \\ &\times [D_{M\Lambda+\Sigma}^{*J} |\Lambda, \Sigma\rangle \pm D_{M-\Lambda-\Sigma}^{*J} |-\Lambda, -\Sigma\rangle] \\ &= \frac{1}{\sqrt{2}} [|\Lambda, \Sigma; J, M, \Omega\rangle \\ &\pm |-\Lambda, -\Sigma; J, M, -\Omega\rangle], \end{aligned} \quad (35.76)$$

with only two nonzero expansion coefficients a_{Jc}^K . If both the upper and lower states are well described by Hund's case (a), then each lower component is optically connected only to the upper components with the same value of $|\Sigma|$. Then

$$S_{J'J''}^{\Omega'\Omega''} = (2J'' + 1) | \langle J''\Omega'', 1\Omega' - \Omega | J'\Omega' \rangle |^2, \quad (35.77)$$

with $\Omega'' = \Lambda'' + \Sigma$ and $\Omega' = \Lambda' + \Sigma$.

Hund's case (b) indicates that Λ is well-defined, but spin-orbit coupling is weak. The components correspond to well-defined values of $N = J - S$, ranging from $|J - S|$ to $(J + S)$, with energies approximated by $E \approx BN(N + 1)$, and wave functions of the form

$$\begin{aligned} \psi_{N\pm}^{JM} &= \sum_{\Sigma} (-1)^{S+\Sigma} \langle J - \Omega, S\Sigma | N - \Lambda \rangle \\ &\times \frac{1}{\sqrt{2}} [|\Lambda, \Sigma; J, M, \Omega\rangle \\ &\pm |-\Lambda, -\Sigma; J, M, -\Omega\rangle]. \end{aligned} \quad (35.78)$$

This equation is derivable from *Mizushima's* equation (2-3-26) [14] and *Zare's* equations (2.8), (2.26), and (3.105) [5], using the lab-to-body transformation

$$|SM_S\rangle (\text{lab}) = \sum_{\Sigma} D_{M_S\Sigma}^{*S} (\phi\theta\chi) |S\Sigma\rangle (\text{body}). \quad (35.79)$$

It disagrees with Judd's problem 9.1 [66] by a phase factor $(-1)^{J+2S+\Sigma-N}$ but agrees with Mizushima's expansion of a $^3\Pi$ state [14, p. 287] if the Clebsch–Gordan coefficients are taken from Condon and Shortley [39, p. 76].

If both the upper and lower states are well described by Hund's case (b), these wave functions can be substituted into the general rotational-branch strength equations above. Following Edmonds [67, (6.2.8) and (6.2.13), and Table 5] yields the square of a product of Clebsch–Gordan and Racah coefficients

$$S_{J'J''}^{N'N''} = (2J'' + 1)(2J' + 1)(2N'' + 1) \times \left| \langle N'' \Lambda'', 1 \Lambda' - \Lambda'' | N' \Lambda' \rangle \times W(N', J'', N'', J'; S, 1) \right|^2. \quad (35.80)$$

The Clebsch–Gordan coefficient enforces the case (b) selection rule $\Delta N = 0, \pm 1$, while the Racah coefficient provides the $\Delta J = \Delta N$ propensity rule, which becomes more precise as N increases. A similar propensity rule, $\Delta F = \Delta J$, is common for transitions between hyperfine components (see also Femenias [68]).

Hund's case (c) corresponds to the situation in which spin-orbit coupling is so strong that each level described by the projection Ω actually consists of multiple values of $|\Lambda|$ (e.g., mixing of Σ and Π states) or multiple values of S (e.g., mixing of singlet and triplet spins). This limiting case is formally similar to Hund's case (a), but no assumptions can be made about the relative magnitudes of transition-moment matrix elements $\mu_{\Omega'\Omega''}$. Any of which can be nonzero for $|\Delta\Omega| \leq 1$, for example

$$S_{J'J''}^{\Omega'+\Omega''\pm} = \frac{1}{4} \left| \mu_{\Omega'\Omega''} \zeta(J', \Omega', J'', \Omega'') \pm \mu_{\Omega'-\Omega''} \zeta(J', \Omega', J'', -\Omega'') + \mu_{-\Omega'\Omega''} \zeta(J', -\Omega', J'', \Omega'') \pm \mu_{-\Omega'-\Omega''} \zeta(J', -\Omega', J'', -\Omega'') \right|^2. \quad (35.81)$$

The symmetry (sign) relations between $\mu_{\Omega'\Omega''} \zeta(J', \Omega', J'', \Omega'')$ and $\mu_{-\Omega'-\Omega''} \zeta(J', -\Omega', J'', -\Omega'')$ determine whether this transition occurs only for $\Delta J = \pm 1$ (P - and R -branches) or only for $\Delta J = 0$ (Q -branches).

The interest and complexity of Hund's case (c) were exemplified by a seminal work by Kopp and Hougen [69], who considered $\Omega' = 1/2, \Omega'' = 1/2$ transitions, under the assumption that both states could consist of arbitrary mixtures of $^2\Sigma_{1/2}$ and $^2\Pi_{1/2}$ character. Each of the six rotational branches shows constructive or destructive interference of parallel ($\Delta\Omega = 0$) and perpendicular ($\Delta\Omega = \pm 1$) contributions. Hund's case (c) also describes spin-orbit mixing collisions [70] or dissociation to specific spin-orbit limits [71–73].

Hund's case (d) arises in the investigation of Rydberg series [74], in which the separation between Σ and Π from the same orbital configuration approach each other as the prin-

cipal quantum number (n) increases. Spin-orbit coupling between these projections also diminishes. The eigenfunction components correspond to well-defined values of $\mathbf{R} = \mathbf{J} - \mathbf{L}$, ranging from $|J - L|$ to $(J + L)$, with energies approximated by $E \approx BR(R + 1)$, and wave functions of the form

$$\psi_{RL}^{JM} = \sum_{\Lambda} (-1)^{L+\Lambda} \langle J - \Lambda, L \Lambda | R 0 \rangle | L \Lambda; J M \Lambda \rangle. \quad (35.82)$$

Carroll [74] used intensity formulas provided by Kovacs [58] to analyze, by spectral simulation, the $4p-15p$ ($^1\Sigma_u^+$ and $^1\Pi_u$) Rydberg states of N_2 excited from the ground $X^1\Sigma_g^+$. Three strong Q -form branches survive, corresponding to $R' = J''$, two arising from $\Pi \leftarrow \Sigma$ and one from $\Sigma \leftarrow \Sigma$ case (a) branches. The remaining O -form ($R' = J'' - 2$) and S -form ($R' = J'' + 2$) branches fade rapidly as n increases. With the phase conventions used here, this situation corresponds to body-frame transition matrix elements satisfying

$$\mu_{00} = \mu_{-10} = -\mu_{10}. \quad (35.83)$$

In the opposite case, corresponding to a parity change of the parent-ion core [73], two of the Q -form branches are extinguished, while one Q -form, one O -form, and one S -form branch remain. The transition matrix elements would satisfy

$$\mu_{00} = 0, \quad \mu_{-10} = \mu_{10}. \quad (35.84)$$

Hund's case (d) polyatomics are also known [8].

Hund's case (e) would correspond to a situation in which L and S are strongly coupled to each other, but neither is strongly coupled to the internuclear axis. No examples are known for bound states of molecules.

35.7.5 Symmetric Tops

For transitions between nondegenerate vibronic states, the transition moment must lie along the principal top axis, leading to the selection rule $\Delta K = 0$. Otherwise, Hougen's convenient quantum number [33] $G = \Lambda + l - K$, provides the selection rule $\Delta G = 0, \pm n$ (for an n -fold major symmetry axis) (Sects. 35.3.2, 35.4.3, and Chap. 34). Transitions with $\Delta G = \pm n$ are much weaker than those with $\Delta G = 0$ and are not calculable from a simple formula. Branch intensities can be calculated with the Hönl–London formulas of Sect. 35.7.2.

35.7.6 Asymmetric Tops

In general, no assumptions can be made about the orientation of the transition moment. The vector representations (μ_x, μ_y, μ_z) , (μ_a, μ_b, μ_c) , and $(\mu_0, \mu_{+1}, \mu_{-1})$ can have any

combination of independent nonzero values. It is common that one of the (μ_a, μ_b, μ_c) values is significantly larger than the others, especially for planar molecules with a two-fold symmetry axis. In this case one obtains a type *A*, *B*, or *C* band, if μ_a, μ_b, μ_c dominates, respectively [31, 75]. The tradition of analytic calculation of line strengths from explicit representations of wave functions and transition moments leads to formulas of considerable complexity, with somewhat restrictive assumptions [35, 36, 76]. In the more general notation of Sect. 35.7.2, the rotational line strength can be written as

$$S_{J'J''}^{\tau'\tau''} = \left| \sum_{K'K''} b_{J'\tau'}^{*K'} a_{J''\tau''}^{K''} (\mu_0 \delta_{K'K''} + \mu_+ \delta_{K'K''+1} + \mu_- \delta_{K'K''-1}) \zeta(J', K', J'', K'') \right|^2, \quad (35.85)$$

where

$$\begin{aligned} \mu_0 &= \mu_c, & |\mu_+| &= |\mu_-|, \\ |\mu_+|^2 + |\mu_-|^2 &= \mu_a^2 + \mu_b^2. \end{aligned} \quad (35.86)$$

Papousek and Aliev [18] and Zare [5] follow the present formulation, but with somewhat less generality with respect to wave function expansion coefficients or transition moment components.

35.8 Forbidden Transitions

35.8.1 Spin-Changing Transitions

The formalism presented above permits simulation of any allowed transition or forbidden transitions mediated by spin-orbit or spin-spin perturbations, or any perturbation that is diagonal in Ω . For spin-allowed transitions, the transition moment matrix is taken to be diagonal in and independent of the spin projection, so that

$$\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = \mu_{\Lambda'\Lambda''} \delta_{\Sigma'\Sigma''}. \quad (35.87)$$

For forbidden transitions, or complicated Hund's case (c) mixings, the transition moment matrix elements can be considered as independent variable parameters, limited only by the symmetry constraint

$$\mu_{-\Omega'-\Omega''} = \eta(-1)^{\Omega'-\Omega''} \mu_{\Omega'\Omega''}, \quad (35.88)$$

and the fact that terms with $|\Delta\Omega| > 1$ will be multiplied by zero. Alternatively, a specific set of candidate perturbers can be selected, and the Λ - and Σ -dependence of their contributions to the transition-moment matrix evaluated explicitly.

For example, first-order spin-orbit mixing would lead to terms of the form

$$\begin{aligned} \mu_{\Lambda'\Sigma'\Lambda''\Sigma''}^{S'S''} &= \sum_{\Lambda} \left[\mu_{\Lambda'\Sigma'\Lambda\Sigma'}^{S'S'} \frac{\langle S'\Lambda\Sigma' | H_{SO} | S''\Lambda''\Sigma'' \rangle}{\Delta E''} \right. \\ &\quad \left. + \left(\frac{\langle S'\Lambda'\Sigma' | H_{SO} | S''\Lambda\Sigma'' \rangle}{\Delta E'} \right) \mu_{\Lambda\Sigma''\Lambda''\Sigma''}^{S''S''} \right]. \end{aligned} \quad (35.89)$$

However, care must be taken in reducing these matrix elements using the Wigner–Eckart theorem, for example, following *Lefebvre-Brion* and *Field* [55], in order to satisfy the $\Delta\Omega = 0$ requirement for matrix elements of the rotationless Hamiltonian.

35.8.2 Orbitally-Forbidden Transitions

Even if the upper and lower states share the same value of electron spin, the transition may still be forbidden. The change in orbital angular momentum may be too large, $|\Delta\Lambda| > 1$, or a change in reflection parity, $\Sigma^- \rightarrow \Sigma^+$, may cause the zero-order transition matrix elements to vanish. Spin-orbit mixing with other $^{2S+1}\Lambda$ states, as described above, is usually the largest source of transition probability. In addition, terms in the Hamiltonian of the form $\mathbf{J} \cdot \mathbf{L}$ lead to contributions to the transition strength that increase with J , and that may mix-in higher values of Ω than were present in the zero-order $\Lambda\Sigma$ basis set for the upper and lower states. This situation can be represented by generalizing the formula from Sect. 35.7.2, following *Huestis* et al. [23],

$$S_{J'J''}^{c'e''} = \left| \sum_{K'K''} b_{J'c'}^{*K'} a_{J''e''}^{K''} \sum_{i=-1}^1 \mu_{K'K''}^{(i)} \zeta^{(i)}(J', K', J'', K'') \right|^2, \quad (35.90)$$

where $\mu_{K'K''}^{(0)}$ is the rotationless contribution ($\mu_{K'K''}$ from Sect. 35.7.2) and $\mu_{K'K''}^{(\pm 1)}$ are the new rotation-assisted terms. The new reflection-symmetry rule is

$$\mu_{-K'-K''}^{(i)} = \eta(-1)^{K'-K''+i} \mu_{K'K''}^{(-i)}. \quad (35.91)$$

The revised square-root Hönl–London factors are

$$\zeta^{(0)}(J', K', J'', K'') = \zeta(J', K', J'', K'') \quad (35.92)$$

(from Sect. 35.7.2) and

$$\begin{aligned} &\zeta^{(\pm 1)}(J', K', J'', K'') \\ &= \frac{1}{2} \{ [J'(J'+1) - K'(K' \mp 1)]^{1/2} \\ &\quad \times \zeta(J', K' \mp 1, J'', K'') \\ &\quad + [J''(J''+1) - K''(K'' \pm 1)]^{1/2} \\ &\quad \times \zeta(J', K', J'', K'' \pm 1) \}. \end{aligned} \quad (35.93)$$

As in Sect. 35.7.2 the symbols K' and K'' represent $\Lambda'\Sigma'$ and $\Lambda''\Sigma''$ when used as labels, and Ω' and Ω'' when used as numbers (a distinction that is relevant only when $S \geq |\Lambda|$ and $\Lambda \neq 0$). This formulation is more symmetric than that proposed by Huestis et al. [23], in that it explicitly allows for either the upper or lower state to be mixed by rotation (of significance only for low J and $\Delta\Lambda > 1$).

35.9 Recent Developments

Added by Mark M. Cassar. Astronomical sky spectra are important for an understanding of processes both in Earth's and other terrestrial environments. These spectra are the background spectra obtained through the slit of a spectrometer while excluding the object of primary interest to the astronomer—the star, galaxy, etc. The sky spectrum is subsequently subtracted from the object spectrum so that the final product contains no emissions from extraneous sources—nightglow, zodiacal light, and the light of other stellar objects. This operation then leaves the astronomer with purer astronomical spectra, which can then be compared to theoretical transition probability calculations to identify emission sources. This procedure has recently been used to identify the atomic oxygen green line in the Venus night airglow [77], which relied on an understanding of molecular oxygen emissions. In addition, interpretation of the intensities of molecular oxygen emissions also furthers the understanding of the elementary processes occurring in the Earth's atmosphere [78].

Two recent studies have focused on the radiative properties of the CaN and $^{39}\text{K}^{85}\text{Rb}$ molecules. In the former study, the radiative transition probabilities and lifetimes for the $A^4\Pi - X^4\Sigma^-$ and $B^4\Sigma^- - X^4\Sigma^-$ band systems were calculated [79]. These results will in turn facilitate future spectroscopic studies of CaN showing the essential interplay between theory and experiment, which is required for a deeper understanding of these processes. (Radiative properties are sensitive to electronic coupling schemes and to configuration interaction, and thus present an important testing ground for theoretical models [80, 81].) The second study provides quantitative estimates for the radiative cooling of heteronuclear translationally ultracold molecules [82, 83]. By calculating the radiative transition probabilities for $^{39}\text{K}^{85}\text{Rb}$, which lead to the radiative lifetime through the total Einstein A coefficient, it has been shown that under appropriate laboratory conditions such a cooling process is not relevant [84].

Abstract

Molecular photodissociation is the photoinitiated fragmentation of a bound molecule [1]. The purpose of this chapter is to outline the ways in which molecular photodissociation is studied in the gas phase [2]. The results are particularly relevant to the investigation of the species involved in combustion and atmospheric reactions [3].

Introduction

Conceptually, the photodissociation process can be divided into three stages. During the first stage, the molecule absorbs a photon and is promoted to an excited state. This is generally an excited electronic state but can be a highly excited vibrational state in the ground electronic state. In the second stage, the transient complex evolves through a series of *transition states*, until finally, in the third stage, the molecule enters the *exit channel* and dissociates into the products. Schematically, this might be represented, for a triatomic molecule ABC (Fig. 36.1), as

In the case of the triatomic molecule represented here, the dissociation involves the transformation of one of the vibrational modes to a translational, or dissociative, mode, another vibrational mode (the bending) to rotational motion of the products (j), whilst the third vibrational mode is preserved (v).

When the molecule is promoted to an electronic state that has a purely repulsive potential energy surface (PES), it undergoes very rapid dissociation, often in less than one vibrational period. This is called *direct dissociation*. However, the dissociation of the transient complex can be delayed, taking place over many vibrational periods. This is called *indirect dissociation*, or predissociation, and has been divided into three different categories [4], although as with the division between direct and indirect, this is sometimes somewhat arbitrary.

Vibrational predissociation (Herzberg Type II)

In this case, the transient complex is on a vibrationally adiabatic potential energy surface (this is an effective potential for the molecule when it is in a particular vibrational state v), which is not dissociative or which has a barrier to dissociation. Therefore, to dissociate it must either tunnel through the barrier, which is the only possibility for $v = 0$, or undergo

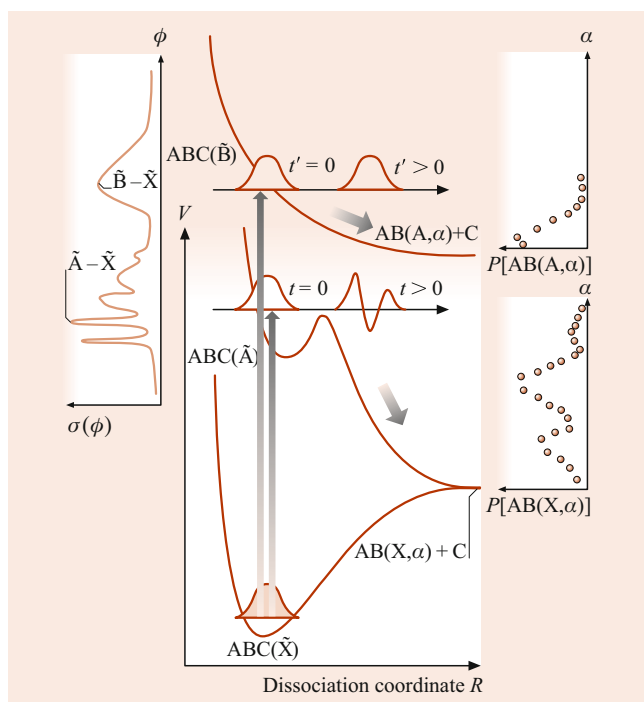

Fig. 36.1 UV photodissociation of a triatomic molecule ABC into products AB(α) and C, illustrating the total absorption cross section $\sigma(\omega)$, evolution of the molecular wave packet, and asymptotic product state distributions $P(\alpha)$, for direct and indirect dissociations on B and \tilde{A} state PESs, respectively

a nonadiabatic transition to a lower vibrational state, thereby transferring energy from a vibrational degree of freedom to the dissociative mode. This process of energy exchange is commonly called the intramolecular redistribution of vibrational energy (IVR).

Rotational predissociation (Herzberg Type III)

In this case, the transient complex is on a nondissociative rotationally adiabatic potential energy surface. Therefore, in a similar manner to vibrational predissociation, if it is to dissociate it must undergo a nonadiabatic transition to a lower rotational state, thereby transferring energy from rotation to the dissociative mode.

Electronic predissociation (Herzberg Type I)

In this case, the PES of the electronic state of the transient complex is not dissociative at the given energy, and in order to dissociate the molecule must undergo a nonadiabatic transition to a second dissociative electronic state. This involves the coupling of nuclear and electronic motion and, therefore, leads to a breakdown of the Born–Oppenheimer (BO) approximation. There are two main types of electronic predissociation. In the first case, there is only a very small coupling, and no actual crossing, between two different electronic states, and the transition between the two is driven by the very high density of vibrational states on

the second electronic state. This is called internal conversion for spin-allowed processes and intersystem crossing for spin-forbidden processes. In the second case, the transition between the electronic states is driven by strong coupling. This coupling can be vibronic (vibrational-electronic) in nature, e.g., for the Renner–Teller and Jahn–Teller effects, or purely electronic, as in the case of a *conical intersection*.

Selection rules

Two sets of selection rules apply to photodissociation. The first set governs the allowed states to which the molecule can be promoted by the photon. These selection rules are simply those for bound-state spectroscopy (Sect. 35.4). Note in particular the selection rule $\Delta J = 0, \pm 1$. This has important practical implications since it means that a molecule that is initially rotationally cold remains so after absorption of a photon. Thus, those observables that are averaged over J will have a clear structure experimentally and will be easier to calculate theoretically. This is in contrast to scattering experiments, which in general involve a summation over many J states (Chap. 38).

The second set of selection rules governs the dissociation process. The transient complex, or prepared (p) state will undergo transitions to a final (f) vibrational, rotational, or electronic state in order to dissociate; these transitions have their own set of selection rules. As for all selection rules, these are determined on the basis of symmetry. For a total wave function Ψ and a perturbation function W , which consists of the coupling terms or neglected terms in the Hamiltonian, $\int \Psi_p^* W \Psi_f d\tau$ must be nonzero for a transition to take place. As W forms a part of the Hamiltonian, it is totally symmetric, and therefore the integral is nonzero only if the prepared and final state irreducible representations are equal, $\Gamma_p = \Gamma_f$. If there is a transition to an excited electronic state, the point groups of the initial and final states are often not the same, in which case the point group formed by the joint elements of symmetry is used, or, in the case where there is no stable geometry for one of the states, the symmetry of the potential is used. These selection rules are given in Table 52.1 for a diatomic molecule.

If the motion can be separated into vibrational, rotational, and electronic parts, so that $\Psi = \Psi^v \Psi^r \Psi^e$ and $W = W^v + W^r + W^e$, it is then possible to derive three separate selection rules: $\Gamma_p^r = \Gamma_f^r$ for the rotational motion, i.e., conservation of internal angular momentum; $\Gamma_p^e = \Gamma_f^e$ for the electronic motion; and $\Gamma_p^v = \Gamma_f^v$ for the vibrational motion. Since the final vibrational state is in the continuum, in practice, all vibrational species (Γ_f^v) are available at a given energy, so that the vibrational selection rule is not significantly restrictive. This separation is not possible in the case of electronic predissociation occurring through the Renner–Teller or Jahn–Teller effect, where it is necessary to consider the vibronic species of the initial and final states.

36.1 Observables

Fundamental to any study of photodissociation is the measurement or calculation of the characteristic properties, or observables, of the reaction, from which the underlying dynamics of the fragmentation process can be inferred.

36.1.1 Scalar Properties

The absorption cross section $\sigma(\omega)$ is a measure of the capacity of the molecule to absorb photons with frequency ω . It is analogous to the line intensity in bound-state spectroscopy. Assuming that the light–matter interaction is weak (Chap. 72), and that the light pulse is on for a long time, the absorption cross section is given by

$$\sigma(\omega) \propto \omega_{\text{fi}} |\langle \Psi_{\text{f}} | \mathbf{E} \cdot \hat{\boldsymbol{\mu}} | \Psi_{\text{i}} \rangle|^2, \quad (36.2)$$

where Ψ_{i} and Ψ_{f} represent the initial and final states, whose energies differ by $\hbar\omega_{\text{fi}}$; \mathbf{E} is a unit vector in the direction of the polarization of the electric field, and $\hat{\boldsymbol{\mu}}$ is the electric dipole operator of the molecule. Assuming the Born–Oppenheimer separation of electronic and nuclear motion, Eq. (36.2) can be rewritten as

$$\sigma(\omega) \propto \omega_{\text{fi}} |\langle \Psi_{\text{f}}^{\text{rv}} | \mu_{\text{fi}} | \Psi_{\text{i}}^{\text{rv}} \rangle|^2, \quad (36.3)$$

where the electronic transition dipole moment μ_{fi} equals $\langle \Psi_{\text{f}}^{\text{e}} | \mathbf{E} \cdot \hat{\boldsymbol{\mu}} | \Psi_{\text{i}}^{\text{e}} \rangle$, and is, in general, dependent on the internal coordinates of the molecule. The superscripts (r, v) will be dropped from now on, and Ψ will refer to the wave function for the internal coordinates of the molecule.

The absorption cross section reflects not only the nature of the transient complex but also its evolution through the transition states. For direct dissociation the absorption cross section is usually very broad and structureless. In contrast, the absorption cross section for predissociation is structured, containing lines that are normally Lorentzian in shape, and whose widths Γ are related to the lifetime of the transient complex at that energy by $\tau = \hbar/\Gamma$.

The partial photodissociation cross sections $\sigma(\omega, \alpha)$ are a measure of the capacity of the molecule to absorb photons with frequency ω and to yield products in quantum state α . They are defined by

$$\sigma(\omega, \alpha) \propto \omega_{\text{fi}} |\langle \Psi_{\text{f}}^{\alpha} | \mu_{\text{fi}} | \Psi_{\text{i}} \rangle|^2, \quad (36.4)$$

where Ψ_{f}^{α} is the final wave function for the products in the quantum state α . The partial cross sections for direct dissociation are broad and featureless. For predissociation, similar structures are seen in the partial cross sections as in the absorption cross section. The absorption or total cross section

is given by the sum of the partial cross sections over all final product states

$$\sigma(\omega) = \sum_{\alpha} \sigma(\omega, \alpha). \quad (36.5)$$

The rotational and vibrational product distributions $P(\omega, \alpha)$ provide information about the amount of product formed by a photon with frequency ω in a particular rotational or vibrational state α . These are related to the partial cross sections by $P(\omega, \alpha) = \sigma(\omega, \alpha)/\sigma(\omega)$. The rotational and vibrational product distributions reflect the nature of the transient complex as it enters the exit channel, as well as the dynamics in the exit channel.

The branching ratios for different chemical species produced in photodissociation are defined as the fraction of the total number of parent molecules that produce the particular species of interest. In Eq. (36.1), the molecule ABC is dissociated into AB + C. It might equally well have dissociated to A + BC, or indeed A + B + C. It is clear then that there may be several different reaction schemes, or channels, for the photodissociation of one particular molecule. Thus, the branching ratio for forming AB is the yield of this first channel divided by the total dissociation yield into all possible channels. Further, it would sometimes be possible to produce AB, or any of the other chemical species, in various electronic, vibrational, or/and rotational quantum states. In this case, the branching ratio for forming AB(α) is the yield of AB in the specific quantum state α divided by the total yield of AB; however, this describes the branching into only this particular reaction channel.

For the reaction scheme represented in Eq. (36.1), the quantum yields of the products AB and C are the same. However, for example, in the reaction

the quantum yield of C is twice that for AB. In general, the quantum yield of a particular product fragment for one reaction channel is the ratio of the number of fragments formed to the number of photons absorbed. However, it is again possible for a molecule to dissociate into various different reaction channels. In such a case, to obtain the overall quantum yield for a particular product, the quantum yield for each reaction channel must be summed over all the available reaction channels, taking into account the branching ratios for the channels.

36.1.2 Vector Correlations

Photodissociation is by its very nature an anisotropic process, as can be seen from Eq. (36.2). The operator $\hat{\boldsymbol{\mu}}$ defines a specific axis in the molecular body-fixed frame of reference. At

the instant of photoexcitation, $\hat{\mu}$ is preferentially aligned parallel to the polarization of the electric field \mathbf{E} in the *external laboratory space-fixed* frame of reference. Hence, \mathbf{E} defines a specific axis, and thus cylindrical symmetry in the body-fixed frame. If fragmentation occurs on a timescale that is short compared with overall rotation of the excited complex, this correlation persists between the body-fixed frame and the space-fixed frame, and a wealth of information can be obtained. However, rotation of the transient complex prior to fragmentation serves to degrade this symmetry in the external body-fixed frame.

Three vectors fully describe the photodissociation process for both the parent molecule and the products: (i) $\hat{\mu}$ in the body-fixed frame (and hence \mathbf{E} , in the space-fixed frame, at the instant of photoexcitation); (ii) \mathbf{v} , the recoil velocity of the products; and (iii) \mathbf{j} , the rotational angular momenta of the fragments. Vector correlations can exist between all of these vectors [5].

The most commonly observed is the angular distribution of the photofragments $I(\theta, \alpha)$, i.e., the relation

$$I(\theta, \alpha) \propto \frac{1}{4\pi} \left[1 + \beta(\alpha) P_2(\cos \theta) \right] \quad (36.7)$$

between \mathbf{v} and \mathbf{E} ; $P_2(x)$ is the second-order Legendre polynomial, and θ is the angle between \mathbf{v} and \mathbf{E} . The *anisotropy parameter* $\beta(\alpha)$ ranges between -1 for a perpendicular transition and $+2$ for a parallel transition. Thus, measuring the angular distribution of the fragments provides information about the type of electronic transition and, hence, the electronic symmetry of the excited state [6]. If the alignment between the body-fixed and space-fixed frames is destroyed, the angular distribution becomes *isotropic* and $\beta(\alpha) = 0$. The anisotropy parameter depends on the product channel α .

A second vector correlation concerns the direction of \mathbf{j} with respect to \mathbf{E} . Fragmentation generates rotational motion in the nuclear plane; for a perpendicular transition, this is perpendicular to the plane containing the atoms, leading to the projection of \mathbf{j} being preferentially aligned parallel to $\hat{\mu}$, and thus \mathbf{E} in the space-fixed frame. For a parallel transition, the opposite would be true, i.e., \mathbf{j} would be aligned in the plane perpendicular to $\hat{\mu}$. The alignment of \mathbf{j} leads to polarized emission/absorption depending on whether molecules are created in an electronically excited/ground state. Therefore, the orientation of the product polarization with respect to the original photolysis polarization \mathbf{E} also yields information about the symmetry of the electronic states involved in dissociation.

The final association in this series is independent of the space-fixed frame, since \mathbf{v} and \mathbf{j} are both defined in the body-fixed frame. Unlike the two previous correlations, a long lifetime does not destroy the alignment, as it is not established until the bond breaks, and the two fragments recoil. For a tetratomic (or larger) molecule there are, in principle,

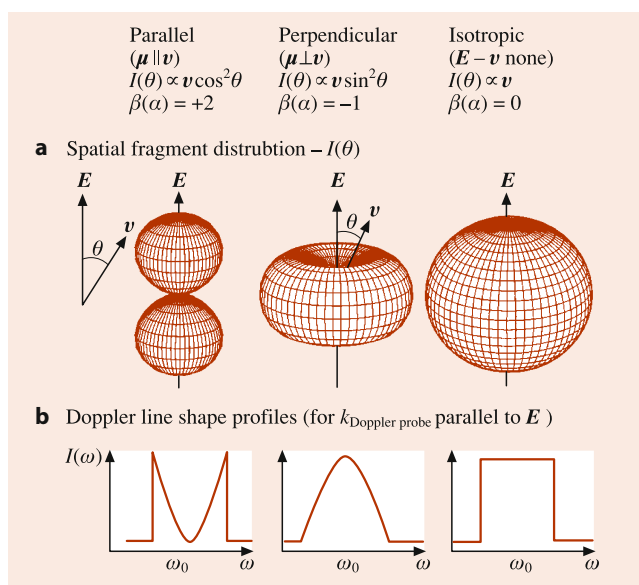

Fig. 36.2 Spatial recoil anisotropies and Doppler line shape profiles for parallel and perpendicular transitions compared with an isotropic distribution

two possible sources of product rotational excitation: bending motion in a plane of the molecule producing fragments with \mathbf{v} perpendicular to \mathbf{j} or torsional motion leading to fragment rotation out of the plane. A prime example of this is the distinction between frisbee and propeller-type motion of the two OH fragments in the dissociation of hydrogen peroxide [7, 8]. Measurement of only the scalar properties *cannot* discriminate between these two possibilities, highlighting the additional information that can be gained about the bond rupture and the exit channel dynamics by the study of vector correlations (Fig. 36.2).

36.2 Experimental Techniques

Early photochemical experiments used broad white-light continuum sources and large diffractometers [4]. However, it has been the development of lasers in combination with molecular-beam techniques that has dramatically increased the understanding of photodissociation processes. The ever-increasing spectral and time resolutions of lasers, in addition to the power and range of wavelengths available, have made it possible to excite molecules selectively and with high efficiency. This has enabled state-specific preparation of the parent molecule, the study of time evolution, as well as the measurement of the scalar and vector properties of the asymptotic products [9].

Specification of the initial state

A room-temperature sample of a gas will have a Boltzmann distribution over rotational states. Molecular beam

techniques provide an improved specification of the initial angular momenta in the parent molecule by isentropically cooling its internal rotational energy [10]. Full quantum state specification can be achieved by various two-photon excitation schemes, e.g., stimulated emission pump (SEP) spectroscopy and vibrationally mediated dissociation. SEP is commonly used to study dissociation on the ground state PES; the molecules are excited to a stable upper electronic state, stimulated emission back to the ground state prepares a *single* quasi-bound state. Vibrationally mediated dissociation provides information about both ground and upper electronic states; the molecules are excited to a stable intermediate vibrational level on the ground state, and further excitation promotes this fully defined wave function to an upper dissociative electronic state [11].

Detailed measurement of the absorption cross section

UV and VUV electronic spectroscopy has proven to be a very powerful tool for examining the interaction of a photon with a parent molecule. Absorption cross sections are typically measured by scanning the frequency domain and monitoring either the intensity of radiation absorbed or the flux of product molecules produced. State-specific detection of the product flux yields the partial cross section $\sigma(\omega, \alpha)$. Explicit measurement of $\sigma(\omega)$ is a direct application of the Beer-Lambert law (Sect. 73.2) and, thus, depends on the length of the optical cavity; cavity ring-down spectroscopy with multiple passes through a cell provides an effective cell length of several tens of kilometers.

Evolution of the transient complex

The evolution of the molecular wave packet can be probed by time-resolved spectroscopy, as discussed in Chap. 37 and [12]. Real-time analysis of the molecular wave packet provides a direct insight into the forces acting during molecular photodissociation. This type of time-resolved spectroscopy and the energy-resolved spectroscopy described above are mutually exclusive due to the time-energy uncertainty principle (Sect. 84.3.1).

Asymptotic properties

The vast majority of photodissociation studies determine asymptotic properties of the dissociation process, measuring either internal energy, recoil velocity, or angular distributions of the dissociation products. The product state distributions are usually explicitly probed by laser-induced fluorescence (LIF), resonance-enhanced multiphoton ionization (REMPI) spectroscopy, or coherent Raman scattering with the relative populations of the products obtained via line intensities.

The distribution and anisotropy of the recoil velocities are measured using Doppler spectroscopy or time-of-flight (TOF) techniques [13]. Doppler spectroscopy uses the Doppler-broadening of lines in the LIF or REMPI ex-

citation spectra (Sect. 73.6); the profile of the line shape also depends on the recoil anisotropy of the probed species (Fig. 36.2). However, many important molecular fragments are not amenable to spectroscopic detection. Thus, though lacking the ultimate state specificity of spectroscopy, TOF techniques by virtue of their general applicability provide an appealing alternative route to determine the product state distributions. In TOF techniques, the time is recorded for photofragments to recoil a known distance from the interaction region to a detector. Due to total energy and momentum conservation, the translational energy distribution of a fragment state specifically detected directly implies the internal energy distribution of the other partner product. In less favorable cases where this is not possible, *coincidence* detection schemes are employed to define the partition between translational and internal energies. Rotation of the detection axis with respect to the polarization of the photolysis laser yields the recoil anisotropy. Advances in spatially resolved detection schemes are now providing an improved measure of vector correlations. Mass spectrometry can be used to measure branching ratios and quantum yields, which can also be obtained from the techniques described above.

36.3 Theoretical Techniques

The calculation of the observables of photodissociation can be carried out using quantum mechanics either in the time-independent or the time-dependent frame, as well as using classical mechanics [1]. Theoretical studies have contributed greatly to the understanding of photodissociation processes, as they provide the ability not only to calculate the observables, but also, through the knowledge of the wave function, to view the dissociation dynamics directly. This has enabled the inference of the underlying dynamics from the observables of the reaction to be more precisely established.

Due to computer limitations, the majority of quantum mechanical studies currently only treat three degrees of freedom fully, and, thus, have mainly concentrated on triatomic molecules. Jacobi coordinates are usually used, with the appropriate set for the dissociation of ABC into AB and C as follows: R , denoting the distance between the atom C and the center of mass of the AB fragment; r , denoting the internal vibration coordinate of AB; and γ , denoting the bending angle between R and r .

The initial state Ψ_i is generally taken to be a single bound state. It is obtained either by the solution of the Schrödinger equation at a particular energy (Sect. 33.4) or simply by taking a product of three Gaussians in the three coordinates, with the parameters of the Gaussians being determined from spectroscopic information on the ground state.

Further, to calculate the observables it is also necessary to have information about μ_{fi} . However, this is often assumed

to be a constant, i.e., independent of the internal coordinates of the molecule. The *Franck–Condon principle* assumes that the nuclear geometry changes after the electronic transition and not during it. Therefore, a molecule, with a particular geometry, will, when promoted by the photon to the excited electronic state, be centered around the same geometry, which is thus referred to as the Franck–Condon region or point.

To carry out any dynamical calculations it is necessary to have PESs for the electronic states involved. These are usually obtained from ab-initio calculations, which are described in Chap. 33. The accuracy of the PES surface largely determines the accuracy of the results obtained, as the PES essentially determines the dynamics of the fragmentation process.

In the *time-independent* approach, a solution of the time-independent Schrödinger equation

$$(\hat{H} - E)\Psi^\alpha = 0, \quad (36.8)$$

is sought for a specific total energy E subject to appropriate boundary conditions at infinite product separation. There are many different approaches to solving this problem, but they can be broadly separated into two groups: scattering methods and \mathcal{L}^2 methods. The scattering methods involve the solution of the coupled channel equations described in Chap. 38. These can be solved directly to yield the wave functions, which can then be used to calculate the observables, or they can be solved indirectly to provide similar information. The use of \mathcal{L}^2 methods, which attempt to expand Ψ in a finite basis set, is not directly applicable since the wave functions are in the continuum and spread out to infinite distances in the R coordinate. Thus, various modifications have been intro-

duced in order to take this into account. The most important of these use variational principles [14], such as that due to *Kohn* [15]. In the Kohn variational principle, the wave function in the inner or interaction region is expanded in a finite \mathcal{L}^2 basis. However, in the outer region, the wave function is expanded in an energy-dependent basis of outgoing and incoming waves, which are approximate solutions of the coupled channel equations. Other methods which can sometimes be used to indirectly extract information about the observables are stabilization [16] and complex scaling [17].

In the *time-dependent* approach [18], one solves the time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} \Phi(t) = \hat{H} \Phi(t) \quad (36.9)$$

for the wave packet $\Phi(t)$ with initial condition $\Phi(0) = \Psi_i$, i.e., it is assumed that the molecule is *vertically* promoted by an infinitely short pulse to the electronic state under consideration. The wave packet is a coherent superposition of stationary wave functions Ψ^α (Chap. 37), and since it comprises many of the stationary states, it contains all the information necessary to characterize the dissociation (Fig. 36.3).

The total absorption cross section is given by

$$\sigma(\omega) \propto \int_{-\infty}^{+\infty} dt S(t) e^{-i\omega t}, \quad (36.10)$$

where the autocorrelation function $S(t)$ is defined as

$$S(t) = \langle \Phi(0) | \Phi(t) \rangle. \quad (36.11)$$

The autocorrelation function reflects the motion of the wave packet, and is, therefore, a convenient means for visualizing

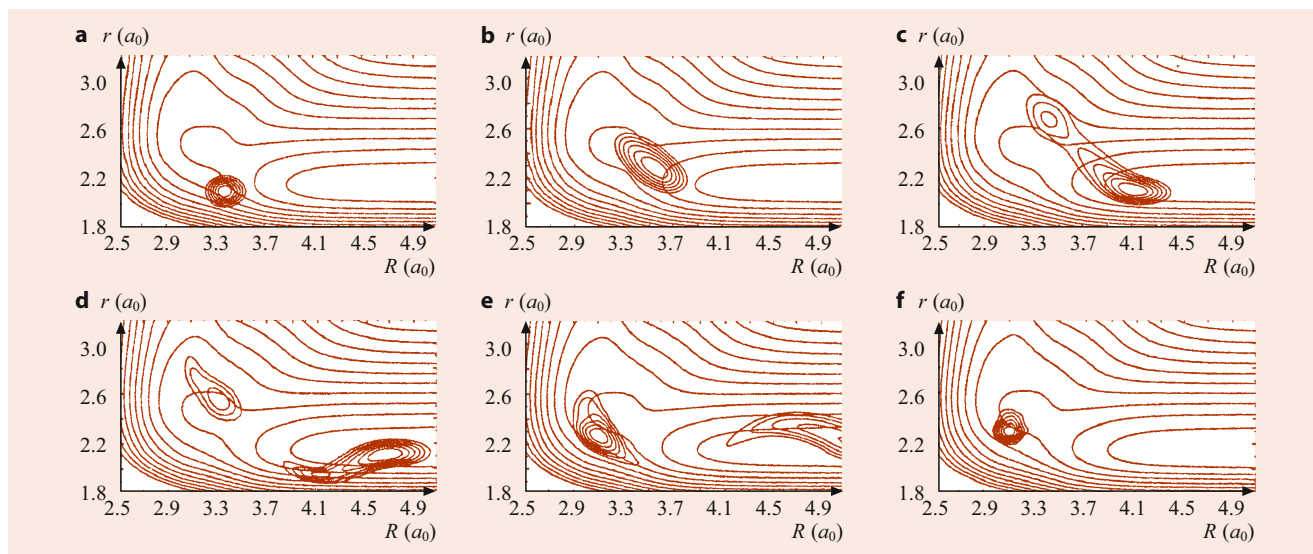

Fig. 36.3 Time evolution of a wave packet in the dissociation of FNO in the S_1 state

the molecular dynamics. The individual partial cross sections can be obtained in the limit $t \rightarrow \infty$ by projection of the wave packet onto the stationary wave functions of the products, i.e., plane waves in the dissociation coordinate and vibrational-rotational wave functions for the free products.

36.4 Concepts in Dissociation

There has been substantial experimental and theoretical work to elucidate the processes involved in photodissociation from knowledge of the observables, and much progress has been made. In this section, an attempt is made to present some of the simpler ideas which have emerged [1].

36.4.1 Direct Dissociation

Direct dissociation is the very fast rupture of a bond after a molecule has been promoted to an electronic state that has a purely repulsive PES. A very clear picture of this process can be obtained from wave packet calculations; the wave packet that is placed on the repulsive surface moves directly down the PES and into the exit channel. The autocorrelation function decays from one to zero in a short time and does not show any recurrences, i.e., oscillations in the autocorrelation function. The absorption cross section $\sigma(\omega)$, which is the Fourier transform of the autocorrelation function in Eq. (36.10), is, therefore, a very broad Gaussian with no structure. The breadth of $\sigma(\omega)$ is inversely proportional to the width of the autocorrelation function and, using simple classical pictures, can be taken to be approximately proportional to the steepness of the potential at the Franck–Condon point. The partial cross sections have a similar structure to the total cross section, although they have differing intensities and are shifted relative to each other on the energy scale.

The product distributions can be predicted using simple classical pictures. These methods can be divided into two groups, depending on the extent of the excitation/de-excitation, or coupling, in the exit channel. If there is very little excitation/de-excitation in the exit channel, the rotational and vibrational product distributions are best described using Franck–Condon mapping. Another model that gives good results for the rotational distributions is the impact parameter, or impulsive, model. If excitation/de-excitation in the exit channel is not negligible, the product distributions are best described using the *reflection principle*. This relates the distribution of the initial wave packet in γ to the final rotational distributions through the classical excitation function. Similarly, the distribution of the initial wave packet in space is related to the final vibrational distributions through another classical excitation function.

Even for a purely repulsive PES, the potential may be very flat in the Franck–Condon region, so that the molecule may be able to undergo one internal vibration before it dissociates. In this case, there is a diffuse structure in $\sigma(\omega)$, associated with recurrences in the autocorrelation function. The spacing of the structures in $\sigma(\omega)$ are related to the period of the internal vibrations by $\Delta E = 2\pi\hbar/T$. Diffuse structures in $\sigma(\omega)$ have also been linked to unstable periodic orbits.

36.4.2 Vibrational Predissociation

Vibrational predissociation is dissociation delayed due to the trapping of the energy of the molecule in modes orthogonal to the dissociation coordinate. It can be explained very clearly in the time-independent picture as resonances (sometimes known as Feshbach resonances), which are simply extensions of the bound states into the continuum; $\sigma(\omega)$ in this case consists of a series of Lorentzian lines, whose width is inversely proportional to the lifetime of the resonance. In the case where the internal modes of the molecule are not strongly coupled to each other or to the dissociation mode, these resonance states can often be assigned, with the number of quanta in each mode being specified. In this case, the lines in $\sigma(\omega)$ form a series of progressions. The widths of these lines, and thus the lifetimes of the resonance states, often show trends relating the lifetimes to the assignment. This is called *mode specificity*. In the case when the system is strongly mixed, it is not possible to make an assignment of the resonances, and the lifetimes show strong fluctuations. This is called *statistical state specificity* [19].

The resonances can also be seen in the time-dependent picture, where the autocorrelation function shows many recurrences with periods T , depending on the fundamental frequencies of the internal modes $\omega = 2\pi/T$ (Chap. 37).

The partial cross sections for vibrational predissociation also consist of Lorentzian lines, with positions and widths exactly as for the total cross sections but with differing intensities. The partial widths, which describe the rate of dissociation into each product channel, are given by

$$\Gamma_{\alpha} = \Gamma \frac{\sigma(\omega, \alpha)}{\sigma_{\text{tot}}(\omega)}. \quad (36.12)$$

In the weak coupling case, simple pictures can be used to describe the product distributions. The rotational product distributions can be explained using, again, the reflection principle; but in this case, instead of considering the distribution of the initial wave function in γ , the distribution of the wave function at the transition state is used. The vibrational product distributions can often be well described by examining vibrationally adiabatic curves.

In the case when the modes are strongly coupled, the simple models break down. It is then sometimes possible

to use statistical models to describe both the rates and the product distributions. One example of these unimolecular-statistical theories is the Ramsperger–Rice–Karplus–Marcus (RRKM) theory, which is widely used for the description of unimolecular dissociations [20]. Another example is phase space theory (PST) [21, 22], which is often used to calculate the product distributions for reactions that have no barrier. The quantum mechanical results fluctuate about these average values. These fluctuations, which can be considered as being independent of the system and can be described well by the predications of random matrix theory [23].

36.4.3 Electronic Predissociation

Nonadiabatic transitions between two or more electronic states are a common phenomenon in photodissociation [24] as well as in other chemical reactions (Chap. 52). Such transitions can result in the production of both electronically excited and ground state fragments.

Adiabatic molecular PESs can vary in complex fashions. Many of these contortions arise from avoided and real crossings of the surfaces, and in all such cases, the physical and chemical understanding is greatly facilitated by expressing the adiabats in terms of the diabatic states (Chap. 33). The electronic diabatic states are chosen to simplify the structure of the electronic wave functions by incorporating the off-diagonal or coupling elements as a pure potential energy term, rather than as a kinetic term, or a mixture of both.

Under these conditions, the BO approximation is inadequate since there is coupling between the different adiabatic states, and the electronic and nuclear motion cannot be separated. Therefore, the solution of the time-dependent Schrödinger equation (Sect. 36.3) requires the set of coupled equations

$$i\hbar \frac{\partial}{\partial t} \begin{pmatrix} \Psi_1 \\ \Psi_2 \end{pmatrix} = \begin{pmatrix} V_{11} + T_{11} & V_{12} \\ V_{12} & V_{22} + T_{22} \end{pmatrix} \begin{pmatrix} \Psi_1 \\ \Psi_2 \end{pmatrix} \quad (36.13)$$

to be propagated, where the coupling between the diabatic surfaces is in the potential (V) and not the kinetic (T) terms. The wave packet evolves on both diabatic (or adiabatic) surfaces and shows a complicated motion in moving between the two surfaces. The coupling between the nuclear and electronic motion can be thought of as resulting in the nuclear motion forcing the transfer of a valence electron to another molecular orbital. Since the efficiency of this transfer is greatest when the orbitals are degenerate, the crossings of the wave packet between the PESs are generally localized around their degeneracies. Finally, the wave packet moves out on the adiabatic surfaces towards the products, with which they are correlated.

36.5 Recent Developments

In recent years, the field of photodissociation has seen a number of intriguing applications and comparisons between detailed experimental data and high-quality ab-initio calculations. These applications have become feasible mainly because of the possibility to construct accurate potential energy surfaces from first-principle electronic structure calculations. Cases in which the fragmentation proceeds via two or several electronic states have been especially concentrated on [25]. In these cases, the Born–Oppenheimer approximation is not valid, and the coupling between electronic and nuclear degrees of freedom is essential (Sect. 36.4.3). A nice example is the photodissociation of water in the second absorption band. Since water has only ten electrons, highly accurate potential energy surfaces have been calculated theoretically, and these have been used in extensive dynamics calculations – including motion on three potential energy surfaces [26]. The agreement between the calculated and the measured absorption cross section at room temperature is outstanding [27]. From the elaborate analysis of product state distributions (rotational, vibrational, and electronic), many details about the coupled motion on several potential energy surfaces have been learned [28, 29]. The electronic density of water is small, and therefore the photodissociation can be treated on a nearly exact level. For other triatomic molecules, with more electrons and a higher density of electronic states, this is generally not feasible. An important example is ozone, which plays a vital role in the atmosphere. The electronic structure of O_3 is illustrated in Fig. 36.4, where many spin-allowed as well as spin-forbidden fragmentation pathways are seen [30]. The photodissociation of ozone in the UV range has been the target of many experimental studies [31]. The interpretation of the many experimental results on the basis of realistic potential energy surfaces is a great challenge for theoretical chemistry.

Photodissociation studies are particularly rewarding if the lifetime in the excited electronic state is long because then the absorption spectrum shows well-resolved lines (resonances), the widths of which are inversely related to the state-specific lifetimes [32]. A typical situation is the excitation of a particular vibrational-rotational state in a bound electronic state, which can decay only via coupling to a dissociative electronic state. The lifetime then reflects the coupling of this state to the continuum of the dissociative state (predissociation). An example is the photodissociation of HCO [33, 34]; in this case, the upper and the lower state are coupled by Renner–Teller coupling. A similar example is the photodissociation of HNO. For this molecule, the lower state has a deep potential well that supports long-lived states in its own continuum. The mixing between the quasi-bound states of the upper state with the resonance states of the lower state leads to interest-

Fig. 36.4 Electronic structure of ozone. Shown are cuts through the potential energy surfaces for the singlet and triplet states. After [30]

ing behavior in the lifetime as a function of the rotational quantum number [35] (resonance between resonances).

Resonances are also prominent features of ground state potential energy surfaces; they are the continuation of the true bound states into the continuum (Sect. 36.4.2). Since resonances determine the kinetics of chemical reactions, they are usually studied in the framework of *unimolecular dissociations* or *unimolecular reactions* [36]. On the other hand, these resonance states can be excited by photons, and therefore it is meaningful to discuss them also in the context of photodissociation. In the past few years, numerical methods have been developed to efficiently calculate the resonance parameters [37–39]; see [36] for a comprehensive overview. Several triatomic molecules with dramatically different intramolecular dynamics have been investigated. The main observation is a strong fluctuation in the resonance lifetimes over several orders of magnitude, even for molecules whose classical dynamics is chaotic, such as NO_2 [40]. Figure 36.5 shows the results for $\text{HOCl} \rightarrow \text{HO} + \text{Cl}$ [41, 42]. The large fluctuations of the lifetimes (or dissociation rates) are believed to affect the fall-off behavior of recombination rate coefficients [43].

Fig. 36.5 Overview of the calculated dissociation rates of HOCl as a function of the excess energy. The solid line is the prediction of a statistical model. After [42]

The concept of first calculating a potential energy surface as function of all coordinates and then performing dynamics calculations is suitable only for triatomics. For molecules with more than four atoms, it is not applicable, simply because of the rapidly increasing number of degrees of freedom. For larger molecules, *direct dynamics* simulations, in which the methodology of classical trajectory simulations is coupled directly to electronic structure calculations, are the method of choice [44, 45]. In these simulations, the derivatives of the potential, which are required for the numerical integration of the equations of motion, are obtained directly from electronic structure theory without the need for an analytic potential energy surface. An important application of direct dynamics is the study of post-transition state intramolecular and unimolecular dynamics. When the dissociation proceeds through a transition state, it may be sufficient to start trajectories at the transition state and to follow them into the product channels [46, 47]

36.6 Summary

Photodissociation of polyatomic molecules is an ideal field for studying the details of molecular dynamics. The primary goal of the experimental and theoretical approaches (Sects. 36.2 and 36.3) is to understand the connection between the observables (Sect. 36.1) and the underlying chemical dynamics (Sect. 36.4). Once this connection has been established, it is possible to have a detailed understanding of the dissociation dynamics, transition state geometries, and the PESs that ultimately govern the molecular chemical reactivity. The interplay between powerful experimental and

theoretical techniques has enabled this goal to be realized for many photodissociation reactions.

Abstract

The interaction of molecules with ultrashort laser pulses results in the preparation of nonstationary quantum states and may trigger photophysical and photochemical processes. As a result, measurements of molecular observables explicitly depend on time, thus reflecting the underlying dynamics. This chapter presents a theoretical description of a so-called pump-probe scheme that involves the preparation and detection of the molecular motion. As a particular example, the experimental realization of transient absorption spectroscopy is described. Utilizing this technique, a photochemical reaction proceeding differently in dependence on the solvent environment is discussed, illustrating the versatility of pump-probe measurements for investigating the dynamics of chemical reactions in real time. Further topical experimental

developments in the ultrafast spectroscopy of molecular systems are outlined. These recent approaches comprise coherent two-dimensional spectroscopy, X-ray and electron diffraction, and also the possibility of quantum control with shaped laser pulses.

37.1 Introduction

Time-resolved experiments have been performed on a multitude of molecular systems. Applications of spectroscopic techniques that work in the time domain range from the detection of simple vibrational motion of a diatomic molecule to the direct determination of relaxation times in polyatomic molecules in a liquid environment, or the recording of isomerization processes in biomolecules. The underlying principles of these experiments are more or less the same. Here, we summarize the basic ideas of transient spectroscopy. First, the quantum-mechanical description of a so-called “pump-probe” scheme is given, where two time-delayed interactions prepare and detect molecular dynamics (Sect. 37.2). This is followed in Sect. 37.3 by a summary of experimental realizations of the pump-probe scheme. To further illustrate the latter, an example of transient absorption measurements in the liquid phase is presented in Sect. 37.4. Finally, more recent developments and additional aspects are outlined in Sect. 37.5.

There exists an extensive amount of literature on the topic of time-resolved molecular dynamics. To follow the developments over the years and keep track of the evolution of the exciting field and its latest innovations, it is instructive to consult the book series related to the biennial “International Conference on Ultrafast Phenomena” [1–11].

37.2 The Principle of Time-Resolved Spectroscopy

We exemplarily look at the phenomenon of wave packets and discuss how to coherently induce and subsequently observe them with ultrashort laser pulses. Regard a molecule with Hamiltonian \hat{H}_0 so that the time-independent Schrödinger equation reads

$$\hat{H}_0 |\psi_n\rangle = E_n |\psi_n\rangle. \quad (37.1)$$

Here, $|\psi_n\rangle$ are the eigenstates with eigenenergies E_n . The time-dependent Schrödinger equation for a general state $|\psi(t)\rangle$ is

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = \hat{H}_0 |\psi(t)\rangle. \quad (37.2)$$

If the state at the initial time $t = 0$ is an eigenstate, i.e., $|\psi(0)\rangle = |\psi_n\rangle$, the time-evolution simply reads

$$|\psi_n(t)\rangle = e^{-\frac{i}{\hbar} E_n t} |\psi_n\rangle, \quad (37.3)$$

and the expectation value of an operator \hat{A} is time-independent

$$\begin{aligned} \langle \hat{A} \rangle(t) &= \langle \psi_n(t) | \hat{A} | \psi_n(t) \rangle = \langle \psi_n(0) | \hat{A} | \psi_n(0) \rangle \\ &= \langle \hat{A} \rangle(0). \end{aligned} \quad (37.4)$$

This means that if a measurement of an observable A with associated operator \hat{A} is performed on a molecule in an eigenstate, then the result of the measurement does not depend on time.

Assume now that the state of the molecule at time $t = 0$ is a superposition of eigenstates so that

$$|\psi\rangle = \sum_n c_n |\psi_n\rangle, \quad (37.5)$$

with coefficients c_n . Such superposition states are called wave packets, and their time dependence is given by

$$|\psi(t)\rangle = \sum_n c_n e^{-\frac{i}{\hbar} E_n t} |\psi_n\rangle. \quad (37.6)$$

Taking the expectation value of \hat{A} with respect to this state, we find that it now depends on time

$$\langle \hat{A} \rangle(t) = \sum_m \sum_n c_m^* c_n e^{i \Delta_{mn} t} \langle \psi_m | \hat{A} | \psi_n \rangle, \quad (37.7)$$

with $\Delta_{mn} = (E_m - E_n)/\hbar$. The time-dependence is contained in the phase factors that result in characteristic oscillations with frequencies determined by the energy differences between the molecular eigenenergies.

The obvious principle evolving from the above considerations is that a time-dependent experiment may reflect the induced dynamics, if we prepare the system in a superposition state. This is possible if it is subject to a time-dependent perturbation which, as we here are concerned with spectroscopic measurements, is a laser field. The time-dependent Schrödinger equation is then

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = \left(\hat{H}_0 + \hat{W}_1(t) \right) |\psi(t)\rangle, \quad (37.8)$$

with the molecule–field interaction $\hat{W}_1(t)$, which starts at the reference time $t = 0$. Writing the state vector as

$$|\psi(t)\rangle = \sum_n b_n(t) e^{-\frac{i}{\hbar} E_n t} |\psi_n\rangle, \quad (37.9)$$

with time-dependent coefficients $b_n(t)$, the Schrödinger equation can, by projection, be transformed to a coupled system of linear differential equations for the coefficients, which reads

$$i\hbar \frac{\partial}{\partial t} b_m(t) = \sum_n b_n(t) e^{i \Delta_{mn} t} \langle \psi_m | \hat{W}_1(t) | \psi_n \rangle. \quad (37.10)$$

In order to find conditions for the preparation of wave packets, we regard the situation where the time-dependent interaction results in photon absorption. Inserting the explicit form of the electric dipole interaction we have

$$\hat{W}_1(t) = -\frac{1}{2} \hat{\mu} f_1(t) e^{-i\omega_1 t}, \quad (37.11)$$

where $\hat{\mu}$ is the projection of the dipole operator on the polarization vector of the electric field, ω_1 the frequency of the laser pulse (commonly referred to as the *pump pulse*), and $f_1(t)$ is an envelope function. Then Eq. (37.10) takes the form

$$i\hbar \frac{\partial}{\partial t} b_m(t) = -\frac{1}{2} \sum_n \langle \psi_m | \hat{\mu} | \psi_n \rangle b_n(t) f_1(t) e^{i(\Delta_{mn} - \omega_1)t}. \quad (37.12)$$

The coefficients $b_m(t)$ become time-independent when the interaction is over ($b_m(t) = \bar{b}_m$), and we have

$$\bar{b}_m = b_m(0) + \frac{1}{i\hbar} \sum_n \langle \psi_m | \hat{\mu} | \psi_n \rangle I_{mn}(1), \quad (37.13)$$

with the integrals

$$I_{mn}(1) = -\frac{1}{2} \int_0^\infty dt b_n(t) f_1(t) e^{i(\Delta_{mn} - \omega_1)t}, \quad (37.14)$$

where the argument (1) refers to the properties of the pump pulse. In general, several of the coefficients will be nonzero

so that, after the interaction, the state vector is a wave packet

$$|\psi(t)\rangle = \sum_n \bar{b}_n e^{-\frac{i}{\hbar} E_n t} |\psi_n\rangle. \quad (37.15)$$

The characteristic timescales for the molecular motion are determined by the energy differences

$$T_{mn} = \left| \frac{2\pi}{\Delta_{mn}} \right|, \quad (37.16)$$

where the longest oscillation period T_{\max} is obtained for the smallest energy separation between two eigenstates. If the pulse duration T_{p1} is longer than T_{\max} , and the excitation of the molecule is resonant with a single transition, i.e., $\Delta_{m_r n_r} - \omega_1 = 0$, then, due to the oscillating phase factors, only one integral $I_{mn}(1)$ is nonzero. This means that, for longer interaction times, a single eigenstate rather than a linear combination of states is excited. Thus, the condition for the preparation of wave packets is that the pulse duration is smaller than, or in the order of, the longest characteristic timescale for the molecular motion, i.e., $T_{p,1} < T_{\max}$. Typical, oscillation periods for the vibrational motion of molecules are in the femtosecond range, so that time-resolved experiments need ultrashort pulses in the femtosecond regime. The same applies to the fastest photochemical reactions, which, for direct dissociations, take place on the sub-100-fs timescale. On the other hand, rotational periods are in the order of picoseconds (and longer), so they can be resolved with ps laser pulses.

Having prepared a wave packet with the pump interaction at the reference time $t = 0$, the question is how to detect its motion. This is realized in perturbing the system, at a defined delay time T , with another laser pulse (the *probe pulse*). Restricting the discussion to a second photon absorption, the interaction energy is as in Eq. (37.11), but the pulse envelope $f_2(t)$ starts at the delay time, and the frequency ω_2 may be different. The wave packet at time T is now written as

$$|\psi(t')\rangle = \sum_n d_n(t') e^{-\frac{i}{\hbar} E_n(t'+T)} |\psi_n\rangle, \quad (37.17)$$

where $d_n(0) = \bar{b}_n$, and the new time variable starts at $t' = 0$. Following the same procedure as above, one arrives at the coupled equations

$$i\hbar \frac{\partial}{\partial t'} d_m(t') = -\frac{1}{2} \sum_n \langle \psi_m | \hat{\mu} | \psi_n \rangle \times d_n(t') f_2(t') e^{i(\Delta_{mn} - \omega_2)t'} e^{i\Delta_{mn}T}. \quad (37.18)$$

We may integrate this equation and regard times after the interaction when the coefficients become time-independent,

so that

$$\bar{d}_m = d_m(0) + \frac{1}{i\hbar} \sum_n \langle \psi_m | \hat{\mu} | \psi_n \rangle I_{mn}(2) e^{i\Delta_{mn}T}, \quad (37.19)$$

where

$$I_{mn}(2) = -\frac{1}{2} \int_0^\infty dt' d_n(t') f_2(t') e^{i(\Delta_{mn} - \omega_2)t'}. \quad (37.20)$$

Regarding the quantity $I_{mn}(2)$ we see again that for a pulse being substantially longer than the oscillations times T_{mn} , the probe laser couples only levels that are in resonance with its frequency ω_2 .

If we now regard the wave packet after the two laser interactions [Eq. (37.17) with $d_n(t') = \bar{d}_n$], the expectation value of an operator \hat{A} depends not only on the propagation time t' but also on the delay time between the pump pulse and the probe pulse. This scheme is readily extended to experiments that involve more than two interactions. For example, in a third-order photon echo experiment, three pulses are delayed to each other. Then the expectation value of the dipole operator, which is the third-order polarization, depends on two delay times τ , T and on the propagation (or detection) time t' .

As described in the previous sections, the preparation of wave packets and the detection of their motion are essential to time-resolved spectroscopy [12–14]. If regarded in coordinate space, the probability density of a wave packet changes as a function of time. As an example, we regard a one-dimensional, coupled electron-nuclear motion. The employed model of this reduced dimensionality dynamics is such that the nuclear motion can be described with the Born–Oppenheimer approximation [15]. Then, the nuclear probability density moves in a bound-state potential, and the electronic density follows the nuclear dynamics. This is illustrated in the left-hand panels of Fig. 37.1. The densities move towards larger distances R , and upon reflection at the outer potential wall, the motion is reversed. The right-hand panels illustrate another case where the bound-state potential curve exhibits a potential barrier at $R = 0$, and the mean energy of the electron-nuclear wave packet is in the order of the barrier height. Then, a splitting occurs where the densities are partly reflected at the barrier.

One-dimensional wave packet motion has been studied extensively using pump-probe fluorescence [16, 17]. Later, other techniques like pump-probe ionization [18, 19] or time-resolved CARS spectroscopy [20] were applied. A beautiful example is the detection of vibrational motion in the Na₂ molecule via time-resolved photoelectron spectroscopy. Following theoretical studies [21, 22], it was documented that the time-dependent probability density of nuclear wave packets can be directly mapped onto the energy dependence of the photoelectron spectra [23–25].

Fig. 37.1 Wave packet bound-state motion. From the solution of the time-dependent Schrödinger equation for a simplified one-dimensional electron-nuclear motion, the nuclear ($\rho_N(R, t)$) and electronic ($\rho_{el}(r, t)$) probability densities are obtained. The motion proceeds adiabatically, so that the electronic density follows the nuclear geometry changes. *Left-hand panels:* the nuclear wave packet moves in a bound-state potential outward until it is reflected at a potential wall. The electronic density adapts adiabatically to the nuclear motion. *Right-hand panels:* the nuclear density is partly reflected at a potential barrier, and the same applies to the electronic density. The data was originally discussed in [15]

37.3 Pump-Probe Scheme

The pump-probe scheme outlined above can be realized in various ways. In the majority of experiments on ultrafast dynamics, the time resolution is obtained by employing two laser pulses: the first one (termed pump pulse) interacts with the sample and starts the process to be studied, whereas after a well-defined, adjustable delay time T , a second laser pulse (called probe pulse) interacts and thereby monitors the time evolution induced by the pump pulse [26–28]. In order to detect signals as a function of T , different detection schemes have been realized and depend on the sample that is investigated. Nonoptical detection may record the amount

of ions or electrons generated by the probe pulse, e.g., from a molecular beam, a liquid microjet, a surface, or its adsorbate in a vacuum chamber system; optical detection may comprise the emission intensity from a higher-lying state reached by the probe pulse (laser-induced fluorescence) or the degree of attenuation of the probe pulse (transient absorption).

Generally, the signal detected reflects the temporal evolution of the system as induced by the pump pulse. In the case of wave packet dynamics, an oscillatory behavior can be detected, because the wave packet's spatial distribution varies with time (Fig. 37.1), and properties like the ionization cross section or the absorption coefficient are, thereby, transiently modulated. Beyond coherent effects, many processes can cause signal changes on an ultrafast timescale, among them relaxation and solvation, or actual reactions originating from the state reached by the pump pulse, e.g., photodissociation, energy or charge transfer, photoisomerization, rearrangement and other geometrical changes, intersystem crossing and quenching, and very often a combination of several of these processes.

There are also ultrafast techniques that do not incorporate two laser pulses interacting with the sample. In fluorescence upconversion as well as in fluorescence Kerr gating, the emitted light from a sample excited by the pump pulse is strobed by a second laser pulse (often called the gate pulse) in a nonlinear process. Since the delay time between the pump (and thus the fluorescence) and the gate pulse is again adjustable in a well-defined fashion, the temporal emission profile is obtained. Great advances have also been achieved by an ultrashort pump pulse in combination with streak cameras or time-correlated single-photon counting, yet the best time resolution can be achieved in the nonlinear approaches with very short laser pulses [27].

In the past decades, laser sources have been perpetually improved. In the visible spectral domain, pulse durations of 20 fs are routinely employed; soft X-rays even allow the generation of attosecond pulses. The accessible spectral range has been continuously extended as well, so that pump-induced dynamics can be performed or probed with pulses from the far-infrared [29] or from the X-ray regime (Sect. 37.5.2), and basically all spectral regions in between.

37.4 Transient Absorption in the Liquid Phase

Chemical reaction dynamics in solution can be elucidated with ultrafast transient absorption spectroscopy in a unique fashion. A schematic experimental implementation is shown in Fig. 37.2a. The spectrally resolved intensity of the probe beam is measured as a function of the pump-probe delay T . To separate the transient from stationary absorption signals, the difference in optical density is determined from two

Fig. 37.2 Three ultrafast liquid-phase spectroscopy approaches (plotted with lenses and a minimal amount of optics for simplicity). **a** Transient absorption: a spectrometer determines the probe spectrum for different values of the pump-probe delay T . **b** Coherent 2-D spectroscopy in pump-probe geometry. The spectrometer measures the probe spectrum for each combination of pump-probe delay T and the delay τ of a phase-stable pump-pulse pair, here generated by a liquid-crystal display (LCD) pulse shaper in a folded zero-dispersion compressor setup. Subsequent Fourier transformation with respect to τ yields 2-D spectra for each value of T . **c** Coherent 2-D spectroscopy in boxcars geometry: the phase-stable pump pulses and the probe pulse traverse the sample from different directions, a local oscillator heterodynes the signal field emitted. Thus, the spectrometer measures the interference of the signal field and the local oscillator for each combination of T and τ

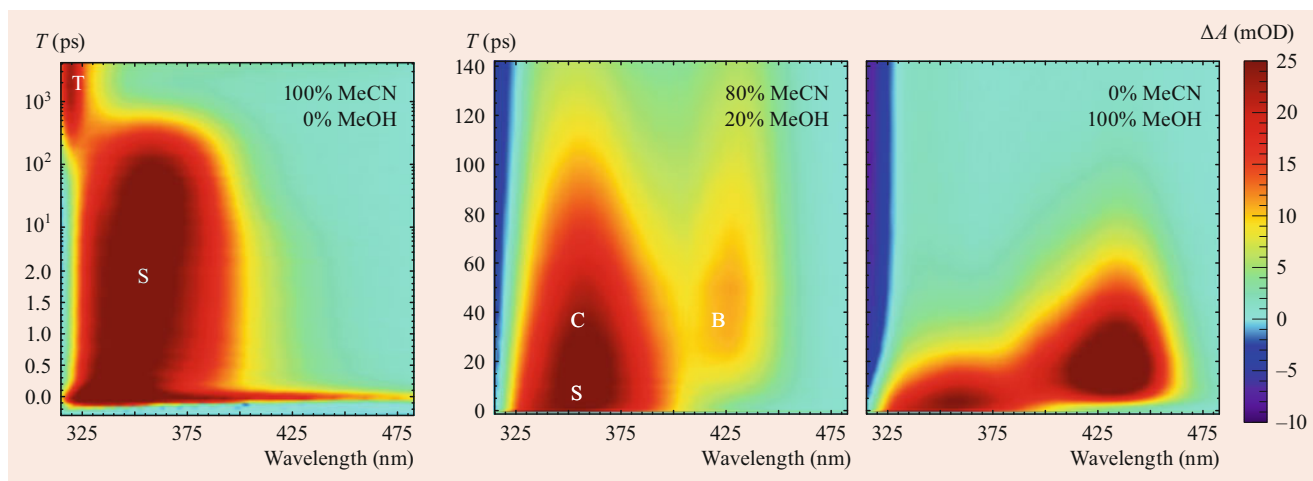

Fig. 37.3 Transient absorption maps of Ph_2CN_2 in binary solvent mixtures of MeCN and MeOH. Note the logarithmic ordinate for T values beyond 2 ps in the left panel. The data was originally discussed in [30], and graphs are adapted therefrom

measurements, one with and one without the pump pulse, respectively

$$\Delta OD(\lambda_{\text{probe}}, T) = -\log_{10} \left[\frac{I_{\text{pumped}}(\lambda_{\text{probe}}, T)}{I_{\text{unpumped}}(\lambda_{\text{probe}})} \right]; \quad (37.21)$$

ΔOD is positive if the probe encounters absorbing species that were not there in the absence of the pump pulse, i.e., excited reactants or products, whereas it is negative for stimulated emission from excited species or in case of the ground-state bleach caused by a reduced number of reactants in the ground state.

As an example, the photodynamics of Ph_2CN_2 (diphenyldiazomethane) in different solvent environments are shown in Fig. 37.3. Upon excitation at $T = 0$ with a pump pulse centered at 285 nm, N_2 is photolyzed off, and a reactive carbene $^1\text{Ph}_2\text{C}$ is formed, which is initially in a singlet configuration. The singlet absorption is observed around 355 nm (labeled **S** in Fig. 37.3). In the aprotic solvent MeCN (acetonitrile), $^1\text{Ph}_2\text{C}$ (**S**) will turn into a triplet $^3\text{Ph}_2\text{C}$ (**T**) within several hundred ps. In the presence of the protic solvent MeOH (methanol), a benzhydryl cation Ph_2CH^+ (**B**) or a hydrogen-bonded complex $^1\text{Ph}_2\text{C} \cdots \text{HOME}$ (**C**) can be formed, depending on whether or not the close-by MeOH molecule is part of a hydrogen-bond network with other MeOH molecules, respectively. Both **B** and **C** react on to an ether that does not absorb in the covered spectral range. As can be seen in Fig. 37.3, the signal of the benzhydryl cation **B** is the most pronounced and decays the most rapidly in the absence of MeCN. Thus, these exemplary data sets emphasize that transient absorption is a powerful tool to reveal the different reaction pathways and the characteristic time scales of chemical reactions in solution.

37.5 Further Implementations

The arsenal of ultrafast experimental techniques is increasing at an incredible speed. Besides extending to new spectral regions and lower pulse durations, the nonlinearity of the light–matter interaction and also the number of laser pulses employed are adapted to unravel previously unexplored photophysical and photochemical aspects. In the following, a few of these recent developments are outlined.

37.5.1 Coherent Two-Dimensional Spectroscopy

While in a transient absorption experiment, molecules are excited with a wavenumber $\tilde{\nu}_{\text{pump}}$ and probed with $\tilde{\nu}_{\text{probe}}$ (note that often frequency or wavenumber rather than wavelength is used for data presentation) after a delay time T , a transient absorption map as in Fig. 37.3 is a representation of the system response as a function of the latter two quantities only. To gain information on the role of the pump wavenumber, the spectral position of the pump pulse can be tuned, and each time a transient absorption map is recorded (Fig. 37.4a). However, the spectral bandwidth of the pump pulse limits the spectral resolution along $\tilde{\nu}_{\text{pump}}$. This can be overcome by splitting the pump pulse into a phase-stable pulse pair whose delay τ is scanned (e.g. by a pulse shaper as in Fig. 37.2b), a subsequent Fourier transform of the detected signal with respect to τ yields the dependence on $\tilde{\nu}_{\text{pump}}$. Hence, for each delay time T , which can be varied as well to capture the full dynamics, the information is spread along two frequency

axes (Fig. 37.4b), thereby allowing in an intuitive way the identification of couplings, transfer processes, or generally how a pumped species interacts with or turns into a probed one. This technique of coherent two-dimensional (2-D) spectroscopy [31–37] can be understood as an optical analogue of recording frequency-correlation spectra in 2-D nuclear magnetic resonance.

Many different implementations of 2-D spectroscopy exist, all with pros and cons, the most versatile but possibly also experimentally most challenging being the boxcars geometry (Fig. 37.2c), where the three pulses all come from different directions, and the desired signal from the sample is emitted in yet another direction. With the help of an adequate local oscillator, that is a further pulse that together with the signal field impinges upon the detector, the signal field can be fully retrieved in both amplitude and phase, and thus the system's response to the interacting fields is fully accessible.

2-D spectroscopy is successfully applied in many spectral ranges, from THz [38] to ultraviolet [39–43]. In 2-D infrared spectroscopy, vibrations are labeled by the pump event, and subsequent processes (coupling between vibrational modes, spectral diffusion, relaxation, chemical exchange, ...) are monitored, making it a versatile tool for assessing molecular structure and associated dynamics [34, 35, 44]. 2-D electronic spectroscopy correlates electronic transitions and has proven to be particularly powerful for unraveling electronic couplings and exciton dynamics in light-harvesting systems [45, 46] and has opened the door to tackle the pressing question as to which extent coherent phenomena affect functionality in chemical or biological systems [46].

37.5.2 Ultrafast Dynamics Studied with X-Ray and Electron Pulses

In recent years, ultrashort pulses have been extended into the X-ray regime [47–52]. Laboratory-based sources often rely on a laser-induced plasma or a high-harmonic-generation (HHG) process. In the latter, photons at odd multiples of the initial laser frequency are generated in a strong-field nonlinear effect up to a spectral cutoff region, so that the radiation comprises coherent soft X-rays, which even allow the formation of attosecond pulses. Pump-probe schemes involving these soft X-rays opened a new way for unraveling nuclear and electron dynamics in atoms but also in molecules, both for gas-phase samples and in the condensed phase, providing insight into processes like charge transfer, ring opening, and photofragmentation [51–53]. Many of these experiments make use of a high photon-energy pump pulse in order to prepare core-excited states such that the following dynamics could be detected with a time-delayed optical probe pulse. In a second scenario, a visible or UV pump pulse initiates a chemical reaction that is followed by a time-delayed

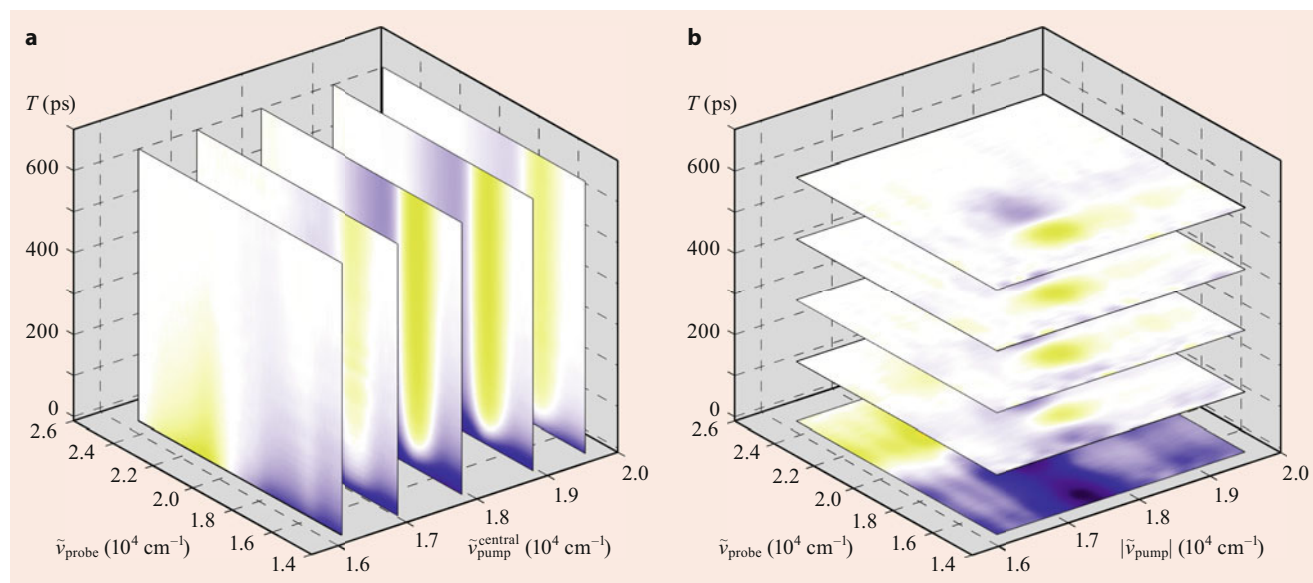

Fig. 37.4 Ultrafast spectroscopy data for the molecule 6-nitro-1', 3', 3'-trimethylspiro[2*H*-1-benzopyran-2, 2'-indoline] (6-nitro-BIPS). By transient absorption with different central pump wavenumbers $\tilde{\nu}_{\text{pump}}^{\text{central}}$ (a), the dynamics can be investigated in a 3-D space with dimensions representing the central pump wavenumber, the pump-probe delay time T , and the probe wavenumber. 2-D spectroscopy (b) measurements can span the same 3-D space but without the disadvantage of a spectral blurring along the pump wavenumber axis as present in transient absorption as a consequence of the pump pulse's spectral width. The graphs are adapted from [37]

X-ray pulse, which is then able to selectively excite core levels of the atoms involved in the process and thereby track the transient changes due to structural dynamics. This requires femtosecond hard X-ray pulses, as are available from storage rings with electron-bunch slicing and more recently from X-ray free-electron lasers (XFELs) delivering high-intensity hard X-ray pulses with durations of a few fs. Hard X-ray pulses have helped to elucidate structural changes after photoexcitation, e.g., in iron complexes that exhibit rapid spin-crossover processes: for $[\text{Fe}^{\text{II}}(\text{bpy})_3]^{2+}$, absorption changes near the K-edge of Fe disclose bond lengthening after spin-crossover [48], resonant inelastic X-ray scattering applied to $\text{Fe}(\text{CO})_5$ in an ethanol jet can separate triplet and ligation reaction channels on sub-ps time scales after photolysis of one CO [54].

These soft and hard X-ray approaches provide insight into structural dynamics not accessible in a similar fashion with ultrafast techniques in more conventional spectral regimes. A further example is the ring-opening reaction of 1,3-cyclohexadiene to 1,3,5-hexatriene, which has been extensively studied both with ultrafast spectroscopy and dynamics simulations (as e.g., summarized in [55]). The reaction dynamics could also be investigated by X-ray core ionization from an XFEL [56], the temporal evolution of the valence electronic structure was explored by soft X-rays near the carbon K-edge generated by HHG [57], while fs X-ray scattering in combination with calculated reaction trajectories provide real-space images of transient structures in this electrocyclic reaction [58].

The latter study is an example of a time-resolved X-ray diffraction experiment, an area that strongly benefits from recent advances in XFELs [49, 50]. Instead of using electromagnetic waves, a complementary approach with pulses of electrons (ultrafast electron diffraction) has been developed, with high sensitivity and spatiotemporal resolution so that structural dynamics are followed in real time [59, 60]. These powerful techniques provide an auspicious perspective for resolving structural dynamics with unprecedented possibilities, probing changes in molecular geometry rather than in energy.

37.5.3 Dynamics and Control

As has been discussed throughout this chapter, molecular motion can be traced with the help of time-resolved spectroscopy. It is also possible to go one step ahead and use laser pulses to control molecular motion. For a long time, the field of "quantum control" has been dominated by theoretical work, see the textbooks [25, 61, 62]. However, the technical advances in laser technology have led to experimental realizations of proposed theoretical schemes. Employing sophisticated devices to modify the amplitude, phase, and/or polarization state of the laser pulses in a well-defined way [63], e.g., pulse shapers [64] as in Fig. 37.2b, the outcome of a chemical reaction can be influenced by specifically tailored light pulses. For the determination of the latter, feedback algorithms can be employed [65]. The range of photochemical reactions for which such an approach

was demonstrated spans from molecular dimers in the gas phase via reactions on surfaces, organic molecules in solution, processes in solids, to large biological systems relevant in photosynthesis. It is worthwhile taking a look at one of the reviews [66–70] summarizing the accomplishments with quantum control approaches.

Volker Engel Volker Engel studied Physics at the University of Göttingen, where he also received his Doctorate in 1986. Afterwards he worked at UC Santa Barbara and the University of Freiburg. In 1994, he was appointed as Professor of Theoretical Chemistry at the University of Würzburg. The focus of his research is on time-dependent quantum mechanics and spectroscopy.

Patrick Nuernberger Patrick Nuernberger received his Doctorate in Physics from the University of Würzburg in 2007. He further worked at SUNY Stony Brook, Ecole Polytechnique, and Ruhr-University Bochum. Since 2019, he has held the Chair of Physical Chemistry at the University of Regensburg. His research focuses on investigating femtosecond dynamics and photochemical reactions with advanced ultrafast spectroscopic methods and quantum control approaches.

Abstract

The basic formulations of nonreactive scattering are presented in the sections to follow. The quantal approach to this problem is outlined. Specific symmetries, and their closely related conservation laws, which reduce the complexity of computation, are discussed, along with the usual coordinate systems used to express the necessary scattering equations. The derivation of the matrix elements needed for a given calculation is provided in

the case of a diatom-diatom collision. Semiclassical and quasi-classical methods are also briefly introduced. The chapter ends with a comparison between theory and experiment for the benchmark CO–H₂ system and an outline of future directions in the field.

Keywords

classical trajectory · relative collision · Coriolis coupling · centrifugal potential · Wigner coefficient · quasi-classical and semi-classical scattering · Feshbach resonances

38.1 Definitions

The cross section σ for a transition from state i to f is defined classically as

$$\sigma(i \rightarrow f) = 2\pi \int_0^{\infty} P_b(i \rightarrow f) b db, \quad (38.1)$$

where P_b is the transition probability for impact parameter b (Fig. 38.1). The impact parameter is related to the relative angular momentum quantum number, ℓ , by

$$\begin{aligned} 2\mu E b^2 &= \ell(\ell + 1) \\ &= k^2 b^2, \end{aligned} \quad (38.2)$$

where k is the wave number at relative collision energy E , and μ is the reduced mass; atomic units ($e = m_e = \hbar = 1$) are used throughout. Differentiating Eq. (38.2) and setting $d\ell = 1$ in the quantal limit,

$$bdb = \frac{2\ell + 1}{2k^2},$$

whence the quantum mechanical equivalent of Eq. (38.1) may be obtained

$$\sigma(i \rightarrow f) = \frac{\pi}{k_i^2} \sum_{\ell} (2\ell + 1) P_{\ell}(i \rightarrow f), \quad (38.3)$$

Fig. 38.1 Classical scattering by a fixed scattering center. The trajectory is symmetric about the point of closest approach, which is the time origin

k_i being the wave number in the initial state. If the initial state is degenerate, and ω_i is the degeneracy, then

$$P_{\ell}(i \rightarrow f) = \frac{1}{\omega_i} |T_{\ell}(i, f)|^2, \quad (38.4)$$

where T_{ℓ} is an element of the transmission matrix \mathbf{T} , which contains all the information on the scattering event. The scattering matrix \mathbf{S} is related to the \mathbf{T} matrix by

$$\mathbf{S} = \mathbf{1} - \mathbf{T} \quad (38.5)$$

and thence to the reactance matrix \mathbf{K} through

$$\mathbf{S} = \frac{\mathbf{1} + i\mathbf{K}}{\mathbf{1} - i\mathbf{K}}. \quad (38.6)$$

The elements of the \mathbf{K} matrix are real. Conservation of the incident flux of particles requires that

$$\sum_f |S(i, f)|^2 = 1. \quad (38.7)$$

Microreversibility (time-reversal symmetry) implies that the \mathbf{S} matrix is symmetric,

$$S(i, f) = S(f, i),$$

and hence

$$\sigma(i \rightarrow f) k_i^2 \omega_i = \sigma(f \rightarrow i) k_f^2 \omega_f. \quad (38.8)$$

The thermally averaged (Maxwellian) rate coefficient for a transition from state i to f is

$$\langle \sigma v \rangle_{i \rightarrow f} = \left(\frac{8k_B T}{\pi \mu} \right)^{\frac{1}{2}} \int_0^{\infty} x_i \sigma(i \rightarrow f) e^{-x_i} dx_i, \quad (38.9)$$

where $x_i = \mu v_i^2 / 2k_B T$, v_i being the relative collision velocity; k_B is Boltzmann's constant, and $(8k_B T / \pi \mu)^{\frac{1}{2}}$ may be identified with the mean thermal velocity at temperature T . From Eqs. (38.8) and (38.9),

$$\langle \sigma v \rangle_{i \rightarrow f} \omega_i \exp \frac{-\varepsilon_i}{k_B T} = \langle \sigma v \rangle_{f \rightarrow i} \omega_f \exp \frac{-\varepsilon_f}{k_B T}, \quad (38.10)$$

where $\varepsilon_i, \varepsilon_f$ denote the energies of the states i, f with respect to the reference level. Equation (38.10) relates the rate coefficients of forwards and reverse transitions to their relative degeneracies and excitation energies.

38.2 Quantal Method

The usual approach to nonreactive scattering [1] is based on the Born–Oppenheimer (BO) approximation. This approximation postulates that electrons adapt adiabatically to the motion of the much heavier nuclei. The BO approximation allows us to describe inelastic collisions as the motion of nuclei on the interaction potential V , which is a known function of the nuclear coordinates. The total Hamiltonian may then be written as

$$H = -\frac{1}{2\mu} \nabla_R^2 + h_1(\mathbf{x}_1) + h_2(\mathbf{x}_2) + V(\mathbf{R}, \mathbf{x}_1, \mathbf{x}_2), \quad (38.11)$$

where \mathbf{R} is the intermolecular distance, the first term represents the relative kinetic energy of the target and projectile, and h_1, h_2 are functions of the intramolecular nuclear coordinates $\mathbf{x}_1, \mathbf{x}_2$. In the time-independent scheme, the eigenfunctions ψ_1, ψ_2 of h_1, h_2 describe the internal motions of the colliding partners and form a basis for expanding the total wave function Ψ of the system

$$\Psi(\mathbf{R}, \mathbf{x}_1, \mathbf{x}_2) = \sum_{\alpha_1 \alpha_2 \ell m} \frac{F(\alpha_1 \alpha_2 \ell m | R)}{R} \times Y_{\ell m}(\Theta, \Phi) \psi_1(\alpha_1 | \mathbf{x}_1) \psi_2(\alpha_2 | \mathbf{x}_2). \quad (38.12)$$

In Eq. (38.12), α_1, α_2 denote the sets of quantum numbers required to specify the states of the isolated molecules, and $Y_{\ell m}(\Theta, \Phi)$ is a spherical harmonic function of the angular coordinates of the intermolecular vector \mathbf{R} ; $F(\alpha_1 \alpha_2 \ell m | R)$ are R -dependent expansion coefficients, which are solutions of the (time-independent) Schrödinger equation

$$(H - E)\Psi = 0, \quad (38.13)$$

where E is the total energy. These solutions may be arranged as the columns of a square matrix, $\mathbf{F}(R)$, in which each

column is labeled by a different initial scattering state. The radial functions must satisfy the physical boundary conditions,

$$\begin{aligned} \mathbf{F}(R) &\rightarrow \mathbf{0} && \text{as } R \rightarrow 0 \\ \mathbf{F}(R) &\rightarrow \mathbf{J}(R)\mathbf{A} - \mathbf{N}(R)\mathbf{B} && \text{as } R \rightarrow \infty, \end{aligned}$$

where \mathbf{J} and \mathbf{N} are diagonal matrices whose nonvanishing elements are given by

$$J_{ii} = k_i^{\frac{1}{2}} R j_\ell(k_i R), \quad (38.14)$$

$$N_{ii} = k_i^{\frac{1}{2}} R n_\ell(k_i R), \quad (38.15)$$

and j_ℓ, n_ℓ are spherical Bessel functions of the first and second kinds; k_i is the wave number in channel i (a given set of values of the quantum numbers $\alpha_1 \alpha_2 \ell m$). The reactance matrix,

$$\mathbf{K} = \mathbf{B}\mathbf{A}^{-1}, \quad (38.16)$$

yields the state-to-state cross sections. We note that the quantum scattering equations can also be solved in a time-dependent scheme by propagation of a wave packet. In contrast to the time-independent approach, the wave-packet method is not adapted to cold and ultracold collisions due to difficulties in damping outgoing waves with long de Broglie wavelengths.

38.3 Symmetries and Conservation Laws

The expansion of the total wave function, Eq. (38.12), does not explicitly incorporate the invariance of the Hamiltonian under an arbitrary rotation in space or reflection in the coordinate origin. The Hamiltonian commutes with \mathbf{J}^2 , where \mathbf{J} is the total angular momentum, and any component of \mathbf{J} , J_x , J_y , or J_z , although these components do not commute amongst themselves. Eigenfunctions of H may, therefore, be chosen to be simultaneous eigenfunctions of \mathbf{J}^2 and (conventionally) J_z , with eigenvalues $J(J+1)$ and M . If \mathbf{j}_1 and \mathbf{j}_2 are the angular momenta of the isolated collision partners, then

$$\mathbf{j}_{12} = \mathbf{j}_1 + \mathbf{j}_2$$

is their resultant, and

$$\mathbf{J} = \mathbf{j}_{12} + \boldsymbol{\ell},$$

where $\boldsymbol{\ell}$ denotes the relative angular momentum of the two molecules. The coupling of the angular momenta to the multipolar expansion of the electromagnetic field (i.e., the interaction potential) gives rise to collisional selection rules.

The parity operator, P , reflects the coordinates in the origin. Because two successive operations with P restore

the original values of the coordinates, the corresponding eigenvalue p satisfies the equation $p^2 = 1$ or $p = \pm 1$. For electromagnetic interactions, the commutation of P and H implies conservation of the parity of the system.

If one takes advantage of the conservation laws associated with these symmetries of the system, substantial savings in computing time can be made: only one value of the total angular momentum and of the parity need to be considered simultaneously, i.e., J and the parity are conserved during the collision.

38.4 Coordinate Systems

The natural choice of coordinate system in which to express the interaction potential, $V(\mathbf{R}, \mathbf{x}_1, \mathbf{x}_2)$, is a body-fixed (BF) system in which the z -axis coincides with the direction of the intermolecular vector $\mathbf{R} = (R, \Theta, \Phi)$. A rotation of the space-fixed (SF) coordinate system through the Euler angles $(\Phi, \Theta, 0)$ generates such a BF frame. The intramolecular coordinates $\mathbf{x}_1, \mathbf{x}_2$ must then be expressed relative to the BF frame, as must the Laplacian operator ∇_R^2 , which appears in the expression for the total Hamiltonian, Eq. (38.11). The latter may be written as

$$\begin{aligned} \nabla_R^2 &= \frac{1}{R} \frac{\partial^2}{\partial R^2} R - \frac{\ell^2}{R^2} \\ &= \frac{1}{R} \frac{\partial^2}{\partial R^2} R - \frac{(\mathbf{J} - \mathbf{j}_{12})^2}{R^2}, \end{aligned} \quad (38.17)$$

which are the forms suitable for calculations in SF and BF coordinates, respectively.

A unitary transformation relates the normalized eigenfunctions of a given parity in SF and BF coordinates. In Dirac notation,

$$\begin{aligned} |j_{12} \ell JM\rangle_{\text{SF}} \\ = \sum_{\bar{\Omega}} |j_{12} \bar{\Omega} \varepsilon JM\rangle_{\text{BF}} \langle j_{12} \bar{\Omega} \varepsilon JM | j_{12} \ell JM \rangle, \end{aligned} \quad (38.18)$$

where $\bar{\Omega} = |\Omega|$ and Ω is the projection of \mathbf{J} on the BF z -axis. As the projection of $\boldsymbol{\ell}$ on the intermolecular axis is zero, Ω is also the projection of \mathbf{j}_{12} on the BF z -axis. The absolute value of Ω appears in the transformation because $|j_{12} \pm \Omega JM\rangle$ are *not* eigenfunctions of the parity operator P , whereas the linear combinations

$$|j_{12} \bar{\Omega} \varepsilon JM\rangle = \frac{|j_{12} \Omega JM\rangle + \varepsilon |j_{12} - \Omega JM\rangle}{[2(1 + \delta_{\bar{\Omega}0})]^{\frac{1}{2}}}$$

($\varepsilon = \pm 1$) are eigenfunctions of P . The factor $[2(1 + \delta_{\bar{\Omega}0})]^{\frac{1}{2}}$ ensures the correct normalization of these functions. The elements of the matrix that performs the unitary transformation

in Eq. (38.18) are

$$\begin{aligned} & \langle j_{12} \bar{\Omega} \varepsilon JM | j_{12} \ell JM \rangle \\ &= \left[\frac{2(2\ell + 1)}{(1 + \delta_{\bar{\Omega}0}) (2J + 1)} \right]^{\frac{1}{2}} C_{\bar{\Omega}0\bar{\Omega}}^{j_{12}\ell J}, \end{aligned} \quad (38.19)$$

where $C_{\bar{\Omega}0\bar{\Omega}}^{j_{12}\ell J}$ is a Clebsch–Gordan coefficient.

38.5 Scattering Equations

Schrödinger's equation for the scattering system may be reduced to a set of coupled, ordinary, second-order differential equations for the radial functions $F(R)$. Expressed in matrix form, these coupled-channel or close-coupling equations become

$$\left[\mathbf{1} \frac{d^2}{dR^2} + \mathbf{W}(R) \right] \mathbf{F}(R) = 0. \quad (38.20)$$

There exists a set of equations in Eq. (38.20) for each value of the total angular momentum J and parity p (Sect. 38.3). The matrix \mathbf{W} may be written as

$$\mathbf{W}(R) = \mathbf{k}^2 - 2\mu \mathbf{V}_{\text{eff}}, \quad (38.21)$$

where \mathbf{k}^2 is a diagonal matrix whose nonvanishing elements are

$$k_{\alpha_1 \alpha_2}^2 = 2\mu(E - \varepsilon_{\alpha_1} - \varepsilon_{\alpha_2}); \quad (38.22)$$

$k_{\alpha_1 \alpha_2}$ is the wave number at infinite separation ($R \rightarrow \infty$) when the collision partners are in eigenstates α_1, α_2 with eigenenergies $\varepsilon_{\alpha_1}, \varepsilon_{\alpha_2}$; \mathbf{V}_{eff} is the matrix of the effective potential,

$$V_{\text{eff}} = V(\mathbf{R}, \mathbf{x}_1, \mathbf{x}_2) + \frac{\ell^2}{2\mu R^2}, \quad (38.23)$$

in which V is the interaction potential, and $\ell^2/(2\mu R^2)$ may be identified with the centrifugal potential. There exist standard computer codes for solving equations of the form in Eq. (38.20) [2–4].

38.6 Matrix Elements

38.6.1 Interaction Potential

The interaction potential is usually expressed and computed in BF coordinates. For the purposes of the analysis, it is convenient to derive a multipolar expansion of the potential from

Fig. 38.2 The body-fixed Jacobi coordinates system for the scattering of two rigid rotors

a least-squares fit to the original data points. If the collision calculations are being done in the BF frame, the potential matrix elements may be evaluated directly. However, if the SF frame is to be used, the potential expansion must first be transformed into SF form.

Consider the interaction between two rigid rotors. This example serves as a paradigm. The geometry of the collisional complex is characterized by three angles θ_1 , θ_2 , and ϕ , and the distance R between the centers of mass of the two colliding partners (Fig. 38.2). The polar angles of the two rigid rotor with respect to \mathbf{R} are denoted θ_1 and θ_2 , respectively, while ϕ denotes the dihedral angle. In the BF frame, the potential can be expanded as

$$V(R, \theta_1, \theta_2, \phi) = \sum_{l_1, l_2; \mu} v_{l_1, l_2; \mu}(R) s_{l_1, l_2; \mu}(\theta_1, \theta_2, \phi). \quad (38.24)$$

The basis functions $s_{l_1, l_2; \mu}(\theta_1, \theta_2, \phi)$ are products of associated Legendre functions P_{lm}

$$\begin{aligned} s_{l_1, l_2; \mu}(\theta_1, \theta_2, \phi) &= \left(\frac{2\mu + 1}{4\pi} \right)^{1/2} \\ &\times \left\{ \langle l_1 0 l_2 0 | l_1 l_2 \mu 0 \rangle P_{l_1 0}(\theta_1) P_{l_2 0}(\theta_2) \right. \\ &+ \sum_m (-)^m 2 \langle l_1 m l_2 - m | l_1 l_2 \mu 0 \rangle \\ &\left. \times P_{l_1 m}(\theta_1) P_{l_2 m}(\theta_2) \cos(m\phi) \right\}, \end{aligned} \quad (38.25)$$

where $\langle \dots | \dots \rangle$ is a Clebsch–Gordan coefficient.

The P_{lm} functions are related to spherical harmonics. Here, l_1, l_2 are associated to the rotational motion of the two collision partners.

The matrix elements of the potential are

$$\begin{aligned} & \langle j_1 j_2 j_{12} l J M | V(R, \theta_1, \theta_2, \phi,) | j_1' j_2' j_{12}' l' J M \rangle \\ &= (4\pi)^{-3/2} \sum_{l_1, l_2, \mu} v_{l_1, l_2; \mu}(R) (-1)^{j_1 + j_2 + j_{12}' + J} \\ & \quad \times [(2j_1 + 1)(2j_2 + 1)(2j_1' + 1)(2j_2' + 1) \\ & \quad \times (2j_{12} + 1)(2j_{12}' + 1)(2l + 1)(2l' + 1) \\ & \quad \times (2l_1 + 1)(2l_2 + 1)]^{1/2} (2\mu + 1) \begin{pmatrix} l' & l & \mu \\ 0 & 0 & 0 \end{pmatrix} \\ & \quad \times \begin{pmatrix} j_1' & j_1 & l_1 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} j_2' & j_2 & l_2 \\ 0 & 0 & 0 \end{pmatrix} \\ & \quad \times \begin{Bmatrix} l' & l & \mu \\ j_{12} & j_{12}' & J \end{Bmatrix} \begin{Bmatrix} j_{12}' & j_2' & j_1' \\ j_{12} & j_2 & j_1 \\ \mu & l_2 & l_1 \end{Bmatrix}, \quad (38.26) \end{aligned}$$

where $\begin{pmatrix} \dots \\ \dots \\ \dots \end{pmatrix}$ is a Wigner $3j$ -coefficient, $\begin{Bmatrix} \dots \\ \dots \\ \dots \end{Bmatrix}$ a $6j$ -coefficient, and $\left\{ \begin{matrix} \dots \\ \dots \\ \dots \end{matrix} \right\}$ a $9j$ -coefficient.

The close-coupling method has been applied to rigid symmetric and asymmetric tops colliding with a spherical atom and/or a rigid rotor and to open-shell systems. The main difference resides in the computation of the matrix elements of the potential, and we refer the reader to references [5–10].

38.6.2 Centrifugal Potential

When evaluated in the SF frame, the matrix of the centrifugal potential is diagonal, with nonvanishing elements $\ell(\ell + 1)/(2\mu R^2)$. In the BF frame, the diagonal elements are (see Eq. (38.17))

$$\begin{aligned} & \langle j_{12} \bar{\Omega} \varepsilon J M | (\mathbf{J} - \mathbf{j}_{12})^2 / 2\mu R^2 | j_{12} \bar{\Omega} \varepsilon J M \rangle \\ &= [J(J + 1) + j_{12}(j_{12} + 1) - 2\bar{\Omega}^2] / (2\mu R^2), \quad (38.27) \end{aligned}$$

and, in addition, there are off-diagonal elements

$$\begin{aligned} & \langle j_{12} \bar{\Omega} \varepsilon J M | (\mathbf{J} - \mathbf{j}_{12})^2 / 2\mu R^2 | j_{12} \bar{\Omega} \pm 1 \varepsilon J M \rangle \\ &= -\{(1 + \delta_{\bar{\Omega}0})(1 + \delta_{\bar{\Omega} \pm 1, 0}) \\ & \quad \times [J(J + 1) - \bar{\Omega}(\bar{\Omega} \pm 1)] \\ & \quad \times [j_{12}(j_{12} + 1) - \bar{\Omega}(\bar{\Omega} \pm 1)]\}^{1/2} / (2\mu R^2). \quad (38.28) \end{aligned}$$

The matrix elements in Eq. (38.28), which are off-diagonal in $\bar{\Omega}$, are associated with the rotation in space of the BF coordinate system (Coriolis coupling). In the *coupled states* approximation [11, 12], the off-diagonal elements in Eq. (38.28) are neglected, and the diagonal elements in

Eq. (38.27) are often replaced by their SF equivalent form $\ell(\ell + 1)/(2\mu R^2)$. The matrix of the interaction potential, on the other hand, continues to be evaluated in BF coordinates. The net effect of these approximations is to ignore the rotation of the BF frame in the course of the collision, and the associated dynamical terms.

38.7 Semi and Quasi-Classical Methods

The above quantal method is the most accurate approach, but it is also computationally very expensive if the density of energy levels of both the target and the projectile is large. Besides decoupling approximations such as the coupled-states approach, semiclassical and quasi-classical approximations offer useful alternatives. The former consists in solving the time-dependent Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = H \Psi, \quad (38.29)$$

while in the latter, the classical Hamilton equations of motion are integrated

$$\frac{dq}{dt} = \frac{\partial H}{\partial p}, \quad (38.30)$$

$$\frac{dp}{dt} = -\frac{\partial H}{\partial q}, \quad (38.31)$$

where q are the coordinates and p the conjugate momenta. Their common feature is that at least one degree of freedom in the collision system is treated classically. Difficulties in the application of semiclassical theories have precluded their being employed routinely. In contrast, quasi-classical methods have been widely employed in both reactive and nonreactive scattering studies. In the quasi-classical trajectory (QCT) approach, batches of trajectories are sampled with random (Monte Carlo) initial conditions and analyzed through statistical methods. State-resolved cross sections are extracted by use of the correspondence principle combined with bin histogram methods. QCT methods are very efficient, but, of course, they ignore purely quantum effects such as interferences, tunneling, and resonances [13].

38.8 Example: CO–H₂

An important result of quantal theory for nonreactive scattering is the prediction of a rich resonance structure at low collisional energy. Two different types of scattering resonances can occur, shape or Feshbach. A shape (or orbiting) resonance corresponds to a quasi bound state that is confined behind a centrifugal barrier and correlates with the initial or final monomer levels of the colliding partners. A Feshbach resonance corresponds to a quasi bound state that corre-

Fig. 38.3 Cross section for the CO rotational excitation $j = 0 \rightarrow 1$ induced by *normal*-H₂ as function of collision energy. The experimental data (circles) are compared to theory (full line)

lates with an energetically inaccessible or “closed” monomer level. Both types of resonances are predicted to occur at collision energies lower than the well depth of the interaction potential. Observing these resonances experimentally remained elusive until recent crossed molecular beam experiments [14, 15]. Such experimental data are presented in Fig. 38.3 for the CO excitation $j = 0 \rightarrow 1$ by *normal*-H₂. The measured resonance structures are in good quantitative agreement with the close-coupling calculations presented in [16], suggesting that theory and experiment have converged for this benchmark system.

38.9 New Directions

An important application field of nonreactive scattering studies is astrophysics. Indeed, since collisions compete with radiative processes in altering the populations of energy levels, the estimation of molecular abundances in the interstellar medium from spectral line data requires collisional rate coefficients with the most abundant collision partners, i.e., He, H and H₂, and free electrons [17]. Hence, one of the major challenge for the coming years is the study of vibrational excitation of interstellar polyatomics since important molecules such as HCN, C₂H₂, or CH₄ have been observed in vibrationally excited levels in various astrophysical environments, such as stellar envelopes and protoplanetary disks. Analysis of their emission spectra requires collisional data, and the development of new methods to deal with vibrational excitation will have to be considered.

Special attention will have to be given also to complex organic molecules with more than five atoms. There is only very little data for these species despite the fact that they are the object of many investigations using ground-based and space telescopes. For such heavy molecules with small rotational and vibrational constants, the main limitation is the computing resources, and approximate methods will have to be employed.

Another important application field is cold chemistry. Novel experimental techniques allow the formation of molecules cooled down to very low temperatures ($T < 1$ K). These cold molecules allow new insights into molecular interaction dynamics. In particular, purely quantum effects are expected to dominate collisional processes at these low temperatures, and it will be essential to have accurate quantum theoretical results to support the new experiments.

Alexandre Faure Alexandre Faure received his PhD from the University Joseph Fourier at Grenoble (France) in 1999. He worked at University College London in the UK and at the Laboratoire d'Astrophysique de Grenoble. His research focuses on computational molecular physics and is mainly concerned with processes of astrophysical relevance.

David R. Flower David R. Flower is Emeritus Professor of Physics at the University of Durham (UK). He was awarded his PhD by the University of London in 1969. After working at the Observatoire de Paris (Meudon, France) and at the ETH (Zuerich, Switzerland), he joined the Physics Department of the University of Durham in 1978. He has been Professor of Physics since 1994. His research interests are in atomic and molecular physics related to astrophysics.

François Lique François Lique received his PhD from Sorbonne University in Paris (France) in 2006. He worked at the University of Maryland in USA and at the University of Le Havre Normandy (France). He is now full professor at the University Rennes 1 (France). His research mainly focuses on the modeling of physical and chemical processes of astrophysical interest.

Abstract

The rates of gas phase chemical processes can generally be described by rate laws in which the rate of formation of products or disappearance of reactants is related to the product of the concentrations of reactants raised to various powers [1]. Rate laws are deterministic expressions that are usually accurate even though they are used to represent a stochastic reality. Rate equations may fail in the limit of small numbers of reacting particles, where both fluctuations and discrete aspects are important. Exceptions to the reliability of rate equations have been found recently in a variety of fields including surface chemistry on small particles [2]. Moreover, both Monte Carlo and master equation methods can be used in their place, given sufficient computing power [3–6].

Keywords

rate coefficient · transition state theory · microscopic reversibility · phase space theory · tunneling correction

39.1 Introduction

As an example of a rate law, consider the rate of disappearance of reactant A in a gas mixture containing species A , B , and C . The rate law for this disappearance can be expressed by the equation

$$\frac{d[A]}{dt} = -k[A]^a[B]^b[C]^c, \quad (39.1)$$

where the symbols $[]$ refer to concentration, and the rate coefficient k is dependent on temperature, and possibly other parameters such as the total gas density. The above law is not the most general that can be envisaged. For example, if species A reacts via more than one set of processes, more than one negative term on the right-hand side of the equation will be needed. In addition, if the reverse reaction to form A from products is appreciable, a positive term must also be included. At equilibrium, the rate of change of reactant must be zero.

The relation above does not necessarily refer to one chemical reaction, but to a succession of elementary reactions known collectively as a mechanism. The most elementary reaction is a simple bimolecular process with a second order rate law of the type

$$\frac{d[C]}{dt} = -\frac{d[A]}{dt} = k[A][B], \quad (39.2)$$

where two species A and B collide to form products, one of which can be labeled C . In this law, the rate coefficient k is related simply to the reaction cross section σ via the equation

$$k = \sigma v, \quad (39.3)$$

where v is the relative velocity of reactants. The rate coefficient in a bimolecular process has units of volume per time, typically $\text{cm}^3 \text{s}^{-1}$. In a thermal system, the rate coefficient $k(T)$ is averaged over all degrees of freedom of the reactants, both internal and translational. The most specific rate coefficient is termed a state-to-state coefficient and refers to a process in which reactant A in quantum state a reacts with reactant B in quantum state b at a specific translational energy \mathcal{T} to form products in specific states separating with a specific translational energy [7].

Although normal bimolecular processes produce more than one product, it is also possible for the two reactants A and B to stick together if sufficient energy is released in the form of a photon

Such a process is called radiative association [8], and has mainly been studied for ion-molecule systems, i.e., reactions in which one of the two reactants is an ion. The process of radiative association is normally thought to occur in two steps. The first step produces a collision complex AB^* , which is a molecule existing in a transitory fashion above its dissociation limit

Once formed, the complex, which is often thought of as an ergodic entity retaining memory only of its total energy and angular momentum, can either redissociate into reactants, or emit a photon of sufficient energy to stabilize itself

Since redissociation of the complex is generally more rapid than radiative emission, radiative association rate coefficients are normally small. Emission of one infrared photon is sufficient to achieve stabilization, but stabilization of a complex via electronic emission may be a more rapid mechanism if suitable electronic states exist [8, 9]. The lifetime of the complex against redissociation into reactants is a strong direct function of the binding energy of the species and the number of atoms it possesses.

In addition to bimolecular processes, two other types of reactions often referred to as elementary are unimolecular and termolecular reactions. Although complex reaction mechanisms are sometimes divided into unimolecular and termolecular steps, these are not strictly elementary because they can be subdivided into a series of bimolecular steps. In a unimolecular reaction [10, 11], a molecule A is destroyed at sufficiently high gas density by a process that has the seemingly simple first order rate law

$$\frac{d[A]}{dt} = -k[A] . \quad (39.7)$$

At low pressures, on the other hand, the rate law is second order. A simplified series of events, called the Lindemann mechanism, explains these limiting cases by invoking the activation of species A by strong inelastic collisions with bath gas M to form an activated complex A^* which can either be deactivated by inelastic collisions or spontaneously decompose, since it possesses sufficient energy to do so. The steps are written as

where the spontaneous destruction of A^* can be thought of as a truly elementary unimolecular reaction, akin to spontaneous emission of radiation. Studies of spontaneous dissociation occupy an important place in gas phase reaction theory, and are discussed in Sects. 39.2.2 and 39.2.4 in the context of dissociation of intermediate complexes. If the rate coefficients for the forward and reverse processes in Eq. (39.8) are labeled k_1 and k_{-1} respectively, and the rate-coefficient for spontaneous dissociation of A^* into products is labeled $k_2(\text{s}^{-1})$, application of the steady-state principle to the concentration of the activated complex, namely,

$$\frac{d[A^*]}{dt} = k_1[A][M] - k_{-1}[A^*][M] - k_2[A^*] \approx 0 \quad (39.10)$$

leads to the rate law

$$-\frac{d[A]}{dt} = k'[A][M] , \quad (39.11)$$

where

$$k' = \frac{k_1 k_2}{k_{-1}[M] + k_2} . \quad (39.12)$$

At low pressures, $k_{-1}[M] \ll k_2$ and $k' \approx k_1$ so that a second order rate law prevails. At high pressures, $k_{-1}[M] \gg k_2$ and $k' \approx k_1 k_2 / k_{-1}[M]$ so that the rate law becomes first order

$$-\frac{d[A]}{dt} \approx \frac{k_1}{k_{-1}} k_2 [A] . \quad (39.13)$$

Since both the activation and deactivation of complexes occur stepwise, rather than in single strong collisions, reality is far more complex than the Lindemann mechanism [12], and, at the highest degree of detail, master equation treatments are needed, especially for intermediate pressures [13].

In a termolecular reaction, which is actually the inverse of a unimolecular process [13], two species B and C collide to form a collision complex A^* , which can be regarded as the activated complex of stable species A . The collision complex can be stabilized by subsequent strong collisions with other species

or can redissociate into reactants. If the complex formation step occurs with a bimolecular rate coefficient k_{-2} , and k_{-1} and k_2 refer to complex stabilization and dissociation as in the unimolecular case, the rate law for the termolecular process can be written

$$\frac{d[A]}{dt} = k'[B][C][M], \quad (39.15)$$

where

$$k' = \frac{k_{-2}k_{-1}}{k_{-1}[M] + k_2}. \quad (39.16)$$

At low pressures, $k' \approx k_{-2}k_{-1}/k_2$ and the rate law is third order. At high pressures, when every activated complex is deactivated, the rate law becomes second order since $k' \approx k_{-2}/[M]$. Actually, at very low pressures radiative stabilization of the complex dominates and the rate law once again becomes second order. As in the unimolecular case, the complex does not really undergo strong inelastic collisions, so that reality is once again more complex than pictured here [13]. For detailed theories of thermal reactions, there is the additional problem in Eqs. (39.12) and (39.16) of deciding when thermalization of the partial rate coefficients should be undertaken. In reality, the partial rate coefficients refer to reactions with specific amounts of energy and angular momentum, and should not be thermally averaged before incorporation into the equations for k' .

39.2 Normal Bimolecular Reactions

The rates of elementary (bimolecular) chemical reactions are governed by Born–Oppenheimer potential surfaces, which contain electronic energies and nuclear-nuclear repulsions. Reactions can be classified as exoergic or endoergic depending upon whether the 0 K energies of the products lie below or above those of the reactants, respectively. In the simplest types of exoergic chemical reactions, the potential energy flows downhill from reactants to products, or flows downhill from reactants to a global minimum (the reaction complex) after which it flows uphill to products. More commonly, the morphology of the potential surface is such that after some long-range attraction, the potential rises as old chemical bonds are broken before falling as new bonds are formed. Generally, there is a minimum energy pathway through the region of large potential referred to as the reaction coordinate. The system is said to traverse a transition state barrier, which refers to the configuration of atoms at which a potential saddle point occurs. The height of this transition state barrier is related to the activation energy barrier E_a in the classical Arrhenius rate law

$$k(T) = A(T) \exp \frac{-E_a}{k_B T}, \quad (39.17)$$

for rate coefficients of bimolecular reactions which contain short-range barriers [1]. In the Arrhenius expression, k_B is the Boltzmann constant, and the pre-exponential factor $A(T)$ can be related to the form of the long-range potential, or to an equilibrium coefficient between the transition state and reactants (see the discussion of activated complex theory in Sect. 39.2.3). Although fits of experimental data over short temperature ranges often assume the pre-exponential factor to be totally independent of temperature, theories show that this is not strictly true in most instances. A more serious problem with the expression undoubtedly occurs at low temperatures since tunneling will clearly lead to deviations.

Although, in principle, it is possible to calculate reaction cross sections and rate coefficients via the quantum theory of scattering, in practice few systems have been studied by this technique given the immense computational effort required [14, 15]. Another set of approaches, which has been used to study a large variety of systems, is known as classical molecular dynamics (see Chap. 62). In these approaches, the atoms move classically on the quantum mechanically generated Born–Oppenheimer potential surfaces. For many reactions, however, neither technique is applicable, and a variety of simpler approaches has been developed, using capture and statistical approximations; these approaches will be emphasized here. Indeed, the use of an ergodic complex in our preliminary discussion of association and unimolecular reactions above presages the use of statistical approximations. An excellent high-level review article on many of the topics covered here has been written by Troe [16].

39.2.1 Capture Theories

For reactions that do not possess a potential energy barrier at short-range, it is tempting to apply long-range capture theories between structureless particles to calculate the reaction rate coefficient. Such theories assume that (a) all hard collisions lead to reaction, and (b) hard collisions occur for all partial waves up to a maximum impact parameter b_{\max} or relative angular momentum quantum number L_{\max} . This is normally defined so that the reactant translational energy \mathcal{T}_{AB} is just sufficient to overcome a centrifugal barrier. The centrifugal barrier produces a long-range maximum in the effective potential energy function V_{eff} given by the relation

$$V_{\text{eff}}(r, b) = V(r) + \mathcal{T}_{AB} b^2 / r^2, \quad (39.18)$$

where r is the separation between reactants and $\mathcal{T}_{AB} b^2 / r^2$ is the angular kinetic energy. If the reactants overcome the centrifugal barrier, they will spiral in towards each other in the absence of short-range repulsive forces. The approach has had its most notable success for exoergic reactions between ions and nonpolar neutral molecules [17]. The long-range po-

tential in this situation is simply (in cgs-esu units)

$$V(r) = -e^2\alpha_d/2r^4, \quad (39.19)$$

where α_d is the polarizability of the neutral reactant. This potential leads to the Langevin rate coefficient

$$k = v\pi b_{\max}^2 = 2\pi e \left(\frac{\alpha_d}{\mu} \right)^{1/2}, \quad (39.20)$$

where μ is the reduced mass of the reactants. The theory leads to a temperature-independent rate coefficient with magnitude $\approx 10^{-9} \text{ cm}^3 \text{ s}^{-1}$. Numerous experiments from above room temperature to below 30 K confirm its validity for the majority of ion–molecule reactions, which appear rarely to possess potential energy surfaces with short-range barriers [18, 19].

An analogous central force potential for structureless neutral–neutral reactants is the van der Waals or Lennard–Jones attraction

$$V(r) = \frac{-C_6}{r^6}, \quad (39.21)$$

where C_6 can be defined simply in terms of the ionization potentials and polarizabilities of the reactants [20, 21]. The rate coefficient obtained using a capture theory with this long-range potential is given, after translational thermal averaging, by the equation [21]

$$k(T) = 8.56 C_6^{1/3} \mu^{-1/2} (k_B T)^{1/6}, \quad (39.22)$$

where all quantities are in cgs units. Equation (39.22) leads to estimates for the rate coefficient at room temperature in the range $\approx 10^{-10}$ – $10^{-9} \text{ cm}^3 \text{ s}^{-1}$. Unlike the situation for ion–molecule reactions, this estimate has not received much attention mainly because most neutral–neutral reactions involve activation energy. Even for those systems without activation energy, the approximation appears to lead to rate coefficients that are too large by at least a factor of a few [21]. In place of the result of Eq. (39.22), kineticists often use the simple hard-sphere model with atomic dimensions for the reaction cross section. The hard-sphere model leads to a temperature dependence of $T^{1/2}$, which is in disagreement with a whole series of new experiments on fast neutral–neutral reactions down to temperatures near 10 K [22].

Both long-range potentials considered above are isotropic in nature. A variety of capture theories [23, 24] have been developed which take angular degrees of freedom into account. For ion–molecule systems in which the neutral species has a permanent dipole moment μ_d , the long-range potential becomes

$$V(r, \theta) = -\frac{e^2\alpha_d}{2r^4} - \frac{e\mu_d \cos \theta}{r^2}, \quad (39.23)$$

where θ is the angle between the radius vector from the charged species to the center-of-mass of the dipolar species and the dipole vector. Adiabatic effective (centrifugal) potential energy curves can be defined at any given fixed intermolecular separation r by diagonalizing angular kinetic energy and potential energy matrices using a suitable basis set. If an atomic ion is reacting with a linear neutral, a suitable basis set would consist of spherical harmonics for the rotation of the linear molecule (angular momentum j) as well as rotation matrices for the relative motion (angular momentum L) between the species. The eigenvalues of a matrix with fixed total angular momentum J then correspond to the effective radial potential energy functions V_{eff} at each r . The L, j labeling of the potential curves can be ascertained by starting the calculation at sufficiently large r so that L and j are reasonably good quantum numbers. Additional approximations, such as the centrifugal sudden approximation, can be made to facilitate the calculation [25]. Making the adiabatic assumption that transitions between these potentials are not allowed at long range, one obtains an adiabatic capture rate coefficient for each initial value of j and translational (radial kinetic) energy \mathcal{T}_{AB} from the criterion

$$V_{\text{eff}}(j, L_{\max}, R) = \mathcal{T}_{AB}, \quad (39.24)$$

where R is the separation corresponding to the maximum effective potential. Unlike the Langevin approach, the rate coefficients thermalized over translation for each j show an inverse dependence on temperature, with the $j = 0$ state showing the most severe dependence since the dipole is essentially *locked* for this state. Thermal averaging over j typically leads to rate coefficients with an inverse dependence on temperature between $T^{-1/2}$ and T^{-1} [26]. Rate coefficients as large as $10^{-7} \text{ cm}^3 \text{ s}^{-1}$ can be obtained as the temperature approaches 10 K. Although most ion–dipole reactions seem to obey capture theory models at low temperature, there are exceptions.

An alternative approach to ion–dipole reactions using the classical concept of adiabatic invariants has been developed [27]. In addition, variants to the capture theory discussed here have been formulated. A statistical adiabatic approach has been developed [23], in which adiabatic effective potential maxima are not used to define capture cross sections, but to define rate coefficients via the activated complex (transition state) theory discussed in Sect. 39.2.3, which posits thermal equilibrium between reactants and the species existing at the potential maxima. One advantage of this simplification is that it permits the adiabatic treatment to be more easily extended to complex geometries, especially if perturbation approximations are utilized. Other approaches involve the variational principle; an upper bound to the capture rate coefficient can be determined within the transition state, or bottleneck approach, which defines the

transition state through minimization of the number of available vibrational/rotational states at the bottleneck [28] (see Sect. 39.2.3).

Nonspherical capture theories have also been used [29, 30] to study rapid neutral–neutral reactions. The role of atomic fine structure at low temperatures is an especially interesting application; reactions involving atomic C and O with a variety of reactants have been studied. Use of an electrostatic potential shows that the reactivity of C or O atoms in their 3P_0 states with dipolar species is minimal. This is particularly important for atomic carbon since at low temperatures it lies primarily in its ground 3P_0 state. The choice of an electrostatic potential has been disputed [21] because experimental results for C–hydrocarbon reactions at room temperature are best understood if the long-range potential is dispersive (Lennard–Jones) in character rather than electrostatic.

Reactions between radicals in $^2\Pi$ states (e.g. OH) and $^2\Sigma$ states (e.g. CN) and stable molecules have also been considered, especially at low temperature, with long range potentials that contain both electrostatic and dispersion terms. The results can be compared with new low temperature experimental results on the CN–O₂ reaction, but the temperature dependence is not matched by theory if the dispersion term is included [30, 31]. In general, even the most recent capture theories are not as reliable as those for ion–molecule systems [32]. Rapid neutral–neutral reactions can also be treated by transition state theories (see below) [33] or, rarely, by detailed quantum mechanical means [34].

The last five years have witnessed a burgeoning interest in rapid neutral–neutral reactions at low temperature studied with the so-called CRESU technique (an acronym for Cinétique de Réaction en Ecoulement Supersonique Uniforme) [22, 35–37]. The new data should provoke new attempts at theoretical understanding.

39.2.2 Phase Space Theories

Capture theories tell us neither the products of reaction, if several sets of exoergic products are available, nor the distributions of quantum states of the products. The simplest approach to these questions for reactions with barrierless potentials is to make a statistical approximation – all detailed outcomes being equally probable as long as energy and angular momentum are conserved. Such a result requires strong coupling at short range. The most prominent treatment along these lines is referred to as phase space theory [38]. In this theory, the cross section σ for a reaction between two species A and B with angular momentum quantum numbers J_A and J_B and in specific vibrational-electronic states colliding with asymptotic translational kinetic energy \mathcal{T}_{AB} to form products C and D in specific vibrational-electronic states with angu-

lar momentum quantum numbers J_C and J_D is

$$\begin{aligned} \sigma(J_A, J_B \rightarrow J_C, J_D) &= \frac{\pi \hbar^2}{2\mu \mathcal{T}_{AB}} \sum_{L_i, J} (2L_i + 1) \\ &\times P(J_A, J_B, L_i \rightarrow J) P'(J \rightarrow J_C, J_D), \end{aligned} \quad (39.25)$$

where J is the total angular momentum of the combined system, L_i is the initial relative angular momentum of reactants, P is the probability that the angular momenta of the reactants add vectorially to form J , P' is the probability that the combined system with angular momentum J dissociates into the particular final state of C and D , μ is the reduced mass of reactants, and the summation is over the allowable ranges of initial relative angular momentum and total angular momentum quantum numbers. P' is equal to the sum over the final relative angular momentum L_f , of angular momentum allowed ($J \rightarrow L_f, J_C, J_D$) combinations leading to the specific product state divided by the sum of like combinations for all energetically accessible product and reactant states. The ranges of initial and final relative angular momenta are given by appropriate capture models (e.g. Langevin, ion–dipole, Lennard–Jones) as well as angular momentum triangular rules. This procedure involves the implicit assumption that strong coupling does not occur at long range; rather, adiabatic effective potentials can be assumed for initial and final states. The state-to-state rate coefficient is simply the cross section multiplied by the relative velocity of the two reactants. Summation over all product states, as well as thermal averaging over the reactant state distributions and the translational energy distribution, can all be undertaken. Strategies for summing/integrating over rotational/vibrational degrees of freedom have been given [39]. As can be seen by writing out the expression for P' , the phase space formula for the state-to-state cross section in Eq. (39.25) obeys microscopic reversibility

$$\begin{aligned} 2\mu \mathcal{T}_{AB} \sigma(J_A, J_B \rightarrow J_C, J_D) &= 2\mu' \mathcal{T}'_{AB} \sigma(J_A, J_B \leftarrow J_C, J_D), \end{aligned} \quad (39.26)$$

where the reduced mass and asymptotic translational energy of the products are denoted by primes. Thus, thermalization of the forward and backward rates leads to detailed balancing.

As a detailed theory for prediction of reaction products and their state distributions, phase space theory and its variants have had mixed success. It is true that the theory correctly predicts that exoergic reactions occurring on barrierless potential surfaces proceed on every strong collision. It is also true, however, that the theory is generally not useful in predicting the branching ratios among several sets of exoergic products because potential surfaces do not

often show barrierless pathways for more than one set of products. When applied to product state distributions, the theory yields statistical results, so that population inversions in nondegenerate degrees of freedom (such as the vibrations of a diatomic molecule) are not replicated. With respect to more thermalized entities, such as total cross sections versus collision energy for endoergic reactions [40], the theory can be quite successful, especially when the potential surface involves a deep minimum or intermediate complex. In this instance, the strong coupling hypothesis comes closest to actuality. A deep well is also associated with a high density of vibrational states in the quasicontinuum above the dissociation limit of the molecular structure defined by the potential minimum [1, 41, 42]. Such a high density renders direct (specific) dynamical processes less likely.

A useful variant of phase space theory if complex lifetimes are needed [43] (see Sects. 39.2.4 and 39.3) is based on a unimolecular decay theory of *Klots* [44]. The reaction is considered to proceed via a capture cross section to form the intermediate complex, which then can dissociate into all available reactant and product states consistent with conservation of energy and angular momentum. The complex dissociation rate k_{uni} into a specific state can be obtained via the principle of microscopic reversibility in terms of the capture cross section from that state, obtained with $P' = 1$ in Eq. (39.25), to form the complex. In particular, if a complex with total angular momentum J can dissociate into one state of reactants A and B separating with translational energy \mathcal{T}_{AB} , then

$$k_{\text{uni}} = \rho_{\text{vib}}^{-1} g(J)^{-1} g(J_A) g(J_B) 2\mu \mathcal{T}_{AB} \sigma(J_A, J_B \rightarrow J), \quad (39.27)$$

where ρ_{vib} is the density of complex vibrational states obtained via a variety of prescriptions [1, 41, 42], and g is the rotational degeneracy. A cross section analogous to that in Eq. (39.25) can be formulated in terms of capture to form the complex multiplied by the complex dissociation rate into a particular state divided by the total (summed) dissociation rate. Note that the dissociation rate of the complex is proportional to ρ_{vib}^{-1} . Since ρ_{vib} is a strong function of the well depth, long-lived complexes are associated with large well depths (>1 eV). The *Klots* form for k_{uni} is especially useful for ion–molecule systems, where the cross section for complex formation can be assumed to be Langevin or ion–dipole. The concept of a long-range potential is less useful for most neutral–neutral systems, so that unimolecular rate coefficients for unstable entities are normally obtained quite differently in terms of ρ_{vib} at the transition state (Sect. 39.2.4).

For smaller reaction systems, especially those involving ions, it is quite common for the electronic states of reactants to correlate with more than one potential surface of the com-

bined system, although typically only one surface leads to energetically accessible products. In such instances, it is normal to assume statistical partitioning, although fine structure effects can complicate this picture. A generalization of phase space theory to account for multiple potential surfaces has been proposed for the $\text{C}^+ + \text{H}_2$ reaction [45].

Phase space theory has been used to predict product branching ratios for dissociative recombination reactions between polyatomic positive ions and electrons [46]; its success here has been limited at best.

39.2.3 Short-Range Barriers

Most reactions involving neutral molecules, as well as a minority of ion–molecule reactions, possess potential surfaces with short-range barriers. The experimental rate coefficients of these systems over selected temperature ranges are normally fit to the Arrhenius expression in Eq. (39.17).

The simplest theoretical method of taking short-range potential barriers into account is the line-of-centers approach, which resembles the capture theories previously discussed [7]. In this crude approximation, it is assumed that structureless reactants colliding with impact parameter b along a repulsive potential must reach some minimum distance, d , for reaction to occur. If the potential energy in the absence of angular momentum at d is E_0 , this condition implies that the asymptotic translational energy of reactants \mathcal{T}_{AB} must exceed the sum of E_0 and the centrifugal energy $\mathcal{T}_{AB} b^2/d^2$, which in turn yields a maximum impact parameter b_{max} . Thermal averaging of the rate coefficient $k = v \pi b_{\text{max}}^2$ over a Maxwell–Boltzmann distribution then yields

$$k(T) = \pi d^2 \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} \exp \frac{-E_0}{k_B T}, \quad (39.28)$$

which bears some resemblance to the Arrhenius expression if one equates the parameter E_0 with the activation energy. Assuming $T = 300$ K, $\mu = 10$ u, and $d = 1$ Å, the pre-exponential factor is $2.5 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$, which lies in a typical range.

The simple line-of-centers approach reduces the problem to that of structureless particles. The standard method of including all degrees of freedom is to use canonical ensemble statistical mechanics and to imagine that the transition state is in equilibrium with reactants. In the transition state, one of the vibrational degrees of freedom of a normal polyatomic molecule is replaced by a degree of freedom (the reaction coordinate) along which the potential is a maximum (with a corresponding imaginary frequency of vibration). The reaction coordinate is treated as a separable translation, so that the reaction rate coefficient can be envisaged as the equilibrium coefficient between transition state (minus one

coordinate) and reactants multiplied by the (average) speed of the transition state structure over the saddle point in the potential energy surface. The canonical result for $k(T)$ is given by [1, 7]

$$k(T) = \frac{k_B T}{h} \frac{q_{AB^\ddagger}}{q_A q_B} \exp \frac{-E_0}{k_B T} \quad (39.29)$$

for reactants A and B , where E_0 is the energy difference between the transition state and the reactants referred to zero-point levels, the \ddagger refers to the transition state, and the q are partition functions per unit volume. The partition functions can be factored into products representing electronic, vibrational, rotational, and translational degrees of freedom [47]. This formulation for $k(T)$ is known as the activated complex theory (ACT); a more appropriate name would be transition state theory since the term activated complex is also used to refer to an unstable state of a molecule in a deep potential well. The rate coefficient can also be written in terms of the thermodynamic parameters ΔH^\ddagger and ΔS^\ddagger [1].

Both the size and temperature dependence of the pre-exponential factor depend critically on the characteristics of transition state and reactants. Originally, ACT theory was used mainly to fit transition state characteristics to rate data. Increasingly accurate ab initio calculations of potential surfaces now allow purely theoretical determinations of $k(T)$ [48].

In addition to the assumption of a separable reaction coordinate that can be treated as a translation, several other assumptions have gone into the derivation of the ACT rate coefficient. First, molecules at the saddle point configuration (the transition state) have been arbitrarily chosen to be in equilibrium with reactants. More recently, the transition state assumption has been generalized to refer to that portion of the potential surface in which the reaction flux or number of states is a minimum [49], whether or not this occurs at a well-defined saddle point. Loose transition states can thus be defined even if there is no barrier along the reaction coordinate [50]. The procedure can be undertaken for transition states as a function of temperature, energy, or, in its most detailed version, energy and angular momentum. The variational theorem shows rate coefficients determined in this way to be upper bounds to the true rate coefficients, the more detailed procedures leading to the better bounds [23, 49, 50]. Secondly, the implicit assumption is made that translation along the reaction coordinate at the transition state structure invariably leads to products. Sometimes a transmission coefficient κ is used as an unknown factor in the expression for $k(T)$ to account for the possibility that translation leads back to reactants instead. Thirdly, the assumption is made that two-body collisions can lead to canonical statistical equilibrium. This assumption becomes worse as temperature declines, because at low temperatures

the long-range centrifugal constraints on angular momentum become more significant [8]. The influence of the long-range potential on ACT is contained in the statistical adiabatic theory discussed earlier [23]. Here loose transition states are defined as the maxima of effective adiabatic potential curves, and Eq. (39.29) must be modified since, as in detailed variational transition state theory, the transition states are themselves dependent on energy and angular momentum. A related problem is how to treat angular momentum constraints at low temperatures for potential surfaces which also contain a large short-range barrier or tight transition state. One approach is discussed in Sect. 39.2.4.

Rate coefficients derived from ACT do not indicate what the reaction products or sets of products might be. This information can be obtained from ab initio studies of the potential surface if different transition states lead to different products.

39.2.4 Complexes Followed by Barriers

Since long-range forces are always attractive, it makes sense to consider theories in which attraction and repulsion occur sequentially. For ion–molecule systems, this is especially important because many potential surfaces are monotonically attractive from long range to formation of a deep minimum at short range, but possess transition state barriers in their exit channels which are not large enough to prevent reaction but which affect the reaction dynamics. In addition, there are ion–molecule systems with potential surfaces closer to the norm for neutral–neutral species; in these systems there is only a weak long-range minimum followed by a short-range transition state barrier with energy above that of reactants. For the former type and, more arguably, for the latter type of potential surface, one can assume that the reaction proceeds through initial formation of an ergodic complex, followed by dissociation of the complex back into reactants or over the transition state barrier. If the reactants are labeled A and B , the complex AB^* , and the transition state AB^\ddagger , the mechanism is

which leads to the steady-state rate law

$$\frac{d[A]}{dt} = -k[A][B] , \quad (39.31)$$

$$k = \frac{k_{cf}}{k_{cd} + k_{cd'}} , \quad (39.32)$$

where k_{cf} , k_{cd} , and $k_{cd'}$ are the rate coefficients for complex formation, redissociation into reactants, and dissociation into products over the transition state, respectively. One statistical approach to such systems is to use a capture theory for complex formation, to use the Klots formulation of complex redissociation into reactants, and to use a different theory for

the unimolecular dissociation of the complex into products. Transition state theories of unimolecular complex decay have been studied for many years [1]. The current version is called RRKM theory, after the four authors Rice, Ramsperger, Kassel, and Marcus [10–13]. This theory builds upon the earlier RRK approach, in which random intramolecular vibrational energy transfer leads to large amounts of energy in the bond to be broken. An alternative hypothesis, in which amplitudes of well-defined normal modes add up to extend the bond to be broken past a certain amount, is now discredited [51]. In the RRKM approach, which is perfectly analogous to ACT theory, an equilibrium is envisaged between the activated complex and transition state species. The main use of the theory is in thermal unimolecular decay where it explains complex activation, deactivation, and random unimolecular dissociation as a function of gas density. At high density in a thermal environment, an equilibrium among complex, activated complex, and transition state leads to a thermal unimolecular decay rate in Eq. (39.13)

$$k_{\text{RRKM}}(T) = \frac{k_{\text{B}}T}{h} \frac{q_{\text{AB}^\ddagger}}{q_{\text{AB}}} \exp \frac{-E_0}{k_{\text{B}}T}, \quad (39.33)$$

which is perfectly analogous to the ACT result. At lower pressures, the activated complex is not in thermal equilibrium with the stable complex and the details of complex activation and deactivation are important [12, 13].

In the microcanonical formulation of RRKM theory, the dissociation rate coefficient k_{RRKM} as a function of (activated) complex total energy E and angular momentum J is given by

$$k_{\text{RRKM}}(E, J) = \frac{N^\ddagger[E - E_0 - E_{\text{rot}}(J)]}{h\rho^*[E - E_{\text{rot}}(J)]}, \quad (39.34)$$

where N^\ddagger refers to the total number of vibrational states of the transition state from its minimum allowable saddle point energy E_0 through E , and ρ^* refers to the density of vibrational states of the complex at energy E . For both the transition state and the complex, the available vibrational energy is the total available energy minus the rotational energy $E_{\text{rot}}(J)$, which is a function of the angular momentum. The energy not used for vibration and rotation in the transition state is considered to belong to the separable reaction coordinate. The most common expressions for the number and density of vibrational states are the semiclassical empirical values [1, 41, 42]; direct counting schemes also exist [52]. Both empirical and direct counting refer to states representing a bath of harmonic oscillators; anharmonic effects are rarely treated.

A theory of reaction rates for the mechanism in Eq. (39.30) incorporating a capture theory, and the Klots and RRKM unimolecular decays has been applied successfully to a variety of ion–molecule reactions in competition with asso-

ciation channels for which the reaction proceeds via a deep well and an exit channel barrier (see Sect. 39.3.3) [53–55]. Some authors prefer to use RRKM theory to describe redissociation of the complex into reactants [13, 56] by means of a loose transition state [57], which can be defined via a variety of variational and other methods [50]. Some recent work on unimolecular decay of polyatomic ions and neutrals following excitation indicates the superiority of the variational RRKM approach to unimolecular decay [58], especially if there is a significant amount of energy. Both the Klots and RRKM approaches to complex redissociation have problems associated with them: the Klots expression obeys microscopic reversibility but requires both a capture cross section and the assumption that the phase space formulation of the probability of individual quantum states is accurate; the RRKM expression does not obviously obey microscopic reversibility and, unless a variational calculation is performed, can create a somewhat artificial transition state.

Reaction mechanisms with more than one potential barrier can also be treated via a combination of ACT, capture, and unimolecular approaches [59, 60].

39.2.5 The Role of Tunneling

The role of tunneling in bimolecular and unimolecular reactions grows in importance as the temperature is lowered and hopping over potential barriers becomes more difficult. A simple one-dimensional correction for tunneling in the ACT expression for bimolecular rate coefficients, obtained by *Wigner* [1, 61], appears to be reasonable if the tunneling mechanism is not dominant. This correction $\Gamma > 1$ is simply the quantum correction to the partition function for the reaction coordinate

$$\Gamma \approx 1 - \frac{(h\nu_i)^2}{24(k_{\text{B}}T)^2} + \dots, \quad (39.35)$$

where ν_i is the (imaginary) harmonic frequency at the saddle point. Improved corrections have also been developed [62, 63] and, for the $H + H_2$ reaction, tested versus accurate quantum calculations [64]. At very low temperatures, such as those found in the interstellar medium, tunneling corrections are likely to be very large and to require proper multidimensional treatments.

A one-dimensional tunneling correction to the RRKM expression for the microcanonical unimolecular decay rate coefficient also exists [65]. The effective potential representing the reaction coordinate at the saddle point is assumed to be an Eckart barrier. The probability of tunneling for each vibrational state of the transition state is computed, and this probability takes the place of simply counting the state in the standard formula for k_{RRKM} . In particular, $N^\ddagger(E - E_0 - E_{\text{rot}})$

in the equation for $k_{\text{RRKM}}(E, J)$ is replaced by

$$N_{\text{QM}}^{\ddagger}(E - E_0 - E_{\text{rot}}) = \sum_n P(E - E_0 - E_{\text{rot}} - \epsilon_n), \quad (39.36)$$

where ϵ_n is the vibrational energy of state n of the transition state with respect to its zero point energy, and the sum is over all states n for which the energy in the reaction coordinate (the energy in parentheses on the right-hand-side) is negative, but not so negative that the classical energy in the reaction coordinate lies below the minimum of the complex potential well. In general, only a few vibrational states of the transition state need be considered for the tunneling correction.

This tunneling correction has been incorporated into statistical theories for the rate of reactions that proceed via complexes and transition state barriers [60]. It has been used recently in a calculation of the slow ion–molecule reaction

which successfully reproduces the observation that, despite initially decreasing as the temperature is reduced below 300 K, the reaction rate coefficient begins to increase as the temperature is decreased below 100 K [66]. The parameters for the calculation were obtained from an ab initio calculation of the potential surface, which shows the system to proceed through a weakly-bound long-range complex before encountering a transition state with a rather small barrier of ≈ 0.25 eV. Although the dynamical theory is not quantitative (presumably because of the one-dimensional tunneling approximation), it does reproduce the isotope effects seen when the reactants $\text{NH}_3^+ + \text{D}_2$ and $\text{ND}_3^+ + \text{H}_2$ are used, definitively showing that tunneling is the cause. The actual increase in rate at very low temperature comes from the fact that the tunneling rate is less dependent on temperature than the dissociation rate of the complex into reactants. Similar calculations have been performed for the analogous ion–molecule reaction

to explain a similar observation, although in this latter instance there is still a controversy concerning whether or not the reaction is truly exoergic [67]. It is interesting to speculate on whether similar effects can be detected for analogous neutral radical– H_2 reactants with moderate activation energy barriers, such as

This system possesses a transition state of rather moderate energy [48], but the only long-range complex is presumably the very weakly-bound van der Waals structure. Unlike the ion–molecule case, there are very few experimental studies of low temperature neutral–neutral reactions. Studies of pressure broadening at very low temperatures do reveal, however, the strong influence of the van der Waals bond [68].

39.3 Association Reactions

Association reactions have been studied for both ion–molecule and neutral–neutral systems. For the ion–molecule case, association processes can be investigated in great detail at low densities near or in the radiative association regime because ions can be stored in low pressure traps. Review articles [69, 70] describe such experiments for small and large ions, respectively. The results of many higher pressure studies of termolecular ion–molecule association, especially those undertaken in the SIFT apparatus, are also available [71]. In general, below the high pressure limit, the rate of association reactions without activation energy is known to increase with (a) an increase in the size of the reactants, (b) an increase in the bond energy of the product species, and (c) a decrease in temperature. These trends are all reproduced by statistical theories in which association proceeds by the formation of a complex followed by radiative and/or collisional stabilization [8]. More limited data for termolecular neutral–neutral reactions, with and without short-range potential barriers, have also been reviewed [72]. Although radiative stabilization can proceed via a single photon, collisional stabilization proceeds most probably in a stepwise fashion rather than in a single strong collision. The most detailed statistical theories incorporating multistep collisional stabilization use master equation techniques; in general it is preferable to solve the inverse problem of unimolecular dissociation via detailed RRKM theory and then invoke detailed balance [13, 56]. Such theories are more successful than strong collision approaches, especially in considering the dependence of ternary association rates on pressure. This dependence can be especially difficult to treat when association competes with an exoergic channel which does not necessarily dominate because of a barrier in the exit channel.

39.3.1 Radiative Stabilization

The problem of radiative association in the absence of competitive exoergic channels is in principle much more simple. In addition to the rates of complex formation and dissociation, one needs only the rate of stabilization via spontaneous emission. If the complex abundance is at steady state, the rate law for radiative association of species A and B is simply

$$\frac{d[A]}{dt} = -k_{\text{ra}}[A][B], \quad (39.40)$$

$$k_{\text{ra}} = \frac{k_{\text{cf}}}{k_{\text{cd}} + k_{\text{rad}}} k_{\text{rad}}, \quad (39.41)$$

where k_{ra} represents the rate coefficient for radiative association and k_{rad} refers to the rate coefficient for radiative stabilization. If ternary association is considered in addition,

the rate coefficient for radiative association is the low pressure limit of a more complex rate expression.

Radiative stabilization, which is normally considered to proceed via emission of a single infrared photon, has been studied in some detail [73–75]. If the unstable complex is imagined to be a collection of harmonic oscillators, each vibrational state i , which is best regarded as a Feshbach resonance, can be expressed as a set of occupation numbers $n_1^i, n_2^i, \dots, [n^i]$ for the assorted modes. If it is further assumed that upon formation, the complex has a probability P_i of being formed in state i , the rate of single-photon vibrational emission k_{rad} (s^{-1}) is then given by

$$k_{\text{rad}} = \sum_{i,j} P_i A_{i \rightarrow j} = \sum_{[n^i],[n^j]} P_{[n^i]} A_{[n^i] \rightarrow [n^j]}, \quad (39.42)$$

where the sum is over initial states i and final states j , and A is the Einstein coefficient for spontaneous emission. With some algebraic manipulation and the assumption that dipole selection rules apply, the result simplifies to

$$k_{\text{rad}} = \sum_{k=1}^s \sum_{n_k} P_{n_k}^k n_k A_{1 \rightarrow 0}^k, \quad (39.43)$$

where the index k refers to each of the s normal modes, the index n_k to the occupation number of mode k , and the Einstein A coefficient, which here refers to the fundamental transition of mode k , can be expressed in terms of the absorption intensity (see Chap. 11). The probability $P_{n_k}^k$ that mode k is excited to state n_k is given by the statistical formula

$$P_{n_k}^k = \frac{\rho'_{\text{vib}}(E_{\text{vib}} - n_k h\nu_k)}{\rho_{\text{vib}}(E_{\text{vib}})}, \quad (39.44)$$

where ρ_{vib} is the vibrational density of states and ρ'_{vib} is the reduced density of states when n_k quanta are assigned to mode k . The role of overtone and combination contributions to the radiative emission rate has also been investigated [74], as have a canonical approximation to the microcanonical formulation discussed here [75] and the small additional effect of stabilization by sequential emission [73]. With the use of the classical approximation to the standard vibrational density of state functions [41, 42], Eq. (39.43) for k_{rad} reduces to a linear function of the vibrational energy

$$k_{\text{rad}} = \frac{E_{\text{vib}}}{s} \sum_{k=1}^s \frac{A_{1 \rightarrow 0}^k}{h\nu_k}. \quad (39.45)$$

The constant of proportionality between k_{rad} and E_{vib} depends strongly on the fundamental intensities; many of these can be obtained from infrared absorption spectra, although there is normally insufficient information for all of the active modes in polyatomic molecules, especially ions. Reasonable

estimates, as well as limited experimental data, show that k_{rad} varies between 10 and 1000 s^{-1} for vibrational energies up to a few eV [69, 70, 73–75]. The radiative stabilization rate typically decreases slightly with increasing molecular size due to the inclusion of infrared inactive modes of vibration. There also appears to be a distinction between ions and neutral species, with rates for ions apparently faster.

Since spontaneous emission rates between electronic states are often far more rapid than infrared vibrational rates, the possibility that radiative stabilization can proceed via electronic emission has been examined [9]. The well-studied association between C^+ and H_2 appears to proceed via electronic relaxation, with a radiative stabilization rate one to two orders of magnitude larger than would be the case for vibrational emission. Whether or not the association between CH_3^+ and H_2 proceeds via an electronically excited complex has been debated for some time; the answer is apparently negative [69].

39.3.2 Complex Formation and Dissociation

The formation and dissociation of the complex can be studied with a variety of statistical approximations other than what is discussed in this section. In particular, complex dissociation has been treated by a thermal RRKM approach [70, 75], an energy but not angular momentum specific RRKM approach [73], variational transition state theory, statistical adiabatic theory, and flexible transition state theory [72]. We first consider a simple thermal approximation for systems without activation energy incorporating microscopic reversibility [8]. In the limit that the complex redissociation into reactants is much more rapid than radiative stabilization, the rate coefficient k_{ra} for radiative association in the thermal model is

$$k_{\text{ra}} = K(T)k_{\text{rad}}, \quad (39.46)$$

where $K(T)$ is the ratio between k_{cf} and k_{cd} in a canonical ensemble, and the radiative stabilization rate has been assumed to be independent of temperature. The equilibrium coefficient $K(T)$ between complex and reactants can be rewritten in terms of partition functions in the standard way [47]. However, the partition function of the complex is best calculated via the equation

$$q_{AB^*} = \int_0^\infty \rho_{\text{vr}}(E + D_0) \exp \frac{-E}{k_{\text{B}}T} dE, \\ \approx \rho_{\text{vr}}(D_0)k_{\text{B}}T, \quad D_0 \gg k_{\text{B}}T, \quad (39.47)$$

where ρ_{vr} is the density of vibrational-rotational states [41, 42], E is the energy of reactants, and D_0 is the bond energy of the complex. One immediate prediction of this approach

(deriving mainly from the rotational partition functions of the reactants) is that k_{ra} possesses a strong inverse dependence on temperature since

$$K(T) \propto T^{-(r_A+r_B+1)/2}, \quad (39.48)$$

where r refers to the number of rotational degrees of freedom (two for a linear molecule and three for a nonlinear one). It also predicts a strong dependence on well depth and size of the complex since the density of complex states is a strong function of both these parameters. Although the thermal model agrees with the strong inverse temperature dependence of the coefficients for both radiative and, more commonly, ternary ion–molecule association [8, 71] (in which case, the thermal model with strong collisions replaces k_{rad} with a collisional rate coefficient), the absolute rate coefficients calculated tend to range up to an order of magnitude too high. Given the large range of values exhibited by radiative association rate coefficients (10^{-20} – 10^{-9} cm³ s⁻¹), this might not seem too large a problem. It has been shown, however, that the thermal model is deficient, especially at low temperatures because thermal equilibrium cannot be achieved by two-body collisions [8]. A revised approach, called the modified thermal theory, replaces the rovibrational density of complex states in the thermal model with a vibrational density of states coupled with sums over the allowable ranges of complex angular momentum achievable from the specific capture model assumed [8]. The result is a somewhat lessened inverse temperature dependence and somewhat smaller rate coefficients, especially at low temperatures. Both modifications result in better agreement with experiment [8].

The modified thermal approach considers structureless reactants; full consideration of the internal states of the reactants is achieved via the Klots version of phase space theory, in which k_{cf} and k_{cd} in Eq. (39.41) are the capture and unimolecular rates discussed in Sect. 39.2.2. The phase space treatment reduces to the modified thermal treatment for small reactant angular momentum if the possibility of saturation [$k_{\text{cd}}(E, J) < k_{\text{rad}}$] may be ignored. Both conditions are normally met. The phase space approach has also been used for ion–molecule ternary association reactions, but here is coupled with the strong collision hypothesis and must be regarded as inferior to the more detailed RRKM calculations with master equation treatments for collisional stabilization [13, 56].

39.3.3 Competition with Exoergic Channels

There have been numerous reactions reported (especially ion–molecule reactions) in which exoergic reaction channels compete with association channels, both radiative (at low pressure) and ternary (at higher pressures). One view

of such competition is that it occurs via a sequential mechanism in which the reactants form a long-lived collision complex which either redissociates, dissociates into exoergic products, or is stabilized [53, 54]. The rate coefficient for competitive radiative association is then given by the steady-state expression

$$k_{\text{ra}} = \frac{k_{\text{cf}}}{k_{\text{cd}} + k_{\text{cd}'} + k_{\text{rad}}} k_{\text{rad}}, \quad (39.49)$$

where $k_{\text{cd}'}$ refers to complex dissociation into products. The additional and normally large $k_{\text{cd}'}$ term in the denominator means that the thermal and modified thermal theories cannot, in general, be used. The phase space treatment for this mechanism [53, 54, 76, 77] shows that association cannot compete with exoergic channels unless there is a significant barrier in the exit channel which considerably slows the dissociation rate of the complex into products, especially for partial waves of high angular momentum. Such barriers tend to be large enough to slow dissociation down, but not large enough to require tunneling. Although the results of phase space calculations are in good agreement with experiment for a variety of competitive systems [69, 76], they are once again inferior to RRKM calculations with master equation collisional deactivation when the competition involves collisional stabilization of the complex [13, 53, 54, 56].

Another mechanism exists for competition between association and normal exoergic channels [69]. Ab initio studies show that there is a parallel type of competition in which the product and association channels occur on different portions of the potential surface, with a branching at long range in the entrance channel. For example, the competing reactions [69, 78]

occur via distinct pathways. The former reaction is a possibly endoergic direct process in which the molecular hydrogen attacks perpendicularly, leading to the cyclic form of the C_2H_3^+ ion, whereas the association reaction occurs via the deep well of the ethylene ion. The competition in the analogous $\text{C}_3\text{H}^+ + \text{H}_2$ system is not currently well understood, with both parallel and series mechanisms suggested [69, 79].

39.4 Concluding Remarks

While the study of chemical reaction dynamics and kinetics is a relatively mature area of investigation, many challenges remain. A central one is the development of an efficient, fully quantum mechanical method for evaluating $k(T)$ that can be applied to a range of systems [80]. A second set of

challenges comes in the intrinsically non-adiabatic nature of chemical reactions. As a system moves from reactants to products, there is a dramatic change in the electronic wave function. In fact the very existence of a transition state reflects the avoided crossing of two potential energy surfaces. There is experimental and theoretical evidence that the fact that the dynamics takes place on multiple potential surfaces has a large effect on the gas-phase state-to-state dynamics, and eventually the rate coefficients. Finally, as the evaluation of the electronic structure of atoms and molecules becomes more easily accomplished through the use of sophisticated computer packages, researchers will be able to ask more detailed questions about the relationships between the topology of potential surfaces and the corresponding rate coefficients than was possible as recently as ten years ago [81].

Abstract

Ionic reactions in the gas phase is a broad field encompassing a multitude of interactions between ions (both positively and negatively charged), electrons and neutrals. These can be as simple as the transfer of an electron between molecules, or can be complex with considerable bond breaking, reforming and rearrangement. Reactions of the general type

illustrating this diversity, are given in Table 40.1. The reaction process can be considered as consisting of three parts: (a) the initial interaction, in which the colliding particles, $A^{+\cdot-}$ and $B^{-\cdot n}$ are drawn together by an attractive potential, (b) the reaction intermediate and transition state, in which reactants are transformed into products and (c) the weakening interaction as the product particles separate. Interactions can also occur where only elastic scattering is involved but these are considered elsewhere.

Keywords

rate coefficient · proton affinity · intermediate complex · electron attachment · dissociative recombination

40.1 Overview

Part (a) of the interaction is readily studied theoretically by classical mechanics in terms of reactant particle motions controlled by the interaction potential $u(r)$ between the particles, where r is the interparticle separation. For ion–neutral interactions, this can take the form (i) of an attractive ion-polarization or induced dipole potential [1] $u(r) = -\alpha_d q^2 / 2r^4$, where α_d is the polarizability of the neutral and q is the charge on the ion; anisotropy in the polarizability can also be taken into account [2], (ii) of an ion-permanent dipole potential [3] with $u(r) = -q\mu_D \cos \theta / r^2$, where μ_D is the permanent dipole of the neutral and θ is the angle that the dipole makes with r , and (iii) of an ion-quadrupole potential [4] with $u(r) = -Qq(3 \cos^2 \theta - 1) / 2r^3$, where Q is the quadrupole moment and θ is the angle the quadrupole axis makes with r . Such capture theories are considered in Chap. 39. Other interaction potentials can be considered, but these are of lesser significance. Coulombic interaction potentials $u(r) = -q_1 q_2 / r$, where q_1 and q_2 are the charges on the interacting particles, are appropriate for positive ion–negative ion recombination (more correctly termed mutual neutralization) and electron–ion recombination. For processes involving electrons, i.e., electron attachment and electron–ion recombination, the wave nature of the electron also has to be considered [5, 6].

In addition to providing a means of bringing the reactant particles together, the attractive interaction potential has another function. In part (b) of the reaction mechanism, where considerable rearrangement of the atoms in the colliding species may occur (i.e., in the intermediate complex and transition state), there may be barriers to reaction. Here, the kinetic energy gained from the interaction potential is available in the intermediate complex for overcoming such energy barriers (very much less interaction energy is available in neutral–neutral reactions and the effects of energy barriers are very much more evident [7]). Of course, this energy has to be reconverted to potential energy as the product particles separate, and is therefore not available to drive the overall

Table 40.1 Examples illustrating the range of ionic reactions that can occur in the gas phase

Reaction Process	Reaction Type
Ar ⁺ + O ₂ → O ₂ ⁺ + Ar O ₂ ⁻ + NO ₂ → NO ₂ ⁻ + O ₂	Nondissociative charge transfer/charge exchange
He ⁺ + O ₂ → O ⁺ + O + He	Dissociative charge transfer
C ₆₀ ³⁺ + Corannulene → Corannulene ²⁺ + C ₆₀ ⁺	Multiple charge transfer
O ⁺ + N ₂ → NO ⁺ + N	Ion/atom interchange or atom abstraction
O ⁻ + CH ₄ → OH ⁻ + CH ₃	Atom abstraction
H ₃ O ⁺ + HCN → H ₂ CN ⁺ + H ₂ O OH ⁻ + HCN → CN ⁻ + H ₂ O	Proton transfer
OH ⁻ + H → H ₂ O + e ⁻	Associative detachment
C ⁺ + C ₂ H ₂ → C ₃ H ⁺ + H	Atom insertion
CH ₃ ⁺ + H ₂ + M → CH ₅ ⁺ + M Cl ⁻ + BCl ₃ + M → BCl ₄ ⁻ + M	Ternary collisional association
He ₂ ⁺ + e ⁻ → He ₂ (2He) + hν	Radiative electron–ion recombination
HCO ⁺ + e ⁻ → H + CO	Dissociative electron–ion recombination
NO ⁺ + NO ₂ ⁻ → NO + NO ₂	Ion–ion recombination (mutual neutralization)
e ⁻ + CCl ₄ → Cl ⁻ + CCl ₃	Dissociative electron attachment
e ⁻ + C ₇ F ₁₄ → C ₇ F ₁₄ ⁻	Nondissociative electron attachment
e ⁻ + O ₂ + M → O ₂ ⁻ + M	Ternary collisionally stabilized attachment
¹³ C ⁺ + ¹² CO ⇌ ¹² C ⁺ + ¹³ CO OD ⁻ + NH ₃ ⇌ OH ⁻ + NH ₂ D	Isotope exchange

reaction. However, the amount of energy returned may differ from that initially converted to kinetic energy since the polarizability/dipole moment of the product neutral(s) may differ from those of the reactant neutrals. Generally, the final part (c) of the interaction has little influence on the magnitude of the reaction rate coefficient or on the product distribution once the products have significantly separated (i.e., beyond the range at which processes such as long range electron transfer can occur). Thus, to a major degree, part (b) of the mechanism and the reaction energetics determine the products of the reaction. Theories which address this part of the interaction are also discussed in Chap. 39 and these have met with mixed success. Thus, at present, experimental measurements are providing a more definitive understanding of reactions and their mechanisms.

Also, the situation is not in general clear as to the form of the thermodynamic energy that governs whether a reaction will proceed spontaneously, i.e., whether it is controlled by the enthalpy change ΔH in the reaction or by the Gibbs' free energy change $\Delta G = \Delta H - T\Delta S$, where ΔS is the entropy change in the reaction [8]. This is discussed in more detail in Sect. 40.2.

Rate coefficients and product distributions for these reaction processes are important in all ionized media where molecular species exist, such as interstellar gas clouds [9], planetary atmospheres [10] (including that of the Earth [11, 12]), comets (Chap. 87), the space shuttle environment [13], laser plasmas [14], plasmas used to etch semiconductors [15], hydrocarbon flames [16], etc.

40.2 Reaction Energetics

The availability of sufficient energy is a primary consideration for determining whether a reaction can proceed spontaneously. Criteria for determining whether energy is given out or absorbed in a reaction are (i) exo- or endoergicity, ΔE representing the internal energy change involved in a single interaction, (ii) exo- or endothermicity for an ensemble of particles in thermal equilibrium as defined by the enthalpy change per mole, ΔH , in the reaction and (iii) exergonic or endergonic as defined by the Gibbs' free energy change, ΔG [17]. ΔE is related to ΔH at temperature T by

$$\Delta H_T \approx -N\Delta E_T, \quad (40.2)$$

where N is Avogadro's number. ΔE is usually deduced from bond energies [18–20], ionization potentials [21], electron affinities [22, 23], proton affinities [22, 24, 25], gas phase basicities [22, 24–26], etc. ΔH_T^0 is determined from the heats of formation $H_{f,T}^0$ by [27]

$$\Delta H_T^0 = \sum_{\text{products}} H_{f,T}^0 - \sum_{\text{reactants}} H_{f,T}^0, \quad (40.3)$$

where the superscript 0 refers to the standard state [17] of the reactants and products [for example, see Eq. (40.1)]. ΔG_T^0 is determined from ΔH_T^0 and the entropy change ΔS_T^0 by

$$\Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0, \quad (40.4)$$

where

$$\Delta S_T^0 = \sum_{\text{products}} S_T^0 - \sum_{\text{reactants}} S_T^0, \quad (40.5)$$

and the S_T^0 are the standard entropies [17]. In cases where all of the $H_{i,T}^0$ and S_T^0 are not available, they can often be deduced by constructing other reactions involving the species of interest and other species for which the required thermodynamic information is known ([17] discusses the details of ways in which this can be achieved). Alternatively, the magnitude of a thermodynamic parameter can be calculated using equilibrium statistical thermodynamics, if the energies of all of the occupied molecular energy levels are known [28]. For studies where all reacting particles of a given type have the same energy, such as in beam/beam interactions where cross sections $\sigma(E)$ are measured, then ΔE is most appropriate. Alternatively, for reactions involving an ensemble of particles in thermal equilibrium at a temperature T , such as those studied in high pressure mass spectrometer ion sources or afterglows where rate coefficients $k(T)$ are measured, ΔH and ΔG are more appropriate. (The terms *rate coefficient* and *rate constant* are used interchangeably in the literature.) $\sigma(E)$ and $k(T)$ are directly related via

$$k(T) = \int_0^{\infty} v(E) f(E) \sigma(E) dE, \quad (40.6)$$

where $v(E)$ is the relative speed of the reactants and $f(E)$ is the Maxwell–Boltzmann energy distribution. Whether ΔH or ΔG is more important for determining reaction spontaneity depends on the degree of interaction of the reacting systems with the surroundings during the course of the whole reaction process. For example, if the reactions occur at low pressure such that the reaction time is much less than the collision time with the background gas, there will be no interactions with the surroundings, and the only energy available in the reactions will be ΔH . Here, ΔS can only determine the probability that the intermediate complex dissociates forward to products or back to reactants. At the other extreme, if the reactions are conducted at high pressure such that the reaction species are always in thermal equilibrium with the surroundings (the limiting case of this is reaction in solution), then the additional energy $T\Delta S$ is available, and ΔG determines whether the reactions are spontaneous. Obviously, for intermediate pressures, there is a varying degree of contact with the surroundings, and which of ΔH and ΔG is most applicable is more obscure. The definition of surrounding is also somewhat loose, since in the present context it represents anything that can provide a source of energy during the reaction (for example, vibrational modes of the

reacting species that are not involved in the interaction and which could be cooled as the reaction proceeds). Usually, the $T\Delta S$ term is not sufficiently large that ΔH and ΔG have different signs so that confusion about the spontaneity of reactions often does not arise. Recently, however, reactions have been discovered which appear to proceed spontaneously even though ΔH is positive, and there has been considerable discussion of this [8].

Eventually, all reaction processes will reach equilibrium as defined by

$$\Delta G = -RT \ln K, \quad (40.7)$$

where

$$K = \frac{p_C^c p_D^d}{p_A^a p_B^b} \quad (40.8)$$

is the equilibrium constant for the reaction

The subscripts to the pressures p denote the components A to D , and the superscripts represent the stoichiometries [17, 28]. The equilibrium constant K also equals k_f/k_r , the ratio of the forward to reverse rate coefficients, obtained for thermalized particles at temperature T . Thus, from measurements of k or the equilibrium constant at a series of temperatures, ΔH and ΔS of the reaction can be separately obtained.

40.3 Chemical Kinetics

The rate coefficient k for the reaction process

is defined by the rate equation [29]

$$\frac{d[A]}{dt} = \frac{d[B]}{dt} = -k[A][B], \quad (40.11)$$

where the square parentheses represent the concentrations of the enclosed species, and the units of k are typically $\text{cm}^3 \text{molec}^{-1} \text{s}^{-1}$ (often molec^{-1} is not written explicitly in the units). These k are deduced from the time variation of specific concentrations of thermalized reactants under a variety of conditions. For ion–neutral reactions, with A being the positive or negative ion species, the situation can usually be achieved in the laboratory where $[B] \gg [A]$, i.e., a pseudo first-order reaction. Simple integration yields

$$[A]_t = [A]_0 \exp(-k [B]_0 t), \quad (40.12)$$

where the subscript 0 indicates that this concentration is time invariant. Similar circumstances apply to binary electron attachment reactions, where $[A] = [e]$, the electron number density (the symbol β is often used here in place of k). If the reaction proceeds by association that is stabilized by collision with a third body M then

and the solution is

$$[A]_t = [A]_0 \exp(-k [B]_0 [M]_0 t), \quad (40.14)$$

with k now having units of $\text{cm}^6 \text{molec}^{-2} \text{s}^{-1}$. Note that situations exist where binary and ternary reactions can occur simultaneously.

If $[B] \gg [A]$, the solution of Eq. (40.11) is different. For the special case $[B] = [A]$, integration yields

$$\frac{1}{[A]_t} - \frac{1}{[A]_0} = kt, \quad (40.15)$$

and similarly for $[B]$. This situation is usually achieved in the laboratory for the determination of k for electron–ion and ion–ion recombination (the symbols α_e and α_i respectively are often used to replace k here). In many applications where several processes contribute to changes in $[A]$ and $[B]$, and where the simple limits are not applicable, the situation has to be analyzed numerically.

40.4 Reaction Processes

Recently, a nine volume series, concerned with all aspects of mass spectrometry, is being published of which Volume 1 deals with theoretical and experimental aspects of ionic reactions in great detail [30]. The reader is recommended to first consult the present chapter to get an overview of the reaction processes, and to go to this other text if more detail is required.

The wide variety of possible reaction processes is listed in Table 40.1 by specific examples. However, the reaction mechanisms illustrated are completely general. Magnitudes of the rate coefficients for binary interactions between charged and neutral particles, vary from $10^{-7} \text{cm}^3 \text{s}^{-1}$ for electron attachment [31, 32] to 10^{-8} or $10^{-9} \text{cm}^3 \text{s}^{-1}$ for unit efficiency ion–molecule reactions [33–36]. The efficiency is defined as the ratio of the measured k to the theoretical collisional value, i.e., that determined using the appropriate interaction potential. Ion–molecule reactions involving molecules with large permanent dipoles (for example, HCN at 2.98 D and HCl at 1.08 D [37]), can have $k > 10^{-7} \text{cm}^3 \text{s}^{-1}$ at low T [37–39] due to locking of the dipole along the

line joining the reactant species, thereby maximizing the strength of the interaction. Rate coefficients can be much smaller (by orders of magnitude) than these upper limits if the efficiency of part (b) of the mechanism is small. The part of the mechanism after collision occurs is treated by transition state theory in terms of the partition function of the transition state; where the transition state is, and its partition function, relates to the number of ways that the available energy can be distributed in the transition state [40]. More details of the theories are given in Chap. 39 and [41].

For dissociative electron–ion recombination, the upper limits on k are generally much larger as a consequence of the long range Coulombic interaction potential, varying from $\approx 10^{-7} \text{cm}^3 \text{s}^{-1}$ for diatomic ions to $> 10^{-6} \text{cm}^3 \text{s}^{-1}$ for more polyatomic species [42–45]. For ion–ion recombination, the rate coefficients are about an order of magnitude smaller than these values because of the larger mass of the negative ion relative to the electron, and thus the smaller interaction velocity (the σ of the two processes are, in fact, similar) [46]. Electron–ion recombinations that are radiatively stabilized generally have a small k , as small as $\approx 10^{-12} \text{cm}^3 \text{s}^{-1}$ [47], because of the large magnitude of the radiative lifetime of the reaction intermediate compared with the time for autoionization. For most reaction types, experimental rate coefficients are available at room temperature, and for some, the temperature and/or energy dependencies have also been determined [31, 32, 43, 44, 46, 48]. Generally, only the ion products are identified using mass spectrometry, and the product neutrals are not determined (unless the energetics allow only one neutral product), and the states of excitation of the products are not identified.

For ternary processes involving association, k varies from totally saturated at the binary collision limit to very small ($\approx 10^{-32} \text{cm}^6 \text{s}^{-1}$) for ion–neutral reactions [33, 34] and similarly for electron attachment [49]. Little is known about collision stabilized recombination [50]. Each type of reaction process has its own characteristic behavior and dependence on temperature. Rate coefficients, temperature dependencies, and product distributions (where available) have been tabulated for ion–neutral reactions [33, 34, 51] and electron attachment [31, 32]. Less data are available for electron–ion and ion–ion recombination, so no attempts have been made to compile these. Data are available in [6, 42–44, 46].

40.4.1 Binary Ion–Neutral Reactions

Over the years, these reaction processes have been reviewed several times, but from different perspectives. Most recently, studies of positive ion–molecules in flow tubes [52] and negative ion–molecule reactions from an organic mechanistic viewpoint [53] have been discussed.

Charge Transfer and Charge Exchange

These processes involve the exchange of an electron which can occur at relatively large interparticle separations (i.e., up to $\approx 6 \text{ \AA}$ [54]). Thus, in principle, k values can be larger than the collisional limiting value. Such reactions are, in general, relatively fast, although there are some notable exceptions (for example, $\text{He}^+ + \text{H}_2$, $k = 1 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$; $\text{Ne}^+ + \text{H}_2$, $k < 2 \times 10^{-14}$ and $\text{Ne}^+ + \text{N}_2$, $k = 1.1 \times 10^{-13}$ [33]). Attempts have been made to relate the efficiency of charge transfer to the Franck–Condon overlap between the neutral reactant and the product ion, with mixed success [55]. More energy is generally available in the positive ion reactions than the negative ion reactions since ionization potentials are much larger than electron affinities, and thus more dissociative products would be expected, as is usually observed. The reaction

is particularly interesting and has been studied in considerable detail. The product distribution slightly favors N^+ (60%) rather than N_2^+ [56], with the N^+ channel becoming even more important with increasing vibrational temperature of the N_2 [57]. Spectroscopic emission studies [58] have shown that a significant fraction ($\geq 5\%$) of the reactions proceed by charge transfer into the N_2^+ ($\text{C}^2\Sigma_g^+$) state followed by the radiative decay

This channel competes with the predissociation

A new mechanism has recently been observed in which charge transfer occurs in parallel with chemi-ionization (or, equivalently, electron detachment)

Such a process is, of course, only energetically possible for high recombination energy ions like He^+ and Ne^+ [59]. Also, multiply charged C_{60} (C_{60}^{3+}) has been seen to undergo two electron transfer with Corannulene and some Polycyclic Aromatic Hydrocarbons (PAH's), generally in parallel with a whole series of other reaction channels [60].

Proton Transfer

Where proton transfer is significantly exoergic, as determined by the difference in the proton affinities of the reactant and product neutrals, reaction usually proceeds at the collisional rate [61]. If the reaction is close to thermoneutral, then the amount of phase space available when the intermediate

complex dissociates to products is similar to that available when it dissociates back to the reactants, and the k approximates to one-half the collisional value. For proton transfer reactions which are not highly exo- or endoergic, k_f and k_r can be measured and thus ΔG determined (using Eq. (40.7)). If ΔS can be determined in some way, or if k_f/k_r can be determined as a function of T , then ΔH can be deduced and used to obtain the proton affinity difference (ΔS can also be determined in the latter case). This has been used to construct proton affinity scales [24, 25]. Care is required in such studies to ensure that no vibrational excitation remains in the reactant ion due to its formation, and that the identities (i.e., isomeric forms) of the reactant and product ions are known (e.g. whether the ion is HCO^+ or the higher energy form COH^+ [62]).

Often the individual reaction processes do not occur in isolation. For example, in the reactions of CH_4^+ with COS , H_2S , NH_3 , H_2CO and CH_3OH , both charge transfer and proton transfer are energetically possible, and both channels are observed. Here, the least exoergic channel is favored in all cases [63]. Proton transfer also occurs in negative ion reactions, for example those of OH^- and NH_2^- giving H_2O and NH_3 respectively (e.g. see Table 40.1), and these types of reactions are production sources for many negative ions [53, 64].

Ion–Atom Interchange and Atom Abstraction

In many simple cases, these two processes are the same, for example

but not so for the more complicated molecules (e.g., $\text{O}^- + \text{CH}_4$; see Table 40.1). Such reactions, when exoergic, usually occur close to the collisional rate although somewhat slower. Series of such reactions with H_2 occur in the interstellar medium and are responsible for producing the hydrogenation in many of the species observed there, for example, in CH_3^+ production from CH^+ , NH_4^+ from NH^+ and H_3O^+ from OH^+ (see Chap. 86). The reaction,

is particularly interesting. At temperatures greater than 300 K, the reaction shows an activation energy barrier of 2 kcal mol^{-1} . The rate coefficient k decreases with decreasing T , reaching a minimum of $2 \times 10^{-13} \text{ cm}^3 \text{ s}^{-1}$ at 80 K and then increases at lower T due to tunneling through the barrier [48]. This behavior occurs because, at the higher temperatures, the lifetime of the intermediate complex is not sufficient for significant tunneling to occur, but there is sufficient energy in the reacting species to overcome the barrier. At lower temperatures, there is not sufficient energy available

to overcome the barrier, but the lifetime of the intermediate complex becomes long enough for significant tunneling to occur [65]. This explanation has been substantiated by the isotopic studies of the reactions $\text{NH}_3^+ + \text{D}_2$, and $\text{ND}_3^+ + \text{H}_2$ and D_2 [66].

For some reactions, isotopic labeling has been used to identify the reaction mechanism. For example, the reaction

has been shown to be predominantly charge transfer, rather than ion–atom interchange, by labeling the ion as $^{18}\text{O}^+$ [67, 68].

Associative Detachment

For negative ions, an additional process is possible for which there is no equivalent positive ion analog (although there is the related process of chemi-ionization, i.e., $AB + C \rightarrow ABC^+ + e^-$). In this process, the negative ion and the neutral associate, and the association is stabilized by the ejection of the electron (see Table 40.1). Such reactions can only occur when the electron detachment energy is less than the energy of the bond that is produced. Therefore, these reactions usually involve radical species which produce stable molecules. k values are usually an appreciable fraction of the collisional values [69, 70]. Infrared emissions have been detected from a series of these reactions [71], for example O^- with CO and F^- , Cl^- and CN^- with H , and show that the reactions populate the highest vibrational levels that are energetically accessible.

Other Binary Ion–Molecule Reaction Channels

As reactant species become more polyatomic, there is a greater variety of reaction processes that can occur, and these often occur in parallel. The processes that occur are too numerous to list so a few examples will have to suffice. Reactions that occur in isolation are insertion reactions of the type [72]

and

Multiple channels are very evident in reactions of ions produced from species with large ionization potentials and small proton affinities, for example, NH^+ [73],

In addition to charge and proton transfer, other channels requiring more rearrangement are evident.

Isotopically Labeled Reactants

A great deal can be learned about reaction mechanisms in significantly exoergic ion–neutral reactions by isotopic labeling. Some such reactions have been mentioned above, but a particularly graphic example is the reaction

which was assumed to be either proton transfer and/or H-atom abstraction, depending on the interaction energy. By studying the reaction with both the ion and the neutral reactants separately deuterated, the reaction was shown to be much more complex, with the product ions being CH_4D^+ (10%), CH_3D_2^+ (22%), CH_2D_3^+ (43%) and CHD_4^+ (25%) for the reaction of CH_4^+ with CD_4 [74]. The reaction clearly proceeds via a long-lived intermediate in which there is a large degree of isotope mixing before unimolecular decomposition to products.

A further class of isotopic reactions are those for which the exoergicity is provided only by the different zero point energies of the reactants and products. Many such reactions have been studied. Examples of the various types are: (i) The symmetrical charge transfer

which proceeds in both directions at more than half the collisional rate. This implies that the reaction proceeds via long-range charge transfer, a conclusion substantiated by the fact that no mixed product $^{14}\text{N}^{15}\text{N}^+$ is produced [67]. (ii) Proton transfer reactions exemplified by $^{14}\text{N}_2\text{H}^+ + ^{15}\text{N}_2$ and $\text{H}^{12}\text{CO}^+ + ^{13}\text{CO}$, which are both exoergic by about 1 meV [48]. Some isotopic scrambling has been observed in the latter reaction by using the double isotopic substitution [75],

Other examples where considerable isotope scrambling occurs are H/D exchange in the reaction systems $\text{H}_3^+ + \text{H}_2$, $\text{CH}_3^+ + \text{H}_2$, $\text{H}_3\text{O}^+ + \text{H}_2\text{O}$, $\text{CH}_5^+ + \text{CH}_4$, etc. [48]. Such scrambling reactions are believed to proceed via proton bound dimer intermediates (e.g., $\text{H}_2\text{O} \cdots \text{H}^+ \cdots \text{D}_2\text{O}$). (iii) Isotope exchange reactions such as $^{13}\text{C}^+ + ^{12}\text{CO} \rightarrow ^{12}\text{C}^+ + ^{13}\text{CO}$ have also been studied. For this reaction, both k_f and k_r increase with decreasing T due to an increase in the intermediate complex lifetime; k_r decreases at lower T due to the endoergicity in this reaction direction [74].

Isotope exchange is also observed to occur with negative ions, viz.

and is a common process. Particularly significant is the comparison where MH is H_2 and NH_3 . These species have very similar gas phase acidities, and thus the exoergicities of the reactions are similar. However, NH_3 has a larger polarizability than H_2 and, in addition, has a permanent dipole moment. The observation that the k for the NH_3 reaction is a factor of ten larger than that for the H_2 reaction is explained as being due to the stronger interaction potential which makes more energy available in the intermediate complex and facilitates H/D exchange [64].

Temperature Dependencies of Binary Reactions

When the k values at room temperature are close to the collisional value, appreciably exoergic reactions generally exhibit little temperature dependence. For slower reactions, a significant inverse temperature dependence is observed, being $\approx T^{-1/2}$ for several reactions. This behavior is rationalized as a decreasing lifetime of the intermediate complex with increasing temperature, thus allowing less time for reaction [48].

40.4.2 Ternary Ion–Molecule Reactions

In cases where binary channels are not energetically possible, association reactions can still occur, both for positive and negative ions. The reactions can be as simple as

to associations more complex than those listed in Table 40.1. Rate coefficients k_3 at room temperature vary from $1 \times 10^{-31} \text{ cm}^6 \text{ s}^{-1}$ for reactions such as Eq. (40.27) to in excess of $1 \times 10^{-25} \text{ cm}^6 \text{ s}^{-1}$, this upper limit being due to experimental constraints rather than the reaction itself. The mechanism usually postulated is

where M stabilizes the excited intermediate, $(AB^\pm)^*$ by removing energy in the collision. For this type of reaction, there is a considerable dependence of k on T . Statistical theory predicts (see Chap. 39),

$$k_3 \propto T^{-(\ell/2+\delta)} , \quad (40.30)$$

where ℓ is the number of rotational degrees of freedom in the separated reactants, and δ is a parameter attributed to the temperature variation of the collision efficiency of the stabilizing third body M . Experimentally, many association reactions exhibit such power law dependencies of the k_3 [48, 51] with δ being small (≈ 0.2 or 0.3) for a helium third body. Also, some evidence exists for a contribution of vibrational degrees of freedom to the temperature coefficient in cases where the vibrational levels in the reactant neutral are closely spaced [76].

For complex reactant species, lifetimes of intermediate complexes become very long so that, in the higher pressure experiments (see below), all intermediate complexes are stabilized, and thus the reaction is independent of the pressure of M . This form of *saturation* can be eliminated in many cases by using low pressure experiments, so that the time between collisions is long, and normal ternary kinetics in Eq. (40.14) are restored. Under these conditions, sometimes there is still a pressure independent component to the k which is postulated as being due to radiative stabilization of the intermediate, viz.

An example of this is the reaction [77]

The stabilizing photon is often considered to be in the infrared due to a vibrational transition within the ground electronic state (with a radiative lifetime of $\approx 10^{-2}$ to 10^{-3} s). Note that only a photon with $h\nu > 3/2k_B T$ is required for the complex (although still vibrationally excited) to be stable against unimolecular dissociation. However, there are cases where it is believed that an electronically excited state is accessed [78, 79]. Examples are

and

As yet, radiative association has not been observed directly (i.e., by the detection of the emitted photon), however, the kinetic evidence is strong for the existence of this process.

For the more rapid collisional associations, competition with binary channels is possible, for example

where the percentages refer to product abundances at a He pressure of 0.2 Torr [80].

40.5 Electron Attachment

These reactions have generally been studied by different techniques from those used to examine ion–neutral reactions and also by different workers [31, 32]. Analogous to the ion–neutral situation, there are dissociative processes,

and nondissociative processes,

the former being stabilized by dissociation, and the latter occurring because of the long lifetime of the intermediate against autodetachment with eventual collisional stabilization (cf. saturation in ion–neutral association reactions; Sect. 40.4.2). Measured rate coefficients vary in the range 1×10^{-7} to the smallest measurable value of $\approx 1 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ [31, 32]. The upper limit on k for this process is determined, from a consideration of the electron de Broglie wavelength $\lambda = \lambda/2\pi$, to be $\approx 5 \times 10^{-7} (300/T)^{1/2} \text{ cm}^3 \text{ s}^{-1}$ [81], or, more rigorously,

$$k(E) = \sum_i (\sigma/\pi\lambda^2)_i / [h\rho(E)], \quad (40.37)$$

where $\rho(E)$ is the density of states and

$$\sigma/\pi\lambda^2 \approx 1 - \exp[-(4\gamma^2\mathcal{T})^{1/2}], \quad (40.38)$$

with $\gamma^2 R_\infty = (2\mu/m)^2 \alpha_d/a_0^3$ [5]; σ is the collision cross section, \mathcal{T} the kinetic energy, α_d the polarizability, a_0 the Bohr radius, μ the reduced mass, and i represents the available product channels. Where k is less than the upper limit value, this is usually due to activation energy barriers, and k shows Arrhenius behavior

$$k(T) = k_0 \exp \frac{-\Delta E}{k_B T}, \quad (40.39)$$

where k_B is the Boltzmann constant, with the barrier height ΔE being in the range 0 to $\approx 300 \text{ meV}$ [32]. If the attachment is nondissociative, and the lifetime of the intermediate complex against autoionization is small compared with the collision time (as occurs for less complex species), the reaction exhibits normal ternary behavior, for example,

Some interesting mechanisms have been identified for attachment. Different product ions have been observed in experiments conducted at very different pressures, for example, in the reaction

at high pressures ($\approx 1 \text{ Torr}$), the products, as indicated, were observed with an association channel [see Eq. (40.42)] being detected [82]. This association channel was not seen in low pressure experiments [83]. Such behavior is explained in terms of the relative magnitudes of the autodetachment lifetime and the time between collisions. When the former time is larger, the association product will dominate, whereas if the converse is true, dissociation products dominate. Thus, the different product distributions, rather than indicating discrepancies, yield information about the autodetachment lifetime.

In attachments to the Br-containing compounds, CF_2Br_2 , CFBr_3 , and $\text{CF}_2\text{BrCF}_2\text{Br}$ and $\text{CH}_2\text{BrCH}_2\text{Br}$, in which the Br atoms are on different carbon atoms, up to a 20% Br_2^- product is observed [84]. This shows that atoms in product molecules can come from spatially separated parts of the reactant molecule. Thus, considerable distortion and rearrangement must occur in the intermediate complex.

40.6 Recombination

This process has been much less studied than ion–neutral reactions with only ≈ 100 reactions being studied [44] compared to about 10,000 in the former case [33]. Also, relatively little information is available concerning the products since these are neutral and very much more difficult to detect than ions.

40.6.1 Electron–Ion Recombination

Electron–ion recombination can proceed by series of mechanisms, which have been discussed in detail recently [85], and these are included in Table 40.1. In brief, these are radiative recombination, where the neutralized ion (excited into the continuum) is stabilized by radiation emission, dielectronic recombination, which is similar to radiative recombination, except that there is a double electron excitation into the continuum, collisionally stabilized recombination, where the intermediate is stabilized by collisions with electrons or a heavy third body (combined collisional radiative recombination is also possible), and dissociative recombination. Dissociative recombination can obviously only occur when the recombining ion is molecular, however, when it occurs it is usually several orders of magnitude faster than the other recombination processes. Thus, only dissociative recombination will be discussed here.

Rate coefficients for dissociative electron–ion recombination at room temperature vary from $> 1 \times 10^{-6}$ for polyatomic ions to $\approx 1 \times 10^{-7} \text{ cm}^3 \text{ s}^{-1}$ for diatomic ions [42, 43]. For large k , there is little temperature dependence, temperature dependencies being more marked for the slower reactions.

Two mechanisms were initially proposed: (i) the direct mechanism [86] where the neutralized ion undergoes a radiationless transition to a repulsive potential curve on which dissociation to products occurs, and (ii) the indirect mechanism [87] where the neutralized ion initially transfers to a Rydberg state and then undergoes a radiationless transition to the repulsive curve. For the former process, the theoretical temperature dependence is $T_e^{-0.5}$, while it is $T_v^{-1} T_T^{-1.5}$ for the latter, where the subscripts T and e refer to the thermal ion vibrational and electron temperatures respectively [6]. There is no reason why these two processes cannot occur in parallel, although it is not straightforward to determine the relative contributions [87]. Fortunately, both processes are automatically included in multichannel quantum defect theory (MQDT) [88]. Experimental T -dependencies for reactions which are not close to the collisional limit have power law dependencies in the range ≈ 0.7 to 1.5 [43, 89, 90], i.e., between the theoretical predictions. In cases where there is detailed temperature data, e.g., for some hydrocarbon ions (CH_5^+ , C_2H_3^+ , C_2H_5^+ , C_3H_7^+ , C_6H_7^+) [89, 90], the dependence changes from the lower dependence at low temperature to the higher dependence at higher temperature.

Less is known about the products. Detailed theory carried out for the diatomic ions O_2^+ , NO^+ and N_2^+ , and to a large degree HCO^+ , are in general agreement with experiment [91, 92]. For the more polyatomic ions, the theory is not yet sufficiently quantitative [93, 94] and reliance is placed on experiment. H-atom contributions to the product distributions for ten ions (N_2H^+ , HCO^+ , HCO_2^+ , N_2OH^+ , OCSH^+ , H_2CN^+ , H_3O^+ , H_3S^+ , NH_4^+ and CH_5^+) vary from $\approx 20\%$ for OCSH^+ to 120% for CH_5^+ [95]. OH is a substantial product (30 to 65%) in the above reactions where it is energetically possible [96] (i.e., excluding HCO^+), except in the case of OCSH^+ , perhaps indicating that the proton is exclusively on the S-atom rather than the O-atom (i.e., in the lowest energy form [97, 98]). More complete product distributions are now being obtained, initially using flowing afterglows (O_2H^+ , HCO_2^+ , H_2O^+ , H_3O^+) [99], but more recently using storage rings (including H_3^+ , CH_2^+ , H_2O^+ , NH_2^+ , H_3O^+ , CH_3^+ , NH_4^+ , CH_5^+) [100]. These studies are showing that fragmentation to give three products is a common, indeed dominant, mechanism [101]. Dissociative recombination has recently been reviewed by [102].

Electron-ion recombination is an energetic process and electronically excited states can also be populated. Vibrational population distributions for these states can readily be determined if Einstein A coefficients are known for the observed transitions ($I \propto A[*]$, where I is the photon intensity, and $[*]$ is the number density of the excited state). The N_2 ($\text{B}^3\Pi_g$) state and the CO ($\text{a}^3\Pi_r$) state vibrational population produced in the recombinations of N_2H^+ , HCO^+ , HCO_2^+ and CO_2^+ have been determined [103, 104]. Possible

mechanisms [105] have been suggested for this vibrational excitation: (i) the impulsive force on the molecular fragments as the neutralized ion rapidly dissociates, and (ii) the Franck-Condon overlap between the wave functions of the molecular products (in various vibrational states) and the wave function of this particular fragment in the neutralized ion before it dissociates. Theory underestimates the populations of the higher levels, but does predict the small observed oscillation in the occupancy of the various vibrational levels in the CO ($\text{a}^3\Pi_r$) state generated in the recombination of HCO^+ [106].

The theories of recombination discussed above assume favorable potential curve crossings, however, it has been shown both experimentally [107, 108] and theoretically [109] that such are not necessary when quantum tunneling can occur. Experimental evidence has been obtained in the recombinations of N_2H^+ and N_2D^+ where the populations of the $\nu' = 6$ vibrational level of the N_2 electronically excited ($\text{B}^3\Pi_g$) state is greatly enhanced (≈ 6 at 100 K) for N_2H^+ over N_2D^+ . This level is resonant with the $\nu = 0$ vibrational level of the recombining ion, making tunneling more facile; and H atom tunneling is further enhanced because of the smaller mass [108].

40.6.2 Ion-Ion Recombination (Mutual Neutralization)

Less information is available on this process than on electron-ion recombination; a detailed review has recently been published [110]. k values vary from about 4×10^{-8} to $1 \times 10^{-7} \text{ cm}^3 \text{ s}^{-1}$ at room temperature [44, 46] with power law temperature dependencies of ≈ 0.4 for the only two systems that have been studied as a function of T ($\text{NO}^+ + \text{NO}_2^-$ and $\text{NH}_4^+ + \text{Cl}^-$) [46]. This is consistent with theory [111] in which the Landau-Zener approximation is used to determine the probability of a crossing between the Coulombic ion-ion attractive potential and the potentials of the neutral products. This transition occurs by an electron transfer (the optimum distance for such a transfer when a favorable crossing exists is about 10 \AA). Theory gives that

$$k \approx 2(v^2 Q) \left(\frac{\mu}{2\pi k_B T} \right)^{1/2}, \quad (40.43)$$

where Q is the cross section

$$Q = \pi R_c^2 [1 + (R_c E)^{-1}]. \quad (40.44)$$

R_c is the crossing distance, E is the interaction energy and v is the relative velocity at the crossing point [111]. Once neutralized by electron transfer, the products continue undeflected with the velocity gained from the Coulombic field. Photon emission has been detected from a series of excited state products. Following the early detection [112] of

NO ($A^2\Sigma^+$) emissions from $\text{NO}^+ + \text{NO}_2^-$, a variety of NO emissions have been detected from NO^+ recombinations with molecular (SF_6^- , C_6F_6^- , and $\text{C}_6\text{F}_5\text{CH}_3^-$) and atomic (Cl^- and I^-) negative ions [113, 114] and He_2 emissions from He_2^+ recombinations with C_6F_6^- and $\text{C}_6\text{F}_5\text{Cl}^-$ [113]. These emissions were interpreted in terms of long-range electron transfer [112], however, in the recombination of Kr^+ and Xe^+ with SF_6^- , KrF , and XeF , excimer emissions have been seen [113], suggesting an intimate encounter in these cases. Also, few data are available on the effects of pressure. For the reactions $\text{SF}_3^+ + \text{SF}_5^-$ and $\text{NO}^+ + \text{NO}_2^-$, k increases by about a factor of 4 between 1 and 8 Torr [46, 50].

Abstract

Clusters are small aggregates of atoms or molecules which are transitional forms of matter between atoms or molecules and their corresponding bulk forms. Just as this definition spans an incredibly broad range of clus-

ters from, say, He_2 to Na_{10000} , so do the properties of these clusters span a broad range. This chapter attempts to bring order to this diverse cluster kingdom by first sorting them into six general categories. Within each category, the physics and chemistry of the more or less similar cluster species are described. Particular emphasis is placed on the unique properties of clusters owing to their finite size and finite lattice.

This chapter summarizes one of the youngest topics in this volume. Much of what is known is highly qualitative and has not yet been assembled into overarching tables or equations. Thus, this review is best regarded as a progress report on the current knowledge in this rapidly advancing field. Many of the concepts and the language used to discuss clusters are derived from condensed matter physics. The nature of these clusters impels such descriptions.

Keywords

metal cluster · excess electron · carbon cluster · molecular cluster · fullerene cage

41.1 Introduction

Clusters discussed in this chapter are isolated species composed primarily of a single type of atom or molecule. Most of these clusters are highly reactive and can only be made and studied under rarified conditions such as in a molecular beam. In keeping with the definition of clusters given above, this chapter will not attempt to cover the truly vast literature on atomic and molecular dimers and trimers. A great many of these species have been thoroughly characterized, however they are better described as molecules rather than *tiny clusters*. Stabilized clusters in the form of Zintl ions, colloids, and nanoparticles have also been made. While it is impossible to resist mentioning these clusters throughout this chapter, they are more appropriate to condensed matter physics. Finally, experimental and theoretical techniques for

forming and studying clusters will not be covered; excellent reviews of these methods are available elsewhere [1–6].

41.2 Metal Clusters

Clusters of a wide variety of refractory and nonrefractory metals have been made and studied. These include clusters of alkali metals, transition metals, coinage metals, main group metals, and lanthanides. Clusters of alkali metals, particularly sodium, are the most well studied and understood. The emerging picture of alkali clusters is that they behave much like quasifree electron metal spheres. Thus, approximations such as the jellium model used for describing bulk metals explain a large number of alkali metal properties quite well [2]. Other metallic clusters, such as some main group metal and noble metal clusters, can also be understood within the jellium model. Nonetheless, there are examples of metallic clusters which deviate significantly from these simple models, particularly among the transition metal clusters.

41.2.1 Geometric Structures

The ground state geometry is known accurately for only a handful of small metal clusters. Examples include lithium and sodium clusters containing up to nine atoms, where electronic spectra are compared with accurate *ab initio* quantum chemical calculations to deduce their structures [5–7]. Such an approach is not a general one, either experimentally or theoretically. As the size and/or atomic valency of the metal cluster increases, the number of possible ground state structures grows enormously. Interpretation of experimental spectra requires theoretical guidance, which means that each one of these structures must be calculated using an accurate electronic structure calculational method. Thorough theoretical investigation is only practical with current computational tools for clusters containing up to about thirteen atoms. Methods such as molecular dynamics combined with density functional calculations have been used to speed up the process of finding and comparing various isomers [4, 8]. Such approaches are still restricted by available computational power to clusters with relatively few atoms and valence electrons per atom. Metal clusters of atoms with higher valency, e.g., mid-row transition metals, have proved to be quite difficult to treat accurately [9]. The large electron correlation problems inherent in these clusters must be treated semi-empirically, leading to large uncertainties in the relative energies between isomers of different spin and geometry.

Despite these difficulties, approximate geometries are known for many metal clusters. For cluster sizes greater than, roughly, several tens of atoms, there is strong experimental evidence that spherical close packed geometries, particularly

the Mackay filled icosahedra, predominate the geometric structures [7, 10, 11] (The Mackay filled icosahedra contain concentric closed icosahedral shells of atoms plus one central atom. These structures are pentagonally symmetric and occur every n atoms by $n = 13, 55, \dots, 1/3(2n + 1)(5n^2 + 5n + 3)$ [4]). These geometries have been deduced by a variety of means. For example, abundance mass spectra of metal clusters up to sizes containing thousands of atoms show intensity enhancements, termed *magic numbers*, at each cluster size which corresponds to a complete Mackay icosahedron. Saturation coverages of transition metal clusters with various reagents can be explained in terms of covering the icosahedral faces of these clusters. The persistence of icosahedral structures to large cluster sizes raises the question about where the crossover to the metallic packing occurs. For example, a spherical piece of an fcc metal would have cuboctohedral symmetry rather than noncrystalline icosahedral symmetry. Ultrafine metal particles containing 10^4 to 10^5 atoms typically have bulk crystalline geometries [12]. Little theoretical or experimental data currently exist to resolve the question of when the bulk crystalline structure emerges [10]. The point of crossover must involve kinetic as well as energetic factors. Although icosahedral packing is seen in beam experiments on metal clusters containing hundreds to thousands of atoms, high resolution electron microscopy experiments on supported metal particles in this size range show fluctuating structures that can rapidly evolve between icosahedral, cuboctohedral, and other crystalline arrangements, depending on cluster temperature [13].

41.2.2 Electronic and Magnetic Properties

A number of electronic properties have been measured for metallic clusters, particularly alkali metal and noble metal clusters. These include ionization potentials, electronic affinities, polarizabilities, and photoabsorption cross sections.

The spherical jellium approximation is generally a good model for these properties in clusters of alkali and noble metals [2, 7]. This model treats the valence electrons of the cluster as a delocalized sea of electrons smeared over a uniform spherical background of ionic cores. The energy levels of such a jellium sphere can be calculated by confining the jellium electrons to a three dimensional potential. A suitable form of this potential yields level spacings that are given by principal and angular momentum quantum numbers (n) and (l). There are no restrictions on l for a given n , and the degeneracy of a given l level is $2(2l + 1)$. The levels order as 1s, 1p, 1d, 2s, 1f, 2p, 1g, 2d, 3s, \dots . The electron configuration of a cluster is given by filling successive energy levels (termed shells) with the available valence electrons. Special stability occurs for those clusters with a closed shell config-

uration. This stabilization can be seen in the experimental measurements of the dependences of total binding energies, ionization potentials, electron affinities, and polarizabilities on cluster size [2, 7, 10, 11, 13, 14]. The potential used to calculate the energy levels within the jellium model has been formulated to include elliptical distortions of open shell clusters [7]. This refinement has been successful in describing the fine structures of these trends. Despite the usefulness of the jellium model, it is not applicable for very small or very large clusters. In many smaller clusters containing up to a few tens of atoms, electron-ionic lattice interactions cannot be neglected, and the spherical approximation is poor. For these clusters, accurate quantum chemical calculations must be used to determine the electronic structure. Alternatively, for clusters larger than roughly 500 to 3000 atoms (depending on which clusters and the cluster temperature), the level spacings become increasingly continuous, blurring the shell structure. When this occurs, other effects are seen to dominate the trends in cluster stability, particularly the stability arising from completing a geometric shell of atoms on the cluster [7, 10, 11, 15, 16].

The convergence of cluster electronic structure to bulk metal electronic structure has been seen in the evolution of metal cluster ionization potentials (I_P) and electron affinities (A_e) as a function of cluster size. A good approximation for the overall trend in the I_P as a function of cluster size (N is the number of atoms) is given by the electrostatic model for the work function of a classical conducting sphere [2]

$$I_{P,N} = W_B + A \frac{e^2}{R_N}, \quad (41.1)$$

where W_B is the work function of the bulk metal, e is the electron charge, and R is the cluster radius, which is often set proportional to $N^{1/3}$. A is a constant which is found experimentally to have values of about 0.3 to 0.5; the theoretically derived value for A depends on the model used [2, 11]. A similar form of Eq. (41.1), where A is replaced by $(A - 1)$, describes the A_e of a negatively charged cluster. Experimentally, the I_P and A_e of alkali metal, noble metal, and some main group metal clusters behave as described by Eq. (41.1) with shell structure superimposed on the overall trend [2, 6, 14]. Equation (41.1) predicts a smooth convergence of the work function to the bulk value with increasing cluster size. This has been seen experimentally, such as in copper cluster valence and inner shell A_e which extrapolate smoothly to the corresponding bulk values [17]. In mercury clusters, the transition to bulk metallic behavior occurs more abruptly and clusters with less than ≈ 17 atoms appear to behave as nonmetals [18]. Transition metal clusters often deviate strongly from the trend in Eq. (41.1) [10].

Electronic spectra are available for a number of metal clusters including alkali, noble metal, transition metal, and aluminum clusters [7, 10, 11]. Small alkali clusters exhibit

rich spectra in the visible. Many of these spectra have been assigned using accurate electronic structure calculations as described above. Visible spectra of larger alkali metal clusters and other metal clusters are typified by giant resonances with cross sections reaching values as large as 2000 \AA^2 [6, 7]. In the absence of detailed electronic structure information, these spectra have been assigned using comparisons with bulk metal spectra. In particular, the giant resonances are assigned to collective excitations of the cluster valence electrons, in an analogy to bulk metal plasmon resonances. Theoretical treatments of these giant resonances for clusters have been derived from classical treatments of conducting spheres driven by an external electromagnetic field [7, 10]. While the blue shift of the resonance frequency with increasing cluster size is well predicted by the classical models, other details are less well described, such as the magnitude of the shift and the width of the resonance. Clusters which are known to be nonspherical from other measurements exhibit multiple resonance peaks; these have yet to be quantitatively described by theory. Transition metal clusters also show evidence of collective excitations; however, the magnitudes of these absorptions are 2 to 5 times larger than predicted by classical models [19]. An intriguing *non sequitur* occurs when the classical models are extended down to describe the resonances of small alkali clusters. This is illustrated by the example of Na_8 , which exhibits a large single resonance in the photoabsorption spectrum. At first glance, the classical jellium model does fine: it predicts a spherical closed shell cluster which should exhibit a single resonance. Yet, a more thorough examination of the time dependence of this feature has revealed that it consists of four overlapping absorptions [10, 20]. These multiple absorptions clearly must arise from one-electron excitations, not a collective all-electron excitation [5]. Further work is needed to weave together the two disparate pictures of collective versus one electron excitations in metal clusters.

Inner shell electrons of some metal clusters have been probed spectroscopically. Whereas excitations of the delocalized valence electrons primarily reflect the entire cluster environment, excitations of the localized inner shell electrons reflect the atomic environment. In mercury clusters, excitation of the 5d core electrons reveals a transition from insulating clusters at small sizes to more metal-like clusters with increasing s-p hybridization typical of bulk mercury [21]. Inner core electron spectra of copper and antimony clusters also reveal details regarding the evolution of the cluster lattice structure as a function of size [11, 17]. Such valuable information can be obtained from inner shell electron spectra of metal clusters that more experiments are warranted.

Magnetic moments have been measured and described theoretically for a range of transition metal, rare earth, and Group III metal clusters [5, 7, 10, 22–24]. Examples of clusters which exhibit a positive magnetic moment include

cobalt, iron, nickel, gadolinium, and terbium clusters. Clusters of metals such as vanadium, palladium, chromium, and aluminum are observed to be diamagnetic. The effective moment per atom, μ , in magnetic clusters is greater than in the bulk because of the lower average coordination number in clusters [24]. As the cluster size increases, the surface to volume atom ratio decreases and μ converges to the bulk value. The size of these magnetic clusters is smaller than the critical domain size for bulk ferromagnetism, thus they are best described as paramagnetic with a single moment given by $N\mu$, where N is the number of atoms in the cluster. Stern–Gerlach deflection data have been obtained to measure μ . A critical parameter in interpreting these data is the so-called blocking temperature T_B , the temperature at which the cluster moment unlocks from the cluster axes and orients thermally in an external field. For clusters with temperatures $T > T_B$, the observed effective moment μ_{eff} for paramagnetic clusters is given by [24]

$$\mu_{\text{eff}} = \mu \left[\coth \left(\frac{N\mu H}{k_B T} \right) - \frac{k_B T}{N\mu H} \right], \quad (41.2)$$

where k_B is the Boltzmann constant, and H is the magnetic field strength. Medium size iron and cobalt clusters behave well according to this classically derived expression. Deviations from this model are observed in internally cold clusters and rare earth clusters which can be explained by partial and complete locking of the magnetic moment to the cluster lattice. Also, in very large clusters, $N\mu$ becomes sufficiently large that alignment overwhelms thermal statistical behavior.

41.2.3 Chemical Properties

The chemistry of both charged and neutral metal clusters has been studied, particularly for clusters of transition metals and Group III metals [6, 7, 25, 26]. Both chemisorption and physisorption are seen, depending on the type of metal cluster and reagent. In many cases, the observed chemistry is quite similar to that observed for the corresponding bulk metal. For example, platinum clusters dehydrogenate hydrocarbons, hydrogen chemisorbs on transition metal clusters with the exception of coinage metal clusters, and oxygen reacts readily with aluminum and iron clusters.

Chemisorption reactions of metal clusters have been seen with a wide variety of reagents. Products, reaction rates, and activation barriers have been measured as a function of cluster size. With a few notable exceptions, such as the reactions of hydrogen with nickel and aluminum clusters, none of these reactions are understood at the microscopic level [10, 11]. Macroscopically, some correlations have been seen between reaction rates and other measured cluster properties. For example, some cluster reactions show evidence

that the shell structure affects reaction rates, with open shell clusters having much higher reaction rate and lower activation barriers than clusters with closed shells. In other cases, the pattern of cluster reaction rates with cluster size correlates with the cluster I_p 's. These correlations have been used to infer the essential cluster-reagent interaction which governs the reactivity for a given set of clusters with a given reagent. For example, open shell clusters and clusters with low I_p 's favor reactions which involve electron donation from the cluster to the reagent at a critical point along the reaction coordinate. Such generalities must be made with caution, however, since they do not hold up well over a broad range of cluster sizes, compositions, and reagents. Even a single cluster size can exhibit complex reactivity: isomers with different reactivity have been observed for niobium clusters and, in some cases, these isomers have been interconverted by annealing. Of course, complexity is to be expected, given the richness and diversity of chemistry that is known to occur for different metal systems in various electronic and geometric environments.

Geometric structures of transition metal clusters have been studied using physisorption reactions. Weakly bound adsorbates such as hydrogen, water, and ammonia show strong saturation behavior in their uptake by metal clusters [10, 11, 27, 28]. Trends in the saturation coverage with cluster size yield information about the type of binding site and total number of binding sites for a given cluster size. Additional information regarding the nature of the adsorbate site is often available from studies of the corresponding physisorption on bulk metal surfaces. This knowledge is used to sort through possible cluster structures and deduce which geometries exhibit the correct number and type of adsorbate binding sites. For example, saturation coverages of iron, cobalt, and nickel clusters correlate with icosahedrally packed geometries over a wide range of sizes. Adsorbate binding energies have also been determined in some cases [27, 28].

41.2.4 Stable Metal Cluster Molecules and Metallocarbohedrenes

Thus far, this section has focussed entirely on the properties of metal clusters isolated in the gas phase. This discussion would not be complete, however, without mentioning that a number of metal cluster molecules have been made which are sufficiently stable that they can be made in quantity and bottled [7, 10, 11, 29, 30]! Also, recently a new class of metal–carbon clusters has been discovered, termed metallocarbohedrenes, that are believed to be sufficiently stable and abundant that they can be made in bulk. The brief overview of these isolatable clusters given below is not meant to be complete but is intended to introduce the large and impressive body of work in this field. Interested readers

are encouraged to consult the reviews cited and references therein.

Metal cluster molecules consist of a metal cluster core surrounded by a stabilizing ligand shell. A large number of such metal cluster molecules has been made, including some with metal cores as large as 300 platinum or 561 palladium atoms. In many cases, crystals of single size clusters have been made with an exactly known number of metal atoms in the core. The availability of macroscopic samples of these clusters has made it possible to measure a number of their properties. Exact structures are known for many metal cluster molecules from X-ray crystallography. Electronic and magnetic properties have been determined which reveal the development of metallic behavior within the metal core. The ligand shell is found to interact strongly with the metal atoms on the surface of the metal core. This outer shell of metal atoms does not behave as a surface of metal atoms with free valence electrons such as is found on the surface of a bulk metal. Undoubtedly, such strong interactions between surface metal atoms and coordinating ligands are necessary to make a cluster which is sufficiently stable to be isolated and crystallized without coalescing. The core of atoms inside the outer metal shell of atoms does not appear to be greatly perturbed by the coordinating ligands. Studies of the electronic and magnetic properties of the core show the onset of metallic properties as a function of particle size and atomic packing.

A distinct class of transition metal-carbon clusters has been recently found which have been termed metal-carbohedrenes [31]. Within this class, the clusters M_8C_{12} ($M = \text{Ti, V, and Zr}$) are particularly abundant and stable. Extensive electronic structure calculations show that the structure of M_8C_{12} is metallic and should be viewed as a distorted M_8 cube where each face is decorated with a C_2 dimer [32]. This structure differs greatly from the corresponding bulk metal carbides, which have cubic rock salt crystalline forms. Furthermore, the metal carbide cluster formation conditions can be adjusted to yield cubic fragments of the bulk. The related metal nitride clusters are only observed to form cubic structures. Theoretical calculations on the metalcarbohedrene and cubic forms of these metal carbides and nitrides show that they are comparable in energy for the carbides, but that the cubic structures are much more stable in the metal nitride clusters [33]. Despite their apparent stability, none of the metalcarbohedrenes has yet been isolated and purified.

41.3 Carbon Clusters

The discovery of the especially stable, spherical cluster of sixty carbon atoms, named buckminsterfullerene, has ignited an intense research effort in carbon clusters [7, 8, 10, 11, 34–39]. The family of pure carbon clusters that have been made

extends from the dimer all the way up to tubular shaped clusters containing thousands of atoms. Several of these clusters, most notably C_{60} and C_{70} , have been isolated as a single size in macroscopic quantities [40]. The fascinating properties of bulk materials made of pure and doped C_{60} and C_{70} are outside the scope of this review [8, 10, 11, 37, 39, 41].

Carbon clusters can be roughly grouped into three distinct classes. The first consists primarily of small carbon clusters which have linear or ring geometries. Hollow spheres (termed fullerenes) appear at about 28 carbon atoms and persist up to at least several hundred atoms. Very large carbon clusters containing hundreds to thousands of atoms assume various forms, including onion-like structures of concentric spheres and hollow tubes.

41.3.1 Small Carbon Clusters

Theoretical and experimental studies have found that rings and linear chains are the most stable configurations for small carbon clusters. Below about ten atoms, linear cumulenes are the most stable structures for odd numbered carbon clusters and ionic carbon clusters [13, 26, 42, 43]. For the even numbered neutral carbon clusters, C_4 , C_6 , and C_8 , however, cyclic and linear geometries are nearly isoenergetic [7, 11, 13, 42]. Various theoretical and experimental studies have yielded conflicting results as to which geometry is more stable for each of these three clusters [7, 42, 44]. Much of the controversy over the experimental evidence probably arises because the two structures are so close in energy that either isomer or both may be present, depending on the preparation conditions. By way of proof, direct experimental data have been found for coexisting linear and cyclic isomers of C_{7-9}^+ and C_{11} [26, 44]. Also, some experimental probes are not equally sensitive to the signature from a linear versus a cyclic geometry.

At ten carbon atoms, a distinct transition occurs from linear to cyclic structures [26, 43, 44]. Starting at this size, the additional bonding stabilization accrued by joining the two ends of the linear chain overcomes the strain energy resulting from ring closure. Stable monocyclic ring structures are observed for carbon clusters over a surprisingly wide range of sizes, even persisting into the size range where three dimensional fullerenes appear. Bicyclic rings, higher order polycyclic rings, and graphitic fragments also occur in this size range but many of these configurations appear to be metastable [43, 45].

A_e 's and I_P 's have been measured for these small carbon clusters. Dramatic effects appear in the size dependence of the A_e 's as a result of the changeover from linear to ring structures [44]. A_e 's of the chain structures are noticeably higher than for ring structures for carbon clusters containing similar numbers of atoms. Distinct odd-even alternations in

the A_e 's are also seen, plus there is evidence for aromatic stabilization according to the $4n + 2$ rule. No break in the I_p 's is seen across the structural transition, but the trend in the I_p 's also follows the $4n + 2$ rule expected for aromaticity.

Chemical reactions have been observed for both neutral and charged small carbon clusters, particularly for the cations [7, 26, 43]. In general, the linear cationic clusters, containing fewer than ten atoms, react readily with a variety of reagents and exhibit reactivity typical of carbenes. The ring shaped cationic clusters with ten or more atoms are much less reactive, and often show no detectable reaction with reagents that react efficiently with the smaller carbon clusters. It is this differential reactivity which has revealed the presence of co-existing linear and cyclic isomers. Evidence for polyacetylene versus cumulene structure in the small linear chains can also be seen in the cluster reaction patterns.

41.3.2 Fullerenes

Fullerenes make up a class of carbon clusters with closed hollow carbon atom cage morphologies. The term *fullerene* was inspired by the geodesic domes of architect R. Buckminster Fuller, and has come into widespread usage despite its non-standard nomenclature. The fullerene cage network is composed of interlocking rings of sp^2 hybridized carbon atoms, where every carbon atom is bonded to three other carbon atoms. Five and six member rings predominate in the cages. Highly strained four and smaller membered rings are unfavorable. Seven and higher membered rings usually can readily rearrange within the network to form five and six membered rings. Delocalization of the π electrons over the cage contributes significantly to the stabilization of the fullerenes.

Assuming at least five-membered rings, the smallest possible fullerene is C_{20} , consisting of twelve pentagons. However, the observed fullerenes all contain about 30 atoms or more. Larger fullerenes are formed by joining together pentagons, hexagons, and heptagons, with the pentagons providing the curvature necessary to close the cage. In fullerene structures composed entirely of pentagons, hexagons, and heptagons, it can be rigorously shown from Euler's theorem that, $N_5 = N_7 + 12$, where N_5 is the number of pentagons and N_7 the number of heptagons. By far the most abundant fullerene that is seen is C_{60} . There are 1812 possible isomers for C_{60} but only one forms in great abundance [37], which has each of its 12 pentagons isolated and surrounded by its 20 hexagons. The resulting molecule, resembling a soccer ball, belongs to the highest point symmetry group I_h , where all the carbon atoms are equivalent [34–37]. The *isolated pentagon rule* arises out of minimizing strain and maximizing resonance energy and is a powerful tool for predicting the most stable fullerene isomers [37]. Besides C_{60} , a number of other fullerenes have been seen, most notably C_{70} which

is the next larger fullerene that can be constructed using the isolated pentagon rule. The largest proven fullerene structure contains 84 carbon atoms. It is possible to construct increasingly larger fullerene cages containing hundreds of carbon atoms. Such giant fullerenes have yet to be conclusively verified in experiments, however evidence for their existence has been seen in bulk samples containing fullerene mixtures and in gas phase abundances of carbon clusters [36, 37, 39].

A number of the fullerenes has been made and purified as a single size in macroscopic quantities [37, 39, 40]. This has enabled their geometries to be determined quite accurately using a wide variety of spectroscopic and theoretical techniques. Even structures of fullerenes such as C_{76} , C_{78} , and C_{84} which occur as isomeric mixtures have been elucidated. The electronic structures of many of these fullerenes have been calculated and compared with experiment [37, 38].

Yet to be resolved is the issue of how these low entropy fullerene structures can form so efficiently in carbon vapor. One proposal is that cup-like prefullerenes form first which add new carbon moieties to close the cage. Other suggestions include coalescence of small carbon rings such as C_6 or C_{10} , or stacking of intermediate size rings on a small *seed* ring such as C_{10} , or folding up of large defective graphitic fragments to form closed hollow spheroids [8, 10, 36, 37]. Some intriguing insights into this open question are provided by experiments on nonfullerene metastable forms of carbon clusters in the fullerene size regime [43]. These species can be made in the gas phase and are found to have bicyclic, graphitic, and other polycyclic ring shapes which are not in the form of partial fullerene cages. Upon annealing, some of these ring forms are seen to convert into the fullerenes, which suggests that they are important intermediates for forming the fullerene cage. Similar polycyclic ring shapes are observed during the initial *melting* of fullerenes in molecular dynamics simulations [46].

Since the fullerenes are hollow, much attention has focussed on putting something inside. A wide variety of noble gas atoms and metal atoms has been successfully loaded into fullerenes, forming a family of so-called *endohedral* complexes [36, 37, 39, 47–51]. Noble gas atoms encapsulated in fullerenes appear to assume central positions within the cage and do not perturb the overall electronic structure of the fullerene [11, 47, 52]. Endohedral complexes where the encapsulated species is a metal atom, called *metallofullerenes*, encompass a wide range of metals (M) and fullerene sizes from $U@C_{28}$ to $Sc_3@C_{82}$ (@ denotes that the metal atom is inside the fullerene). Separation and purification of a macroscopic amount has been achieved for several of these [48, 49, 51]. Theoretical and experimental data indicate that the endohedral metallofullerenes have considerable charge transfer from metal atom(s) to the fullerene cage [37, 47, 48, 51, 52]. This interaction affects the oxidation states of the metal atom(s) and the cage and, in some

cases, causes the metal atom(s) to locate off-center. It is yet to be generally understood why, within the range of known fullerene sizes, only some form endohedral complexes, particularly C_{28} , C_{60} , C_{70} , C_{74} , C_{80} , C_{82} , and C_{84} . The $M@C_{28}$ endohedral complex is especially intriguing because it appears that C_{28} itself does not form as an empty fullerene.

The unsaturated surfaces of fullerenes undergo a broad range of chemical reactions. The availability of macroscopic samples of fullerenes, especially C_{60} and C_{70} , has enabled the preparation of numerous fullerene derivatives. With their high electron affinities, fullerenes readily form a wide variety of charge transfer compounds. These include the so-called *exohedral* complexes, where metal atoms are attached to the outside of the cage. Particularly stable exohedral metal-fullerene clusters have been observed which have one alkaline earth atom decorating each ring of the cage [53]. The unsaturated double bonds of the fullerenes can be functionalized with reagents such as halogens, aromatics, and alcohols [37, 39]. Some of the bulk forms of these complexes and derivatives exhibit amazing properties such as superconductivity at temperatures as high as 33 K seen in C_{60} films doped with alkali or alkaline earth metals [51]. References [37, 39, 51] contain recent reviews.

41.3.3 Giant Carbon Clusters: Tubes, Capsules, Onions, Russian Dolls, Papier Mâché

Giant clusters of pure carbon have been found which have tubular, capsular, and spherical shapes [8, 10, 37, 51, 54]. These clusters occur both as single entities and with multiple concentric layers. The basic structure consists of a spiralled or rolled graphitic sheet made up of hexagonal rings of sp^2 hybridized carbon atoms. Just as in the fullerenes, pentagonal rings provide the curvature required to form a ball or to cap the ends of tube shapes. Negative curvature has also been seen which is believed to result from heptagonal rings. Carbon tubes and capsules are formed prolifically in the same carbon arcs which produce fullerenes. Typical diameters range from about 5 to 100 nm, depending on the inner diameter and number of layers, and lengths of up to several microns are seen. For concentric or spiralled structures, the average interlayer spacing is 3.4 to 3.5 Å which is slightly larger than in crystalline graphite. Although tubes and capsules are the most commonly seen morphologies, these are observed to convert to layered spherical *onion* structures under intense irradiation [8]. This suggests that collapsed onion structures are more stable. Currently, there exists some debate over whether the multilayer tubes or capsules consist of layers of complete shells within shells, such as in a *Russian doll*, or whether these layers are so highly defective that the overall structures are best described as *papier-mâché* consisting of numerous overlying graphitic fragments [54].

Little experimental detail is available on the electronic or mechanical properties of these tubes. Theoretical calculations have been performed on the electronic properties of perfect tubes constructed in various ways [37, 51]. Numerous configurations of tubes are possible, depending on the tube diameter and the overall screw axis formed by the rows of carbon hexagons wound around the tube waist. The geometrical arrangement strongly affects the electronic properties of a tube. Appropriate choices of diameter and tilt angle of the screw axis yield tubes which are metallic or semiconducting. Tubes and capsules with perfect lattice arrangements are calculated to be extremely stiff, forming the strongest carbon fibers known. Almost no data exist on the chemical properties of carbon tubes, capsules, and onions. While they are stable enough to isolate in air, reaction occurs with O_2 and CO_2 at high temperatures which destroy the tubes [51]. Finally, as for the fullerenes, tubes, capsules, and onions have a hollow cavity which can be filled. These *nanocapsules* have been successfully loaded with lead and gold atoms, as well as crystalline metal carbide particles [51].

41.4 Ionic Clusters

A growing body of experimental and theoretical evidence on alkali halide and alkaline earth oxide clusters shows that these tiny clusters of ionic materials are ionically bound. Most of these clusters have highly ordered crystal structures even at very small sizes. Thus, these clusters offer excellent systems for studying electron localization on finite-sized crystalline lattices.

41.4.1 Geometric Structures

Most ionic clusters of alkali halides and alkaline earth oxides assume the cubic rock salt lattice typical of bulk sodium chloride [6, 7, 10, 13, 55]. This lattice is favored not only for clusters of rock salt cubic solids such as NaCl and NaF, but also for other clusters such as Cs_xI_y where the bulk form has the cesium chloride cubic crystal structure. Exceptions occur when the cluster size is smaller than, roughly, a unit cube, or when the cluster anions and cations differ greatly in ionic radius, such as in lithium bromide clusters (even though solid LiBr has the NaCl crystal structure) [10]. The bulk rock salt lattice is retained even for clusters where the number of anions and cations are unequal, as long as the deviation from stoichiometry is not too great. In clusters with a large excess of alkali atoms, the extra metal atoms segregate to a face of the cluster and form a metallic overlayer [55].

Maximization of ionic interactions and minimization of surface energy leads to cuboid crystal morphologies for these clusters which have as many (1 0 0) faces as possible. Partic-

ularly stable clusters occur for sizes where the cuboid lattice is completely filled and has nearly equal numbers of ions on all sides [55]. Excess electrons or holes also play a crucial role in the stability of ionic clusters. For example, while the $[\text{Na}_{14}\text{Cl}_{13}]^+$ cluster forms a particularly stable cube (with 9 atoms on each square face and one atom in the center), its counterpart $[\text{Na}_{13}\text{Cl}_{14}]^+$ does not because it has fewer holes than the available electrons; however, the anion $[\text{Na}_{13}\text{Cl}_{14}]^-$ does form a particularly stable cube [11, 55].

41.4.2 Electronic and Chemical Properties

The I_p 's, A_e 's, photoabsorption spectra and photoabsorption cross sections have all been measured for ionic clusters, particularly alkali halide $[\text{M}_j\text{X}_k]$ clusters. Understanding the role of the coulombic interactions, particularly excess electrons, in these clusters is key to understanding the trends in their electronic properties with cluster size, composition, and overall charge. Excess electrons are known to localize in at least four distinct ways: at anion vacancies, in weakly bound surface states, on specific alkali metal ions, or in cation-anion pair dipole fields [11, 55, 56].

First, there is a large class of ionic clusters which contain equal numbers of electrons and holes, such as clusters in the series $[\text{M}_{j+1}\text{X}_j]^+$. I_p and A_e of clusters within this class reflect the overall stability associated with forming the *perfect* filled cuboid lattices described in Sect. 41.4.1. Such *perfect* clusters do not chemisorb polar molecules, whereas the *imperfect* clusters readily do [55]. The lowest energy absorptions for clusters in this class result from charge transfer excitations, just as in perfect ionic solids. Spectra obtained for $[\text{Cs}_{j+1}\text{I}_j]^+$ clusters show large cross sections for absorption, consistent with charge transfer, and features which converge towards the bulk for the perfectly cubic cluster, $[\text{Cs}_{14}\text{I}_{13}]^+$ [57].

Other ionic clusters do not contain equal numbers of electrons and holes; clusters with excess electrons have been the most studied. One such class consists of clusters with at least one anionic vacancy and one or more excess electrons. In this class, e.g., $[\text{Na}_{14}\text{Cl}_{12}]^+$, the excess electron localizes at the lattice site of the missing anion. This is conceptually similar to an *F*-center in an ionic bulk crystal. Enhanced stabilization is observed for those size clusters within this class where the excess electron sitting at an anionic site yields a filled cuboid lattice. Nonetheless, because the localized electron has a large zero-point energy, its binding energy is much less than an anion at the same site. This is reflected in both the first and second I_p 's, as well as the A_e 's of this class of clusters [55]. Just as for *F*-centers in ionic crystals, clusters with an excess electron localized on an anionic vacancy have strong optical absorptions at energies well below the charge transfer bands [55].

The next class of ionic clusters with excess electrons consists of perfect cuboid ionic clusters which contain one or more excess electrons, but do not have a defect binding site such as an anionic vacancy or an excess metal atom. In these clusters, e.g., $\text{Na}_{14}\text{Cl}_{13}$, the electron is quite weakly bound in a surface state which primarily involves the surface metal cations. These clusters have particularly low electron binding energies; for example, the I_p of $\approx 1.9\text{eV}$ determined for $\text{Na}_{14}\text{F}_{13}$ is the lowest I_p measured for any compound [55].

In the other two known classes of ionic clusters with excess electrons, the extra electrons have been calculated to localize on a metal cation or in a dipole potential well [58]. Some evidence for these forms of localization has been seen in photoabsorption, I_p 's and A_e 's [10, 11, 55]. For example, the photoelectron spectra of some $[\text{Na}_{j+1}\text{Cl}_j]^-$ clusters show that the two excess electrons are singlet-coupled, and localized either at an anion vacancy, or at a single Na site so that they behave as a Na^- anion loosely bound to a neutral $[\text{Na}_j\text{Cl}_j]$ cluster. The spectral behavior of other clusters within this same series, however, suggests they have the two excess electrons in a triplet coupled state, forming the analog of a bipolaron in a solid [10].

41.5 Semiconductor Clusters

Semiconductor clusters make up a class of clusters where, by analogy with bulk semiconductors, covalent forces are expected to dominate electronic and geometric structure. Silicon clusters are by far the most studied of the semiconductor clusters. Some information is available on germanium clusters and compound clusters made of Groups III and V atoms or Groups II and IV atoms. Also, there are the well known stable molecules of bulk semiconductors such as the P_4 tetrahedron and various sulfur rings; these have been reviewed in detail elsewhere [3]. Clusters of other possible semiconductors have been made, but little data beyond their nascent distributions are available [3]. There is also a growing body of data on silicon, III–V, and, especially II–VI semiconductor clusters in the nanometer size regime where bulk samples of stabilized forms of these clusters have been made and isolated. The crystalline and electronic structure properties, particularly quantum confinement effects, are reviewed in [10, 11, 59–61].

41.5.1 Silicon and Germanium Clusters

The geometries of small silicon clusters depart radically from microcrystalline fragments of the bulk silicon diamond lattice. The structures of silicon clusters containing up to about 13 atoms have been studied extensively both experimentally and theoretically [62]. These structures are more compact

and, starting at Si_7 which has a pentagonal bipyramidal structure, have higher coordination than silicon in the bulk lattice. Multiple isomers of similar energy also appear starting at about Si_{10} . For example, the tetracapped trigonal prism and the symmetric tetracapped octahedron structures of Si_{10} are nearly isoenergetic; microcrystalline fragments such as the adamantane form of Si_{10} are much higher in energy. The geometric structures of larger silicon clusters are less well known. The gross shapes of clusters containing up to about 60 silicon atoms have been found experimentally to undergo a transition between Si_{20} and Si_{30} from increasingly elongated structures to more spherical structures [26]. In the transition region, both prolate and oblate isomers are observed for a single cluster size. Multiple isomers over a wide range of silicon cluster sizes have been repeatedly observed in various experiments; it appears that somewhat different sets of isomers can be produced depending on the cluster formation conditions [26]. Elucidating the ground state structures of these larger clusters theoretically is, in general, an intractable problem and requires simplifying approaches. Use of semiempirical quantum mechanical techniques or silicon interaction potentials derived from bulk silicon, however, has led to unsatisfactory results, which suggests that the silicon atoms in silicon clusters are strongly reconstructed away from the usual sp^3 silicon atom environment [63, 64]. Some consensus has recently emerged that larger silicon clusters consist of internal silicon atoms strongly interconnected to a surrounding cage that has been described as a buckled fullerene [63, 65, 66]. Such a silicon cage must not be construed as a true fullerene, however, since silicon does not form the strong double bonds which stabilize the interconnected carbon rings of the fullerenes. Within this scenario, the shape change is believed to occur at the point where the cage begins to contain one or more internal atoms which provide the additional bonding needed to stabilize a spherical geometry.

I_p 's and A_e 's, cohesive energies, and photoabsorption spectra have been measured for silicon clusters containing up to several hundred atoms. Silicon cluster I_p 's start near the Si atom I_p , fall abruptly between 20 and 22 silicon atoms where the shape change has been observed, and then slowly converge towards the bulk work function. This convergence is apparently quite gradual since little change is seen between Si_{100} and Si_{200} [67]. A_e 's are only known for silicon clusters up to ≈ 15 atoms and reflect the large structural changes which occur in this small size regime [3]. Indication of a structural shape change is not observed in either the trends in the cohesive energies or the electronic spectra for silicon clusters. The cohesive energies increase smoothly with increasing size and exceed the cohesive energy of bulk silicon by 10–20% [68]. Silicon clusters exhibit strong sharp absorption spectra in the near UV. A common set of absorption features appears at $\approx \text{Si}_{15}$ and persists up to at least Si_{70} [69]. This suggests that the strong absorptions arise from

localized Si–Si bond excitations, and that these obscure the delocalized excitations which are more sensitive to silicon cluster structure. The most unusual aspect of these spectra is that the common signature for these minute clusters which are strongly reconstructed from the bulk is, nonetheless, strikingly similar to the spectrum of bulk diamond-lattice crystalline silicon.

Silicon cluster ions are observed to react with a variety of reagents [3, 26, 68]. For example, silicon clusters chemisorb small organic molecules such as ethylene, and inorganic molecules such as O_2 , NH_3 , and XeF_2 . Some of these reactions are sufficiently exothermic that they cause cluster fragmentation, or loss of small neutral fragments. The chemistry of silicon clusters often bears a close relationship to that known for bulk silicon surfaces; however, the clusters are often much less reactive by as much as several orders of magnitude. Silicon cluster reactions reveal the presence of numerous isomers which differ in their reaction rate for a given reagent. Isomerization has been induced by adding sufficient thermal energy to some clusters; the resulting more stable cluster form may or may not be more reactive than the higher energy isomer. This is particularly well illustrated in reactions of oblate versus prolate isomers where the more reactive isomer varies depending on cluster size [26]. In general, differential chemistry is not a useful predictor of cluster geometry *per se*, and appears to correlate more readily with other factors such as the number and type of dangling bonds available for reaction.

Much less is known about germanium clusters. The most stable structures that have been calculated for germanium clusters are quite similar to those for silicon clusters, although the overall binding energies are lower for germanium clusters [3, 7]. Available data such as A_e 's and photoelectron spectra for germanium clusters also underscore their similarities to silicon clusters in general [3]. The chemistry of germanium clusters has not been reported.

41.5.2 Group III–V and Group II–VI Semiconductor Clusters

Geometric structures have been calculated for some of the smaller III–V and II–VI clusters, particularly aluminum phosphide, gallium arsenide, and magnesium sulfide clusters [3, 11, 70–72]. As for silicon clusters, these clusters differ significantly from microcrystalline fragments snipped from their corresponding bulk crystalline forms. Electronegativity differences between the two constituent atoms play a major role in determining and stabilizing these structures. This is manifested in several ways. The bonding arrangements in the most stable structures have, in general, alternating electropositive and electronegative atoms. In those clusters such as III–V clusters where electronegativity dif-

ferences are smaller, covalent interactions predominate ionic interactions and the energetics of the various geometric structures are similar to those of the covalent silicon clusters. In II–VI clusters, electronegativity differences are much larger, and these clusters have structures more comparable to those seen in ionic clusters where ionic interactions are maximized.

Some data are available on the electronic structures of III–V clusters. A strong even–odd alternation occurs in both the I_p 's and A_e 's of gallium arsenide clusters where those clusters having a total even number of atoms have higher I_p 's and lower A_e 's than neighboring odd-numbered clusters [3, 73]. This has been explained by electronic structure calculations which find that, in general, the odd clusters are triplets while the even clusters of gallium arsenide are singlets [70–72]. Electronic absorption spectra have also been recorded for indium phosphide clusters which exhibit strong differences with cluster size and stoichiometry [74]. These spectra are also consistent with odd-numbered In_xP_y clusters having open-shell configurations, and even-numbered In_xP_y clusters having closed-shell singlet ground states, even for clusters which are considerably off-stoichiometry. A strikingly similar strong continuum-like absorption appears in the blue end of spectra for the even-numbered In_xP_y clusters. The onset of these absorptions lies close to the bulk indium phosphide band gap. The overall spectral behavior, however, is quantitatively similar to the absorptions seen in semiconductor glasses.

Little is known about the chemical properties of these clusters, with gallium arsenide clusters being the only ones studied. Hydrogen chloride is observed ubiquitously to etch $[\text{Ga}_x\text{As}_y]^-$; however, multiple isomers are seen with differing degrees of reactivity [3]. Chemisorption of ammonia on $[\text{Ga}_x\text{As}_y]^+$ has also been seen with the highest rates of reactivity occurring for the stoichiometric ($x = y$) clusters [75].

41.6 Noble Gas Clusters

Clusters have been made of all of the stable noble gases including helium. As a general class, these clusters are the most weakly bound of all clusters, and are held together only by van der Waals forces. These interactions are well understood theoretically, and thus noble gas clusters are excellent model systems for studying a variety of structural and electronic effects at finite sizes. Helium clusters behave much as quantum liquids, and are treated separately in the discussion below.

41.6.1 Geometric Structures

The overall evolution of noble gas cluster structures as a function of size is well established [4, 6, 11, 76, 77]. Icosahedral packing dominates at small cluster sizes. This packing involves polyicosahedral structures for the small cluster

sizes, and different noble gas clusters exhibit somewhat different preferred arrangements. Starting at 100 to 250 atoms (depending on which noble gas), formation of closed-shell Mackay icosahedra dominates the structures [78]. Finally, at somewhere in the range 600 to 6000 atoms, the structures cross over to the close-packed fcc arrangement of the noble gas solids.

The increased coordination characteristic of the Mackay icosahedra explains why this morphology is adopted at small cluster sizes. With the addition of each successive icosahedral shell however, this five-fold symmetric packing becomes increasingly strained as a result of both atom–atom radial compression and tangential dilation. At some size, icosahedral structures are no longer more stable than fcc structures, and the noble gas clusters undergo a phase change. Currently, the critical size required for fcc packing is a matter of some dispute. Experimental evidence for this transformation at ≈ 600 atoms comes from electron diffraction data [76]. The spectral signatures of molecules doped in noble gas clusters suggest however, that this transition occurs at ≈ 2000 atoms [77]. Theoretical studies find a range of critical sizes, depending on the treatment used, but typically favor an even larger size regime [4, 11, 13, 77].

Knowledge of accurate pair-wise interaction potentials for noble gases has enabled extensive simulations of the physical properties of noble gas clusters [4, 6, 7, 79–81]. Phenomena such as specific heat, bond length and coordination number fluctuations, phase equilibria, dynamical freezing and melting, isomerization, and solvation have been explored using various molecular dynamics simulations. Numerous effects peculiar to the finite sizes and proliferation of isomers in small noble gas clusters are observed. For example, the melting temperature decreases significantly with an overall decrease in cluster size. Internal diffusion rates depend strongly on cluster size and the stability of certain favored structures such as the complete Mackay icosahedra. A well-studied finite size effect is the dependence of the mean energy per particle in a cluster versus the particle temperature (the so-called *caloric curve*) in the region where the particle is observed to *melt*. Unlike in the bulk, calculations find hysteresis in the melting transition of small noble gas clusters where solid-like and liquid-like forms are observed to coexist. Such coexistence is quite size-dependent. It becomes more pronounced when the clusters are rapidly heated or cooled, and appears to be a finite time averaging effect [4, 6, 7].

41.6.2 Electronic Properties

The fragility of noble gas clusters has hampered measurements of their I_p 's and A_e 's. Extensive fragmentation is known to accompany ionization, making it difficult to establish the size of the ionized parent cluster. Nonetheless,

I_p 's have been measured for cluster sizes containing up to several tens of atoms [82]. Measured I_p 's agree with theoretical predictions which are based on the assumption that the ionizing state within the cluster is a dimer, trimer, or higher n -mer cationic core [6, 82]. Absorption profiles of noble gas cations provide supporting evidence for the delocalization of the positive charge over a n -mer unit within the cluster, although consensus has yet to be reached on the size of this cationic cluster within the cluster [6, 11].

Several distinct types of electronic excitations are observed in absorption spectra of neutral noble gas clusters [6, 7, 11, 83]. Clusters containing less than ≈ 30 atoms exhibit broad absorptions near the atomic resonance lines. These absorptions are molecular-like, but have not been described in detail above the dimer. In addition, broad continuum absorptions assigned to Rydberg excitations are observed at these small sizes. Bulk-like excitations corresponding to surface and bulk excitons in solid noble gases emerge for clusters larger than ≈ 50 atoms. The profiles of these excitonic absorptions indicate that they arise from delocalized excitations analogous to Wannier excitons in bulk solids. These cluster exciton absorptions are blue-shifted relative to the bulk as a result of quantum confinement of the exciton within the small cluster. Another type of excitonic excitation has also been reported which appears to be a localized excitonic state whose character is sensitive to the cluster structure. Relaxation of cluster excited states is accompanied by extensive fragmentation [7]. Details of the relaxation processes differ according to noble gas, cluster size and cluster structure. Again, these differences can be traced to finite size effects in these noble gas clusters [4].

41.6.3 Doped Noble Gas Clusters

Various chromophores have been added to noble gas clusters as a microscopic variation of matrix isolation [3, 4, 7, 10, 11, 77, 84]. A wide range of chromophores have been studied including other noble gas atoms, metal atoms, small polyatomic molecules such as SF₆, CH₃F, and HCl, and a variety of organic molecules such as benzene, carbazole, and naphthalene. Comparisons of the electronic and vibrational spectra of these guest molecules with their spectra in noble gas liquids or solid matrices have revealed information such as noble gas cluster structure, solvation effects, and solute diffusion.

A crucial issue in understanding the spectral signatures of doped noble gas clusters is the location of the solute in or on the noble gas cluster. Chromophores well-embedded in a noble gas cluster behave as molecules surrounded by a dielectric medium, which is most correctly viewed as both imperfect and finite sized [4, 7, 84, 85]. The evolution of the spectral changes with cluster size reflect the interplay of re-

pulsive forces and collective dielectric effects as the cluster builds the solvent shell around the solute core. Both theoretical and experimental data illustrate this evolution and show how, once the first few solvent shells are established, the spectrum converges asymptotically to the matrix isolation value. For smaller clusters, the effects of too few or incomplete solvation shells appear as shifts and/or broadening of the spectral lines relative to the bulk [3, 4]. Differential solvation of the ground and excited states causes spectral shifts which are typically to lower energy since the excited state is usually more stabilized than is the ground state. Spectral broadening results from multiple isomers. Broadened electronic spectra have also been explained as a signature of cluster melting, although this interpretation has been questioned [3, 4, 84, 85]. Some infrared spectra of solute molecules have also yielded information on the nature of the solute binding site, revealing that the solvating noble gas cluster undergoes an icosahedral to fcc phase transition in a critical size regime [77].

Not all dopant species are found well-solvated, or *wetted* in the cluster interior. Both electronic and infrared dopant spectra indicate the existence of chromophores bound to the cluster surface. In some cases, the chromophore is ubiquitously *nonwetting*, such as for SF₆-Xe_{*n*} and SiF₄-Ar_{*n*}, and resides exclusively on the cluster surface [77]. In other systems, e.g., carbazole-Ar_{*n*} and CF₃Cl-Ar_{*n*}, both wetting and nonwetting are observed [7, 77, 84]. Systems such as these have enabled measurements of solute diffusion rates into or out of the cluster. Finally, wetting-nonwetting transitions have been observed which depend on cluster size and/or cluster temperature [7, 84]. Understanding this wide variety of behavior requires modeling cluster solute-solvent structures (in both ground and excited states in order to interpret electronic spectra) as a function of size and temperature. To date, most of the theoretical simulations have focussed on smaller clusters at a given temperature [4, 7, 77, 84, 85]. Nonetheless, theoretical models have provided qualitative and quantitative explanations for some of the observed spectral shifts, and have shown that the propensity for wetting/nonwetting can be related to the degree to which maximum possible coordination within the solvent is attainable.

41.6.4 Helium Clusters

Quantum effects play a dominant role in helium clusters since they consist of very weakly interacting small mass particles. Statistical effects are also expected since ³He is a fermion and ⁴He is a boson. Overall, helium clusters are believed to be in fluid-like or superfluid-like states with highly fluctuating structures [86].

Neutral helium clusters have been made experimentally in sizes ranging from the dimer up to 10⁶ atoms [4, 11, 77]. The

diatomic He_2 , has just been detected recently and is found to have a binding energy of only $\approx 10^{-7}$ eV with an average internuclear distance of $\approx 55 \text{ \AA}$ [87, 88]. Evidence for magic numbers in the helium cluster abundances is seen; however, the sizes of these especially stable clusters differ substantially from what is seen in the other noble gas clusters [4]. Helium cluster structures have been theoretically investigated using fully quantum mechanical treatments [4, 86]. These studies find that $^4\text{He}_n$ clusters should be bound at all sizes, but that a minimum number of atoms, ≈ 30 , are required for $^3\text{He}_n$ clusters to be stable. The latter prediction has not yet been verified experimentally, owing to the expense of ^3He , and the difficulties of ascertaining the true size of helium clusters since they easily boil off atoms upon ionization. Calculations reveal that the packing of helium clusters is highly delocalized with no evidence of icosahedral morphology. The structures derived have been found to be extremely sensitive to temperature and total angular momentum. Cluster binding energies and densities increase smoothly and monotonically with increasing size, approaching bulk behavior at about 300 atoms. Thus, helium clusters do not exhibit any especially stable sizes (magic numbers) such as the heavier noble gases do. In short, helium clusters behave as liquid-like quantum fluids, and may even be superfluid-like at the temperatures required to stabilize them in beam experiments. Based on these calculations, it appears that the magic numbers observed experimentally in abundance spectra pertain to the more strongly bound ionized helium clusters, rather than the neutral clusters which are the subject of this discussion.

Electronic absorption spectra have recently been recorded for clusters containing $\approx 50\text{--}10^6$ helium atoms [89]. Broad strong absorption bands are observed which do not behave like the Wannier exciton bands seen for the heavier noble gas clusters, nor are they well-described by the Frenkel excitonic model. Note that although the Wannier and Frenkel exciton models were originally developed for solids with translational symmetry, they are also good descriptions for excitations in liquid noble gases [4]. At this writing, the helium cluster electronic spectra cannot be compared with absorption spectra of liquid or solid helium because these latter spectra have not yet been measured! With this limitation and a current lack of sufficient theoretical guidance, the helium cluster spectra have not yet been thoroughly interpreted. Theoretical calculations are available which describe the collective excitations in helium clusters on the electronic ground state surface [86]. Spectra in this energy regime have not yet been recorded.

Experimentally, it has been quite easy to dope helium clusters with various atomic and molecular species such as other noble gas atoms, oxygen, and SF_6 [4, 11, 77]. Electrons, however, are not well-solvated and negatively charged helium clusters only appear for sizes containing more than $10^5\text{--}10^6$ atoms [11]. Impurity species provide a spectro-

scopic probe for studying the properties of the solvating helium cluster. Infrared spectra of helium clusters doped with SF_6 show that the impurity molecule resides on the cluster surface, in contradiction of theoretical calculations which predict that it should be found inside a helium cluster. Understanding this discrepancy has stimulated further theoretical investigations that reveal the dramatic structural effects which can occur when angular momentum is added to these very fragile clusters during dopant pick-up [90].

41.7 Molecular Clusters

Molecular clusters are in many ways similar to noble gas clusters. Both are weakly bound, and the interactions between the particles which make up the cluster can usually be described to a good approximation as the sum of pairwise interactions. The molecule constituency adds complexity, however, which is reflected in the diversity seen amongst these clusters. Molecular clusters provide model systems for studying solvation, including electron solvation, nucleation, and phase transitions at finite sizes. Furthermore, properties which are often difficult to study in the bulk, such as phase transition dynamics, are much more amenable to study in molecular clusters.

Numerous molecular clusters have been made and studied. By far the most work has focussed on the smaller molecular clusters such as molecular dimers, trimers and tetramers. A number of outstanding reviews are available on this subset of molecular clusters [3, 4, 6, 76, 91, 92].

41.7.1 Geometric Structures and Phase Dynamics

In contrast to noble gas clusters, molecular clusters typically assume bulk phase structures at relatively small sizes. Thus, the range of condensed phases of molecular solids is reflected in the variety of packing structures found in molecular clusters. At one extreme are clusters of small nearly-spherical molecules such as CH_4 and N_2 which form clusters closely connected to noble gas clusters [76]. Small clusters of these molecules are packed in polyicosahedral arrangements at small sizes, and cross over to fcc structures at sizes containing several thousand atoms. At another extreme are clusters such as water clusters where stronger hydrogen bonding forces lead to the formation of crystalline networks such as in a diamond cubic phase [76]. Some molecular clusters appear to be liquid-like with thermal motion wiping out any persistent periodic order. The liquid-like structure observed in clusters of molecules such as benzene and various hydrocarbons may freeze into a crystalline or amorphous state at sufficiently low temperatures.

Some molecular clusters have been found to exhibit a panoply of phases, depending on size and temperature. For example, not only do clusters of TeF_6 assemble into the bulk body-centered cubic and orthorhombic phases, they can also be made in other phases including two trigonal forms, a rhombohedral phase, and two monoclinic phases [93, 94]. Similarly complex phase formation has been found in other clusters of other hexafluoride molecules such as SF_6 , SeF_6 , MoF_6 , and WF_6 .

Phase transitions in molecular clusters have been examined both experimentally and theoretically using molecular dynamics. Transition temperatures are found to depend on cluster size, and span a much broader range than in the corresponding bulk phase transitions. Large rates for nucleation and phase changes are seen in molecular clusters. Once the critical nucleus, which initiates the phase change, forms in the interior of the cluster, the remainder of the cluster transforms to the new phase extremely rapidly. Critical nucleus sizes depend on the cluster size and are typically quite small, e.g., for TeF_6 clusters, they contain only a few dozen molecules for clusters consisting of a few hundred molecules [10, 93, 94]. A key finding is that phase transitions in molecular clusters appear to violate *Ostwald's step rule*, which states that equilibrium systems must pass through all intermediate-energy stable phases during a transition from a higher energy to a lower energy phase [10]. This non-compliance apparently occurs because of the speed at which molecular clusters undergo phase transitions: intermediate phases simply do not have time to form.

41.7.2 Electronic Properties: Charge Solvation

I_p 's, A_e 's, and some spectral data are available for larger molecular clusters. Nearly all of the spectra measured pertain to clusters containing less than ten molecules [3, 4, 6, 76, 91, 92]. Precise molecular orientations within many of these clusters have been derived from detailed analyses of these spectra. Such information has not yet emerged from the few spectra that have been measured for larger molecular clusters [3, 6]. Alternatively, measurements of electronic properties of larger clusters have generally targeted a different issue: solvation of excess positive or negative charge in a restricted bulk-like system.

Charged molecular clusters provide model systems for studying the mechanism of charge stabilization within the confines of a finite system. Excess positive charge appears to be highly localized in molecular clusters, residing on a small unit containing at most a few monomers. This positive core is surrounded and stabilized by overlying shells of molecules. For example, $(\text{CO}_2)_n^+$ clusters behave as the dimer cation $(\text{CO}_2)_2^+$, surrounded by the remaining CO_2 molecules [4]. Positively charged solutes such as alkali cations have also

been introduced to study solvation of positive charge within molecular clusters [10]. For those dopants which have much lower ionization potentials than the solvating molecules, the positive charge remains strongly localized on the impurity. The cluster molecules are observed to build up solvation shells around this central impurity. The first few solvation shells are strongly affected by the positive charge, which has a decreasing influence with each successive layer. The structure of such a cluster reflects the accommodation between the geometry of the molecules influenced by the central positive charge, and those in the outer solvation layers where intermolecular forces predominate [10, 95]. Evidence for intracluster reactions in positively charged clusters has also been seen, such as proton transfer in cationic water or ammonia clusters [3, 11].

Whereas virtually every molecular cluster containing as little as two molecules exists stably as a positive ion, the same cannot be said for the negative cluster ions. Measurements of the minimum number of molecules required within the cluster to support an additional electron show that, while the dimeric $(\text{HCl})_2^-$, $(\text{SO}_2)_2^-$, and $(\text{H}_2\text{O})_2^-$ clusters are stable, ≈ 35 or ≈ 41 molecule-clusters of ND_3 or NH_3 , respectively, are required to stabilize an electron [4]. Spectroscopic studies show evidence for internal and external solvation of the excess electron in these anionic clusters.

Charge solvation in water clusters has been examined in some detail. Of particular interest is the $(\text{H}_2\text{O})_{20}$ cluster which, from experimental and theoretical data, appears to form an especially stable, well-defined clathrate cage. The interior of this cage is large enough that it can and does hold various cations such as NH_4^+ , H_3O^+ , and alkali ions [10]. This cage is not observed to surround negative ions or electrons, which instead, reside on the surface [10]. This is a general result for excess negative charge in water clusters in this size regime where excess charge can be external to the cluster. Excess electrons in water clusters are found on the cluster surface for small cluster sizes up to 60 to 70 water molecules. Above this size, the electron resides in the cluster interior, and behaves analogously to hydrated electrons in bulk water [4, 7].

41.8 Recent Developments

Added by Mark M. Cassar. Experimental and theoretical work on clusters has continued to be an active and rapidly growing area of research over the past decade. This section provides a non-exhaustive snapshot of some recent work in the vast field of cluster science.

The original focus on the scalable properties of clusters (concerning a smooth transition from small particles to bulk matter) has now extended to include important non-scalable properties. These properties, particularly at the nanoscale

level, have enormous potential for technological application [96–98]. Studies aimed at understanding the underlying atomic structure of noble-metal clusters and nanoparticles, which is the first step toward their controlled use in future nanotechnologies, e.g., catalysis, labeling, or photonics, have been carried out [99]. Ab initio all-electron molecular-orbital calculations for small ($n = 7–11$) and medium ($n = 12–20$) silicon clusters Si_n have been performed in order to study their structure and relative stability [100, 101]; such calculations are important in determining the scalability of present day semiconductor technology.

Other interesting work has been done on the electron transfer properties of metal clusters that could act as conducting bridges between molecular wires [102]; and in the role that tetramanganese clusters play in one of the active photosynthesis sites (photosystem II) in green plants, and in certain bacteria and algae [103].

The reader is referred to various reviews that can be found in the literature: for time-resolved photoelectron spectroscopy (TRPES) of clusters, which allows the dynamics along the entire reaction coordinate to be followed, see [104]; for ultrafast dynamics in cluster systems and atomic clusters, see [105, 106]; for small carbon clusters, important in the chemistry of carbon stars, comets, interstellar molecular clouds, and hydrocarbon flames, see [107]; for the relation between electronic structure, atomic structure and magnetism of clusters of transition elements, see [97].

Abstract

Coblentz determined the relation between infrared spectra and molecular identity. Infrared spectroscopy became a tool for chemical analysis widely used in analytical chemistry laboratories. Prism or grating “dispersive” spectrometers fulfill this function well. Molecular spectroscopy was first practiced in the visible and UV range using large high-resolution spectrographs to record the fine spectral lines of vapor phase molecules. Extension to the infrared region was impeded by the lack of sensitivity of single-element infrared detectors and the challenge of making ever larger spectrometers to achieve high resolution. Dispersive spectrometers were superseded by “interferometric” spectrometers that possessed a much larger optical throughput and, when combined with the Fourier technique, permitted multiplexing the entire spectrum efficiently on a single detector enabling extending high-resolution molecular spectroscopy to the infrared region. As Fourier transform spectroscopy technology matured, measurement accuracy and reproducibility were also enabled. Quantitative infrared spectroscopy has opened a wide range of new applications in industry, environmental monitoring, and monitoring of atmospheric variations in relation to weather forecasting. Space probes use Fourier transform spectrometers to determine the chemical nature of planetary atmospheres and surfaces and even the measurement of the cosmic background radiation remnant. Low-cost Fourier transform spectrometers have also replaced dispersive spectrometers in analytical chemistry laboratories. Given its importance in a wide range of applications, a detailed description of the technique is provided.

42.1 Introduction

Infrared spectroscopy consists of the measurement of interactions of waves of the infrared (IR) part of the electromagnetic spectrum with matter. The IR spectrum starts just beyond the red part of the visible spectrum at a wavelength of approximately $\lambda = 700$ nm extending to 2500 nm and is usually called near-IR, from $\lambda = 2500$ to 25,000 nm or $\lambda = 2.5$ to 25 μm called mid-IR, and from $\lambda = 25$ to 1000 μm called far-IR. For the mid-IR ($\sigma = 4000$ to 400 cm^{-1}) and far-IR regions ($\sigma = 400$ to 10 cm^{-1}), it is common practice to use frequency σ expressed in number of wavelengths per cm (wavenumbers, cm^{-1}) instead of wavelengths.

The interactions observed in the mid-IR region principally involve energies associated with molecular structure change. Harmonic overtones, as well as combinations of mid-IR frequencies, are expressed in the near-IR region and can also be associated with the same molecular structure change as can be observed in the mid-IR but appear less obvious. Interactions observed in the far-IR involve molecular structure change having low energy. These are predominantly changes in molecular rotation energy.

The most common IR analysis of a sample is by IR absorption spectroscopy. Samples may consist of solid or liquid samples, called condensed phase samples and gas phase samples. IR absorption spectroscopy involves transmitting a beam of intense IR radiation through the sample and observing the distribution of wavenumbers absorbed by molecules when compared to a spectrum measured without the sample. Condensed phase samples generally absorb strongly in the mid-IR region, requiring a path length through the sample of only a fraction of a mm. In the near-IR, these samples absorb at least an order of magnitude less, permitting path lengths through a sample of up to a cm. Gas phase samples absorb much less due to their lower density compared with condensed phase samples and may require a path length of several meters in the mid-IR. Molecules in a sample may also be studied by IR emission spectroscopy simply by observing specific wavenumbers being emitted by virtue of their nonzero absolute temperature. Finally, radiation reflected from a smooth surface of a solid sample also provides information about the molecular structure of the material by virtue of the anomalous dispersion associated with absorption bands.

Historically, infrared spectroscopy started out as a *qualitative* method for identifying different molecular species present in a sample, as is also done by various titration methods used by chemists. Today, infrared spectroscopy has been extended to include accurate quantitative determination of molecular concentrations. This has enabled applications such as quality assurance and process control in chemical manufacturing and applications where multiple different spectrometers are required to provide quantitatively reproducible measurements. The evolution from qualitative to

increasingly accurate quantitative infrared analysis will be described. Molecular spectroscopy research covers spectral analysis at high spectral resolution covering the UV to the far-infrared. Infrared spectroscopy plays a key role in remote sensing. Satellite-based thermal infrared emission and near-infrared reflected solar spectroscopy is an essential part of weather forecasting, pollution monitoring, and climate change research related to Earth's atmosphere. Infrared remote sensing is also used extensively in conjunction with interplanetary space probes, as well as astronomy.

42.2 Historical Evolution of Infrared Spectroscopy Practice

After the discovery of infrared radiation by *Herschel* in 1800 [1, 2], it was not until the late nineteenth century that *William Coblentz* [3] obtained infrared spectra of many substances using both glass and salt prisms, reaching as far as $\lambda = 15$ μm in the mid-infrared. By studying the correlations amongst spectra of different substances Coblentz derived a number of important properties of infrared spectra, such as conservation of the unique spectral band positions and shapes of a given substance in mixtures of a sample. The unique correlation between the infrared spectral signatures and the molecular species being measured even in complex mixtures permitted Coblentz to establish infrared spectroscopy as a tool for identifying molecular structure for a variety of chemical species. These observations led to the concept of functional groups in infrared spectroscopy that permits us to elucidate a wide range of molecular structures from infrared and Raman spectra [4]. A great diversity of unique spectral signatures is found in the region from 400 to 2000 cm^{-1} and is commonly known as the "fingerprint" region.

It was not until the 1940s that infrared spectroscopy became a widely used tool for chemical analysis. This was driven by the need for chemical analysis in support of the development and manufacture of synthetic chemical products such as rubber and aviation fuels. Several thousand spectrometers were produced for this purpose. More widespread use of infrared spectrometers was enabled by the introduction of the Perkin Elmer model 137 "Infracord" [5] in 1956, a double-beam spectrometer that traced the sample *transmittance* directly on paper in real time. This quickly became a popular analytical tool for the chemistry laboratory displacing tedious titration methods for general chemical identification.

Prisms made from various infrared transparent materials and diffraction gratings angularly disperse incident radiation as a function of the wavelength. Intensities at these wavelengths can be measured sequentially by scanning the dispersed radiation past a narrow slit. Gratings mostly re-

placed prisms for infrared spectroscopy starting in the 1950s, following improvements in the uniformity of groove spacing, as well as the technique of replicating gratings from masters, thereby greatly reducing cost. Today, the use of spectrometers consisting of a grating and a linear detector array covering the full dispersed spectrum simultaneously is common for the UV and visible regions, as well as the near-infrared down to about 1700 nm (5880 cm^{-1}). These are simple, easy to use spectrometers for which economical and performant detector arrays are available. Extension to the mid and far-IR of this combination has been impeded by the cost and complexity of linear detector arrays for these regions, which require operation at low temperature to achieve optimal sensitivity. With two-dimensional imaging detector arrays, a line with many fields of view along the length of a slit can be measured simultaneously, where the spectra are dispersed along the columns of the 2-D array perpendicular to the rows of fields of view. Scanning the slit across an extended field of view and repeatedly recording two-dimensional data arrays builds up a hyperspectral image.

Gratings have several significant advantages over prisms. Groove spacing provides flexibility in resolution and spectral region selection, gratings with blazed grooves improve optical efficiency for selected spectral regions, and concave gratings minimize the need for additional focusing optics. A limitation of gratings is that multiple different wavelengths are diffracted at the same angle, presenting multiple orders to a detector. Therefore, gratings require order selection filtering to avoid superposition of orders of different spectral regions.

Starting in the 1950s infrared spectroscopy was being developed for use beyond the chemistry laboratory in three distinct areas. One area was the development of quantitative methods of chemical analysis, another was the development of high-resolution IR molecular spectroscopy, and, finally, a variety of remote-sensing applications.

42.3 Quantitative Analysis by Infrared Spectroscopy

Least squares comparison of a measured infrared spectrum with a reconstruction of spectral signatures for each of the components in a sample is impractical for condensed phase samples. Spectral features of a condensed phase sample compared with the spectral features of the same sample in the vapor phase shows a strong broadening due to intermolecular interactions of close neighbor molecules. Vapor phase spectral features typically have a width $< 0.1\text{ cm}^{-1}$ at atmospheric pressure, whereas in the condensed phase, these features often have widths of $> 4\text{ cm}^{-1}$. In a mixture of different molecules, these intermolecular interactions vary somewhat from the homogeneous case, thus slightly distort-

ing band shapes in a mixture with respect to pure component band shapes. Infrared spectroscopic determination of accurate molecular concentration for condensed phase samples, therefore, requires the acquisition of infrared spectra of prepared standard mixtures representative of the range of sample variations to be analyzed. These standards are used in a principal component analysis. Since the set of standard mixtures used for the principal component modeling may not permit exact reconstruction of the measured spectrum, a chemometric technique of "partial least squares" is employed [6, 7]. It permits controlling overrepresentation of a measured spectrum by the reconstructed spectrum. This technique was first employed in the determination of concentrations of protein and moisture in wheat via near-IR diffuse reflection to establish its commercial value [8].

It was soon realized that measurements of spectra employing different spectrometers presented significant errors. As a result, the prepared standards measured with different spectrometers expanded the number of standard spectra used as inputs for the principal component analysis. Improvement of grating spectrometers with respect to reproducibility such as to minimize the need for standard samples to be measured with multiple different spectrometers met with limited success. Small variations in slit geometry as well as scanning mechanisms prevented the achievement of adequate reproducible measurements. Improved reproducibility for spectrometers used at different sites was one of the driving forces for the development of Fourier transform spectroscopy.

42.4 Molecular Spectroscopy

Molecular spectroscopy dates back to the 1920s, following the elegant description of molecular dynamics via quantum mechanics. It is carried out mainly using samples in the vapor phase where intermolecular interaction is minimized such that spectra consist of narrow spectral features. Resolving many different spectral features and determining precise wavelengths of these features is key to determining the detailed energy states of a molecule and, thereby, its structure [9]. An early study was carried out using large high-resolution monochromators and photographic recording of spectra. Extension to the infrared was enabled by the availability of sensitive infrared detectors operating at low temperatures starting in the 1950s. To achieve high resolution, large gratings are required to minimize dispersion by diffraction and projection of a greatly expanded spectral dispersion at a narrow slit requiring long focal length optics. Scanning all the wavelengths of a highly dispersed spectrum is time consuming using a single infrared detector and is much less efficient than photographic recording of the full spectrum. This was another driving force behind the development of Fourier transform spectroscopy [10].

42.5 Remote Sensing

Measuring infrared spectra of remotely located targets is highly variable and is dependent on the temperature and emissivity of the targets. Spectrometers used for remote sensing require the best achievable sensitivity. Over time, Fourier transform spectrometers have become the spectrometers of choice for remote sensing not only for their favorable sensitivity but also for the flexibility of operating parameters, such as spectral resolution, spectral range, and measurement speed. Atmospheric remote sensing from satellites has become an essential tool for weather prediction by providing vertical distribution profiles of temperature and moisture, which are the most important thermodynamic drivers of weather. The technique is also used to determine the detailed composition of the atmosphere and its variations over time and geographic location.

42.6 The Evolution of Fourier Transform Infrared Spectroscopy (FTIR)

Infrared detectors represent an important aspect of infrared spectroscopy. Pyroelectric bolometric mid-infrared detectors operating at ambient temperature are widely used for chemistry laboratory infrared analysis. Using a pyroelectric detector with a scanning grating spectrometer, spectral measurements are time consuming, and the spectra are of modest quality. A Fourier transform spectrometer records an encoded signal for all wavelengths simultaneously on a single detector. The Fourier transform type spectrometer using a pyroelectric detector permits significant enhancement of measurement speed and quality.

A semiconductor made from a small bandgap material can, in principle, provide broadband detection like a bolometer; however, thermal noise currents increase rapidly at smaller bandgaps, requiring operation at ever lower temperature. A proliferation of different bandgap infrared detectors are available, permitting optimization of sensitivity and degrees of cooling for targeted spectral regions.

The demand for measurement speed, spectral resolution, reproducibility, and sensitivity are driven by a proliferation of applications of infrared spectroscopy. An alternative to the dispersive spectrometer was sought. In the 1960s, the Fourier transform spectrometer was seen as a strong candidate but required much technological development.

Fourier transform spectroscopy was pioneered early in the twentieth century by *Albert A. Michelson* [11] as an alternative use of the two-beam interferometer he had invented for the purpose of determining the inhomogeneity of the velocity of light. However, due to a lack of tools to measure and process data he relied on visual observation of “visibility curves” that permitted him to characterize some aspect

of spectra. *Lord Rayleigh* [12] pointed out to Michelson that the relation between the observed visibility curves of the interferometer and their spectra is the Fourier transformation. Observing all wavelengths simultaneously with a Michelson interferometer, like recording the complete spectrum with photographic film, was not realized until 1949 by the work of *P. Fellgett* [13, 14]. Fellgett computed the Fourier transform of a limited set of measurements laboriously by hand. As digital computers started their exponential growth in capacity and computation speed, year over year Fourier transform spectroscopy became increasingly accessible. In the 1960s, Fourier transform spectroscopy became usable but required access to a large computing center. Early implementations of the scanning Michelson interferometer were sensitive to perturbations and required a skilled operator to maintain the alignment of the scanning mirror. The high cost and complexity of operating an early version of an FTIR limited its use to research centers. Nevertheless, the great increase in sensitivity and measurement speed provided access to measurement problems not available with dispersive spectrometers. As an example, *Buijs* and *Gush* [15] described the high-resolution measurement of the electric field induced absorption spectrum of hydrogen with a homemade Fourier transform spectrometer. In 1965, the interferometer scanning mirror positions were determined using a Hg¹⁹⁸ lamp as monochromatic metrology source, since lasers were not yet available. Furthermore, the computation of the Fourier transform of the interferograms containing about 4000 numerical data points typically took up to 20 min on a large mainframe IBM 7094 computer. In the late 1960s, *Cooly* and *Tukey* [16, 17] presented a method of factoring the Fourier transform calculation making use of symmetries in the trigonometric matrix and, thereby, greatly reducing the number of calculations required; this is commonly called the fast Fourier transform or FFT. The same calculation as above on the same computer was realized in about 10 s. As well, in the late 1960s, lasers became available. The He-Ne laser permitted scan control of the moving mirror with much higher precision than the Hg¹⁹⁸ lamp and over much longer mirror displacements. It is seen that over a period of 20 years Fourier transform spectroscopy progress depended greatly on new technological developments.

By 1984 the introduction of the personal computer (PC) and advances in interferometer design permitted the realization of a low-cost versatile and easy to use Fourier transform spectrometer. The efficiency of measuring all wavelengths simultaneously called the multiplex advantage as described by *Fellgett* [13, 14] and the greater light throughput by elimination of the narrow slit as described by *Jacquinot* [18] allowed infrared spectra to be measured much more rapidly and with much greater signal-to-noise ratio. This development led to a rapid replacement of dispersive spectrometers in chemistry laboratories by FTIR, particularly for the mid-IR and the far-

IR. In the near-IR, the intensity of illumination sources, such as the tungsten lamp, and the availability of high sensitivity of InGaAs, PbS, and other room-temperature semiconductor detectors allowed both near-IR grating spectrometers and FT-NIR to flourish.

The availability of linear array detectors in the visible and UV that have intrinsic noise lower than photon statistics noise permit dispersive spectrometers to perform more favorably than FT spectrometers. Both techniques measure all spectral elements simultaneously; however, the array detector of a dispersive spectrometer localizes excess photon noise due to intense spectral features at certain elements of the detector array and avoids adding this noise to the lower photon noise of weaker spectral features at other elements of the detector array. The FT spectrometer, however, accumulates the photon noise of all spectral features on a single detector. This is particularly disadvantageous for FT spectrometers when measuring wide spectral intervals. UV and visible dispersive spectrometers with an array detector that has intrinsic noise lower than the source photon statistics noise can, therefore, measure weak spectral features with lower noise than strong features, effectively increasing the dynamic range of intensity measurement, which the FT spectrometer does not permit.

With the maturing of FTIR technology, a great diversity of infrared spectroscopy applications has been enabled. With FTIR, spectral resolution and spectral range can be varied freely. Current scanning Michelson interferometers are constructed to maintain the precise alignment required either using “cube corner” retroreflectors instead of flat mirrors or servo-controlled dynamic alignment applied to flat mirrors. This advanced control of interferometer alignment has opened the possibility to operate FTIRs in hostile environments of vibration and temperature with minimal effect on performance. It has also permitted scanning the mirror distances as large as several meters to offer spectral resolution that far exceeds that of dispersive spectrometers.

In the vapor phase at pressures well below atmospheric, spectral lines of specific energy transitions may be very narrow. Here the line width is limited by doppler shifts due to thermal motion of the molecules and is dependent on temperature and is linearly proportional to the molecular weight and frequency. As pressure is increased line width increases due to random collisions of molecules that are density dependent. At room temperature and low density in the mid-IR, spectral linewidths may be $< 0.002 \text{ cm}^{-1}$. FT spectrometers where the scanning mirror can be translated through several meters are also capable of resolution down to $< 0.002 \text{ cm}^{-1}$, which is far higher than any dispersive spectrometer, while still maintaining sufficient optical efficiency due to the Jacquinot advantage. These spectrometers are capable of covering the full infrared range and have enabled efficient extension of molecular spectroscopy to the infrared beyond photographic recording.

42.7 Laser-Based Infrared Spectroscopy

In the quest for the study of ever finer detail in infrared spectra, the use of tunable lasers has permitted still higher resolution and with significantly higher precision. Using cavity-enhanced absorption spectroscopy such as cavity ring-down or integrated cavity-enhanced spectroscopy, faint spectral lines can be observed with great clarity. Today, much research on molecular structure by infrared spectroscopy is performed using tunable laser spectroscopy. As well, cavity-enhanced absorption spectroscopy is used to measure ultralow concentrations of components in a gas mixture for the purpose of environmental monitoring and contamination assessments. Current tunable lasers have a limited spectral range capability requiring multiple lasers to cover a wide spectral range.

Given its versatility for infrared spectroscopy applications it is useful to describe the common practice and elements of infrared Fourier transform (FTIR) spectroscopy.

42.8 Intensities of Infrared Radiation

For strong interactions of electromagnetic waves with matter, the emitted and absorbed intensities are governed by Planck's radiation law in addition to the emissivity and absorptivity of the material. Planck's radiation law for thermal radiation from an ideal black body is

$$P_{bb}(\sigma T)d\sigma = \frac{C_1\sigma^3 d\sigma}{\exp\left(\frac{h\sigma}{K_b T}\right) + 1}, \quad (42.1)$$

where σ is the frequency in cm^{-1} , h is Planck's constant, K_b is the Boltzmann constant, T is the temperature of the black-body in K, and C_1 is a proportionality constant. Depending on the definition of C_1 , $P_{bb}(\sigma T)$ may represent a radiation density per unit spectral interval cm^{-1} in a cavity at temperature T in ergs/cm^3 , or an energy flux emitted from a surface in $\text{W}/(\text{cm}^2\text{-steradians})$. At frequencies that are low compared with $h/K_b T$, the energy distribution increases with σ^2 and is approximately proportional to T at a given σ . At high frequency, the energy distribution falls off exponentially. In the near-IR, a high temperature is required to emit radiation. Room-temperature objects emit the most strongly in the 500 to 1800 cm^{-1} region and emit negligible energy above 3000 cm^{-1} . Materials cooled to liquid nitrogen temperature (77 K) only emit below 100 cm^{-1} , while materials cooled to liquid He temperature (4.2 K) emit below 20 cm^{-1} . In contrast to visible spectroscopy, IR absorption spectroscopy is complicated by emission of IR radiation from the sample and the surrounding environment.

42.9 Sources for IR Spectroscopy

A silicon carbide element electrically heated to 1400 K provides a strong continuum of IR radiation over a major part of the IR spectrum. It is commonly used as a source of radiation for IR absorption spectroscopy. For near-IR spectroscopy, a tungsten filament lamp operated at 2800 K provides a strong continuum all the way up to the visible part of the spectrum; it is not useful below 3000 cm^{-1} because of absorption by the glass or quartz envelope. Various electrically heated ceramic elements, such as the Nernst glower and high-temperature carbon rods, have been devised to achieve higher intensity.

42.10 Relationship Between Source Spectrometer Sample and Detector

Since a sample at room temperature emits IR radiation in the mid-IR, it is important to distinguish between the transmitted radiation used in the determination of its absorption spectrum and its emission spectrum. By employing an intense IR beam, the effect of emission is minimized. A further distinction is achieved by encoding the IR beam before it impinges on the sample. With classical grating or prism spectrometers, the source radiation is chopped by means of a mechanical chopper before it passes through the sample. The IR detector is provided with a means of synchronously decoding the chopped signal, thereby eliminating the emitted spectrum. Often, the chopper is arranged such that it alternately switches between an empty reference beam and the sample. The logarithm of the ratio of the demodulated sample and reference spectra provides the absorption spectrum directly.

In Fourier transform infrared (FTIR) spectroscopy, a scanning Michelson interferometer provides the encoding function directly, and no chopper is required. The interferometer is commonly placed before the sample so that it does not encode the thermally emitted radiation of the sample.

If it is not convenient to place the sample after the scanning Michelson interferometer, the absorption spectrum of a sample placed in front of the interferometer can be deduced by subtracting the separately recorded emission spectrum from the combined transmission plus emission spectrum. Infrared emission and reflection spectroscopy form the basis for remote sensing. Solid and gaseous (cloud) objects may be identified and quantified by direct observation of their IR spectra at a distance. Gaseous clouds reflect poorly, providing only transmitted or emitted IR radiation. Their emission spectrum is contrasted directly with the spectrum of the scene or object beyond the cloud. With a background at lower temperature than the gas cloud, the gas spectrum appears in emission, while with a warmer background, the gas spectrum appears in absorption. Only a few solid materials transmit IR radiation

over a substantial thickness. Remote sensing of solid objects, therefore, relates to surface emission and (diffuse) reflection of IR radiation from the surrounding environment.

42.11 Simplified Principle of FTIR Spectroscopy

In FTIR spectroscopy, the spectrum of a beam of incident IR radiation is obtained by first generating and recording an interferogram with a scanning Michelson interferometer. Subsequently, the interferogram is inverted into the spectrum by means of a cosine Fourier transform.

42.11.1 Interferogram Generation: The Michelson Interferometer

The scanning Michelson interferometer shown in Fig. 42.1 consists of a beamsplitter, which is a substrate with a dielectric coating such that 50% of an incident beam is reflected, and the remaining 50% is transmitted, and two plane mirrors (M_1 and M_2), one or both of which are translated along the direction of the beam. After splitting, the two equal amplitude wavefronts are propagated along different optical paths. The mirrors at the end of each path return the wavefronts to the beamsplitter, which then acts as a wavefront combiner. Because of their common coherent origin, the wavefronts interfere with one another when they combine. The state of interference is varied by scanning one or both of the mirrors such that there is a variable time delay between the two separated beams. The resulting intensity variation of the combined output beam as a function of relative time delay is the interferogram.

Fig. 42.1 The Michelson interferometer

42.11.2 Description of Wavefront Interference with Time Delay

The intensity $I_0(\vartheta)$ at frequency ϑ of a plane wave in space is given by the expectation value of its electric field vector $E(\vartheta, t) = E(\vartheta)e^{-i2\pi\vartheta t}$

$$I_0(\vartheta) = \langle E(\vartheta, t) | E(\vartheta, t) \rangle = E(\vartheta)^2. \quad (42.2)$$

The intensity at the output of the interferometer due to an incident intensity $I_0(\vartheta)$ is given by $I(\vartheta, \delta)$, where δ is the time delay between the two wavefronts, which have propagated along different paths. Further,

$$\begin{aligned} I(\vartheta, \delta) &= \langle E(\vartheta, t) + E(\vartheta, t + \delta) | E(\vartheta, t) + E(\vartheta, t + \delta) \rangle \\ &= \frac{1}{2} I_0(\vartheta) [1 + \cos(2\pi\vartheta\delta)]. \end{aligned} \quad (42.3)$$

As can be seen, the output intensity of a single frequency source at the output of an ideal scanning Michelson interferometer fluctuates sinusoidally between zero and the input intensity $I_0(\nu)$ as the time delay δ between the separated wavefronts is varied by means of scanning one of the mirrors.

The quantity δ is related to mirror displacement x with respect to equal distance of the mirrors from the beamsplitter by

$$\delta = 2 \frac{x}{c} \cos \theta, \quad (42.4)$$

where θ is the angle between of the wavefront and the optical axis of the spectrometer, and the optical axis is the normal to each mirror M1 and M2. From this, Eq. (42.3) becomes

$$I(\nu, x(\theta)) = \frac{1}{2} I_0(\nu) \left\{ 1 + \cos \left[2\pi\nu \left(2 \frac{x}{c} \cos \theta \right) \right] \right\} \quad (42.5)$$

or, using $\sigma = \frac{\nu}{c}$,

$$I(\sigma, x(\theta)) = \frac{1}{2} I_0(\sigma) \{ 1 + \cos[2\pi\sigma(2x \cos \theta)] \}. \quad (42.6)$$

Thus, the output intensity fluctuates at spatial frequency σ by $2x \cos \theta$ as a function of the mirror displacement x . The incident intensity generally consists of a distribution of intensities over many frequencies $S(\nu)d\nu$ with integrated intensity

$$I_0 = \int S(\nu) d\nu. \quad (42.7)$$

The intensity fluctuations for all frequencies in the incident beam is given by

$$I_0(\delta) = 1/2 \int S(\nu) [1 + \cos(2\pi\nu\delta)] d\nu. \quad (42.8)$$

The second term on the right-hand side of Eq. (42.8) has the form of the cosine Fourier transform of the spectrum. By rearrangement of Eq. (42.8), it is given by

$$\frac{1}{2} \int [S(\nu) \cos 2\pi\nu\delta] d\nu = I_0(\delta) - \frac{1}{2} I_0. \quad (42.9)$$

The constant term I_0 provides no useful information about the spectrum. The inverse cosine Fourier transform of $2I_0(\delta)$ results in the spectrum $S(\nu)$ according to

$$S(\nu) = 2 \int I_0(\delta) \cos(2\pi\nu\delta) d\delta, \quad (42.10)$$

$$S(\sigma) = 2 \int I_0(\delta) \cos(2\pi\sigma\delta) d\delta. \quad (42.11)$$

Some early FTIR spectrometers were arranged with the same dual beam for direct determination of the transmittance of a sample as was done for dispersive spectrometers. It was quickly determined that the reproducibility of two spectra recorded sequentially using a single optical path was significantly more precise than the reproducibility for two separate optical beams. The manipulation of the numerical representations of the sequentially measured sample and reference spectra became negligible using a digital computer.

Contrary to classical spectrometers, where the spectrum is sequentially scanned, there is no segregation of frequencies of the input intensity. All frequencies in the source are modulated simultaneously by the scanning Michelson interferometer into a single interferogram signal. It contributes to a large advantage in sensitivity compared with dispersive spectrometers and is referred to as the Fellgett or multiplex advantage.

The reciprocal of the sampling interval Δx of optical path difference determines the extent of the numerically computed spectrum. A higher density of sampling permits a wider spectral range to be determined

$$\sigma_{\max} = \frac{1}{2\Delta x}. \quad (42.12)$$

Beyond σ_{\max} , the spectrum repeats in reverse order, and beyond $2\sigma_{\max}$, the spectrum repeats as is. This is called spectral aliasing and results from the incomplete knowledge of the full interferogram function between the discrete numeric representation.

To ensure that the numeric representation of the interferogram describes the continuous function uniquely, it is important to band limit the interferogram information to the range 0 to σ_{\max} by means of optical and electrical filtering.

Conversely, the higher the density of sampling in the spectral domain, the longer the interferogram needs to be. For a wavenumber interval $\Delta\sigma$, the interferogram length is

$$x_{\max} = \frac{1}{2\Delta\sigma}. \quad (42.13)$$

42.11.3 Operation of Spectrum Determination

The interferogram signal is detected by an IR detector that converts the intensity variations $I_0(x)$ as a function of different mirror positions x into an electrical signal. Continuous

determination of the inverse cosine Fourier transform of the evolving interferogram requires continuous multiplication of the signal by cosine functions with all the different frequencies of the spectrum and integrating these products. It is, however, far more practical to capture the interferogram signal in numerical form, using an analog to digital converter, store the digitized data in computer memory, and compute the Fourier transform numerically after the mirror displacement range has been covered.

A particularly convenient and accurate way to establish the sampling locations of the interferogram is the use of a single-frequency laser directed coaxially with the source radiation through the scanning Michelson interferometer. The intensity of the laser at the output of the interferometer is a pure cosine wave with one cycle per change in mirror movement of one half wavelength of the laser light, typically about 400 nm. It has long been the practice to digitize the interferogram signal at the precise mirror positions provided by the laser signal. However, as in digital audio recording, the currently highest fidelity of numerical representation of an analog signal is obtained with $\Delta\Sigma$ analog to digital (ADC) technology, which can represent a precisely linear signal dynamic range up to 2^{24} to 1. However, these ADCs can only operate at a constant measurement rate.

When applying a constant rate of digitizing to an interferogram signal the optical path different intervals measured depend on the velocity of scanning of the mirror of the interferometer. Since this is a mechanical displacement it is subject to velocity variations due to perturbations resulting from shocks and vibrations. The parallel monochromatic laser light passing through the interferometer (metrology signal) being a pure sinusoidal function of the optical path difference can provide path difference information at the same time that the infrared signal is digitized. By employing high-density “uniform time” sampling of an interferogram, intensities at a “uniform mirror displacement” can be accurately computed by interpolation based on the measured timing of the metrology signal information [19]. This approach has become a key feature in obtaining highly accurate and reproducible spectra, even in the presence of scan velocity perturbations. Errors in the spacing of measured interferogram data points along the path difference axis have the same effect as errors in the spacing of grooves of a diffraction grating; it leads to ghost features in the spectra. Residual sampling errors in modern FTIRs may be as low as subnanometers even in the presence of significant scan velocity variations.

By the above-described approach, the numerical representation of the interferogram is determined at uniform intervals of mirror displacement Δx . The computed spectrum is then determined at uniform intervals of spatial frequency $\Delta\sigma$ by the discrete cosine Fourier transform

$$S(j\Delta\sigma) = \sum_n 2I_0(n\Delta x) \cos(2\pi jn\Delta\sigma\Delta x). \quad (42.14)$$

Fig. 42.2 The *solid curve* is the ILS (interpolated), and the *dashed curve* is ILS (interpolated) for an apodized interferogram. The *vertical grid lines* are locations where the output of the Fourier transform computation occur

From the orthogonality property of the discrete cosine Fourier transform, unique linearly independent information can occur only at spectral intervals equal to or greater than the sampling interval $\Delta\sigma$. Hence, the sampling interval in the spectrum is related to the achievable resolution. The full width at half maximum of the representation of a single frequency in the spectrum is $1.2\Delta\sigma$. This factor applies for the case where a single cosine wave interferogram has been abruptly truncated at the end of the mirror scan. The lineshape function for this case is quite oscillatory due to the abrupt termination of the interferogram signal at the end of the scan, known as the *Gibbs* phenomenon [20]. This is not always satisfactory, and frequently the interferogram is modified by a “windowing” or “apodization” function to make the lineshape more localized and monotonic. Apodization always results in an increase in the full width at half maximum. Figure 42.2 illustrates this.

42.11.4 Optical Aspects of FTIR Technology

The description of wavefront interference developed in Sect. 42.11.2 applies to interference of plane wave fronts only. A plane wave of IR radiation is obtained at the output of a collimator optics having an IR point source at its focus. In practice, a point source has insignificant intensity. A finite size source, which may be represented by a distribution of point sources in the focal plane of a collimator, provides a distribution of plane wavefronts with different angles of propagation through the scanning Michelson interferometer.

As shown in Eq. (42.4), this distribution of angles results in a distribution of modulation frequencies as a function of mirror displacement x of the output intensity for a given IR wavenumber. This is illustrated in Fig. 42.3, which shows, for a single-frequency IR source, the distribution of output intensity modulation frequencies for an ideal point source a on the optical axis, a circularly symmetric distribution of uniform intensity centered on the optical axis b, and, finally,

Fig. 42.3 *left*: distribution of interferogram modulation frequencies for a single optical frequency; *right*: the observed instrumental line shape functions (ILS) obtained from Fourier transformation of a finite data set representing the frequency distributions shown on the *left*

a circularly symmetric distribution positioned slightly off the axis of the collimator c [21].

As a result of illuminating the scanning Michelson interferometer with a finite size source, a single IR frequency is observed having a distribution of modulation frequencies in its interferogram signal. This distribution limits the ability to resolve two closely spaced IR frequencies and determines the *optical* resolution limit of the FTIR; the larger the extent of the source, the more restricted the resolution becomes. The ratio $\sigma/\Delta\sigma$ is the resolving power R of the scanning Michelson interferometer and, based on Eq. (42.4), is given by

$$R = \frac{1}{(1 - \cos \theta_m)}, \quad (42.15)$$

where θ_m is the maximum off-axis angle of illumination. For small θ_m , $\cos \theta_m \approx 1 - \frac{1}{2}\theta^2$, so that

$$R \approx \frac{2}{\theta^2}. \quad (42.16)$$

From Eq. (42.13), a resolution limit is also imposed by the maximum length of the interferogram recorded. The interferogram length-dependent resolution is constant for all spectral regions, while the optical resolution is proportional to the spectral frequency. Both resolution limits combine to give the overall resolution of an FTIR. At low resolution, the available throughput is so high that the optical resolution is often negligible compared with the length resolution. At high resolution, the throughput is at a premium, and the optical resolution is often closely matched to the length resolution at the frequency of interest.

To ensure a symmetrical frequency distribution, the area integrated illumination must increase as $\sin \theta$, which is approximately linear for small angles, up to its maximum θ_m ,

as shown with the centered circular illumination in Fig. 42.3. Any deviation from this, such as off-axis positioning of the circle, noncircular shapes, or a poorly focused centered symmetrical circle, will result in a gradual roll-off of the distribution on the low-frequency side only [21]. This results in an asymmetric spectral lineshape.

For a collimator of given focal length and for a given resolving power, it is easily shown that the area of the source, or the stop that delineates it, is much larger than the slit area for classical grating spectrometers. This is particularly the case at high resolving powers. The stop that delineates the source extent for a scanning Michelson interferometer is often referred to as the Jacquinot stop or the field of view stop.

42.12 The Scanning Michelson Interferometer

Optical throughput is not only determined by the area of the field of view stop but also the solid angle subtended by the rays traversing this area. The solid angle Ω of rays traversing a Jacquinot stop positioned in the focal plane of an input collimator is given by the ratio of the interferometer beam area divided by the square of the focal length of the collimator.

For a given collimator focal length, the area of the Jacquinot stop is inversely proportional to the resolving power. To maintain equal throughput, the area of the interferometer optics should be increased as the resolving power is increased to offset the decrease in the Jacquinot stop area.

It is common to construct interferometers with 2.5 cm diameter optics for resolving powers up to 5,000, 5.0 cm diameter optics for resolving powers up to 40,000, and 7.5 cm diameter optics for resolving powers up to 1,000,000.

In order to obtain a uniform state of interference across the entire beam of the interferometer, the beamsplitter substrate

and the two mirrors must be flat to within a small fraction of the wavelength used. Also, these elements must be oriented correctly so that the optical path difference error across the beam is less than a small fraction of the wavelength.

Figure 42.1 shows two substrates at the beamsplitter position. One of the substrates supports the beamsplitting coating, while the companion substrate of precisely the same thickness acts as a compensating element to insure identical optical paths through the two arms of the interferometer. To avoid secondary interference effects, both beamsplitter and compensator substrates are normally wedged. The direction of the wedges of the two substrates must be aligned again to insure symmetry in both arms of the interferometer.

The maintenance of a close angular alignment tolerance of the two mirrors with respect to the beamsplitter in a stable manner over time and while scanning one of the mirrors has been a significant challenge of interferometer design and has also been the greatest weakness of FTIR.

In early FTIR models, alignment was maintained by means of a stable mechanical structure and often using a highly precise linear air bearing for the scanning mirror. Satisfactory operation required a stable environment and frequent alignment tuning and could be achieved for mirror displacements of only several centimeters, thus limiting the maximum resolution.

Different techniques have been developed to overcome this weakness of FTIR. The two most prominent are: (1) dynamic alignment of the interferometer, where optical alignment is servo-controlled using the reference laser not only for mirror displacement control but also for mirror orientation control, and (2) the use of cube corner mirrors in place of the flat mirrors in the interferometer. Dynamic alignment has the advantage of retaining simplicity in the optical design of the interferometer. On the other hand, it is more complex electronically. Cube corner mirrors have the property of always reflecting light 180° to incident light independent of orientation. Cube corners always ensure wavefront parallelism at the point of recombination of the two beams in the interferometer. Cube corners lack a defined optical axis. In a cube corner interferometer, the optical axis is defined by the direction in which the wavefronts undergo zero shear.

The scanning Michelson interferometer is normally provided with a drive mechanism to displace one of the mirrors precisely parallel to its initial position and at uniform velocity. The uniform velocity translates the mirror displacement-dependent intensities into time-dependent intensities. This facilitates signal processing electronics. In some measurement scenarios, however, where the sample spectrum may vary with time, it is undesirable to deal with the multifrequency time-varying intensities of the interferogram signal. In this case, it is preferable to scan the moving mirror in a stepwise mode, where the mirror is momentarily stationary

at the time of signal measurement and then advanced rapidly to the next position. The mirror scan velocity v can also be varied, so that electrical signals can have different frequencies for the same optical frequencies

$$f = \frac{\sigma}{2v} . \quad (42.17)$$

The scan velocity is normally selected to provide the most favorable frequency regime for the detector and electronics used and for the mechanical capabilities of the mirror drive. Typically, the velocity range is from 0.05 to 4 cm s^{-1} , putting the frequencies in the audio range. At these velocities, the measurement scan may be completed in a shorter time than is desired for signal averaging purposes. In this case, it is common to repeat the scan a number of times and add the results together; this is called coadding of scans.

As stated earlier, in FTIR there is no segregation of frequencies of the input intensity. All frequencies of the spectrum are transmitted through the interferometer simultaneously. In the commonly encountered case where the field of view is small, so that the interferogram length determines the resolution and lineshape, the lineshape closely matches the same analytical function for all spectral components. Along with the absence of dispersion in the interferometer providing a highly linear frequency scale that is calibrated at a single frequency FTIR provides a high degree of reproducibility.

This is frequently used to reconstruct observed spectra based on predetermined spectral parameters for molecules present in the sample. By least squares fitting several attributes of the sample can be determined.

42.13 Infrared Spectroscopy Application Activity 2020

Infrared spectroscopy using FTIR has become a mature activity with many thousands of simple benchtop units produced. Due to innovative design and efficient manufacturing these FT spectrometers cost much less than the early pioneering versions. Below is a description of some of the areas of use of infrared spectroscopy using FTIR. The laboratory applications are routine, while applications outside the laboratory are more specialized, particularly some of the remote-sensing applications.

42.13.1 Analytical Chemistry Laboratories

The traditional analytical chemistry laboratory is routinely equipped with an FTIR that covers the spectral range from about 400 to about 5000 cm^{-1} . It is used mostly for the

analysis of liquid samples in transmittance and solids (in powder form) by diffuse reflectance. Condensed phase samples (liquids and solids) show spectral features that are mostly $> 4 \text{ cm}^{-1}$ wide and are rarely narrower than 2 cm^{-1} . Hence, the full width at half maximum intensity (FWHM), spectral resolution selected is mostly 4 cm^{-1} . To avoid the need for spectral filtering, the numerically computed spectra typically cover the range from 0 to about 8000 cm^{-1} or higher.

The absorptivity of most condensed phase samples is high, particularly in the 400 to 2000 cm^{-1} fingerprint region. A short pathlength is, therefore, selected to avoid regions of zero transmittance. An efficient sampling method is to place a drop of liquid sample or a small amount of powder on the surface of an IR transparent crystal with a high index of refraction through which IR radiation is propagated via total internal reflection. The presence of the sample permits penetration of an evanescent wave several μm into the sample and, thereby, produces a transmittance spectrum corresponding to a path length of typically up to about $10 \mu\text{m}$; this is called attenuated total internal reflection (ATR) spectroscopy.

The measured spectra are typically used for the semiquantitative determination of molecular concentration. However, since the frequency axis in FTIR is calibrated via the scan control metrology laser, the precision (repeatability) is exceptionally high. In the numerical format, the method of spectral subtraction can bring to light subtle differences between comparable samples typically due to small amounts of contaminants mixed in the samples. Moreover, the scaled spectral subtraction is a powerful method of concentration determination.

42.13.2 Biomedical and Pharmaceutical Laboratories

Medical formulations may consist of mixtures of complex molecular compounds. Infrared spectroscopy is one of the many analysis techniques employed for the determination of accuracy of formulation. It is found that the efficacy of a formulation may not only depend on a particular molecular formulation but also on the “chirality” of the formulation. In stereo chemistry, chirality provides the distinction between two enantiomers of otherwise identical molecules. Enantiomers are the right-hand and left-hand versions of otherwise identical molecules; a “spiral spring” may be coiled in two different ways, right-hand and left-hand, without affecting its spring property. Determination of the chirality of a sample by infrared spectroscopy consists of measuring the difference in absorption of right and left circular polarized radiation. Since this difference in absorption is typically five orders of magnitude weaker than the normal absorption

spectrum it is challenging to measure chirality. A Fourier transform spectrometer provided with a means of rapidly switching between right and left circular polarization, such as using a photoelastic modulator, permits demodulation of the difference absorption of the two circular polarizations [22].

42.13.3 Forensic Investigation

Due to the capability of mid-IR spectroscopy to relate a large number of different substances to their unique infrared spectra, IR spectroscopy is an indispensable tool in forensic laboratories. The emphasis here is to analyze samples in many forms and frequently in exceedingly small amounts. The analysis of liquids by transmission is a small subset of the variety of samples that may occur. Many of the samples to be investigated may not be transparent or just have a surface contaminant that is of interest. Both specular and diffuse reflection are, therefore, often employed. In forensic investigation, sometimes extremely small amounts of sample may be of particular interest. Many microsampling accessories are available, amongst which the IR microscope is the most powerful. The IR microscope permits focusing the modulated IR beam onto spots as small as $10 \mu\text{m}$ and analysis of 50 to $100 \mu\text{m}$ areas is routine. To be sure the focusing down to an area of less than $100 \mu\text{m}$ utilizes only a small fraction of the available intensity of the FTIR. IR microscopes are normally provided with dedicated liquid nitrogen cooled Hg-Cd-Te semiconductor detectors. Increasingly available mid-IR, Hg-Cd-Te imaging detector arrays with high image frame rates are being used in conjunction with IR microscopes. These provide the capability of examining microscopic samples with inhomogeneous composition distribution.

A common property of infrared detectors is that their noise level is proportional to the square root of their area. Hence, a single pixel detector of a detector array with small area will have significantly lower noise than a larger single detector module. This permits recording a 2-D array of spectra of a microsample with low noise, where individual pixels may cover an area as small as a few μm .

A complementary method used in forensic investigation and other applications is Raman spectroscopy. Spectra like mid-IR spectra of a sample are obtained via inelastic scattering of laser illumination from their surface. Raman spectroscopy is more tolerant to sample shape irregularity and texture and does not require contact. For some samples, fluorescence induced by the laser illumination can interfere with the Raman spectrum.

Identifying the chemical makeup of samples from their measured mid-IR or Raman spectra is achieved using search algorithms applied to digital IR libraries of IR and Raman spectra. As many as 225,000 infrared spectra are available

for searching. Because of small variations in sample accessories, instrument calibrations, and contaminants in the sample, the spectral identification is presented as a probable identification with a confidence index. Several probable identification candidates are returned with a decreasing confidence index.

42.13.4 Infrared Spectroscopy in Quality Assurance Laboratories

A quality assurance laboratory evaluates conformity to the required specification of manufactured products or the concentration of essential components in products such as wheat, milk, medicinal formulations, and industrial chemical formulations. The demands of the QA laboratory are quite different from those of the analytical chemistry laboratory. The measurement accuracy (the agreement with a production standard) needs to be in line with the specifications of uniformity of the product.

Increasingly, the manufacture of FTIR spectrometers includes a specification of reproducibility in addition to repeatability and low noise of the measured spectra. This means that the FTIR spectrometer, including the sampling arrangement, must conform to a limit of sameness of frequency scale calibration, sameness of instrumental lineshape function, FWHM, and sameness of the transmittance of a standard sample.

Mid-IR sampling requires a short optical path through samples to avoid excessive absorption. Typically, the path length is below 50 μm and may be as low as a few μm . For quantitative concentration determinations, the path length is a required parameter. Therefore, the near-IR is preferred because, here, the harmonics and combinations of the mid-IR bands absorb much less strongly than the fundamental bands in the mid-IR and can be measured with longer path-length liquid cells that can have quite accurate path-length values. The determination of concentrations is done by means of chemometric models, such as partial least squares, which uses a set of standard samples to build a model. In order to insure accurate reproducibility of spectra, FTIR spectrometers are tested with a “golden standard” sample for which the spectrum can be rendered reproducible. Often, a sample, such as toluene with 99.99% purity at constant temperature, is used. This has led to the ability of deploying spectrometers at different measurement sites while maintaining identical measurement results. In these applications, FTIR, due to its laser-controlled scanning, provides significantly more accurate measurements than a dispersive grating spectrometer. The above is an example of applying FTIR at short wavelengths in the near-IR. Due to the brightness of near-IR light sources, the constraint of photon statistics noise in FTIR is not present.

42.13.5 Process Monitoring by Infrared Spectroscopy

Continuous process monitoring of parameters such as temperature and pressure are common. In some processes, it is valuable to continuously monitor the product composition as well. Like methods used in quality assurance laboratories, process monitoring most frequently uses quantitative near-IR spectroscopy. An illustrative example is the blending of gasoline in refineries.

There are several challenges in the blending of gasoline related to performance, as indicated by octane number, as well as insuring low viscosity in cold weather conditions and low evaporation in hot weather, and, finally, to conform to environmental restrictions. All these factors complicate the formulation, allowing only a limited number of different solvents to be used for blending. Figure 42.4 shows a near-infrared spectrum of gasoline identifying the bands attributed to different types of hydrocarbons.

In the range of permitted gasoline blends, the near-IR spectra such as shown in Fig. 42.4 vary by only a few percent in absorbance. To continuously monitor the blending process and report the required parameters requires highly accurate and stable spectroscopy; the overlay of spectra of the same sample measured with 14 different analyzers is shown in Fig. 42.4. The reporting of (nonspectroscopic) quality parameters is derived from chemometric models with many combinations of different known standard samples. Application of FT-NIR to this requirement has been shown to be exceptionally stable over time, as well as highly reproducible for different analyzers. The latter is significant because it avoids the costly and extensive recalibration of analyzers.

Table 42.1 shows a typical performance summary achieved with a process FT-NIR that continuously monitors the blending process. It is used to control and adjust the blending process in real time.

Fig. 42.4 Near-IR absorbance spectra of gasoline identifying bands of different hydrocarbons

Table 42.1 Summary of reproducibility, accuracy, and precision of measured components

Gasoline property data				FTNIR transportability	
Measurement	Units	NIR		ASTM	On-line to on-line North American refinery blender
		Typical	Range		
		Std. dev.		Std. dev.	Absolute difference
RON	Octane number	0.30	0.2–0.4	0.21	0.05
MON	Octane number	0.30	0.2–0.4	0.32	0.05
Total aromatics	%	1.50		1.20	0.11
Total olefins	%	1.00		1.80	0.05
RVP	psi	0.15	0.1–0.2	0.15	0.09
E200	%	1.50		1.19	0.03
E300	%	1.00		0.54	0.10

10%	°F	6.00		3.25	0.21
30%	°F	2.90		2.80	0.95
50%	°F	4.80		2.80	0.06
70%	°F	4.20		2.80	0.51
90%	°F	4.90		1.60	0.75
FBP	°F	6.70		5.70	1.05

42.13.6 Environmental Monitoring

Infrared spectroscopy is used extensively for the continuous monitoring of emission gases from a variety of industrial and utility smokestacks. The purpose is to comply with environmental regulations. Combustion processes produce large concentrations of carbon dioxide, as well as moisture. It is common to precipitate moisture from a gas sample prior to IR measurement. This permits the employment of simple, low-cost nondispersive IR analyzers (discrete narrowband filter-based analyzers). Particularly challenging is the monitoring of smokestacks that may emit water soluble gases such as HCl and HF. With a sample without precipitation of moisture, the infrared spectrum shows much interference by strong moisture bands covering large spectral regions. FTIR spectroscopy has been particularly effective in such applications because interference is minimized by choosing a spectral resolution that permits separating spectral features of the different components.

42.13.7 Remote Sensing

In remote sensing, spectral information about remote objects is obtained by their thermal emission. At ambient temperature, the radiation emitted is the strongest in the 500 to 1800 cm^{-1} region and is, therefore, widely used.

Satellite-based remote sensing of Earth's atmosphere is of particular interest to support weather prediction and to determine levels of pollution. Satellite-based thermal infrared measurements routinely provide input data for weather prediction and climate change models. Thermal emission from a gas depends on the opacity (absorbance) of the gas. Oxygen and nitrogen, which make up most of Earth's atmosphere,

have virtually no opacity. Thermally emitted radiance by Earth's atmosphere is dependent on small amounts of gases such as carbon dioxide, ozone, water vapor, and other minor constituents present in the atmosphere that have infrared absorption bands.

The major thermodynamic drivers that affect Earth's weather the most are temperature and water vapor variations. Meteorologists working with large computer simulations of local and extended weather patterns count on hourly updates of accurately measured three-dimensional maps (geographic and altitude resolved) atmospheric temperature, and water vapor distribution. In addition, the knowledge of detailed maps of surface emissivity and temperature, as well as albedo for solar reflection, are important drivers of weather.

In Fig. 42.5 the reduced radiance near 650 cm^{-1} is due to thermal emission to space by carbon dioxide in the upper atmosphere where it is much colder than 305 K. Likewise some reduced radiance near 1000 cm^{-1} is due to colder ozone and beyond 1300 cm^{-1} due to cold water vapor.

It can be seen that if Earth had no atmosphere, it would radiate more radiance to space (smooth curve), keeping Earth at a lower temperature than in the presence of our atmosphere; this is a clear demonstration of the greenhouse effect.

Temperature as a function of altitude can be derived from these spectra by realizing that the concentration of carbon dioxide is known and is uniformly mixed through the atmosphere. Having different band intensities provides the information to retrieve temperature as a function of altitude. The recent introduction of sophisticated new satellite-based Fourier transform spectrometer sounders has greatly improved the accuracy and detail in the vertical profiles of both temperature and moisture [23]. These new sounders have demanding requirements of spectral reproducibility, sensitivity, and speed of measurement. In order to map the entire globe

Fig. 42.5 A typical, clear sky, radiance in $\text{W}/\text{cm}^2\text{-sr}\text{-cm}^{-1}$ in the thermal infrared observed from space. The *smooth line* is a Planck curve for a high-emissivity surface at 305 K

more than once per day they typically produce over 400,000 spectra/day.

Exploration of the Solar System by interplanetary probes was started by sending probes to the moon in order to determine the suitability of landing there. Mars has been extensively surveyed both on the surface and in its atmosphere. Besides visual images, infrared spectroscopy has been used to determine surface and atmospheric composition. One of the more recent probes is the Cassini–Huygens probe [24] to investigate Saturn and some of its moons. Saturn being almost 10 times further from the Sun as our Earth it receives much less heat from the Sun. Infrared spectroscopy of this probe is primarily centered on far-infrared thermal emission.

A spectacular feat of infrared spectroscopy has been the measurement of the remnant of cosmic background radiation. Expected to be a Planck-type blackbody radiation at only an estimated 2.7 K, its spectrum occurs in the range 0 to about 20 cm^{-1} and has a peak near 5 cm^{-1} . Both the NASA COBE satellite mission [25] and the COBRA suborbital rocket experiment [26] used Fourier transform spectrometers. Since almost any part of the spectrometer might have a comparable temperature to the source of interest, the COBRA FTIR consisted of a precisely balanced dual-input and dual-output interferometer. The experiment measured the difference spectrum between the space view at one input against a calibrated blackbody at the second input. Adjusting the temperature of the blackbody to achieve a null interferogram provided a precise value for the temperature. Spectral analysis of the residual null interferogram confirmed that the structure of the spectrum closely matched the Planck blackbody curve at 2.736 K.

42.14 Conclusion

Infrared spectroscopy is widely used to identify the chemical nature of a range of different substances in a variety of measurement settings. A compact low-cost FTIR spectrome-

ter is a required tool for the chemistry laboratory. Expanding on this, today, the power of identifying the chemical nature of substances is incorporated into compact handheld FTIR and Raman spectrometers that permit noncontact “point and measure” for the determination of the molecular nature of chemicals. The sampling approach may be diffuse reflection and laser Raman scattering or on a small area point contact by means of attenuated total internal reflection (ATR).

Due to continual improvement in operation stability, FTIR has become well known for its precise repeatability, including outstanding stability over time. The repeatability of FTIR is attributable to the highly precise measurement of the interferometer scan distance using a wavelength stabilized single-mode laser. The instrumental lineshape function (ILS) is determined by the precision of the scan distance measurement and not by any geometric factors in the instrument. This fundamental difference in the aspect of measurement precision has led to the development not only of high accuracy spectral measurements but additionally to excellent reproducibility amongst FTIRs. These developments have led to a reputation of FTIR as an accurate quantitative analysis tool. Increasingly, FTIR is being deployed for quality assurance in chemical manufacturing. An example is the determination of the hydroxyl value in a variety of surfactants. Here, easy-to-operate FTIR has replaced a laborious skill-demanding and costly titration method.

These features have been quite useful in molecular spectroscopy research as well. This permits accurate reproducibility of the frequency scale from instrument to instrument. The instrumental lineshape function when defined by the field of view stop (sometimes called the Jacquinot stop) can be expressed by an analytical function and is invariant over a defined frequency range. This is a key factor in achieving precisely reproducible spectral response with different instruments. Finally, a reason for the diversity of applications enabled with FTIR is its ease of adaptability to various needs for spectral resolution as well as scan velocities and spectral ranges.

Abstract

Recent technical developments in sub-millimeter and far-infrared laser spectroscopy are described. This includes new laser sources, both side-band and difference-frequency generation. An experiment which uses fixed-frequency far-infrared lasers to study open-shell molecules (free radicals) is described; the technique is known as laser magnetic resonance (LMR). Sub-millimeter and far-infrared laser spectroscopies are finding expensive use in the detection and monitoring of molecules in astrophysical sources and in the earth's atmosphere.

43.1 Introduction

Research in the submillimeter and far-infrared (SM-FIR) regions of the electromagnetic spectrum (1000 to 150 μm , 0.3 to 2.0 THz; and 150 to 20 μm , 2.0 to 15 THz, respectively) had been relatively inactive until about 30 years ago. Three

events were responsible for enhanced activity in this part of the electromagnetic spectrum: the discovery of far-infrared (FIR) lasers [1], the development of background-limited detectors [2], and the invention of the FIR Fourier transform (FT) spectrometer [3]. Following these developments major discoveries have taken place in laboratory spectroscopic studies [4, 5], in astronomical observations [6], and in spectroscopic studies of our upper atmosphere [7].

Rotational transition frequencies of light molecules (such as hydrides) lie in this region, and the associated electric dipole transitions are especially strong at these frequencies. In fact they are 10,000 times stronger than at microwave frequencies because they are 100 times typical microwave frequencies and their peak absorptivities depend approximately on the square of the frequency. Fine structure transitions of atoms and molecules also lie in this region; however, they are much weaker, magnetic dipole transitions. The observation of fine structure spectra is very important in determining atomic concentrations in astronomical and atmospheric sources and for determining the local physical conditions. Bending frequencies of larger molecules also lie in this region, but their transitions are not as strong as rotational transitions (typically a factor of 10^3 weaker).

Spectral accuracy has been increased by several orders of magnitude with the extension of direct frequency measurement metrology into the SM-FIR region [8]. Transitions whose frequencies have been measured (including absorptions and laser emissions) are useful wavelength calibration sources ($\lambda_{\text{vac}} = c/\nu$) for FT spectrometers. FIR spectra of a series of rotational transitions have been measured in CO [9], HCl [10], HF [11], and CH₃OH [12] to be used for FT calibration standards. These lines are ten to a hundred times more accurately measured than can be realized in present state-of-the-art Fourier transform spectrometers; thus, they are excellent calibration standards. High-accuracy and high-resolution spectroscopy has permitted the spectroscopic assignment of the SM-FIR lasing transitions themselves [13] resulting in a much better understanding of the lasing process.

Astronomical spectroscopy in this region [6] may be in emission or absorption and is performed using either interferometric [14] (wavelength-based), or heterodyne (frequency-based) [15] techniques to resolve the individual spectral features.

Most high resolution spectra of our upper atmosphere have been taken with FT spectrometers flown above the heavily absorbing water vapor region in the lower atmosphere. Emission lines are generally observed in these spectrometers [7].

43.2 Experimental Techniques Using Coherent SM-FIR Radiation

The earliest sources of coherent SM radiation came from harmonics of klystron radiation generated in point-contact semiconductor diodes [16]. Spectroscopically useful powers up to about one terahertz are produced. This technique is being replaced by electronic oscillators which oscillate to over one terahertz [17]. The group at Cologne University, Germany [18] has been particularly successful with this approach. Spectroscopy above this frequency generally is performed with either lasers or FT spectrometers (see Chap. 42).

Laser techniques use either tunable radiation synthesized from the radiation of other lasers, or fixed-frequency SM-FIR laser radiation and tuning of the transition frequency of the species by an electric or magnetic field. Spectroscopy with tunable far-infrared radiation is called TuFIR spectroscopy. Spectroscopy with fixed frequency lasers is called either laser electric resonance (LER) or laser magnetic resonance (LMR). LMR is applicable only to paramagnetic species and is noteworthy for its extreme sensitivity. LMR spectroscopy has been more widely applied than LER, and is discussed in this chapter.

Tunable SM-FIR radiation has been generated either by adding microwave sidebands to radiation from a SM-FIR laser [19] or by using a pair of higher frequency lasers and generating the frequency difference [20]. The sideband technique was first reported by *Dymanus* [19] and uses a Schottky diode as the mixing element. It has been used up to 4.25 THz and produces a few microwatts of radiation [21]. Groups at Berkley, California [22] and Cologne, Germany [23] have developed this technique to good effect. The CO₂ laser frequency-difference technique with difference generation in the metal-insulator-metal (MIM) diode covers the FIR region out to over 6 THz and produces about 0.1 μW. This technique uses fluorescence-stabilized CO₂ lasers whose frequencies have been directly measured, and it is about two orders of magnitude more accurate than the sideband technique. However, it is somewhat less sensitive because of the decreased power available. There are several review articles on the laser

sideband technique [21, 24], and only the laser difference technique is described here.

43.2.1 Tunable FIR Spectroscopy with CO₂ Laser Difference Generation in a MIM Diode

There are two different ways of generating FIR radiation using a pair of CO₂ lasers and the MIM diode. One is by second-order generation, in which tunability is achieved by using a tunable waveguide CO₂ laser as one of the CO₂ lasers; it is operated at about 8 kPa (60 Torr) and is tunable by about ±120 MHz. The second technique uses third-order generation, in which tunable microwave sidebands are added to the difference frequency of the two CO₂ lasers. The complete spectrometer which can be operated in either second or third order is shown in Fig. 43.1.

The FIR frequencies generated are

$$\text{second-order: } \nu_{\text{fir}} = |\nu_{1,\text{CO}_2} - \nu_{\text{W,CO}_2}| \quad (43.1a)$$

$$\text{third-order: } \nu_{\text{fir}} = |\nu_{1,\text{CO}_2} - \nu_{\text{W,CO}_2}| \pm \nu_{\text{mw}} \quad (43.1b)$$

where ν_{fir} is the tunable FIR radiation, ν_{1,CO_2} and $\nu_{\text{W,CO}_2}$ are the CO₂ laser frequencies, and ν_{mw} is the microwave frequency.

Different MIM diodes are used for the two different orders: in second-order, a tungsten whisker contacts a nickel base and the normal oxide layer on nickel serves as the insulating barrier; in third-order, a cobalt base with its natural cobalt oxide layer is substituted for the nickel base. The third-order cobalt diodes produce about one third as much FIR radiation in each sideband as there is in the second-order difference; hence third-order generation is not quite as sensitive as second-order. The much larger tunability, however, makes it considerably easier to use.

The common isotope of CO₂ is used in both the waveguide laser and in laser 2; in laser 1, one of four isotopic species is used. Ninety percent of all frequencies from 0.3 to 4.5 THz can be synthesized; the coverage decreases between 4.5 and 6.3 THz. Ninety megahertz acoustooptic modulators (AOMs) are used in the output beams of the two CO₂ lasers which irradiate the MIM diode; they increase the frequency coverage by an additional 180 MHz and isolate the CO₂ lasers from the MIM diode. This isolation decreases amplitude noise in the generated FIR radiation, caused by the feedback to the CO₂ laser from the MIM diode, by an order of magnitude; hence, the spectrometer sensitivity increases by an order of magnitude.

The radiations from laser 1 and the waveguide laser are focused on the MIM diode. Laser 2 serves as a frequency reference for the waveguide laser; the two lasers beat with each other in the HgCdTe detector and a servosystem offset-locks the waveguide laser to laser 2. Lasers 1 and 2 are frequency

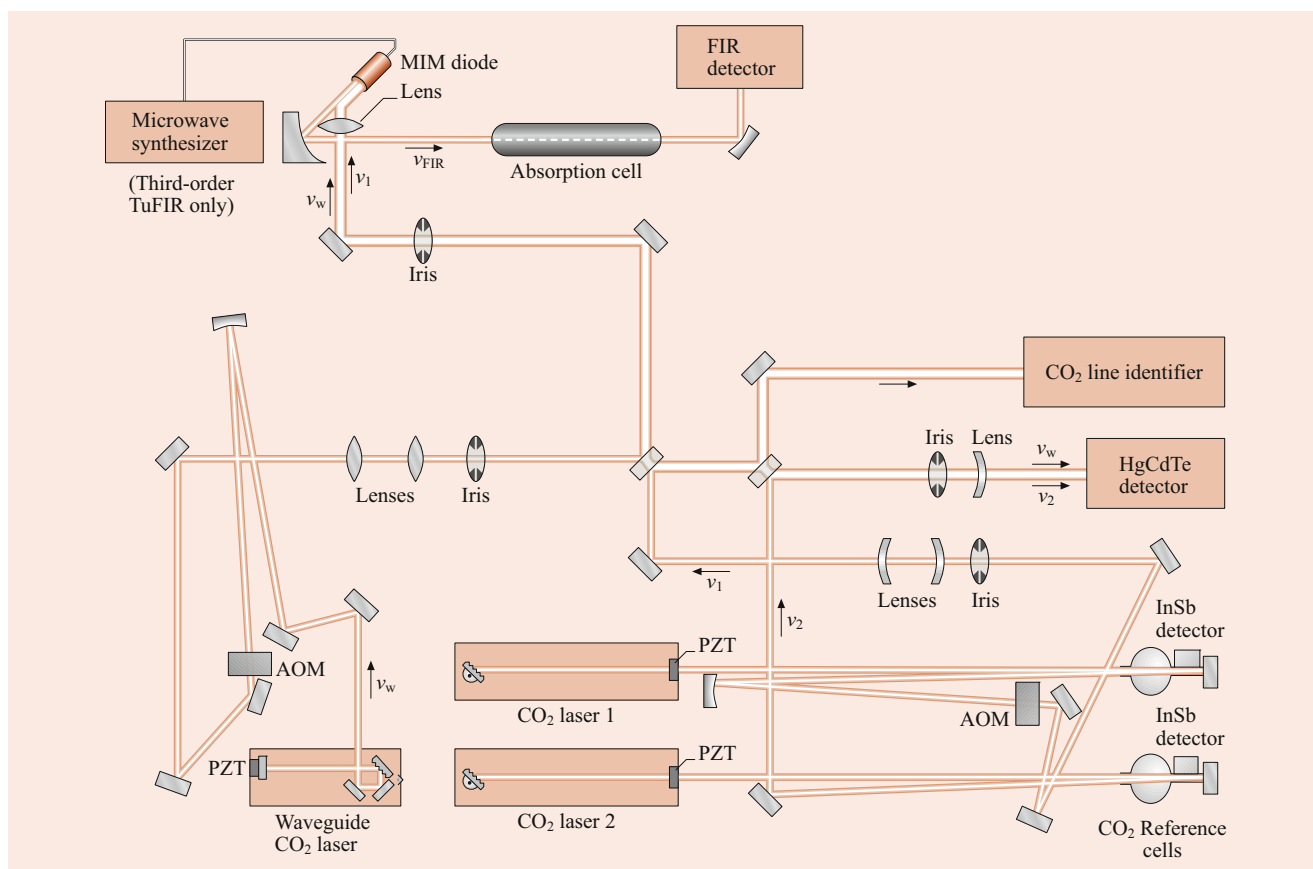

Fig. 43.1 Tunable far-infrared (TuFIR) spectrometer for second- or third-order operation using CO₂ laser difference-frequency generation in the MIM diode

modulated using piezoelectric drivers on the end mirrors, and they are servoed to the line center of 4.3 μm saturated fluorescence signals obtained from the external low-pressure CO₂ reference cells. In both second and third order, the CO₂ reference lasers are stabilized to line center with an uncertainty of 10 kHz. The overall uncertainty in the FIR frequency due to two lasers is thus $\sqrt{2} \times 10$ or 14 kHz. This number was determined experimentally in a measurement of the rotational frequencies of CO out to $J = 38$ (4.3 THz), with the analysis of the data set determining the molecular constants [9].

The CO₂ radiation is focused by a 25 mm focal length lens onto the conically sharpened tip of the 25 μm diameter tungsten whisker. The FIR radiation is emitted from the 0.1 to 3 mm long whisker in a conical long-wire antenna pattern. Then it is collimated to a polarized beam by a corner reflector [25] and a 30 mm focal length off-axis segment of a parabolic mirror.

The largest uncertainty in the measurement of a transition frequency comes from finding the centers of the Doppler broadened lines. This is about 0.05 of the line width for lines observed with a signal-to-noise ratio of 50 or better and corresponds to about 0.05 to 0.5 MHz. A linefitting program [26] improves the line center determinations by nearly

an order of magnitude. The FIR radiation is frequency modulated due to a 0.5 to 6 MHz frequency modulation of CO₂ laser 1; this modulation is at a rate of 1 kHz. The FIR detector and lock-in amplifier detect at this modulation rate; hence the derivatives of the absorptions are recorded.

Absorption cells from 0.5 to 3.5 m in length with diameters ranging from 19 to 30 mm have been used in the spectrometer. The cells have either glass, copper, or Teflon walls and have polyethylene or polypropylene windows at each end. These long absorption cells lend themselves naturally to electrical discharges for the study of molecular ions. A measurement of the HCO⁺ line at 1 THz exhibited a signal-to-noise ratio of 100 : 1 using a 1 s time constant; this is the same signal-to-noise ratio that was obtained using the laser sideband technique.

The instrumental resolution of the spectrometer is limited by the combined frequency fluctuation from each CO₂ laser (about 15 kHz). This is less than any Doppler-limited line width and, therefore, does not limit the resolution. The entire data system is computerized to facilitate the data recording and optimize the data handling.

Improvements in this TuFIR technique may come from either better diodes or detection schemes. The nonlinearity

Fig. 43.2 40 μm to 1000 μm Far-infrared laser magnetic resonance (LMR) spectrometer using an optically pumped FIR laser

of the MIM diode is extremely small, and conversion efficiencies could be much larger if a more efficient diode is discovered. Differential detection (which requires more sensitive detectors) could also significantly improve the sensitivity and permit the detection of weaker lines.

43.2.2 Laser Magnetic Resonance

Laser magnetic resonance (LMR) is performed by magnetically tuning the transition frequencies of paramagnetic species into coincidence with the fixed frequency radiation from a laser. LMR is a type of Zeeman spectroscopy [27], and its chief forte is its extreme sensitivity. Approximately one hundred species have been observed in the SM-FIR region. These include atoms, diatomics (especially hydrides), polyatomics, ions, metastables, metastable ions [28], and many *first observations* of free radicals. These observations are summarized in several review articles on LMR [29–31].

The FIR LMR spectrometer at NIST, Boulder is shown in Fig. 43.2. This spectrometer has an intracavity paramagnetic sample in a variable magnetic field which is labeled *sample volume* in the figure. A regular 38 cm EPR magnet with a 7.5 cm air gap is used. The laser cavity is divided into two parts by a Brewster angle polypropylene beam splitter about 12 μm thick. A CO_2 laser optically pumps the FIR laser gas. This pump beam makes many nearly perpendicular passes reflected by the walls of the gold-lined Pyrex tube. A 45° coupler serves to couple out the FIR radiation from the cavity to the helium-cooled detector. Mirrors each with an 89 cm radius of curvature are used in the nearly confocal geometry of the 94 cm cavity. One of the gold-coated end

mirrors is moved with a micrometer to tune the cavity to resonance and also to determine the oscillating wavelength by moving the end mirror several half-wavelengths. The beam splitter is rotatable so that the polarization of the laser can be varied with respect to the magnetic field. Quartz spacers are used to minimize the thermal expansion of the cavity. This LMR spectrometer oscillates at wavelengths between 40 and 1000 μm . The technology of FIR lasers has been reviewed by Douglas [32].

The LMR technique requires a close coincidence (typically within 20 GHz) between the absorption line and the frequency of the laser. Zero field frequencies which are 100 times more accurate than those obtained from optical spectra are obtained from the analysis of the Zeeman spectra observed (i.e. using the laser frequency and the magnetic field values). The accuracy is within 1 or 2 MHz and has permitted the far infrared astronomical observation of many of these species.

Atomic FIR LMR spectra are due to fine structure transitions and are magnetic dipole transitions; hence, they are several orders of magnitude weaker than electric dipole rotational spectra of molecules. The production of a sufficient atomic number density can be difficult; however, *atomic flames* have been very effective sources, and the high sensitivity of LMR has been the most successful spectroscopic technique for measuring these transitions. The atoms O, C, metastable Mg, S, Si, Fe, Al, N^+ , C^+ , P^+ , Fe^+ , and F^+ have been measured by FIR LMR. Atomic Zeeman spectra are relatively simple to analyze, and fine structure frequencies accurate to within 1 MHz can be determined.

In a FIR LMR spectrometer the sample is inside the laser cavity; hence, sub-Doppler line widths can be observed by

operating the sample at low pressure and observing saturation dips in the signals. This has permitted the resolution of proton hyperfine structure in a number of hydrides. The observation of the resolved hyperfine structure is useful in the identification of the species involved and also yields accurate values of the hyperfine splittings.

Rotational spectra of most hydrides lie in this spectral region and many of the hydrides, such as OH, CH, SH, and NH have been observed. Others, such as CaH, MnH, TiH, and ZnH are excellent candidates for LMR studies. Ions are much more difficult because of their low concentrations; however, the use of a special microwave discharge operating in the magnetic field has proved to be an extremely productive source of ions for LMR studies [28].

The spectra of a number of polyatomic species has been observed by LMR: for example, NO₂, HO₂, HCO, PH₂, CH₂, NH₂, AsH₂, HO₂, HS₂, CH₃O, and CCH. The spectra of these polyatomic species are more difficult to analyze, resulting in a somewhat less accurate prediction of the zero-field frequencies. Spectra of the extremely elusive CH₂ and CD₂ radicals have finally yielded to analysis with the simultaneous observation of FIR LMR spectra [33] and IR LMR spectra [34]. The data yield rotational constants which predict the ground state rotational transition frequencies and permit the determination of the singlet–triplet splitting in that molecule [35].

In the last ten years, there has been an experimental push to higher frequencies in FIR spectroscopy. In the LMR spectrometer (shown in Fig. 43.2), this has been achieved principally by reducing the internal diameter of the gold-lined tube in the pumping region to 19 mm so as to increase the overlap between the laser gain medium and the FIR radiation field in the laser cavity. As a result, many new laser lines have been discovered; the system operates down to below 40 μm. This has enabled molecules with larger fine-structure intervals to be studied (e.g., FO and HF⁺ [36, 37]) and has also led to the first detection of vibration-rotation transitions in molecules with low-frequency bending vibrations (CCN, HCCN, FeH₂) [38–40].

The sensitivity of TuFIR is only about 1% of that of laser magnetic resonance, but it is difficult to compare the two because the sample can be very large in the TuFIR spectrometer and is limited to about 2 cm³ in the LMR spectrometer.

43.2.3 TuFIR and LMR Detectors

Four different detectors have been used in the TuFIR and LMR spectrometers: (1) an InSb 4 K, liquid ⁴He-cooled, hot-electron bolometer, operating from 0.3 to 0.6 THz with a noise equivalent power (NEP) of about 10⁻¹³ W/√Hz; (2) a gallium doped germanium bolometer, cooled to the lambda

point of liquid-helium, operating from 0.6 to 8.5 THz with an NEP of about 10⁻¹³ W/√Hz; (3) a similar, but liquid ³He-cooled bolometer, with a NEP two orders of magnitude smaller; and (4) an unstressed Ge:Ga photoconductor, cooled to 4 K, with an NEP of 10⁻¹⁴ W/√Hz, operating from 2.5 to 8.5 THz. The optimization of detector systems for this new technique has been responsible for a significant improvement in sensitivity of these spectrometers.

43.3 Submillimeter and FIR Astronomy

Submillimeter astronomy is reviewed in [6]. Many atomic species (both neutrals and ions) and more than 100 molecules have been detected in interstellar space; many were first observed in the submillimeter and FIR region. In the microwave and submillimeter region, radio (heterodyne) techniques are employed in the receivers. At higher frequencies, interferometric techniques are used [14]; however, heterodyne techniques recently have been employed at these higher frequencies and have resulted in the detection of CO [41] and OH [42] at 2.5 THz and a search for the IR band of methylene [43] at 30 THz. Submillimeter radio astronomy observatories (at high altitudes above much of the water vapor absorptions in our atmosphere) use laboratory determined frequencies. For example, the Kuiper Airborne Observatory and the submillimeter and FIR telescopes on Mauna Kea, Hawaii require frequencies accurate to about 1 MHz in their heterodyne receivers. For heterodyne detection, fixed frequency FIR gas lasers generally serve as local oscillators, and the frequencies of these lasers must be known.

The discovery and direct frequency measurement of FIR laser lines has continued apace since the last major review of this topic was published in 1986 [44]. Almost 1000 lines were listed in that publication; the present number is at least twice this. Two main factors have fuelled this progress. First, the design of CO₂ lasers has continued to develop so that now a single laser can produce 275 individual transitions from the regular, hot [45], and sequence [46] bands of CO₂ with power levels from 2 to 30 W. Secondly, many new, short-wavelength laser lines have been discovered in a cavity specially designed to promote them. As a result, many high frequency lines have now been characterized, several in the range of 26 to 45 μm. The main lasing molecules used in this work are CH₃OH [47–50] and hydrazine, N₂H₄ [51].

Recent observations of FIR transitions in molecules in the interstellar medium have been made from satellite-based platforms such as the Infrared Space Observatory (ISO) [52] using Fourier Transform methods. Attention has been paid to the measurement of less abundant isotopic forms, such as ¹⁸OH and ¹⁷OH, because of the information that they provide about star formation processes.

There are four main goals of laboratory SM-FIR spectroscopy which serve the needs of the SM-FIR radio astronomy field:

1. To provide accurate frequencies of SM-FIR species for their detection,
2. To find new far infrared active species,
3. To measure the frequencies of FIR species which can be used to calibrate Fourier transform spectrometers, and
4. To measure frequencies of far-infrared lasers for use as local oscillators in radio astronomy receivers (and to be used in the analysis of laboratory LMR data).

43.4 Upper Atmospheric Studies

A very impressive set of SM-FIR spectra of our upper atmosphere has been observed using balloon-borne FT spectrometers flown at altitudes where the lines are narrow and the spectrometer is above the *black*, heavily absorbing water vapor transitions [7]. A number of very important species with strong SM-FIR spectra have been observed. They include: O₂, H₂O, NO, ClO, OH, HO₂, O₃, and O. Numerous lines have not yet been identified. It is difficult to calibrate these instruments absolutely because the spectra come from the species emitting at temperatures of about 200 K, and from an indeterminate path length. The high sensitivity of LMR might provide an alternate way of measuring the paramagnetic species in our upper atmosphere by flying an LMR spectrometer to high altitudes. A light-weight solenoid magnet could be used to increase the path length. Absolute concentrations of the paramagnetic species such as OH, HO₂, NO, and O could be obtained.

Acknowledgements We have benefitted invaluable from the help and collaboration of I. G. Nolt of NASA, Langley for his assistance with the detector technology, and of Kelly Chance for his line shape fitting program and his assistance with our studies of upper atmospheric species.

John M. Brown Professor Brown obtained his Ph.D. degree from the University of Cambridge in 1966. Before moving to Oxford in 1983, he was a Lecturer in the Department of Chemistry at Southampton University. He was a high-resolution, gas-phase spectroscopist with a special interest in free radical species. In addition to experimental studies at all wavelengths, he was interested in the development of theoretical models to describe the experimental results. He was elected a Fellow of the Royal Society in 2003. He passed away in 2009 soon after his retirement.

Abstract

As a primary research tool, the laser plays a fundamental role in the spectroscopic study of atomic and molecular systems. This Chapter describes the basic operating principles, configurations, and characteristic parameters of lasers. Laser designs are discussed and then the details of the interaction of the laser light with matter delineated. The reader is also referred to other chapters in the book for further information on laser principles and types of lasers.

Keywords

optical parametric oscillator · gain medium · integrated cross section · frequency comb · hole burning

44.1 Laser Basics

44.1.1 Stimulated Emission

A cross section σ_{21} for absorption of radiation by a lower state 1 engenders a balancing cross section σ_{12} for emission stimulated by radiation interacting with an upper state 2. Detailed balance relates these two cross sections according to

$$g_2\sigma_{12} = g_1\sigma_{21}, \quad (44.1)$$

where g_1 and g_2 are the statistical degeneracies of their respective states [1].

For a collection of emitting and absorbing states with densities n_2 and n_1 , amplification may occur when $n_2\sigma_{12} > n_1\sigma_{21}$, which leads to a requirement for an *inversion* of the state populations

$$n_2/n_1 > g_2/g_1. \quad (44.2)$$

The rate of spontaneous emission at frequency ν can be modeled itself by stimulated emission induced by a noise source of the magnitude of the density of states $\rho(\nu)$

$$\gamma_{12}(\nu) = \sigma_{12}(\nu)\rho(\nu)/c = \sigma_{12}(\nu)8\pi\lambda^{-2}. \quad (44.3)$$

44.1.2 Laser Configurations

A practical laser combines a population inversion with a means for controlling the radiation.

The basic laser source is the laser oscillator, an amplifier possessing positive feedback. The usual form is simply a piece of active gain medium placed inside a resonant optical cavity (Fig. 44.1). Tunability is produced if the resonant cavity is frequency selective and adjustable (Fig. 44.2). Many laser sources use an amplifier after the oscillator.

Fig. 44.1 Simple laser oscillator and beam parameters. Distances z are generally measured from the minimum beam waist w_0 . The beam appears with a far-field divergence angle θ_0

Fig. 44.2 Tunable laser oscillator geometries. **a** Fabry-Perot: tuning is usually done by changing the cavity length, although changing the index of refraction by changing the temperature or current is common with solid state laser diodes. **b** Littrow prism line selector: typical of atomic ion lasers capable of multiple line output. **c** Littrow grating tuning: common in pulsed dye lasers with high gain (> 10) per pass. Telescope increases resolution by filling, and reducing angular divergence at the grating. **d** Grazing incidence, mirror tuned, grating mount

44.1.3 Gain

The fundamental gain per pass is given by

$$G = J/J_0 = \exp[(\kappa - \mu)L], \quad (44.4)$$

where J/J_0 is the ratio of light output to input, κ is the gain coefficient, μ is the nonradiative loss rate, and L is the path length. The gain coefficient

$$\kappa = n^* \sigma_{12} \quad (44.5)$$

depends upon the net inversion n^* ,

$$n^* = n_2 - (g_1/g_2)n_1. \quad (44.6)$$

If λ is the wavelength of radiation, F_{12} is the emission line shape function normalized over frequency ν , τ_2 is the lifetime of the transition, and f_{12} is the branching ratio for the upper state to undergo this transition, then the stimulated

emission cross section is

$$\sigma_{12} = \frac{\lambda^2 f_{12} F_{12}(\nu)}{8\pi \tau_2}. \quad (44.7)$$

For a Lorentzian lifetime-broadened line, the cross section for stimulated emission at the line center becomes

$$\sigma_{12} = \frac{\lambda^2 f_{12}}{4\pi^2 \Gamma_{12} \tau_2}, \quad (44.8)$$

where Γ_{12} is the full width at half maximum of the line.

44.1.4 Laser Light

Lasers are inherently bright sources of radiation: the radiation field within a practical laser must be high enough for stimulated emission to compete with spontaneous emission. The effective source of spontaneous fluctuations approximates that of the density of states. In terms of the beam parameters photon flux J per solid angle Ω , and frequency ν , this is

$$\frac{d^2 J}{d\Omega d\nu} = \frac{2\nu^2}{\epsilon_r c^2}. \quad (44.9)$$

Beam *quality* is given by the product of the angular divergence times the beam width. Highest beam quality is associated with diffraction limited light emitted from a Gaussian spot. For circular laser beams traveling in the z -direction, this corresponds to a solution of the electromagnetic wave equation

$$u(r, \phi, z) = \psi(r, z) \exp(-ikz), \quad (44.10)$$

where u is a polarization component of the field. For high values of $k = 2\pi/\lambda$, corresponding to short wavelength, the adiabatic radial solution is also Gaussian

$$\psi(r, z) = \exp\{-i[P + kr^2/(2q)]\}, \quad (44.11)$$

where the complex phase shift P , beam parameter q , and beam radius w are functions of z

$$P(z) = -i \ln \left[1 - i \frac{\lambda z}{\pi w_0^2} \right] \\ = -i \ln \sqrt{1 + \left[\frac{\lambda z}{\pi w_0^2} \right]^2} - \tan^{-1} \left[\frac{\lambda z}{\pi w_0^2} \right], \quad (44.12)$$

$$q(z) = i\pi w_0^2/\lambda + z, \quad (44.13)$$

$$w^2(z) = w_0^2 \left[1 + \left(\frac{\lambda z}{\pi w_0^2} \right)^2 \right]. \quad (44.14)$$

Here, w_0 is the beam waist parameter, the minimum width of the Gaussian beam at a focused spot. For Gaussian beams, the product of the minimum beam waist and beam divergence angle θ_0 is given by

$$\theta_0 w_0 = \lambda / \pi . \quad (44.15)$$

The beam waist and divergence follow optical imaging according to paraxial ray theory.

Higher order circular modes with p radial nodes and l angular node planes are specified by multiplying Eqs. (44.11) and (44.12) by angular and radial factors to obtain

$$\psi_{pl}(r, \phi, z) = \left(\sqrt{2}r/w \right)^l L_p^l(2r^2/w^2) e^{il\phi} \psi(r, z) , \quad (44.16)$$

$$P_{pl}(z) = (2p + l + 1)P(z) . \quad (44.17)$$

Here, the functions $L_p^l(x)$ are the Laguerre polynomials as defined in Sect. 9.4.2. The radial phase shifts produce a wave front curvature of effective radius

$$R = z + [(2p + l + 1)/2 + w_0^2\pi/\lambda^2]w_0^2\pi/z . \quad (44.18)$$

Modes with the same values of $2p + l$ have identical axial and radial phase shifts. The two polarization components of the electromagnetic field double the degeneracies of all modes considered here. Often these degeneracies are split in practice by optical inhomogeneities of the medium through which they pass. More details can be found in the summary of *Kogelnick and Li* [2], or in the texts by *Verdeyen* [3] or *Svelto* [4].

Some applications require knowledge of the electric field in addition to the flux density J . For purely sinusoidal single mode beams, the rms field is

$$\langle E \rangle = \left(\frac{h\nu J}{c\epsilon_0} \right)^{1/2} . \quad (44.19)$$

Nonlinear effects are often expressed in terms of powers of the field by

$$\langle E^n \rangle = 2^{(n-1)/2} \langle E \rangle^n \quad (44.20)$$

for single mode and multimode radiation of random frequency spacings. For m equally spaced modes, this is increased by $m!/(m-n)!$.

44.2 Laser Designs

44.2.1 Cavities

The simple Fabry–Perot cavity consists of two spherical mirrors facing one another. The surfaces are chosen to be constant phase surfaces for the desired modes in Eq. (44.18).

Fig. 44.3 Stability parameters for simple two-mirror laser cavities of length L and mirror radii of curvature R_1 and R_2 . Here, $x = \frac{1}{2}(L/R_1 - L/R_2)$ is the mean curvature difference of the two mirrors; $y = \frac{1}{2}(L/R_1 + L/R_2)$ is the mean curvature of the two mirrors. Cavities with parameters in the unshaded region are stable

Stability criteria are shown in Fig. 44.3. A cavity is stable when initial angles θ and displacements r of paraxial rays transform during a round trip into θ' and r' satisfying

$$-2 < \frac{\partial\theta'}{\partial\theta} + \frac{\partial r'}{\partial r} < 2 . \quad (44.21)$$

At frequencies for which the round-trip phase change per passage

$$\begin{aligned} \delta(\nu) &= 2\pi(z_2 - z_1)\nu/c + 2[P_{pl}(z_2) - P_{pl}(z_1)] \\ &\approx 2\pi(z_2 - z_1)/\lambda + \pi(2p + l + 1) \end{aligned} \quad (44.22)$$

is an integer multiple of 2π , the phases from different passages interfere constructively, giving longitudinal modes. (Here $P_{pl}(z_i)$ gives the additional phase shift for higher transverse modes at mirrors $i = 1, 2$.)

For a particular radial mode structure in an empty Fabry–Perot cavity, the ratio of the maximum cavity decay time for these standing waves to the minimum cavity decay time for frequencies between longitudinal modes is

$$(1 + r)^2/(1 - r)^2 . \quad (44.23)$$

Here r is the reflectivity of the end mirrors; for cavities with mirrors having different reflectivities, one may use the square

Fig. 44.4 Ring laser. The Faraday rotator and half-wave plate permit circulation of the cavity fields in only one direction

root of the product of their reflectivities. A simple Fabry–Perot cavity may be tuned by changing the cavity length or by changing the index of refraction of the cavity material. Since both of these may be properties of temperature, temperature tuning may be possible. The index of refraction of a material may also be sensitive to the intensity of excitation. Diode lasers consisting of a semiconductor die with polished, reflecting faces are often tuned by changing temperature and pumping current.

For lasers with a dispersive optical element within the cavity, highest selectivity is obtained when the light has low angular divergence and impinges upon the dispersive element as nearly plane waves. A beam expander may reduce the angular spread while simultaneously increasing the beam width. For a grating used as a mirror in a Littrow mount, the dispersion equation is

$$\Delta\lambda = (d/n) \cos\phi \Delta\phi, \quad (44.24)$$

where n is the diffraction order, d is the distance between lines, and ϕ is the angle of incidence off normal.

Cavities with prisms or gratings can be conveniently tuned by rotating the angle of the dispersive element. For a grating used as a mirror in a Littrow mount, the grating equation is

$$\lambda = (2d/n) \sin\phi. \quad (44.25)$$

Often, more than one longitudinal cavity mode operates within the selected frequency band, and tuning consists of *hopping* from mode to mode, rather than smoothly sweeping a single line across a band of frequencies. Smooth frequency tuning can be achieved, for example, in a design by *Wallenstein* and *Hänsch* [5], in which the grating and Fabry–Perot cavity are placed together inside a chamber. The whole laser is then tuned by changing the index of refraction of the gas inside by varying its pressure.

The current trend with pulsed lasers is to use a very lossy, short oscillator cavity in which the longitudinal modes are nearly absent, making up for the cavity losses with a very high gain lasing medium. The front, output mirror of such a cavity may actually be *antireflection* coated, with a reflectivity of only a percent or less.

Low gain, continuous wave (cw) lasers often use a combination of cavity length tuning along with dispersive element rotation, such as a prism or Lyot filter. Often, lasing on a traveling wave in a ring configuration is used to avoid longitudinal modes, as illustrated in Fig. 44.4. Some commonly used gain media are listed in Tables 44.1 and 44.2.

44.2.2 Pumping

Many methods, including electrical discharges and flash-lamps, have been used to pump the gain media of lasers. Generally, the best pump is another laser.

Two notable pump lasers have dominated the field of tunable, visible lasers: pulsed neodymium YAG, frequency doubled to ≈ 503 nm, and cw Ar II ion at 514.5 nm. Both are extremely effective at exciting the highly efficient rhodamine class dyes in the red–yellow portion of the visible spectrum. The typical pump beam of a Nd/YAG laser enters the amplifying dye cell transversely along one of the faces of the cell. The typical cw pump beam enters the dye almost collinearly with the laser axis.

By temporarily *spoiling* the Q by making the laser cavity lossy, lasing can be held off until the gain medium stores a greater energy density than the minimum required for lasing. Rapidly switching off the loss mechanism releases this energy in one giant pulse. An electronic optical shutter, such as a Pockels cell, or a saturable dye inside the laser cavity, designed to photobleach from the spontaneous emission just before the laser reaches threshold, are commonly used.

Periodically spoiling the laser gain or the cavity Q at the period of a round trip produces intense, short pulses. Viewed from the frequency domain, the phases of individual longitudinal modes are *locked* together to produce a light packet circulating at the frequency of the reciprocal of the mode spacing. Extremely short pulses (< 1 ps) can be produced by mode locking. Practically, mode locking can be achieved by using a thin, saturable absorber near one of the cavity mirrors [6], or by acoustically modulating an optical element in the cavity – even an end mirror itself. One of the best ways of mode locking is to pump a short lifetime gain medium, such as a dye, with mode locked laser light, such as from a mode locked argon ion laser [7].

44.3 Interaction of Laser Light with Matter

44.3.1 Linear Absorption

The absorption cross section σ_{fi} for transition to the final state $|f\rangle$, when integrated over frequency ν , is given theoretically by the leading first-order perturbation of the initial

Table 44.1 Fixed frequency lasers

Laser	Wavelength (nm)	Excitation method
ArCl	≈170 (band)	Pulsed, gas discharge
ArF	≈193	Pulsed, gas discharge

state $|i\rangle$ in the electric dipole approximation

$$\int \sigma_{fi}(v) dv = 4\pi^2 \alpha \bar{v} \left| \langle f | \sum_e \mathbf{r}_e \cdot \hat{\boldsymbol{\epsilon}} | i \rangle \right|^2, \quad (44.26)$$

where the sum is over all charges e at distances r_e , $\hat{\boldsymbol{\epsilon}}$ is a unit polarization vector, and \bar{v} is the averaged transition energy. Averaged over orientations and summed over possible final states, each electron contributes to the total integrated absorption cross section one electron oscillator, $\pi r_0 c \approx 0.03 \text{ cm}^2 \text{ s}^{-1}$; here, r_0 is the classical electron radius. Electronic absorption bands typically contain an oscillator strength $f = 0.01\text{--}0.5$ of an *electron oscillator*, while weaker vibrational transitions have $f = 10^{-6}\text{--}10^{-4}$ in each band.

For narrow lines with radiation of broader band width $\Delta\nu$ at flux density J , the linear absorption rate constant can be usefully estimated as $(\pi r_0 c) f J / \Delta\nu$.

44.3.2 Multiphoton Absorption

Second-order perturbation theory gives the theoretical two-photon contribution to the absorption. An absorption cross section $\sigma^{(2)} J_1$ for a photon of frequency ν_2 is induced by an off-resonance monochromatic field of frequency ν_1 and photon flux density J_1 . When integrated over the frequency of the second photon, the second-order cross section can be related to the dipole matrix elements

$$\int \sigma_{fi}^{(2)}(\nu_1, \nu_2) J_1 d\nu_2 = \frac{4\pi^2 \alpha^2}{\nu_1 \bar{\nu}_2} J_1 \times \left| \sum_m \frac{\nu_{fm} \nu_{mi} \langle r_{fm} \rangle \langle r_{mi} \rangle}{\nu_{mi} - \nu_1} \right|^2, \quad (44.27)$$

where

$$\begin{aligned} \langle r_{fm} \rangle &= \langle f | \sum_e \mathbf{r}_e \cdot \hat{\boldsymbol{\epsilon}}_2 | m \rangle, \\ \langle r_{mi} \rangle &= \langle m | \sum_e \mathbf{r}_e \cdot \hat{\boldsymbol{\epsilon}}_1 | i \rangle, \end{aligned} \quad (44.28)$$

and the sum is taken over intermediate states $|m\rangle$ having frequencies ν_{mi} and ν_{fm} for transitions to the initial and final states. The energy for the overall transition comes from two photons; hence the two-photon resonance condition $\nu_{fi} = \nu_1 + \nu_2$. A special case often occurs when only one radiation frequency is used: then $\nu_1 = \nu_2$, and two-photon resonance is achieved when the energy of the transition corresponds to twice the frequency of the radiation field.

This integrated, induced cross section is roughly of the order $\alpha(\pi r_0 c)^2 J_1 / (\nu_1 \bar{\nu}_2)$. Two-photon absorption becomes

comparable to the one-photon absorption with off-resonance fields on the order of

$$J_1 \approx \frac{\nu_1 \nu_2}{\alpha \pi c r_0}, \quad (44.29)$$

or about $10^{21} \text{ photons s}^{-1} \text{ cm}^{-2}$ ($10^{17} \text{ W m}^{-2} \text{ s}^{-1}$ for typical green light).

Typical dipole-allowed molecular multiphoton absorption cross sections are $\approx 10^{-58} \text{ m}^4 \text{ s}$ for two photons and $10^{-94} \text{ m}^6 \text{ s}^2$ for three photons.

Multiphoton absorption was one of the first effects explored with lasers. Two-photon absorption was first reported for inorganic crystals containing europium ions [8]. Blue and ultraviolet fluorescence appeared in the interaction of red ruby laser light with organic compounds [9–12]. Others observed two-photon absorption directly [13, 14]. Selection rules for multiphoton absorption are summarized by *McClain* [15]; recent work is reviewed by *Ashfold* and *Howe* [16].

Highly excited states may subsequently ionize in the intense fields in a multiphoton ionization (MPI) process. The ionization signal is often detected in a proportional ionization cell. A low pressure cell containing the vapor of a transition metal organometallic, such as iron carbonyl or ferrocene which photodissociates to give the metal atom, may be used for wavelength calibration by MPI.

44.3.3 Level Shifts

High radiation power causes resonant frequencies to shift, responding to the ac Stark effect [17, 18]. Even moderate fields, tuned near resonance, interact strongly with an atom or small molecule, which undergoes rapid excitation and stimulated emission at the characteristic power dependent Rabi frequency,

$$\nu_{\text{Rabi}} = \frac{2\pi g_1}{g_1 + g_2} \sigma_{21} J. \quad (44.30)$$

Fluorescence from such an interacting system has a characteristic *head and shoulders* spectrum best understood as radiation at the fundamental frequency amplitude modulated at the Rabi frequency [19].

44.3.4 Hole Burning

Radiation at a particular frequency generally moves population out of states that absorb that radiation. Molecules that interact resonantly with the radiation may also spontaneously emit at different frequencies, thereby ending in nonabsorbing states. This optical pumping effect can make resonance

features in an absorption spectrum disappear at high power levels [20]. Depletion may appear as a *hole* in the absorption spectrum [21]. Recently, interest has shifted to permanent *hole burning* as a method of information storage in materials.

Hole burning is the basis for Doppler-free Lamb-dip spectroscopy, in which only absorbing atoms or molecules having little or no velocity component along the axis of two counterpropagating beams are temporarily depleted [22]. This technique is commonly used for laser frequency stabilization, such as with the iodine-locked He–Ne laser.

44.3.5 Nonlinear Optics

Multiplying

Nonlinear susceptibility of an optical medium can generate radiation at frequencies which are multiples of the frequency of laser radiation passing through. Phenomenologically, the second order polarization

$$P_{2\nu} = \epsilon_0 \chi^{[2]} E_\nu^2 \quad (44.31)$$

is given in terms of the second order nonlinear susceptibility $\chi^{[2]}$, a third rank tensor, and the electric field at the fundamental frequency (see Chap. 76). This nonlinear susceptibility can range from 0.5–5 pm/V for typical materials used for frequency doubling. Typical materials and their use are reviewed by *Bordui* and *Fejer* [23].

For a nonlinear process occurring over a length l in a cylindrical region with Gaussian waist w_0 with polarization P_0 on axis, the far field flux is given by

$$J(R, \theta) = \frac{\pi^4 \nu^3 n^3 w_0^4 P_0^2}{4hc^3 \epsilon_0 R^2} \left(\frac{\sin^2[(k_0 - k \cos \theta)l/2]}{(k_0 - k \cos \theta)^2} \right) \times \exp[-k^2 w_0^2 \sin^2(\theta)/2]. \quad (44.32)$$

Here, n is the index of refraction and k the propagation constant for the induced radiation, while k_0 is that for the induced polarization, the vector sum of those of the original radiation. When phase matched, $k_0 - k \cos \theta = 0$, and the term in the brackets maximizes to $(l/2)^2$.

The greatest difficulty is in selecting materials which can be phase matched such that the relative phases of the fundamental and overtone radiation propagate together through the material; otherwise radiation at the higher frequency generated at different places inside the material destructively interfere. Phase matching is usually achieved by either angle tuning of a birefringent crystal, or by temperature tuning.

Only materials without a center of inversion in their crystal structures have a second order nonlinear susceptibility. All materials, including gases, will have a third order nonlinear susceptibility $\chi^{[3]}$. This can be used to generate

third harmonics, especially in the vacuum ultraviolet (VUV), where doubling materials are not available [24, 25].

Mixing

The same materials that permit frequency doubling and tripling also allow 3-wave and 4-wave frequency mixing. The frequency matching conditions are, respectively,

$$\begin{aligned} \nu_1 \pm \nu_2 &= \nu_3, \\ \nu_1 \pm \nu_2 \pm \nu_3 &= \nu_4. \end{aligned} \quad (44.33)$$

Tunable UV radiation may be generated by adding the frequencies of a fixed and tunable visible outputs. Tunable IR has been obtained by differencing fixed and tunable visible lasers. Mixing of radiation from an Ar ion laser with that from a tuned R6G dye laser in lithium iodate to produce tunable 2200–4600 nm radiation is noteworthy.

Optical Parametric Oscillator

It is possible to reverse 3-wave mixing, generating two frequencies whose sum is that of the input radiation. In parametric generation, the output frequencies are given by the phase match conditions. Both the desired frequency and the secondary *idler* frequency must be allowed to build up in the nonlinear medium. The idler radiation is not present initially, but results from the frequency mixing process itself. The process has many of the characteristics of a laser oscillator, including that of a gain threshold. This makes tuning of an optical parametric oscillator similar to that of a laser, but with more degrees of freedom: now oscillation at two frequencies must be attained simultaneously, along with the correct *phase matching* of the nonlinear material [26].

44.3.6 Raman Scattering

It is possible to have one or more of the fields in a mixing process belong to just polarization, rather than radiation. The frequency additive case of multiphoton absorption has already been considered; the frequency subtractive case is Raman scattering.

Incoherent Raman Scattering

Radiation at a higher frequency can excite a lower frequency vibration or rotation within a material, with appearance of radiation at the frequency of the incident radiation minus that of the absorption. The integrated cross section for this effect is given by Eq. (44.27). However, in this case the cross section is for *emission* of the second photon. The rate of spontaneous Raman emission is obtained by multiplying Eq. (44.27) by the spectral flux density of the zero-point field, $8\pi \nu^2 / \epsilon_1 c$. Typical vibrational Raman cross sections for

transparent molecules are about $10^{-34} \text{ m}^2 \text{ sr}^{-1}$ in the blue-green (488 nm) [27].

Alternatively, energy can be extracted from an excited state, with the inelastically scattered photon departing with the sum of the incident frequency and that of the deexcitation. The term *anti-Stokes* distinguishes it from the more usual *Stokes* type of Raman scattering.

Coherent Raman Emission

The integrated cross section for emission stimulated at the Raman frequency is given directly by Eq. (44.27).

A fourth-order mixing process that is less susceptible to saturation involves coherent anti-Stokes Raman scattering (CARS). Two beams excite the material: the difference of their frequencies corresponds to an excitation of the material. Stimulated Raman scattering excites the material, which then deexcites through an anti-Stokes process, giving rise to a third, higher frequency radiation field. The phase is determinate, and the radiation leaves the region of scattering as a beam [28].

If the incident radiation induces a Raman process over a sufficiently long path, the stimulated Raman process can be used for gain at both the Stokes and anti-Stokes frequencies. Since spontaneous Raman processes are proportional to the integrated cross section, while gain in the stimulated Raman process is proportional to the peak cross section, simple materials with sharp, simple line spectra are most suitable for Raman gain media. While Raman lasers have been produced using vibrational excitation of organic liquids, currently the most important technical application is for Raman shifting the output of lasers, tunable or otherwise, to frequencies which otherwise would be inaccessible. The high pressure H_2 Raman shifter produces, at low powers, beams consisting almost entirely of well separated, sharp lines shifted by 4160 cm^{-1} from the pump beam; at high powers, a series of Stokes and anti-Stokes bands appear, each separated by 4160 cm^{-1} from each other.

44.4 Recent Developments

One of the most exciting advancements in the past decade in laser physics has been the generation of optical frequency combs; and, more specifically, their applicability in the domain of high-resolution laser spectroscopy. Basically, through a superposition process of many continuous wave modes, a short train of frequency spikes may be produced from a mode-locked laser [29] (see also Sect. 30.1.5). These spikes are equally spaced and are referred to as a frequency comb. The frequency ω_n of the n -th cavity mode may be expressed as

$$\omega_n = n\omega_r + \omega', \quad (44.34)$$

where ω_r is characteristic of the laser and ω' is a frequency offset due to the difference between the phase and group velocity of the superposed waves.

The microwave frequencies ω_r and ω' are determined through the use of nonlinear optics. Once these two parameters are determined, any unknown optical frequency ω_o may be measured by recording the beat frequency between it and the closest comb frequency. This technique gives experimenters a high-precision method for the spectroscopic determination of such fundamental quantities as the fine structure constant, the Rydberg constant, and the Lamb shift [30, 31].

Abstract

Cavity-enhanced spectroscopy (CES) methodology provides a much higher degree of sensitivity than that available from conventional absorption spectrometers. The aim of this chapter is to present the fundamentals of the method and the various modifications and extensions that have been developed. In order to set the stage, the limitations of traditional absorption spectrometers are discussed first, followed by a description of cavity ring-down spectroscopy (CRDS), the most popular CES embodiment. A few other well-known CES approaches are also de-

scribed in detail. The chapter concludes with a discussion of recent work on extending CRDS to the study of liquids and solids.

Keywords

cavity ring-down spectroscopy · tunable diode laser absorption spectroscopy · cavity · effective path length · integrated cavity output spectroscopy

45.1 Limitations of Traditional Absorption Spectrometers

An absorption spectrometer measures the difference in intensity between the incident light intensity I_0 and the transmitted light intensity $I(x, \lambda)$. Beer's law relates the absorbed light to the sample absorption $\alpha(\lambda)$

$$I(x, \lambda) = I_0 e^{-\alpha(\lambda)x}, \quad (45.1)$$

where λ is the wavelength, and x is the path length. Absorption is related to concentration C through the extinction coefficient $\varepsilon(\lambda)$, namely $\alpha(\lambda) = C\varepsilon(\lambda)$. Typically, a spectral feature, called an absorption peak, of the target species is measured in order to obtain its concentration. The performance of a spectrometer has two figures of merit: sensitivity and selectivity.

Sensitivity is the smallest detectable change in 1 cm of path length that a spectrometer can measure during 1 s. If many measurements can be made within a second, averaging may be used to further improve (by a factor of the square root of the number of measurements or the square root of the data acquisition rate) the achievable sensitivity. Sensitivity has units of $\text{cm}^{-1} \text{Hz}^{-1/2}$. Sensitivity can also be quantified using the minimum detectable absorption loss (MDAL), i.e., the normalized standard deviation of the smallest detectable change in absorption (units of cm^{-1}). Equation (45.1) shows

that the sensitivity of a spectrometer depends not only on the light path's length through the sample but also on the intensity noise of the light source.

Selectivity is the ability of a spectrometer to distinguish between two different species absorbing at similar wavelengths. The instrument must be able to resolve the different spectral lines. Thus, selectivity depends on spectral resolution, which has units of frequency (MHz), wavelength (nm), or wavenumbers (cm^{-1}).

Traditional spectrometers, such as nondispersive infrared (NDIR) and Fourier transform infrared (FTIR), use incoherent thermal light sources. For both techniques, the physical length of their sample chamber limits their sensitivity. Some devices try to fold the light path several times through the sample chamber in order to improve sensitivity, but this approach encounters physical size and mechanical stability limitations. Typical MDAL are in the 10^{-5} cm^{-1} range. These instruments, therefore, rely on measuring the strongest absorption transitions available, which are found in the mid-infrared range (3 to $12 \mu\text{m}$). Often, however, the strongest transitions overlap with features of other species found in the sample mixture. The instrument's performance becomes a sensitivity–selectivity tradeoff.

Laser-based optical detection methods, called tunable diode laser absorption spectroscopy (TDLAS), circumvent some of these problems by exploiting the coherent nature of laser light. A tunable continuous-wave laser source brings two benefits:

- A narrow linewidth, which allows high spectral resolution scans to be performed.
- Low spatial beam divergence, which allows it to be folded hundreds, if not thousands, of times.

By transmitting laser light with a small beam size over long distances, multipass cells can be designed to achieve up to a kilometer of path length enhancement. Multipass cell laser spectroscopy systems have demonstrated MDAL down to 10^{-9} cm^{-1} . However, such instruments still remain limited by laser intensity fluctuations and interference fringes. Moreover, standard multipass techniques do not provide an absolute optical loss measurement.

45.2 Cavity Ring-Down Spectroscopy

Cavity ring-down spectroscopy (CRDS) is a more recently developed TDLAS approach that replaces a multipass cell with a stable optical resonator, called the ring-down cavity (RDC). CRDS is based on the principle of measuring the rate of decay of light intensity inside the RDC. The transmitted wave decays exponentially in time. The decay rate is proportional to the total optical losses inside the RDC.

In a typical CRDS setup, light from a laser is first injected into the RDC, and is then interrupted. The circulating light inside the RDC is both scattered and transmitted by the mirrors on every round-trip and can be monitored using a photodetector placed behind one of the cavity mirrors. The decay constant, also called the ring-down time τ , is then measured as a function of the laser wavelength to obtain a spectrum of the cavity optical losses. Detailed mathematical treatments of CRDS can be found in [1]. A simple derivation is presented here.

For a given wavelength λ , the transmitted light $I(t, \lambda)$ from the RDC is given by

$$I(t, \lambda) = I_0 e^{-\frac{t}{\tau(\lambda)}}, \quad (45.2)$$

where I_0 is the transmitted light at the time the light source is shut off, and $\tau(\lambda)$ is the ring-down time constant. The total optical loss inside the cavity is $L(\lambda) = [c\tau(\lambda)]^{-1}l_{\pi}$, where c is the speed of light. The total optical loss comprises the empty cavity optical loss and the sample optical loss. CRDS provides an absolute measurement of these optical losses. The empty cavity (round-trip) optical loss $L_{\text{empty}}(\lambda)$ comprises the scattering and transmission losses of the mirrors. In general, better mirrors provide lower empty cavity losses and higher sensitivity. The sample (round-trip) optical loss is $A(\lambda) = \alpha(\lambda)l_{\pi}$, where l_{π} is the cavity round-trip length and is simply the difference between total cavity losses and empty cavity losses, namely $A(\lambda) = L(\lambda) - L_{\text{empty}}(\lambda)$. Once the absorption spectrum $\alpha(\lambda)$ of the sample has been measured, the sample concentration can be readily computed using the absorption cross section and lineshape parameters.

The MDAL for a CRDS system is defined by

$$\alpha_{\min} = \frac{1}{l_{\text{eff}}} \left(\frac{\Delta\tau}{\tau} \right), \quad (45.3)$$

where $(\Delta\tau/\tau)$ is called the shot-to-shot noise of the system. The effective path length of a CRDS measurement is $l_{\text{eff}} = c\tau$. For typical RDC mirrors with a reflectivity of 99.995% and scattering losses of less than 0.0005%, the path length enhancement can exceed 20,000. For a 20 cm long sample cell, the effective path length is 8 km, which exceeds the best performance of multipass spectroscopy by a factor of 3, based on the effective path length alone. A good CRDS system can achieve a shot-to-shot variation of 0.03%, leading to an MDAL of $4 \times 10^{-10} \text{ cm}^{-1}$. Note also that the CRDS measurement is not dependent on either the initial intensity of the light inside the cavity, provided that the signal has a sufficient signal-to-noise ratio at the detector, or on the physical sample path length like traditional absorption spectroscopy. Moreover, CRDS can use laser sources with narrow linewidths and achieve high spectral resolution.

CRDS can resolve all three limitations of absorption spectroscopy, namely sensitivity, selectivity, and dependence on

Fig. 45.1 Typical P-CRDS setup

the intensity noise of the light source [1]. CRDS has been implemented using many different approaches. This chapter will discuss several commonly used variations on the CRDS technique.

45.2.1 Pulsed Cavity Ring-Down Spectroscopy

Early implementations of CRDS used pulsed laser sources (P-CRDS) [2]. A typical P-CRDS setup is shown in Fig. 45.1. Today, CRDS has been implemented in the broadest possible range of wavelengths, from the UV (216 nm) to the mid-infrared (10 μm). Because of its experimental simplicity, P-CRDS has become a widespread tool for chemists and spectroscopists, finding applications in the measurement of predissociation dynamics, photolysis products, radiative lifetimes, aerosols or soot detection, temporal imaging, overtone vibrational spectroscopy, and kinetic studies. Typical P-CRDS sensitivity is $1 \times 10^{-9} \text{ cm}^{-1} \text{ Hz}^{-1/2}$.

P-CRDS methods have also been combined with other detection methodologies. Variations on P-CRDS include:

- Fourier-transform (FT) P-CRDS [3], where an RDC is excited with a broadband source, and time-resolved FT scans of the RDC output waveform are taken. Inversion of the interferogram then produces time-dependent ring-down waveforms at all resolved frequencies within the source wavelength range.
- Polarization P-CRDS [4], where the spectral splitting induced by the magnetic field is observed from the difference of the ring-down spectra of the two orthogonal polarizations.
- Pulse-stacked P-CRDS [5], where the length of the RDC is set so that pulses from a very high repetition rate pulsed source coherently add together, which increases the effective cavity light throughput to yield improved detection of the ring-down waveform.

The spectral resolution and sensitivity of P-CRDS are, however, limited by the use of short-pulse lasers. The effects of pulsed laser bandwidth on spectral resolution of P-CRDS

have been studied extensively and have led to system designs where only a single longitudinal and transverse mode of the RDC is excited [6]. However, single-mode P-CRDS is difficult to implement experimentally and still has limited sensitivity because the laser pulse is substantially attenuated by the RDC mirrors at the cavity output. The requirement for both improving CRDS sensitivity by reducing the variability in the measurement of the decay constant from shot to shot with single-mode excitation and improving the light transmission through the cavity to increase the signal-to-noise ratio of the decay waveform on the detector, provided the catalyst to implement continuous wave (CW) lasers in CRDS.

45.2.2 Continuous-Wave Cavity Ring-Down Spectroscopy (CW-CRDS)

CW lasers have narrow linewidths (< 50 MHz) and can be tuned in small spectral increments (< 50 MHz) to achieve high spectral resolution with excellent wavelength reproducibility. Moreover, owing to their narrow linewidths, they are better suited for efficient coupling into a single mode of a high finesse RDC, thereby reducing shot-to-shot variations in the measured ring-down decay constant. Furthermore, they can be directly modulated, thereby allowing higher data repetition rates, which, in turn, leads to improved sensitivity.

The first efforts in CW-CRDS involved optically locking a laser diode to a high-finesse cavity, but the performance was limited because the laser diode would drift and lock to different RDC modes. The use of sufficient optical isolation and an external optical switch resolved this issue. The most common approach used today is to sweep a RDC mode through the emission profile of a diode laser and shut the laser off with an acousto-optic modulator (AOM) (Fig. 45.2) when sufficient light is injected into the cavity [7]. Numerous variations on this approach exist. For example, CW-CRDS can be implemented by rapidly sweeping the cavity mode into and out of resonance with the laser. The simplest approach is to sweep the laser wavelength into and out of resonance with a cavity mode and directly modulate the laser source current [8]. The most popular CW lasers used today are distributed feedback (DFB) diode lasers.

In most CW-CRDS embodiments, the ring-down cavities are linear, i.e., consist of two mirrors. Ring resonators (e.g., triangular or bow-tie cavities) can also be used. Ring cavities provide the benefits of minimizing optical feedback and eliminating the need for extensive isolation or frequency shifting of the laser source. Moreover, ring resonators break the frequency degeneracy between cavity modes with orthogonal polarizations, effectively creating two coupled resonators with high and low finesse, respectively. The low-finesse cavity can be used to lock the laser

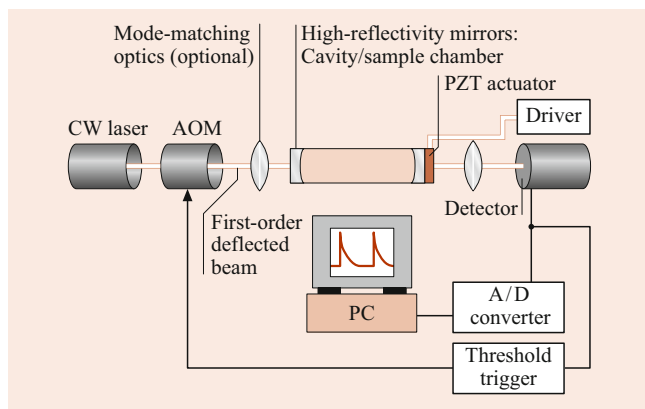

Fig. 45.2 Typical CW-CRDS setup

to single-cavity mode, while the high finesse cavity can be used for CRDS. The AOM acts as both a frequency-shifter and an on-off switch. This method was used to demonstrate the highest CRDS sensitivity achieved to date, namely $1.0 \times 10^{-12} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ [9].

Prism-based, rather than mirror-based, cavities have also been used [10]. Such cavities comprise two prisms whose intracavity facing angles are at Brewster's angle, and whose extracavity facing angles are such that total internal reflection occurs and results in unit reflectivity. One of the prisms has a curved facet to create a stable optical resonator. The purpose of this design is to extend operation over a much broader range of wavelengths than can be achieved using dielectric coatings. Currently, high-reflectivity mirrors are limited in bandwidth to about $\pm 15\%$ of their center wavelength.

CW-CRDS has been applied over a wide range of wavelengths. It has been used for medical breath analysis, trace gas detection in environmental and process control applications, and isotopic analysis. In the near-infrared, CW-CRDS systems achieve sensitivities of $10^{-11} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ and a concentration measurement repeatability of 1 part in 5000. Similar performance in the mid-infrared ($3 \mu\text{m}$) resulted in the detection of parts-per-trillion ethylene concentrations [11].

Extensions of the basic CW-CRDS technique have also been developed:

- Phase-shifted CW-CRDS [12]: the phase shift accrued by a sinusoidally modulated CW laser is measured for both an empty RDC and one with a sample. The concentration is deduced from these two measurements.
- Heterodyne CW-CRDS [13]: enhances the power in the ring-down decay waveform by mixing with a local oscillator. For example, the local oscillator can be the orthogonal polarization used to lock the laser to the RDC or can be the reflected signal from the RDC when laser is frequency shifted (by the local oscillator frequency) off resonance from the RDC mode. Heterodyne CRDS can approach the shot-noise limit.

- V-cavity CW-CRDS [14]: a three-mirror V-shaped RDC is exploited to achieve consistent repetitive optical locking of a DFB diode laser to a single cavity mode, thereby significantly enhancing light throughput.

CW-CRDS is now maturing to a level of robustness and reliability such that it can be commercially deployed in industrial applications, where the sensitivity requirements can no longer be met by FTIR, NDIR, or gas chromatography.

45.3 Cavity-Enhanced Spectroscopy

Most CRDS systems capture the ring-down waveform using a digital oscilloscope. The Levenberg–Marquardt (LM) method produces the optimal fit, so that LM methods have become the de-facto *gold standard* in CRDS [15]. However, the LM algorithm can require multiple iterations, thereby limiting the data acquisition times to several hundred Hz. Fast-fitting algorithms that closely approximate the LM fit but allow data acquisition rates up to 10 kHz have recently gained widespread deployment [16]. Today, the data acquisition rates are no longer limited by the back-end numerical fit. Rather, the speed of CRDS systems is limited by the speed of laser modulation itself.

Cavity-enhanced spectroscopy (CES) was developed in an effort to simplify CRDS and eliminate the requirement for the digitization of a time-domain signal and laser modulation. CES has many different implementations. All CES methods are based on the principle that the buildup of intracavity power, and hence cavity throughput, depends on intracavity losses, which include absorption by a sample. CES involves measuring the steady-state transmission through a cavity as a function of wavelength in order to determine changes in the integrated transmitted intensity caused by the absorbing species.

For a cavity with two mirrors of intensity reflectivity, R , and length, L , the effective steady-state path length is $L_{\text{eff}} = L/(1 - R)$. If an absorbing gas is present, the reflectivity will be reduced by the Beer–Lambert factor $e^{-\alpha L}$ namely $R' = R e^{-\alpha L}$, so that one can effectively relate the ratio R'/R to the Beer–Lambert ratio I/I_0 for a single pass. The steady-state transmitted laser intensity for such a cavity is given by $I = I_L C_p T [2(1 - R)]^{-1}$, where T is the intensity transmissivity, I_L is the laser intensity, and C_p is the coupling efficiency in the cavity mode. Thus, for an absorbing gas, the change in transmitted intensity at a given wavelength is

$$\Delta I/I = GA(1 + GA)^{-1}, \quad (45.4)$$

where $A = 1 - e^{-\alpha L}$ and $G = R/(1 - R)$ so that for $\alpha L \ll 1$, $(\Delta I/I) \approx GA \approx G\alpha L$. This latter relation has been interpreted as a linear response in absorption loss, multiplied by

an effective cavity *gain* of $R/(1 - R)$, i.e., the absorbance is measured over the effective length of the cavity, which corresponds to the number of cavity passes occurring within the cavity ring-down time constant. Note that the transmitted power level will be attenuated by the mirror transmissivity, T , so that these methods are limited by laser power and detector sensitivity.

Because CES techniques measure transmitted light intensity, they are no longer immune to laser intensity noise. Furthermore, when the absorbance becomes comparable to the cavity loss, the sensitivity improvement of CES saturates, as the sample absorption begins to dominate the effective number of cavity passes. Note that in this case, the effective path length becomes a function of the sample concentration, which underlines another limitation of CES: this technique is not independent of the cavity length and, hence, depends on cavity alignment. Moreover, CES systems are not self-calibrated to the species extinction coefficient, and therefore require calibration against a known sample concentration, or against the absolute cavity loss, often measured using CRDS. Finally, it should be noted that the rate of data collection in CES is limited by the RDC time constant, because the cavity acts like a single-pole, low-pass filter with a 3 dB frequency of $(2\pi\tau)^{-1}$, which can range from 5 to 50 kHz. Unlike CRDS, CES does not require fast digitization of the decay waveform followed by a nonlinear fit, so that the data acquisition hardware can be a much slower, less expensive A/D converter, and spectral data can be acquired almost instantaneously.

Five distinguishable variants of CES have been developed and are discussed. The first three methods, called cavity-enhanced transmission spectroscopy (CETS), find their origins in CRDS. These methods are cavity-enhanced absorption spectroscopy (CEAS) [17], integrated cavity output spectroscopy (ICOS) [18], and off-axis ICOS [19]. For these three approaches, the laser intensity is no longer interrupted to observe a *ring-down event*, although the path-length enhancing properties of the RDC remain. More sensitive CES methods involve locking the laser to the cavity mode resonance. These will be referred to as locked cavity-enhanced transmission spectroscopy and have two variations: locked cavity-enhanced transmission spectroscopy (L-CETS) [20] and noise-immune, cavity-enhanced optical heterodyne molecular spectroscopy (NICE-OHMS) [21].

45.3.1 Cavity-Enhanced Transmission Spectroscopy (CETS)

CETS has been implemented using several variations, all of which are based on measuring the time-integrated transmission through a high-finesse RDC as a function of the wavelength. As stated earlier, the transmitted light provides

an effectively enhanced path length to any sample absorption inside the cavity. In all CETS approaches, the transmitted light intensity is a small fraction [about $(1 - R)$] of the incident intensity, which reduces the signal to noise on detection, so that averaging is required. All CETS approaches are also dependent on laser intensity noise and sample path length.

The tradeoff in using a high-finesse cavity is that in steady state, its transmission is a nonuniform function of the wavelength and consists of a series of sharp cavity mode peaks, namely the transverse and longitudinal modes. This transmission pattern repeats itself periodically in every free spectral range (FSR). The density of the mode spacing is a function of the cavity design: the round-trip length and the mirror radius of curvature. The quality of mode matching between the laser and the RDC determines the number of modes into which light can couple efficiently.

CEAS is the simplest CETS approach: the laser, coupled through an RDC, is tuned in wavelength over the absorption feature of interest, and the integrated cavity transmission is measured as a function of the wavelength [17]. The cavity length is free-running (neither modulated nor locked to the laser). In order to minimize the nonuniformity of the cavity transmission, CEAS exploits cavity geometries such that the inherent mode structure is as dense as possible. No mode matching is employed, so that laser light is coupled into as many modes as possible. The laser is scanned multiple times over the cavity modes in order to time average over the unstabilized cavity length. Extensive averaging can be required to achieve reasonable performance. The residual mode structure of the cavity can be significant and produces intensity modulation in the spectrum. Typically, the laser linewidth is larger than the individual cavity mode resonances, so that the output can be very noisy. CEAS does appear to have mechanical stability advantages, in that a cavity length change or deformation is, in fact, desirable to randomize the excited modes over wavelength. Typical sensitivities of CEAS range from 5×10^{-7} to $10^{-9} \text{ cm}^{-1} \text{ Hz}^{-1/2}$.

ICOS tries to achieve uniform transmission through the RDC by systematically disrupting the cavity mode resonances in order to recover the frequency-averaged response of the cavity as a function of the wavelength [18]. RDC length modulation was implemented by either moving one of the cavity mirrors using a piezo-electric transducer (PZT) or by slightly modulating the angle of injection in the cavity using a PZT-driven mirror mount. When the laser is scanned over the desired wavelength range with only the RDC modulation sweeping the modes (5 to 10 free spectral ranges), the resulting absorption spectra show an intensity modulation of about 10%. This intensity modulation results from a periodic nonuniformity in the mirror movement at the turning points of the PZT modulation, where the increased overlap time between the cavity mode and laser produces a higher

Fig. 45.3 Typical off-axis ICOS setup

transmitted light intensity. In order to eliminate this intensity modulation, the laser wavelength is frequency modulated simultaneously. The typical sensitivity of the ICOS approach is about $2 \times 10^{-7} \text{ cm}^{-1} \text{ Hz}^{-1/2}$.

A third approach, called off-axis ICOS, resolves the cavity transmission uniformity problem of CEAS and eliminates the need for modulation of ICOS. In off-axis ICOS, shown in Fig. 45.3, the RDC is aligned so as to generate a set of spatially separated reflections within the cavity that eventually satisfy the reentrant condition [19]. Furthermore, the mirrors are slightly astigmatized, which results in Lissajous spot patterns on the mirrors. The combination of this alignment and slight astigmatism significantly reduces the RDC mode degeneracy. As a result, the cavity mode spacing can become smaller than the cavity mode width and the cavity transmission appears to become largely frequency independent, or *white*. Thus, the RDC provides path length enhancement without introducing intensity noise in the transmitted spectrum. However, increasing the number of spots on the mirrors usually requires larger mirrors (e.g., 2 inches for off-axis ICOS versus 0.5 inches for CRDS), which in turn results in a larger cavity (sample) volume. In cases of low sample flow, sample chamber filling times can limit the measurement time. Moreover, the system is now dependent on the mechanical stability of the cavity and the laser to cavity alignment. The best off-axis ICOS sensitivity achieved to date is $3 \times 10^{-11} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ and is comparable to CW-CRDS.

45.3.2 Locked Cavity-Enhanced Transmission Spectroscopy (L-CETS)

An alternative approach (L-CETS) achieves higher sensitivity by locking the laser frequency to a single cavity resonance and then scanning the cavity over the absorption feature of interest [20]. In this case, the cavity throughput becomes uniform across the entire spectral scan, and the cavity transmission increases to the maximum theoretical value, leading to better signal to noise at the detector than CETS ap-

proaches. Laser wavelength jitter at high frequencies, which cannot be compensated by the locking control loops, will lead to increased noise in the spectral scans. In order to lock the laser and cavity together robustly, the laser linewidth typically cannot exceed the cavity mode resonance linewidth, so that for a high-finesse sample cavity, the laser choice can be limited. Sensitivities of $10^{-11} \text{ cm}^{-1} \text{ Hz}^{-1/2}$ have been demonstrated using L-CETS.

The NICE-OHMS technique was developed to overcome the dependence of L-CETS on laser wavelength jitter [21]. NICE-OHMS combines the benefits of frequency modulation (FM) spectroscopy with the path length enhancements of a high-finesse optical resonator. The technique is called *noise immune*, because it does not depend on the quality of the laser and cavity lock. Effectively, it is immune to laser frequency noise, although residual amplitude modulation can reduce the performance. NICE-OHMS sensitivity depends on the laser power transmitted, the efficiency and bandwidth of the photodetector, and the FM modulation index. NICE-OHMS has exploited cavities with a finesse of 100,000 to achieve sensitivities of $1 \times 10^{-14} \text{ cm}^{-1} \text{ Hz}^{-1/2}$. NICE-OHMS holds the world record in detection sensitivity of all cavity-enhanced techniques.

In a NICE-OHMS experiment, phase modulation of the laser produces sidebands that are set to equal the free spectral range of the high-finesse resonator. Because the sidebands are transmitted by the cavity in the same manner as the carrier, any small wavelength fluctuations in the laser or small optical phase shifts of the transmitted carrier that contribute to noise in the transmitted intensity will appear identically in the sidebands. After demodulation, this noise will cancel out. Thus, the transmitted carrier and sidebands are an accurate representation of the carrier and sidebands impinging on the input mirror of the cavity. The carrier laser frequency is locked to the peak of the optical cavity mode and tracks this mode if the cavity length is changed in order to produce a spectral scan. The sidebands are detected and demodulated as in conventional FM spectroscopy. The key to NICE-OHMS is that the noise level can approach the intrinsic shot noise of the laser at the FSR frequency (namely hundreds of MHz).

If there is no sample in the cavity, the transmitted sidebands will cancel after demodulation because they have opposite phases. No signal will be observed. If there is a sample in the cavity, the sidebands will experience different transmission amplitudes, so that demodulation will produce a signal proportional to the difference in absorption between the sideband frequencies. In addition, the absorption feature produces a phase shift that pulls the carrier cavity mode frequency, so that the sidebands become detuned from the mode peak and acquire a phase shift on transmission. This sideband phase shift contributes to the demodulated signal.

45.4 Extensions to Solids and Liquids

Thus far, the discussion of cavity-enhanced techniques has addressed traditional optical resonators formed using high-reflectivity dielectric mirrors that encompass gas samples. Extensions of cavity-enhanced methods to liquid and solid media has required additional innovation, specifically in the optical cavities used.

45.4.1 Evanescent-Wave Cavity Ring-Down Spectroscopy (EW-CRDS)

Evanescent-wave CRDS (EW-CRDS) exploits the fact that total internal reflection allows probing the surface layer of a sample in contact with a prism. The simplest configuration places a Brewster prism inside a linear ring-down cavity. The prism folds the cavity beam path by 90 degrees, thereby producing one point in the prism with a total internal reflection [22]. The evanescent wave produced by this internal reflection can be used to probe liquid or solid samples. Another possible embodiment is a ring cavity with its optical path inside a multifaceted polygon, where at each facet, total internal reflection occurs [23]. Light is coupled into and out of the polygon by photon tunneling – which effectively controls the overall finesse of the cavity. The absorbing sample material can then be placed on any one or more of the polygon facets, and its detection is done using the polygon's evanescent waves.

45.4.2 Cavity Ring-Down of Condensed Media for Analytical Chemistry

More direct approaches to measuring liquid samples involved confining the liquid samples within a more traditional RDC. The most direct method involves placing a liquid directly into the cavity, but this approach results in very limited sensitivity. By placing a Brewster cell filled with liquid sample in an RDC, the sensitivity of the P-CRDS can be slightly improved. By matching the Brewster angles to the refractive indices of the adjacent media (the outside angle matches the air-filled RDC, while the inner angle matches the index of the liquid), the sensitivity can be improved dramatically [24]. The peak-to-peak baseline noise level of such a P-CRDS system was 1.0×10^{-5} absorbance units (AU), rivaling the best available commercial ultraviolet-visible (UV-VIS) direct absorption detectors. The performance remained limited by the excitation of multiple cavity modes. A CW-CRDS system using the same angle-matched Brewster cell [25] improved the peak-to-peak baseline noise by a factor of 50 to 2×10^{-7} AU. This CRDS detector outperformed the best commercially available UV-VIS detector by a factor of 30, again

illustrating the potential for CRDS to replace standard absorption spectroscopy techniques.

Similar inroads into liquid measurement have been made using CEAS with incoherent broadband sources such as Xenon lamps or more practically solid-state light-emitting diodes (LEDs). Given that most liquid solutions have broad and fairly featureless absorption spectra, the integrated intensity measurement is an easier approach than measuring very short ring-down times. Unfortunately for the incoherent broadband sources used, matching the Brewster angle for all wavelengths is not possible, so a 0-degree geometry that overlaps the back reflection with the excitation beam was adopted. In this approach, the reflectivity of the cavity is balanced between extending the mirror reflectivity spectral range for broadband spectra, maximizing the cavity enhancement factor, and maintaining a detectable cavity output signal [26]. Interestingly, the lower limit for detection obtained with this approach was only five times worse than that obtained with the elaborate laser-based, pulsed CRDS setup [27]. Target applications for liquid CRDS focused mainly on improving the sensitivity of liquid chromatography absorption detection.

Solid samples have also been placed inside linear CRDS cavities for characterization. Mostly, P-CRDS are used. Examples of applications include characterization of C-60 films, thin-film coatings, and silicon wafers.

45.4.3 Cavity Ring-Down Spectroscopy Using Waveguides

The typical setup of fiber loop cavity ring-down leverages optical components developed for DWDM telecommunications, so that the laser, fiber loop with Bragg gratings, and detector are all coupled together with fiber splices or telecommunications fiber connectors, leading to a robust and relatively straightforward system assembly. The cavity can be either a linear one with two Bragg gratings at either end, or a fiber loop with a very low loss coupler to extract the detector signal.

Fiber cavities are attractive because they can extend the use of CRDS into harsh environments, can probe liquids as well as gases, and can be used to measure bending loss [28] (when applied to the fiber loop), pressure [29] (when applied to the fiber loop), and temperature [30] (via physical changes in a fiber Bragg grating inserted into the fiber loop). The high-reflectivity mirrors on each end of the fiber can be either dielectrically coated, as in a traditional ring-down cavity design, or can consist of fiber Bragg gratings. Fiber-based CRDS has also been applied to detection in liquid media via a fiber loop cavity wherein a liquid sample replaced the index matching fluid in the gap between fibers at the connector splice [31]. This approach produced a hundredfold enhancement over linear detection.

The most recent and interesting application of waveguide-based CRDS is the detection of analytes delivered using a microcapillary to a gap in the loop. The dimensions of the flow channel govern the choice of waveguide: the cross section of the detection region and the flow channel need to be similar in size in order to not build up pressure in the flow channel or build up a large “dead volume”. The emerging field of absorption detection in microfluidics using CRDS still remains largely unexplored, although attempts have begun [32].

It is anticipated that CRDS will eventually reach sensitivities for liquid and thin film samples that are comparable to those achieved in gases. CRDS is also expected to find commercial applications in high-performance liquid chromatography, thin film characterization, and biological detection. Combination techniques of CRDS and fluorescence, or CRDS and Raman spectroscopy, may also be on the not-so-distant horizon, where CRDS provides the quantification, while the complementary technique provides identification [33].

Overall, the CRDS field has expanded rapidly in the last decade from an average of 16 papers published per year between 1985 and 1995, 240 papers published per year between 1995 and 2005, to 913 papers published per year between 1995 and 2015. Most recently, the number of annual published papers exceeded 1,000 in 2012 and exceeded 1,500 in 2018, showing the wide applicability of the methodology in fields ranging from atmospheric chemistry, medical breath analysis, thin film growth and process monitoring in solid-state physics, combustion and plasma studies, molecular transient studies in astrophysics, and analytical chemistry [34].

Acknowledgements We have benefited invaluable from the collaboration with our co-workers at Picarro, and would like to extend our gratitude to Prof. Richard N. Zare and Dr. Marc Levenson for their unwavering support in helping make CRDS a commercial reality over the past two decades. We would also like to express our appreciation to all of our scientific collaborators worldwide, both industrial and academic, for their friendship, openness, and help over the years. Barb would like to dedicate this chapter to her father, Prof. Josef Paldus, who has been an inspiration to her throughout her career, and with whom it is an honor to share a publication in the same book.

Abstract

The design of UV spectroscopic experiments and apparatus must conform to the constraints associated with producing, dispersing, and detecting UV (ultraviolet) photons. In this chapter, we review the instrumentation available for UV spectroscopy, concentrating on the VUV (vacuum ultraviolet), where special instrumentation is necessary.

An inclusive review of vacuum ultraviolet techniques can be found in *Vacuum Ultraviolet Spectroscopy I & II* (1998), edited by Samson and Ederer [1]. There are many comprehensive reviews of VUV light sources, spectrometers, and detectors, which are referenced in the appropriate sections of this chapter.

Keywords

synchrotron radiation · harmonic generation · grazing incidence · silicon photodiode · dark count rate

The ultraviolet (UV) spectral region extends from the short wavelength side of the visible, about 400 nm, to the long wavelength side of the X-ray region at approximately 10 nm. Ultraviolet photon energies range from about 3 to 120 eV. Because laboratory air at standard temperature and pressure does not transmit below about 200 nm, the UV region is conventionally subdivided into the near ultraviolet, wavelengths $\lambda > 200$ nm, and the vacuum ultraviolet (VUV), $\lambda < 200$ nm.

Further subdivisions are widespread but not uniformly adopted. The term middle ultraviolet (MUV) is sometimes used to designate the 200–300 nm wavelength region, with the term near UV used only for 300–400 nm.

VUV wavelengths are often divided into the far ultraviolet (FUV), 100–200 nm, and the extreme ultraviolet (EUV), 10–100 nm. In this review, we will simply refer to the UV (10–400 nm), the near UV (200–400 nm), and the VUV (10–200 nm).

The absorption of UV radiation by atoms and molecules involves transitions to highly excited discrete and continuum levels. The relevant atomic and molecular physics of highly excited states is discussed in Chaps. 15, 25, 26, and 65. Ultraviolet absorption initiates many important photochemical reactions; applications in astrophysics, aeronomy, and combustion are reviewed in Chaps. 86 and 88. The experimental techniques used at ultraviolet wavelengths include high-resolution spectroscopic measurements of wavelengths and line shapes (Chap. 11), absolute photoabsorption oscillator strength and radiative lifetime measurements (Chap. 18), fluorescence spectroscopy, and energy, angle, and spin-resolved photoelectron spectroscopy (Chap. 65).

46.1 Light Sources

46.1.1 Synchrotron Radiation

Synchrotron radiation (SR) facilities provide intense continuum radiation in the infrared, visible, UV, and soft X-ray spectral regions. The radiation is emitted by relativistic electrons (or positrons) accelerated by the Lorentz force of a magnetic field. In addition to its continuum nature, synchrotron radiation is characterized by high degrees of collimation and polarization. Advances in specialized magnet designs, e.g., wigglers and undulators, which dramatically increase spectral brightness at selectable wavelengths, have stimulated continuing growth in synchrotron-radiation-based spectroscopic research. References [2–12] present general reviews on the nature of synchrotron radiation and on specific SR-based experimental techniques.

SR facilities use either a linear accelerator, a microtron, or a synchrotron to accelerate electrons or positrons to relativistic energies (0.1–10 GeV). The particles are then injected into a storage ring, where a series of bending magnets steers them in a closed orbit. The particles in the storage ring radiate energy, which is replaced by radio-frequency accelerating cavities that are part of the ring. These accelerating systems produce well-defined, regularly spaced bunches of stored particles, so that radiation from SR facilities is characterized by subnanosecond pulses with an interbunch spacing of a few nanoseconds, leading to repetition rates of several hundred MHz. Some beamline experiments require a lower repetition rate, for example the study of the dynamics of photo-induced processes through pump-probe experiments. In modern facilities, this class of experiments is accommodated via so-called “temporal modes” with 1–10 MHz repetition rates and 20–100 ps pulse widths.

Typical storage ring currents are on the order of 100 mA to 1 A. The current decreases continuously because of collisions with residual gas molecules and electron–electron (or positron–positron) scattering. During operation, some facili-

ties are able to periodically inject a small number of electrons into the storage ring, resulting in a quasi-constant total current ($\delta I/I$ of a few percent). Typically, injections occur every 2–5 min. In addition to the advantage of producing an almost constant photon flux at the experimental level, this mode also results in better machine and beamline stability. Storage ring pressures must be in the 10^{-10} Torr range in order to reduce collisions to acceptable levels; such pressure requirements can restrict the types of measurements performed at SR facilities.

The spectral properties of synchrotron radiation can be derived from Larmor’s formula for an accelerating relativistic charged particle [3, 13–17]. The total power P radiated by a beam of current I and energy E in a bending magnet field B is

$$P = 0.0265 E^3 I B \quad [\text{kW}], \quad (46.1)$$

where, throughout this chapter, I is in mA, E is in GeV, and B is in T. For example, a 300 mA beam of 1 GeV electrons radiates at a rate of about 8 kW when traversing the field of a typical 1.0 T bending magnet. One-half of the total power is radiated above the critical wavelength, λ_c , where

$$\lambda_c = \frac{1.9}{BE^2} \quad [\text{nm}]. \quad (46.2)$$

For the example just considered, $\lambda_c = 1.9$ nm.

The power radiated by, and the flux from, synchrotron radiation sources is often expressed per fractional (or percent) bandwidth. For example, the flux, in units of photons $(\text{cm}^2 \text{s})^{-1}$, at 10 nm (124 eV) per 1% bandwidth is the flux in a 0.1 nm band centered at 10 nm, which is the same as that in a 1.24 eV energy band. The radiated power per fractional bandwidth peaks at $\lambda \approx 0.75\lambda_c$.

The flux per fractional bandwidth reaches a broad maximum at $\lambda \approx 3.3\lambda_c$ and decreases slowly at longer wavelengths, with a limiting behavior that is proportional to $\lambda^{-1/3}$ for $\lambda \gg \lambda_c$. Thus, although the photon flux typically peaks in the soft X-ray region, a high flux is also present throughout the VUV wavelength range. Below λ_c , the flux drops rapidly, with little usable radiation at wavelengths below about $0.1\lambda_c$.

The angular distribution of the radiated light is sharply peaked in the instantaneous direction of the beam of radiating particles. Practically all the radiation is emitted into an opening half-angle θ that at $\lambda = \lambda_c$ is equal to $1/\gamma$, where $\gamma = E/mc^2$; i.e.,

$$\theta = \frac{1}{\gamma} = \frac{5.11 \times 10^{-4}}{E} \quad [\text{rad}]. \quad (46.3)$$

Radiation from beams with energies of a few GeV has a divergence somewhat less than 1 mrad at λ_c . The divergence

increases at longer wavelengths, with

$$\theta = \frac{1}{\gamma} \left(\frac{\lambda}{\lambda_C} \right)^{\frac{1}{3}} \quad [\text{rad}]. \quad (46.4)$$

Radiation from bending magnets maintains this narrow divergence only in the vertical plane; in the orbital plane, the radiation is emitted in an opening angle equal to the bending angle of the magnet (typically a few 10s of mrad). Typical beam cross sections are 0.01 to 1 mm². Thus, the extremely high spectral brightness, i.e., photon flux per unit solid angle and % bandwidth, of synchrotron sources reflects both the very low divergence of the radiation and the small source size. A typical brightness associated with bending magnet radiation is on the order of 10¹² photons (s mm² mrad² 0.1% bandwidth)⁻¹. At the time of this review, some facilities are undertaking a significant machine technical upgrade to “diffraction limited storage rings” (DLSRs). In these “fourth-generation” synchrotron light sources, a low emittance should be achievable in both the horizontal and vertical planes, leading to a typical improvement in brightness of one to three orders of magnitude. DLSRs will be especially beneficial for soft and hard X-ray beamlines [18].

The pulsed nature of the radiation at synchrotron facilities is ideal for subnanosecond time-resolved spectroscopies [19–23].

Electron bunch lengths l_b are typically a few centimeters; radiation is, thus, observed from each bunch for a time interval given by $l_b/c \leq 100$ ps. The time for one full orbit is determined by the size of the storage ring and varies from about 20 ns at the smallest rings to 500–1000 ns at the larger rings. In modern facilities, the geometry and number of bunches stored are quite flexible and can be adapted to a variety of experiments that require particular temporal structures [24].

Third-generation synchrotron facilities incorporate straight sections between bending magnets to accommodate insertion devices such as wigglers and undulators. These are linear arrays of magnets with alternating polarities that cause the beam trajectory to oscillate, although no net displacement of the beam occurs. The oscillations produce synchrotron radiation that is characterized by extremely high brightness and that can be spectrally tailored to individual experiments [3, 12, 16, 25, 26].

Wigglers and undulators are distinguished by the value of their deflection parameter K , which is a measure of the maximum bending angle of the stored particle beam in units of θ , the angular divergence of the emitted radiation. The deflection parameter K is determined by the peak strength of the alternating magnetic field B_0 and its spatial period x_B by

$$K = 0.934 B_0 x_B, \quad (46.5)$$

with x_B in cm.

In the wiggler regime, $K \gg 1$; i.e., the angle at which the magnets deflect the electron beam is large compared with θ . The resulting spectrum resembles that from a bending magnet but is brighter by a factor of N_m of magnet periods (usually 10–100). Wigglers are generally used as wavelength shifters; magnetic fields larger than those available in conventional bending magnets decrease the critical wavelength of the spectral distribution and shift the overall spectrum to shorter wavelengths.

In the undulator regime, $K \approx 1$; i.e., the angle at which the electrons are deflected is on the order of θ , and radiation from individual oscillations adds coherently at certain resonant wavelengths, producing a gain of N_m^2 in brilliance. Undulator radiation is characterized by sharp peaks at a fundamental wavelength λ_1 and its odd harmonics; λ_1 is determined by the beam energy and x_B

$$\lambda_1 \approx \frac{0.1 x_B}{2\gamma^2} = 1.3 x_B E^{-2} \quad [\text{nm}], \quad (46.6)$$

where x_B is in cm. For example, the fundamental wavelength is 6.5 nm for a 1 GeV beam traversing an undulator with a spatial period of 5 cm. The fractional bandwidth of the peaks in an undulator spectrum is $\approx 1/N_m$. Unlike the radiation from a bending magnet, the angular divergence of undulator radiation is sharply peaked both vertically and in the orbital plane; the brightness of undulator radiation is $\approx 10^{18}$ to 10^{19} photons (s mm² mrad² 0.1% bandwidth)⁻¹, about six orders of magnitude greater than bending magnet radiation. The wavelength of the fundamental is tunable; the strength of the peak magnetic field is altered via changes in the size of the gaps between the poles of the magnets or by changes in the strength of the magnetic fields.

Typically, experiments require a single undulator harmonic interacting with the sample and, thus, a system to filter out higher harmonics at the experimental end-station is used. In the UV, materials that have a limited transmission in the VUV can be used for this purpose: MgF₂, LiF, CaF₂, or fused silica. At higher energies, windowless gas filters, with continuous flows of noble gases, remove the undulator harmonics falling above the atomic ionization energy. Xenon, krypton, argon, and neon are used to remove harmonics at wavelengths below 102.2, 88.6, 78.7, and 57.5 nm, respectively [27, 28].

Synchrotron radiation has well-characterized polarization properties. Within the orbital plane, the radiation is completely linearly polarized with the electric field vector in the orbital plane; above and below the orbital plane, the radiation is elliptically polarized, with the degree of polarization dependent on both wavelength and viewing angle.

Undulator designs incorporating either crossed planar magnets or a helical array of magnets can produce circularly polarized light [29, 30]. Considerable progress has been

made on undulator-based beamline designs that offer high flux, stability, and tunability, as well as a controlled and tailored level of elliptical polarization. The undulator can provide any orientation of the electrical field vector over the spectral range covered by a beamline. However, the state of polarization is rarely conserved throughout a beamline due to chromatic phase shifts introduced by the reflection of the beam off mirrors. In order to determine precisely the polarization state at the sample and to compensate for beamline phase shifts, purely reflective UV-VUV polarimeters have been developed [31, 32], providing almost perfectly circularly polarized light over the entire VUV region [33].

Synchrotron-based circular dichroism studies, which take advantage of the broad polarization options afforded by modern undulator designs, reveal essential structural information on biomolecules in solution and can be seen as complementary to conventional high-resolution biomolecular x-ray crystallography [34, 35]. In the UV and near VUV regions, photoelastic modulators are robust optical devices that can be used to convert linearly polarized incident light to right or left circularly polarized light; this technique is used routinely and has been employed, for example, in CD measurements on thin films [36, 37] and biomolecules in aqueous solution [38]. Photoelectron circular dichroism (PECD) has been exploited at synchrotron facilities and provides a much stronger CD signal on gas phase chiral targets than conventional absorption techniques. PECD is a very sensitive technique for both the study of photoionization dynamics and molecular structure; a review can be found in [39].

46.1.2 Laser-Produced Plasmas

When the output of a high-power pulsed laser is focused onto a solid target, a short-lived, high-temperature ($T \approx 50$ to 100 eV), high-density ($n_e \approx 10^{21} \text{ cm}^{-3}$) plasma is created. The radiation from certain target materials, particularly the rare earths ($57 \leq Z \leq 71$) and neighboring metals in the periodic table, produces a strong VUV quasi continuum that is essentially free of discrete lines [40, 41]. The continua are the most intense in the 4–30 nm region but often extend to about 180 nm. A review of laser-produced plasmas and their applications in the VUV can be found in [42].

The primary mechanisms responsible for the continua are recombination radiation (ionization stages up to ≈ 16 are attained) and bremsstrahlung. The absence of discrete features in rare earth plasmas is thought to be caused by the extreme complexity of rare earth atomic energy level structures; individual emission lines are blended into an apparent continuum [43]. The necessary peak laser powers, which are in the range of 10^{10} to $10^{12} \text{ W cm}^{-2}$, are easily achieved with commercially available Q -switched lasers. The continuum pulse duration is comparable to the duration of the laser

pulse. The target material is often a cylindrical rod that is rotated to present a fresh surface for each laser shot. References [44–48] present and discuss the spectral characteristics of several laser-produced plasma sources. Atomic photoabsorption techniques based on laser-produced plasma sources are described in [43, 49, 50].

46.1.3 Arcs, Sparks, and Discharges

Several laboratory sources of VUV line and continuum radiation are based on gas discharges, high-pressure arcs, and low-pressure and vacuum sparks. While these well-established radiation sources are not as intense as synchrotron radiation and laser-produced plasmas, the traditional sources have the advantages of being portable and inexpensive. Reviews can be found in [51, 52].

Direct current discharges (approximately 100–500 mA) through 1–2 Torr of H_2 or D_2 generate continuum radiation from about 165 to 350 nm [53]. The continuum is produced by transitions from the bound $1s\sigma 2s\sigma a^3 \sum_g^+$ state to the repulsive $1s\sigma 2p\sigma b^3 \sum_u^+$ state [54]; the very steep potential curve of the lower state results in the extended nature of the continuum. The photon flux per unit wavelength from such lamps peaks at about 185 nm; below 165 nm the many-line spectra of H_2 or D_2 begin to dominate. A commercially available electrodeless xenon discharge source, heated by a CW laser, produces broadband light from 170 nm into the infrared.

Hollow cathode discharges [55], which are easy and inexpensive to construct and operate, are the most common line-emission sources used in UV spectroscopy. Low-power (approximately 5 W) lamps designed to produce spectra of about 70 elements are commercially available for spectrochemical and atomic absorption spectroscopy. Line widths are narrow, so blends are minimized. Most manufacturers can provide lamps with transmissive windows for use at VUV wavelengths.

High-current, differentially pumped hollow cathode sources, which have been developed for use as radiometric standards in the 40–125 nm wavelength range [56], can also be used as line sources. At shorter wavelengths, e.g., 5–40 nm, the Penning discharge has proved to be a useful source of line radiation [52, 57]. Electron-beam excitation sources [52] produce stable and reproducible line emission spectra and find use as VUV calibration standards [55, 58]. Electron-beam ion trap (EBIT) sources [59, 60] generate VUV and X-ray spectra of highly ionized atomic species.

46.1.4 Supercontinuum Radiation

Continua extending throughout the near UV wavelength range to below 200 nm can be produced by focusing

femtosecond laser pulses in liquids, noble gases, and glasses. This supercontinuum generation allows for time-resolved, subpicosecond spectroscopy of photochemical reactions [61]. The supercontinuum arises from a number of competing nonlinear processes [62–64]. Access to the UV was demonstrated in the 1990s both by focusing 308 nm laser pulses in water [65] and by focusing 248 nm laser pulses in high pressure (10–40 atm) cells of Ne, Ar, and Kr [66]. The continuum produced using H₂O is particularly broad, extending from 200 to 600 nm. More recently, supercontinuum radiation has been demonstrated down to 120 nm with He-filled and Ne-filled hollow-core photonic crystal fibers [67].

46.2 VUV Lasers

Advances in recent decades in laser technologies have led to an impressive increase in spectroscopically useful VUV laser sources (Chap. 75). Early reviews can be found in [68, 69]. The following summary of VUV lasers does not cover the rapidly developing fields of X-ray and soft X-ray lasers [70, 71] or the development of free electron lasers ([72, 73] and references therein, also in Chap. 75).

46.2.1 Primary Lasers

Pulsed lasing at VUV wavelengths is achieved in a number of media, including the molecular gases H₂, CO, and F₂, excimer systems (Ar₂, Kr₂, Xe₂, ArF, KrF, XeF, XeCl), and Auger-pumped noble gases (Xe, Kr) [74]. The fundamental barrier to producing stimulated emission in the VUV is the ν^3 dependence of the spontaneous emission rate, which necessitates very high pump powers to create and maintain population inversions. Existing VUV primary lasers have generally not been widely used in spectroscopic applications because of either a lack of tunability or unacceptably broad line widths.

Pulsed lasing in CO, H₂ and F₂ occurs between rovibronic levels of a high-lying electronic state and excited vibrational levels of the ground electronic state. The lasing output consists of discrete lines and is not tunable. The CO and H₂ outputs [75, 76] span relatively broad regions (181–197 and 110–164 nm, respectively), while the F₂ laser output consists of two or three closely spaced lines at 157 nm [77]. Pulse energies are in the 1–100 μ J range for CO and H₂ lasers. Commercially available F₂ lasers offer pulse energies of about 50 mJ at 50 Hz repetition rates.

Noble-gas and noble-gas-halide excimer lasers operate via bound-upper-level to continuum-lower-level transitions. (Reviews of excimer laser technologies can be found in [78, 79].) The resulting gain profiles are broad, and the outputs are typically tunable over about 2 nm. ArF excimer sys-

tems (193 nm) are pumped by high-pressure gas discharges; lasers with pulse energies of \approx 20 to 40 mJ are commercially available; Xe₂ (173 nm), Kr₂ (146 nm), and Ar₂ (126 nm) lasers [80–82] produce comparable pulse energies but require electron beam excitation. Auger-pumped lasers achieve a population inversion through the ejection of an inner-shell electron from a neutral atom to produce a highly excited singly ionized species, followed by Auger decay to excited states of the doubly ionized species. The soft X-ray (approximately 100 eV) pump photons often originate from a laser-produced plasma. The lasing output is not tunable. Lasing in Xe (108.9 nm) and Kr (90.7 nm) [83, 84] has been achieved with output pulses in the range of a few μ J.

46.2.2 Nonlinear Techniques

In the past 40 years, developments in the techniques of nonlinear optics have extended the range of tunable, pulsed coherent radiation to VUV wavelengths. Nonlinear frequency conversion techniques, such as stimulated anti-Stokes Raman scattering, harmonic generation, sum-frequency and difference-frequency mixing (Chaps. 75 and 76), and high-harmonic generation (appears in Chap. 75) can produce narrow-bandwidth radiation spanning the entire VUV. The generated VUV radiation has the spectral and spatial characteristics of the input laser radiation. Pulses of 10^{10} to 10^{12} photons are commonly generated with bandwidths on the order of 0.1 cm^{-1} . Many reviews are available on this subject [74, 85–91]. A comprehensive review of precision laser spectroscopies in the extreme ultraviolet can be found in [92]. The standard nonlinear techniques for producing tunable coherent radiation with $\lambda < 200 \text{ nm}$ are summarized below.

Second harmonic generation in nonlinear optical crystals is a well-established method for generating tunable laser light in the near UV. At the shortest wavelengths, second harmonic generation in β -barium borate (BBO) produces usable outputs down to approximately 205 nm, below which the phase matching requirement between the fundamental and the second harmonic cannot be met. Sum-frequency mixing ($\omega = \omega_1 + \omega_2$) in BBO [93, 94], where ω_1 is typically the Nd:YAG fundamental (1064 nm), and ω_2 is tunable UV light, extends the useful range of BBO to approximately 190 nm, where the crystal begins to exhibit strong absorption.

Stimulated anti-Stokes Raman scattering of UV laser light in molecular gases (e.g., H₂, N₂, CH₄) is used to generate coherent radiation down to about 120 nm, although low conversion efficiencies often restrict the usable output to $\lambda > 160 \text{ nm}$. The scattering is a four-wave mixing process resulting in a series of output frequencies shifted from the pump laser frequency by multiples of the vibrational splitting of the ground electronic state of the gas [95]. Because

high anti-Stokes orders are not efficiently generated, H₂, with its large ground state vibrational splitting of 4155 cm⁻¹, is often the gas of choice. The experimental requirements are relatively minimal; a tunable visible or UV source (e.g., a frequency-doubled dye laser) and a high-pressure gas cell (about 2–10 atm of H₂ in a 1 m cell). Conversion efficiencies are a few percent for the first few anti-Stokes orders in H₂ with pump laser energies of about 10–50 mJ [96]; efficiencies then drop continuously, reaching about 10⁻⁵ to 10⁻⁶ for the highest orders ($n = 9$ to 13) reported. Stokes seeding techniques [97] have been shown to increase efficiencies for the highest anti-Stokes orders by as much as a factor of 100.

Third harmonic generation ($\omega = 3\omega_1$), sum-frequency mixing ($\omega = 2\omega_1 + \omega_2$), and difference-frequency mixing ($\omega = 2\omega_1 - \omega_2$) in appropriate noble gases and metal vapors are broadly applicable methods for producing tunable VUV light. These processes result from the presence of the third-order nonlinear term in the expansion of the induced macroscopic polarization of the gas as a power series in the electric field (Chap. 76). (The second-order term, which is responsible for frequency doubling in crystals, is zero for isotropic media such as gases.) The power generated in third-order effects is proportional to

$$N^2 |\chi^{(3)}|^2 P_1^2 P_2 F, \quad (46.7)$$

where N is the number density of the gas, $\chi^{(3)}$ is the third-order nonlinear susceptibility, P_1 and P_2 are the input laser powers at ω_1 and ω_2 , and the factor F describes the phase matching between the generated VUV light and the induced polarization [98, 99]. For third harmonic generation, $P_1^2 P_2$ is replaced by P_1^3 .

A critical constraint in third-order frequency conversion is the phase matching requirement; a comprehensive treatment is presented in [100]. The factor F is a function of the product $b\Delta k$, where b is the confocal beam parameter of the focused input radiation, and Δk is the phase mismatch between the generated VUV light and the input radiation

$$\Delta k = k - (2k_1 + k_2), \quad (46.8)$$

where k_i is the wave vector of the radiation with frequency ω_i . In the standard case of tight focusing ($b \ll L$, where L is the linear dimension of the gas cell) for sum-frequency mixing and third harmonic generation processes, F is nonzero only for $\Delta k < 0$. Therefore, these techniques are applicable only in spectral regions where the gas exhibits negative dispersion. In contrast, for difference-frequency mixing, the factor F is nonzero in regions of both positive and negative dispersion, and wider tuning ranges are generally possible.

Conversion efficiencies for sum-frequency and difference-frequency mixing schemes are usually in the range of 10⁻⁷ to 10⁻⁴ with input peak laser powers of 1–10 MW.

Resonant enhancement of $\chi^{(3)}$, achieved by tuning the input radiation to transition frequencies in the gas, dramatically increases conversion efficiencies (by factors of about 10⁴) and allows for much lower (≈ 1 kW) input laser powers. Most commonly, one of the incident frequencies is tuned to an allowed two-photon transition, with the second input frequency providing subsequent tunability in the VUV; resonant methods, therefore, require two tunable inputs.

Metal vapors (e.g., Mg, Zn, Hg) are negatively dispersive over fairly broad regions of the VUV between 85 and 200 nm and are consequently used for sum-frequency mixing and third harmonic generation. Conversion efficiencies are further enhanced in these vapors by three-photon resonances ($2\omega_1 + \omega_2$) with the ionization continuum or broad autoionizing features [85]. One experimental drawback is the complexity associated with generating the metal vapors in ovens or heat pipes.

Noble gases are generally less suited for sum frequency mixing because they exhibit negative dispersion over fairly limited spectral ranges in the VUV. However, they do provide an experimentally simple medium for difference-frequency mixing schemes. In particular, Xe, Kr, and Ar (as well as H₂) have been used in resonant and nonresonant difference-frequency mixing schemes to produce tunable radiation over the 100–200 nm region [101–107]. The noble gases are also used for sum-frequency mixing and third harmonic generation. Kr, Ar, and Ne are used for the generation of tunable radiation down to 65 nm [101, 108–111]. Below the LiF transmission cutoff (105 nm), the gases are introduced as pulsed jets. In [112], a narrowband tunable extreme ultraviolet laser system based on resonance-enhanced four-wave mixing in Kr, is described, and in [113, 114], an ultranarrow bandwidth (0.008 cm⁻¹) system, utilizing resonance-enhanced sum-frequency mixing in rare gases, capable of producing coherent radiation between 62 and 124 nm is described. A representative summary of third-order frequency conversion schemes is presented in Table 46.1.

Most third-order frequency conversion designs use nano-second-pulsed lasers as primary sources. With the higher intensities ($> 10^{13}$ W/cm²) that are associated with picosecond and femtosecond pulsed lasers, higher-order frequency conversion is readily achieved. These conversion techniques have been used to generate both fixed frequency and tunable coherent radiation shortward of 70 nm. Tunable radiation at 58 nm was produced through fifth harmonic generation in C₂H₂ using the frequency-doubled output of a dye laser [124, 125]; a high repetition rate (up to 500 kHz) fiber-amplifier based system with harmonics down to 30 nm is reported by [90]. A picosecond tunable system with continuous tunability over the 40–100 nm region with sub-cm⁻¹ resolution has been developed using high-order harmonic generation in Ar and Kr [126]. Frequency combs, first up-converted into the VUV in 2005 [127, 128], allow for ultra-high precision

Table 46.1 Representative third-order frequency conversion schemes for generation of tunable coherent VUV light

Medium	λ (nm)	Process	Reference
Sr	165–200	res. diff. mixing	[115]
	178–196	res. sum mixing	[116]
Mg	121–174	res. sum mixing	[85]
Zn	106–140	res. sum mixing	[117]
Hg	142–182	nonres. tripling	[98]

spectroscopies and metrology in the VUV [129, 130]; the relevant techniques are reviewed in [92].

46.3 Spectrometers

46.3.1 Grating Spectrometers

The design and characteristics of VUV grating spectrometers and monochromators are reviewed by many authors [131–135]. Two basic types of spectrometer are used in the VUV: normal incidence instruments for $200 \text{ nm} > \lambda > 30 \text{ nm}$ and grazing incidence instruments for $50 \text{ nm} > \lambda > 2 \text{ nm}$. The particulars of these two types are largely dictated by the low reflectivities of both metal and dielectric surfaces in the VUV.

Concave gratings are used almost exclusively in VUV spectrometers. Such gratings provide both dispersion and focusing, thus eliminating the need for additional mirrors and their associated reflection losses. Most VUV spectrometers make use of the focusing properties of the Rowland circle, which is tangent to the grating at its center, lies in a plane perpendicular to the grating grooves, and has a diameter equal to the radius of the curvature of the grating [136]. A source on a horizontal Rowland circle is focused horizontally by the grating to a location also on the circle. The dispersion introduced by the grating results in a focused, diffracted spectrum lying on the Rowland circle. Almost all normal incidence and grazing incidence VUV instruments are designed with the entrance and exit slits lying on, or nearly on, the Rowland circle.

The image formed by a concave grating is not stigmatic, i.e., the vertical focus does not coincide with the horizontal focus. Hence, a point source is imaged into a vertical line on the Rowland circle [133, 137]. Astigmatism is particularly severe at grazing incidence angles, resulting in both loss of signal (the image of the entrance slit being larger in extent than the exit slit) and loss of resolution (the image of the entrance slit is curved in the dispersion direction). Aspherical concave gratings (e.g., toroidal gratings) reduce the astigmatism associated with conventional spherical gratings ([137] and references in [138]). The most important advances in concave grating production are the use of interference techniques to produce holographic gratings [138, 139] and the development of variable line spacing gratings [140, 141]. Interference techniques eliminate the periodic irregularities in conventionally ruled gratings that lead to spectroscopic “ghosts”, reduce the level of scattered light by significant amounts, allow for very high groove densities (e.g., 4800 mm^{-1}), and can be relatively easily applied to aspheric surfaces. Mechanically ruled variable line spacing gratings correct for spherical aberrations and allow for relatively simple focusing and scanning designs in EUV spectrometers and monochromators [141].

Normal incidence grating designs are appropriate for wavelengths greater than about 30–40 nm. The most common types include the Eagle, Wadsworth, and Seya–Namioka designs [131, 133, 134]. Eagle mounts, with entrance and exit slits on the Rowland circle and approximately equal angles of incidence and reflection ($< 10^\circ$), can be either in-plane or off-plane. Photoelectric resolving powers $\lambda/\delta\lambda$ of 2×10^5 were achieved in the 100 nm region with 6.65 m Eagle mount instruments [142–144], although most of these large instruments have now been decommissioned. In the Wadsworth mount, the light source is at a large distance from the grating, and no entrance slit is required. This design is appropriate for collimated light sources such as synchrotron radiation. It has the advantages of high throughput and minimal astigmatism [132]. The Seya–Namioka mount is a Rowland circle instrument in which the angle subtended by the fixed entrance and exit slits relative to the center of the grating is approximately 70° . The spectrometer remains in good focus for small grating rotations, resulting in a simple scanning mechanism and, thus, an inexpensive design. Seya–Namioka instruments provide high throughput at moderate spectral resolutions (typically 0.02–0.05 nm) [132].

The normal incidence reflectance of all standard metal coatings is no greater than a few percent for $\lambda < 30 \text{ nm}$ [133]; in this wavelength region, grazing incidence instruments take advantage of the total reflection of photons at extreme grazing angles. There is a sharp reflectance cutoff at photon energies above a characteristic energy that typically limits the use of grazing incidence optics to $\lambda > 1 \text{ nm}$. Grazing

incidence designs, tailored to the constraints of synchrotron radiation facilities, are described in [3, 132, 135].

Astigmatism becomes severe at grazing angles; interferometrically produced aspherical gratings and mechanically ruled variable line spacing gratings are used to reduce this aberration [139, 141]. The resolving power of a grazing incidence instrument is generally lower than that of a comparably sized normal incidence instrument, in large part because of the decreased effective width of the grating at grazing incidence.

A number of nonstandard instrument designs are reported in the literature, often for use in VUV astronomy and aeronomy applications. These novel designs take advantage of the properties of conical diffraction [145–147] and dual-grating crossed dispersion or echelle mounts [148, 149] to reduce the effects of aberrations. Reference [131] reviews many specialized VUV spectrometer designs.

46.3.2 Fourier Transform Spectrometers

Fourier transform spectroscopy (FTS) is a well-established technique for high-resolution emission and absorption spectroscopy at infrared and visible wavelengths (Chap. 42). An interferometric signal is recorded as a function of an optical path difference made possible, for example, by the displacement of a Michelson interferometer mirror. FTS can be understood as a transfer of optical frequencies into the audio range via the beating interferometric signal as a scan is recorded; the low-frequency interferogram is suitable for time-resolved photodetection. The technique has been extended into the near UV and VUV regions, where FTS is characterized by the large optical throughput, high spectral resolution, and accurate linear wavenumber scale available at longer wavelengths [150]. However, the multiplex advantage of FTS is not realized at UV wavelengths because the signal-to-noise ratio is photon-noise limited rather than detector limited. Moreover, the required stabilities, both for the light source and the interferometer optics, make the extension of this technique quite challenging at short wavelengths. A review of interferometric techniques in the VUV can be found in [151].

A scanning Michelson interferometer with a fused silica beamsplitter has achieved a resolving power of 1.8×10^6 at wavelengths down to 178 nm [150]. The same interferometer design, with a MgF_2 beamsplitter, has achieved a resolving power of 8.5×10^5 at wavelengths down to 150 nm [152]. This spectral resolution is significantly better than that realized by the best VUV grating instruments [153]. At shorter wavelengths, FTS based on wave amplitude division interferometers is fundamentally limited by the transmission of VUV materials such as MgF_2 (≈ 115 nm) or LiF (≈ 105 nm). The manufacture of VUV beamsplitters becomes extremely

challenging due to both the strong absorption of these materials and the high optical quality required for a strong interferometric signal. Membrane-based beamsplitters have been proposed, but, up to now, these are mainly adapted to laser-based applications [154].

A Fourier transform spectrometer based on an all-reflecting wave-front-division interferometer has been developed to operate over a large spectral range, allowing the extension of FTS into the far VUV region [155]. Two roof-shaped reflectors split and reflect the incident light following a design similar to the standard Fresnel bimirror interferometer. The displacement of one reflector's position is controlled and measured by a separate He-Ne stabilized laser interferometer. The instrument has been coupled to a UV-VUV undulator-based synchrotron beamline, allowing Fourier transform absorption spectroscopy in the range 300–40 nm [156]. A raw line width of 0.13 cm^{-1} was measured on the Rydberg series of Kr near 88 nm, corresponding to a resolving power greater than 10^6 [155]. In contrast to wave amplitude division interferometers, wavefront division interferometers require a certain degree of spatial coherence, and thus, this technique is not well adapted to low brilliance sources.

Diffraction gratings can be used as division-of-amplitude beamsplitters to create all-reflecting interference spectrometers for VUV-XUV wavelengths; this idea has been applied to a Mach-Zender interferometer configuration [157, 158].

In parallel with the development of tunable laser-based laboratory sources in the UV-VUV range, original designs that can be related to FTS have been proposed for spectroscopy applications. When a VUV laser pulse created via high harmonic generation is split by a pair of mirrors, and one of the mirrors is translated to create a time delay between the resulting two pulses, the far field profile of the recombined pulses displays an interference pattern that can be exploited as a source diagnostic [159, 160]. Another method produces pulse pairs in the infrared that emerge as phase-locked harmonics in the VUV. Precise control of the pulse delay can be generated by a conventional Michelson interferometer [161, 162] or a movable wedge prism system [163]. This latter design has been applied to the measurement of the spatially resolved absorption of an inhomogeneous thin film in the VUV but with a rather limited spectral resolution [164].

Frequency comb sources operating in the infrared have been coupled to Fourier transform spectrometers, revealing a remarkable potential for unprecedented sensitivity and spectral resolution [165]. In recent years, an innovative approach combining two phase-locked frequency combs (dual comb spectroscopy) has led to high resolution FTS without any moving components [166–168]; a review presenting the advances and the application offered by frequency comb sources in the field of molecular and atomic spectroscopy can be found in [169]. This technique could possibly be implemented in the VUV by coupling a double comb to

harmonic generation based on femtosecond enhancement cavities [170].

46.4 Detectors

There is a wide variety of photon detectors with useful response and sensitivity at VUV wavelengths. With the exception of those involving the photoionization of gases, VUV detectors are based on the same underlying principles as their counterparts in the visible and infrared regions – the common detection schemes are initiated by surface photoemission or electron–hole pair creation in semiconducting materials. The details of the design of VUV detectors, and the constraints on their use, are often determined by the low levels of transmission of VUV light through suitable window and semiconducting materials. Nevertheless, VUV detectors with single-photon counting sensitivities and/or imaging capabilities are widely available. Reviews of VUV detectors can be found in [1, 171–175]. References [176–178] review the operating characteristics and calibration of VUV detector standards. More general summaries of photon detector technologies are presented in [179, 180]. Below, we summarize and compare the most common VUV detection schemes, including the use of photomultiplier tubes, multichannel plate detectors, silicon photodiodes, and charge-coupled devices.

46.4.1 Photomultiplier Tubes

Photomultiplier tubes (PMTs) [181] are used through the VUV for single-photon-counting, nonimaging, applications. Dark count rates are low (about 1 s^{-1}) for solar-blind tubes with 1 cm^2 photocathodes; pulse rise times are about 1–10 ns ([182] for a general review of amplifying detectors in the VUV). In the 105–200 nm region, useful PMT window materials are fused silica, MgF_2 , and LiF ; sapphire is also used in environments where ionizing radiation, which causes sapphire to fluoresce, is not present. In the windowless region of the VUV wavelength range ($2\text{ nm} \leq \lambda \leq 105\text{ nm}$), two options are available: the PMT may be operated bare, i.e., without a window, or a fluorescent coating can be deposited on the window to down-convert the VUV light to longer wavelengths.

Peak quantum efficiencies for VUV photomultiplier tubes are about 15–20%. Some of the most useful coatings for photocathodes in the VUV are CsI, KBr, and other alkali halides. These materials combine high VUV quantum efficiencies with a solar-blind response – their relatively high photoelectric work functions result in long wavelength cutoffs between 150 and 300 nm. Solar-blind PMTs have low dark count rates and minimal response to stray ambient light.

Bare PMTs, although used in some applications, are constrained by the degradation of many photocathode and dynode

surfaces upon exposure to air and humidity. Metal surfaces such as tungsten and aluminum/ Al_2O_3 [172] must be used rather than the higher efficiency alkali halide coated surfaces. Sodium salicylate is the most commonly used VUV-visible conversion phosphor; others include lithium, terphenyl, and coronene [183, 184]. The conversion efficiency of sodium salicylate (peak fluorescence about 430 nm) is relatively constant for VUV light from 30 to 200 nm.

The review by *Krizan* [185] discusses recent advances in fast single-photon detection, including multianode PMTs and hybrid PMT-microchannel-plate designs.

46.4.2 Microchannel Plates

The microchannel plate (MCP) detector is a photo-emissive array detector that combines the single-photon counting sensitivity of a PMT with high-resolution imaging capability. See [186, 187] for recent reviews; other general references include [171–173, 182, 188]. An MCP consists of an array of semiconducting glass channels with diameters of about 10–25 μm and length-to-diameter ratios of about 50:1. Electrons ejected from the front surface of an MCP via the photoelectric effect are accelerated through the channels; repeated collisions with the channel walls result in an amplification of the charge by about 10^6 . The exiting charge clouds are detected by a variety of position-sensing anode structures.

Bare MCPs have quantum efficiencies of about 10% for $\lambda \leq 100\text{ nm}$ and a long wavelength cutoff of about 120 nm. Alkali halide coatings increase the quantum efficiency to about 20% and extend MCP sensitivities toward longer wavelengths. Feedback instabilities produced by positive ions created in the channels during the electron cloud amplification are minimized through two common channel geometries: the chevron configuration, where two or more straight-channel MCPs oriented at different angles are cascaded [189], or a configuration with one set of curved channels [190].

Readout schemes for determining the position of individual detected photons rely on either direct detection of the resulting electron cloud or conversion of the electron cloud into visible photons via a phosphor to produce an optical image [182]. Direct detection schemes include centroid-detecting anodes, such as the wedge and strip design [191] and cross strip anodes [192]. Other designs are described in [193, 194].

46.4.3 Silicon Photodiodes

Broad use of silicon photodiodes at VUV wavelengths has traditionally been limited by the strong absorption of VUV photons in the outer SiO_2 passivation layer that covers the p–n junction of these devices. Standard silicon detectors are

sensitive throughout the infrared and visible regions and also in the soft X-ray ($\lambda < 2$ nm) and X-ray regions. Significant improvements in silicon photodiode sensitivities in the VUV are realized by thinning the SiO₂ passivation region to thicknesses of about 5–10 nm. Reference [195] reviews VUV semiconductor photodiode designs.

There has been active development of non-silicon-based photodiodes as VUV detectors, e.g., wide bandgap materials such as GaN, e.g., [196, 197], and significant work on a variety of innovative semiconductor designs based on nanofabrication techniques – see [175, 198] for recent reviews. The development of photodiodes with appreciable VUV sensitivity and good temporal stability has led to their use as radiometric transfer standards [199]. Because silicon photodiodes respond strongly to radiation throughout the visible, IR, and X-ray regions, a method for rejection of stray light is essential for their effective use in the VUV. Reference [200] reports on the use of thin-film filters, deposited on the photodiode surface, to restrict the bandpass of the radiation impinging on the diode to selected VUV wavelengths. Wide bandgap semiconductors reject visible light with their natural solar-blind response [199].

46.4.4 Charge-Coupled Devices

CCDs are widely used for low light level imaging applications throughout the visible and near-IR regions. In the VUV, charge-coupled devices suffer from strong absorption both by surface gate structures and by the inactive passivation layer [182]. Two approaches are employed to overcome these limitations: the CCD front surface is overcoated with a photon down-converting phosphor [201] or a thinned and surface-treated CCD is back-illuminated with VUV light [202, 203]. Such techniques have resulted in CCD VUV quantum efficiencies that rival those of photoemissive devices such as microchannel plates. Recent CCD designs with multilayer antireflection coatings based on molecular beam epitaxial doping technologies [204, 205] achieve quantum efficiencies above 60% in the spectral region centered around 200 nm.

46.5 Optical Materials

The design of VUV instrumentation is dictated in large part by the constraints of VUV optical materials. Transmission through bulk materials is limited to $\lambda > 105$ nm, the short wavelength transmission limit of LiF. Normal incidence reflectance from metal surfaces and coatings decreases dramatically at short wavelengths; polarizers and narrow-band interference filters are relatively difficult to produce because of the lack of materials with suitable optical con-

stants. Below, we briefly summarize the properties and uses of VUV optical materials. Comprehensive discussions can be found in [1, 206].

46.5.1 Windows

Few bulk materials transmit light below 200 nm; none transmit light from about 2 to 105 nm. In the 105–200 nm wavelength region, the most common window materials are synthetic fused quartz or suprasil (with a short wavelength transmission cutoff of about 160 nm), sapphire (145 nm), CaF₂ (125 nm), MgF₂ (112 nm), and LiF (105 nm). Compilations of the transmission characteristics of these and other materials are presented in [133, 207, 208]. Single crystal windows with dimensions up to 10 cm can be obtained for most of these materials. Sapphire fluoresces when struck by ionizing radiation and is, therefore, not suitable for certain environments.

46.5.2 Capillaries

In the windowless region, 2–105 nm, it is standard practice to use differentially pumped slits or circular apertures to isolate different pressure regions, e.g., to isolate an absorption cell from a vacuum spectrometer. This technique has the drawback of requiring large pumping capacities and limiting optical throughputs. Thin films (see below) can be used below 105 nm as windows, but they provide limited transmission in narrow bandpasses and cannot support large pressure differentials. Differentially pumped MCP capillary arrays can serve as an alternative window in the VUV; see, for example, [209]. The capillaries are typically ≈ 3 mm in length and have diameters of 10–100 μ m. Measured optical transmissions are in the 20–50% range throughout the VUV; tradeoffs must be considered between optical throughput and gas conductance. One significant limitation to an MCP window is its small angular aperture.

46.5.3 Thin Films

Below 105 nm, thin (about 10–200 nm) metallic films are used as transmission filters with bandpasses of approximately 10–50 nm. Details of filter properties are given in [208, 210]. Reference [211] describes composite metallic filters (e.g., Al/Ti/C, Ti/Sb/Al), developed for the Extreme Ultraviolet Explorer satellite, with transmission bandpasses of about 10–20 nm and high rejection at wavelengths of strong VUV geocoronal lines. The stability of metallic thin films under intense EUV irradiation is discussed in [212].

46.5.4 Coatings

Above 120 nm, the principal broadband reflector for VUV wavelengths is Al with a thin protective overcoat of MgF₂, having a normal incidence reflectance of ≈ 80 to 85% [213]. The normal incidence reflectivities of all materials drop dramatically below about 100 nm. A compilation of coating reflectivities at normal and grazing incidence is presented in [214]. Materials with the highest reflectivities include Os, Pt, Au, and Ir, with reflectivities of 15–30% from 30 to 110 nm [215]. Reference [216] reports grazing incidence reflection coefficients for Rh, Os, Pt, and Au from 5 to 30 nm; Rh has the highest reflectivity in this region.

46.5.5 Interference Filters and Multilayer Coatings

The development of interference filters for VUV wavelengths has been limited by the availability of coating materials with both high transmission and appreciable range of refractive differentials [217]. Multilayer dielectric reflectors, thus, require many layers to compensate for the small reflectivities at the material interfaces. The theory of multilayer reflecting optics and optic designs are reviewed in [218]. A variety of multilayer coatings with high narrowband reflectivities have been developed, references include [219–226]. Metal-dielectric bandpass filters with reflectivities as high as 90% in the ultraviolet are described in [227].

Normal incidence optics with multilayer reflection coatings can also be used in the nominally grazing incidence spectral region below 30 nm [228–230]. References [231–236] describe normal incidence gratings coated with Mo/Si multilayers. The performances of other multilayer coatings are described in [237–240].

46.5.6 Polarizers

The production and detection of linearly polarized light in the VUV is discussed in [133, 241]. Above about 112 nm, transmission polarizers, based on the birefringence of MgF₂, are often employed [242]. Reference [243] describes multilayer transmissive and reflective polarizing coatings for the hydrogen Lyman-alpha line. Reflection polarizers are usually used below 112 nm (e.g., [244]); [245] describe transmission multilayer polarizers for the 55–90 eV region. An analysis of double-reflection circular polarizers is given in [246], and multilayer transmission quarter wave plates for the generation of circular polarization are described in [247].

Glenn Stark Professor Stark's research interest is in the field of experimental molecular spectroscopy. His laboratory programs emphasize molecular transitions of interest to the astrophysics and aeronomy communities, primarily involving the measurement and interpretation of high-resolution absorption spectra of vacuum ultraviolet and extreme ultraviolet transitions. Related activities include Fourier transform spectroscopy of diatomic molecules and laser spectroscopies of diatomics.

Nelson de Oliveira Nelson de Oliveira received a PhD in Optics and Photonics from the Université Pierre et Marie Curie (Paris) in 2001. His main scientific interest is the development of instrumentation and sample environments for spectroscopy applications, designed to operate in the VUV spectral range. He is currently working at the Synchrotron Soleil facility as a beamline scientist on the DESIRS beamline.

Peter Smith Peter Smith (PhD Physics Caltech 1972) retired in 2009 after 36 years at the Harvard-Smithsonian Center for Astrophysics, performing measurements of atomic and molecular parameters at ultraviolet wavelengths for analyses of astronomical spectra, designing/calibrating instruments for ultraviolet spectral radiometric measurements of the Sun from satellites, and helping manage instrument development for the SDO satellite. He failed at retirement and spent 2013–2016 helping manage development of an instrument for the Parker Solar Probe.

Part D
Scattering Theory

Part D collects together the topics and approaches used in scattering theory. A handy compendium of equations, formulae, and expressions for the classical, quantal, and semiclassical approaches to elastic scattering is given; reactive systems and model potentials are also considered. The dependence of scattering processes on the angular orientation of the reactants and products is discussed through the analysis of scattering experiments, which probe atomic collision theories at a fundamental level. The detailed quantum mechanical techniques available to perform accurate calculations of scattering cross sections from first principles are presented. The theory of elastic, inelastic, and ionizing collisions of electrons with atoms and atomic ions is covered and then extended to include collisions with molecules. The powerful methods of quantum defect theory are discussed and applied to low-energy scattering processes, including multichannel processes. The standard scattering theory for electrons is extended to include positron collisions with atomic and molecular systems. Slow collisions of atoms or molecules within the adiabatic approximation are discussed; important deviations from this model are presented in some detail for the low energy case. Applications to collision processes involving Rydberg atoms in ultracold gases are particularly highlighted. The main methods in the theoretical treatment of ion-atom and atom-atom collisions are summarized with a focus on intermediate and high collision velocities. The molecular structure and collision dynamics

involved in ion-atom charge exchange reactions is studied. Both the perturbative and variational capture theories of the continuum distorted wave model are presented. The Wannier theory for threshold ionization is then developed. Studies of the energy and angular distribution of electrons ejected by the impact of high-velocity atomic or ionic projectiles on atomic targets are overviewed. A useful collection of formulae, expressions, and specific equations that cover the various approaches to electron-ion and ion-ion recombination processes is given. A basic theoretical formulation of dielectronic recombination is described, and its importance in the interpretation of plasma spectral emission is presented. Many of the equations used to study theoretically the collisional properties of both charged and neutral particles with atoms and molecules in Rydberg states are collected together; the primary approximations considered are the impulse approximation, the binary encounter approximation, and the Born approximation. The Thomas mass-transfer process is considered from both a classical and a quantal perspective. Additional features of this process are also discussed. The theoretical background, region of validity, and applications of the classical trajectory Monte Carlo method are then delineated. One-photon processes are discussed, and aspects of line broadening directly related to collisions between an emitting, or absorbing, atom and an electron, a neutral atom, or an atomic ion are considered.

Classical, Quantal, and Semiclassical Propagators and Applications to Elastic Scattering

Abstract

Semiclassical methods predate even full quantum mechanics starting with Bohr's atom model. Semiclassical propagators have been developed continuously in chemical physics ever since Miller's seminal classical S-matrix. Semiclassics was revived with the success of periodic orbit quantization and chaotic dynamics entering the quantum domain. Today, semiclassical and even classical concepts are accepted to describe microscopic phenomena, from protein folding over plasma physics all the way to atoms in strong laser fields. Thereby, semiclassical approximations are used for computation as well as for physical insight. Explicit formulae are given for elastic scattering, always covering quantum, classical, and semiclassical expressions.

47.1 What Is Semiclassics?

Broadly speaking, semiclassics is asymptotic quantum theory taking \hbar as a small parameter and is, therefore, an approximation between full quantum mechanics and clas-

e-mail: rost@pks.mpg.de

sical mechanics. The latter has always played an important role for molecular dynamics to describe molecular reactions and spectra. More recently, it has been widely applied also in electronic problems, most prominently when bound electrons move under the influence of intense laser pulses and are eventually ionized. Hence, we will briefly provide the quantum (finite \hbar) and the classical propagator ($\hbar = 0$) before introducing the standard semiclassical propagator ($\hbar \ll 1$).

What does a reader expect from a *Handbook of AMO Physics* chapter in the age of limitless internet access? If one is only vaguely familiar with a topic, e.g., semiclassics, one does not know how things are related and what may matter – my intention is to provide a guideline for this situation and some recipes. Newcomers may also not know which are the relevant methods, mechanisms and therefore key words, suitable to access additional resources from the internet. For this reason, we will put such phrases that are important in the context of semiclassics in italics in the following. Clearly, even for providing an overview (not a review!) the topics covered by *semiclassics* are by far too many. Hence, we do restrict ourselves to a subjective selection relevant for elastic scattering. The methods introduced are influenced by few-body physics, although most concepts are not restricted in the number of degrees of freedom (DoF). For the same reason, only nonrelativistic real-time propagation will be addressed, while imaginary time propagation describing thermal ensembles will not be covered, although it is treatable semiclassically as well. Furthermore, we will not touch semiclassical approximations to second quantization or many-body techniques even though there has been interesting progress.

There are, of course, excellent monographs about semiclassics; a recent one being [1] with a time-dependent phase space perspective and intuitive arguments, written by Eric Heller, who has been deeply involved in chemical and atomic physics as well as in chaotic dynamics and billiards. A bit older and maybe easier to approach is the monograph [2], which is based on Matthias Brack's research interest and provides an additional aspect related to nuclear and cluster physics. A real treat (and not so difficult to read) is Martin Gutzwiller's book [3], and a more mathematical account but well approachable for physicists is provided by Alfredo Ozorio Almeida in [4]. An original project lead by Predrag Cvitanovic is the online "chaos book", with part V being relevant for semiclassics [5]. Out of the many reviews, we would like to point out two "classic" ones, namely that about elastic scattering by Berry and Mount [6], and arguably the foundation for the useful application of semiclassical propagators for quantum dynamics, Bill Miller's review of his own work on the "classical S-matrix", which is, in fact, semiclassical [7]. Directly relevant in particular for the first sections of this chapter is [8].

47.2 Quantum, Classical, and Semiclassical Propagators

47.2.1 The Quantum Propagator as a Feynman Path Integral

The most general mathematical object describing evolution in the time domain is the propagator,

$$K(q, q', t) \equiv \langle q | e^{-\frac{iHt}{\hbar}} | q' \rangle = \int \mathcal{D}[q_t] e^{\frac{iS[q_t]}{\hbar}}, \quad (47.1)$$

where for simplicity we restrict ourselves to time-independent Hamiltonians H . Semiclassically, any time-dependent Hamiltonian can be turned by a formal extension of phase space into a time-independent one. Formulated as a Feynman path integral, the propagator contains *all* paths q_t leading from q' to q in time t , where q is a state (often position or momentum) for an arbitrary number of degrees of freedom F , and the action S is the integral over the classical Lagrangian while the paths themselves are not classical in general [9]. Arguably, the path integral is not a very transparent expression. Moreover, it is difficult to compute. This is one motivation to resort to a semiclassical approximation to be introduced in Sect. 47.2.3.

Analytical quantum propagators exist for a few problems only. The commonly known ones are those for the free particle of mass m and initial and final spatial coordinates \mathbf{x}' and \mathbf{x} , respectively,

$$K_0^{(F)}(\mathbf{x}, \mathbf{x}', t) = \left(\frac{m}{2\pi i \hbar t} \right)^{\frac{F}{2}} \exp \left[\frac{-m(\mathbf{x} - \mathbf{x}')^2}{2i \hbar t} \right] \quad (47.2a)$$

and the harmonic oscillator with frequency ω

$$K_{\text{HO}}^{(F)}(\mathbf{x}, \mathbf{x}', t) = \left(\frac{m\omega}{2\pi i \hbar \sin \omega t} \right)^{F/2} \times \exp \left[- \left(\frac{m\omega((\mathbf{x}^2 + \mathbf{x}'^2) \cos \omega t - 2\mathbf{x}\mathbf{x}')}{2i \hbar \sin \omega t} \right) \right]. \quad (47.2b)$$

The corresponding propagators in momentum space read

$$K_0^{(F)}(\mathbf{p}, \mathbf{p}', t) = \delta(\mathbf{p} - \mathbf{p}') \exp \left[- \frac{i t \mathbf{p}^2}{2m \hbar} \right] \quad (47.2c)$$

and for the harmonic oscillator

$$K_{\text{HO}}^{(F)}(\mathbf{p}, \mathbf{p}', t) = \left(\frac{1}{2\pi i \hbar m \omega \sin \omega t} \right)^{F/2} \times \exp \left[- \left(\frac{(\mathbf{p}^2 + \mathbf{p}'^2) \cos \omega t - 2\mathbf{p}\mathbf{p}'}{2i \hbar m \omega \sin \omega t} \right) \right], \quad (47.2d)$$

where the latter is easily obtained from Eq. (47.2b) through the equivalence $x \leftrightarrow p/(m\omega)$.

Since propagation in each degree of freedom for both problems is independent, the propagator for F degrees of freedom is simply the product, e.g., in coordinate space

$$K_F(\mathbf{x}, \mathbf{x}', t) = \prod_{j=1}^F K_1(x_j, x'_j, t). \quad (47.2e)$$

This also implies, of course, that N particles in d dimensions are simply described by $F = 2Nd$ DoF.

There are other scarce analytical results, mostly quite involved and requiring an algebraic computer manipulation tool to handle them, such as, e.g., for the Coulomb interaction [10].

47.2.2 The Classical Propagator

Classically, densities (not amplitudes) and corresponding observables of a system are evolved in time. The quantum expression that answers the question “What is the probability of finding a system after time t at q given that it was initially at q' ” is answered by the probability density $\mathcal{P}(q, q', t) = |K(q, q', t)|^2$. Classically, it has the intuitive form of a *correlation function* over phase space,

$$\mathcal{P}_{\text{cl}}(q, q', t) = \frac{1}{\Gamma} \int dq' dp' \delta(q - q_t) \delta(q' - q_0), \quad (47.3)$$

where $q_t = q(t)$ is a variable evolving under the system dynamics, and Γ is a normalization constant. The phase space integral can, in principle, be taken at any time; here, we carry it out with the conjugate phase space variables at time $t = 0$, since then the integration over q' is trivial. For the integral over p' , one has to find those initial momenta p'_j that fulfil the remaining δ -function and the integral reduces to the sum over trajectories

$$\mathcal{P}_{\text{cl}}(q, q', t) = \sum_j \mathcal{P}_j \quad (47.4a)$$

$$\mathcal{P}_j = \frac{1}{\Gamma} \left| \left[\frac{\partial q_t(p', q')}{\partial p'} \right] \right|_{q_t(p'_j, q')=q}^{-1}, \quad (47.4b)$$

where each trajectory contributes the weight equation (47.4b). Here, and in the following, $[M] = \det M$ if M is a matrix. This expression holds again in arbitrary dimensions, i.e., q and p can be vectors, and the absolute value of the determinant from $\partial q/\partial p'$, the *Jacobi matrix*, measures the phase space volume around the trajectory j . The function $q = q_t(p', q')$, and generally a set of final variables γ as a function of the initial variables γ' , is called a *deflection*

function. The quite transparent interpretation of the classical probability density equation (47.3) is with the help of Eqs. (47.4a) and (47.4b) a sum over individual probability densities for all classical trajectories that connect q and q' in time t . To obtain the normalization Γ we ask “What is the probability of finding the system at time $t = 0$ with a momentum p' in the neighborhood $\Delta p'$, if it is located within $\Delta q'$ of q' ?” We know that the system is in this neighborhood for sure, and since the phase space integral in Eq. (47.3) is trivially fulfilled, we get

$$1 = \mathcal{P}(p', q') \Delta p' \Delta q' = \frac{1}{\Gamma} \Delta p' \Delta q', \quad (47.5a)$$

which means $\Gamma = \Delta p' \Delta q'$, the phase space volume the system occupies initially (or more precisely at the time, the integration $dp' dq'$ is performed). We can ask the same question quantum mechanically: “What is the probability of finding momentum $|p'\rangle$ for a system in state $|q'\rangle$?” Since there is nothing to propagate, the answer is

$$|K(p', q', 0)|^2 = |\langle p' | q' \rangle|^2 = \left| \frac{e^{ip'q'/\hbar}}{(2\pi\hbar)^{\frac{F}{2}}} \right|^2 = \frac{1}{(2\pi\hbar)^F}, \quad (47.5b)$$

for F degrees of freedom. A comparison with Eq. (47.5a) reveals that the classical normalization compatible with the quantum result is $\Gamma_F = (2\pi\hbar)^F$, for F DoF. Obviously, this is a reasonable normalization, and if one wants to describe microscopic systems classically, it must be emphasized that this is a judicial choice. By no means does the classical propagator Eq. (47.3) contain an \hbar -dependence per se.

47.2.3 The Semiclassical Propagator

Essentially an asymptotic expansion of the Feynman path integral Eq. (47.1) to first order in \hbar , the *semiclassical propagator* is more subtle to formulate. The decisive step is the reduction of paths. It is justified by the argument of stationary phase: the phase $S[q_t]/\hbar$ varies substantially for $\hbar \ll 1$ for different paths connecting q and q' , rendering their added contribution marginal. The surviving paths have an action that is stationary under variation of the paths, $\delta S[q_t]/\delta q_t = 0$. Since this stationarity condition defines the classical equations of motion, the surviving paths are exactly the trajectories following Newtonian dynamics. Hence, the stationary phase argument for small \hbar reduces the path integral to a sum over the trajectories.

The van Vleck–Gutzwiller (VG) propagator reads

$$K_{\text{sc}}(q, q', t) = \sum_j \mathcal{P}_j^{\frac{1}{2}} \exp\left(-\frac{iv_j \pi}{2} + \frac{iS_j(q, q', t)}{\hbar}\right), \quad (47.6)$$

where \mathcal{P}_j is the classical probability density from Eq. (47.4b) with the normalization $\Gamma = (2\pi\hbar)^F$ for F degrees of freedom, as derived in Eqs. (47.5a) and (47.5b). At a first glance, the semiclassical propagator has the simple and intuitive form of a sum over classical trajectories whose weights are now complex amplitudes formed by the square root of the classical probability and multiplied by a phase factor given by the classical action of the trajectory, as originally suggested already in 1928 by *van Vleck* [11]. The truth is more complicated, as the semiclassical propagator retains a memory about the topology of the paths contributing between q and q' . At certain points in time, the trajectory bundle around traj. j may not span the full local phase space volume $|\partial q(t)/\partial p'_j|$ due to a *focal point* or a *caustic*. Propagating the trajectory across such a point where the determinant is singular may change the sign of $[\partial q(t)/\partial p'_j]$. This is formally encoded in the *Maslov phase* ν_j counting the number of sign changes of the eigenvalues of the Jacobi matrix in time along trajectory j , as pointed out by *Gutzwiller* only in 1967 [12].

Two features make the van Vleck–Gutzwiller propagator difficult to compute. To determine ν_j is cumbersome and, also, to find the initial momenta p' that allow a trajectory to start at q' and end at q in time t requires numerically expensive root searches. An alternative formulation in phase space is particular suitable for numerical propagation.

The Hermann Kluk propagator is given [13] as an integral over the initial conditions (p_0, q_0) of the trajectories (q_t, p_t) , propagated under a classical Hamiltonian H ,

$$K_\gamma(q, q', t) = \frac{1}{(2\pi\hbar)^F} \iint d^F q_0 d^F p_0 R_\gamma(p_t, q_t) \times \exp\left(\frac{i}{\hbar} S(p_t, q_t)\right) f_\gamma(q, q_t, p_t) f_\gamma^*(q', q_0, p_0). \quad (47.7)$$

Each trajectory is the center of a Gaussian

$$f_\gamma(q, q', p') = \exp\left(-\frac{\gamma^2}{2}(q - q')^2 + \frac{i}{\hbar} p'(q - q')\right). \quad (47.8)$$

The action $S = \int(p\dot{q} - H) dt$ accumulated along the trajectory enters Eq. (47.7) as well as the probability density of each trajectory $R_\gamma(p_t, q_t)$, which contains all four blocks

$$M_{xy}(t, 0) = \frac{\partial x_t}{\partial y_0}, \quad (47.9)$$

$\in \mathbb{R}^F \times \mathbb{R}^F$ of the *monodromy matrix*

$$\begin{pmatrix} \delta q_t \\ \delta p_t \end{pmatrix} = \begin{pmatrix} M_{qq} & M_{qp} \\ M_{pq} & M_{pp} \end{pmatrix} \begin{pmatrix} \delta q_0 \\ \delta p_0 \end{pmatrix}. \quad (47.10)$$

The actual form of the probability density depends on a width parameter γ , which determines the admixture of the different blocks M_{xy} in the determinant

$$R_\gamma(p_t, q_t) = \left[\frac{1}{2} \left(M_{qq} + M_{pp} - i\gamma^2 \hbar M_{qp} - \frac{1}{i\gamma^2 \hbar} M_{pq} \right) \right]^{\frac{1}{2}}. \quad (47.11)$$

Although this semiclassical propagator is not uniquely defined through its dependence on a suitable chosen parameter γ , it is exactly the feature that provides approximate global *uniformization* since at a *caustic*, R_γ always remains finite, which is an important advantage over other forms. Secondly, as was already pointed out, one does not have to keep track of *Maslov indices*. Instead, one has to make R_γ continuous as the radicant crosses the branch cut. Finally, the root search has been circumvented. All semiclassical propagators with this property use the *initial value representation* (IVR), i.e., the integral is over phase space coordinates at a single point in time (typically the initial time) only.

By taking $\gamma \rightarrow \infty$ or $\gamma \rightarrow 0$, one obtains the semiclassical IVR propagators in position or momentum space, respectively.

Expressions take a particularly simple and appealing form if the propagator Eq. (47.7) is used in conjunction with wavefunctions that contain the Gaussians with the same width γ . The correlation function $c(t) = \langle \Psi | \exp(-iH/\hbar) | \Psi \rangle$ probing the spectrum of H is a general example.

The semiclassical correlation function c_{sc} using Eq. (47.7) with a normalized Gaussian $\Psi = (\gamma^2/\pi)^{3/4} f_\gamma(q, q', p')$ reads

$$c_{sc}(t) = \langle \Psi | K_\gamma(t) | \Psi \rangle = \frac{1}{(2\pi\hbar)^F} \iint d^F q_0 d^F p_0 R(p_t, q_t) \times \exp\left(\frac{i}{\hbar} S(p_t, q_t)\right) \times g_\gamma(q_0, p_0, q', p') g_\gamma^*(q_t, p_t, q', p'), \quad (47.12)$$

where

$$g_\gamma(q, p, q', p') = \exp\left(-\frac{\gamma^2}{4}(q - q')^2 - \frac{1}{4\gamma^2 \hbar^2}(p - p')^2 + \frac{i}{2\hbar}(p + p')(q - q')\right). \quad (47.14)$$

The integral in Eq. (47.12) is again over phase space representing the initial conditions (q_0, p_0) of the trajectories (q_t, p_t) and is calculated in practice by *Monte Carlo integration*. The number of sampling points (trajectories to be run)

to achieve convergence depends on the initial wave packet Ψ and the part of the spectrum of H covered by it through the parameters (γ, p', q') .

Analytical semiclassical propagators. For interactions up to quadratic order (constant, linear, and harmonic potentials) $\langle V'(x) \rangle = V'(\langle x \rangle)$ holds, and, therefore, the quantum system observables can, indeed, be described with classical trajectories. This is a consequence of the *Ehrenfest theorem*, which casts quantum observables into a form similar to *Hamilton's equations*

$$m \frac{d\langle x \rangle}{dt} = \langle p \rangle, \quad \frac{d\langle p \rangle}{dt} = -\langle V'(x) \rangle. \quad (47.15)$$

Hence, the quantum propagators for the free particle and the harmonic oscillator in arbitrary dimensions Eqs. (47.2a)–(47.2e) are identical to the corresponding semiclassical propagators.

47.3 Advantages and Disadvantages of Semiclassics

Advantages of Semiclassics:

- Relies on classical mechanics only but describes quantum interference
- Reveals dominant structure of a quantum problem (via *stationary phase*)
- Is exact for interactions up to quadratic order (Ehrenfest theorem)
- Excellent approximation if dynamics evolves through many degrees of freedom
- Formally offers a quantum formulation (complex amplitudes) and can, therefore, be seamlessly blended in approximation containing other quantum parts
- Offers many possibilities for additional approximations
- Is straightforward to compute.

Disadvantages of Semiclassics:

- “Hard” quantum properties, such as *tunnelling*, *diffraction* and *entanglement*, are not described.
- While straightforward to code, the numerical effort may be exponential due to the nonlinearity of classical mechanics.
- Instabilities and serious errors can occur at *caustics*, when two stationary phase points (trajectories) coalesce. *Uniformization* (higher-order correction) is then necessary, which is tedious and often does not yield an improvement worth the effort.

In particular, fragmentation into several particles is ideally suited for classical and semiclassical treatments since one can follow the particle trajectories numerically to their asymptotic momenta and simply bin them into finite intervals to arrive at a cross section. Analytical expressions that also give an idea about the singularities one encounters in classical and semiclassical scattering can be best exemplified with elastic scattering. A more exhaustive account of elastic scattering is given in previous editions of the Handbook.

47.4 Applications to Elastic Scattering

Elastic scattering is governed by the Hamiltonian $H = \mathbf{p}^2/(2m) + V(\mathbf{r})$ in the center-of-mass frame for the relative motion of two collision partners with reduced mass m .

47.4.1 Central Field

For a conservative (real) potential $V(r)$ depending only on the distance r from the scattering center O , the total energy $E > 0$ and orbital the angular momentum L are conserved. Due to the different mathematical structures classical and quantum theory take advantage of this effect in quite different ways. Classically, the deflection function mapping the impact parameter b to the scattering angle θ in the scattering plane characterizes elastic scattering. Quantum mechanically, the phase shift for each angular momentum component is relevant, as it describes the change of the corresponding partial wave due to scattering. Alternatively, initial (vectorial) momentum \mathbf{p}' is converted into final momentum \mathbf{p} through scattering, and the ensuing scalar product $\mathbf{p}' \cdot \mathbf{p} = 2mE \cos \theta$ encloses the scattering angle θ . This description can be applied in quantum and classical mechanics.

47.4.2 Center-of-Mass to Laboratory Coordinate Conversion

Let ψ_1, ψ_2 be the angles for scattering and recoil, respectively, of the projectile by a target initially at rest in the lab frame. Then,

$$\begin{aligned} \sigma_1(\psi_1) d\Omega_1 &= \sigma_2(\psi_2) d\Omega_2 \\ &= \sigma_{\text{cm}}^{(1,2)}(\theta) d\Omega_{\text{cm}}, \quad 0 \leq \theta \leq \pi; \\ \sigma_{\text{cm}}^{(2)}(\theta, \phi) &= \sigma_{\text{cm}}^{(1)}(\pi - \theta, \phi + \pi). \end{aligned} \quad (47.16)$$

(A) Elastic scattering of two bodies with masses m_1 and m_2 without conversion of translational kinetic energy into

internal energy: (1) + (2) \rightarrow (1) + (2).

$$\begin{aligned}\sigma_1(\psi_1) &= \sigma_{\text{cm}}(\theta) \frac{(1 + 2x \cos \theta + x^2)^{3/2}}{|1 + x \cos \theta|}; \\ \sigma_2(\psi_2) &= \sigma_{\text{cm}}(\theta) \left| 4 \sin \frac{1}{2} \theta \right|; \\ \psi_2 &= \frac{1}{2}(\pi - \theta), \quad 0 \leq \psi_2 \leq \frac{1}{2}\pi; \\ \tan \psi_1 &= \frac{\sin \theta}{(x + \cos \theta)}, \quad x = m_1/m_2. \quad (47.17)\end{aligned}$$

$m_1 > m_2$: As $0 \leq \theta \leq \theta_c = \cos^{-1}(-m_2/m_1)$,
 $0 \leq \psi_1 \rightarrow \psi_1^{\text{max}} = \sin^{-1}(m_2/m_1) < \frac{1}{2}\pi$.

As $\theta_c \leq \theta \rightarrow \pi$, $\psi_1^{\text{max}} \leq \psi_1 \rightarrow 0$;
 θ is a double-valued function of ψ ;

$m_1 = m_2$: $\sigma_1(\psi_1) = (4 \cos \psi_1) \sigma_{\text{cm}}(\theta = 2\psi_1)$,
 $0 \leq \psi_1 \leq \frac{1}{2}\pi$, $\psi_1 + \psi_2 = \frac{1}{2}\pi$;
 no backscattering;

$m_1 \ll m_2$: $\sigma_1(\psi_1) = \sigma_{\text{cm}}(\theta = \psi_1)$;
 lab and cm frames identical.

(B) Two-body elastic scattering process with conversion of translational kinetic energy into internal energy: (1) + (2) \rightarrow (3) + (4). For conversion of internal energy ε_i so that kinetic energy of relative motion (in the cm frame) increases from E_i to $E_f = E_i + \varepsilon_i$. For $j = 3, 4$,

$$\begin{aligned}\sigma_j(\psi_j) &= \sigma_{\text{cm}}(\theta) \frac{[1 + 2x_j \cos \theta + x_j^2]^{3/2}}{|1 + x_j \cos \theta|}, \\ x_3 &= \left(\frac{m_1 m_3 E_i}{m_2 m_4 E_f} \right)^{1/2}, \\ x_4 &= - \left(\frac{m_1 m_4 E_i}{m_2 m_3 E_f} \right)^{1/2}, \\ \tan \psi_3 &= \frac{\sin \theta}{(x_3 + \cos \theta)}, \quad \tan \psi_4 = \frac{\sin \theta}{(|x_4| - \cos \theta)}. \quad (47.18)\end{aligned}$$

47.5 Quantal Elastic Scattering

Throughout this section we use reduced energy k^2 and potential $U(r)$,

$$\begin{aligned}k^2 &= (2m/\hbar^2)E, \\ U(r) &= (2m/\hbar^2)V(r).\end{aligned}$$

The basic quantity in quantal elastic scattering is the differential cross section

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 \quad (47.19)$$

in terms of the complex *scattering amplitude* $f(E, \theta)$ contained in the wavefunction

$$\Psi(\mathbf{r}) \rightarrow \exp(ikz) + \frac{1}{r} f(\theta) \exp(ikr) \quad (47.20)$$

as $r \rightarrow \infty$.

47.5.1 Scattering Amplitude from the Propagator

The scattering amplitude from incident momentum \mathbf{p}' to scattered momentum \mathbf{p} can be expressed with the *S-matrix* through the relation

$$\langle \mathbf{p} | S - 1 | \mathbf{p}' \rangle = -\frac{m}{2\pi i \hbar} \delta(E - E') f(\mathbf{p}, \mathbf{p}'). \quad (47.21a)$$

Using the definition of the S-matrix in terms of the propagator K_0 for free motion Eq. (47.2c),

$$S = \lim_{t \rightarrow \infty} K_0^\dagger(t) K(2t) K_0^\dagger(t), \quad (47.21b)$$

and the representation

$$\begin{aligned}\delta(E - E') &= \frac{m}{p} \delta(p - p') \\ &= \frac{m}{p} \lim_{t \rightarrow \infty} \left(\frac{t}{2\pi i \hbar m} \right)^{1/2} \exp\left(\frac{i(p - p')^2 t}{2m\hbar} \right)\end{aligned} \quad (47.21c)$$

of the δ -function we get [8]

$$\begin{aligned}f(\mathbf{p}, \mathbf{p}') &= \frac{p}{m} \lim_{t \rightarrow \infty} ((2\pi i \hbar m)^3 / t)^{1/2} \\ &\times \langle \mathbf{p} | K_0^\dagger(t) K(2t) K_0^\dagger(t) - 1 | \mathbf{p}' \rangle, \quad (47.21d)\end{aligned}$$

which is a representation for the scattering amplitude that can be used for the semiclassical formulation in conjunction with the propagators given in Sect. 47.2.3. For the direct quantum calculation, one normally makes use of the conserved angular momentum for partial waves. Using all constants of motion an S-matrix element between initial and final variables can be written as

$$\langle E, \ell, m | S | E', \ell', m' \rangle = S_\ell(E) \delta(E - E') \delta_{\ell\ell'} \delta_{mm'}. \quad (47.22)$$

Since the S-matrix is unitary, $S_\ell = \exp(2i\eta_\ell)$ can be expressed through a phase η_ℓ . Why this is called phase shift and how it is most conveniently determined will become clear through partial wave expansion.

47.5.2 Partial Wave Expansion

Due to the spherical symmetry, angular momentum ℓ is conserved, and the wavefunction $\Psi(\mathbf{r})$ as well as the scattering

amplitude $f(\theta)$ can be expanded into partial waves for each ℓ with the coefficients formulated in terms of phase shifts $\eta_\ell(E)$

$$\Psi(\mathbf{r}) = \frac{1}{kr} \sum_{\ell=0}^{\infty} A_\ell v_\ell(kr) P_\ell(\cos \theta), \quad (47.23a)$$

$$A_\ell = i^\ell (2\ell + 1) \exp(i\eta_\ell). \quad (47.23b)$$

The phase shift η_ℓ is obtained from the asymptotic solution of the radial Schrödinger equation

$$\frac{d^2 v_\ell}{dr^2} + \left(k^2 - \frac{2mV(r)}{\hbar^2} - \frac{\ell(\ell+1)}{r^2} \right) v_\ell(r) = 0, \quad (47.24)$$

where v_ℓ is normalized so that

$$\begin{aligned} v_\ell(r) &\stackrel{r \geq r_0}{=} \cos \eta_\ell F_\ell(kr) + \sin \eta_\ell G_\ell(kr) \\ &\rightarrow \sin\left(kr - \frac{1}{2}\ell\pi + \eta_\ell\right) \text{ as } r \rightarrow \infty. \end{aligned} \quad (47.25)$$

Hence, $v_\ell(r)$ is expressed in terms of the regular and irregular solution of the free radial Schrödinger equation ($V = 0$) containing the spherical Bessel j_ℓ and Neumann n_ℓ functions, respectively,

$$\begin{aligned} F_\ell(kr) &= (kr)j_\ell(kr) \\ &\rightarrow \begin{cases} (kr)^{\ell+1}/(2\ell+1)!!, & r \rightarrow 0 \\ \sin\left(kr - \frac{1}{2}\ell\pi\right), & r \rightarrow \infty, \end{cases} \end{aligned} \quad (47.26)$$

$$\begin{aligned} G_\ell(kr) &= -(kr)n_\ell(kr) \\ &\rightarrow \begin{cases} (2\ell-1)!!/(kr)^\ell, & r \rightarrow 0 \\ \cos\left(kr - \frac{1}{2}\ell\pi\right), & r \rightarrow \infty. \end{cases} \end{aligned} \quad (47.27)$$

The standard asymptotic scattering solution Eq. (47.25) contains the effect of scattering through the phase shift η_ℓ in the regular standing wave. By changing the normalization of A_ℓ one can express this effect in many different ways. The most common ones are to add to the regular standing wave either an irregular standing wave of real amplitude K_ℓ in Eq. (47.30) or, a spherical outgoing wave of amplitude T_ℓ in Eq. (47.31). Another possibility is to convert in Eq. (47.32) the incoming spherical wave of unit amplitude to an outgoing spherical wave of amplitude S_ℓ . The different amplitudes are related as

$$S_\ell(k) = \exp(2i\eta_\ell), \quad (47.28a)$$

$$T_\ell(k) = \sin \eta_\ell \exp(i\eta_\ell), \quad (47.28b)$$

$$K_\ell(k) = \tan \eta_\ell. \quad (47.28c)$$

The different asymptotic forms and normalizations for v_ℓ read

$$\begin{aligned} \text{(a)} \quad A_\ell &= i^\ell (2\ell + 1) \exp i\eta_\ell, \\ v_\ell(r) &\rightarrow \sin\left(kr - \frac{1}{2}\ell\pi + \eta_\ell\right); \end{aligned} \quad (47.29)$$

$$\begin{aligned} \text{(b)} \quad A_\ell &= i^\ell (2\ell + 1) \cos \eta_\ell, \\ v_\ell(r) &\rightarrow \sin\left(kr - \frac{1}{2}\ell\pi\right) + K_\ell \cos\left(kr - \frac{1}{2}\ell\pi\right); \end{aligned} \quad (47.30)$$

$$\begin{aligned} \text{(c)} \quad A_\ell &= i^\ell (2\ell + 1), \\ v_\ell(r) &\rightarrow \sin\left(kr - \frac{1}{2}\ell\pi\right) + T_\ell e^{i(kr - \ell\pi/2)}; \end{aligned} \quad (47.31)$$

$$\begin{aligned} \text{(d)} \quad A_\ell &= \frac{1}{2} i^{\ell+1} (2\ell + 1), \\ v_\ell(r) &\rightarrow e^{-i(kr - \ell\pi/2)} - S_\ell e^{i(kr - \ell\pi/2)}. \end{aligned} \quad (47.32)$$

47.5.3 Phase Shift and Cross Sections

The scattering amplitude in terms of partial waves ℓ reads

$$\begin{aligned} f(\theta) &= \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell + 1) [\exp(2i\eta_\ell) - 1] P_\ell(\cos \theta) \\ &= \sum_{\ell=0}^{\infty} f_\ell(\theta). \end{aligned} \quad (47.33a)$$

The phase shifts η_ℓ can be determined from the numerical solution of the radial Schrödinger equation Eq. (47.24).

The differential cross section (DCS) can be reexpanded in Legendre polynomials $P_\ell(\cos \theta)$,

$$\frac{d\sigma(E, \theta)}{d\Omega} = \frac{1}{k^2} \sum_{L=0}^{\infty} a_L(E) P_L(\cos \theta), \quad (47.34a)$$

$$\begin{aligned} a_L &= \sum_{\ell=0}^{\infty} \sum_{\ell'=|\ell-L|}^{\ell+L} (2\ell + 1)(2\ell' + 1) \\ &\quad \times (\ell\ell'00 | \ell\ell'L0)^2 \\ &\quad \times \sin \eta_\ell \sin \eta_{\ell'} \cos(\eta_\ell - \eta_{\ell'}), \end{aligned} \quad (47.34b)$$

where $(\ell\ell'mm' | \ell\ell'LM)$ are Clebsch–Gordan coefficients.

The integral cross section simplifies considerably since integration over the angle reveals the orthogonality of the partial waves,

$$\sigma(E) = 2\pi \int_0^\pi |f(\theta)|^2 d(\cos \theta) = \sum_{\ell=0}^{\infty} \sigma_\ell(E), \quad (47.35a)$$

with the partial cross sections

$$\sigma_\ell(E) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2 \eta_\ell . \quad (47.35b)$$

Optical theorem

$$\sigma(E) = (4\pi/k) \text{Im}[f(0)] . \quad (47.36)$$

S, P wave ($\ell = 0, 1$) net contribution

$$\frac{d\sigma}{d\Omega} = \frac{1}{k^2} \left\{ \sin^2 \eta_0 + [6 \sin \eta_0 \sin \eta_1 \cos(\eta_1 - \eta_0)] \right. \\ \left. \times \cos \theta + 9 \sin^2 \eta_1 \cos^2 \theta \right\} , \quad (47.37)$$

$$\sigma(E) = \frac{4\pi}{k^2} (\sin^2 \eta_0 + 3 \sin^2 \eta_1) . \quad (47.38)$$

For pure S -wave scattering, the DCS is isotropic. For pure P -wave scattering, the DCS is symmetric about $\theta = \pi/2$, where it vanishes; the DCS rises to equal maxima at $\theta = 0, \pi$. For combined S and P -wave scattering, the DCS is asymmetric with forward-backward asymmetry.

Collision integrals. Averages of $\sigma^{(n)}(E)$ over a Maxwellian distribution at temperature T are

$$\Omega^{(n,s)}(T) = [(s+1)!(kT)^{s+2}]^{-1} \int_0^{\infty} \sigma^{(n)}(E) \\ \times \exp(-E/kT) E^{s+1} dE . \quad (47.39)$$

Normalization factors are chosen so that the above expressions for $\sigma^{(n)}$ and $\Omega^{(n,s)}$ reduce to πd^2 for classical rigid spheres of diameter d .

Mobility. The mobility K of ions of charge e in a gas of density N is given by the Chapman–Enskog formula

$$K = \frac{3e}{8N} \left(\frac{\pi}{2MkT} \right)^{1/2} [\Omega^{(1,1)}(T)]^{-1} . \quad (47.40)$$

47.5.4 Identical Particles: Symmetry Oscillations

Colliding particles, each with spin s , in a total spin S_t resolved state in the range $(0 \rightarrow 2s)$ Particle interchange: $\Psi(\mathbf{r}) = (-1)^{S_t} \Psi(-\mathbf{r})$

$$I_{A,S}(\theta) = \frac{1}{2} |f(\theta) \mp f(\pi - \theta)|^2 , \quad (47.41a)$$

$$\Psi_{A,S}(\mathbf{r}) \rightarrow [\exp(ikZ) \mp \exp(-ikZ)] \\ + \frac{1}{R} [f(\theta) \mp f(\pi - \theta)] \exp(ikr) , \quad (47.41b)$$

$$I_{A,S}(\theta) = \frac{1}{4k^2} \left| \sum_{\ell=0}^{\infty} \omega_\ell (2\ell + 1) [\exp 2i\eta_\ell - 1] P_\ell(\cos \theta) \right|^2 , \quad (47.41c)$$

$$\sigma_{A,S}(E) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} \omega_\ell (2\ell + 1) \sin^2 \eta_\ell , \quad (47.41d)$$

where A and S denote antisymmetric and symmetric wavefunctions (with respect to particle interchange) for collisions of identical particles with odd and even total spin S_t

$$\text{A: } S_t \text{ odd } \quad \omega_\ell = 0 \ (\ell \text{ even}) ; \quad \omega_\ell = 2 \ (\ell \text{ odd}) ;$$

$$\text{S: } S_t \text{ even } \quad \omega_\ell = 2 \ (\ell \text{ even}) ; \quad \omega_\ell = 0 \ (\ell \text{ odd}) .$$

Spin states S_t unresolved S/A combination

$$I(\theta) = g_A I_A(\theta) + g_S I_S(\theta) , \quad (47.42a)$$

$$\sigma(E) = g_A \sigma_A(E) + g_S \sigma_S(E) , \quad (47.42b)$$

where g_A and g_S are the fractions of states with odd and even total spins $S_t = 0, 1, 2, \dots, 2s$. For fermions (F) with half integer spin s and bosons (B) with integral spin s ,

$$\text{F: } g_A = (s+1)/(2s+1) , \quad g_S = s/(2s+1) ,$$

$$\text{B: } g_A = s/(2s+1) , \quad g_S = (s+1)/(2s+1) ,$$

so that Eqs. (47.42a) and (47.42b) have the alternative forms

$$I(\text{F}) = |f(\theta)|^2 + |f(\pi - \theta)|^2 - \mathcal{I} , \quad (47.43a)$$

$$\sigma(\text{F}) = \frac{1}{2} [\sigma_S + \sigma_A] - \frac{1}{2} [\sigma_S - \sigma_A] / (2s+1) , \quad (47.43b)$$

$$I(\text{B}) = |f(\theta)|^2 + |f(\pi - \theta)|^2 + \mathcal{I} , \quad (47.43c)$$

$$\sigma(\text{B}) = \frac{1}{2} [\sigma_S + \sigma_A] + \frac{1}{2} [\sigma_S - \sigma_A] / (2s+1) , \quad (47.43d)$$

where the interference term is

$$\mathcal{I} = \left(\frac{2}{2s+1} \right) \text{Re}[f(\theta) f^*(\pi - \theta)] . \quad (47.43e)$$

Example: for fermions with spin $1/2$,

$$\sigma(E) = \frac{2\pi}{k^2} \left[\sum_{\ell=\text{even}}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \right. \\ \left. + 3 \sum_{\ell=\text{odd}}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \right] . \quad (47.44)$$

Symmetry oscillations originate from the interference between unscattered incident particles in the forward ($\theta = 0$) direction and backward scattered particles ($\theta = \pi, \ell = 0$). Symmetry oscillations are sensitive to the repulsive wall of the interaction.

Singlet–triplet spin flip cross section

$$\sigma_{\text{ST}}(E) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2(\eta_{\ell}^{\text{s}} - \eta_{\ell}^{\text{t}}), \quad (47.45)$$

where $\eta_{\ell}^{\text{S,T}}$ are the phase shifts for individual scattering by the singlet and triplet potentials, respectively.

47.5.5 Low-Energy $E \rightarrow 0$ Scattering

Blatt–Jackson effective range formula For short-range potentials,

$$k \cot \eta_0 = -\frac{1}{a_s} + \frac{1}{2} r_e k^2 + \mathcal{O}(k^4) \quad (47.46a)$$

with effective range

$$r_e = 2 \int_0^{\infty} [u_0^2(r) - v_0^2(r)] dr, \quad (47.46b)$$

where $u_0 = \sin(kr + \eta_0)/\sin \eta_0$ is the $k = 0$ limit of the potential-free $\ell = 0$ radial wavefunction and normalized so that $u_0(r)$ goes to unity as $k \rightarrow 0$. The potential distorted $\ell = 0$ radial function v_0 is normalized at large r to $u_0(r)$. The effective range is a measure of the distance over which v_0 differs from u_0 . The outside factor of 2 in Eq. (47.46b) is chosen such that $r_e = a$ for a square well of range a .

The elastic cross section for $k \rightarrow 0$ can be expressed as

$$\begin{aligned} \sigma(k \rightarrow 0) &= \frac{4\pi}{k^2} \sin^2 \eta_0 \\ &= 4\pi a_s^2 \left(\left(1 - \frac{1}{2} k^2 a_s r_e\right)^2 + k^2 a_s^2 \right)^{-1} \end{aligned} \quad (47.47a)$$

$$\rightarrow 4\pi a_s^2 [1 + a_s k^2 (r_e - a_s)], \quad (47.47b)$$

with the

scattering length

$$a_s = -\lim_{k \rightarrow 0} f(\theta). \quad (47.47c)$$

Relation with Bound Levels

Levinson's theorem A radial potential $V(r)$ can support n_{ℓ} bound states of angular momentum ℓ and energy E_n , such that

$$\lim_{k \rightarrow 0} \eta_0(k) = \begin{cases} n_0 \pi, & E_n < 0 \\ (n_0 + \frac{1}{2}) \pi, & E_{n+1} = 0, \end{cases} \quad (47.48a)$$

$$\lim_{k \rightarrow 0} \eta_{\ell}(k) = n_{\ell} \pi, \quad \ell > 0. \quad (47.48b)$$

If an $\ell = 0$ bound level of energy $E_n = -\hbar^2 k_n^2/2m$ is sufficiently close to the dissociation limit, the effective range and scattering lengths, r_e and a_s , respectively, are related by

$$-\frac{1}{a_s} = -k_n + \frac{1}{2} r_e k_n^2 + \dots \quad (47.49)$$

Wigner causality condition If η_{ℓ} provides the dominant contribution to $f(\theta)$, then

$$\frac{\partial \eta_{\ell}(k)}{\partial k} \geq -a_s, \quad (47.50)$$

where a_s is the scattering length ($\ell = 0$) and is a measure of the range of the interaction.

Effective range formulae The Blatt–Jackson formula must be modified [14–16] for long-range interactions as follows.

(1) Coulomb tail: $V(r) \approx Z_1 Z_2 e^2/r$

$$\begin{aligned} 2(K/a_0) &= -(1/a_s) + \frac{1}{2} r_e k^2 \\ K &= \frac{\pi \cot \eta_0}{e^{2\pi\alpha} - 1} - \ln \beta - 0.5772 \\ &\quad + \beta^2 \sum_{n=1}^{\infty} [n(n^2 + \beta^2)]^{-1}, \end{aligned} \quad (47.51)$$

where $\beta = Z_1 Z_2 e^2/\hbar v = Z_1 Z_2/(ka_0)$ and $\alpha = Z_1 Z_2 e^2/(2Er_e)$.

(2) Polarization: $V(r) = -\alpha_d e^2/2r^4$,

$$\begin{aligned} \tan \eta_0 &= -a_s k - \frac{\pi}{3} C_4 k^2 - \frac{4}{3} C_4 a_s k^3 \ln(ka_0) \\ &\quad + D k^3 + F k^4, \end{aligned} \quad (47.52a)$$

$$\tan \eta_1 = \frac{\pi}{15} C_4 k^2 - a_s^{(1)} k^3, \quad (47.52b)$$

$$\begin{aligned} \tan \eta_{\ell} &= \frac{\pi C_4 k^2}{(2\ell + 3)(2\ell + 1)(2\ell - 1)} \\ &\quad + \mathcal{O}(k^{2\ell+1}), \end{aligned} \quad (47.52c)$$

for $\ell > 1$, where

$$C_4 = \frac{2m}{\hbar^2} \left(\frac{\alpha_d e^2}{2} \right) = \left(\frac{\alpha_d}{a_0} \right) \left(\frac{m}{m_e} \right).$$

Example: $e^- - \text{Ar}$ low energy collisions. The values

$$\begin{aligned} a_s &= -1.459 a_0; & D &= 68.93 a_0^3 \\ a_s^{(1)} &= 8.69 a_0^3; & F &= -97 a_0^4 \end{aligned}$$

allow for an accurate fit to measurements [17].

(3) Van der Waals: $V(r) = -C/r^6$

$$\begin{aligned} k \cot \eta_0 &= -\frac{1}{a_s} + \frac{1}{2} r_e k^2 - \frac{\pi}{15 a_s^2} \left(\frac{2mC}{\hbar^2} \right) k^3 \\ &\quad - \frac{4}{15 a_s} \left(\frac{2mC}{\hbar^2} \right) k^4 \ln(ka_0) + \mathcal{O}(k^4). \end{aligned} \quad (47.53)$$

e-Atom collisions with polarization attraction As $k \rightarrow 0$, the differential cross section is

$$\frac{d\sigma}{d\Omega} = a_s^2 \left[1 + \frac{C_4}{a_s} k \sin \frac{\theta}{2} + \frac{8}{3} C_4 k^2 \ln(ka_0) + \dots \right], \quad (47.54)$$

and the elastic and diffusion cross sections are

$$\sigma(k \rightarrow 0) = 4\pi a_s^2 \left[1 + \frac{2\pi C_4 k}{3a_s} + \frac{8}{3} C_4 k^2 \ln(ka_0) + \dots \right], \quad (47.55)$$

$$\sigma_d(k \rightarrow 0) = 4\pi a_s^2 \left[1 + \frac{4\pi C_4 k}{5a_s} + \frac{8}{3} C_4 k^2 \ln(ka_0) + \dots \right]. \quad (47.56)$$

For e⁻-noble gas collisions, the scattering lengths are

	He	Ne	Ar	Kr	Xe
$a_s(a_0)$	1.19	0.24	-1.459	-3.7	-6.5

For atoms with $a_s < 0$, a Ramsauer–Townsend minimum appears in both σ and σ_d at low energies, provided that scattering from higher partial waves can be neglected, because from Eq. (47.52a), $\eta_0 \simeq 0$ at $k = -3a_s/\pi C_4$.

Semiclassical scattering lengths. In the limit $E \rightarrow 0$, the semiclassical phase shift tends to

$$\eta_0^{\text{SC}} = \left(\frac{2m}{\hbar^2} \right)^{1/2} \int_{r_m}^{\infty} |V(r)|^{1/2} dr, \quad (47.57)$$

where r_m is the turning point. Equation (47.57) can be used to calculate some scattering lengths analytically and estimate the number of bound states in the potential [16]:

(a) Hard-core + well

$$V(r) = \begin{cases} \infty, & r < r_0 \\ -V_0, & r_0 \leq r < r_1 \\ 0, & r_1 < r, \end{cases}$$

$$a_s = [1 - \tan \eta_0^{\text{SC}}/(k_0 r_1)] r_1, \quad (47.58a)$$

$$\eta_0^{\text{SC}} = k_0(r_1 - r_m), \quad k_0^2 = 2mV_0/\hbar^2. \quad (47.58b)$$

The phase-averaged scattering length is $\langle a_s \rangle = r_1$.

(b) Hard-core + power law ($n > 2$)

$$V(r) = \begin{cases} \infty, & r < r_0 \\ \pm C/r^n, & r > r_0. \end{cases} \quad (47.59)$$

Repulsion (+): with $\gamma^2 = 2mC/\hbar^2$,

$$a_s^{(+)} = \left(\frac{\gamma}{n-2} \right)^{2/(n-2)} \Gamma\left(\frac{n-3}{n-2}\right) / \Gamma\left(\frac{n-1}{n-2}\right). \quad (47.60)$$

Attraction (-): with $\theta_n = \pi/(n-2)$,

$$a_s^{(-)} = a_s^{(+)} [1 - \tan \theta_n \tan(\eta_0^{\text{SC}} - \frac{1}{2}\theta_n)] \cos \theta_n, \quad (47.61)$$

$$\eta_0^{\text{SC}} = \gamma \int_{r_m}^{\infty} r^{-n/2} dr = \frac{2\gamma r_0^{1-n/2}}{n-2}, \quad (47.62)$$

$$\langle a_s^{(-)} \rangle = a_s^{(+)} \cos \theta_n. \quad (47.63)$$

Number of bound states

$$N_b = \text{int} \left\{ \frac{1}{\pi} \left[\eta_0^{\text{SC}} - \frac{1}{2}(n-1)\theta_n \right] \right\} + 1, \quad (47.64)$$

where $\text{int}(x)$ denotes the largest integer of the real argument x . For integer x , $a_s^{(-)}$ is infinite, and a new bound state appears at zero energy.

Born approximation for phase shifts

$$\tan \eta_\ell^{\text{B}}(k) = -k \int_0^{\infty} U(r) [j_\ell(kr)]^2 r^2 dr. \quad (47.65)$$

For $\lambda = (\ell + 1/2) \gg ka$, substitute

$$\langle k^2 r^2 [j_\ell(kr)]^2 \rangle = \frac{1}{2} (1 - \lambda^2/k^2 r^2)^{-1/2}. \quad (47.66)$$

Born S-wave phase shift

$$\tan \eta_0^{\text{B}}(k) = -\frac{1}{k} \int_0^{\infty} U(r) \sin^2(kr) dr. \quad (47.67)$$

Examples: (i) $U = U_0 \frac{e^{-\alpha r}}{r}$, (ii) $U = \frac{U_0}{(r^2 + r_0^2)^2}$;

$$(i) \tan \eta_0^{\text{B}} = -\frac{U_0}{4k} \ln(1 + 4k^2/\alpha^2), \quad (47.68)$$

$$(ii) \tan \eta_0^{\text{B}} = -\frac{\pi U_0}{4k r_0^3} [1 - (1 + 2kr_0)e^{-2kr_0}]. \quad (47.69)$$

Born phase shifts (large ℓ) For $\ell \gg ka$,

$$\tan \eta_\ell^{\text{B}} = -\frac{k^{2\ell+1}}{[(2\ell+1)!!]^2} \int_0^{\infty} U(r) r^{2\ell+2} dr, \quad (47.70)$$

valid only for finite range interactions $U(r > a) = 0$.

Example: $U = -U_0, r \leq a$ and $U = 0, r > a$.

$$\tan \eta_\ell^{\text{B}}(\ell \gg ka) = U_0 a^2 \frac{(ka)^{2\ell+1}}{[(2\ell+1)!!]^2 (2\ell+3)}. \quad (47.71)$$

For $\ell \gg ka$, $\eta_{\ell+1}/\eta_\ell \approx (ka/2\ell)^2$.

47.5.6 Nonspherical Potentials

The plane wave scattering states are

$$\phi_{\mathbf{k}}(\mathbf{r}) = \exp(i\mathbf{k} \cdot \mathbf{r}) = \phi_{\mathbf{k}}^*(\mathbf{r}), \quad (47.72)$$

and the full scattering solutions have the form

$$\Psi_{\mathbf{k}}^{(\pm)}(\mathbf{r}) \approx \phi_{\mathbf{k}}(\mathbf{r}) + \frac{f(\mathbf{k}, \mathbf{k}')}{r} \exp(\pm ikr), \quad (47.73a)$$

where the scattering amplitude is

$$f(\mathbf{k}, \mathbf{k}') = -\frac{1}{4\pi} \langle \phi_{\mathbf{k}'}(\mathbf{r}) | U(\mathbf{r}) | \Psi_{\mathbf{k}}^{(+)}(\mathbf{r}) \rangle. \quad (47.73b)$$

Close to analytical solutions can typically only be obtained in the following.

Born approximation: Set $\Psi_{\mathbf{k}}^+ = \phi_{\mathbf{k}}$ in Eq. (47.73b). Then

$$f_{\text{B}}(K) = -\frac{1}{4\pi} \int U(\mathbf{r}) \exp(i\mathbf{K} \cdot \mathbf{r}) d\mathbf{r}, \quad (47.74)$$

with momentum transfer $\mathbf{K} = \mathbf{k} - \mathbf{k}'$, and $K = 2k \sin \frac{1}{2}\theta$. For a symmetric potential,

$$f_{\text{B}}(K) = -\int \frac{\sin kr}{kr} U(r) r^2 dr \quad (47.75)$$

is consistent with Eq. (47.65) since

$$\frac{\sin kr}{kr} = \sum_{\ell=0}^{\infty} (2\ell + 1) [j_{\ell}(kr)]^2 P_{\ell}(\cos \theta). \quad (47.76)$$

The static e^- -atom scattering potential and Born scattering amplitude are

$$V(r) = -\frac{Ze^2}{r} + e^2 \int \frac{|\psi(\mathbf{r}')|^2 d\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|}, \quad (47.77)$$

$$f_{\text{B}}(K) = \frac{2me^2}{\hbar^2} \frac{[Z - F(K)]}{K^2}, \quad (47.78)$$

where the *elastic form factor* is

$$F(K) = \int |\psi(\mathbf{r})|^2 \exp(i\mathbf{K} \cdot \mathbf{r}) d\mathbf{r}. \quad (47.79)$$

For a pure Coulomb field, $F(K) = 0$, and $\sigma_{\text{B}}(\theta, E) = |f_{\text{B}}(K)|^2$ reduces to Eq. (47.177e).

47.5.7 Reactive Systems

All nonelastic processes (e.g., inelastic scattering and rearrangement collisions/chemical reactions) can be viewed as a net absorption from the incident beam current vector \mathbf{J} and modeled by a complex optical potential

$$V(r) = V_{\text{r}}(r) + iV_{\text{i}}(r). \quad (47.80)$$

The continuity equation is then

$$\nabla \cdot \mathbf{J} = -\frac{2}{\hbar} V_{\text{i}}(r) |\Psi(\mathbf{r})|^2, \quad (47.81)$$

so that particle absorption implies $V_{\text{i}} > 0$ and particle creation $V_{\text{i}} < 0$. Since particle conservation implies $|S_{\ell}|^2 = 1$, the phase shift

$$\delta_{\ell}(k) = \eta_{\ell}(k) + i\gamma_{\ell}(k) \quad (47.82a)$$

is also complex. Then

$$S_{\ell} = A_{\ell}(k) \exp(2i\eta_{\ell}), \quad (47.82b)$$

where the absorption (inelasticity) factor is

$$A_{\ell} = \exp(-2\gamma_{\ell}) \leq 1. \quad (47.82c)$$

The elastic, absorption, and total cross sections read

$$f_{\text{el}}(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell + 1) (A_{\ell} e^{2i\eta_{\ell}} - 1) P_{\ell}(\cos \theta), \quad (47.83a)$$

$$\sigma_{\text{el}}(k) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) |A_{\ell} e^{2i\eta_{\ell}} - 1|^2, \quad (47.83b)$$

$$\sigma_{\text{abs}}(k) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) (1 - A_{\ell}^2), \quad (47.83c)$$

$$\sigma_{\text{tot}}(k) = \sigma_{\text{el}}(k) + \sigma_{\text{abs}}(k). \quad (47.83d)$$

Upper limits to the partial cross sections are

$$\sigma_{\ell}^{\text{el}} \leq \frac{4\pi}{k^2} (2\ell + 1), \quad \sigma_{\ell}^{\text{abs}} \leq \frac{\pi}{k^2} (2\ell + 1), \quad (47.84a)$$

$$\sigma_{\ell}^{\text{tot}} \leq \frac{4\pi}{k^2} (2\ell + 1) = \frac{4\pi}{k} \text{Im}[f_{\ell}^{\text{el}}(\theta = 0)]. \quad (47.84b)$$

For pure elastic scattering with no absorption, $A_{\ell} = 1$. All nonelastic processes ($0 \leq A_{\ell} < 1$) are always accompanied by elastic scattering, even in the ($A_{\ell} = 0$) limit of full absorption.

Eikonal formulae for forward reactive scattering

$$f_{\text{el}}(\theta) = -ik \int_0^{\infty} (e^{2i\delta} - 1) J_0(2kb \sin \frac{1}{2}\theta) b db, \quad (47.85a)$$

$$\sigma_{\text{el}}(k) = 2\pi \int_0^{\infty} |(1 - e^{-2\gamma} e^{2i\eta})|^2 b db, \quad (47.85b)$$

$$\sigma_{\text{abs}}(k) = 2\pi \int_0^{\infty} (1 - e^{-4\gamma}) b db, \quad (47.85c)$$

$$\sigma_{\text{tot}}(k) = 4\pi \int_0^{\infty} (1 - e^{-2\gamma} \cos 2\eta) b db, \quad (47.85d)$$

where the phase shift function $\delta = \eta + i\gamma$ at impact parameter b can be either the Jeffrey–Born phase

$$\delta_{\text{JB}}(b) = -\frac{m}{k\hbar^2} \int_b^{\infty} \frac{V(r) dr}{(1 - b^2/r^2)^{1/2}}, \quad (47.86)$$

where $kb = \lambda = (\ell + 1/2)$, or the eikonal phase

$$\delta_{\text{E}}(b) = -\frac{m}{2k\hbar^2} \int_{-\infty}^{\infty} V(b, Z) dZ. \quad (47.87)$$

Fraunhofer diffraction by a black sphere For a complex spherical well V

$$V = \begin{cases} V_r + iV_i, & R < a \\ 0, & R > a. \end{cases} \quad (47.88)$$

The eikonal phase function Eq. (47.87) is

$$\delta(b) = \begin{cases} mV/(k\hbar^2)(a^2 - b^2)^{1/2}, & 0 \leq b \leq a \\ 0 & b > a. \end{cases} \quad (47.89)$$

The absorption factor is

$$A(b)^2 \equiv e^{-4\gamma} = \exp[-2(a^2 - b^2)^{1/2}/\lambda], \quad (47.90)$$

where $\lambda = k\hbar^2/(2mV_i)$ is the mean free path towards absorption. For strong absorption, $\lambda \ll a$, so that

$$f_{\text{el}}(\theta) = ik \int_0^a J_0\left(2kb \sin \frac{1}{2}\theta\right) b db, \quad (47.91)$$

$$\frac{d\sigma_{\text{el}}}{d\Omega} = (ka)^2 \left(\frac{J_1(2ka \sin \frac{1}{2}\theta)}{2ka \sin \frac{1}{2}\theta} \right)^2 a^2, \quad (47.92)$$

which has a diffraction-shaped peak of width $\approx \theta \leq (ka)^{-1}$ about the forward direction, and

$$\sigma_{\text{tot}} = \frac{4\pi}{k} \text{Im}[f_{\text{el}}(\theta = 0)] = 2\pi a^2 \quad (47.93)$$

is composed of πa^2 for classical absorption and πa^2 for edge diffraction or shadow (nonclassical) elastic scattering. This result also holds for the perfectly reflecting sphere (πa^2 for classical elastic scattering and πa^2 for edge diffraction).

47.6 Classical Elastic Scattering

Conservation of energy $E > 0$ and orbital angular momentum L for a central field $V(r)$ imply classically that the relative motion with reduced mass m takes place in the plane perpendicular to the angular momentum vector $\mathbf{L} = \mathbf{b} \times \mathbf{p}'$, where the impact parameter \mathbf{b} and the initial momentum \mathbf{p}' with $|\mathbf{p}'| = p_a = (2mE)^{1/2}$, normally taken perpendicularly, define this plane. Hence, classically, elastic scattering reduces for central potentials to the analysis of a one-dimensional deflection function Θ , mapping the initial impact parameter b into the final scattering angle θ in the scattering plane. This can be surprisingly complicated if trajectories exist that circle the scattering center several times before exiting with θ , corresponding to a nonmonotonic deflection function.

47.6.1 Elastic Scattering Cross Section

The differential cross section $\frac{d\sigma}{d\Omega}$ asks which area of initial conditions, typically parameterized by the impact parameter $d\sigma = b db$, is scattered into the solid angle $d\Omega = d \cos \theta d\phi$.

With the general formulation Eq. (47.4a) of classical propagators and Eqs. (47.96a) and (47.96b) the classical differential cross section for elastic scattering from a central potential reads

$$\begin{aligned} \frac{d\sigma}{d\Omega} &= 2\pi \int db b \delta(\cos \Theta(b, E) - \cos \theta) \\ &= \frac{2\pi}{|\sin \theta|} \sum_j b_j \left| \frac{d\Theta}{db} \right|_{\cos \Theta(b_j) = \cos \theta}^{-1}, \end{aligned} \quad (47.94)$$

where the sum runs over all trajectories j connecting an impact parameter b_i with a scattering angle θ . If $\cos \Theta(b)$ is monotonic, Eq. (47.94) simplifies to $\frac{d\sigma}{d\Omega} = b db / d(\cos \theta)$.

47.6.2 Deflection Functions

The deflection function $\Theta(E, b)$, $(-\infty \leq \Theta < \pi)$ can be expressed through $\Theta(E, b) = \pi - 2\psi(r \rightarrow \infty; E, b)$ with the

angle ψ between initial (or final) momentum vector and the line that connects the scattering center with the point r_m of closest approach of the scattering trajectory, defined through radial momentum $p(r_m) = 0$. We define

$$\begin{aligned} p(r) &= [p_a^2 - 2mV(r) - L^2/r^2]^{\frac{1}{2}} \\ &= [p_a^2 - 2mV(r) - b^2E/r^2]^{\frac{1}{2}}, \\ &= [p_a^2 - 2mV_{\text{eff}}(r)]^{1/2}, \end{aligned} \quad (47.95)$$

with $p_a = \sqrt{2mE}$. Then we can write

$$\begin{aligned} \Theta(E, L) &= \pi - 2\psi(r \rightarrow \infty; E, L) \\ &= \pi + 2 \frac{\partial}{\partial L} \int_{r_m}^{\infty} p(r) dr, \end{aligned} \quad (47.96a)$$

$$\begin{aligned} \Theta(E, b) &= \pi - 2\psi(r \rightarrow \infty; E, b) \\ &= \pi + \frac{2}{p_a} \frac{\partial}{\partial b} \int_{r_m}^{\infty} p(r) dr. \end{aligned} \quad (47.96b)$$

Small-angle scattering With $V(r_m)/E \ll 1$, $b \approx r_m$

$$\begin{aligned} \Theta(E, b) &= \left(\frac{r_m}{E}\right) \int_{r_m}^{\infty} \frac{[V(r_m) - V(r)]r dr}{(r^2 - r_m^2)^{3/2}} \\ &= \frac{1}{E} \int_0^1 \frac{[V(r_m) - V(r_m/x)]dx}{(1 - x^2)^{3/2}}, \end{aligned} \quad (47.97a)$$

$$= \frac{1}{E} \int_0^1 \frac{[V(r_m) - V(r_m/x)]dx}{(1 - x^2)^{3/2}}, \quad (47.97b)$$

where $x = r_m/r$. Other forms are

$$\Theta(E, b) = -\frac{1}{E} \frac{\partial}{\partial b} \int_b^{\infty} \frac{V(r) dr}{(1 - b^2/r^2)^{1/2}} \quad (47.97c)$$

$$= -\frac{b}{E} \int_b^{\infty} \left(\frac{dV}{dr}\right) \frac{dr}{(r^2 - b^2)^{1/2}} \quad (47.97d)$$

$$= -\frac{1}{2E} \frac{\partial}{\partial b} \int_{-\infty}^{\infty} V(b, z) dz. \quad (47.97e)$$

Straight-line paths With $r^2 = b^2 + v^2t^2$, Eq. (47.96b) yields the impulse-momentum result

$$\Theta(E, b) = \frac{1}{mv} \int_{-\infty}^{\infty} F_{\perp}(t) dt = \frac{\Delta p_{\perp}}{p_a}, \quad (47.98)$$

where Δp_{\perp} is the momentum transferred perpendicular to the incident direction, and $F_{\perp} = -(\partial V/\partial r)(b/r)$ is the impulsive force causing scattering. Special cases are:

Head-on collisions ($b = 0$):	$\Theta(E, 0) = \pi$.
Overall repulsion:	$0 < \Theta \leq \pi$.
Overall attraction:	$-\infty \leq \Theta \leq 0$.
Forward glory:	$\Theta = -2n\pi$.
Backward glory:	$\Theta = -(2n - 1)\pi$,
	$n = 0, 1, 2, \dots$
Rainbow scattering:	$(d\Theta/db) = 0$ at $\Theta_r < 0$.
Deflection range:	$\Theta_r \leq \Theta \leq \pi$.
Orbiting collisions:	cf. Eq. (47.100).
Diffraction scattering:	$\Theta \rightarrow 0$ as $b \rightarrow \infty$.

The scattered particle may wind or spiral many times around ($\Theta \rightarrow -\infty$) the scattering center. The experimentally observed quantity is the scattering angle θ ($0 \leq \theta \leq \pi$), which is associated with various deflections

$$\begin{aligned} \Theta_i &= +\theta, -\theta, -2\pi \pm \theta, -4\pi \pm \theta, \dots \\ &\quad (i = 1, 2, \dots, n) \end{aligned}$$

resulting from n different impact parameters b_i ; see Eq. (47.94).

Small-angle diffraction scattering The small-angle scattering regime is defined by the conditions $V(r_m)/E \ll 1$, $b \geq r_m$, where $\theta = |\Theta|$. The main contribution to $d\sigma/d\Omega$ for small-angle scattering arises from the asymptotic branch of the deflection function Θ at large impact parameters b and is primarily determined by the long-range (attractive) part of the potential $V(r)$ (Sect. 47.7.3).

Large-angle scattering The main contribution to $d\sigma/d\Omega$ for large-angle scattering arises from the positive branch of Θ at small b and is mainly determined by the repulsive part of the potential.

47.6.3 Glory and Rainbow Scattering

Glory The deflection function Θ passes through $-2n\pi$ (forward glory) or $-(2n + 1)\pi$ (backward glory) at finite impact parameters b_g . Since $\sin \theta = \sin \Theta = 0$, the prefactor $1/|\sin \theta|$ in the cross section Eq. (47.94) diverges.

Rainbow The deflection function Θ passes through a minimum at b_r , so that

$$\Theta(b) = \Theta(b_r) + \omega_r(b - b_r)^2, \quad (47.99a)$$

$$\omega_r = \frac{1}{2} \frac{d^2\Theta}{db^2} \Big|_{b_r} > 0. \quad (47.99b)$$

The classical cross section diverges as

$$\frac{d\sigma}{d\Omega} = \frac{b_r}{2 \sin \theta} [\omega_r(\theta_r - \theta)]^{-\frac{1}{2}}, \quad \theta < \theta_r \quad (47.99c)$$

and is augmented by the contribution from the positive branch of $\Theta(b)$.

47.6.4 Orbiting and Spiraling Collisions

If strong enough, attractive interactions $V(r)$ can bind particles with $E > 0$ held inside the maximum of the effective potential $V_{\text{eff}}(r) = V(r) + b^2 E/r^2$. The trajectory that touches this maximum at r_o does not move radially and defines an orbiting resonance through the conditions

$$\left. \frac{dV_{\text{eff}}}{dr} \right|_{r=r_o} = 0 \quad \text{and} \quad p_{b_o, E}(r_o) = 0 \quad (47.100)$$

which determine r_o and b_o . The corresponding total cross section is

$$\sigma_{\text{orb}}(E) = \pi b_o^2. \quad (47.101)$$

For $b < b_o$, the particle spirals inwards.

47.6.5 Deflection Function and Time Delay from Action

Relevant is the change in action of a classical path from incoming momentum p' to final momentum p due to interaction with the potential $V(r)$ relative to the free path for a given L or b . In spherical momentum coordinates (p, L) , the action reduces to radial momenta integrals only, since L is conserved

$$\begin{aligned} S(E, L) &= - \int_{p'}^p (\mathbf{r} - \mathbf{r}_o) d\mathbf{p}'' \\ &= -2 \int_0^{p_a} (r(p) - r_o(p)) dp \quad (47.102a) \end{aligned}$$

$$= 2 \int_{r_m}^{\infty} p(r) dr - 2 \int_{b(E, L)}^{\infty} p_0(r) dr. \quad (47.102b)$$

The boundary terms are the same with $r(p)$ and without potential $r_o(p)$, and, therefore, Eq. (47.102b) holds. The deflection angle Θ is conjugate to L . Hence, the deflection function is given by

$$\Theta(E, L) = \left. \frac{\partial S(E, L)}{\partial L} \right|_E = \pi - 2L \int_{r_m}^{\infty} \frac{dr}{p(r)r^2} \quad (47.103a)$$

in agreement with Eqs. (47.96a), (47.96b) since $2L \int_b^{\infty} (p_0(r)r^2)^{-1} dr = \pi$. Similarly, the time delay τ , conjugate to E , is given by

$$\tau(E, L) = \left. \frac{\partial S(E, L)}{\partial E} \right|_L. \quad (47.103b)$$

47.6.6 Approximate Actions

Jeffrey–Born phase function For small V/E and $b \approx r_m$, we get the action S_{JB} , better known as the Jeffrey–Born phase, $\eta_{JB} = S_{JB}/\hbar$,

$$S_{JB}(E, b) = - \frac{m}{p_a} \int_b^{\infty} \frac{V(r) dr}{(1 - b^2/r^2)^{1/2}}. \quad (47.104)$$

Eikonal action For small V/E and a linear trajectory $r^2 = b^2 + z^2$, the action reduces to

$$S_{\text{Eiko}}(E, \mathbf{b}) = - \frac{m}{p_a} \int_{-\infty}^{\infty} V(\mathbf{b}, z) dz. \quad (47.105)$$

Applying Eq. (47.103a) to these actions one gets the corresponding deflection functions Eqs. (47.97a)–(47.97e).

47.7 Semiclassical Elastic Scattering

Semiclassical elastic scattering is conceptually quite involved since the scattering angle is defined over a finite range $\theta \in [0, \pi]$, while classically action and its conjugate, the deflection angle, are accumulated along a collision path without limits. Hence, several deflections differing by $\Delta\theta = 2n\pi$ contribute to differential scattering Eq. (47.94). Moreover, as a constitutive element for the construction of the scattering amplitude from the semiclassical propagator, we need the action in a “mixed representation”, that is, mapping $(p', L') \rightarrow (p, \Theta)$ and not in full momentum representation $(p', L') \rightarrow (p, L)$ as defined in $S(E, L)$ of Eqs. (47.102a) and (47.2e). The change of variables is achieved with a Legendre transformation

$$S^C(\Theta) = S(E, L) - L\Theta(E, L). \quad (47.106)$$

Decomposition into partial waves for constant angular momentum quantum number ℓ (Sect. 47.5.3) and the description of elastic scattering with resulting phase shifts η_ℓ is a powerful technique. Its semiclassical formulation requires quantizing the classical angular momentum such that the classical L is replaced for semiclassical partial waves by

$$L/\hbar \rightarrow \lambda = \ell + \frac{1}{2}, \quad (47.107)$$

which is a consequence of the Langer modification taking into account that the radial coordinate is only positive.

47.7.1 Semiclassical Amplitudes and Cross Sections

With the structure of the semiclassical propagator Eq. (47.6) and the classical cross section Eq. (47.94), the semiclassical

scattering amplitude is a sum over contributions from trajectories j starting with different impact parameters b_j , or equivalently, angular momenta λ_j ,

$$f(\theta) = \sum_{j=1}^N f_j(\theta), \quad (47.108)$$

where each classical path $b_j = b_j(\theta)$ or SP-point $\lambda_j = \lambda_j(\theta)$ contributes $f_j(\theta)$ to the amplitude

$$f_j(\theta) = -i\alpha_j \beta_j \sigma_j^{1/2}(\theta) \exp[iS_j^C(\theta)/\hbar] \quad (47.109)$$

$$\Theta'_j = (d\Theta/d\lambda)_j, \quad (47.110)$$

$$\alpha_j = e^{\pm i\pi/4}; \quad (+), \Theta'_j > 0; \quad (-), \Theta'_j < 0; \quad (47.111a)$$

$$\beta_j = e^{\pm i\pi/4}; \quad (+), \Theta_j > 0; \quad (-), \Theta_j < 0. \quad (47.111b)$$

The classical cross section for each trajectory [Eq. (47.94)] is

$$\sigma_j(\theta) = b_j \left| \frac{d \cos \Theta}{db} \right|_{\cos \Theta(b_j) = \cos \theta}^{-1} = \frac{1}{k^2} \frac{\lambda_j}{\sin \theta |\Theta'_j|}, \quad (47.112)$$

with $kb = (\ell + 1/2) = \lambda$; N classical deflections Θ_j provide the same θ

$$\Theta_j = \Theta(\lambda_j) = \theta, -\theta, -2\pi \pm \theta, -4\pi \pm \theta, \dots \quad (47.113)$$

resulting in the phases $s(\Theta) \equiv S^C(E, L; \Theta)/\hbar$

$$s_j = 2\eta(\lambda_j) - \lambda_j \Theta(\lambda_j) \quad (47.114a)$$

$$= 2\eta(\lambda_j) - \lambda_j \theta, \quad 0 \leq \theta \leq \pi \quad (47.114b)$$

$$= 2\eta(\lambda_j) + \lambda_j \theta - m\pi, \quad \theta < 0, \quad (47.114c)$$

where $m = 0, 1, 2, \dots$ is the number of times the ray has traversed the backward direction during its attractive windings about the scattering center.

A. Amplitude addition: for three well-separated regions of stationary phase $\lambda_1 < \lambda_2 < \lambda_3$. A scattering angle θ in the range $0 < \theta < \theta_r$ (rainbow angle) typically results from deflections Θ_j at three impact parameters b (or λ): $\theta = \{\Theta(b_1), -\Theta(b_2), -\Theta(b_3)\} \equiv \{\Theta_j\}$. Scattering in the range $\theta_r \leq \theta < \pi$ results from one deflection at b_1 ; b_1 is in the positive branch (inner repulsion), and $b_{2,3}$ are in the negative branch (outer attraction) of the deflection function $\Theta(b)$, such that $b_1 < b_2 < b_3$. Thus,

$$f(\theta) = \sum_{j=1}^3 f_j(\theta) = \sum_{j=1}^3 [\sigma_j(\theta)]^{1/2} \exp(is_j), \quad (47.115)$$

where the overall phases of each f_j are

$$s_1 = 2\eta(\lambda_1) - \lambda_1 \theta - \pi/2, \quad (47.116a)$$

$$s_2 = 2\eta(\lambda_2) + \lambda_2 \theta - \pi, \quad (47.116b)$$

$$s_3 = 2\eta(\lambda_3) + \lambda_3 \theta - \pi/2, \quad (47.116c)$$

which are appropriate, respectively, to deflections $\Theta_1 = \theta$ at λ_1 , $\Theta_2 = -\theta$ at λ_2 and $\Theta_3 = -\theta$ at λ_3 , within the range $-\pi \leq \Theta \leq \pi$.

The elastic differential cross section

$$\begin{aligned} \sigma(\theta) &= \sum_{j=1}^3 \sigma_j(\theta) + 2 \sum_{i<j}^3 [\sigma_i(\theta) \sigma_j(\theta)]^{1/2} \cos(s_i - s_j) \\ &\equiv \sigma_c(\theta) + \Delta\sigma(\theta) \end{aligned} \quad (47.117)$$

exhibits interference effects. The first term σ_c is the classical background DCS with no oscillations. The second term $\Delta\sigma$ provides the oscillatory structure that originates from interference between classical actions associated with the different trajectories resulting in a given θ . The part of $s_i - s_j$ most rapidly varying with θ is the angular action changes $(\lambda_1 + \lambda_2)\theta$, $(\lambda_1 + \lambda_3)\theta$, and $(\lambda_2 - \lambda_3)\theta$. Interference oscillations between the action phases s_1 and s_2 or between s_1 and s_3 then have angular separations

$$\Delta\theta_{1;(2,3)} = \frac{2\pi n}{(\lambda_1 + \lambda_{2,3})}, \quad (47.118)$$

which are much smaller than the separation

$$\Delta\theta_{2;3} = \frac{2\pi n}{(\lambda_2 - \lambda_3)}, \quad (47.119)$$

for interference between phases s_2 and s_3 . The oscillatory structure in $\Delta\sigma(\theta)$ is, therefore, composed of supernumerary rainbow oscillations with large angular separations $\Delta\theta_{2;3}$ from s_2 and s_3 interference, with superimposed rapid oscillations with smaller separation $\Delta\theta_{1;(2,3)}$ from interference between s_1 and s_2 or s_1 and s_3 .

For deflections $\Theta_j = \theta, -\theta, -2\pi \mp \theta, -4\pi \mp \theta, \dots$, then the Δ^+ -branch of Eq. (47.158a) provides additional contributions to Eq. (47.115) with phases

$$s_{2m}^{\pm} = 2\eta(\lambda_{2m}) \pm \lambda_{2m} \theta - 2m\pi - \pi, \quad (47.120a)$$

$$s_{3m}^{\pm} = 2\eta(\lambda_{3m}) \pm \lambda_{3m} \theta - 2m\pi - \pi/2, \quad (47.120b)$$

for $m = 1, 2, 3, \dots$

B. Uniform Airy result: for two regions of stationary phase that can coalesce. The combined contribution

$f_{23}(\theta)$ from the λ_2 and λ_3 attractive regions in Δ^+ branch is

$$f_{23}(\theta) = \sigma_2^{1/2} e^{is_2} F_{23} + \sigma_3^{1/2} e^{is_3} F_{23}^*, \quad (47.121a)$$

$$F_{23} = (A + iB) e^{-is_{23}/2}, \quad (47.121b)$$

$$s_{23} = s_2 - s_3 = 2(\eta_2 - \eta_3) + (\lambda_2 - \lambda_3)\theta - \frac{1}{2}\pi, \quad (47.121c)$$

$$A(z) = \pi^{1/2} z^{1/4} \text{Ai}(-z), \quad (47.121d)$$

$$B(z) = \pi^{1/2} z^{-1/4} \text{Ai}'(-z), \quad (47.121e)$$

$$\frac{4}{3}|z|^{3/2} = s_{23} + \frac{1}{2}\pi. \quad (47.121f)$$

The amplitude f_{23} tends to the primitive result $f_2(\theta) + f_3(\theta)$ in the limit of well-separated regions ($z \gg 1$), when $F_{23} \rightarrow 1$. An equivalent form of Eq. (47.121a) is

$$f_{23}(\theta) = \left[A(\sigma_2^{1/2} + \sigma_3^{1/2}) + iB(\sigma_2^{1/2} - \sigma_3^{1/2}) \right] \times \exp(i\bar{s}), \quad (47.122)$$

where the mean phase $\bar{s} = \frac{1}{2}(s_2 + s_3)$. This form is useful for analysis of caustic regions at $\theta \approx \theta_r$, where $z \rightarrow 0$.

C. Transitional result: neighborhood of caustic or rainbow at $(\theta_r, b_r, \lambda_r)$. In the vicinity of rainbow angle $\theta \approx \theta_r$,

$$\Theta' = \frac{\partial \Theta}{\partial \lambda} = [2(\theta_r - \theta)\Theta''(\lambda_r)]^{1/2} \quad (47.123)$$

$$z = (\theta_r - \theta)[2/\Theta''(\lambda_r)]^{1/3} > 0 \quad (47.124)$$

$$s_r = \frac{1}{2}(s_1 + s_2) = 2\eta(\lambda_r) + \lambda_r \theta_r - \frac{3}{4}\pi. \quad (47.125)$$

The scattering amplitude

$$f_{23}(\theta_r) = \left(\frac{2\pi\lambda_r}{k^2 \sin \theta_r} \right)^{\frac{1}{2}} \left(\frac{2}{\Theta''(\lambda_r)} \right)^{\frac{1}{3}} \text{Ai}(-z) e^{is_r} \quad (47.126)$$

is finite at the rainbow angle θ_r . In Eq. (47.122), the $(\theta_r - \theta)^{-1/4}$ divergence in $|\Theta'_\ell|^{1/2}$ of Eq. (47.123) arising in the constructive interference term $(\sigma_2^{1/2} + \sigma_3^{1/2})$ is exactly balanced by the $z^{1/4}$ term of $A(z)$. Also, $(\sigma_2^{1/2} - \sigma_3^{1/2}) \rightarrow 0$ in Eq. (47.122) more rapidly than $z^{-1/4}$ in $B(z)$, so that Eq. (47.122) at θ_r is finite and reproduces Eq. (47.126).

The uniform semiclassical DCS

$$\frac{d\sigma}{d\Omega} = \left| \sigma_1^{\frac{1}{2}} e^{is_1} + \sigma_2^{\frac{1}{2}} F_{23} e^{is_2} + \sigma_3^{\frac{1}{2}} F_{23}^* e^{is_3} \right|^2 \quad (47.127)$$

contains, in addition to the s_i/s_j interference oscillations in the primitive result Eq. (47.117), the θ -variation of the Airy function $|\text{Ai}(z)|^2$, which has a principal finite (rainbow) maximum at $\theta \leq \theta_r$, the classical rainbow angle, and subsidiary maxima (supernumary rainbows) at smaller angles. The DCS decreases exponentially as θ increases past θ_r into the classical forbidden region and tends to $\sigma_1(\theta)$ at larger angles. For $\theta_r < \theta < \pi$,

$$f(\theta) = \sigma_1^{1/2}(\theta) \exp(is_1). \quad (47.128)$$

47.7.2 Diffraction and Glory Amplitudes

Diffraction

Diffraction arises from the outer (attractive) part of the potential. Many contributions arise from the attractive Δ^+ branch appropriate for negative Θ at large b where η is small. Here, Θ and Θ' tend to zero.

Glory

The deflection function Θ passes through zero at a finite λ_g . A confluence of the two maxima of each phase shift from the positive and negative branches of $\Theta(b)$ occurs at $b_1 = b_2 = b_g = \lambda_g/k$; η_g is maximum for $\Theta = 0$. In general, $\Theta(b_m) = -2m\pi$ (forward glory); $\Theta(b_m) = -(2m-1)\pi$ (backward glory); $m = 0, 1, 2, \dots$. There is only a forward glory at $\Theta = 0$ when the deflection at the rainbow is $|\Theta_r| < 2\pi$. In contrast to diffraction, the glory contribution can be calculated by the *stationary phase approximation*.

Transitional results for forward and backward glories

Forward glories Contributions arise from $\Theta = \pm\theta, -2\pi \pm \theta, \dots, -2m\pi \pm \theta$ as $\theta \rightarrow 0$. The stationary phase points λ_m are located at

$$\Theta(\lambda_m) = \Theta_m = -2m\pi; \quad m \geq 0. \quad (47.129)$$

The phase function in the neighborhood of a glory is

$$\eta(\lambda) = \eta_m - m\pi(\lambda - \lambda_m) + \frac{1}{4}\Theta'_m(\lambda - \lambda_m)^2. \quad (47.130)$$

The $m = 0$ term provides zero deflection Θ due to a net balance of attractive and repulsive scattering for a finite impact parameter b_g or λ_g , where $\eta(\lambda)$ attains its maximum value η_m . The glories at θ are due to a confluence of the two contributions from the deflections $\Theta_m = -2m\pi \pm \theta$ at the stationary phase points $\lambda_{mn} = \lambda_{m1}$ and λ_{m2} . SP integration of Eq. (47.161a) with Eq. (47.130) yields the forward glory amplitude

$$f_{FG} = \frac{1}{k} \sum_{n=1}^2 \sum_{m=0}^{\infty} \lambda_{mn} \left(\frac{2\pi}{|\Theta'_m|} \right)^{1/2} J_0(\lambda_{mn}\theta) e^{is_{mn}^{(g)}}, \quad (47.131)$$

$$s_{mn}^{(g)} = 2\eta(\lambda_{mn}) + m\pi(\lambda_{mn} - 1) - \frac{3}{4}\pi. \quad (47.132)$$

Backward glories Contributions arising from $\Theta = -\pi \pm \alpha, -3\pi \pm \alpha, \dots, -(2m-1)\pi \pm \alpha$ coalesce as $\alpha \equiv \pi - \theta \rightarrow 0$. The phase function near a backward glory is

$$\eta(\lambda) = \eta(\lambda_m) + \frac{1}{2}\Theta_m(\lambda - \lambda_m) + \frac{1}{4}\Theta'_m(\lambda - \lambda_m)^2. \quad (47.133)$$

The $m = 0$ term provides the normal backward amplitude due to head-on ($b = 0$) repulsive collisions; $m > 0$ terms provide contributions from attractive collisions for which there are two points λ_{mn} of stationary phase for each m in $\Theta_m = -(2m - 1)\pi \pm \alpha$.

The backward glory amplitude at $\theta = \pi - \alpha$ is

$$f_{\text{BG}} = \frac{1}{k} \sum_{n=1}^2 \sum_{m=0}^{\infty} \lambda_{mn} \left(\frac{2\pi}{|\Theta'_{mn}|} \right)^{1/2} J_0(\lambda_{mn}\alpha) e^{i s_{mn}^{(\text{g})}}, \quad (47.134)$$

$$s_{mn}^{(\text{g})} = 2\eta(\lambda_{mn}) + \pi(2m - 1) \left(\lambda_{mn} - \frac{1}{2} \right) - \frac{3}{4}\pi. \quad (47.135)$$

In contrast to the Bessel amplitudes (below), these transitional formulae do not uniformly connect with the primitive semiclassical results for $(f_1 + f_2)$ away from the critical glory angles.

Uniform Bessel amplitude for glory scattering The combined contributions from $\Theta_1 = -N\pi + \theta$ and $\Theta_2 = -N\pi - \theta$, where $N = 2m$, for forward and $N = 2m - 1$ for backward scattering, yield [6]

$$f_{\text{G}}(\theta) = \frac{\alpha_j}{2i} e^{-iN\pi/2} (\pi s_{21})^{1/2} \exp[i\bar{s}(\theta)] \times \left[(\sigma_1^{1/2} + \sigma_2^{1/2}) J_0\left(\frac{1}{2}s_{21}\right) - i(\sigma_1^{1/2} - \sigma_2^{1/2}) J_1\left(\frac{1}{2}s_{21}\right) \right], \quad (47.136)$$

where $s_{21}(\theta) = s_2 - s_1$ is the difference of the collision phases Eq. (47.114a),

$$s_i(\theta) = 2\eta(\lambda_i) - \lambda_i \Theta_i, \quad i = 1, 2, \quad (47.137)$$

with mean

$$\bar{s}_{21}(\theta) = \frac{1}{2}(s_2 + s_1), \quad (47.138)$$

and

$$\alpha_j = e^{\pm i\pi/4}; \quad (+), \Theta'_j > 0; \quad (-), \Theta'_j < 0, \quad (47.139)$$

and the ordinary Bessel functions $J_n(z)$ satisfy the relationships $J_1(z) = -J'_0(z)$, $J_1(-z) = -J_1(z)$. This formula, valid for both forward ($\theta \approx 0$) and backward ($\theta \approx \pi$) glories, does uniformly connect the primitive result for $(f_1 + f_2)$, valid when $s_{21} \gg 1$ and to the transitional results Eqs. (47.131) and (47.134), valid only in the vicinity of the glories.

47.7.3 Small-Angle (Diffraction) Scattering

Diffraction originates from scattering in the forward direction by the long-range attractive tail of $V(r)$, where Θ , Θ' and $\eta \rightarrow 0$. The cross section is formed from many contributions with small action $S(\lambda) = \hbar\eta(\lambda)$ at a large angular momentum λ . A representation of the scattering amplitude as an integral over $\eta(\lambda)$ avoids the classical singularity; see Sect. 47.7.8.

47.7.4 Small-Angle (Glory) Scattering

Amplitude and cross section The other contribution to forward scattering is the forward glory, which originates from the combined null effect of attraction and repulsion at a specified glory impact parameter $b_g = \lambda_g/k$, where $\eta(\lambda)$ attains a maximum value of η_g . The $m = 0$ term of Eq. (47.131) yields

$$f_{\text{G}}(\theta) = \sigma_{\text{G}}^{1/2}(\theta) \exp[iS_{\text{G}}(E)], \quad (47.140a)$$

$$\sigma_{\text{G}}(\theta) = \frac{\lambda_g^2}{k^2} \left(\frac{2\pi}{|\Theta'_g|} \right) J_0^2(\lambda_g\theta), \quad (47.140b)$$

$$S_{\text{G}}(E) = 2\eta_g(E) - \frac{3}{4}\pi, \quad (47.140c)$$

where $J_0^2(x) \approx 1 - \frac{1}{4}x^2 + \dots$. The classical divergence is recovered by averaging Eq. (47.140b) over several oscillations with $\langle J_0^2(x) \rangle = (\pi x)^{-1}$.

Diffraction-glory oscillations

$$\sigma(E) = \frac{4\pi}{k} \text{Im}[f_{\text{D}}(0) + f_{\text{G}}(0)] \quad (47.141a)$$

$$= \sigma_{\text{D}}(E) + \Delta\sigma_{\text{G}}(E), \quad (47.141b)$$

where the diffraction cross section is Eq. (47.171), and where

$$\Delta\sigma_{\text{G}}(E) = \frac{4\pi}{k^2} \lambda_g \left(\frac{2\pi}{|\Theta'_g|} \right)^{1/2} \sin\left(2\eta_g(E) - \frac{3}{4}\pi\right) \quad (47.142)$$

oscillates with E .

For sufficiently deep attractive wells, the phase shift η_g successively decreases with increasing E through a series of multiples of $\pi/2$. Writing $\eta_g(E) = \pi(N - 3/8)$, maxima appear at $N = 1, 2, \dots$, and minima at $N = 3/2, 5/2, 7/2, \dots$. The glories are indexed by N in order of appearance, starting at high energies. $\eta_g(E \rightarrow 0)$ is related to the number n of bound states by Levinson's theorem: $\eta_0(E \rightarrow 0) = (n + 1/2)\pi$. Diffraction-glory oscillations also occur in the DCS at a frequency governed entirely by the energy variation of $\eta_g(E)$ and n of Eq. (47.175).

Fig. 47.1 All the various oscillatory effects for elastic scattering by a Lennard–Jones (12,6) potential of well depth ϵ and equilibrium distance R_e . Ordinate $\sigma^* = \sigma/(2\pi R_e^2)$, abscissa $v^* = \hbar v/(\epsilon R_e)$

47.7.5 Oscillations in Elastic Scattering

Figure 47.1 is an illustration [18, Chap. 1, p. 47] of all the various oscillatory structure and effects – Ramsauer–Townsend minimum (Sect. 47.5.5), orbiting resonances Eq. (47.204), diffraction-glory oscillations Eq. (47.141b), and symmetry oscillations Eq. (47.41d) – for elastic scattering by a Lennard–Jones (12, 6) potential. Note the shift of velocity dependence from $v^{-2/5}$ at low v to $v^{-2/11}$ at high v ; $\sigma = 2\pi r_e^2$ is the averaged cross section $2\pi b_0^2$ in Eq. (47.168) at $b_0 = r_e$. The region $\sigma^* > 1$ probes the attractive part of the potential at low speeds, and $\sigma^* < 1$ probes the repulsive part at high speeds. The four distinct types of structure originate from the nonrandom behavior of $\sin^2 \eta$ in Eq. (47.166). Orbiting trajectories exist for $E < 0.8\epsilon$ (Sect. 47.9).

47.7.6 Scattering Amplitude in Poisson Sum Representation

With the help of the (exact) Poisson sum formula one can convert a sum over discrete variables into an integral of a continuous variable. This allows one to directly derive from the quantum partial wave expansion Eq. (47.33a) semiclassical expressions for the phase shift in terms of classical paths. The Poisson sum formula reads for $\lambda = \ell + \frac{1}{2}$ [Eq. (47.107)]

$$\sum_{\ell=0}^{\infty} F\left(\ell + \frac{1}{2}\right) = \sum_{m=-\infty}^{\infty} (-1)^m \int_0^{\infty} F(\lambda) e^{i2m\pi\lambda} d\lambda. \quad (47.143)$$

When applied to Eq. (47.33a),

$$f(\theta) = (ik)^{-1} \sum_{m=-\infty}^{\infty} (-1)^m \int_0^{\infty} \lambda (e^{2i\eta(\lambda)} - 1) \times P_{\lambda-\frac{1}{2}}(\cos \theta) e^{i2m\pi\lambda} d\lambda, \quad (47.144)$$

where $\eta(\lambda)$ and $P_{\lambda-1/2} \equiv P(\lambda, \theta)$ are now phase functions and Legendre functions of the continuous variable λ , being interpolated from discrete to continuous ℓ . This infinite-sum-of-integrals representation for $f(\theta)$ is, in principle, exact. The particular merit of the Poisson sum in the present context is that the index m labels the classical paths that have encircled the (attractive) scattering center m times, and that the terms with $m < 0$ have no regions of stationary phase (SP). For deflections Θ in the range $-\pi < \Theta < \pi$, the only SP contribution is the $m = 0$ term.

47.7.7 Semiclassical Phase Shifts

Semiclassical analysis ([6] and references therein) involves reducing Eq. (47.144) by the three approximations represented by cases A to C below. Since the integrands can oscillate very rapidly over large regions of λ , the main contributions to the integrals arise from points λ_i of the stationary phase of each integrand. The amplitude can then be evaluated by the method of stationary phase, the basis of semiclassical analysis.

A. Legendre Function Asymptotic Expansions

Main range: $\sin \theta > \lambda^{-1}$, θ not within λ^{-1} of zero or π .

$$P_\ell(\cos \theta) = (2/(\pi \lambda \sin \theta))^{1/2} \cos(\lambda\theta - \pi/4). \quad (47.145)$$

Forward formula: θ within λ^{-1} of zero.

$$P_\ell(\cos \theta) = [\theta/\sin \theta]^{1/2} J_0(\lambda\theta), \quad (47.146a)$$

$$J_0(\lambda\theta) = \frac{1}{\pi} \int_0^\pi e^{-i\lambda\theta \cos \phi} d\phi. \quad (47.146b)$$

Backward formula: θ within λ^{-1} of π .

$$P_\ell(\cos \theta) = \left(\frac{\pi - \theta}{\sin \theta}\right)^{1/2} \times J_0[\lambda(\pi - \theta)] e^{-i\pi(\lambda-1/2)}. \quad (47.147)$$

Equations (47.145)–(47.147) are useful for analysis of caustics (rainbows), diffraction, and forward and backward glories, respectively. Also, a useful identity is

$$\sum_{\ell=0}^{\infty} (2\ell + 1) P_\ell(\cos \theta) = \begin{cases} 4\delta(1 - \cos \theta), & \theta > 0 \\ 0 & \theta = 0, \end{cases}$$

where $\delta(x)$ is the Dirac delta function.

B. JWKB Phase Shift Functions

$$\eta(\lambda) = \int_{r_m}^{\infty} k_{\lambda}(r) dr - \int_{\lambda/k}^{\infty} \left(k^2 - \frac{\lambda^2}{r^2}\right)^{1/2} dr \quad (47.148a)$$

$$= \lim_{r \rightarrow \infty} \left[\int_{r_m}^{\infty} k_{\ell}(r') dr' - kr \right] + \frac{1}{2}\lambda\pi, \quad (47.148b)$$

with local wavenumber

$$k_{\lambda}^2(r) = k^2 - U(r) - \lambda^2/r^2. \quad (47.149)$$

The wavenumber is related to the impact parameter b and to Eqs. (47.102a) and (47.2e) through $\eta = S(E, \lambda\hbar)/\hbar$ and the Langer modification Eq. (47.107)

$$b = \frac{\sqrt{\ell(\ell+1)}}{k} = \frac{\ell+1/2}{k} = \frac{\lambda}{k}. \quad (47.150)$$

We note a useful identity. As $r \rightarrow \infty$,

$$\sin \left[\int_{\frac{\lambda}{k}}^r \left(k^2 - \frac{\lambda^2}{r^2}\right)^{1/2} dr + \frac{\pi}{4} \right] \rightarrow \sin \left(kr - \frac{1}{2}\ell\pi \right). \quad (47.151)$$

JWKB phase functions are valid when variation of the potential over the local wavenumber $k_{\lambda}^{-1}(r)$ is a small fraction of the available kinetic energy $E - V(r)$. Many wavelengths can then be accommodated within a range Δr for a characteristic potential change ΔV . The classical method is valid when $(1/k)(dV/dr) \ll (E - V)$.

Phase-deflection function relation

$$\Theta(\lambda) = 2 \frac{\partial \eta(\lambda)}{\partial \lambda}. \quad (47.152)$$

C. Stationary Phase Approximations (SPA) to Generic Integrals

$$A^{\pm}(\theta) = \int_{-\infty}^{\infty} g(\theta; \lambda) \exp[\pm i\gamma(\theta; \lambda)] d\lambda, \quad (47.153)$$

for parametric θ . In cases where the phase function γ has two stationary points, a phase minimum γ_1 at λ_1 , and a phase maximum γ_2 at λ_2 , then $\gamma'_i = 0$, $\gamma''_1 > 0$, $\gamma''_2 < 0$, where $\gamma'_i = (d\gamma/d\lambda)$ at λ_i and $\gamma''_i = (d^2\gamma/d\lambda^2)$ for $i = 1, 2$. Since g is real, $A^- = (A^+)^*$, $g_i(\theta) = g(\theta, \lambda_i)$.

Uniform Airy result

$$A^+(\theta) = a_1(\theta) e^{i(\gamma_1 + \pi/4)} F^*(\gamma_{21}) + a_2(\theta) e^{i(\gamma_2 - \pi/4)} F(\gamma_{21}), \quad (47.154a)$$

$$a_i(\theta) = [2\pi/|\gamma''_i|]^{1/2} g_i(\theta), \quad i = 1, 2, \quad (47.154b)$$

$$\gamma_{21}(\theta) = \gamma_2 - \gamma_1 \equiv \frac{4}{3}|z(\theta)|^{3/2} > 0, \quad (47.154c)$$

$$F[\gamma_{21}(\theta)] = [z^{1/4} \text{Ai}(-z) + iz^{-1/4} \text{Ai}'(-z)] \sqrt{\pi} \times e^{-i(\gamma_{21}/2 - \pi/4)}, \quad (47.154d)$$

where Ai and Ai' are the Airy function and its derivative.

This result holds for all separations $(\lambda_2 - \lambda_1)$ in the location of stationary phases including a caustic (or rainbow), which is a point of inflection in γ , i.e. $\gamma_1 = \gamma_2$, $\gamma'_i = 0 = \gamma''_i$. An equivalent expression is [6]

$$A^+(\theta) = [(a_1 + a_2)z^{1/4} \text{Ai}(-z) - i(a_1 - a_2)z^{-1/4} \text{Ai}'(-z)] \sqrt{\pi} e^{i\bar{\gamma}}, \quad (47.155)$$

where the mean phase is $\bar{\gamma} = \frac{1}{2}(\gamma_1 + \gamma_2)$. The first form of Eq. (47.154a) is useful for analysis of widely separated regions of stationary phase when $\gamma_{21} \gg 0$ and $F \rightarrow 1$. The equivalent second form Eq. (47.155) is valuable in the neighborhood of caustics or rainbows when the stationary phase regions coalesce as $a_1 \rightarrow a_2$.

Primitive result

For widely separated regions λ_1 and λ_2 , $F \rightarrow 1$ and

$$A^{\pm}(\epsilon) = [a_1(\epsilon) \mp ia_2(\epsilon) e^{\pm i\gamma_{21}}] e^{\pm i(\gamma_1 + \pi/4)}, \quad (47.156a)$$

$$A^{\pm}(\epsilon) = a_1(\epsilon) \exp\left[\pm i\left(\gamma_1 + \frac{\pi}{4}\right)\right] + a_2(\epsilon) \exp\left[\pm i\left(\gamma_2 - \frac{\pi}{4}\right)\right]. \quad (47.156b)$$

Note that the minimum phase γ_1 is increased by $\pi/4$, and the maximum phase γ_2 is reduced by $\pi/4$.

Transitional Airy result

In the neighborhood of a caustic or rainbow where $\gamma'' = 0$, at the inflection point $\lambda_1 = \lambda_2 = \lambda_r$, and then

$$A^{\pm}(\theta) = 2\pi \left| \frac{2}{\gamma'''(\lambda_r)} \right|^{1/3} g(\theta; \lambda_r) \text{Ai}(-z) e^{\pm i\gamma(\theta; \lambda_r)} \quad (47.157a)$$

$$z = \frac{2}{|\gamma'''(\lambda_r)|^{1/3} \gamma'(\theta; \lambda_r)}. \quad (47.157b)$$

Only over a very small angular range does this result agree in practice with the uniform result Eq. (47.154a), which

uniformly connects Eqs. (47.156a) and (47.157a). These stationary-phase formulae are not only applicable to integrals involving (λ, θ) but also to (t, E) and (R, p) combinations, which occur in the method of variation of constants and in Franck–Condon overlaps of vibrational wavefunctions, respectively.

47.7.8 Semiclassical Amplitudes: Integral Representation

A. Off-Axis Scattering: $\sin \theta > \lambda^{-1}$

Except in the forward and backward directions, Eq. (47.144) with Eq. (47.145) reduces to

$$f(\theta) = -\frac{1}{k(2\pi \sin \theta)^{1/2}} \sum_{m=-\infty}^{\infty} (-1)^m \times \int_0^{\infty} d\lambda \lambda^{1/2} \times \left(e^{i\Delta^+(\lambda, m)} - e^{i\Delta^-(\lambda, m)} \right), \quad (47.158a)$$

$$\Delta^\pm(\lambda; m) = 2\eta(\lambda) + 2m\pi\lambda \pm \lambda\theta \pm \pi/4 \equiv S^C \pm \pi/4, \quad (47.158b)$$

where S^C is the classical action Eq. (47.106) divided by \hbar .

The stationary phase condition $d\Delta^\pm/d\lambda = 0$ yields the deflection function Θ to the scattering angle θ relation

$$\Theta(\lambda_i) = \mp\theta - 2m\pi, \quad (47.159)$$

where λ_i are points of stationary phase (SP). Since $\pi \geq \Theta \geq -\infty$, integrals with $m < 0$ have no SPs and vanish under the SPA. For cases involving no orbiting (where $\Theta \rightarrow -\infty$) and when $\pi > \Theta > -\pi$, integrals with $m > 0$ also vanish under SPA, so that the only remaining contribution from $m = 0$ to Eq. (47.158b) is

$$f(\theta) = -\frac{1}{k(2\pi \sin \theta)^{1/2}} \times \int_0^{\infty} \lambda^{1/2} \left[e^{i\Delta^+(\lambda)} - e^{i\Delta^-(\lambda)} \right] d\lambda, \quad (47.160a)$$

$$\Delta^\pm(\lambda) = 2\eta(\lambda) \pm \lambda\theta \pm \pi/4. \quad (47.160b)$$

The attractive branch Δ^+ contributes only negative deflections, and the repulsive branch Δ^- contributes only positive deflections and has one SP point at λ_1 where Δ^- is maximum.

Rainbow angle θ_r : $(\Delta^+)''_{\lambda_r} = 0$, so that $\Theta'(\lambda_r) = 0$, where $\Theta(\lambda_r) < 0$ has reached its most negative value.

$$\begin{aligned} \theta < \theta_r: & \quad \Delta^+ \text{ has two SP points } \lambda_{2,3}; \\ & \quad \text{a maximum at } \lambda_2 \text{ and} \\ & \quad \text{a minimum at } \lambda_3. \end{aligned}$$

$$\begin{aligned} \theta = \theta_r: & \quad \lambda_2 = \lambda_3: \text{ SP's coalesce.} \\ \theta > \theta_r: & \quad \text{no classical attractive scattering.} \\ & \quad \Delta^+ \text{ has no SP points.} \end{aligned}$$

B. Forward Amplitude: $\sin \theta \approx \theta < \lambda^{-1}$

$$f(\theta) = \frac{1}{ik} \left(\frac{\theta}{\sin \theta} \right)^{1/2} \sum_{m=-\infty}^{\infty} e^{-im\pi} \int_0^{\infty} \lambda J_0(\lambda\theta) \times (e^{2i\eta(\lambda)} - 1) e^{2im\pi\lambda} d\lambda. \quad (47.161a)$$

Stationary phase points: $\gamma'(\lambda_m) = 0$.

$$\Theta(\lambda_m) = 2 \left(\frac{\partial \eta}{\partial \lambda} \right) = -2m\pi. \quad (47.161b)$$

Terms with $m < 0$, therefore, make no SP contribution to $f(\theta)$ since $\Theta \leq \pi$. The $m = 0$ term provides diffraction due to $\Theta \rightarrow 0$, $\Theta' \rightarrow 0$ at long range and a forward glory due to $\Theta \rightarrow 0$ at a finite λ_g and nonzero Θ'_g .

C. Backward Amplitude: $\theta \approx \pi - \Theta(\lambda^{-1})$

$$f(\theta) = \frac{1}{k} \left(\frac{\pi - \theta}{\sin \theta} \right)^{1/2} \times \sum_{m=-\infty}^{\infty} e^{im\pi} \int_0^{\infty} \lambda J_0[\lambda(\pi - \theta)] \times e^{i[2\eta(\lambda) + (2m-1)\pi\lambda]} d\lambda. \quad (47.162a)$$

Stationary phase points

$$\Theta(\lambda_m) = 2 \left(\frac{\partial \eta}{\partial \lambda} \right) = -(2m-1)\pi. \quad (47.162b)$$

There are no SPs for $m < 0$. The $m = 0$ term provides a normal backward amplitude due to repulsive collisions ($\Theta = \pi$), and $m > 0$ terms are due to attractive half-windings.

D. Eikonal Amplitude

The $m = 0$ term of Eq. (47.161a) gives

$$f_E(\theta) = \frac{1}{ik} \int_0^{\infty} \lambda (e^{2i\eta(\lambda)} - 1) J_0(\lambda\theta) d\lambda \quad (47.163a)$$

$$= -ik \int_0^{\infty} (e^{2i\eta(b)} - 1) J_0(kb\theta) b db, \quad (47.163b)$$

and for potentials with cylindrical symmetry, $kb\theta$ can be replaced by $2kb \sin \frac{1}{2}\theta = \mathbf{k} \cdot \mathbf{b}$, and

$$f_E(\theta) = -\frac{ik}{2\pi} \int (e^{2i\eta(b)} - 1) J_0(\mathbf{k} \cdot \mathbf{b}) d\mathbf{b}. \quad (47.164)$$

From the optical theorem,

$$\sigma_E(E) = 8\pi \int_0^\infty \sin^2 \eta(b, E) b db . \quad (47.165)$$

E. Small-Angle Diffraction Corrected Scattering

In small-angle scattering θ , θ' , and $\eta \rightarrow 0$, where diffraction occurs due to scattering in the forward direction by the long-range attractive tail of $V(r)$. The main contributions to Eq. (47.163a) arise from a large number of small $\eta(\lambda)$ at large λ . The Jeffrey–Born phase function Eq. (47.104) can, therefore, be used in Eq. (47.163b) for $f(\theta)$ and in Eqs. (47.166) and (47.168), respectively, for $\sigma(E)$. A finite forward diffraction peak as $\theta \rightarrow 0$ is obtained for $f(\theta)$ in contrast to the classical infinite result. With Eq. (47.165) one gets the Landau–Lifshitz cross section

$$\sigma_{LL}(E) = 8\pi \int_0^\infty [\sin^2 \eta_{JB}(E, b)] b db . \quad (47.166)$$

The Massey–Mohr cross section is

$$\eta(E, b_0) = \frac{1}{2}, \quad \langle \sin^2 \eta(E, b < b_0) \rangle = \frac{1}{2}, \quad (47.167)$$

$$\sigma_{MM}(E) = 2\pi b_0^2 + 8\pi \int_{b_0}^\infty \eta_{JB}^2(E, b) b db . \quad (47.168)$$

An example

For $V(r) = -C/r^n$, the Landau–Lifshitz (LL) and Massey–Mohr (MM) cross sections are [Eq. (47.207a)]

$$\sigma_{LL}(E) = \pi \left(\frac{2CF(n)}{(n-1)\hbar v} \right)^{2/(n-1)} \times \pi \left[\sin\left(\frac{\pi}{n-1}\right) \Gamma\left(\frac{2}{n-1}\right) \right]^{-1}, \quad (47.169)$$

$$\sigma_{MM}(E) = \pi \left(\frac{2CF(n)}{(n-1)\hbar v} \right)^{2/(n-1)} \left(\frac{2n-3}{n-2} \right), \quad (47.170)$$

where $F(n) = \sqrt{\pi} \Gamma(\frac{1}{2}n + \frac{1}{2}) / \Gamma(\frac{1}{2}n)$, and v is the relative speed. Both σ_{LL} and σ_{MM} have the general form

$$\sigma_D(E) = \gamma \left(\frac{C}{\hbar v} \right)^{2/(n-1)}. \quad (47.171)$$

Ion–atom collisions

For $n = 4$ attraction at low energy, $\sigma_D \approx v^{-2/3}$, $\gamma_{LL} = 11.373$, and $\gamma_{MM} = 10.613$. For $n = 12$ repulsion at high energy, $\sigma_D \approx v^{-2/11}$, $\gamma_{LL} = 6.584$, and $\gamma_{MM} = 6.296$.

Atom–atom collisions

For $n = 6$ (attraction), $\sigma_D \approx v^{-2/5}$, $\gamma_{LL} = 8.083$, and $\gamma_{MM} = 7.547$ Fig. 47.1. Exact numerical calculations favor σ_{LL} over σ_{MM} ([19, pp. 1325] for details).

Differential cross section

$$\frac{d\sigma}{d\Omega} = f_i^2(\theta) + f_r^2(\theta), \quad (47.172a)$$

$$f_i = \frac{2}{k} \int_0^\infty \lambda \sin^2 \eta(\lambda) \left(1 - \frac{1}{4} \lambda^2 \theta^2 \right) d\lambda \quad (47.172b)$$

$$= \frac{k\sigma_D(E)}{4\pi} \left[1 - \left(\frac{k^2\sigma_D}{16\pi} \right) g_1(n)\theta^2 \right], \quad (47.172c)$$

$$f_r = \frac{1}{k} \int_0^\infty \lambda \sin 2\eta(\lambda) \left(1 - \frac{1}{4} \lambda^2 \theta^2 \right) d\lambda \quad (47.172d)$$

$$= \frac{k\sigma_D(E)}{4\pi} \left[1 - \left(\frac{k^2\sigma_D}{16\pi} \right) g_2(n)\theta^2 \right] \tan\left(\frac{\pi}{n-1}\right), \quad (47.172e)$$

where σ_D is given by Eq. (47.171), and

$$g_j(n) = \pi^{-1} \tan\left(\frac{j\pi}{n-1}\right) \frac{\{\Gamma[2/(n-1)]\}^2}{\Gamma[4/(n-1)]}. \quad (47.173)$$

The optical theorem Eq. (47.36) is satisfied, and

$$f_D(\theta \approx 0) = \sigma_D^{1/2}(E) e^{iS_D(n)}, \quad (47.174)$$

where the (energy-independent) phase is

$$S_D(n) = \frac{\pi(n-3)}{2(n-1)}. \quad (47.175)$$

47.8 Coulomb Elastic Scattering

The Coulomb potential has the remarkable property that the quantum cross section (Rutherford cross section) agrees with the classical and semiclassical result, as well as with the Born approximation. Furthermore, the s-wave phase shift is semiclassically also correct, hence also the Mott cross section containing interferences due to identical particles is semiclassically correct. We will often use the abbreviations

$$\begin{aligned} C &= Z_1 Z_2 e^2, \\ \beta &= C/\hbar v = Z_1 Z_2 / (ka_0), \\ r_c(E) &= Z_1 Z_2 e^2 / (2E) = \beta / (2k). \end{aligned} \quad (47.176)$$

47.8.1 Quantum Phase Shift, Rutherford and Mott Scattering

Direct solution of Eq. (47.24) yields

$$v_\ell \approx \sin(kr - \frac{1}{2}\ell\pi + \eta_\ell^c - \beta \ln 2kr). \quad (47.177a)$$

Coulomb phase shift

$$\eta_\ell^c = \arg \Gamma(\ell + 1 + i\beta) = \text{Im}[\ln \Gamma(\ell + 1 + i\beta)]. \quad (47.177b)$$

Coulomb **S**-matrix element

$$S_\ell^c = \exp(2i\eta_\ell^c) = \frac{\Gamma(\ell + 1 + i\beta)}{\Gamma(\ell + 1 - i\beta)}. \quad (47.177c)$$

Coulomb scattering amplitude

$$f^c(\theta) = -\frac{\beta \exp[2i\eta_\ell^c - i\beta \ln(\sin^2 \frac{1}{2}\theta)]}{2k \sin^2 \frac{1}{2}\theta}. \quad (47.177d)$$

Rutherford cross section

$$\frac{d\sigma^c}{d\Omega} = \frac{Z_1^2 Z_2^2 e^4}{16E^2} \frac{1}{\sin^4 \frac{1}{2}\theta} = r_c(E)^2 \csc^4 \frac{1}{2}\theta, \quad (47.177e)$$

which is the Coulomb differential cross section.

Mott formula for elastic scattering of two indistinguishable charged particles. From Eqs. (47.43a) and (47.43c), one gets the positive (+, symmetric solutions, e.g., spin-zero bosons as for ${}^4\text{He}$ - ${}^4\text{He}$) or negative (-, antisymmetric solutions, e.g., spin- $\frac{1}{2}$ fermions as for H^+ - H^+ , e^\pm - e^\pm)

$$\begin{aligned} \frac{d\sigma^c}{d\Omega} = r_c(E)^2 & \left(\csc^4 \frac{1}{2}\theta + \sec^4 \frac{1}{2}\theta \right. \\ & \left. \pm 2 \csc^2 \frac{1}{2}\theta \sec^2 \frac{1}{2}\theta \cos \gamma \right), \end{aligned} \quad (47.178)$$

where $\gamma = 2\beta \ln(\tan \frac{1}{2}\theta)$.

47.8.2 Classical Coulomb Scattering

There is only a single trajectory, or in other words, the deflection function is monotonic. Hence,

$$\theta(b, E) = |\Theta| = 2 \csc^{-1} \left[1 + \frac{b^2}{r_c(E)^2} \right]^{1/2}, \quad (47.179a)$$

$$b(\theta, E) = r_c(E) \cot \frac{1}{2}\theta, \quad (47.179b)$$

and according to Eq. (47.94) and in agreement with Eq. (47.177e), we get

$$\frac{d\sigma^c}{d\Omega} = \frac{bdb}{d(\cos \theta)} = \frac{r_c(E)^2}{4} \csc^4 \frac{1}{2}\theta. \quad (47.179c)$$

47.8.3 Semiclassical Coulomb Scattering

Since the monotony of the deflection function Eq. (47.179a) allows only for a single trajectory contributing to the cross section, the semiclassical Coulomb cross section between distinguishable particles reduces to the Rutherford cross section Eq. (47.179c).

For semiclassical Mott scattering, we also need the classical action in the scattering amplitude defined with the semiclassical propagator

$$f(\mathbf{p}, \mathbf{p}') = \sum_j \left(\frac{d\sigma_j}{d\Omega} \right)^{1/2} e^{iS_j^c(\mathbf{p}, \mathbf{p}')/\hbar - i\nu_j \pi/2} \quad (47.180)$$

to determine

$$\begin{aligned} \frac{d\sigma}{d\Omega} &= \frac{1}{2} |f(\mathbf{p}, \mathbf{p}') \pm f(\mathbf{p}, -\mathbf{p}')|^2 \\ &= \frac{1}{2} |f(\theta) \pm f(\pi - \theta)|^2, \end{aligned} \quad (47.181)$$

where the sum of the scattering amplitudes refers to bosons and the difference to fermions, while $\mathbf{p} \neq \mathbf{p}'$ denote final and initial momentum, respectively, and $\theta = \arccos[\mathbf{p} \cdot \mathbf{p}' / (pp')]$. The action between any two momenta \mathbf{p}, \mathbf{p}' that are connected by a classical trajectory of energy E under Coulomb interaction, is given by [3, p. 182],

$$\Delta\Phi(\mathbf{p}, \mathbf{p}', E) = -p_a r_c \ln \frac{\sqrt{1+\Delta} + 1}{\sqrt{1+\Delta} - 1} \quad (47.182)$$

$$\Delta = \frac{(p^2 - p_a^2)(p'^2 - p_a^2)}{p_a^2 |\mathbf{p} - \mathbf{p}'|^2}. \quad (47.183)$$

We need the action only in the asymptotic regime outside the range of the potential, $p, p' \rightarrow p_a$, where for all nonzero scattering angles ($\mathbf{p} \neq \mathbf{p}'$), $\Delta \ll 1$. Then [8]

$$S^C(\mathbf{p}, \mathbf{p}') = \lim_{p, p' \rightarrow p_a} \Delta\Phi(\mathbf{p}, \mathbf{p}', E) \quad (47.184)$$

$$= 2(\sigma_0 - p_a r_c \ln[\sin \Theta/2]), \quad (47.185)$$

with

$$\sigma_0 = \frac{p_a r_c}{2} \ln \left[\frac{(p^2 - p_a^2)(p'^2 - p_a^2)}{p_a^4} \right], \quad (47.186)$$

where $p_a = (2mE)^{1/2}$ is the asymptotic momentum, and m the reduced mass of the two colliding particles. The constant $\sigma_0/\hbar = \delta_0$ is the semiclassical phase shift for zero angular momentum, not dependent on the scattering angle θ .

47.8.4 Born Approximation for Coulomb Scattering

The scattering amplitude for Coulomb scattering reads accordingly [see Eq. (47.75)]

$$f_B^c(\mathbf{p}, \mathbf{p}') = \frac{r_c(E)}{2} \frac{1}{\sin^2(\theta/2)}, \quad (47.187)$$

which gives the correct cross section for Rutherford scattering but not for Mott scattering since it lacks the relevant phase for the latter in contrast to the full quantum or semiclassical scattering amplitude.

47.9 Results for Model Potentials

Exact results for various quantities in classical, quantal, and semiclassical elastic scattering are obtained for the model potentials (a)–(s) in Table 47.1.

47.9.1 Classical Deflection Functions and Cross Sections

(a) Hard sphere

$$\theta(b; E) = \Theta = \begin{cases} \pi - 2 \sin^{-1}(b/a), & b \leq a; \\ 0, & b > a. \end{cases} \quad (47.188a)$$

$$b(\theta) = a \cos \frac{\theta}{2}, \quad (47.188b)$$

$$\sigma(\theta) = \frac{d\sigma}{d\Omega} = \frac{1}{4}a^2; \quad \text{isotropic}, \quad (47.188c)$$

$$\sigma = \pi a^2 \quad (\text{geometric cross section}); \quad (47.188d)$$

θ , $\sigma(\theta)$, and σ are all independent of the energy E .

(b) Potential barrier For $E < V_0$, classical scattering is the same as for hard sphere reflection as given by

Eqs. (47.188a)–(47.188d). For $E > V_0$ and $\theta = \Theta$, define $n^2 = 1 - V_0/E$, $b_0 = na$. Then

$$\theta(b) = \begin{cases} 2[\sin^{-1}(b/na) - \sin^{-1}(b/a)] & 0 \leq b \leq b_0 \\ \pi - 2 \sin^{-1}(b/a), & b_0 \leq b \leq a, \end{cases} \quad (47.189a)$$

and $\theta_{\max} = 2 \cos^{-1} n$. For a given θ , the two impact parameters that contribute are

$$b_1(\theta) = \frac{an \sin \frac{1}{2}\theta}{(1 - 2n \cos \frac{1}{2}\theta + n^2)^{1/2}}, \quad 0 < b_1 \leq b_0 \quad (47.189b)$$

$$b_2(\theta) = a \cos \frac{1}{2}\theta, \quad b_0 < b_2 \leq a. \quad (47.189c)$$

For $0 \leq \theta \leq \theta_{\max}$,

$$\frac{d\sigma}{d\Omega} = \frac{1}{4}a^2 + \frac{a^2 n^2 (n \cos \frac{1}{2}\theta - 1)(n - \cos \frac{1}{2}\theta)}{4 \cos \frac{1}{2}\theta (n^2 + 1 - 2 \cos \frac{1}{2}\theta)^2}, \quad (47.189d)$$

and $d\sigma/d\Omega = 0$ for $\theta_{\max} \leq \theta \leq \pi$. Finally,

$$\sigma = \int_{\theta=0}^{\theta_{\max}} \left(\frac{d\sigma}{d\Omega} \right) d\Omega = \pi a^2. \quad (47.189e)$$

Table 47.1 Model interaction potentials

	Potential	$V(r)$
(a)	Hard sphere	$\infty, r \leq a; 0, r > a$
(b)	Barrier	$V_0, r \leq a; 0, r > a$
(c)	Well	$-V_0, r \leq a; 0, r > a$
(d)	Coulomb (\pm)	$\pm C/r$
(e)	Finite-range Coulomb	$-C/r + C/r_s, r \leq r_s; 0, r > r_s$
(f)	Pure dipole	$\pm \alpha/r^2$
(g)	Finite-range dipole	$\pm \alpha \left(\frac{1}{r^2} - \frac{1}{a^2} \right), r \leq a; 0, r > a$
(h)	Dipole + hard sphere	$\pm \alpha/r^2, r \leq a; 0, r > a$
(i)	Power law attractive	$-C/r^n, (n > 2)$
(j)	Fixed dipole + polarization	$-\frac{De \cos \theta_d}{r^2} - \frac{\alpha_d e^2}{2r^4}$
(k)	Fixed dipole + Coulomb	$-\frac{De \cos \theta_d}{r^2} + \frac{e^2}{r}$
(l)	Lennard–Jones ($n, 6$)	$\frac{\epsilon n}{n-6} \left[\frac{6}{n} \left(\frac{r_e}{r} \right)^n - \left(\frac{r_e}{r} \right)^6 \right]$
(m)	Polarization ($n, 4$)	$\frac{\epsilon n}{n-4} \left[\frac{4}{n} \left(\frac{r_e}{r} \right)^n - \left(\frac{r_e}{r} \right)^4 \right]$
(n)	Multiple-term power law	$\frac{C_m}{r^m} - \frac{C_n}{r^n} = V_m(r) - V_n(r)$
(o)	Exponential	$V_0 \exp(-\alpha r)$
(p)	Screened Coulomb	$V_0 \exp(-\alpha r)/r$
(q)	Morse	$\epsilon [e^{2\beta(r_e-r)} - 2e^{\beta(r_e-r)}]$
(r)	Gaussian	$V_0 \exp(-\alpha^2 r^2)$
(s)	Polarization finite	$-V_0/(r^2 + r_0^2)^2$

(c) Potential well The results are similar to those for potential barrier case above, except that there is only a single scattering trajectory with $\theta = -\Theta$, and $n = (1 + V_0/E)^{1/2}$ is the effective index of refraction for the equivalent problem in geometrical optics. Refraction occurs on entering and exiting the well. Then

$$\theta(b) = -2[\sin^{-1}(b/na) - \sin^{-1}(b/a)], \quad (47.190a)$$

$$\theta(b = a) = \theta_{\max} = 2 \cos^{-1}(1/n), \quad (47.190b)$$

$$b(\theta) = \frac{-an \sin \frac{1}{2}\theta}{(1 - 2n \cos \frac{1}{2}\theta + n^2)^{1/2}}, \quad (47.190c)$$

$$\frac{d\sigma}{d\Omega} = \frac{a^2 n^2 (n \cos \frac{1}{2}\theta - 1)(n - \cos \frac{1}{2}\theta)}{4 \cos^2 \frac{1}{2}\theta (n^2 + 1 - 2n \cos \frac{1}{2}\theta)^2}, \quad (47.190d)$$

$$\sigma = \pi a^2. \quad (47.190e)$$

(d) Rutherford or Coulomb The cross section for pure Coulomb scattering is discussed in Sect. 47.8.2.

(e) Finite-range Coulomb

$$r_c(E) = \frac{Z_1 Z_2 e^2}{2E}, \quad \alpha(E) = r_c(E)/r_s, \\ \frac{d\sigma}{d\Omega} = \frac{r_c^2}{4} \left(\frac{1 + \alpha}{\alpha^2 + (1 + 2\alpha) \sin^2 \frac{1}{2}\theta} \right)^2. \quad (47.191)$$

(f) Pure dipole $r_0^2(E) = \alpha/E$.

Repulsion (+): $\Theta > 0$, $\Theta = \theta$,

$$b^2(\Theta) = r_0^2 \left[\left(\frac{1}{\Theta} + \frac{1}{2\pi - \Theta} \right) \frac{\pi}{2} - 1 \right], \quad (47.192a)$$

$$\frac{d\sigma}{d\Omega} = \frac{\pi r_0^2}{4 \sin \theta} \left| \frac{1}{\theta^2} - \frac{1}{(2\pi - \theta)^2} \right|. \quad (47.192b)$$

Attraction (-): $\Theta < 0$.

$$b^2(\Theta) = r_0^2 \left[\left(\frac{1}{|\Theta|} - \frac{1}{|\Theta| + 2\pi} \right) \frac{\pi}{2} + 1 \right]. \quad (47.193a)$$

There is an infinite number of (negative) deflections $\Theta = \Theta_n^\pm$ associated with a given scattering angle θ

$$|\Theta_n^+| = 2\pi n + \theta, \quad n = 0, 1, 2, \dots, \quad (47.193b)$$

$$|\Theta_n^-| = 2\pi n - \theta, \quad n = 1, 2, 3, \dots \quad (47.193c)$$

The infinite sum over contributions from $b_n^\pm = b(\Theta_n^\pm)$ for the attractive dipole yields

$$\frac{d\sigma}{d\Omega} = \frac{\pi r_0^2}{4 \sin \theta} \left| \frac{1}{\theta^2} + \frac{1}{(2\pi - \theta)^2} \right|. \quad (47.193d)$$

(g) Finite Range Dipole Scattering $r_0^2 = \alpha/E$, $(r^\pm)^2 = b^2 \pm r_0^2$, $(b_0^\pm)^2 = a^2 \pm r_0^2$.

Repulsion (+): for $b \leq a$,

$$\Theta(b) = \frac{\pi(r_m^+ - b)}{r_m^+} + \frac{2b}{r_m^+} \sin^{-1} \left(\frac{r_m^+}{b_0^+} \right) \\ - 2 \sin^{-1} \left(\frac{b}{a} \right), \\ \Theta(0) = \pi, \quad \Theta(b \geq a) = 0, \quad \sigma = \pi a^2. \quad (47.194a)$$

Attraction (-): for $b > r_0$,

$$\Theta(b) = \frac{\pi(r_m^- - b)}{r_m^-} + \frac{2b}{r_m^-} \sin^{-1} \left(\frac{r_m^-}{b_0^-} \right) \\ - 2 \sin^{-1} \left(\frac{b}{a} \right), \quad (47.194b)$$

$$\Theta(r_0) \rightarrow \infty, \quad \Theta(b \geq a) = 0, \quad \sigma = \pi a^2. \quad (47.194c)$$

(h) Dipole plus hard sphere scattering $r_0^2 = \alpha/E$, $(r_m^\pm)^2 = b^2 \pm r_0^2$, $(b_0^\pm)^2 = a^2 \pm r_0^2$.

Repulsion (+): for $0 \leq b \leq b_0$,

$$\Theta(b) = \frac{\pi(r_m^+ - b)}{r_m^+} + \frac{2b}{r_m^+} \sin^{-1} \left(\frac{r_m^+}{a} \right) \\ - 2 \sin^{-1} \left(\frac{b}{a} \right), \quad (47.195a)$$

$$b_0 \leq b \leq a; \quad \Theta(b) = \pi - 2 \sin^{-1}(b/a), \quad (47.195b)$$

$$\Theta(0) = \pi, \quad \Theta(b \geq a) = 0, \quad \sigma = \pi a^2. \quad (47.195c)$$

Attraction (-): for $b > r_0$,

$$\Theta(b) = \frac{\pi(r_m^- - b)}{r_m^-} + \frac{2b}{r_m^-} \sin^{-1} \left(\frac{r_m^-}{a} \right) \\ - 2 \sin^{-1} \left(\frac{b}{a} \right),$$

$$\Theta(b) = \Theta_{\min} \text{ at } b = a,$$

$$\Theta(0) = \pi, \quad \Theta(b \geq a) = 0, \quad \sigma = \pi a^2. \quad (47.196)$$

Orbiting or Spiraling Collisions

From Sect. 47.6.5, the parameters are

Orbiting radius: r_0 .

Focusing factor: $F = [1 - V(r_0)/E]$.

Orbiting cross section: $\sigma_{\text{orb}} = \pi r_0^2 F$.

(i) Attractive power law potentials

$$V_{\text{eff}}(r_0) = \left(1 - \frac{1}{2}n\right)V(r_0), \quad n > 2,$$

$$r_0(E) = \left(\frac{(n-2)C}{2E}\right)^{1/n}, \quad F = \left(\frac{n}{(n-2)}\right), \quad (47.197a)$$

$$\sigma_{\text{orb}}(E) = \pi \left(\frac{n}{(n-2)}\right) \left(\frac{(n-2)C}{2E}\right)^{2/n}. \quad (47.197b)$$

For the case $n = 4$ with $V(r) = -\alpha_d e^2/2r^4$, this gives the Langevin cross section

$$\sigma_L(E) = 2\pi r_0^2 = 2\pi \left(\frac{\alpha_d e^2}{2E}\right)^{1/2} \quad (47.198)$$

for orbiting collisions, and the Langevin rate

$$k_L = v\sigma_L(E) = 2\pi(\alpha_d e^2/M)^{1/2}, \quad (47.199)$$

which is independent of E .

The case $n = 6$ with $V(r) = -C/r^6$ is the van der Waals potential for which

$$\sigma_{\text{orb}}(E) = \frac{3}{2}\pi r_0^2 = \frac{3}{2}\pi(2C/E)^{1/3}. \quad (47.200)$$

(j) Fixed dipole plus polarization potential

$$r_0^2(E) = \left(\frac{\alpha_d e^2}{2E}\right)^{1/2}, \quad (47.201a)$$

$$\sigma_{\text{orb}}(E) = 2\pi \left(\frac{\alpha_d e^2}{2E}\right)^{1/2} + \left(\frac{\pi D e \cos \theta_d}{E}\right). \quad (47.201b)$$

For a locked-in dipole, the orientation angle is $\theta_d = 0$, and $\sigma_{\text{orb}}(E) > 0$, for all θ_d , when $E > E_c = (D^2/2\alpha_d)$.

Averaging over all θ_d from 0 to $\theta_{\text{max}} = [\frac{1}{2}\pi + \sin^{-1}(2Er_0^2/De)]$, which satisfies $\sigma_{\text{orb}}(E) > 0$, for all E , then

$$\langle \sigma_{\text{orb}}(E) \rangle_{\theta_d} = \pi \left[\left(\frac{\alpha_d e^2}{2E}\right)^{1/2} + \left(\frac{\alpha_d e^2}{2E_c}\right)^{1/2} \right] + \frac{\pi D e}{4E} \left(1 - \frac{E}{E_c}\right) \quad (47.202a)$$

$$\rightarrow \sigma_L(E) \text{ as } E \rightarrow E_c. \quad (47.202b)$$

(k) Fixed dipole plus Coulomb repulsion

$$r_0^2(E) = e^2/2E. \quad (47.203a)$$

For all E and fixed rotations in the range $0 \leq \theta_d \leq \theta_{\text{max}} = \cos^{-1}(e^2/2De)$,

$$\sigma_{\text{orb}}(E) = (\pi D e \cos \theta_d)/E - \pi r_0^2(E). \quad (47.203b)$$

(l) Lennard–Jones ($n, 6$) For the following two interactions, there are two roots of $E = V_{\text{eff}}(r_0) = V(r_0) + \frac{1}{2}r_0 V'(r_0)$. They correspond to stable and unstable circular orbits [with different angular momenta associated with the minimum and maxima of the different $V_{\text{eff}}(R)$]. Analytical expressions can only be derived for the orbiting cross section at the critical energy E_{max} , above which no orbiting can occur.

For the Lennard–Jones ($n, 6$) potential, orbiting occurs for $E < E_{\text{max}} = 2\epsilon[4/(n-2)]^{6/(n-6)}$. The orbiting radius at E_{max} is

$$r_0(E_{\text{max}}) = r_e[(n-2)/4]^{1/(n-6)}.$$

The orbiting cross section at $E_{\text{max}} = 2\epsilon(r_e/r_0)^6$ is

$$\sigma_{\text{orb}}(E_{\text{max}}) = \pi b_0^2(E_{\text{max}}) = \frac{3}{2}\pi r_0^2 \left(\frac{n}{n-2}\right). \\ n = 12: E_{\text{max}} = 4\epsilon/5, \quad r_0 = 1.165r_e, \\ \sigma_{\text{orb}} = 2.4\pi r_e^2. \quad (47.204)$$

(m) Polarization ($n, 4$) As discussed for case (l),

$$E_{\text{max}} = \epsilon \left(\frac{2}{n-2}\right)^{4/(n-4)}, \quad (47.205a)$$

$$r_0(E_{\text{max}}) = r_e \left(\frac{n-2}{2}\right)^{1/(n-4)}, \quad (47.205b)$$

$$\sigma_{\text{orb}}(E_{\text{max}}) = 2\pi r_0^2 \frac{n}{(n-2)}, \quad (47.205c)$$

$$n = 12: E_{\text{max}} = \epsilon/\sqrt{5}; \\ r_0 = 1.22r_e; \sigma_{\text{orb}} = 3.6\pi r_e^2.$$

Small-Angle Scattering

For the power law potential $V(r) = -C/r^n$, Eqs. (47.96a) and (47.96b) can be expanded in powers of $V(r)/E$ to obtain analytic expressions for Θ and η_{JB} . The general form is

$$\Theta(b) = \sum_{j=1}^{\infty} \left(\frac{V(b)}{E}\right)^j F_j(n) = \frac{2}{k} \frac{\partial \eta}{\partial b}, \quad (47.206a)$$

$$F_j(n) = \frac{\pi^{1/2} \Gamma(\frac{1}{2}jn + \frac{1}{2})}{\Gamma(j+1) \Gamma(\frac{1}{2}jn - j + 1)}. \quad (47.206b)$$

The leading $j = 1$ terms equivalent to Eq. (47.97d) are $F_1(n) \equiv F(n)$, as defined following Eq. (47.169). Then to first order in V/E ,

$$\eta_{\text{JB}} = -\left(\frac{k}{2E}\right) \left(\frac{CF(n)}{n-1}\right) b^{1-n}, \quad (47.207a)$$

$$\frac{d\sigma}{d\Omega} = I_c(\theta) = \left(\frac{CF(n)}{E\theta}\right)^{2/n} \frac{1}{n\theta \sin \theta}. \quad (47.207b)$$

From a log–log plot of $\sin \theta(d\sigma/d\Omega)$ versus E , C and n can both be determined.

The integral cross sections for scattering by $\theta \geq \theta_0$ is

$$\begin{aligned}\sigma(E) &= 2\pi \int_{\theta_0}^{\pi} I_c(\theta) d(\cos \theta) = 2\pi \int_0^{b_{\max}} b db \\ &= \pi \left(\frac{CF(n)}{E\theta_0} \right)^{2/n},\end{aligned}\quad (47.208)$$

where θ_0 is the smallest measured scattering angle corresponding to a trajectory with impact parameter $b_{\max} = [CF(n)/E\theta_0]^{1/n}$. A plot of $\ln \sigma(E)$ versus $\ln E$ is a straight line with slope $(-2/n)$.

The Landau–Lifshitz cross section Eq. (47.169) and the Massey–Mohr cross section Eq. (47.170) follow from use of the JB phases Eq. (47.207a).

(n) Multiple-term power-law potentials

$$\Theta(E, b) = \frac{1}{E} [V_m(b)F(m) - V_n(b)F(n)]. \quad (47.209)$$

For example, a Lennard–Jones ($n, 6$) potential Table 47.1 has the following features

$$\begin{aligned}\text{Forward glory: } \Theta &= 0 \quad \text{when } b_g = \alpha_n^{1/(n-6)} r_e, \\ &\quad \text{where } \alpha_n = 6F(n)/[nF(6)].\end{aligned}$$

$$\text{Rainbow: } d\Theta/db = 0 \text{ at } b_r = (n\alpha_n/6)^{1/(n-6)} r_e.$$

$$\Theta_r = -F(n)(E/E)(r_e/b_r)^n, \quad (47.210a)$$

$$\omega_r = \frac{1}{2} (d^2\Theta_r/db^2)_r = \frac{3n}{b_r^2} |\Theta(b_r)|. \quad (47.210b)$$

(o) Exponential potential

$$\begin{aligned}\eta_{\text{JB}}(E, b) &= -\frac{1}{2} kb \frac{V_0}{E} K_1(\alpha b) \\ &\xrightarrow{\text{large } b} -\frac{1}{2} kb \frac{V(b)}{E} \left(\frac{\pi b}{2\alpha} \right)^{1/2}.\end{aligned}\quad (47.211)$$

(p) Screened Coulomb potential

$$\begin{aligned}\Theta(E, b) &= \alpha(V_0/E) K_1(\alpha b) \\ &\xrightarrow{\text{large } b} \left(\frac{1}{2} \pi \alpha b \right)^{1/2} V(b)/E,\end{aligned}\quad (47.212a)$$

$$\begin{aligned}\eta_{\text{JB}}(E, b) &= -\frac{k}{2E} V_0 K_0(\alpha b) \\ &\xrightarrow{\text{large } b} -\frac{k}{2E} V(b) \left(\frac{\pi b}{2\alpha} \right)^{1/2}.\end{aligned}\quad (47.212b)$$

(q) Morse potential

$$\begin{aligned}\Theta(E, b) &= (2\beta b) \left(\frac{\epsilon}{E} \right) \\ &\quad \times [e^{2\beta r_e} K_0(2\beta b) - e^{\beta r_e} K_0(\beta b)] \\ &\xrightarrow{\text{large } b} (\pi\beta b)^{1/2} \left(\frac{\epsilon}{E} \right) [e^{2\beta(r_e-b)} - \sqrt{2} e^{\beta(r_e-b)}], \\ b_r &= r_e + (2\beta)^{-1} \ln 2, \\ \Theta_r &= -(\pi\beta b_r)^{1/2} (\epsilon/2E), \\ \omega_r &= \beta^2 |\Theta_r| r_e^2.\end{aligned}\quad (47.213)$$

Large-Angle Scattering

For power law potentials $V(r) = C/r^n$,

$$\Theta(b) = \pi - \sum_{j=1}^n \left(\frac{E}{V(b)} \right)^{(2j-1)/n} G_j(n), \quad (47.214a)$$

$$G_j(n) = \frac{(-1)^{j-1}}{\Gamma(j)\Gamma(k)} \left(\frac{2\pi^{1/2}}{n} \right) \Gamma\left(\frac{2j-1}{n} \right), \quad (47.214b)$$

with $k = [(2j-1)/n] - j - \frac{1}{2}$. For the $j = 1$ term,

$$\Theta(b) = \pi - \left(\frac{E}{C} \right)^{1/n} G_1(n) b, \quad (47.214c)$$

$$I_c(\theta) = \frac{d\sigma}{d\Omega} = \left(\frac{C}{E} \right)^{2/n} G_1^{-2}(n), \quad (47.214d)$$

which is isotropic. Including both $j = 1$ and 2 terms provides a good approximation to the entire repulsive branch of the deflection function Θ . Series Eq. (47.214a) for large angles and Eq. (47.206a) for small angles eventually diverge for impact parameters $b < b_c$ and $b > b_c$, respectively, where

$$b_c = n^{1/2} \left(\frac{C}{2E} \right)^{1/n} \frac{|n-2|^{1/n}}{|n-2|^{1/2}}. \quad (47.214e)$$

47.9.2 Amplitudes and Cross Sections in Born Approximation

$$k^2 = 2mE/\hbar^2, \quad K = 2k \sin \frac{1}{2}\theta,$$

$$U_0 = 2mV_0/\hbar^2, \quad U_0/k^2 = V_0/E,$$

in the general expression Eq. (47.75) for the first Born approximation.

(a) Exponential $V(r) = V_0 \exp(-\alpha r)$

$$f_{\text{B}}(\theta) = -\frac{2\alpha U_0}{(\alpha^2 + K^2)^2}, \quad (47.215a)$$

$$\begin{aligned}\sigma_{\text{B}}(E) &= \frac{16\pi}{3} U_0^2 \frac{3\alpha^4 + 12\alpha^2 k^2 + 16k^4}{\alpha^4(\alpha^2 + 4k^2)^3}, \\ &\xrightarrow{E \rightarrow \infty} \frac{4}{3} \pi \left(\frac{V_0}{E} \right) \left(\frac{U_0}{\alpha^4} \right).\end{aligned}\quad (47.215b)$$

(b) **Gaussian** $V(r) = V_0 \exp(-\alpha^2 r^2)$

$$f_B(\theta) = -\left(\frac{\pi^{1/2} U_0}{4\alpha^2}\right) \exp(-K^2/4\alpha^2), \quad (47.216a)$$

$$\sigma_B(E) = \left(\frac{\pi^2 U_0}{8\alpha^4}\right) \left(\frac{V_0}{E}\right) [1 - \exp(-2k^2/\alpha^2)]. \quad (47.216b)$$

(c) **Spherical well** $V(r) = V_0$ for $r < a$, $V(r) = 0$ otherwise

$$f_B(\theta) = -\frac{U_0}{K^3} (\sin Ka - Ka \cos Ka), \quad (47.217a)$$

$$\sigma_B(E) = \frac{\pi V_0}{2E} (U_0 a^4) [1 - (ka)^{-2} + (ka)^{-3} \sin 2ka - (ka)^{-4} \sin^2 2ka]. \quad (47.217b)$$

(d) **Screened Coulomb** $V(r) = V_0 \exp(-\alpha r)/r$, $V_0 = Z_1 Z_2 e^2$, $U_0 = 2Z_1 Z_2 / a_0$

$$f_B(\theta) = -\frac{U_0}{\alpha^2 + K^2}, \quad (47.218a)$$

$$\sigma_B(E) = \frac{4\pi U_0^2}{\alpha^2(\alpha^2 + 4k^2)} \rightarrow \pi \left(\frac{V_0}{E}\right) \left(\frac{U_0}{\alpha^2}\right). \quad (47.218b)$$

When $\alpha \rightarrow 0$, then $f_B(\theta) = -U_0/K^2$.

(e) **e⁻-atom**

$$V(r) = -Ne^2[Z/a_0 + 1/r] \exp(-2Zr/a_0), \quad (47.219a)$$

H(1s): N = 1, Z = 1; He(1s²): N = 2; Z = 27/16.

$$f_B(\theta) = \frac{2N}{a_0} \left(\frac{2\alpha^2 + K^2}{(\alpha^2 + K^2)^2} \right), \quad \alpha = 2Z/a_0, \quad (47.219b)$$

$$\sigma_B(E) = \frac{\pi a_0^2 N^2 (12Z^4 + 18Z^2 k^2 a_0^2 + 7k^4 a_0^4)}{3Z^2 (Z^2 + k^2 a_0^2)^3}. \quad (47.219c)$$

Also, f_B decomposes Eq. (47.78) as

$$f_B(K) = f_B^{eZ}(K) + f_B^{ee}(K)F(K), \quad (47.219d)$$

where f_B^{ij} are two-body Coulomb amplitudes for (i, j) scattering, and $F(K)$ is the elastic form factor Eq. (47.79).

(f) **Dipole** $V(r) = V_0/r^2$.

$$f_B(\theta) = \pi U_0 / 2K. \quad (47.220)$$

(g) **Polarization** $V(r) = V_0(r^2 + r_0^2)^{-2}$

$$f_B(\theta) = -\frac{\pi U_0}{4 r_0} \exp(-Kr_0), \quad (47.221a)$$

$$\sigma_B(E) = \frac{\pi^3 U_0 V_0}{32r_0^4 E} [1 - (1 + 4kr_0) \exp(-4kr_0)]. \quad (47.221b)$$

Abstract

This chapter deals with the concepts of orientation and alignment in atomic and molecular physics. The terms refer to parameters related to the shape and dynamics of an excited atomic or molecular level, as it is manifested in a nonstatistical population of the magnetic sublevels. To take full advantages of the possibilities of this approach, one utilizes *third generation experiments*, i.e., scattering experiments that exploit the planar scattering symmetry, contrary to an angular differential cross section determination (a *second generation experiment*) having

cylindrical symmetry, or a total cross section measurement (a *first generation experiment*) integrating over all scattering angles. In this way, one is often able to probe atomic collision theories at a more fundamental level, and in favorable cases approach a *perfect scattering experiment* in which the complex quantal scattering amplitudes are completely determined. This term was coined by *Bederson* [1] and has since served as an ideal towards which scattering experiments attempt to strive.

Keywords

density matrix · differential cross section · coherence analysis · reflection symmetry · Stokes vector · polarization · orientation · alignment

48.1 Introduction

The study of anisotropies has a long history in atomic physics, with light polarization, or Stokes parameter analysis, as a prominent example. A pioneering review by *Fano* and *Macek* [2] laid the mathematical and conceptual foundation for most of the later work. Advances in coincidence techniques, laser preparation methods, and the development of efficient sources for polarized electrons [3] have boosted the field further. Parallel developments of powerful computational codes have enabled a matching theoretical effort. In this way, detailed insights into the collision dynamics have been obtained, such as the locking radius model for low-energy atomic collisions, propensity rules for orientation in fast electronic and atomic collisions, and spin effects in polarized electron-heavy atom scattering. Presentations of these developments are contained in [4] and Chaps. 39, 53, 55, 67, 68, and 70. A comprehensive and critical review of the literature and the mathematical formalism was initiated by the National Institute of Standards and Technology (NIST) [5–7].

Space limitations allow only presentation of the formalism for the simplest case of excitation. Recent developments in the description of processes involving polarized beams are included. The presentation is restricted to atomic outer-shell excitation. Other reviews describe excitation of inner shells [8] and molecular levels [9]. Related material on density matrices is contained in Chap. 7 [10].

48.2 Collisions Involving Unpolarized Beams

48.2.1 The Fully Coherent Case

Consider first the simplest nontrivial case of $S \rightarrow P$ excitation. A general property of an atomic collision is that the total reflection symmetry with respect to the scattering plane of the total wave function describing the system is conserved. In simple cases, such as electron impact excitation of He singlet states, or atom excitation by fast, heavy particle impact, the projectile acts as a structureless particle, with only the target atom changing its quantum state. In this case, the reflection symmetry of the target wave function alone is conserved.

Figure 48.1 shows the angular parts of the simplest $|lm\rangle$ -states with $l = 0, 1, 2$. The arrows indicate how the two families of states with positive or negative reflection symmetry may couple internally. Thus, in an $S \rightarrow P$ transition, an atom initially in an S-state may be excited to the (p_{+1}, p_{-1}) subspace, while the p_0 -state is not accessible. A characteristic feature of the corresponding electron charge cloud is that it has *zero height*, i.e., zero electron density in the direction perpendicular to the scattering plane. Furthermore, the expectation value of the orbital angular momentum has a nonvanishing component in this direction only.

The resulting electron charge cloud may, thus, have a shape as shown in Fig. 48.2a. We shall now discuss the parametrization of the wave function of this state and analyze the connection between the wave function and the corresponding photon radiation pattern emitted when the state decays back to the initial S-state, using the properties of electric dipole radiation.

Basic Definitions and Coordinate Frames

The coordinate frames that are of particular use in describing the wave function are as follows. The *collision frame*, (x^c, y^c, z^c) , is defined by $\hat{z}^c \parallel \mathbf{k}_{\text{in}}$ and $\hat{y}^c \parallel \mathbf{k}_{\text{in}} \times \mathbf{k}_{\text{out}}$. The *natural frame*, (x^n, y^n, z^n) , is defined by $\hat{x}^n \parallel \mathbf{k}_{\text{in}}$ and $\hat{z}^n \parallel \mathbf{k}_{\text{in}} \times \mathbf{k}_{\text{out}}$. Finally, the *atomic frame* is identical to the natural frame, except that it is rotated by an angle γ around $z^n = z^a$ such that x^a is parallel to the major symmetry axis of the P-state charge cloud, as shown in Fig. 48.2. Most scattering calculations use the collision coordinate system as the reference frame, while mathematical analysis is of-

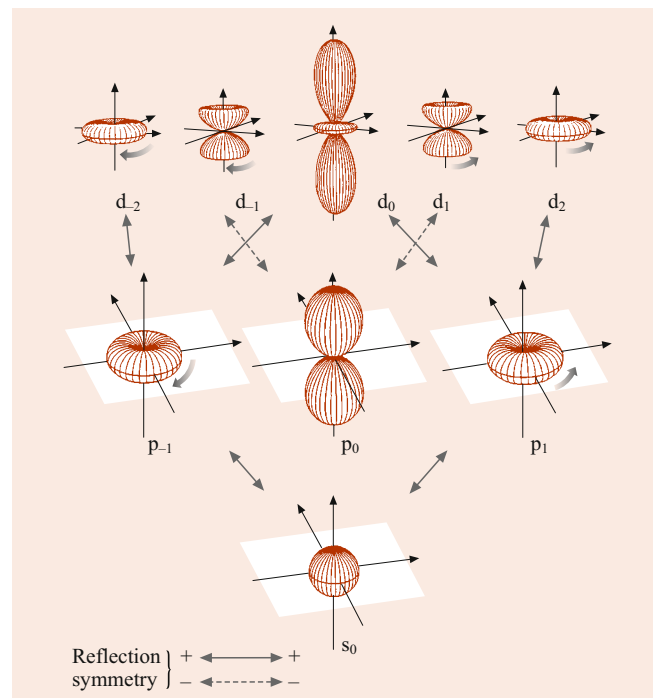

Fig. 48.1 Reflection symmetry of the simplest spherical harmonics, corresponding to S, P, and D-states

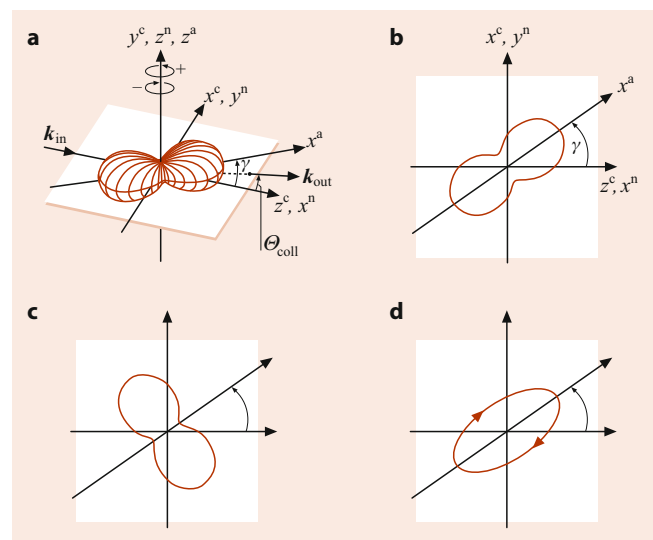

Fig. 48.2 **a** Shows the shape, or the angular part, of a P-state with positive reflection symmetry with respect to the scattering plane. Some relevant coordinate frames are also indicated; **b** shows a cut of this shape in the scattering plane. **c** is the angular distribution of photons emitted in the scattering plane; **d** is the polarization ellipse for light emitted in the direction perpendicular to the plane, as observed from above

ten most conveniently performed in the natural frame, where the algebra is particularly simple. Many expressions are even simpler in the atomic frame, but it has the disadvantage that the angle γ varies with collision parameters, such as impact velocity, impact parameter, etc.

The expansion of the P-state wave function in the three coordinate systems is

$$|\Psi\rangle = a_{+1}^c |p_{+1}^c\rangle + a_0^c |p_0^c\rangle + a_{-1}^c |p_{-1}^c\rangle \quad (48.1)$$

$$= a_{+1}^n |p_{+1}^n\rangle + a_{-1}^n |p_{-1}^n\rangle \quad (48.2)$$

$$= a_{+1}^a |p_{+1}^a\rangle + a_{-1}^a |p_{-1}^a\rangle . \quad (48.3)$$

Conservation of reflection symmetry in the scattering plane implies

$$a_{+1}^c = -a_{-1}^c , \quad (48.4)$$

$$a_0^n = 0 , \quad (48.5)$$

$$a_0^a = 0 . \quad (48.6)$$

The normalization condition implies

$$\begin{aligned} |a_0^c|^2 + 2|a_{+1}^c|^2 &= |a_{+1}^n|^2 + |a_{-1}^n|^2 \\ &= |a_{+1}^a|^2 + |a_{-1}^a|^2 \\ &= 1 . \end{aligned} \quad (48.7)$$

Finally, the a_m coefficients are related to the scattering amplitudes f_m and the differential cross section $\sigma(\theta)$ by

$$a_m = f_m(k_{\text{out}}/k_{\text{in}})^{\frac{1}{2}} \sigma(\theta)^{-\frac{1}{2}} \quad (48.8)$$

$$\sigma(\theta) = (k_{\text{out}}/k_{\text{in}}) \left(|f_0^c|^2 + 2|f_{+1}^c|^2 \right), \text{ etc.} \quad (48.9)$$

Except for an arbitrary phase factor, the pure state in Eq. (48.1) may thus be characterized by two dimensionless parameters. Traditionally, they have been chosen as (λ, χ) defined as [11]

$$\lambda = \frac{|a_0^c|^2}{|a_0^c|^2 + 2|a_{+1}^c|^2} , \quad (48.10)$$

$$\chi = \arg(a_{+1}^c a_0^{c*}) . \quad (48.11)$$

An alternative parametrization (L_{\perp}, γ) is given by [5]

$$L_{\perp} = \frac{|a_{+1}^n|^2 - |a_{-1}^n|^2}{|a_{+1}^n|^2 + |a_{-1}^n|^2} , \quad (48.12)$$

$$\begin{aligned} \gamma &= \frac{1}{2} \arg(a_{-1}^n a_{+1}^{n*}) \pm \frac{\pi}{2} , \\ &= -\frac{1}{2} (\delta \pm \pi) , \end{aligned} \quad (48.13)$$

with the notation of Fig. 48.3. Referring to the natural coordinate frame, the expectation value of the electronic orbital angular momentum is, thus,

$$\langle \Psi | L | \Psi \rangle = (0, 0, L_{\perp}) . \quad (48.14)$$

Coherence Analysis: Stokes Parameters

We now discuss the information obtainable from a polarization analysis of the emitted light. In the notation of classical

Fig. 48.3 Fully coherent $S \rightarrow P$ excitation may be described by two independent scattering amplitudes, characterized by their relative size and phase

optics (e.g., *Born and Wolf* [12]) the components of the Stokes vector (P_1, P_2, P_3) measured in the direction $+y^c$ ($+z^n$) perpendicular to the scattering plane and defined by

$$IP_1 = I(0^\circ) - I(90^\circ) , \quad (48.15)$$

$$IP_2 = I(45^\circ) - I(135^\circ) , \quad (48.16)$$

$$IP_3 = I(\text{RHC}) - I(\text{LHC}) , \quad (48.17)$$

with

$$\begin{aligned} I &= I(0^\circ) + I(90^\circ) \\ &= I(45^\circ) + I(135^\circ) \\ &= I(\text{RHC}) + I(\text{LHC}) , \end{aligned} \quad (48.18)$$

are given by

$$P_1 = 2\lambda - 1 , \quad (48.19)$$

$$P_2 = -2\sqrt{\lambda(1-\lambda)} \cos \chi , \quad (48.20)$$

$$P_3 = 2\sqrt{\lambda(1-\lambda)} \sin \chi , \quad (48.21)$$

or, alternatively,

$$P_1 = P_l \cos 2\gamma , \quad (48.22)$$

$$P_2 = P_l \sin 2\gamma , \quad (48.23)$$

$$P_3 = -L_{\perp} , \quad (48.24)$$

with

$$P_l = \sqrt{P_1^2 + P_2^2} . \quad (48.25)$$

Here, $I(\theta)$ is the intensity transmitted through an ideal linear polarizer with the transmission direction tilted by an angle θ with respect to the z^c or x^n -direction. Similarly, RHC (LHC) (right (left) hand circularly polarized light) refers to photons with negative (positive) helicity. Inspection of Eqs. (48.19) to (48.25) shows that determination of the Stokes vector in the direction perpendicular to the collision plane determines the wave function in Eq. (48.1) completely. A determination of the Stokes vector, thus, constitutes a *perfect scattering experiment*.

The Stokes vector (P_1, P_2, P_3) is a unit vector characterizing the state $|\Psi\rangle$, and it may be represented by a point on the Poincaré sphere; see Fig. 48.4.

Fig. 48.4 The Poincaré sphere. The Stokes vector for a pure state $|\Psi\rangle$ corresponds to a characteristic polarization ellipse, represented by a point on the unit sphere. Generally, the light is elliptically polarized, with the sense of rotation indicated by the arrows on the selected ellipses drawn. Special cases are the north and south poles, where the polarization is purely circular, and the equator, where it is purely linear, with the direction indicated by the orientation of the lines

Correlation Analysis

Another experimental approach is to map the angular distribution of the photons emitted in the subsequent $S \rightarrow P$ decay. For this purpose, we first note that the angular part $\Upsilon(\theta, \phi)$ of the electron probability density $\langle \Psi | \Psi \rangle$ corresponding to the wave function in Eq. (48.1) may be written as

$$\Upsilon(\theta, \phi) = \frac{1}{2} [1 + P_l \cos 2(\phi - \gamma)] \sin^2 \theta. \quad (48.26)$$

Figure 48.2b shows a cut of this charge cloud in the scattering plane,

$$\Upsilon\left(\frac{1}{2}\pi, \phi\right) = \frac{1}{2} [1 + P_l \cos 2(\phi - \gamma)]. \quad (48.27)$$

The relative length, l , and width, w of the charge cloud are given by

$$l = \frac{1}{2}(1 + P_l), \quad (48.28)$$

$$w = \frac{1}{2}(1 - P_l). \quad (48.29)$$

The degree of linear polarization P_l is, thus, a measure of the shape of the charge cloud, since

$$P_l = \frac{l - w}{l + w}. \quad (48.30)$$

According to the properties of electric dipole radiation, the pattern $I(\phi)$ in the scattering plane is

$$I(\phi) = \frac{1}{2} [1 - P_l \cos 2(\phi - \gamma)]. \quad (48.31)$$

A mapping of the radiation pattern in the collision plane determines γ and P_l , and thereby the absolute value of the angular momentum by

$$|L_\perp| = \sqrt{1 - P_l^2}. \quad (48.32)$$

However, the sign of L_\perp cannot be determined by correlation analysis, and accordingly this approach does not qualify for classification as a *perfect scattering experiment*.

Density Matrix Representation

Recalling that $\rho_{mn} = a_m a_n^*$, the density matrices in the various basis sets introduced above are

$$\rho^c = \frac{1}{\sqrt{8}} \begin{pmatrix} \frac{1}{\sqrt{2}}(1 - P_1) & -P_2 + iP_3 & -\frac{1}{\sqrt{2}}(1 - P_1) \\ -P_2 - iP_3 & \sqrt{2}(1 - P_1) & P_2 + iP_3 \\ -\frac{1}{\sqrt{2}}(1 - P_1) & P_2 - iP_3 & \frac{1}{\sqrt{2}}(1 - P_1) \end{pmatrix}, \quad (48.33)$$

$$\rho^n = \frac{1}{2} \begin{pmatrix} 1 + L_\perp & 0 & -P_l e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l e^{2i\gamma} & 0 & 1 - L_\perp \end{pmatrix}, \quad (48.34)$$

$$\rho^a = \frac{1}{2} \begin{pmatrix} 1 + L_\perp & 0 & -P_l \\ 0 & 0 & 0 \\ -P_l & 0 & 1 - L_\perp \end{pmatrix}. \quad (48.35)$$

The density matrices illustrate the algebraic simplifications obtained using the natural coordinate frame. In the following, this frame will be used unless otherwise stated, and we therefore suppress the superscript n below.

Postcollisional Depolarization Due to Fine Structure and Hyperfine Structure Effects

After the collision, the isolated atom evolves under the influence of internal forces, such as fine structure and hyperfine structure, until the optical decay. While typical collision times are of the order 10^{-15} s, the light emission occurs after a time interval of 10^{-9} s. This is long compared with the Larmor precession time of the electron spin ($\approx 10^{-12}$ s), and one can, thus, assume that the atom has completely relaxed into, e.g., its ${}^2P_{1/2}$ and ${}^2P_{3/2}$ -states before the photon emission. For the simplest nontrivial case of electron spin $S = \frac{1}{2}$, the Stokes vector $\mathbf{P}(S)$ of the subsequent ${}^2P \rightarrow {}^2S$ transition

is modified to become

$$P_{1,2}\left(\frac{1}{2}\right) = \frac{3}{7}P_{1,2}(0), \quad (48.36)$$

$$P_3\left(\frac{1}{2}\right) = P_3(0), \quad (48.37)$$

and the Stokes vector is, thus, no longer a unit vector. In general, the Stokes vector components are reduced by depolarization factors c_i (a table of c_i coefficients for the most common values of electron and nuclear spin is given in Appendix B of [5])

$$P_i(S) = c_i P_i(0). \quad (48.38)$$

This suggests introduction of *reduced polarizations*

$$\bar{P}_i = P_i(S)/c_i. \quad (48.39)$$

The *reduced* Stokes vector $(\bar{P}_1, \bar{P}_2, \bar{P}_3)$ is again a unit vector, and the formalism developed above for the spinless case can then be applied. We shall assume that this correction has been made, and the *bar* will be dropped.

48.2.2 The Incoherent Case with Conservation of Atomic Reflection Symmetry

The picture outlined above has to be modified in cases where the experiment sums over several, in principle distinguishable, channels, each of which, however, conserves reflection symmetry. Prototype examples are electron impact excitation of hydrogen or light alkali atoms. Here, the excitation process is described by singlet and triplet scattering amplitudes, respectively, and we have the possibility of direct and exchange scattering. This doubles the number of scattering amplitudes from two to four. The experimental results are, thus, an incoherent sum over these channels (singlet and triplet), the unraveling of which would require the application of spin-polarized beams; see Sect. 48.3. The atomic P-state can no longer be described as a single pure state, Eq. (48.1), but as a mixed state (Chap. 7). The expressions in Eqs. (48.33) to (48.35) for the density matrix are unchanged, but the matrix elements are now sums of the contributions from the individual channels (we shall discuss its decomposition below); P_l and L_\perp are now independent quantities, and the (reduced) Stokes vector \mathbf{P} is generally no longer a unit vector. The degree of polarization P may thus be less than 1, i.e.,

$$P^2 = P_1^2 + P_2^2 + P_3^2 = P_l^2 + L_\perp^2 \leq 1. \quad (48.40)$$

For electron impact excitation, deviation of the parameter P from unity may, thus, serve as a measure of the effect of electron exchange. Accordingly, we have three independent observables, e.g., (L_\perp, γ, P_l) . This set of variables is

frame independent. A photon correlation experiment in the scattering plane may extract the (γ, P_l) pair, while coherence analysis in the z -direction provides the complete set. An alternative set of (frame-dependent) parameters used in particular for hydrogen is (λ, R, I) , with

$$\lambda = \frac{1}{2}(1 + P_1), \quad (48.41)$$

$$R = -\frac{1}{\sqrt{8}}P_2, \quad (48.42)$$

$$I = \frac{1}{\sqrt{8}}P_3. \quad (48.43)$$

48.2.3 The Incoherent Case Without Conservation of Atomic Reflection Symmetry

In the general case, the assumption of positive reflection symmetry with respect to the scattering plane for the wave function of the excited atom cannot be maintained. For example, for electron impact excitation of a P-state of a heavy atom, spin-orbit effects may be so strong that they flip the electron spin, thereby allowing population of the $|p_0^n\rangle$ -state. Thus, the total number of scattering amplitudes is now six. Typical examples are mercury or the heavy noble gases. The total angular momentum of the excited state is $J = 1$, the fine structure being completely resolved in these cases. Strictly speaking, the density matrix elements no longer describe the electronic charge cloud, but rather the excited state ($J = 1$) distribution. Similarly, L_\perp should be replaced by J_\perp , but, for simplicity, we keep the notation. This state radiates as a set of classical oscillators, completely analogous to the 1P_1 -state described above, so we shall maintain our previous notation, simply replacing the term charge cloud density by oscillator density. The main difference from the cases considered above is that the density now displays a height; see Fig. 48.5.

Blum, da Paixão, and collaborators, [13, 14], were the first to formulate a parametrization of the general case. Here, we shall use the expression for the density matrix in the natural frame as the starting point and decompose it into the two terms with positive and negative reflection symmetry, respectively,

$$\rho^n = (1 - h) \frac{1}{2} \begin{pmatrix} 1 - P_3 & 0 & -P_l^+ e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l^+ e^{2i\gamma} & 0 & 1 + P_3 \end{pmatrix} + h \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (48.44)$$

Fig. 48.5 The top row shows classical oscillator densities for height parameters $h = 0$ and $h = 1/3$, respectively. The alignment angle is $\gamma = 35^\circ$ and $P_l^+ = 0.6$ in both cases. Cuts along the symmetry axes are shown in the other rows

where the linear polarization P_l^+ is labeled with a + referring to the positive reflection symmetry. Similarly, we define

$$L_\perp^+ \equiv -P_3, \quad (48.45)$$

$$P^{+2} \equiv P_1^2 + P_2^2 + P_3^2 \leq 1. \quad (48.46)$$

The shape of the density is now characterized by the three parameters

$$l = (1 - h) \frac{1}{2}(1 + P_l), \quad (48.47)$$

$$w = (1 - h) \frac{1}{2}(1 - P_l), \quad (48.48)$$

$$h = \rho_{00}, \quad (48.49)$$

with $l + w + h = 1$. There are, thus, four independent observables, chosen as $(L_\perp^+, \gamma, P_l^+, h)$. Again, this set of variables is frame independent. Determination of the height parameter evidently requires observation from a direction other than the z^n -direction. Traditionally, the Stokes parameter $(P_4, 0, 0)$ is measured from the y^n -direction to obtain

$$h = \frac{(1 + P_l)(1 - P_4)}{4 - (1 - P_l)(1 - P_4)}. \quad (48.50)$$

Thus, all four parameters may be obtained from analysis of the light coherence, but two directions of observation are necessary. Similarly, photon correlation analysis in two planes is required to extract (γ, P_l^+, h) ; see, e.g., [5] for a discussion.

The various cases with unpolarized beams discussed in this section are summarized in Table 48.1.

Table 48.1 Summary of cases of increasing complexity and the orientation and alignment parameters necessary for unpolarized beams; N_p is the number of independent parameters, and N_d is the number of observation directions required

Variable	Sect. 48.2.1	Sect. 48.2.2	Sect. 48.2.3
Forces	Coulomb	+exchange	+spin-orbit
Representation	Wave func.	ρ_{mn}	ρ_{mn}
Refl. symmetry	+	+	+, -
Ang. mom.	L_\perp	L_\perp	L_\perp^+
Align. angle	γ	γ	γ
Linear pol.	P_l	P_l	P_l^+
Degree of pol.	$P = 1$	$P \leq 1$	$P^+ \leq 1$
Height	$h = 0$	$h = 0$	$h \geq 0$
N_p	2	3	4
N_d	1	1	2

48.3 Collisions Involving Spin-Polarized Beams

In this section, we discuss the additional information that can be gained by the application of a polarized beam compared with an unpolarized beam. Collisions with polarized electron beams are discussed in particular, but most of the ideas presented are easily generalized to beams of atoms in polarized, or otherwise prepared, states. We shall keep the order of increasing complexity introduced in the previous section.

48.3.1 The Fully Coherent Case

As can be seen in Sect. 48.2.2, a simple example of a fully coherent excitation process is $\text{He } 1^1\text{S} \rightarrow n^1\text{P}$ excitation, for which complete information can be obtained from experiments using unpolarized beams. Consequently, in this case, the application of polarized electrons will add nothing new. Also, the polarization of the scattered electron can be trivially predicted, since no change is possible in the scattering process.

48.3.2 The Incoherent Case with Conservation of Atomic Reflection Symmetry

The targets of interest here are hydrogen or light alkali atoms with an electron spin $S = \frac{1}{2}$. Since we now have the possibility of triplet (t) and singlet (s) scattering, this doubles the number of scattering amplitudes from two to four (recall that $f_0 = 0$); see Fig. 48.6.

The amplitudes of interest are

$$f_{+1}^t = \alpha_+ e^{i\phi_+}, \quad (48.51)$$

$$f_{-1}^t = \alpha_- e^{i\phi_-}, \quad (48.52)$$

$$f_{+1}^s = \beta_+ e^{i\psi_+}, \quad (48.53)$$

$$f_{-1}^s = \beta_- e^{i\psi_-}. \quad (48.54)$$

Fig. 48.6 For ${}^2S \rightarrow {}^2P$ electron impact excitation of hydrogen or light alkali atoms, four scattering amplitudes come into play

Neglecting an overall phase, seven independent parameters are needed to characterize the amplitudes completely. Traditionally, one is chosen as the differential cross section σ_u corresponding to unpolarized particles. Six additional dimensionless parameters may be defined: three to characterize the relative lengths of the four vectors, and three to define their relative phase angles.

The density matrix is parametrized, in analogy to the unpolarized beam case, according to [15]

$$\rho^t = \sigma^t \frac{1}{2} \begin{pmatrix} 1 + L_{\perp}^t & 0 & -P_l^t e^{-2i\gamma^t} \\ 0 & 0 & 0 \\ -P_l^t e^{2i\gamma^t} & 0 & 1 - L_{\perp}^t \end{pmatrix}, \quad (48.55)$$

$$\rho^s = \sigma^s \frac{1}{2} \begin{pmatrix} 1 + L_{\perp}^s & 0 & -P_l^s e^{-2i\gamma^s} \\ 0 & 0 & 0 \\ -P_l^s e^{2i\gamma^s} & 0 & 1 - L_{\perp}^s \end{pmatrix}, \quad (48.56)$$

where

$$\sigma^t = \alpha_+^2 + \alpha_-^2, \quad (48.57)$$

$$\sigma^s = \beta_+^2 + \beta_-^2, \quad (48.58)$$

$$L_{\perp}^t = \frac{1}{\sigma^t} (\alpha_+^2 - \alpha_-^2), \quad (48.59)$$

$$L_{\perp}^s = \frac{1}{\sigma^s} (\beta_+^2 - \beta_-^2), \quad (48.60)$$

$$P_l^t e^{2i\gamma^t} = P_1^t + iP_2^t = -\frac{2\alpha_+\alpha_-}{\sigma^t} e^{-i\delta^t}, \quad (48.61)$$

$$P_l^s e^{2i\gamma^s} = P_1^s + iP_2^s = -\frac{2\beta_+\beta_-}{\sigma^s} e^{-i\delta^s}. \quad (48.62)$$

In the case of an unpolarized beam, the total density matrix becomes the weighted sum of the two matrices ρ^s and ρ^t , i.e.,

$$\rho_u = \sigma_u \frac{1}{2} \begin{pmatrix} 1 + L_{\perp} & 0 & -P_l e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l e^{2i\gamma} & 0 & 1 - L_{\perp} \end{pmatrix}$$

$$= 3w^t \sigma_u \frac{1}{2} \begin{pmatrix} 1 + L_{\perp}^t & 0 & -P_l^t e^{-2i\gamma^t} \\ 0 & 0 & 0 \\ -P_l^t e^{2i\gamma^t} & 0 & 1 - L_{\perp}^t \end{pmatrix} + w^s \sigma_u \frac{1}{2} \begin{pmatrix} 1 + L_{\perp}^s & 0 & -P_l^s e^{-2i\gamma^s} \\ 0 & 0 & 0 \\ -P_l^s e^{2i\gamma^s} & 0 & 1 - L_{\perp}^s \end{pmatrix}, \quad (48.63)$$

where

$$w^t = \frac{\sigma^t}{\sigma^s + 3\sigma^t} = \frac{\sigma^t}{4\sigma_u}, \quad (48.64)$$

$$w^s = \frac{\sigma^s}{\sigma^s + 3\sigma^t} = \frac{\sigma^s}{4\sigma_u} = 1 - 3w^t, \quad (48.65)$$

$$\sigma_u = (3w^t + w^s)\sigma_u = \frac{3}{4}\sigma^t + \frac{1}{4}\sigma^s. \quad (48.66)$$

The six parameters σ_u , w^t , L_{\perp}^t , L_{\perp}^s , γ^t , and γ^s have now been introduced, leaving one parameter still to be chosen. Inspection of Fig. 48.6 suggests, for example, the angle Δ^+ . The fourth angle, Δ^- , is then fixed through the relation

$$\Delta^+ - \Delta^- = \delta^t - \delta^s = 2(\gamma^s - \gamma^t). \quad (48.67)$$

The following set of six dimensionless parameters is thus complete

$$w^t, L_{\perp}^t, L_{\perp}^s, \gamma^t, \gamma^s, \Delta^+. \quad (48.68)$$

Detailed recipes for the extraction of the parameters from coherence experiments are somewhat complicated, and we refer to discussions in the literature [7, 15, 16]. Using spin-polarized electrons and spin-polarized targets, all parameters may be determined, except for information about singlet-triplet phase differences, such as Δ^+ .

The reduced Stokes vector \mathbf{P} of the unpolarized beam experiment is given by the singlet and triplet (unit) Stokes vectors $\mathbf{P}^{s,t}$ as

$$\mathbf{P} = 3w^t \mathbf{P}^t + w^s \mathbf{P}^s, \quad (48.69)$$

from which the set of parameters (L_{\perp}, γ, P_l) for the unpolarized beam experiment may be evaluated from

$$L_{\perp} = 3w^t L_{\perp}^t + w^s L_{\perp}^s, \quad (48.70)$$

$$P_l e^{2i\gamma} = 3w^t P_l^t e^{2i\gamma^t} + w^s P_l^s e^{2i\gamma^s}. \quad (48.71)$$

Since, in general, $L_{\perp}^t \neq L_{\perp}^s$ and $\gamma^t \neq \gamma^s$, this causes the (reduced) degree of polarization P to be smaller than unity.

To summarize this section, Stokes parameter analysis may provide five dimensionless parameters, the relative phase between the two f_{+1}^t and f_{-1}^t amplitudes and the relative phase between the two f_{+1}^s and f_{-1}^s amplitudes, as well as the relative sizes of all four amplitudes. However, none of the relative phases between any triplet and singlet amplitude can be

Fig. 48.7 For $J = 0 \rightarrow J = 1$, electron impact excitation of heavy atoms six scattering amplitudes come into play since spin-flip may occur

determined, and coherence analysis alone is, thus, not able to provide a *perfect scattering experiment*. The missing phase may be extracted from the so-called STU parameters of the scattered electron, ([16, 17] and Chap. 7).

48.3.3 The Incoherent Case Without Conservation of Atomic Reflection Symmetry

The results of coherence analysis of a $J = 0^e \rightarrow J = 1^o$ transition will now be discussed. We only analyze the photon polarization in the exit channel, not the electron spin parameters. There are six independent scattering amplitudes for a $J = 0 \rightarrow J = 1$ transition (Fig. 48.7), thereby requiring the determination of one absolute differential cross section, five relative magnitudes, and another five relative phases of the scattering amplitudes.

This large number of independent parameters leads to considerable complications. Nevertheless, the natural coordinate system enables disentangling of the scattering amplitudes and generalization of the parametrization of the density matrix for the case of unpolarized beams in a straightforward way [7, 18–20]. The nonvanishing amplitudes $f^n(M_f, m_f, m_i)$ in the natural frame (Fig. 48.7) for a $J = 0 \rightarrow J = 1$ transition are

$$f^n\left(1, \frac{1}{2}, \frac{1}{2}\right) \equiv f_{+1}^{\uparrow} = \alpha_+ e^{i\phi_+}, \quad (48.72)$$

$$f^n\left(1, -\frac{1}{2}, -\frac{1}{2}\right) \equiv f_{+1}^{\downarrow} = \beta_+ e^{i\psi_+}, \quad (48.73)$$

$$f^n\left(-1, \frac{1}{2}, \frac{1}{2}\right) \equiv f_{-1}^{\uparrow} = \alpha_- e^{i\phi_-}, \quad (48.74)$$

$$f^n\left(-1, -\frac{1}{2}, -\frac{1}{2}\right) \equiv f_{-1}^{\downarrow} = \beta_- e^{i\psi_-}, \quad (48.75)$$

$$f^n\left(0, \frac{1}{2}, -\frac{1}{2}\right) \equiv f_0^{\downarrow} = \beta_0 e^{i\psi_0}, \quad (48.76)$$

$$f^n\left(0, -\frac{1}{2}, \frac{1}{2}\right) \equiv f_0^{\uparrow} = \alpha_0 e^{i\phi_0}, \quad (48.77)$$

where we have omitted $J_i = M_i = 0$ and $J_f = 1$. Equations (48.72)–(48.75) represent noflip amplitudes that leave the projectile spin unchanged, while Eqs. (48.76) and (48.77) describe the cases where the electron spin is flipped.

We first assume a polarization perpendicular to the scattering plane, i.e., along the z -direction. In Eq. (48.44), the density matrix for heavy atoms such as Xe or Hg was decomposed into a pair of matrices with one having positive reflection symmetry with respect to the scattering plane, and the other one having negative reflection symmetry, respectively. The extension of this decomposition to the case of polarized electron beams is a pair of density matrices, one for spin-up electron impact excitation and one for spin-down excitation, where *up* and *down* correspond to the initial spin component orientation with respect to the scattering plane. Hence,

$$\begin{aligned} \rho_u &= \sigma_u \left[(1-h) \frac{1}{2} \begin{pmatrix} 1 + L_{\perp}^+ & 0 & -P_l^+ e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l^+ e^{2i\gamma} & 0 & 1 - L_{\perp}^+ \end{pmatrix} \right. \\ &\quad \left. + h \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right] \\ &= w^{\uparrow} \rho^{\uparrow} + w^{\downarrow} \rho^{\downarrow} \\ &= w^{\uparrow} \sigma_u \left[(1-h^{\uparrow}) \frac{1}{2} \right. \\ &\quad \times \begin{pmatrix} 1 + L_{\perp}^{+\uparrow} & 0 & -P_l^{+\uparrow} e^{-2i\gamma^{\uparrow}} \\ 0 & 0 & 0 \\ -P_l^{+\uparrow} e^{2i\gamma^{\uparrow}} & 0 & 1 - L_{\perp}^{+\uparrow} \end{pmatrix} \\ &\quad \left. + h^{\uparrow} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right] \\ &\quad + w^{\downarrow} \sigma_u \left[(1-h^{\downarrow}) \frac{1}{2} \right. \\ &\quad \times \begin{pmatrix} 1 + L_{\perp}^{+\downarrow} & 0 & -P_l^{+\downarrow} e^{-2i\gamma^{\downarrow}} \\ 0 & 0 & 0 \\ -P_l^{+\downarrow} e^{2i\gamma^{\downarrow}} & 0 & 1 - L_{\perp}^{+\downarrow} \end{pmatrix} \\ &\quad \left. + h^{\downarrow} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right]. \quad (48.78) \end{aligned}$$

Here, we have defined

$$L_{\perp}^{+\uparrow} = \frac{\alpha_+^2 - \alpha_-^2}{\alpha_+^2 + \alpha_-^2} = -P_3^{\uparrow}, \quad (48.79)$$

$$L_{\perp}^{+\downarrow} = \frac{\beta_+^2 - \beta_-^2}{\beta_+^2 + \beta_-^2} = -P_3^{\downarrow}, \quad (48.80)$$

$$P_l^{+\uparrow} e^{2i\gamma^{\uparrow}} = P_1^{\uparrow} + iP_2^{\uparrow} = -\frac{2\alpha_+\alpha_- e^{i(\phi_- - \phi_+)}}{\alpha_+^2 + \alpha_-^2}, \quad (48.81)$$

$$P_l^{+\downarrow} e^{2i\gamma^{\downarrow}} = P_1^{\downarrow} + iP_2^{\downarrow} = -\frac{2\beta_+\beta_- e^{i(\psi_- - \psi_+)}}{\beta_+^2 + \beta_-^2}, \quad (48.82)$$

$$\sigma^{\uparrow} = \alpha_+^2 + \alpha_-^2 + \alpha_0^2, \quad (48.83)$$

$$\sigma^{\downarrow} = \beta_+^2 + \beta_-^2 + \beta_0^2, \quad (48.84)$$

$$\begin{aligned} \sigma_u &= \frac{1}{2} (\alpha_+^2 + \alpha_-^2 + \alpha_0^2 + \beta_+^2 + \beta_-^2 + \beta_0^2) \\ &= \frac{1}{2} (\sigma^{\uparrow} + \sigma^{\downarrow}), \end{aligned} \quad (48.85)$$

$$h^{\uparrow} = \alpha_0^2 / \sigma^{\uparrow}, \quad (48.86)$$

$$h^{\downarrow} = \beta_0^2 / \sigma^{\downarrow}, \quad (48.87)$$

$$w^{\uparrow} = \sigma^{\uparrow} / (2\sigma_u), \quad (48.88)$$

$$w^{\downarrow} = \sigma^{\downarrow} / (2\sigma_u) = 1 - w^{\uparrow}. \quad (48.89)$$

From these definitions it follows that

$$\begin{aligned} (1-h)L_{\perp}^+ &= w^{\uparrow} (1-h^{\uparrow}) L_{\perp}^{+\uparrow} \\ &\quad + w^{\downarrow} (1-h^{\downarrow}) L_{\perp}^{+\downarrow}, \end{aligned} \quad (48.90)$$

$$\begin{aligned} (1-h)P_l^+ e^{2i\gamma} &= w^{\uparrow} (1-h^{\uparrow}) P_l^{+\uparrow} e^{2i\gamma^{\uparrow}} \\ &\quad + w^{\downarrow} (1-h^{\downarrow}) P_l^{+\downarrow} e^{2i\gamma^{\downarrow}}, \end{aligned} \quad (48.91)$$

$$\begin{aligned} h &= w^{\uparrow} h^{\uparrow} + w^{\downarrow} h^{\downarrow} \\ &= (\alpha_0^2 + \beta_0^2) / (2\sigma_u), \end{aligned} \quad (48.92)$$

$$P_l^{+\uparrow 2} + L_{\perp}^{+\uparrow 2} = P_l^{+\downarrow 2} + P_3^{\uparrow 2} = 1, \quad (48.93)$$

$$P_l^{+\downarrow 2} + L_{\perp}^{+\downarrow 2} = P_l^{+\downarrow 2} + P_3^{\downarrow 2} = 1. \quad (48.94)$$

Extraction of these parameters is facilitated by the introduction of *generalized Stokes parameters* [18]. In this way, $L_{\perp}^{+\uparrow}$, $L_{\perp}^{+\downarrow}$, γ^{\uparrow} , γ^{\downarrow} may be determined. If, in addition, h is known, e.g., by polarization analysis in the y -direction, the following set of seven dimensionless independent parameters can be derived from the generalized Stokes parameters in the z -direction

$$L_{\perp}^{+\uparrow}, L_{\perp}^{+\downarrow}, h^{\uparrow}, h^{\downarrow}, w^{\uparrow}; \gamma^{\uparrow}, \gamma^{\downarrow}. \quad (48.95)$$

This leaves three relative phases unknown. In the notation of Fig. 48.7, we can see from inspection that

$$\Delta^+ - \Delta^- = \delta^{\uparrow} - \delta^{\downarrow} = 2(\gamma^{\downarrow} - \gamma^{\uparrow}), \quad (48.96)$$

Table 48.2 Summary of cases of increasing complexity for spin-polarized beams. The number of independent dimensionless parameters N_p is listed, along with N_{OA} , the number determined from orientation and alignment only; N_d is the number of observation directions required

Variable	Sect. 48.3.1	Sect. 48.3.2	Sect. 48.3.3
Forces	Coulomb	+exchange	+spin-orbit
Representation	Wave func.	ρ_{mn}^{ts}	$\rho_{mn}^{\uparrow,\downarrow}$
Refl. symmetry	+	+	+, -
N_p	2	6	10
N_{OA}	2	5	9
N_d	1	1	2

in analogy to Eq. (48.67). A convenient choice for the remaining phase angles is $(\Delta^+, \Delta^0, \delta^{\uparrow,\downarrow})$, with

$$\delta^{\uparrow,\downarrow} \equiv \phi_+ - \psi_0. \quad (48.97)$$

A complete set of dimensionless independent parameters is then given by

$$(w^{\uparrow}, L_{\perp}^{+\uparrow}, L_{\perp}^{+\downarrow}, h^{\uparrow}, h^{\downarrow}, \gamma^{\uparrow}, \gamma^{\downarrow}, \Delta^+, \Delta^0, \delta^{\uparrow,\downarrow}). \quad (48.98)$$

Information about the remaining three phase angles may be obtained in experiments with *in-plane* spin polarization. Further analysis shows that the generalized Stokes parameters in the y (or x)-direction with in-plane spin polarization P_y or P_x provides two additional phases. None of the relative phases Δ^+ between f_{+1}^{\uparrow} and f_{+1}^{\downarrow} , etc., enter. Determination of the final remaining angle requires determination of generalized STU parameters, describing the electron spin in the exit channel.

Table 48.2 summarizes the various cases with polarized beams discussed in this section.

48.4 Example

48.4.1 The First Born Approximation

As a simple, illustrative example, consider the predictions of the first Born approximation (FBA). Here, $S \rightarrow P$ excitation by electron impact is described as creation of a pure p -orbital along the direction of the linear momentum transfer $\Delta\mathbf{k} = \mathbf{k}_{in} - \mathbf{k}_{out}$, along which there is axial symmetry. Evidently,

$$L_{\perp}^{FBA} = 0, \quad (48.99)$$

and, consequently,

$$P_l^{FBA} = 1. \quad (48.100)$$

The alignment angle is found from simple geometrical considerations; see Fig. 48.8. Denoting the incident energy by E

Fig. 48.8 Diagram for evaluation of the alignment angle γ in the first Born approximation

and the energy loss by ΔE , the relation between the projectile scattering angle Θ_{col} and the alignment angle γ is directly read from the figure,

$$\tan \gamma^{\text{FBA}} = \frac{\sin \Theta_{\text{col}}}{\cos \Theta_{\text{col}} - x}, \quad (48.101)$$

where $x = [E/(E - \Delta E)]^{1/2}$. For $\Delta E > 0$, γ^{FBA} is always negative, with its minimum value when $\Delta \mathbf{k} \perp \mathbf{k}_{\text{out}}$. Any theoretical effort beyond the FBA involves serious computations.

48.5 Further Developments

48.5.1 S \rightarrow D Excitation

The generalization of the formalism of Sect. 48.3.2 to the case of S \rightarrow D excitation involves the introduction of three scattering amplitudes, corresponding to a complete parameter set of one cross section, two relative amplitude sizes, and two relative phases. Analysis shows that a full coherence analysis of the light emitted in the subsequent D \rightarrow P optical decay is not sufficient for a complete experiment, instead two solutions are obtained. A triple coincidence experiment may resolve the ambiguity [21].

48.5.2 P \rightarrow P Excitation

By proper optical preparation of the atomic target, collision studies involving specific excited states may be performed as a function of the scattering angle. For collision-induced P \rightarrow P transitions, a systematic preparation of specific initial P-states, combined with Stokes parameter analysis of the radiation pattern from the final P-state, may lead to a complete scattering experiment. The corresponding complete set of nine parameters describes the process in terms of five independent scattering amplitudes. In addition to the charge cloud shape and orientation parameters, three Euler angles are needed to describe the atomic reference frame of the charge cloud with respect to the laboratory frame [22].

48.5.3 Relativistic Effects in S \rightarrow P Excitation

It has been discussed to what extent relativistic effects can be studied for excitation of the two fine structure components of the resonance transitions of heavy alkali atoms, such as Rb or Cs. For electron-impact excitation, standard Stokes parameter analysis turns out to be extremely insensitive to the inclusion of relativistic effects in the numerical treatment, which explains the success of nonrelativistic theories. If spin-polarized electrons are used, either in the incident channel through measurement of spin asymmetries or in the final channels by performing a time-reversed generalized Stokes parameter experiment with a laser-prepared target and a spin-polarized electron beam, distinct relativistic effects, typically at the 5% level, may be revealed [23].

48.6 Summary

A selection of fundamental formulas describing orientation and alignment in atomic collisions is given, with emphasis on the simplest case, S \rightarrow P excitation. A tutorial introduction to the field with a series of examples and applications may be found in a recent textbook [20]. Other examples and discussions of perfect scattering experiments may be found in [24].

Abstract

This chapter summarizes the theory of electron collisions with atoms, ions, and molecules. Section 49.1 discusses elastic, inelastic, and ionizing collisions with atoms and atomic ions from close to threshold to high energies where the Born series becomes applicable. Section 49.2 extends the theory to treat electron collisions with molecules. Finally, the theory of electron–atom collisions in intense laser fields is discussed in Sect. 49.3. This chapter will not present detailed comparisons of theoretical predictions with experiment. Such comparisons are given in many books and review articles, such as [1–6]. The need

for proper uncertainty quantification in such calculations has recently been emphasized [7].

Keywords

electron collisions · scattering amplitudes and cross sections · potential scattering · born series · resonance theory · collisions in laser fields · optical-potential method · coupled-channel methods · close-coupling expansion

49.1 Electron–Atom and Electron–Ion Collisions

49.1.1 Low-Energy Elastic Scattering and Excitation

In this section, we consider the process

$$e^- + A_i \rightarrow e^- + A_j, \quad (49.1)$$

where A_i and A_j are bound states of the target atom or ion and where the speed of the incident or scattered electron is of the same order or less than that of the target electrons actively involved in the collision.

We assume initially that all relativistic effects can be neglected, which restricts the treatment to low- Z atoms and ions. The time-independent Schrödinger equation (TISE) describing the scattering of an electron by a target atom or ion containing N electrons and nuclear charge Z is

$$H_{N+1}\Psi = E\Psi, \quad (49.2)$$

where E is the total energy of the system. The $(N + 1)$ -electron nonrelativistic Hamiltonian H_{N+1} is given in atomic units by

$$H_{N+1} = \sum_{i=1}^{N+1} \left(-\frac{1}{2} \nabla_i^2 - \frac{Z}{r_i} \right) + \sum_{i>j=1}^{N+1} \frac{1}{r_{ij}}, \quad (49.3)$$

where $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$, and \mathbf{r}_i and \mathbf{r}_j are the vector coordinates of electrons i and j relative to the origin of coordinates taken to be the target nucleus, which is assumed to have infinite mass.

The target eigenstates Φ_i and the corresponding eigenenergies w_i satisfy the equation

$$\langle \Phi_i | H_N | \Phi_j \rangle = w_i \delta_{ij}, \quad (49.4)$$

where H_N is defined by Eq. (49.3) with $N + 1$ replaced by N . The calculation of accurate target states is discussed in Chap. 22. The solution of Eq. (49.2), corresponding to the process Eq. (49.1), has the asymptotic form

$$\Psi_i \underset{r \rightarrow \infty}{\approx} \Phi_i \chi_{\frac{1}{2}m_i} e^{ik_i z} + \sum_j \Phi_j \chi_{\frac{1}{2}m_j} f_{ji}(\theta, \phi) e^{ik_j r}. \quad (49.5)$$

In Eq. (49.5), $\chi_{\frac{1}{2}m_i}$ and $\chi_{\frac{1}{2}m_j}$ are the spin eigenfunctions of the incident and scattered electrons, where the direction of spin quantization is usually taken to be the incident beam direction, and $f_{ji}(\theta, \phi)$ is the scattering amplitude. The spherical polar coordinates of the scattered electron are denoted by r, θ , and ϕ . The wave numbers k_i and k_j are related to the total energy of the system by

$$E = w_i + \frac{1}{2}k_i^2 = w_j + \frac{1}{2}k_j^2. \quad (49.6)$$

The outgoing-wave term in Eq. (49.5) contains contributions from all target states that are energetically allowed; i.e., for which $k_j^2 \geq 0$. If the energy is above the ionization threshold, this includes target continuum states. For an atomic ion, a logarithmic phase factor is also needed (see Eq. (49.16)).

The differential cross section for a transition from an initial state $|i\rangle = |\mathbf{k}_i, \Phi_i, \chi_{\frac{1}{2}m_i}\rangle$ to a final state $|j\rangle = |\mathbf{k}_j, \Phi_j, \chi_{\frac{1}{2}m_j}\rangle$ is given by

$$\frac{d\sigma_{ji}}{d\Omega} = \frac{k_j}{k_i} |f_{ji}(\theta, \phi)|^2, \quad (49.7)$$

and the total cross section is obtained by averaging over initial spin states, summing over final spin states, and integrating over all scattering angles.

In order to solve the Schrödinger equation to obtain the scattering amplitude and cross section at low energies, we make a partial-wave expansion of the total wave function

$$\begin{aligned} \Psi_j^\Gamma(\mathbf{X}_{N+1}) &= \mathcal{A} \sum_{i=1}^n \overline{\Phi}_i^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_N; \hat{\mathbf{r}}_{N+1} \sigma_{N+1}) \frac{F_{ij}^\Gamma(r_{N+1})}{r_{N+1}} \\ &+ \sum_{i=1}^m \chi_i^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_{N+1}) b_{ij}^\Gamma, \end{aligned} \quad (49.8)$$

where $\mathbf{X}_{N+1} \equiv \mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_{N+1}$ represents the space and spin coordinates of all $N + 1$ electrons, $\mathbf{x}_i \equiv \mathbf{r}_i \sigma_i$ represents the space and spin coordinates of the i -th electron, and \mathcal{A} is the operator that antisymmetrizes the first summation with respect to exchange of all pairs of electrons in accordance with the Pauli exclusion principle. The channel functions $\overline{\Phi}_i^\Gamma$, assumed to be n in number, are obtained by coupling the orbital and spin angular momenta of the target states Φ_i with those of the scattered electron to form eigenstates of the total orbital and spin angular momenta L and S , their z components M_L and M_S , and the parity π , where

$$\Gamma \equiv LM_L SM_S \pi \quad (49.9)$$

is conserved in the collision. The square-integrable correlation functions χ_i^Γ allow for additional correlation effects not included in the first expansion in Eq. (49.8), which goes over a limited number of target eigenstates and possibly pseudo-states.

By substituting Eq. (49.8) into the Schrödinger equation (49.2), projecting onto the channel functions $\overline{\Phi}_i^\Gamma$ and the square-integrable functions χ_i^Γ , and eliminating the coefficients b_{ij}^Γ , we obtain n coupled integro-differential equations satisfied by the reduced radial functions F_{ij}^Γ representing the motion of the scattered electron

$$\begin{aligned} \left(\frac{d^2}{dr^2} - \frac{\ell_i(\ell_i + 1)}{r^2} + \frac{2(Z - N)}{r} + k_i^2 \right) F_{ij}^\Gamma(r) &= 2 \sum_{\ell} \left\{ V_{i\ell}^\Gamma(r) F_{\ell j}^\Gamma(r) \right. \\ &+ \left. \int_0^\infty [K_{i\ell}^\Gamma(r, r') + X_{i\ell}^\Gamma(r, r')] F_{\ell j}^\Gamma(r') dr' \right\}. \end{aligned} \quad (49.10)$$

Here, ℓ_i is the orbital angular momentum of the scattered electron, while $V_{i\ell}^\Gamma$, $W_{i\ell}^\Gamma$, and $X_{i\ell}^\Gamma$ are the local direct, nonlocal exchange, and nonlocal correlation potentials, respectively. If the correlation potential, which arises from the χ_i^Γ terms in Eq. (49.8), is not included, Eqs. (49.10) are called the *close-coupling equations*.

The direct potential can be written as

$$\begin{aligned} V_{ij}^\Gamma(r_{N+1}) &= \left\langle \overline{\Phi}_i^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_N; \hat{\mathbf{r}}_{N+1} \sigma_{N+1}) \right| \\ &\times \sum_{i=1}^N \frac{1}{r_{iN+1}} - \frac{N}{r_{N+1}} \\ &\times \left| \overline{\Phi}_j^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_N; \hat{\mathbf{r}}_{N+1} \sigma_{N+1}) \right\rangle, \end{aligned} \quad (49.11)$$

where the integral is taken over all electron space and spin coordinates, except for the radial coordinate of the $(N + 1)$ -th

electron. This potential has the asymptotic form

$$V_{ij}^{\Gamma}(r) = \sum_{\lambda=1}^{\lambda_{\max}} a_{ij}^{\lambda} r^{-\lambda-1} \quad \text{for } r \geq a, \quad (49.12)$$

where a is the range beyond which the orbitals in the target states Φ_i included in the first expansion in Eq. (49.8) are negligible. The $\lambda = 1$ term in Eq. (49.12) gives rise, in second order, to the long-range attractive polarization potential

$$V(r) \xrightarrow{r \rightarrow \infty} -\frac{1}{2} \frac{\alpha}{r^4} \quad (49.13)$$

seen by an electron incident on an atom. For an S -state atom in a state Φ_0 , the dipole polarizability α is given by

$$\alpha = 2 \sum_j \frac{|\langle \Phi_0 | (\frac{4\pi}{3})^{1/2} \sum_{i=1}^N r_i Y_{10}(\hat{r}_i) | \Phi_j \rangle|^2}{w_j - w_0}. \quad (49.14)$$

These long-range potentials have a profound influence on low-energy scattering.

The exchange and correlation potentials, unlike the direct potential, are both nonlocal, and the exchange potential vanishes exponentially for large r . Explicit expressions for these potentials are too complicated to write down, except in the case of e–H scattering, for which the direct and exchange potentials were first given by *Percival* and *Seaton* [8]. In practice, they are evaluated by general computer programs.

The scattering amplitude and cross section can be obtained by solving Eq. (49.10) for all relevant conserved quantum numbers Γ subject to the \mathbf{K} -matrix asymptotic boundary conditions

$$\begin{aligned} F_{ij}^{\Gamma} &\underset{r \rightarrow \infty}{\approx} k_i^{-1/2} \left(\sin \theta_i \delta_{ij} + \cos \theta_i K_{ij}^{\Gamma} \right) \\ &\quad \text{for open channels } (k_i^2 \geq 0); \\ F_{ij}^{\Gamma} &\underset{r \rightarrow \infty}{\approx} 0 \\ &\quad \text{for closed channels } (k_i^2 < 0). \end{aligned} \quad (49.15)$$

Here,

$$\theta_i = k_i r - \frac{1}{2} \ell_i \pi + \frac{z}{k_i} \ln(2k_i r) + \sigma_i, \quad (49.16)$$

with $z = Z - N$ and $\sigma_i = \arg \Gamma(\ell_i + 1 - iz/k_i)$. The \mathbf{S} -matrix and \mathbf{T} -matrix are related to the \mathbf{K} -matrix defined by Eq. (49.15) through the matrix equations

$$\mathbf{S}^{\Gamma} = \frac{\mathbf{I} + i\mathbf{K}^{\Gamma}}{\mathbf{I} - i\mathbf{K}^{\Gamma}}, \quad \mathbf{T}^{\Gamma} = \mathbf{S}^{\Gamma} - \mathbf{I} = \frac{2i\mathbf{K}^{\Gamma}}{\mathbf{I} - i\mathbf{K}^{\Gamma}}. \quad (49.17)$$

The dimensions of the matrices in these equations are $n_a \times n_a$, where n_a is the number of open channels at the energy under consideration for the given Γ . The hermiticity and time-reversal invariance of the Hamiltonian ensures that \mathbf{K}^{Γ} is real and symmetric, while \mathbf{S}^{Γ} is unitary and symmetric.

The scattering amplitude defined by Eq. (49.5) can be expressed in terms of the \mathbf{T} -matrix elements. For a neutral target,

$$\begin{aligned} f_{ji}(\theta, \phi) &= i \left(\frac{\pi}{k_i k_j} \right)^{1/2} \sum_{\substack{LS\pi \\ \ell_i \ell_j}} i^{\ell_i - \ell_j} (2\ell_i + 1)^{1/2} \\ &\quad \times (L_i M_{L_i} \ell_i 0 | L M_L) \\ &\quad \times \left(S_i M_{S_i} \frac{1}{2} m_i | S M_S \right) \\ &\quad \times (L_j M_{L_j} \ell_j m_{\ell_j} | L M_L) \\ &\quad \times \left(S_j M_{S_j} \frac{1}{2} m_j | S M_S \right) T_{ji}^{\Gamma} Y_{\ell_j m_{\ell_j}}(\theta, \phi) \end{aligned} \quad (49.18)$$

describes a transition from an initial state $\alpha_i L_i S_i M_{L_i} M_{S_i} m_i$ to a final state $\alpha_j L_j S_j M_{L_j} M_{S_j} m_j$, where α_i and α_j represent any additional quantum numbers required to completely define the initial and final states, and $(j_1 m_1 j_2 m_2 | J M)$ is a Clebsch–Gordan coefficient. The corresponding total cross section, obtained by averaging over the initial magnetic quantum numbers, summing over the final magnetic quantum numbers, and integrating over all scattering angles, is

$$\sigma_{\text{tot}}(i \rightarrow j) = \frac{\pi}{k_i^2} \sum_{\substack{LS\pi \\ \ell_i \ell_j}} \frac{(2L+1)(2S+1)}{2(2L_i+1)(2S_i+1)} \left| T_{ji}^{\Gamma} \right|^2. \quad (49.19)$$

It describes a transition from an initial target state $\alpha_i L_i S_i$ to a final target state $\alpha_j L_j S_j$. In applications, it is also useful to define a collision strength by

$$\Omega(i, j) = k_i^2 (2L_i + 1)(2S_i + 1) \sigma_{\text{tot}}(i \rightarrow j), \quad (49.20)$$

which is dimensionless and symmetric with respect to interchange of the initial and final states denoted by i and j . For scattering by an ion, the above expression for $f_{ji}(\theta, \phi)$ is modified by the inclusion of the Coulomb scattering amplitude when the initial and final states are identical.

For incident electron energies insufficient to excite the atom or ion, only elastic scattering is possible, and the above expressions simplify. Consider low-energy elastic electron scattering by a neutral atom in a 1S ground state. Then the expression for the scattering amplitude Eq. (49.18) reduces to

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) (e^{2i\delta_{\ell}} - 1) P_{\ell}(\cos \theta), \quad (49.21)$$

where ℓ ($= L = \ell_i = \ell_j$) is the angular momentum of the scattered electron, k is its wave number, and the phase shift δ_ℓ can be expressed in terms of the \mathbf{K} -matrix, which now has only one element, since $n_a = 1$, given by

$$\tan \delta_\ell = K_{11}^\Gamma. \quad (49.22)$$

The corresponding expression for the total cross section is then

$$\sigma_{\text{tot}} = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2 \delta_\ell. \quad (49.23)$$

The momentum-transfer cross section is defined as

$$\begin{aligned} \sigma_{\text{D}} &= 2\pi \int_0^\pi |f(\theta)|^2 (1 - \cos \theta) \sin \theta d\theta \\ &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell + 1) \sin^2(\delta_{\ell+1} - \delta_\ell). \end{aligned} \quad (49.24)$$

This cross section is important when considering the diffusion of electrons through gases.

At low incident electron energies, the behavior of the phase shift for an atom in an S-state is dominated by the long-range polarization potential Eq. (49.13). *O'Malley* et al. [9] showed that for s -wave scattering $k \cot \delta_0$ satisfies the effective-range expansion

$$\begin{aligned} k \cot \delta_0 &= -\frac{1}{a_s} + \frac{\pi\alpha}{3a_s^2} k \\ &\quad + \frac{2\alpha}{3a_s} k^2 \ln\left(\frac{\alpha k^2}{16}\right) + O(k^2), \end{aligned} \quad (49.25)$$

where a_s is the scattering length, while for $\ell \geq 1$

$$k^2 \cot \delta_\ell = \frac{8(\ell + \frac{3}{2})(\ell + \frac{1}{2})(\ell - \frac{1}{2})}{\pi\alpha} + \dots \quad (49.26)$$

Higher-order terms, which extend the energy range of usefulness of the expansion, were derived by Ali and Fraser [10].

Close to threshold, therefore, the total elastic cross section has the form

$$\sigma_{\text{tot}} = 4\pi a_s^2 + \frac{8}{3}\pi^2 \alpha a_s k + \dots \quad (49.27)$$

When an electron is elastically scattered by a positive or negative ion, these formulae for the low-energy behavior of the phase shift are modified. For scattering by a positive ion, *Seaton* [11] showed that

$$\frac{\cot \delta_\ell(k)}{1 - e^{2\pi\eta}} = \cot[\pi\mu(k^2)], \quad (49.28)$$

where $\eta = -z/k$, and $\mu(k^2)$ is the analytic continuation of the quantum defects of the electron-ion bound states to positive energies. This quantum-defect theory enables spectroscopic observations of bound-state energies to be extrapolated to positive energies to yield electron-ion scattering phase shifts. For a negative ion, where the Coulomb potential is repulsive, the phase shift behaves as

$$\delta_\ell \xrightarrow[k \rightarrow 0]{} \exp\left(2\pi \frac{z}{k}\right). \quad (49.29)$$

This vanishes rapidly as k tends to zero, since z is now negative. A discussion of quantum-defect theory is given in Chap. 50.

49.1.2 Relativistic Effects for Heavy Atoms and Ions

As the nuclear charge Z of the target increases, relativistic effects become important even for low-energy scattering. There are two ways in which relativistic effects play a role. First, there is a direct effect corresponding to the relativistic distortion of the wave function describing the scattered electron by the strong nuclear Coulomb potential. Second, there is an indirect effect caused by the change in the charge distribution of the target due to the use of relativistic wave functions discussed in Chap. 23. We will concentrate on the direct effect in this section.

For atoms and ions with small Z , the \mathbf{K} -matrices can first be calculated in LS -coupling while neglecting relativistic effects. The \mathbf{K} -matrices are then recoupled to yield transitions between fine-structure levels. We introduce the pair-coupling scheme

$$\mathbf{L}_i + \mathbf{S}_i = \mathbf{J}_i, \quad \mathbf{J}_i + \boldsymbol{\ell}_i = \mathbf{K}_i, \quad \mathbf{K}_i + \mathbf{s} = \mathbf{J}, \quad (49.30)$$

where \mathbf{J}_i is the total angular momentum of the target, $\boldsymbol{\ell}_i$ is the orbital angular momentum of the scattered electron, \mathbf{s} is its spin, and \mathbf{J} is the total electronic angular momentum, which together with the parity π is conserved in the collision. The transition from LS - to $J\ell K$ -coupling involves the recoupling coefficient

$$\begin{aligned} &\left\langle [(L_i S_i) J_i, \ell_i] K_i, \frac{1}{2}; J M_J \middle| (L_i \ell_i) L, \left(S_i \frac{1}{2}\right) S; J M_J \right\rangle \\ &= [(2J_i + 1)(2L + 1)(2K_i + 1)(2S + 1)]^{\frac{1}{2}} \\ &\quad \times W(L \ell_i S_i J_i; L_i K_i) W(L J S_i \frac{1}{2}; S K_i), \end{aligned} \quad (49.31)$$

where $W(\dots)$ is a Wigner 6- j -symbol. The corresponding \mathbf{K} -matrix elements transform as

$$K_{ij}^{J\pi} = \sum_{LS} \left\langle \left[(L_i S_i) J_i, \ell_i \right] K_i, \frac{1}{2}; JM_J \right\rangle \left\langle (L_i \ell_i) L, \left(S_i \frac{1}{2} \right) S; JM_J \right\rangle \times K_{ij}^F \times \left\langle (L_j \ell_j) L, \left(S_j \frac{1}{2} \right) S; JM_J \right\rangle \left\langle (L_j S_j) J_j, \ell_j \right\rangle K_j, \frac{1}{2}; JM_J \right\rangle. \quad (49.32)$$

This transformation was implemented in a computer program by *Saraph* [12, 13].

For intermediate- Z atoms and ions, relativistic effects can be included by adding terms from the Breit–Pauli Hamiltonian to the nonrelativistic Hamiltonian (*Jones* [14], *Scott and Burke* [15]). We write

$$H_{N+1}^{\text{BP}} = H_{N+1}^{\text{nr}} + H_{N+1}^{\text{rel}}, \quad (49.33)$$

where H_{N+1}^{nr} is defined by Eq. (49.3) and H_{N+1}^{rel} consists of one and two-body relativistic terms. The one-body terms are (Sect. 22.1)

$$H_{N+1}^{\text{mass}} = -\frac{1}{8}\alpha^2 \sum_{i=1}^{N+1} \nabla_i^4 \quad (\text{mass-correction term});$$

$$H_{N+1}^{\text{D1}} = -\frac{1}{8}\alpha^2 Z \sum_{i=1}^{N+1} \nabla_i^2 \left(\frac{1}{r_i} \right) \quad (\text{Darwin term});$$

$$H_{N+1}^{\text{so}} = \frac{1}{2}\alpha^2 \sum_{i=1}^{N+1} \frac{1}{r_i} \frac{\partial V}{\partial r_i} (\boldsymbol{\ell}_i \cdot \mathbf{s}_i) \quad (\text{spin-orbit term}).$$

The two-body terms are less important and are usually not included in collision calculations.

The modified Schrödinger equation defined by Eq. (49.2), with H_{N+1} replaced by H_{N+1}^{BP} , is solved by adopting an expansion similar in form to Eq. (49.8) but now using the pair-coupling scheme in the definition of the channel functions and square-integrable functions. We then obtain coupled integro-differential equations similar in form to Eq. (49.10), from which the \mathbf{K} -matrix, \mathbf{S} -matrix, and \mathbf{T} -matrix can be obtained. The corresponding total cross section in the pair-coupling scheme analogous to Eq. (49.19) is

$$\sigma_{\text{tot}}(i \rightarrow j) = \frac{\pi}{2k_i^2(2J_i + 1)} \sum_{K_i K_j \ell_i \ell_j}^{J\pi} (2J + 1) \left| T_{ji}^{J\pi} \right|^2. \quad (49.34)$$

It describes a transition from an initial target state $\alpha_i J_i$ to a final target state $\alpha_j J_j$. The corresponding collision strength is

$$\Omega(i, j) = k_i^2 (2J_i + 1) \sigma_{\text{tot}}(i \rightarrow j). \quad (49.35)$$

For high- Z atoms and ions, the Dirac Hamiltonian [16, 17]

$$H_{N+1}^{\text{D}} = \sum_{i=1}^{N+1} \left(c\boldsymbol{\alpha} \cdot \mathbf{p}_i + \boldsymbol{\beta}' c^2 - \frac{Z}{r_i} \right) + \sum_{i>j=1}^{N+1} \frac{1}{r_{ij}} \quad (49.36)$$

must be used instead of Eq. (49.3), where $\boldsymbol{\beta}' = \boldsymbol{\beta} - \mathbf{1}$ with $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ being the usual Dirac matrices. The expansion of the total wave functions for a particular $JM_J\pi$ takes the general form of Eq. (49.8). However, now the bound orbitals in the target and the correlation functions, as well as the orbitals representing the scattered electron, are represented by Dirac orbitals. These are defined in terms of large and small components $P(r)$ and $Q(r)$ by

$$\phi(\mathbf{r}, \sigma) = \frac{1}{r} \begin{pmatrix} P_a(r) \chi_{\kappa m}(\hat{\mathbf{r}}, \sigma) \\ Q_a(r) \chi_{-\kappa m}(\hat{\mathbf{r}}, \sigma) \end{pmatrix}, \quad (49.37)$$

for the bound orbitals and

$$F(\mathbf{r}, \sigma) = \frac{1}{r} \begin{pmatrix} P_c(r) \chi_{\kappa m}(\hat{\mathbf{r}}, \sigma) \\ Q_c(r) \chi_{-\kappa m}(\hat{\mathbf{r}}, \sigma) \end{pmatrix}, \quad (49.38)$$

for the continuum orbitals. Here, $a = n\kappa m$, $c = k\kappa m$, and the spherical spinor is

$$\chi_{\kappa m}(\hat{\mathbf{r}}, \sigma) = \sum_{m_\ell m_i} \left(\ell m_\ell \frac{1}{2} m_i \mid j m \right) Y_{\ell m_\ell}(\theta, \phi) \chi_{\frac{1}{2} m_i}(\sigma), \quad (49.39)$$

where $\kappa = j + \frac{1}{2}$ when $\ell = j + \frac{1}{2}$, and $\kappa = -j - \frac{1}{2}$ when $\ell = j - \frac{1}{2}$.

One can derive coupled integro-differential equations for the functions $P_c(r)$ and $Q_c(r)$ in a similar way to the derivation of Eq. (49.10), except that these are now coupled first-order equations instead of coupled second-order equations. The \mathbf{K} -matrix, and hence the \mathbf{S} -matrix and \mathbf{T} -matrix, can be obtained from the asymptotic form of these equations. The total cross section in the jj -coupling scheme is again given by Eq. (49.34), and the corresponding collision strength is given by Eq. (49.35).

49.1.3 Multichannel Resonance Theory

General resonance theories have been developed by *Fano* [18, 19], *Feshbach* [20, 21], and *Brenig and Haag* [22].

They are also discussed in Chap. 26. Here, we will limit our discussion to the effect that resonances have on electron collision cross sections.

Following Feshbach, we introduce the projection operators P and Q , where P projects onto a finite set of low-energy channels in Eq. (49.8), and Q projects onto the orthogonal space. We limit our consideration to the space corresponding to a particular set of conserved quantum numbers Γ . In this space, we have

$$P^2 = P, \quad Q^2 = Q, \quad P + Q = 1. \quad (49.40)$$

The Schrödinger equation (49.2) can then be written as

$$P(H - E)(P + Q)\Psi = 0 \quad (49.41)$$

and

$$Q(H - E)(P + Q)\Psi = 0, \quad (49.42)$$

where we have omitted the subscript $N + 1$ on H and the superscript Γ on Ψ . After solving Eq. (49.42) for $Q\Psi$ and substituting into Eq. (49.41), we find

$$P\left(H - PHQ \frac{1}{Q(H - E)Q} QHP - E\right)P\Psi = 0, \quad (49.43)$$

where the term

$$V_{\text{opt}} = -PHQ \frac{1}{Q(H - E)Q} QHP, \quad (49.44)$$

called the *optical potential*, allows for propagation in the Q -space channels.

We now introduce the eigenfunctions ϕ_i and eigenvalues ε_i of the operator QHQ by

$$QHQ\phi_i = \varepsilon_i\phi_i. \quad (49.45)$$

It follows that the discrete eigenvalues ε_i each give rise to poles in V_{opt} at ε_i . If the energy E is in the neighborhood of an isolated pole or bound state ε_i , we can rewrite Eq. (49.43) as

$$\begin{aligned} & \left(PHP - \sum_{j \neq i} PHQ \frac{|\phi_j\rangle\langle\phi_j|}{\varepsilon_j - E} QHP - E \right) P\Psi \\ & = PHQ \frac{|\phi_i\rangle\langle\phi_i|}{\varepsilon_i - E} QHP\Psi, \end{aligned} \quad (49.46)$$

where the rapidly varying part of the optical potential has been separated and put on the right-hand side of Eq. (49.46). This equation can be solved by introducing Green's function G_0 and the solutions ψ_{0j} of the operator on the left-hand

side of Eq. (49.46). We find that the pole term on the right-hand side of this equation gives rise to a Feshbach resonance, whose position is

$$E_i = \varepsilon_i + \Delta_i - \frac{1}{2}i\Gamma_i = E_{i,r} - \frac{1}{2}i\Gamma_i, \quad (49.47)$$

where the resonance shift is

$$\Delta_i = \langle\phi_i|QHPG_0PHQ|\phi_i\rangle, \quad (49.48)$$

and the resonance width is

$$\Gamma_i = 2\pi \sum_j |\langle\phi_i|QHPP|\psi_{0j}\rangle|^2. \quad (49.49)$$

The summation in this equation is taken over all continuum states corresponding to the operator on the left-hand side of Eq. (49.46), and these states are normalized to a δ -function in energy.

In the neighborhood of the resonance energy $E_{i,r}$, the \mathcal{S} -matrix is rapidly varying with the form

$$\mathcal{S} = \mathcal{S}_0^{\frac{1}{2}} \left(\mathbf{I} - i\Gamma \frac{\boldsymbol{\gamma}_i \times \boldsymbol{\gamma}_i}{E - E_{i,r} + \frac{1}{2}i\Gamma_i} \right) \mathcal{S}_0^{\frac{1}{2}}, \quad (49.50)$$

where \mathcal{S}_0 is the slowly varying nonresonant or background \mathcal{S} -matrix corresponding to ψ_0 , and the partial widths $\boldsymbol{\gamma}_i$ are defined by

$$\langle\phi_i|QHPP|\psi_0\rangle = \Gamma_i^{\frac{1}{2}} \boldsymbol{\gamma}_i \cdot \mathcal{S}_0^{\frac{1}{2}}, \quad (49.51)$$

where $\boldsymbol{\gamma}_i \cdot \boldsymbol{\gamma}_i = 1$. A corresponding resonant expression can be derived for the \mathbf{K} -matrix (Burke [23]).

Let us now diagonalize the \mathcal{S} -matrix according to

$$\mathcal{S} = \mathbf{A} \exp(2i\boldsymbol{\Delta}) \mathbf{A}^T, \quad (49.52)$$

where \mathbf{A} is an orthogonal matrix, while $\boldsymbol{\Delta}$ is a diagonal matrix whose diagonal elements, δ_i , $i = 1, \dots, n_a$, are called the eigenphases. If we define the eigenphase sum δ_{sum} by

$$\delta_{\text{sum}} = \sum_{i=1}^{n_a} \delta_i, \quad (49.53)$$

we can show from Eq. (49.50) that in the neighborhood of the resonance the eigenphase sum follows a Breit–Wigner form

$$\delta_{\text{sum}}(E) = \delta_{0,\text{sum}}(E) + \tan^{-1} \left(\frac{\frac{1}{2}\Gamma_i}{E_{i,r} - E} \right), \quad (49.54)$$

where $\delta_{0,\text{sum}}$ is the slowly varying background eigenphase sum obtained by replacing \mathcal{S} by \mathcal{S}_0 in Eqs. (49.52) and

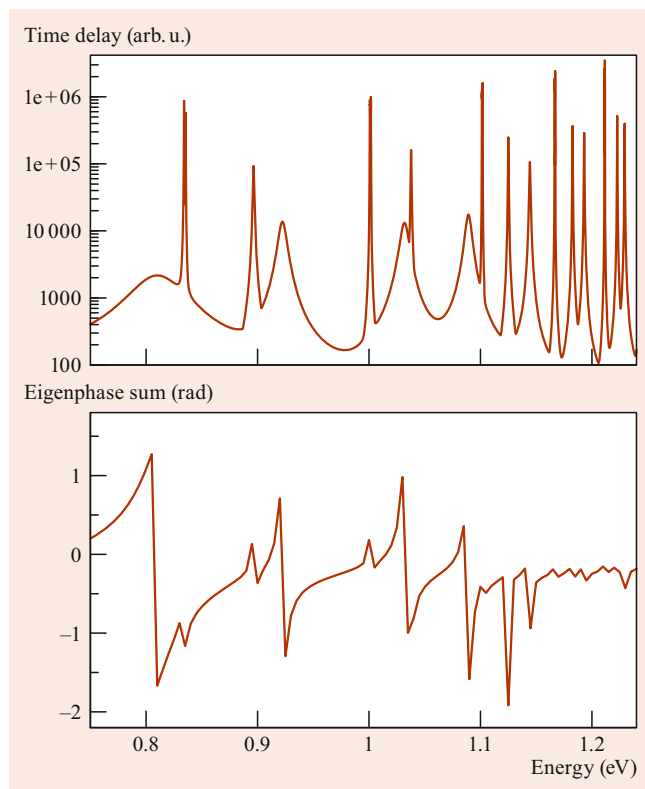

Fig. 49.1 Comparison of the longest time delay (*upper panel*) with the eigenphase sum, given modulo π (*lower panel*), at the same energy for a series of resonances found in $e\text{-N}_2^+$ scattering. Note that with higher energy resolution, some of the time delay peaks can be split to reveal multiple resonances. Adapted from *Little and Tennyson* [25] with thanks to Sergei Yurchenko

(49.53). It follows from Eq. (49.54) that the eigenphase sum increases by π radians in the neighborhood of the resonance energy. If there are m resonances, which may be overlapping, Eq. (49.54) generalizes to

$$\delta_{\text{sum}}(E) = \delta_{0,\text{sum}}(E) + \sum_{i=1}^m \tan^{-1} \left(\frac{\frac{1}{2}\Gamma_i}{E_{i,r} - E} \right). \quad (49.55)$$

This result has proven to be useful in analyzing closely spaced resonances to obtain the individual resonance positions and widths.

However, overlapping resonances can be difficult to fit using a Breit–Wigner form. An alternative approach, due originally to *Smith* [24], is based on the classical concept of time delay during a collision. Quantum-mechanically, the time delay in a collision can be represented in terms of the S -matrix and the time operator as

$$Q = -i\hbar S^* \frac{S}{E}. \quad (49.56)$$

The time delays are obtained by diagonalizing Q with resonances manifesting themselves as the longest time delay or largest eigenvalue. The corresponding eigenvector gives the

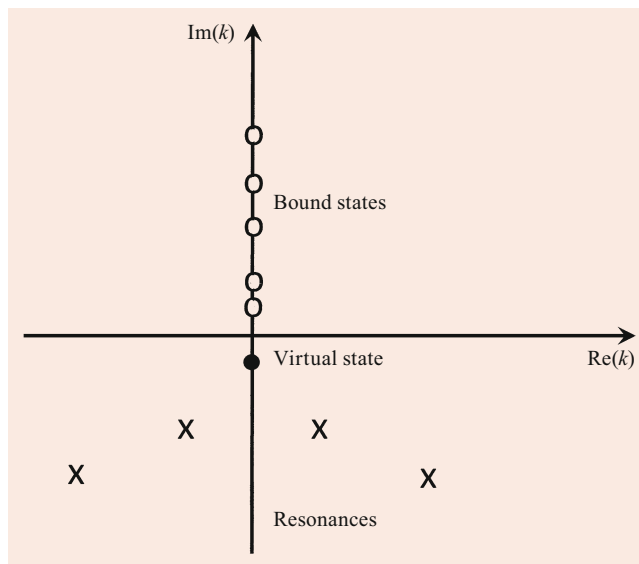

Fig. 49.2 Structure of the S -matrix as a function of complex wave-number, k . The features indicated correspond to poles of different physical meaning

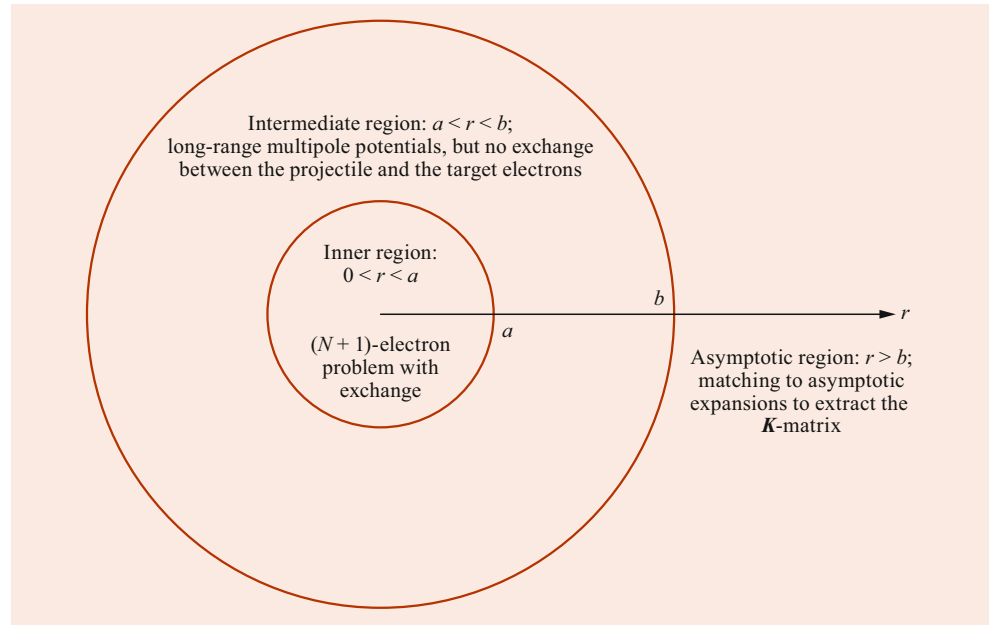

relative partial width associated with each channel. In this formulation, resonances have a Lorentzian shape as a function of energy.

Figure 49.1 compares the structure of the eigenphase sum (plotted modulo π) with that of the longest time delay for a series of resonances; in both cases, the positions of the resonances are readily apparent.

Analysis of the S -matrix as function of complex k also yields information of bound states, virtual states, and resonances. Figure 49.2 illustrates the location of these various features. Bound states are located as poles on the positive imaginary axis, as here $\frac{1}{2}k^2$ is negative. Virtual states, which can lead to pronounced features in low-energy scattering [26], form poles on the negative imaginary axis. Resonances give poles that are symmetrically placed on either side of the negative imaginary axis. Under these circumstances, the energy is complex; see Eq. (49.47). It is possible to characterize resonances by searching the S -matrix as a function of complex k [27], but in practice this is rarely done.

49.1.4 Solution of the Coupled Integro-Differential Equations

This section considers methods that have been developed for solving the coupled integro-differential equations (49.10). These equations arise in low-energy electron–atom and electron–ion collisions. Section 49.2.2 shows that similar equations also arise in low-energy electron–molecule collisions in the fixed-nuclei approximation. Thus, the methods discussed in this section are also applicable to electron–molecule collisions.

Fig. 49.3 The R -matrix method

R-Matrix Method

This method was first introduced in nuclear physics [28–30] in a study of resonance reactions. It has since been applied to a wide range of atomic, molecular, and optical processes, as reviewed in [31]. A comprehensive overview of the method and its many applications can be found in [32]. The review [3] presents a particular focus on electron–molecule problems. Figure 49.3 gives a schematic overview of the method.

The method starts by partitioning configuration space into two regions by a sphere of radius a , chosen so that the direct potential has achieved its asymptotic form given by Eq. (49.12) and the exchange and correlation potentials are negligible for $r \geq a$. The objective is then to calculate the R -matrix with elements $R_{ij}^{\Gamma}(E)$, which is defined by

$$F_{ij}^{\Gamma}(a) = \sum_{\ell=1}^n R_{i\ell}^{\Gamma}(E) \left(a \frac{dF_{\ell j}^{\Gamma}}{dr} - b_{\ell} F_{\ell j}^{\Gamma} \right)_{r=a}, \quad (49.57)$$

by solving Eq. (49.10) in the internal region.

The collision problem is solved for $r \leq a$ by expanding the wave function, in analogy with Eq. (49.8), in the form

$$\begin{aligned} \Psi_k^{\Gamma}(\mathbf{X}_{N+1}) &= \mathcal{A} \sum_{ij} \bar{\Phi}_i^{\Gamma}(\mathbf{x}_1, \dots, \mathbf{x}_N; \hat{\mathbf{r}}_{N+1} \sigma_{N+1}) \\ &\quad \times r_{N+1}^{-1} u_j(r_{N+1}) a_{ijk}^{\Gamma} \\ &\quad + \sum_i \chi_i^{\Gamma}(\mathbf{x}_1, \dots, \mathbf{x}_{N+1}) b_{ik}^{\Gamma}, \end{aligned} \quad (49.58)$$

where the u_j are radial basis functions defined over the range $0 \leq r \leq a$. For radial basis functions u_j satisfying arbitrary boundary conditions at $r = a$, the Hamiltonian H_{N+1} defined

by Eq. (49.3) is not Hermitian in the internal region due to the kinetic energy operators. It can, however, be made Hermitian by adding the Bloch operator [33]

$$L_b = \sum_{i=1}^n |\bar{\Phi}_i^{\Gamma}\rangle \frac{1}{2} \delta(r-a) \left(\frac{d}{dr} - \frac{b_i - 1}{r} \right) \langle \bar{\Phi}_i^{\Gamma}| \quad (49.59)$$

to H_{N+1} , where b_i is an arbitrary parameter. The Schrödinger equation (49.2) then becomes

$$(H_{N+1} + L_b - E) \Psi^{\Gamma} = L_b \Psi^{\Gamma}, \quad (49.60)$$

which can be formally solved as

$$\Psi^{\Gamma} = (H_{N+1} + L_b - E)^{-1} L_b \Psi^{\Gamma}. \quad (49.61)$$

We now expand the Green's function $(H_{N+1} + L_b - E)^{-1}$ in terms of the basis Ψ_k^{Γ} , where the coefficients a_{ijk}^{Γ} and b_{ik}^{Γ} in Eq. (49.58) are chosen to diagonalize $H_{N+1} + L_b$ according to

$$\langle \Psi_k^{\Gamma} | H_{N+1} + L_b | \Psi_{k'}^{\Gamma} \rangle = E_k^{\Gamma} \delta_{kk'}. \quad (49.62)$$

Equation (49.61) can then be written as

$$|\Psi^{\Gamma}\rangle = \sum_k \frac{|\Psi_k^{\Gamma}\rangle \langle \Psi_k^{\Gamma}|}{E_k^{\Gamma} - E} L_b |\Psi^{\Gamma}\rangle. \quad (49.63)$$

Finally, we project this equation onto the channel functions $\bar{\Phi}_i^{\Gamma}$ and evaluate it at $r = a$. Assuming that Ψ^{Γ} is given by Eq. (49.8), we retrieve Eq. (49.57), where the R -matrix elements are calculated from the expansion

$$R_{ij}^{\Gamma}(E) = \frac{1}{2a} \sum_k \frac{w_{ik}^{\Gamma} w_{jk}^{\Gamma}}{E_k^{\Gamma} - E}. \quad (49.64)$$

Here, we have introduced the surface amplitudes

$$w_{ik}^\Gamma = \sum_j u_j(a) a_{ijk}^\Gamma. \quad (49.65)$$

The main part of the calculation involves setting up and diagonalizing the matrix given by Eq. (49.62). This has to be carried out only *once* to determine the \mathbf{R} -matrix for *all* energies E , thereby making the method extremely efficient if results for many energies are required, e.g., for a detailed tracing of resonance structures.

In the external region $r \geq a$, Eq. (49.10) reduces to ordinary differential equations coupled by the potential $V_{ij}^\Gamma(r)$, which has achieved its asymptotic form Eq. (49.12). These equations can be integrated outwards from $r = a$ for each energy of interest, subject to the boundary conditions Eq. (49.57), to yield the \mathbf{K} -matrix given by Eq. (49.15), and hence the \mathbf{S} -matrix and collision cross sections. In practice, this is usually done by propagating the \mathbf{R} -matrix rather than integrating the coupled differential equations to some large but finite radius (b in Fig. 49.3) and then using an asymptotic expansion to find the \mathbf{K} -matrix [34].

There are many numerical implementations of the \mathbf{R} -matrix method in atomic and molecular physics. For electron collisions with atoms and ions, a general computer code [35] was published and continues to be updated and maintained [36]. Similarly, there are a number of general molecular implementations [37, 38]. In particular, the UK molecular \mathbf{R} -matrix codes have been routinely updated and published over time. The current implementation, known as UKRMol [39], is obtainable via the open-access CCPForge program repository and can be run through the Quantemol-N expert system [40, 41].

An important feature of the standard implementation of the \mathbf{R} -matrix method is the use of orthogonal one-electron orbitals for all physical and pseudo states in the expansion of the N -electron target and the $(N + 1)$ -continuum states. Using orthogonal orbitals has numerical advantages in setting up the Hamiltonian matrix in the internal region, but it is not required from first principles – only multielectron target states of the same symmetry must be orthogonal for a Hermitian operator. A disadvantage associated with the use of orthogonal one-electron orbitals is the limitation that such orbitals impose on the flexibility of generating a small configuration-interaction description with term-dependent, individually optimized orbitals for each state of interest. The \mathbf{R} -matrix with pseudo-states (RMPS) method (see Sect. 49.1.5) alleviates some of these problems, but others remain, particularly for complex targets with several open shells.

A very successful method to overcome these problems is the B -spline \mathbf{R} -matrix implementation developed by *Zat-*

sariny and coworkers. First introduced for a photoionization problem [42], it has since been applied in numerous structure and collision calculations, both for photon and electron impacts. The basic idea is to expand all one-electron orbitals into B -splines and then use the excellent numerical properties of this basis. Since neighboring B -splines have (limited) nonvanishing overlaps, it is necessary to handle the nonorthogonality of this basis. While the extension to nonorthogonal orbital sets expanded in the basis further increases the complexity, there are great benefits associated with the additional flexibility. A general BSR computer program using this approach in the nonrelativistic LS -coupling scheme as well as the semirelativistic Breit–Pauli approach was published [43], and later the method was extended to the full relativistic coupling scheme [44]. A comprehensive review of the BSR approach and its many applications can be found in [45]; the approach has recently been extended to molecules [46, 47].

Kohn Variational Method

The application of variational methods in electron–atom collision theory was reviewed by *Nesbet* [48]. An \mathbf{S} -matrix or complex Kohn version of this approach was developed [49], which eliminated singularities present in earlier \mathbf{K} -matrix versions of the theory. This method continues to be particularly important in electron–molecule collision calculations [50].

The approach starts from the basic expansion given by Eq. (49.8), where the reduced radial functions are chosen to satisfy the \mathbf{T} -matrix asymptotic boundary conditions

$$F_{ij}^\Gamma \underset{r \rightarrow \infty}{\approx} k_i^{-\frac{1}{2}} \left(\sin \theta_i \delta_{ij} + (2i)^{-1} e^{i\theta_i} T_{ij}^\Gamma \right), \quad (49.66)$$

which follow by taking linear combinations of the n_a solutions defined by Eq. (49.15) and using Eq. (49.17). We then define the integral

$$\mathbf{I}^\Gamma = -\frac{1}{2} \int_0^\infty (\mathbf{F}^\Gamma)^T \mathbf{L} \mathbf{F}^\Gamma dr, \quad (49.67)$$

where \mathbf{L} is the integro-differential operator given by Eq. (49.10) with all terms taken onto the left-hand side of the equation.

Now consider variations of the integral \mathbf{I}^Γ resulting from arbitrary variations $\delta \mathbf{F}^\Gamma$ of the functions \mathbf{F}^Γ about the exact solution of Eq. (49.10), where these solutions satisfy the boundary conditions Eq. (49.66), while the variations satisfy the boundary condition

$$\delta \mathbf{F}^\Gamma \underset{r \rightarrow \infty}{\approx} (2i)^{-1} \mathbf{k}^{-\frac{1}{2}} e^{i\theta} \delta \mathbf{T}^\Gamma. \quad (49.68)$$

The corresponding variation in \mathbf{I}^Γ to first order is

$$\delta \mathbf{I}^\Gamma = -\frac{1}{2} \int_0^\infty \left[(\delta \mathbf{F}^\Gamma)^T \mathbf{L} \mathbf{F}^\Gamma + (\mathbf{F}^\Gamma)^T \mathbf{L} \delta \mathbf{F}^\Gamma \right] dr, \quad (49.69)$$

which, after some manipulation, yields

$$\delta \mathbf{I}^\Gamma = (4i)^{-1} \delta \mathbf{T}^\Gamma. \quad (49.70)$$

It follows that the functional

$$[\mathbf{T}^\Gamma] = \mathbf{T}^\Gamma - 4i \mathbf{I}^\Gamma \quad (49.71)$$

is stationary for small variations about the exact solution. This is the complex Kohn variational principle.

This variational principle can be used to solve Eq. (49.10) by representing the reduced radial functions F_{ij}^Γ by the expansion

$$F_{ij}^\Gamma(r) = w_{1i}^\Gamma(r) \delta_{ij} + (2i)^{-1} w_{2i}^\Gamma(r) T_{ij}^\Gamma + \sum_k \phi_k^\Gamma(r) c_{ijk}^\Gamma, \quad (49.72)$$

where w_{1i}^Γ and w_{2i}^Γ are zero at the origin and have the asymptotic forms

$$w_{1i}^\Gamma(r) \underset{r \rightarrow \infty}{\approx} k_i^{-\frac{1}{2}} \sin \theta_i, \quad (49.73)$$

$$w_{2i}^\Gamma(r) \underset{r \rightarrow \infty}{\approx} k_i^{-\frac{1}{2}} \exp i \theta_i, \quad (49.74)$$

while the ϕ_k^Γ are square-integrable basis functions. The coefficients c_{ijk}^Γ and the \mathbf{T} -matrix elements T_{ij}^Γ can be determined as variational parameters in the variational principle Eq. (49.71).

Schwinger Variational Method

This method was used to calculate electron–molecule collision cross sections by *McKoy* and coworkers [51]. It starts from the Lippmann–Schwinger integral equation, which corresponds to the integro-differential equations Eq. (49.10), together with the \mathbf{K} -matrix or \mathbf{T} -matrix boundary conditions defined by Eqs. (49.15) or (49.66), respectively. The \mathbf{T} -matrix form of the Lippmann–Schwinger integral equation is

$$F_{ij}^\Gamma(r) = w_{1i}^\Gamma(r) \delta_{ij} + \sum_{k\ell} \int_0^\infty \int_0^\infty G_{ik}^{\Gamma(+)}(r, r') \times U_{k\ell}^\Gamma(r', r'') F_{\ell j}^\Gamma(r'') dr' dr'', \quad (49.75)$$

where $U_{k\ell}^\Gamma$ represents the sum of the potential terms $2(V_{k\ell}^\Gamma + K_{k\ell}^\Gamma + X_{k\ell}^\Gamma)$ in Eq. (49.10), and the multichannel outgoing-

wave Green's function $G_{ik}^{\Gamma(+)}$ is defined, assuming that all channels are open, by

$$G_{ij}^{\Gamma(+)}(r, r') = \begin{cases} -w_{1i}^\Gamma(r) w_{2i}^\Gamma(r') \delta_{ij}, & r < r'; \\ -w_{2i}^\Gamma(r) w_{1i}^\Gamma(r') \delta_{ij}, & r \geq r'. \end{cases} \quad (49.76)$$

Here, w_{1i}^Γ and w_{2i}^Γ are solutions of the Coulomb equation

$$\left(\frac{d^2}{dr^2} - \frac{\ell_i(\ell_i + 1)}{r^2} + \frac{2(Z - N)}{r} + k_i^2 \right) w_i(r) = 0 \quad (49.77)$$

that satisfy the asymptotic boundary conditions Eqs. (49.73) and (49.74), respectively.

An integral expression for the \mathbf{T} -matrix can be obtained by comparing Eqs. (49.66) and (49.75). This gives

$$T_{ij}^\Gamma = -2i \sum_k \int_0^\infty \int_0^\infty w_{1i}^\Gamma(r) U_{ik}^\Gamma(r, r') F_{kj}^\Gamma(r') dr dr', \quad (49.78)$$

or, rewriting this equation using Dirac bracket notation,

$$\mathbf{T} = -2i \langle \mathbf{w}_1 | \mathbf{U} | \mathbf{F}^{(+)} \rangle, \quad (49.79)$$

where the plus sign indicates that $\mathbf{F}^{(+)}$ satisfies the outgoing-wave boundary condition Eq. (49.66). For convenience of notation, we have suppressed the superscript Γ . In a similar way, the Lippmann–Schwinger equation corresponding to the ingoing-wave boundary condition,

$$F_{ij}^\Gamma \underset{r \rightarrow \infty}{\approx} k_i^{-\frac{1}{2}} \left(\sin \theta_i \delta_{ij} - (2i)^{-1} e^{-i\theta_i} T_{ij}^{\Gamma*} \right), \quad (49.80)$$

can be introduced. From that follows the integral expression

$$\mathbf{T} = -2i \langle \mathbf{F}^{(-)} | \mathbf{U} | \mathbf{w}_1 \rangle, \quad (49.81)$$

where $\mathbf{F}^{(-)}$ satisfies the ingoing-wave boundary condition Eq. (49.80). A further integral expression for the \mathbf{T} -matrix is obtained by substituting for \mathbf{w}_1 in Eq. (49.81) from Eq. (49.75), giving

$$\mathbf{T} = -2i \langle \mathbf{F}^{(-)} | \mathbf{U} - \mathbf{U} \mathbf{G}^{(+)} \mathbf{U} | \mathbf{F}^{(+)} \rangle. \quad (49.82)$$

Hence, a combination of Eqs. (49.79), (49.81), and (49.82) yields the functional

$$[\mathbf{T}] = -2i \langle \mathbf{w}_1 | \mathbf{U} | \mathbf{F}^{(+)} \rangle \times \left(\langle \mathbf{F}^{(-)} | \mathbf{U} - \mathbf{U} \mathbf{G}^{(+)} \mathbf{U} | \mathbf{F}^{(+)} \rangle \right)^{-1} \times \langle \mathbf{F}^{(-)} | \mathbf{U} | \mathbf{w}_1 \rangle. \quad (49.83)$$

This functional is stationary for small variations of $\mathbf{F}^{(+)}$ and $\mathbf{F}^{(-)}$ about the exact solution of Eq. (49.10) satisfying the boundary conditions Eqs. (49.66) and (49.80), respectively. It forms the basis for numerical calculations.

Linear Algebraic Equations Method

In this method, the integro-differential equations Eq. (49.10) are reduced directly to a set of linear algebraic (LA) equations [52]. Alternatively, Eq. (49.10) are first converted to integral form, given by Eq. (49.75), which are then reduced to a set of linear algebraic equations [53].

A direct approach [52] has been widely used for electron–atom and electron–ion collisions. As in the \mathbf{R} -matrix method, configuration space is first divided into two regions. A mesh of N points is used to span the internal region $r \leq a$, where

$$r_1 = 0; \quad r_{k-1} < r_k, \quad k = 1, \dots, N; \quad r_N = a. \quad (49.84)$$

In addition, two further mesh points r_{N+1} and r_{N+2} are introduced to enable the solution in the internal region to be matched to the solution in the external region $r \geq a$. In the external region, Eq. (49.10) reduces to coupled differential equations that can be solved by one of the same methods as adopted in the \mathbf{R} -matrix approach.

The n functions $F_{ij}^f(r)$, $i = 1, \dots, n$, in Eq. (49.10) are represented by their values at the mesh points r_k . Using a finite difference representation of the differential and integral operators, Eq. (49.10) reduces to a set of linear algebraic equations for the unknown values $F_{ij}^f(r_k)$ in the internal region. These equations can be solved using standard methods for each linearly independent solution $j = 1, \dots, n_a$ defined by the asymptotic boundary conditions Eq. (49.15).

49.1.5 Intermediate and High-Energy Elastic Scattering and Excitation

For electron–atom and electron–ion collisions at electron impact energies greater than the ionization threshold of the target, an infinite number of channels is open. Consequently, they cannot all be included explicitly in the expansion of the total wave function. Several approaches have been developed to treat collisions at these energies, such as extensions of low-energy methods based on expansion Eq. (49.8) to intermediate energies, the development of optical potentials that account for the loss of flux into the infinity of open channels in some average way, and extensions of the Born approximation to lower energies by including higher-order terms in the Born series.

Pseudostate Methods

In this approach, expansion Eq. (49.8) is extended by including a set of suitably chosen square-integrable pseudostates Φ_i^p that are orthogonal to the eigenstates Φ_i retained in expansion Eq. (49.8). These pseudostates are usually defined by diagonalizing the target Hamiltonian H_N in

a square-integrable basis. This yields an equation analogous to Eq. (49.4), viz.,

$$\langle \Phi_i^p | H_N | \Phi_j^p \rangle = \omega_i^p \delta_{ij}, \quad (49.85)$$

where the energies ω_i^p lie just below the ionization threshold or in the continuum. The pseudostates Φ_i^p , thus, represent in an average way the high-lying Rydberg states and the continuum states of the target, rather than just the low-lying target bound states as in Eq. (49.4). This enables the loss of flux into the continuum states to be represented, thereby enabling accurate excitation cross sections to be calculated at intermediate energies. In addition, by calculating the amplitudes for exciting these pseudostates, accurate ionization cross sections can be determined, as discussed in Sect. 49.1.6.

A proposal to include pseudostates in expansion Eq. (49.8) for e–H scattering was first made by *Burke and Schey* [54]. A modification of this expansion to include polarized pseudostates, which accounted for the long-range dipole and quadrupole polarizability in e–H scattering, was proposed by *Damburg and Karule* [55]. Later detailed e–H scattering calculations that included pseudostates were carried out by a number of authors [56–59]. The considerable success showed the validity of this approach.

The \mathbf{R} -matrix method, discussed in Sect. 49.1.4, was also extended to include pseudostates. This resulted in the intermediate-energy \mathbf{R} -matrix (IERM) method [60–63] and the \mathbf{R} -matrix with the pseudostates (RMPS) method [64–68], with the latter approach being applicable to multielectron atoms, ions, and molecules. Both of these approaches have enabled excitation and ionization cross sections to be accurately calculated above the ionization threshold.

Methods were also developed in which the pseudostates are represented by Sturmian functions. An expansion of this type was first proposed by *Rotenberg* [69]. A major development along these lines is the convergent close-coupling (CCC) method developed by *Bray, Stelbovics, Fursa*, and coworkers, which has been applied with considerable success for both electron impact excitation and ionization of few-electron systems. Comprehensive reviews of the method and references to numerous applications can be found in [70, 71]. The method has also been extended to molecules [72].

As an example of the CCC method, we consider e–H scattering. In this case, the radial functions of the target states are expanded in the complete Laguerre basis

$$\xi_{k\ell}(r) = \left(\frac{\lambda_\ell(k-1)!}{(2\ell+1+k)!} \right)^{1/2} \times (\lambda_\ell r)^{\ell+1} \exp\left(-\frac{\lambda_\ell r}{2}\right) L_{k-1}^{2\ell+2}(\lambda_\ell r), \quad (49.86)$$

where $L_{k-1}^{2\ell+2}(\lambda_\ell r)$ are associated Laguerre polynomials, and k ranges from 1 to the basis size N_ℓ , which depends on the

angular momentum ℓ . The target states $\Phi_{i\ell}$ are expanded for each angular momentum as

$$\Phi_{i\ell} = \sum_{k=1}^{N_\ell} \xi_{k\ell}(r) c_{ki\ell}, \quad i = 1, \dots, N_\ell, \quad (49.87)$$

where the coefficients $c_{ki\ell}$ are obtained by diagonalizing the target Hamiltonian H_1 according to

$$\langle \Phi_{i\ell} | H_1 | \Phi_{j\ell} \rangle = w_{i\ell} \delta_{ij}. \quad (49.88)$$

The states $\Phi_{i\ell}$ corresponding to the lower energies $w_{i\ell}$ provide an accurate representation of the low-lying bound eigenstates of the target for each ℓ , while the states corresponding to the higher energies correspond to pseudostates representing the high-lying Rydberg states and the continuum. As N_ℓ is increased for fixed range parameter λ_ℓ in Eq. (49.87), more bound target eigenstates are accurately represented, while at the same time the states corresponding to the higher energies provide a denser and more accurate representation of the continuum.

The scattering amplitude is written in the close-coupling approximation as

$$\begin{aligned} & \langle \psi_f | H_2 - E | \Psi_i^{S+} \rangle \\ & \simeq \langle \psi_f | I(H_2 - E) [1 + (-1)^S P] I | \Psi_i^{S+} \rangle, \end{aligned} \quad (49.89)$$

where P is the space exchange operator, which ensures that the total wave function has the correct symmetry for each total spin S , I is the projection operator onto the target states $\Phi_{i\ell}$ retained in the calculation, and $\langle \psi_f |$ is an eigenstate of the asymptotic Hamiltonian. The scattering amplitude is obtained by solving the close-coupling equations in momentum space [71].

Optical Potential Methods

The optical potential method [73] is, in principle, also capable of including the effect of all excited and continuum states. Adopting Feshbach projection operators P and Q as in Eq. (49.40), an optical potential V_{opt} is defined by Eq. (49.44), where now P projects onto those low-energy channels that can be treated exactly, for example by solving Eq. (49.10), and Q allows for the remaining infinity of coupled channels, including the continuum.

At sufficiently high energies, it is appropriate to make a perturbation expansion of V_{opt} , where the second-order term is given by

$$V^{(2)} = P V Q \frac{1}{E - \mathcal{T}_e - H_N + i\epsilon} Q V P. \quad (49.90)$$

Here, V is the electron–atom (ion) interaction potential, \mathcal{T}_e the kinetic energy operator of the scattered electron, and

H_N the target Hamiltonian. *Byron* and *Joachain* [74] converted the lowest-order terms of perturbation theory into an ab initio local complex potential for the elastic scattering of electrons and positrons from a number of atoms.

The optical potential calculated in second order was also used by *Bransden* et al. [75, 76] to describe e–H collisions, while *McCarthy* [77] studied an optical-potential approximation that goes beyond second order and also makes allowance for exchange. This method is called the coupled-channels optical (CCO) model. Finally, *Callaway* and *Oza* [78] constructed an optical potential using a set of pseudostates to evaluate the sum over intermediate states and obtained encouraging results for elastic scattering and excitation of the $n = 2$ states in e–H collisions.

Born Series Methods

In the high-energy domain, which can usually be assumed to extend from several times the ionization threshold of the target upwards, methods based on the Born series often give reliable results. Ignoring electron exchange for the moment, the Born series for the direct scattering amplitude can be written as [79, 80]

$$f = \sum_{n=1}^{\infty} f_{n,B}, \quad (49.91)$$

where the n -th Born term $f_{n,B}$ contains the interaction V between the scattered electron and the target atom or ion n times, and Green's function

$$G_0^{(+)} = (H_N + \mathcal{T}_e - E - i\epsilon)^{-1} \quad (49.92)$$

$(n - 1)$ times, where \mathcal{T}_e and H_N are defined following Eq. (49.90).

It is important to consistently retain all terms in the Born series with similar energy and momentum-transfer $\Delta = |\mathbf{k}_i - \mathbf{k}_f|$ dependencies. For elastic scattering, the scattering amplitude converges to the first Born approximation for all Δ , but at lower energies it is necessary to include $\text{Re}(f_{3,B})$, as well as the second Born terms, to obtain the cross section correct to k^{-2} . In the forward direction, convergence to the first Born approximation is slow because of the contribution from $\text{Im}(f_{2,B})$ that, from the optical theorem, corresponds to loss of flux into all open channels.

For inelastic scattering, the first Born approximation does not give the correct high-energy limit for large Δ . Instead, this comes from $\text{Im}(f_{2,B})$. Physically, this can be understood by noting that inelastic scattering at large angles involves two collisions: a collision of the incident electron with the nucleus to give the large scattering angle, followed or preceded by an inelastic collision with the bound electrons to give excitation [81–83]. Again, in the forward direction, it is necessary to retain $\text{Re}(f_{3,B})$ to obtain the cross section correct to k^{-2} .

Since the third Born term is difficult to evaluate, *Byron and Joachain* [84] suggested that, to third order, the scattering amplitude should be calculated using the eikonal Born series (EBS) approximation

$$f_{\text{EBS}} = f_{1,\text{B}} + f_{2,\text{B}} + f_{3,\text{G}} + g_{\text{och}}, \quad (49.93)$$

where $f_{3,\text{G}}$ is the third-order term in the expansion of the Glauber amplitude [85] in powers of V , which can be more easily calculated than $f_{3,\text{B}}$, and g_{och} is the *Ochkur* electron exchange amplitude [86]. The EBS method has been very successful when perturbation theory converges rapidly; namely, at high energies, at small and intermediate scattering angles, and for light atoms. The Born approximation is also routinely used to top up low-energy scattering from dipolar systems for which a large number of partial waves need to be taken into account [87].

Distorted-Wave Methods

The distorted-wave Born approximation (DWBA) is characterized by a separation of the interaction into two parts, one that is treated exactly while the other is treated in first order. The usual approach is based on the integral expressions for the T -matrix given by Eq. (49.79) or Eq. (49.81). The distorted-wave approximation is obtained by replacing the exact solution of Eq. (49.10), denoted by $F^{(+)}$ and $F^{(-)}$ in Eqs. (49.79) and (49.81), respectively, by approximate solutions that are usually obtained by omitting all channels except the final or initial channels of interest. In addition, the potential interaction U is often approximated by just the direct term in Eq. (49.10).

This method becomes more accurate at intermediate energies, as $Z - N$ increases, and as the angular momentum of the scattered electron becomes large. However, it generally gives poor results at low energies, where the coupling between the channels in Eq. (49.10) is strong, and resonances are often important. It has proven to be a very useful way of calculating electron–ion total and differential cross sections at intermediate and high energies well removed from threshold. Some examples can be found in [88].

A thorough introduction to the DWBA method for atomic and ionic targets can be found in [89]. Calculations using this and the closely related first-order many-body theory (FOMBT), which differs from the DWBA by the choice of distortion potentials, can be performed using the Los Alamos Atomic Collision Codes [90].

49.1.6 Ionization

This section discusses processes in which electrons are ejected from the target during the collision, giving rise to ionization. The main focus is single ionization, i.e., (e,2e)

processes of the general form

$$e^-(E_i) + A_i \rightarrow A_j^+ + e^-(E_A) + e^-(E_B). \quad (49.94)$$

Here, E_i , E_A , and E_B are the incident, scattered, and ejected electron energies, respectively. They are related through the energy conservation condition

$$E_i = E_A + E_B + \varepsilon, \quad (49.95)$$

where ε is the binding energy of the ejected atomic electron. The threshold behavior of the ionization cross section leading to the Wannier threshold law is treated in Chap. 56.

The scattering amplitude for the direct ionization process is [91]

$$f_i(\mathbf{k}_A, \mathbf{k}_B) = -(2\pi)^{\frac{1}{2}} e^{i\chi(\mathbf{k}_A, \mathbf{k}_B)} \left\langle (H_{N+1} - E)\Phi \left| \Psi_i^{(+)} \right. \right\rangle, \quad (49.96)$$

where $\Psi_i^{(+)}$ is an exact solution of Eq. (49.2) satisfying plane-wave plus outgoing-wave boundary conditions given by Eq. (49.5), while Φ is a solution of the equation

$$(H_{N+1} - V - E)\Phi = 0 \quad (49.97)$$

satisfying ingoing-wave boundary conditions. Also, \mathbf{k}_A and \mathbf{k}_B are the momenta of the two outgoing electrons, defined in terms of E_A and E_B by

$$\frac{1}{2}k_A^2 = E_A, \quad \frac{1}{2}k_B^2 = E_B. \quad (49.98)$$

In practice, the potential V is chosen so that Φ has a simple form. Thus, for electron scattering by H-like ions with nuclear charge Z , V is often chosen as

$$V = -\frac{Z - Z_A}{r_1} - \frac{Z - Z_B}{r_2} + \frac{1}{r_{12}}, \quad (49.99)$$

so that

$$\Phi(\mathbf{r}_1, \mathbf{r}_2) = \Psi_C^{(-)}(Z_A, \mathbf{k}_A, \mathbf{r}_1)\Psi_C^{(-)}(Z_B, \mathbf{k}_B, \mathbf{r}_2), \quad (49.100)$$

where the $\Psi_C^{(-)}$ are Coulomb wave functions satisfying ingoing-wave boundary conditions, while Z_A and Z_B are the effective charges seen by the two electrons. In order for the scattering amplitude not to contain a divergent phase factor, Z_A and Z_B must satisfy

$$\frac{Z_A}{k_A} + \frac{Z_B}{k_B} = \frac{Z}{k_A} + \frac{Z}{k_B} - \frac{1}{|\mathbf{k}_A - \mathbf{k}_B|}. \quad (49.101)$$

The phase factor in Eq. (49.96) is then given by

$$\chi(\mathbf{k}_A, \mathbf{k}_B) = \frac{Z_A}{k_A} \ln \frac{k_A^2}{k_A^2 + k_B^2} + \frac{Z_B}{k_B} \ln \frac{k_B^2}{k_A^2 + k_B^2}. \quad (49.102)$$

The exchange ionization amplitude $g_i(\mathbf{k}_A, \mathbf{k}_B)$ can be obtained from the *Peterkop* theorem [92]

$$g_i(\mathbf{k}_A, \mathbf{k}_B) = f_i(\mathbf{k}_B, \mathbf{k}_A). \quad (49.103)$$

This result follows from the fact that the amplitudes $f_i(\mathbf{k}_B, \mathbf{k}_A)$ and $g_i(\mathbf{k}_A, \mathbf{k}_B)$ describe the same physical process, where the electron at \mathbf{r}_{N+1} has momentum \mathbf{k}_A , while the electron at \mathbf{r}_N has momentum \mathbf{k}_B . In practice, the Peterkop theorem is not fulfilled if approximate wave functions are used to calculate the ionization amplitude. For this reason, a relative phase $\tau_i(\mathbf{k}_A, \mathbf{k}_B)$ between these two amplitudes is sometimes introduced by

$$g_i(\mathbf{k}_A, \mathbf{k}_B) = e^{i\tau_i(\mathbf{k}_A, \mathbf{k}_B)} f_i(\mathbf{k}_B, \mathbf{k}_A). \quad (49.104)$$

This adds an element of arbitrariness into the calculation, since different choices of this phase lead to different cross sections [93].

The ionization cross sections can be obtained directly from the scattering amplitudes. For random electron spin orientations, the triple-differential cross section (TDCS) for ionization of a target with one active electron from an initial state denoted by $|i\rangle$ is given by

$$\frac{d^3\sigma_i}{d\Omega_A d\Omega_B dE} = \frac{k_A k_B}{k_i} \left(\frac{1}{4} |f_i + g_i|^2 + \frac{3}{4} |f_i - g_i|^2 \right). \quad (49.105)$$

By integrating the TDCS with respect to $d\Omega_A$, $d\Omega_B$, or dE , we can form three different double-differential cross sections, as well as three different single-differential cross sections. Finally, the total ionization cross section is obtained by integrating Eq. (49.105) over all outgoing electron scattering angles and energies. The result is

$$\sigma_i = \frac{1}{k_i} \int_0^{E/2} dE k_A k_B \int d\Omega_A \times \int d\Omega_B \left[\frac{1}{4} |f_i + g_i|^2 + \frac{3}{4} |f_i - g_i|^2 \right], \quad (49.106)$$

where the upper limit of integration over the energy variable is $E/2$, because the two outgoing electrons are indistinguishable.

We conclude this general discussion of the theory of electron impact ionization by mentioning an integral representation for the ionization amplitude [94] that is free from

the ambiguity and divergence problems associated with earlier work [91, 92, 95, 96]. Another important aspect of this development is the fact that its form is suitable for practical calculations.

Next, we consider several approaches that have been used to obtain accurate ionization cross sections. As for electron impact excitation, we commence with low-energy methods and conclude with plane-wave Born and distorted-wave methods.

Pseudostate Methods

An important development was the realization that accurate ionization cross sections, especially close to threshold, can be obtained by representing the ionization continuum by suitably chosen square-integrable pseudostates. As was already discussed when we considered pseudostate approaches in Sect. 49.1.5, several methods, including the intermediate energy \mathbf{R} -matrix method [60–63], the \mathbf{R} -matrix with pseudostates method [64–67] (both in the standard form with orthogonal one-electron orbitals and in the B -spline framework [45]), and the convergent close-coupling method [70, 71] have been used to obtain accurate ionization cross sections.

The essential point is the description of the process in two steps. First, the electron-impact *excitation* problem for both the physical and the pseudostates needs to be treated. In a second step, excitation of the positive-energy pseudostates is (re)interpreted as ionization. To a very good approximation, the total angle-integrated ionization cross section can be obtained directly as the sum of the excitation cross sections for all the pseudostates above the ionization threshold.

A significant challenge, however, concerns the procedure of extracting the information from the wave function obtained for the atom left in an excited pseudostate. In the CCC approach, this is done by first projecting the \mathbf{T} -matrix elements for a pseudostate of given energy E_f to that of a proper continuum state with the *same* energy. In order to obtain results for the desired energy of the ejected electron, it is then necessary to interpolate the \mathbf{T} -matrix elements to this energy. This procedure works well for cases where only one final ionic state of the residual ion is possible, such as in electron impact ionization of atomic hydrogen, where a bare proton is left, or helium if the residual ion is left in $\text{He}^+(1s)$. Some peculiarities occur, however, such as a step function at equal energy sharing, and these have to be dealt with appropriately. Details can be found in [70, 71].

For the BSR approach [45, 97], it was suggested to obtain the scattering amplitudes for the excitation of all energy-accessible atomic pseudostates $\Phi^p(nl n' l', LS)$ and then generate a weighted sum with the weights given by the overlap factors between the true continuum states and the corresponding pseudostates. In this case, it is important to generate the continuum states with the same close-coupling

expansion that is employed to produce the pseudostates. Although this interpolation recipe does not have a formal origin [98], due to the fact that the individual pseudostates and the continuum state of interest have *different* energies, the above scheme has been very successful. In fact, it is applicable to general targets, as well as to cases such as simultaneous ionization plus excitation [45, 97, 99].

Time-Dependent Close-Coupling Method

Electron impact excitation and ionization amplitudes and cross sections can also be determined by solving the time-dependent Schrödinger equation (TDSE) directly [100–103]. In the case of electron scattering by atomic hydrogen or by an atom or atomic ion with one electron outside a closed inert shell, the total wave function can be expanded for each conserved $LS\pi$ symmetry as

$$\Psi^\Gamma(\mathbf{r}_1, \mathbf{r}_2, t) = \sum_{\ell_1 \ell_2} (r_1 r_2)^{-1} P_{\ell_1 \ell_2}^{LS}(r_1, r_2, t) \mathcal{Y}_{\ell_1 \ell_2}^{LM_L}(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2), \quad (49.107)$$

where Γ is defined by Eq. (49.9), and the coupled spherical harmonics $\mathcal{Y}_{\ell_1 \ell_2}^{LM_L}$ are defined by

$$\begin{aligned} \mathcal{Y}_{\ell_1 \ell_2}^{LM_L}(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2) &= \sum_{m_1 m_2} (\ell_1 m_1 \ell_2 m_2 | \ell_1 \ell_2 LM_L) \\ &\times Y_{\ell_1 m_1}(\theta_1, \phi_1) Y_{\ell_2 m_2}(\theta_2, \phi_2). \end{aligned} \quad (49.108)$$

Substituting Eq. (49.107) into the TDSE and projecting onto the coupled spherical harmonics $\mathcal{Y}_{\ell_1 \ell_2}^{LM_L}$ yields the coupled differential equations

$$\begin{aligned} i \frac{\partial P_{\ell_1 \ell_2}^{LS}(r_1, r_2, t)}{\partial t} &= T_{\ell_1 \ell_2}(r_1, r_2) P_{\ell_1 \ell_2}^{LS}(r_1, r_2, t) \\ &+ \sum_{\ell'_1 \ell'_2} V_{\ell_1 \ell_2 \ell'_1 \ell'_2}^L(r_1, r_2, t) P_{\ell'_1 \ell'_2}^{LS}(r_1, r_2, t), \end{aligned} \quad (49.109)$$

where

$$T_{\ell_1 \ell_2}(r_1, r_2) = -\frac{1}{2} \frac{\partial^2}{\partial r_1^2} - \frac{1}{2} \frac{\partial^2}{\partial r_2^2} + V_{\ell_1}(r_1) + V_{\ell_2}(r_2). \quad (49.110)$$

In this equation, V_ℓ is an ℓ -dependent pseudo potential representing the interaction of the valence or scattered electrons with the closed-shell core, and $V_{\ell_1 \ell_2 \ell'_1 \ell'_2}^L$ are the radial coupling potentials obtained by taking the matrix elements of the r_{12}^{-1} interaction between the valence and scattered electrons.

Equations (49.109) are solved on a two-dimensional grid using an explicit time propagator, which can be readily implemented on parallel computers. Commencing at time $t = 0$ with a wave function that is constructed as the appropriately

symmetrized product of an incoming radial wave packet for one electron and the stationary bound initial state for the other electron, the time-dependent equations (49.109) are integrated forward in time. Electron impact excitation and ionization amplitudes, and subsequently the cross section, are determined by projecting the time-evolved radial wave function $P_{\ell_1 \ell_2}^{LS}(r_1, r_2, t)$ onto a complete set of target states. A review of the method is given in [104].

Exterior Complex Scaling Method

In this approach, developed by *Rescigno* et al. [105–107], the time-independent Schrödinger equation for three charged particles is solved numerically on a two-dimensional grid without explicitly imposing asymptotic boundary conditions for three-body breakup. In the case of e–H scattering, the total wave function is partitioned into the sum of an appropriately symmetrized unperturbed wave function $\psi_{k_i}^\Gamma$ describing a free electron with momentum k_i incident on the target ground state and a scattered wave function Ψ_{sc}^Γ , which is expanded in the form

$$\Psi_{sc}^\Gamma(\mathbf{r}_1, \mathbf{r}_2) = \sum_{L \ell_1 \ell_2} r_1^{-1} r_2^{-1} \psi_{\ell_1 \ell_2}^{LS}(r_1, r_2) \mathcal{Y}_{\ell_1 \ell_2}^{L0}(\hat{\mathbf{r}}_1, \hat{\mathbf{r}}_2). \quad (49.111)$$

Since the z -axis is defined to lie along the incident beam direction, M_L in the coupled spherical harmonics defined by Eq. (49.108) is zero. Also, since parity is conserved, the summation in Eq. (49.111) is limited to terms for which $L + \ell_1 + \ell_2$ is even.

Substituting the expression for the total wave function into the Schrödinger equation yields the following set of coupled two-dimensional equations for the radial functions $\psi_{\ell_1 \ell_2}^{LS}$ for each L and S

$$\begin{aligned} [E - H_{\ell_1}(r_1) - H_{\ell_2}(r_2)] \psi_{\ell_1 \ell_2}^{LS}(r_1, r_2) \\ - \sum_{\ell'_1 \ell'_2} V_{\ell_1 \ell_2 \ell'_1 \ell'_2}^L(r_1, r_2) \psi_{\ell'_1 \ell'_2}^{LS}(r_1, r_2) = \chi_{\ell_1 \ell_2}^{LS}(r_1, r_2). \end{aligned} \quad (49.112)$$

In this equation, $H_\ell(r)$ is the radial hydrogenic Hamiltonian

$$H_\ell(r) = -\frac{1}{2} \frac{d^2}{dr^2} + \frac{\ell(\ell+1)}{2r^2} - \frac{1}{r}, \quad (49.113)$$

$V_{\ell_1 \ell_2 \ell'_1 \ell'_2}^L$, as in Eq. (49.109), are the radial coupling potentials obtained by taking the matrix elements of the electron–electron interaction r_{12}^{-1} , and the inhomogeneous term $\chi_{\ell_1 \ell_2}^{LS}(r_1, r_2)$ arises from the partial-wave expansion of the incident wave term.

The coupled differential equations (49.112) are solved on a two-dimensional grid using exterior complex scaling (ECS) boundary conditions, which avoids imposing detailed

asymptotic boundary conditions. The ECS transformation is taken as a mapping $r \rightarrow z(r)$ of all radial coordinates to a contour

$$z(r) \equiv \begin{cases} r, & r \leq R_0 \\ R_0 + (r - R_0)e^{i\eta} & r > R_0 \end{cases}, \quad (49.114)$$

which is real for $r \leq R_0$ but rotated into the upper half of the complex plane for $r > R_0$. This transformation has the desirable property that any outgoing wave evaluated on this contour dies exponentially as the coordinate becomes large. Thus, the ECS procedure transforms any outgoing wave into a function that falls off exponentially outside R_0 but is equal to the infinite-range wave over the finite region of space where the coordinates are real. Producing meaningful ionization cross sections at energies several eV above the ionization threshold requires R_0 to be at least $100 a_0$. The grid must extend beyond R_0 far enough to allow the complex scaled radial function to decay effectively to zero at the edge of the grid, thus requiring grids that extend an additional $25 a_0$ beyond R_0 . It should be checked that the final results do not depend significantly on the choice of R_0 . A detailed discussion of this method is given by *McCurdy et al.* [107].

Born and Distorted-Wave Methods

The integral expression Eq. (49.96) for the direct ionization amplitude provides a starting point for the calculation of cross sections at higher energies. Both the Born series methods and distorted-wave methods, which were described in Sect. 49.1.5 when we considered intermediate and high-energy elastic scattering and excitation, have been used to obtain ionization amplitudes.

An important development of the distorted wave method was made by *Jones and Madison* [108–110]. Their continuum distorted-wave with eikonal initial state (CDW-EIS) commences from the two-potential expression for the transition amplitude given by *Gell-Mann and Goldberger* [111]

$$T_{fi} = \langle \chi_f^- | W_f^+ | \Psi_i^+ \rangle + \langle \chi_f^- | V_i - W_f^+ | \beta_i \rangle. \quad (49.115)$$

In the first term of this equation, Ψ_i^+ is the exact scattering wave function developed from the initial state satisfying outgoing-wave boundary conditions, χ_f^- is a distorted wave corresponding to the final state satisfying incoming-wave boundary conditions, and the corresponding perturbation W_f^+ is the adjoint of the operator W_f and operates to the left. In the second term, β_i is the unperturbed initial state, which in the case of e–H scattering is

$$\beta_i = (2\pi)^{-3/2} \exp(i\mathbf{k}_0 \mathbf{r}_1) \psi_i(\mathbf{r}_2). \quad (49.116)$$

In this case, V_i is the initial-state interaction potential given by

$$V_i = -\frac{1}{r_1} + \frac{1}{r_{12}}. \quad (49.117)$$

An eikonal approximation is made for the initial-state wave function Ψ_i^+ in Eq. (49.115), while the final state χ_f^- is represented by a CDW wave function [112]. In this way, distortion effects are included in both the initial-state and final-state wave functions. Results obtained with the CDW-EIS approximation were compared with ECS calculations for electron impact ionization of atomic hydrogen at 54.4 eV [113] and equal energy sharing between the outgoing electrons. The TDCSs from the two calculations were found to be in very good agreement. More information about this and related approaches, in particular the extension to molecular targets, can be found in [114].

A further development of the distorted-wave method for ionization was made for situations when the incident electron is fast and interacts weakly with the target atom or ion, while the ejected electron is slow and interacts strongly with the residual ion [115, 116]. In this case, Eq. (49.96) is applicable, where the ionizing electron is represented by plane waves or distorted waves, while the initial target state and the ejected-electron–residual-ion interaction are both represented by the close-coupling expansion Eq. (49.8). This hybrid approximation is particularly useful when the ejected electron can be captured into an autoionizing state of the target atom or ion, which then decays giving rise to the excitation-autoionization (EA) process

In this equation, the bracket indicates a resonance state, while q is the charge on the atom A . This process, together with the related resonant excitation double autoionization (REDA) process

and the resonant excitation auto-double ionization (READI) process

have attracted considerable experimental and theoretical interest [117–121]. While the EA process can be accurately treated using a distorted-wave method if the incident electron is fast, both the REDA and READI processes involve capture of the incident electron into a resonant state, and hence a strong-coupling approach is required.

An Example and Conclusions

We conclude this section by mentioning a comparison between theory and experiment for electron impact ionization of hydrogen at 17.6 eV [122]. At this energy, which is only 4 eV above the ionization threshold, strong coupling effects between the incident and ejected electrons as well as the residual proton are important. Consequently, Born series and distorted-wave methods are not applicable. This comparison thus provides a stringent test of theoretical predictions. In the above work [122], TDCS data for coplanar outgoing electrons both having 2 eV energy were compared with ECS and CCC results. The two calculations show excellent overall agreement both with the shape and the magnitude of the experiment for a wide range of scattering angles.

More recently, a similar benchmark study was performed for electron impact ionization of $\text{He}(1s^2)^1S$ leaving the residual ion in its $\text{He}^+(1s)^2S$ ground state [123]. Excellent agreement between experiment and CCC, TDCC, and BSR predictions was obtained.

It is clear that a detailed theoretical understanding of electron impact ionization of simple targets, most notably H and He, has now been obtained over a wide range of energies and angles. Although further work is required to predict accurate cross sections involving highly excited states of interest in plasma physics and astrophysical applications, for example in astrophysical H II regions [124], methods have been developed that should enable these cross sections to be accurately determined.

Good progress has also been made in the study of electron impact ionization of multielectron atoms and ions such as Ne and Ar [125, 126]. Problems still remain both due to the need to obtain accurate target states, which also applies to elastic scattering and excitation, and due to fundamental difficulties in carrying out accurate calculations for REDA and READI processes defined by Eqs. (49.119) and (49.120), respectively. In the latter case, major theoretical difficulties arise in the accurate treatment of resonance states, which decay with the emission of more than one electron.

49.2 Electron–Molecule Collisions

Electron–molecule collision calculations are now routinely performed for a wide variety of reasons. These include precision calculations such as those achieved for the e–H₂ problem by *Zammit, Bray*, and coworkers [72], modeling complex systems, and the provision of data for problems not easily amenable to experimental studies.

49.2.1 Laboratory Frame Representation

The processes that occur in electron collisions with molecules are more diverse than those that occur in electron collisions with atoms and atomic ions because of the possibility of exciting degrees of freedom associated with the motion of the nuclei. In addition, the multicenter and non-spherical nature of the electron–molecule interaction complicates the solution of the collision problem considerably by reducing its symmetry and by introducing multicenter integrals that are more difficult to evaluate than those occurring for atoms and ions.

We first consider the derivation of the equations describing the collision in the laboratory frame of reference discussed by *Arthurs and Dalgarno* [127]. The Schrödinger equation describing the electron–molecule system is

$$(H_m + \mathcal{T}_e + V)\Psi = E\Psi, \quad (49.121)$$

where H_m is the molecular Hamiltonian, \mathcal{T}_e is the kinetic energy operator of the scattered electron, and V is the electron–molecule interaction potential

$$V(\mathbf{R}, \mathbf{r}_m, \mathbf{r}) = \sum_i \frac{1}{|\mathbf{r} - \mathbf{r}_i|} - \sum_i \frac{Z_i}{|\mathbf{r} - \mathbf{R}_i|}. \quad (49.122)$$

Here, \mathbf{R} represents the coordinates \mathbf{R}_i of all the nuclei, \mathbf{r}_m represents the coordinates \mathbf{r}_i of the electrons in the target molecule, and \mathbf{r} represents the coordinates of the scattering electron. The total energy E in Eq. (49.121) refers to the frame of reference where the center of mass of the entire system is at rest.

As in the case of electron–atom and electron–ion collisions, we introduce target eigenstates, and possibly pseudostates Φ_i , by the equation

$$\langle \Phi_i | H_m | \Phi_j \rangle = w_i \delta_{ij}, \quad (49.123)$$

and then expand the total wave function Ψ , in analogy with Eq. (49.8), in the form

$$\Psi_j = \mathcal{A} \sum_i \Phi_i(\mathbf{R}, \mathbf{r}_m) \mathcal{F}_{ij}(\mathbf{r}) + \sum_i \chi_i(\mathbf{R}, \mathbf{r}_m, \mathbf{r}) b_{ij}. \quad (49.124)$$

Here, the spin variables have been suppressed for simplicity of notation, and we have not carried out a partial-wave decomposition of the wave function \mathcal{F}_{ij} representing the scattered electron. The subscripts i and j now represent the

rotational and vibrational states of the molecule as well as its electronic states.

Coupled equations for the functions \mathcal{F}_{ij} can be obtained by substituting expansion Eq. (49.124) into Eq. (49.121) and projecting onto the target states Φ_i and the square-integrable functions χ_j . After eliminating the coefficients b_{ij} , the coupled integro-differential equations

$$(\nabla^2 + k_i^2)F_{ij}(r) = 2 \sum_{\ell} (V_{i\ell} + W_{i\ell} + X_{i\ell})F_{\ell j}(r) \quad (49.125)$$

are obtained, where $k_i^2 = 2(E - w_i)$, and $V_{i\ell}$, $W_{i\ell}$, and $X_{i\ell}$ are the direct, nonlocal exchange, and nonlocal correlation potentials. By expanding F_{ij} in partial waves, a set of coupled radial integro-differential equations result, analogous to Eq. (49.10) for atoms and ions.

The scattering amplitude and cross section for a transition from an initial state $|i\rangle = |k_i, \Phi_i, \chi_{\frac{1}{2}m_i}\rangle$ to a final state $|j\rangle = |k_j, \Phi_j, \chi_{\frac{1}{2}m_j}\rangle$ is given by Eq. (49.7), where now the subscripts i and j refer collectively to the rovibrational and electronic states of the molecule.

49.2.2 Molecular Frame Representation

The theory described in the previous section is completely general and has been the basis of a number of early calculations for simple diatomic molecules such as H_2 . However, major computational difficulties arise because of the very large number of rovibrational channels that need to be retained in expansion Eq. (49.124) for all but the simplest low-energy calculations.

This difficulty can be overcome by making a Born–Oppenheimer separation of the electronic and nuclear motion. The electronic motion is first determined with the nuclei held fixed. This is referred to as the fixed-nuclei approximation (FNA). The molecular rotational and vibrational motion is then included in a second step of the calculation. This procedure owes its validity to the large ratio of the nuclear mass to the electronic mass. It can be adopted when the collision time is much shorter than the periods of molecular rotation and vibration. Thus, it is expected to be valid when the scattered electron energy is not close to a threshold, or when the energy does not coincide with that of a narrow resonance. In these cases, further developments described below are needed to obtain reliable cross sections.

In order to formulate the collision process in this representation, we adopt a frame of reference that is rigidly attached to the molecule. The FNA then starts from the Schrödinger equation

$$(H_{\text{el}} + \mathcal{T}_e + V)\psi = E\psi, \quad (49.126)$$

where H_{el} is the electronic part of the target Hamiltonian obtained by assuming that the target nuclei have fixed coordinates denoted collectively by \mathbf{R} . It follows that H_{el} is related to H_m in Eq. (49.121) by

$$H_m = H_{\text{el}} + \mathcal{T}_R, \quad (49.127)$$

where \mathcal{T}_R is the kinetic energy operator for the rotational and vibrational motion of the nuclei. The remaining quantities \mathcal{T}_e and V are the same as in Eq. (49.121).

The solution of Eq. (49.126) proceeds in an analogous way to the solution of Eq. (49.2) for electron collisions with atoms and ions. We adopt an expansion similar to Eq. (49.8), where we now expand the function representing the motion of the scattered electron in terms of symmetry-adapted angular functions that transform as an appropriate irreducible representation (IRR) of the molecular point group (*Burke et al. [128]*). Substituting this expansion into Eq. (49.126), and projecting onto the corresponding channel functions and onto the square-integrable functions, yields a set of coupled integro-differential equations with the form given by Eq. (49.10), where now the channel indices i , j , and ℓ represent the component of the IRR, as well as the electronic state of the target, and where Γ represents the conserved quantum numbers that include the IRR and the total spin.

The final step is to solve these coupled integro-differential equations for each set of nuclear coordinates \mathbf{R} of importance in the collision, using one of the methods discussed in Sect. 49.1.4. This yields the \mathbf{K} -matrices, \mathbf{S} -matrices, and cross sections for fixed \mathbf{R} . For scattering calculations where only the ground electronic state has been included in the expansion, a number of approaches have been developed that replace the nonlocal exchange and correlation potentials by local potentials [129]. These approaches have proven particularly important in describing electronically elastic collisions of electrons with polyatomic molecules.

49.2.3 Inclusion of the Nuclear Motion

This section discusses how observables involving the nuclear motion, such as rotational and vibrational excitation cross sections, as well as dissociative attachment cross sections, can be obtained from the solutions of the fixed-nuclei equations.

The most widely used approach is the adiabatic-nuclei approximation [130–132]. In the case of diatomic molecules in a $^1\Sigma$ state, the scattering amplitude for a transition between electronic, vibrational, and rotational states represented by $i v j m_j$ and $i' v' j' m'_j$ is given by

$$\begin{aligned} & f_{i'v'j'm'_j, i v j m_j}(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}) \\ &= \langle \chi_{i'v'}(R) Y_{j'm'_j}(\hat{\mathbf{R}}) | f_{i'i}(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}; \mathbf{R}) | \chi_{iv}(R) Y_{j m_j}(\hat{\mathbf{R}}) \rangle, \end{aligned} \quad (49.128)$$

where $f_{i'j'}(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}; \mathbf{R})$ is the fixed-nuclei scattering amplitude, which depends parametrically on the nuclear coordinates \mathbf{R} , while χ_{iv} and Y_{jm_j} are the molecular vibrational and rotational eigenfunctions, respectively. This approximation is valid provided that the collision time is short compared with the vibration and/or rotation times, and it is widely used in such situations.

The cross section is usually averaged over the degenerate sublevels m_j and summed over m'_j , giving the cross section for the transition ivj to $i'v'j'$. This leads to the relation

$$\frac{d\sigma_{i'v'j',ivj}}{d\Omega} = \sum_{j_i=|j-j'|}^{j+j'} [(j0j_i0 | j'0)]^2 \frac{d\sigma_{i'v'j_i,iv0}}{d\Omega}, \quad (49.129)$$

provided that the small differences in the wave numbers for the different rotational channels can be neglected. A similar relation holds for symmetric top molecules such as NH_3 . For spherical-top molecules such as CH_4 , the equivalent relation is [133, 134]

$$\frac{d\sigma_{i'v'j',ivj}}{d\Omega} = \frac{2j'+1}{2j+1} \sum_{j_i=|j-j'|}^{j+j'} \frac{1}{2j_i+1} \frac{d\sigma_{i'v'j_i,iv0}}{d\Omega}. \quad (49.130)$$

The sum in Eq. (49.129) or Eq. (49.130) over the final rotational state j' is independent of the initial state j . Also, if the cross section is multiplied by the transition energy and then summed over j' , the result, which is for the mean energy loss by the incident electron, is still independent of j .

A general code, POLYDCS [135], is available. It uses a frame-transformation to include the effects of rotational motion in FNA scattering calculations. This approach has proved very successful and is the main source of rotational excitation cross sections, as the very small excitation energies for this process means that they largely defy experimental measurement. POLYDCS can also implement a Born correction for scattering off dipole systems, since this has to be performed simultaneously with a treatment of rotational motion that acts to dampen the long-range effects of the dipole.

The adiabatic-nuclei approximation breaks down close to threshold or in the neighborhood of narrow resonances [136]. A straightforward way of including nonadiabatic effects that arise in vibrational excitation is to retain the vibrational terms in the Hamiltonian, but still to treat the rotational motion adiabatically. Hence, instead of Eq. (49.126), the equation

$$(H_{\text{el}} + \mathcal{T}_{\text{vib}} + \mathcal{T}_e + V)\tilde{\psi} = E\tilde{\psi} \quad (49.131)$$

is solved, where \mathcal{T}_{vib} is the kinetic energy operator for the nuclear vibrational motion, and where the other quantities have the same meaning as in Eq. (49.126). Adopting

a frame of reference in which the molecule has fixed spatial orientation and separating out the angular variables of the scattered electron, coupled integro-differential equations coupling the target vibrational states as well the electronic states can be obtained. This approach has been adopted with success [137, 138], but it is computationally demanding, since the number of coupled channels can become very large.

Vibrational excitation and dissociative attachment are particularly important in resonance regions when the scattered electron spends an appreciable time in the neighborhood of the molecule. As a result, several approaches have been developed to describe these processes based on electron–molecule resonance theories (e.g., [139–143]). The basic idea is that a series of fixed-nuclei resonance states $\psi_n^{(r)}$ are introduced for a range of values of R , either by imposing Siegert outgoing-wave boundary conditions [144] or by introducing Feshbach projection operators [20, 21]. The amplitude for a transition from an initial electronic-vibrational state iv to a final state $i'v'$ is then given by

$$T_{i'v',iv} = \sum_n \langle \chi_{i'v'}(R') \zeta_{ni'}(R') | G_n^{(r)}(R', R) \times | \zeta_{ni}(R) \chi_{iv}(R) \rangle, \quad (49.132)$$

where χ_{iv} are the vibrational eigenfunctions, ζ_{ni} are the *entry amplitudes* from the initial or final electronic states into the resonance states $\psi_n^{(r)}$, and $G_n^{(r)}$ are the Green's functions that describe the propagation in the intermediate resonance states $\psi_n^{(r)}$. Dissociative attachment can be described by a straightforward extension of this theory.

The fixed-nuclei \mathbf{R} -matrix method was also extended to treat vibrational excitation and dissociative attachment [145]. A generalized \mathbf{R} -matrix is introduced by an equation that, in analogy with Eq. (49.132), is written as

$$R_{i'v',iv} = \frac{1}{2a} \sum_k \langle \chi_{i'v'}(R') w_{ik}^\Gamma(R') | G_k^{RM}(R', R) \times | w_{ik}^\Gamma(R) \chi_{iv}(R) \rangle, \quad (49.133)$$

where the surface amplitudes $w_{ik}^\Gamma(R)$ are defined by Eq. (49.65), and Green's function G_k^{RM} now describes the propagation in the intermediate \mathbf{R} -matrix states defined by Eq. (49.62). Once the generalized \mathbf{R} -matrix has been determined, the final step in the calculation is to solve the collision problem in the external region that, for diatomic molecules, is defined by the condition that the scattered electron coordinate r is greater than some given radius a , and the internuclear coordinate R is greater than some given radius A .

Electron collisions with CO_2 molecules are important technologically and provide a benchmark problem for the theoretical treatment of vibrational excitation in polyatomic molecules. Such collisions were calculated in the FNA using an electron–polyatomic molecular scattering program

based on the complex Kohn variational method [146]. At low energies, the cross section is dominated by a virtual state at threshold and a ${}^2\Pi_u$ shape resonance at 3.8 eV. As the molecule bends from its ground-state linear configuration, the shape resonance splits into nondegenerate 2A_1 and 2B_1 configurations. The fixed-nuclei complex resonance energy surfaces are parametrized, and motion on these surfaces is computed using a generalization of the boomerang model [147]. The results reproduce the oscillations resulting from the interference between the nuclear and electronic motion that were seen experimentally by *Allan* [148, 149]. Cross sections for excitations between excited states, which are important for plasma studies but not amenable to experimental investigation, are also available [150].

Another approach that includes nonadiabatic effects is the energy-modified adiabatic approximation introduced by *Nesbet* [151]. In this approach, the S -matrix elements connecting the vibrational states are defined by

$$S_{i'v',iv} = \langle \chi_{i'v'} | S_{i'i}(E - H_i; R) | \chi_{iv} \rangle, \quad (49.134)$$

where $S_{i'i}(E - H_i; R)$ are the elements of the S -matrix calculated in the FNA at the internuclear separation R for an energy defined by the operator $H_i = E_i(R) + \mathcal{T}_{\text{vib}}$. This has the effect of including the internal energy of the target into the S -matrix elements, thus giving the correct threshold energies.

Finally, we mention an off-shell T -matrix approach for including nonadiabatic effects discussed first by *Shugard* and *Hazi* [152]. This approach can also extend the range of validity of the adiabatic-nuclei approximation while retaining much of its inherent simplicity. It was applied with success to low-energy vibrational excitation of H_2 and CH_4 [153].

49.2.4 Electron Collisions with Polyatomic Molecules

Computer programs based on the ab initio methods described in Sect. 49.1.4 have been developed and used to calculate cross sections for electron collisions with polyatomic molecules of importance in many applications.

Data are provided for a variety of topics. Examples include technological plasmas where it has been argued that calculations provide the only viable means of providing complete datasets for the entire range of systems [154]. This is particularly true for open-shell species or radicals for which experimental data are almost entirely nonexistent. An example of this sort is the work of *Hamilton* and coworkers, who generated a complete dataset of electron collision cross sections for the NF_x $x = 1, 2, 3$ species [155], which was subsequently used as the input for detailed plasma models of these species [156, 157].

Similarly, input is used for atmospheric reentry plasma [158], fusion plasmas [47], and astrophysics. Astrophysically, electron collisions are important for dissociative recombination, which is a major destroyer of molecular ions in the interstellar medium [159], formation of molecular anions [160], and rotational excitation [161]. The cross sections were placed in databases [162, 163] and assembled into sets to address specific problems [161].

The observation by *Boudaïffa* et al. [164] that the DNA strand breaks, which result from damage by all types of radiation, were substantially caused by collisions with low-energy (sub 10 eV) electrons has led to the creation of a new and very active field of electron collision studies. The interest in characterizing the resonances supported by DNA fragments and DNA itself has led to electron-collision calculations with essentially all the theoretical methods described above and, of course, parallel experimental activity. These studies have been extensively reviewed [165–168]. Similar studies have also been performed on smaller biomolecules that constitute biofuels [168, 169].

49.3 Electron–Atom Collisions in a Laser Field

Electron–atom collisions in the presence of an intense laser field have recently attracted considerable attention because of the importance of these processes in applications such as laser–plasma interactions, and also because of their fundamental interest for atomic collision theory. This section summarizes the basic theory, commencing with the scattering of electrons by a potential in the presence of a laser field. The discussion is then generalized to the scattering of electrons by complex atoms and ions, where *dressing* of the atomic eigenstates by the laser field must be considered, and where simultaneous electron–photon excitation (SEPE) processes, defined by

can occur. Early reviews of some aspects of this subject were given by *Mason* [170], *Newell* [171], and *Mittleman* [172].

49.3.1 Potential Scattering

We adopt a semiclassical description of the collision process, in which the electrons and the target atom are described by the nonrelativistic Schrödinger equation, while the laser field is described classically. This is valid for most high-intensity fields of current interest, where a typical coherence volume of the field contains a very large number of photons [172].

The time-dependent Schrödinger equation describing an electron scattered by a potential $V(\mathbf{r})$ in the presence of an

external electromagnetic (laser) field is

$$\begin{aligned} i\frac{\partial}{\partial t}\Psi(\mathbf{r}, t) = & \left[-\frac{1}{2}\nabla^2 - \frac{i}{c}\mathbf{A}(\mathbf{r}, t) \cdot \nabla \right. \\ & \left. + \frac{1}{2c^2}\mathbf{A}^2(\mathbf{r}, t) + V(\mathbf{r}) \right] \Psi(\mathbf{r}, t), \end{aligned} \quad (49.136)$$

in the Coulomb gauge, such that the vector potential satisfies $\nabla \cdot \mathbf{A} = 0$. We also assume that the laser field is monochromatic, monomode, linearly polarized, and spatially homogeneous (i.e., its wavelength is large compared with the range of the potential, or, more generally, with the size of the atom). Hence we can write

$$\mathbf{A}(\mathbf{r}, t) = \mathbf{A}(t) = \hat{\mathbf{e}}A_0 \cos \omega t, \quad (49.137)$$

where $\hat{\mathbf{e}}$ is a unit vector along the field polarization direction, and ω is the angular frequency. The \mathbf{A}^2 term in Eq. (49.136) can be removed by the unitary transformation

$$\Psi(\mathbf{r}, t) = \exp\left(-\frac{i}{2c^2} \int^t \mathbf{A}^2(t') dt'\right) \Psi_V(\mathbf{r}, t), \quad (49.138)$$

where Ψ_V satisfies the Schrödinger equation in the velocity gauge given by

$$\begin{aligned} i\frac{\partial}{\partial t}\Psi_V(\mathbf{r}, t) = & \left[-\frac{1}{2}\nabla^2 - \frac{i}{c}\mathbf{A}(t) \cdot \nabla + V(\mathbf{r}) \right] \\ & \times \Psi_V(\mathbf{r}, t). \end{aligned} \quad (49.139)$$

The corresponding equation for the free electron with $V = 0$ is readily solved to give the Volkov wave function [173]

$$\chi_k(\mathbf{r}, t) = (2\pi)^{-\frac{3}{2}} \exp[i(\mathbf{k} \cdot \mathbf{r} - \mathbf{k} \cdot \boldsymbol{\alpha}_0 \sin \omega t - Et)], \quad (49.140)$$

where \mathbf{k} is the wave vector and $E = \frac{1}{2}k^2$ the kinetic energy. The quantity $\boldsymbol{\alpha}(t)$ is defined by

$$\boldsymbol{\alpha}(t) = \frac{1}{c} \int^t \mathbf{A}(t') dt' = \boldsymbol{\alpha}_0 \sin \omega t, \quad (49.141)$$

where $\boldsymbol{\alpha}_0 = \mathcal{E}_0/\omega^2$ with \mathcal{E}_0 being the electric field strength.

To solve Eq. (49.139), we introduce the causal Green's function $G_0^{(+)}(\mathbf{r}, t; \mathbf{r}', t')$ satisfying the equation

$$\begin{aligned} \left(i\frac{\partial}{\partial t} + \frac{1}{2}\nabla^2 + \frac{i}{c}\mathbf{A}(t) \cdot \nabla \right) G_0^{(+)}(\mathbf{r}, t; \mathbf{r}', t') \\ = \delta(\mathbf{r} - \mathbf{r}')\delta(t - t'). \end{aligned} \quad (49.142)$$

This Green's function is given by

$$\begin{aligned} G_0^{(+)}(\mathbf{r}, t; \mathbf{r}', t') \\ = -i\theta(t - t') \int \chi_k(\mathbf{r}, t)\chi_k^*(\mathbf{r}', t') d\mathbf{k}, \end{aligned} \quad (49.143)$$

where $\theta(x) = 1$ for $x > 0$ and $\theta(x) = 0$ for $x < 0$. The corresponding causal outgoing-wave solution of Eq. (49.139) is

$$\begin{aligned} \Psi_k^{(+)}(\mathbf{r}, t) = \chi_k(\mathbf{r}, t) + \int_{-\infty}^t dt' \int d\mathbf{r}' G_0^{(+)}(\mathbf{r}, t; \mathbf{r}', t') \\ \times V(\mathbf{r}')\Psi_k^{(+)}(\mathbf{r}', t'), \end{aligned} \quad (49.144)$$

and the S -matrix element for a transition $\mathbf{k}_i \rightarrow \mathbf{k}_f$ in the presence of the laser field is given by

$$S_{k_f, k_i} = -i\langle \chi_{k_f} | V | \Psi_{k_i}^{(+)} \rangle, \quad (49.145)$$

where an integration is carried out over all space and time in this matrix element. The time integration in Eq. (49.145) can be performed using the relation

$$\exp(ix \sin u) = \sum_{n=-\infty}^{\infty} J_n(x) \exp(inu), \quad (49.146)$$

where $J_n(x)$ is an ordinary Bessel function of order n . Then

$$S_{k_f, k_i} = -2\pi i \sum_{n=-\infty}^{\infty} \delta(E_{k_f} - E_{k_i} - n\omega) T_{k_f, k_i}^n, \quad (49.147)$$

where the δ -function ensures energy conservation, and n is the number of photons absorbed or emitted. The differential cross section for the scattering process $\mathbf{k}_i \rightarrow \mathbf{k}_f$ with exchange of n photons can then be defined in terms of the T -matrix elements T_{k_f, k_i}^n by

$$\frac{d\sigma_n}{d\Omega} = (2\pi)^4 \frac{k_f}{k_i} |T_{k_f, k_i}^n|^2. \quad (49.148)$$

There are two limiting cases in which considerable simplification in this expression occurs. First, at high energies or for weak potentials, the first Born approximation can be used to describe scattering by the potential $V(\mathbf{r})$. In this case, Eq. (49.148) reduces to

$$\frac{d\sigma_n^{1,B}}{d\Omega} = (2\pi)^4 \frac{k_f}{k_i} J_n^2(\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0) |\mathcal{V}(\boldsymbol{\Delta})|^2, \quad (49.149)$$

where $\boldsymbol{\Delta} = \mathbf{k}_i - \mathbf{k}_f$ is the momentum-transfer vector and

$$\mathcal{V}(\boldsymbol{\Delta}) = (2\pi)^{-3} \int \exp(i\boldsymbol{\Delta} \cdot \mathbf{r}) V(\mathbf{r}) d\mathbf{r}. \quad (49.150)$$

It follows immediately that

$$\frac{d\sigma_n^{1,B}}{d\Omega} = J_n^2(\mathbf{A} \cdot \boldsymbol{\alpha}_0) \frac{d\sigma^{1,B}}{d\Omega}, \quad (49.151)$$

where $d\sigma^{1,B}/d\Omega$ is the field-free first Born differential cross section. Using the sum rule

$$\sum_{n=-\infty}^{\infty} J_n^2(x) = 1, \quad (49.152)$$

Eq. (49.151) yields

$$\sum_{n=-\infty}^{\infty} \frac{d\sigma_n^{1,B}}{d\Omega} = \frac{d\sigma^{1,B}}{d\Omega}. \quad (49.153)$$

The second limiting case is the low-frequency (soft-photon) limit, where the laser photon energy ω is small compared with the electron energy E_{k_i} . In this limit, the T -matrix element is given by [174]

$$T_{k_f, k_i}^n = J_n(\mathbf{A} \cdot \boldsymbol{\alpha}_0) \langle \chi_{k_f} | \mathcal{T}(E_{k_i}) | \chi_{k_i} \rangle + O(\omega^2), \quad (49.154)$$

where \mathbf{k}'_i and \mathbf{k}'_f are the shifted wave vectors

$$\mathbf{k}'_i = \mathbf{k}_i + \frac{n\omega}{\mathbf{A} \cdot \boldsymbol{\alpha}_0} \boldsymbol{\alpha}_0, \quad \mathbf{k}'_f = \mathbf{k}_f + \frac{n\omega}{\mathbf{A} \cdot \boldsymbol{\alpha}_0} \boldsymbol{\alpha}_0, \quad (49.155)$$

and $\mathcal{T}(E_{k_i})$ is the transition operator in the absence of the laser, corresponding to the energy $E_{k_i} = k_i^2/2$. The angle-differential cross section for the transfer of n photons is

$$\frac{d\sigma_n}{d\Omega} = \frac{k_f}{k_i} J_n^2(\mathbf{A} \cdot \boldsymbol{\alpha}_0) \frac{d\sigma}{d\Omega}(\mathbf{k}'_f, \mathbf{k}'_i) + O(\omega^2), \quad (49.156)$$

where $d\sigma(\mathbf{k}'_f, \mathbf{k}'_i)/d\Omega$ refers to the transition $\mathbf{k}'_i \rightarrow \mathbf{k}'_f$ in the absence of the laser. If the frequency is small enough to neglect the n -dependence of \mathbf{k}'_i and \mathbf{k}'_f , using the sum rule Eq. (49.152) brings Eq. (49.156) to

$$\sum_{n=-\infty}^{\infty} \frac{d\sigma_n}{d\Omega} = \frac{d\sigma}{d\Omega}, \quad (49.157)$$

where $d\sigma/d\Omega$ is the field-free differential cross section. The Kroll–Watson result Eq. (49.156) has been found to be surprisingly accurate, even for cases where $\omega/E_{k_i} \approx 0.5$ [175, 176]. A nonrigorous extension of the Kroll–Watson result to inelastic processes was considered by a number of authors and was found to give qualitative agreement with experiments on helium [177].

49.3.2 Scattering by Complex Atoms and Ions

The time-dependent Schrödinger equation describing an electron scattered by an N -electron atom or ion in the

presence of a laser field can be written in analogy with Eq. (49.136) as

$$\begin{aligned} & i \frac{\partial}{\partial t} \Psi(\mathbf{X}_{N+1}, t) \\ &= \left[H_{N+1} - \frac{i}{c} \sum_{i=1}^{N+1} \mathbf{A}(\mathbf{r}_i, t) \cdot \nabla_i \right. \\ & \quad \left. + \frac{1}{2c^2} \sum_{i=1}^{N+1} \mathbf{A}^2(\mathbf{r}_i, t) \right] \Psi(\mathbf{X}_{N+1}, t), \end{aligned} \quad (49.158)$$

where H_{N+1} is the $(N+1)$ -electron Hamiltonian defined by Eq. (49.3), and \mathbf{X}_{N+1} represents the space and spin coordinates of all $N+1$ electrons defined as in Eq. (49.8).

With the same assumptions made in the reduction of Eqs. (49.136)–(49.139), Eq. (49.152) can be rewritten in the velocity gauge form as

$$\begin{aligned} & i \frac{\partial}{\partial t} \Psi_V(\mathbf{X}_{N+1}, t) \\ &= \left(H_{N+1} + \frac{1}{c} \mathbf{A}(t) \cdot \mathbf{P}_{N+1} \right) \Psi_V(\mathbf{X}_{N+1}, t), \end{aligned} \quad (49.159)$$

where

$$\mathbf{P}_{N+1} = \sum_{i=1}^{N+1} -i\nabla_i \quad (49.160)$$

is the total linear-momentum operator.

The solution of Eq. (49.159) for e–H scattering in a strong laser field at high electron impact energies was considered by Francken and Joachain [178]. They discussed the use of the Born series and the eikonal Born series (EBS) approximations, given by Eq. (49.93), to describe the electron–atom collision and included the dressed wave function of the atomic hydrogen target to first order in the field strength \mathcal{E}_0 . Important effects related to the dressing of the target are the appearance in the cross sections of asymmetries between the absorption and emission of a given number of laser photons, as well as the appearance of new resonance structures in the cross sections.

Early detailed studies of low-energy electron–atom and electron–ion collisions in laser fields include the pioneering work on e–H⁺ collisions by Dimou and Faisal [179]. Collins and Csanak [180] found important resonance effects caused by the field coupling bound states to the continuum, and multichannel quantum defect theory was applied by Zoller and coworkers [181, 182] to study the behavior of Rydberg states in laser fields.

We conclude this section by briefly describing the R -matrix-Floquet method [183] for treating electron collisions with complex atoms and ions in a laser field, based on the R -matrix method discussed in Sect. 49.1.4. In this approach, configuration space is divided into internal and external regions, as in the field-free case. In the internal region,

a further gauge transformation of the field is made to the length gauge, so that the time-dependent Schrödinger equation (49.159) becomes

$$i \frac{\partial}{\partial t} \Psi_L(\mathbf{X}_{N+1}, t) = [H_{N+1} + \mathcal{E}(t) \cdot \mathbf{R}_{N+1}] \Psi_L(\mathbf{X}_{N+1}, t), \quad (49.161)$$

where $\mathbf{R}_{N+1} = \sum_{i=1}^{N+1} \mathbf{r}_i$, and we assume that the electric field $\mathcal{E}(t)$ is given by

$$\mathcal{E}(t) = -\frac{1}{c} \frac{d}{dt} \mathbf{A}(t) = \hat{\epsilon} \mathcal{E}_0 \cos \omega t. \quad (49.162)$$

In order to solve Eq. (49.161), we introduce the Floquet–Fourier expansion [184, 185]

$$\Psi_L(\mathbf{X}_{N+1}, t) = e^{-iEt} \sum_{n=-\infty}^{\infty} e^{-in\omega t} \Psi_n^L(\mathbf{X}_{N+1}). \quad (49.163)$$

Substituting this equation into Eq. (49.161), using Eq. (49.162), and equating the coefficients of $\exp[-i(E + n\omega)t]$ to zero gives

$$(H_{N+1} - E - n\omega) \Psi_n^L + D_{N+1} (\Psi_{n-1}^L + \Psi_{n+1}^L) = 0, \quad (49.164)$$

where we have introduced the operator

$$D_{N+1} = \frac{1}{2} \mathcal{E}_0 \hat{\epsilon} \cdot \mathbf{R}_{N+1}. \quad (49.165)$$

The functions Ψ_n^L can be regarded as the components of a vector Ψ^L in photon space. Equation (49.164) is then written in this space as

$$(\mathbf{H}_F - E\mathbf{I}) \Psi^L = 0, \quad (49.166)$$

where the Floquet Hamiltonian \mathbf{H}_F is an infinite tridiagonal matrix.

In order to solve Eq. (49.166) in the internal region, the components Ψ_n^L are expanded in a basis that, in analogy with Eq. (49.58), has the form

$$\begin{aligned} \Psi_{kn}^L(\mathbf{X}_{N+1}) &= \mathcal{A} \sum_{\Gamma ij} \bar{\Phi}_i^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_N; \hat{\mathbf{r}}_{N+1} \sigma_{N+1}) r_{N+1}^{-1} \\ &\times u_j(r_{N+1}) a_{ijkn}^\Gamma \\ &+ \sum_{\Gamma i} \chi_i^\Gamma(\mathbf{x}_1, \dots, \mathbf{x}_{N+1}) b_{ikn}^\Gamma, \end{aligned} \quad (49.167)$$

where the summation over Γ is required since the total orbital angular momentum L and the total parity π in Eq. (49.9) are no longer conserved. The coefficients a_{ijkn}^Γ and b_{ikn}^Γ are again

determined by diagonalizing $\mathbf{H}_F + \mathbf{L}_b$, where \mathbf{L}_b is an appropriate Bloch operator.

In the external region, the wave function describing the scattered electron is transformed to the velocity gauge, and the corresponding coupled equations are integrated outwards from the internal region boundary for each energy of interest [186]. After a further transformation to the acceleration frame (or Kramers–Henneberger frame [187]), the wave function can be fitted to an asymptotic form to yield the \mathbf{K} -matrix, \mathbf{S} -matrix, and collision cross sections. This approach has been used to calculate laser-assisted electron scattering by H and He atoms [188, 189], and a detailed discussion of the theory is given [190].

Following the rapid development of advanced light sources based, for example, on high-harmonic generation and free-electron lasers, as well as the appearance of intense few-cycle infrared lasers, much effort is currently being devoted to further improving the general description and the accompanying computer programs. Rather than using the Floquet approach for multicycle pulses as described above, it is again necessary to solve the TDSE directly by propagating an initial state under the influence of the laser field and extracting the physically meaningful information using appropriate projection techniques. More information can be found, for example, in [191–196], as well as references therein. In particular, the time-dependent \mathbf{R} -matrix method, originally formulated by *Burke* and *Burke* [197], is now finding practical implementation [198] for atoms and molecules in intense laser fields.

Klaus Bartschat Klaus Bartschat is the Levitt Distinguished Professor of Physics at Drake University. His research focuses on the general theory and computational treatment of electron and photon collisions with atoms and ions, including the direct solution of the time-dependent Schrödinger equation for ultrashort intense laser-matter interactions and the use of the R-matrix (close-coupling) method for electron collisions with complex targets. He is a Fellow of the American Physical Society and was rewarded the Will Allis Prize in 2016.

Jonathan Tennyson Jonathan Tennyson received a PhD from the University of Sussex and after working at the University of Nijmegen and Daresbury Laboratory he moved to UCL. He works on problems involving electron collisions and spectroscopy of molecules with applications to areas including astrophysics and plasma physics. He was elected a Fellow of the Royal Society (London) in 2009.

Phil Burke Phil Burke was Professor of Mathematical Physics at the Queen's University of Belfast (1967–1998). He made significant contributions to the theory of atomic, molecular, and optical physics and played a leading role in developing the theory of resonances in atomic and molecular processes. He received the Guthrie Medal and Prize (1994), the David Bates Prize (2000), and the Will Allis Prize (2012). He was a Fellow of the Royal Society. He passed away in 2019.

Abstract

This chapter summarizes a collection of theoretical techniques collected under the umbrella term “quantum defect theory” (QDT). The simplest and earliest formulations of QDT date back to contributions from Hartree, Ham, and Seaton. This theory was formalized into a comprehensive description of electron collisions with atomic ions by *Seaton*, connecting Rydberg state properties to the behavior of scattering states near ionization thresholds, reviewed comprehensively in [1].

Keywords

multichannel quantum defect theory · frame transformations · smooth reaction matrix · complex resonance · Rydberg states · Fano–Feshbach resonance · autoionization · ultracold collisions

50.1 Overview

Following the initial formulation in the 1960s, the QDT theoretical framework was subsequently generalized to treat atomic and molecular photoabsorption processes involving

e-mail: chgreene@purdue.edu

Rydberg and/or valence electron excitations by *Fano*, *Jungen*, and their collaborators [2–5]. Further generalizations later showed that the ideas of quantum defect theory can be generalized to non-Coulombic long-range Hamiltonians, such as the attractive or repulsive C_4/r^4 long range potential relevant to negative ion photodetachment and ion–atom collisions, or charge-dipole long-range potentials C_2/r^2 relevant in some atomic or negative ion photoabsorption resonances [6–8]. In the modern realm of ultracold atomic collisions occurring at nanokelvin to millikelvin energies, the development of QDT for dipole–dipole interaction potentials C_3/r^3 , or for van der Waals $-C_6/r^6$, has been vital in contributing to advances relating to the behavior and control of degenerate quantum gases [9–13].

50.2 Conceptual Foundation of QDT

The key point of this simplest single-channel form of QDT emerges from the observation that, to an excellent approximation, an electron experiences a simple attractive Coulomb plus centrifugal potential energy, when moved sufficiently far ($r > r_0$) from any atomic ion. That is, if the ion consists of N_c electrons and a nucleus of charge Z , then the long-range potential energy experienced by an electron at $r > r_0$ equals $V(r) \rightarrow -\frac{Z-N_c}{r}$, where r_0 is the Bohr radius. The most common case, historically, is a Rydberg state of a neutral atom, in which case $N_c = Z - 1$; thus the large- r potential energy of the outermost Rydberg electron approaches $-1/r$ at distances beyond a few Bohr radii. The most important initial aspect of any QDT treatment for a long-range Coulomb potential, or any other long-range potential such as C_n/r^n , $n \geq 2$, is to define two linearly independent solutions $f_{\ell\ell}(r)$, $g_{\ell\ell}(r)$ of the radial Schrödinger equation, which have a smooth energy dependence at any finite radius, even for energies crossing a breakup threshold. The resulting characterization of observables in terms of smoothly varying “almost constant” quantities produces a dramatic simplification in the theoretical description, because the observables

such as energy levels, decay widths, and photoabsorption cross sections vary extremely rapidly with energy in the vicinity of ionization thresholds. The mathematical formulation starts from developing a thorough understanding of alternative solutions of the long-range radial Schrödinger equation for a two-body system of reduced mass m , energy ε , orbital angular momentum quantum number ℓ , namely

$$y''_{\varepsilon\ell}(r) + 2m\left(\varepsilon - \frac{C_N}{r^N}\right)y(r) - \frac{\ell(\ell+1)}{r^2}y(r) = 0. \quad (50.1)$$

Solutions $y(r)$ that are both regular at the origin (i.e., $y(0) = 0$) and have an energy-normalized amplitude $\sqrt{\frac{2m}{\pi k}}$ of a real sinusoidal function asymptotically are typically denoted as $f_{\varepsilon\ell}(r)$. In this context, we say that a function $y_{\varepsilon\ell}(r)$ is “energy normalized” in the usual sense, namely that $\int_0^\infty y_{\varepsilon\ell}(r)y_{\varepsilon'\ell}(r)dr = \delta(\varepsilon - \varepsilon')$. An irregular (at $r = 0$) energy-normalized function $g_{\varepsilon\ell}(r)$ is then defined to lag $f_{\varepsilon\ell}(r)$ by $\frac{\pi}{2}$ at large r , and with equal asymptotic amplitude, whereby an energy-normalized eigenfunction of the radial Schrödinger equation with a potential that becomes Coulombic asymptotically ($N = 1$), can simply be written in terms of the non-Coulomb part of the scattering phase shift $\delta_\ell(\varepsilon)$ as

$$y_{\varepsilon\ell}(r) = f_{\varepsilon\ell}(r) \cos \delta_\ell(\varepsilon) - g_{\varepsilon\ell}(r) \sin \delta_\ell(\varepsilon), \quad r > r_0. \quad (50.2)$$

As is discussed at length by *Seaton* [1], these energy normalized solutions (f, g) can be analytically continued rather smoothly to negative energies, by setting $k \rightarrow i\kappa \equiv i/v$, and they are convenient to work with in the sense of quantum defect theory, whereby asymptotic large- r boundary conditions are normally not imposed initially; instead, they are imposed only at the end when observables are computed. In addition to the fact that they are regular or irregular, respectively, at $r = 0$, additional key properties are their asymptotic expansions at positive and negative energies, namely for a unit attractive Coulomb potential,

$$f_{\varepsilon\ell}(r) \rightarrow \begin{cases} \sqrt{\frac{2m}{\pi k}} \sin\left(kr + \frac{1}{k} \ln 2kr - \frac{\ell\pi}{2} + \sigma_\ell(k)\right), & \varepsilon > 0 \\ \sqrt{\frac{m}{\pi\kappa}} [D^{-1}r^{-\nu} e^{\kappa r} \sin \gamma - Dr^\nu e^{-\kappa r} \cos \gamma], & \varepsilon < 0 \end{cases} \quad (50.3)$$

$$g_{\varepsilon\ell}(r) \rightarrow \begin{cases} -\sqrt{\frac{2m}{\pi k}} \cos\left(kr + \frac{1}{k} \ln 2kr - \frac{\ell\pi}{2} + \sigma_\ell(k)\right), & \varepsilon > 0 \\ -\sqrt{\frac{m}{\pi\kappa}} [D^{-1}r^{-\nu} e^{\kappa r} \cos \gamma + Dr^\nu e^{-\kappa r} \sin \gamma], & \varepsilon < 0 \end{cases}, \quad (50.4)$$

where $\sigma_\ell(k) \equiv \arg \Gamma(\ell + 1 - i/k)$, $\gamma \equiv \pi(\nu - \ell)$, $D \equiv \pi^{1/2}(2/\nu)^\nu [\Gamma(\nu - \ell)\Gamma(\nu + \ell + 1)]^{-1/2}$.

50.2.1 Single-Channel Nonrelativistic Quantum Defect Theory

The simplest scenario where QDT is useful is a simple radial potential energy function $V(r)$, which tends asymptotically to an attractive Coulomb potential $-\frac{Z}{r}$. For definiteness in the present discussion, imagine that $V(r) = -\frac{1}{r}$, exactly (to high accuracy), for all $r \geq r_0$. While for many problems this is not strictly satisfied for any finite value of r_0 , it is adequate for most applications to identify a finite r_0 , in practice. This is a reasonable description of the valence electron properties for any atom consisting of an electron that moves outside of a closed-shell ionic core. For this problem, solutions of the radial Schrödinger equation would normally be determined numerically at $r < r_0$, but regardless of the nature of that numerical solution, it will match smoothly in function and derivative to the outer region solution, namely:

$$y_{\varepsilon\ell}(r) \rightarrow f_{\varepsilon\ell}(r) \cos \pi\mu_\ell(\varepsilon) - g_{\varepsilon\ell}(r) \sin \pi\mu_\ell(\varepsilon), \quad r \geq r_0. \quad (50.5)$$

This equation applies both at positive energies where the solution describes scattering or photoionization solutions, and at negative energies where it will represent bound states. Here, $\mu_\ell(\varepsilon)$ is an r -independent constant that corresponds at negative energies to the *quantum defect* of traditional Rydberg state spectroscopy (as we show immediately below). At positive energies, on the other hand, $\pi\mu_\ell(\varepsilon)$ corresponds to the ordinary non-Coulomb part of the scattering phase shift $\delta_\ell(\varepsilon)$. We regard these as synonymous, since *Seaton* [1] has proved that they are equal at the ionization threshold $\varepsilon = 0$. The Rydberg formula is readily derived because the phase-shifted radial solution at an arbitrary negative energy, as written in Eq. (50.5), diverges exponentially at $r \rightarrow \infty$. This divergence occurs unless $\sin \pi(\nu - \ell + \mu_\ell(\varepsilon)) = 0$, which cancels the growing exponential term, i.e., unless $\nu + \mu_\ell(\varepsilon) = n$, an integer, in which case the allowed energies where $y_{\varepsilon\ell}(r)$ is regular at both the origin and at ∞ are quantized to obey

$$\varepsilon_{n\ell} = -\frac{1}{2(n - \mu_\ell)^2}, \quad (50.6)$$

in reduced Hartree energy units. The Hartree energy unit is defined by $E_H = \frac{e^2}{4\pi\varepsilon_0 a_B}$, with the reduced mass scaled value of the generalized Bohr radius given by $a_B = 4\pi\varepsilon_0 \hbar^2 / me^2$. The standard atomic units are defined for an electron in the field of an infinite mass nucleus, where $m = m_e$, and these values are $E_H = 4.359744650(54) \times 10^{-18} \text{ J} = 27.21138602(17) \text{ eV}$, and $a_B = 5.2917721067(12) \times 10^{-11} \text{ m}$. It is often adequate when working at modest levels of precision to use the bare electron mass Hartree energy unit, i.e., with $m = m_e$ in the formula

for the Bohr radius. For high-precision studies, however, the above Rydberg formula of energy levels becomes more precise if the reduced mass of the electron-(atomic-ion) system is used in the formula for the Bohr radius, rather than the bare electron mass. This single-channel quantum defect has a number of simple and desirable properties. One of the most important is that $\mu_\ell(\varepsilon)$ can be expanded into a sum over powers of the energy ε , $\mu_\ell(\varepsilon) \simeq \mu_\ell(0) + \varepsilon\mu'_\ell(0) + \dots$, and for many applications, only the energy-independent constant first term is needed. For an accurate parametrization of the low ℓ experimentally measured Rb Rydberg state energy levels using quantum defect formulas of this type, see [14].

50.2.2 Multichannel QDT

While the single-channel QDT gives a convenient way to relate simple quantities like scattering phase shifts and photoionization matrix elements to discrete state quantum defects and oscillator strengths, the power of the multichannel quantum defect theory (MQDT) yields even more extensive and powerful methods for analyzing complex spectral and collisional phenomena. In this section, the MQDT is described briefly, with a few examples that illustrate the capabilities of this theoretical framework.

An electron in the field of an atomic or molecular ion with many relevant energy levels can reside in a number of alternative channels, i , which collects the set of all the quantum numbers of the combined system of the outermost electron and the ion; typically, this set includes the spin and orbital angular momentum quantum numbers of the Rydberg electron and those of the residual ionic core in an energy eigenstate with energy E_i . For any time-independent quantum calculation performed on a system at total energy E , one can partition all of the fragmentation channels of the system into two groups. The first group is the set of *open channels* for the symmetry being treated, which have summed internal energy levels E_i of the fragmenting constituents that lie below the total energy E at which the calculation is being performed. These channels are energetically open in the sense that it is possible for the system to escape to infinity in them, with positive kinetic energy $E - E_i > 0$, even at infinite separation. All other channels of the system, for which $E - E_i < 0$, are denoted as *closed channels* because there is insufficient energy available for the system to escape to infinity in those channels. Because the energy is too low for the system to fragment in any closed two-body fragmentation channel with threshold energy E_i , its wavefunction component in channel i must decay asymptotically, roughly as $\exp[-\sqrt{2m_i(E - E_i)}r]$. While the total number of closed channels is usually infinite, it can be safely truncated to a finite number, provided that the energy range of interest is not too high. The set of retained closed channels has a further di-

vision into strongly closed and weakly closed channels. In the weakly closed channels, the radial kinetic energy of fragmentation is still positive or at least not too negative at the reaction boundary r_0 , the distance beyond which energy and angular momentum exchanges are negligible. An example illustrates the relevance of the division of channels into open, weakly closed, and strongly closed. Consider the $^1S^e$ states of the neutral helium atom at energy slightly below the energy of the $\text{He}^+(2s, 2p)$ levels. The lone $^1S^e$ channel that is open in this energy range is denoted in QDT as $1s\epsilon s$, whereas there are two weakly closed channels of this symmetry, $2s\epsilon s$ and $2p\epsilon p$. Here, ϵ stands for the outermost electron energy at infinity; $\epsilon_i \equiv E - E_i$, which is slightly negative in the weakly closed channels. The strongly closed channels in this energy range near the $n = 2$ ionization thresholds are all those that are higher, namely, $3s\epsilon s, 3p\epsilon p, \dots 4f\epsilon f$, etc. The use of ϵ in this notation is meant to signify that in quantum defect theory, the energy ϵ of the outermost electron can be either positive or slightly negative. In the i -th channel, the outermost electron has asymptotic kinetic energy $\varepsilon_i \equiv E - E_i$. A key point to keep in mind is that for a system with N open or weakly closed channels at a given total energy E , one expects there to be N linearly independent solutions to the multichannel Schrödinger equation that are well behaved at the origin. One can obtain a set of these N linearly independent solutions in various alternative ways. Popular and effective methods to accomplish this include the Kohn or Schwinger variational principles, while one of the most widely used is a variant of the R -matrix theory. Regardless of the method chosen, the set of N independent solutions can be represented at large electron distances, where the interaction potential is purely Coulombic, as a linear combination of Coulomb functions in every channel. That is, the β -th independent solution of the Schrödinger equation for some specified symmetry and one energy E can be written in the following form, for $r > r_0$,

$$\Psi_\beta = \mathcal{A} \sum_{i=1}^N \Phi_i(\Omega) [f_i(r)I_{i\beta} - g_i(r)J_{i\beta}]. \quad (50.7)$$

Here, \mathcal{A} represents an antisymmetrization operator, $\Phi_i(\Omega)$ is a channel eigenfunction of all spatial and spin degrees of freedom except the radial coordinate of the outermost electron. Note that the constant, energy-dependent matrices $I_{i\beta}$ and $J_{i\beta}$ determined by numerical solution of the Schrödinger equation inside $r < r_0$ are not unique, because right-multiplication by any nonsingular matrix gives an equivalent set of linearly independent solutions. One quite common way to standardize those solutions is to right-multiply by $(I^{-1})_{\beta i'}$, which gives the reaction matrix solutions, whose form at $r > r_0$ is

$$\Psi_{i'}^{(K)} = \mathcal{A} \sum_{i=1}^N \Phi_i(\Omega) [f_i(r)\delta_{ii'} - g_i(r)K_{ii'}]. \quad (50.8)$$

For a time-reversal invariant system with a hermitian Hamiltonian, the reaction matrix K is real and symmetric, which leads to a unitary, symmetric scattering matrix,

$$S = \frac{1 + iK}{1 - iK}. \quad (50.9)$$

For electric dipole photoabsorption processes from an initial state Ψ^{init} to the final states described by the MQDT solutions $\Psi_{i'}^{(K)}$, the cross sections will depend on reduced dipole matrix elements, $d_{i'}^K = \langle \Psi_{i'}^{(K)} || r^{(1)} || \Psi^{\text{init}} \rangle$, which are also normally smooth functions of energy except for isolated poles. (In cases where the poles are problematic or inconvenient to deal with, an alternative formulation of the MQDT equations in terms of nonsingular eigenchannel quantum defects μ_β of the K -matrix, its orthonormal eigenvectors $U_{i\beta}$, and reduced eigenchannel dipole elements d_β , whose physical interpretation was stressed by *Ugo Fano*, [15] can be convenient to work with instead of $\{K, d^K\}$ directly. See, for instance, Eqs. 23–32 of [4].) Everything written above in this paragraph should look familiar to the reader conversant with ordinary scattering theory, but, in fact, there is a fundamental difference with quantum defect theory. In ordinary scattering theory, the sum over channels i would only include the energetically open channels, but in quantum defect theory, this sum is extended to include (weakly) closed channels as well.

The inclusion of closed channels ($i \in Q$) has important mathematical and physical implications. Most importantly, one recalls that (f_i, g_i) are exponentially divergent at $r \rightarrow \infty$, which would seem initially undesirable. However, this exponential growth will be eliminated later in the calculation of observables, as will be demonstrated shortly. Nevertheless, one sometimes refers to this intermediate quantity, the MQDT S -matrix, as the “unphysical” or “single-pass” S -matrix. The reason for introducing this intermediate quantity is because it normally has far less energy dependence than the physical scattering matrix in the open channel subspace, which we denote as S^{phys} . This will be demonstrated with an example later, but first we show the rest of the steps needed to calculate scattering or photoabsorption observables using this smooth information in K or S . The asymptotic forms of the MQDT solutions $\Psi_{i'}^{(K)}$, at an energy E where the channel space includes both open ($\varepsilon_i > 0, i \in Q$) and closed ($\varepsilon_i < 0, i \in P$) channels, can be written in a partitioned matrix notation as follows

$$\begin{bmatrix} \Psi_{i \in P}^{(K)} \\ \Psi_{i \in Q}^{(K)} \end{bmatrix}_{i'} \xrightarrow{r \rightarrow \infty} \begin{bmatrix} \sqrt{\frac{2m}{\pi k_i}} \left[\sin\left(k_i r + \frac{1}{k_i} \ln r + \eta_i\right) \delta_{ii'} \right. \\ \left. + \cos\left(k_i r + \frac{1}{k_i} \ln r + \eta_i\right) K_{ii'} \right] \\ \sqrt{\frac{m}{\pi k_i}} D_i^{-1} r^{-\nu_i} e^{\kappa_i r} \left[\sin \pi(\nu_i - \ell_i) \delta_{ii'} \right. \\ \left. + \cos \pi(\nu_i - \ell_i) K_{ii'} \right] + \mathcal{O}(r^{\nu_i} e^{-\kappa_i r}) \end{bmatrix}, \quad (50.10)$$

where $\eta_i = \frac{1}{k_i} \ln 2k_i - \frac{\ell_i \pi}{2} + \sigma_{\ell_i}(k_i)$. This last expression shows the unphysical exponential divergence of the “energy-smooth” K -matrix solutions at $r \rightarrow \infty$. But since the exponentially growing terms are explicitly displayed, it is simple to analytically find the $N \times N_o$ -matrix of constants needed to right-multiply the radial solution matrix to obtain the “physical” K -matrix or S -matrix solutions,

$$\Psi_j^{(\text{phys})} = \sum_{i'} \Psi_{i'}^{(K)} B_{i',j}.$$

Specifically, with a line or two of algebra, we can see that if we write $B = \begin{pmatrix} B_{PP} \\ B_{QP} \end{pmatrix}$, then to have a physical K -matrix solution in the open channels only, with exponential decay in the closed channels asymptotically, we require $B_{PP} = 1_{PP}$, and $(B_{QP})_{i',j} = -(\tan \gamma + K_{QQ})^{-1} K_{QP}$, where $\gamma = \pi(\nu - \ell)$ is the diagonal matrix of negative energy phase parameters. Thus, we have algebraically enforced the required exponential decay in the closed channels, giving the (smaller) $N_o \times N_o$ physical reaction matrix

$$K^{\text{phys}} = K_{PP} - K_{PQ}(\tan \gamma + K_{QQ})^{-1} K_{QP}, \quad (50.11)$$

one of the most fundamental equations of MQDT. In particular, the inverted matrix in the second term, which becomes nearly singular at closed channel resonances, displays the expected resonance structure explicitly from the infinite number of Rydberg resonances that are attached to closed-channel thresholds. Moreover, if we denote

$$d^{K,\text{phys}} = d_P^K - d_Q^K(\tan \gamma + K_{QQ})^{-1} K_{QP} \quad (50.12)$$

as the vector of reduced dipole matrix elements connecting an unpolarized initial state of total angular momentum J_0 to the final states of angular momentum J described by this K^{phys} -matrix, then the total photoionization cross section at frequency ω is given in atomic units by

$$\sigma^{\text{tot}} = \frac{4\pi^2 \omega \alpha}{3(2J_0 + 1)} d^{K,\text{phys}} \cdot (1 + K^{\text{phys}} \cdot K^{\text{phys}})^{-1} \cdot d^{K,\text{phys}}. \quad (50.13)$$

The simplest nontrivial example of MQDT is a two-channel system with two ionization thresholds at energies E_1, E_2 . For such a system, there are three energy ranges of interest, (i) $E < E_1 < E_2$, where both channels are closed, and only discrete bound states exist; (ii) $E_1 < E < E_2$ where one channel is open and one is closed, and all states have a mixed continuum and bound state character (autoionization region, or Fano–Feshbach resonance region); and (iii) $E_1 < E_2 < E$ where both channels are open, and there are only scattering processes such as $1 \rightarrow 2$. In the discrete region (i), there exists only a set of discrete energy levels for which the wavefunction decays exponentially as $r \rightarrow \infty$ in both channels. The allowed energies are determined by a bound state quantization condition that enforces the exponential decay, and reads

$$\det(\tan \gamma + K) = 0. \quad (50.14)$$

Fig. 50.1 Lu-Fano plot of the $1P^o$ bound levels of Sr, associated with the mixing of the $5snp$ and $4dnp$ channels. Taken from Vaillant et al. [17]

In general, these roots must be found by a numerical search, and it must be remembered that there is a constraint relating the effective quantum numbers ν_1 and ν_2 , namely $E = E_1 - \frac{1}{2\nu_1^2} = E_2 - \frac{1}{2\nu_2^2}$. The roots of the determinantal equation obey a double periodicity in ν_1 and ν_2 modulo an integer, which is strictly obeyed in the limit that the reaction matrix is energy independent. This double periodicity is emphasized in a popular representation of bound state energy levels for systems with two closed channel thresholds, which has come to be called the “Lu-Fano plot” [16]. The basic idea is to plot ν_1 or $\mu_1 \pmod{1}$ in the most weakly closed channel as a function of ν_2 , and then one sees that all levels fall on a single universal curve in this diagram, defined by the roots of the determinantal Eq. (50.14). To find any specific level one must enforce also the constraint equation relating ν_1 and ν_2 through energy conservation. Fig. 50.1 shows an example of a Lu-Fano plot for bound $1P^o$ energy levels of atomic Sr lying below the $5s$ ionization threshold.

In the autoionization region (ii), there is one channel (#2) that is energetically closed and one channel (#1) that is open. As an example of the type of spectrum you can expect in this region of a two-channel problem, consider the following K -matrix (dimensionless) and reduced dipole matrix elements (in a.u.).

The following model problem illustrates the value of having the multichannel Rydberg structure “built-in” to the theoretical description. Consider a system with three ionization thresholds at energies $E_i = \{0, 0.10, 0.105\}$ a.u., and an energy-independent 3×3 K -matrix. That symmetric K -matrix is defined by six independent real numbers, which

have been chosen arbitrarily for this illustrative example to equal

$$K = \begin{pmatrix} 1.4 & 1.0 & 0.5 \\ 1.0 & 0.9 & 1.4 \\ 0.5 & 1.4 & 3.8 \end{pmatrix}. \quad (50.15)$$

The atomic photoionization spectrum is determined by this K -matrix, plus three independent electric dipole matrix elements, chosen for this model to equal $\{d_1^K, d_2^K, d_3^K\} = \{3.0, 4.0, 5.0\}$. Thus, in the notation of Eq. 50.13, we would say that in this energy range, where channel 1 is open and channels 2 and 3 are weakly closed, the lone channel belonging to the P subspace is channel 1, while channels 2 and 3 belong to the Q subspace. Hence, at energies just below the threshold E_2 , there is only a single open channel (#1) with a complicated energy-dependent elastic scattering (physical) phase shift determined analytically, using Eq. 50.11 above, to be

$$\tan \delta \equiv K_{11}^{\text{phys}} = K_{11} - \frac{K_{13}K_{31}}{K_{33} + T_3} - \frac{\left(K_{12} - \frac{K_{12}K_{32}}{K_{33} + T_3}\right)^2}{K_{22} + T_2 - \frac{K_{23}K_{32}}{K_{33} + T_3}}, \quad (50.16)$$

where $T_i \equiv \tan(\pi\nu_i)$.

In the absence of channel interactions, a multichannel Rydberg spectrum would show a separate Rydberg series converging to every ionization threshold. But when short-range channel interactions are taken into account, as they are via the MQDT K -matrix, a complicated series of interacting resonances that mutually perturb each other in their energy eigenvalues and autoionization linewidths. In the absence of channel 3, one would observe a simple regular Rydberg series of levels converging to the threshold E_2 , with autoionization linewidths decreasing with the principal quantum number n in proportion to $(n - \mu_2)^{-3}$. But the presence of an interacting Rydberg series attached to threshold E_3 produces qualitative modifications of the spectrum and phenomena such as Fano linewidth “q-reversal” and “near-zero-width” states. One of the latter is clearly apparent in the model photoabsorption spectrum shown in Fig. 50.2 that is blown up near the complex resonance that modifies the Rydberg series all the way from about $\nu_2 \approx 25$ to $\nu_2 \approx 45$.

Semi-Empirical MQDT Versus Ab Initio MQDT

Historically, some of the early uses of MQDT were focused on developing models that could concisely characterize energy levels, autoionization widths, and bound and continuum oscillator strengths. When the number of channels N is not too large, say, less than five or six, for a given overall symmetry (total angular momentum, parity, etc.), then it is often possible to simply perform a least squares fit and determine an optimized $N \times N$ K -matrix and a set of N electric dipole

Fig. 50.2 Example photoabsorption spectrum for the three-channel model in the vicinity of a complex resonance, in the energy range below the second ionization threshold. This spectrum can be readily recomputed by the reader, for instance, by implementing Eqs. 50.12 and 50.13 with $\gamma = \pi \nu_i$ a 2 by 2 diagonal matrix in the closed-channel subspace $i = 2, 3$. Recall that the effective quantum number ν_i is defined only in the closed channels, where it equals $\nu_i = [2(E_i - E)]^{-1/2}$

matrix elements connecting the K -matrix states to an initial state whose photoabsorption is of interest. This would involve fitting $N(N + 1)/2 + N$ constants, if no theoretical input is used to reduce the number of parameters, and if their energy dependence is negligible over the energy range being fitted. Many early studies were carried out that determined these short-range MQDT parameters by fitting, as in [18], which gave fitted reaction matrices and dipole matrix elements that any experimentalist or theorist could use to accurately describe complex multichannel Rydberg spectra, e.g., for the rare gas atoms or for the alkaline earth metal atoms [19]. Other fits were carried out for the spectra of atomic silicon in a similar manner [20, 21] and, more recently, for several different symmetries of atomic strontium, by [17]. Armed with these fitted K -matrices and the experimentally known ionization thresholds, this allows immediate calculation of an infinite number of spectral levels, autoionizing resonance positions and widths, and spectral lineshapes.

When the number of channels grows much larger than about five or six, however, the fitted K -matrices become far more difficult to determine from any manageable data set, and moreover, the fits tend to be nonunique. For multichannel atomic Rydberg spectra, it is then advantageous to directly compute the smooth MQDT information through *nearly ab initio* computations, followed by small empirical adjustments if extremely high accuracy is required in any particular application. For instance, to describe the photoionization of the atomic barium ground state at energies up to the 6p threshold, this involves determination of a 13×13 reaction matrix and 13 dipole amplitudes, which amounts to

a total of 104 parameters. Various methods for computing the MQDT parameters from first principles have been developed and applied over the years, including the Fano–Lee iterative eigenchannel R-matrix theory, reformulated as a noniterative variational R-matrix treatment by a few different groups, as was reviewed in [22] with applications to atoms in several different columns of the periodic table. Another successful treatment used the relativistic random phase approximation to compute the MQDT K -matrices needed to describe Rydberg spectra in each of the rare gas atoms from Ne to Xe; that approach was developed by Johnson and coworkers, who in [23] tabulated the MQDT information needed to describe $J^\pi = 1^-$ Rydberg bound and autoionizing states to near-spectroscopic accuracy.

50.2.3 Molecular Ionization Channels Treated by the Rovibrational Frame Transformation

The starting point of any multichannel quantum defect calculation usually starts with a decision about which fragmentation channels are to be treated among the “open or weakly closed” set. Usually, all other channels are declared to be “strongly closed” in the energy range being studied, meaning that the enlarged or “unphysical” reaction matrix would have a dimension equal to the number of open or weakly closed channels for the specified symmetry being considered. For singly excited Rydberg states of a molecule such as H_2 , the ionization channels $|i\rangle$ (ignoring fine and hyperfine structure) would be characterized by rovibrational eigenstates $|v_i(N_i^+ \ell)JM\rangle$ of the molecular ion H_2^+ coupled to the quantum numbers of the angular (ℓ) and spin degrees of freedom of the outermost electron. We focus here on the spatial wavefunction of the singlet ungerade channels (omitting the singlet spinor common to all following expressions), which are predominantly p -waves ($\ell = 1$), and for a specific total angular momentum (J) and projection (M). The ionization threshold for channel $|i\rangle$ occurs at an energy E_i . Owing to the small rotational and vibrational spacings, the set of ionization thresholds E_i in a molecule are comparatively dense compared to simple atoms. Consequently, most MQDT treatments in molecules have a rather large number of channels in the reaction matrix K discussed above, e.g., 20–100 channels is not uncommon for diatomic molecules, and for polyatomics such as H_3 , the dimension of K is usually at least an order of magnitude larger. The structure of the reaction matrix K can then be represented as $K_{ii'} = \langle v_i(N_i^+ \ell)JM | \hat{K} | v_{i'}(N_{i'}^+ \ell)JM \rangle$, and once $K_{ii'}$ are known, and once the set of transition dipole matrix elements $d_{i'g}$ connecting these final states to the molecular ground state are known, the standard formulas of MQDT presented

above describe the ground state photoabsorption spectra over a wide range of energies.

Determination of this rather large amount of information contained in $K_{i'g}$ and $d_{i'g}$ might seem a daunting challenge, however, as there are at least dozens of interacting channels, and those channel interactions are known to be quite strong for low ℓ . In an exact theory, determination of $\{K_{i'g}, d_{i'g}\}$ would require solution of a large system of coupled equations, which has been formulated in principle as a “rovibrational close coupling theory” but rarely implemented in practice. Instead, the frame transformation approximation devised by Fano, Jungen, and their collaborators permits an effective and simple solution. This approximation is based on the Born–Oppenheimer separation of the electronic and nuclear motions. The idea is that the short-range electron reaction operator K should be very nearly diagonal in a representation with a fixed angular momentum projection on the internuclear axis (Λ) and with a fixed value of the internuclear distance (R). In physical terms, the conservation of R in a short-range collision follows because the electron zips in and out of the short-range reaction volume so fast that the nuclei do not have time to move appreciably. This approximation identifies the structure of the reaction matrix in the $|R, \ell \Lambda\rangle$ representation as $\langle R, \ell \Lambda | \hat{K} | R', \ell \Lambda' \rangle \simeq \delta(R - R') \delta_{\Lambda \Lambda'} \tan \pi \mu_{\ell \Lambda}(R)$. Here, $\mu_{\ell \Lambda}(R)$ is the body-frame quantum defect function that can be extracted from accurate potential curves $U_{n\ell \Lambda}(R)$ of neutral Rydberg states computed in *ab initio* quantum chemistry, and from the ionic potential curve $U^+(R)$, through the Rydberg formula at each R , i.e., in a.u.,

$$U_{n\ell \Lambda}(R) - U^+(R) \equiv -\frac{1}{2[n - \mu_{\ell \Lambda}(R)]^2}. \quad (50.17)$$

As written here, the weak n -dependence of the fixed-nuclei quantum defect function has been neglected, although in more sophisticated versions of this rovibrational frame transformation theory, it can also be incorporated into the theory. The main upshot is that the spectroscopy and scattering observables can be determined to an excellent approximation by now solving the MQDT equations on an arbitrarily fine energy mesh, using this reaction matrix computed by simple quadrature,

$$K_{i'g} = \sum_{\Lambda} \int dR \langle v_i(N_i^+ \ell) JM | R, \ell \Lambda \rangle \times \tan \pi \mu_{\ell \Lambda}(R) \langle R, \ell \Lambda | v_{i'}(N_{i'}^+ \ell) JM \rangle, \quad (50.18)$$

using the well-known transformation between the two representations, namely the eigenchannel ($|R, \ell \Lambda\rangle$, in Hund’s case b), and the fragmentation channel ($|v_i(N_i^+ \ell) JM\rangle$, in Hund’s case d)

$$\langle v(N^+ \ell) JM | R, \ell \Lambda \rangle = \chi_v^{(N^+)}(R) \langle N^+ | \Lambda \rangle^{(\ell J)}. \quad (50.19)$$

(A more robust singularity-free version of Eq. (50.18) that avoids divergences of the tangent functions can be formulated instead in terms of the $\sin \pi \mu_{\ell \Lambda}(R)$ and $\cos \pi \mu_{\ell \Lambda}(R)$ matrix elements.) Here, $\chi_v^{(N^+)}(R)$ is an ionic vibrational wavefunction, while the angular frame transformation coefficient relating Hund’s case d to b is known to be given in terms of a Clebsch–Gordan coefficient, e.g., in H_2 ,

$$\langle N^+ | \Lambda \rangle^{(\ell J)} = (-1)^{J+\Lambda-N^+} \sqrt{2 - \delta_{\Lambda,0}} \langle (\ell J) N^+ 0 | \ell - \Lambda, J \Lambda \rangle. \quad (50.20)$$

Examples of the power of this method, and the simplicity of the implementation, can be found in [24, 25]. In Fig. 50.3 shown here, the HD photoionization spectrum is plotted in a narrow energy range that is dominated by three-channel physics, and the qualitative resemblance to the three-channel model spectrum above is readily apparent. The ability of the rovibrational frame transformation theory, in combination with MQDT, to describe a complex experimental photoabsorption spectrum is also evident in Fig. 50.3. In addition to solving problems of molecular photoabsorption, in the presence of autoionization and predissociation, this basic formulation has been adopted to treat scattering processes, such as rotational and vibrational excitation of molecules, as well as dissociative recombination. Extensions of these methods to include the effects of hyperfine coupling have also been implemented by *Jungen, Merkt*, and coworkers, [26–28], although this involves more complexity in the angular momentum algebra, as one might expect.

Length limitations do not permit a discussion of a key extension to frame transformation theory, namely the idea of the *local* frame transformation that is needed when a change of coordinates is required. This issue arises, for instance, for the theoretical description of electric field effects on photoabsorption spectra. A mostly analytical theory, originally formulated by *Fano and Harmin*, was later improved by *Giannakeas et al.* [30–33]. The theory involves a spherical-to-parabolic coordinate transformation of the short-range spherical reaction matrix of MQDT, and using related information it can obtain sub-MHz accuracy on Stark-shifted levels of multichannel atoms and molecules.

50.2.4 Ultracold Atom–Atom Collisions in MQDT

One of the most exciting developments in ultracold physics in recent decades has been the demonstration of controllable atom–atom scattering lengths and many-body interactions via magnetic (and other) Fano–Feshbach resonances. [34] Quantum defect theory has been generalized to effectively describe atom–atom van der Waals and many other different types of long-range interactions [6–8, 10, 35] going

Fig. 50.3 Photoionization spectrum of the HD molecule in its ground rovibrational state, in the energy range that exhibits a complex resonance. Shown are both the experimental measurement of [29] and the result of a rovibrational frame transformation theory calculation with no adjustable parameters

far beyond the original scope [1], which was limited to Coulombic long-range potentials. One of the most fruitful generalizations has been to treat ultracold collisions in the sub-mK range of temperatures, which can give a convenient parameterization of field-dependent S -wave scattering lengths $a(B) \equiv -\lim_{k \rightarrow 0} \frac{\tan \delta_{\ell=0}}{k}$ and P -wave scattering volumes $\mathcal{V}(B) \equiv -\lim_{k \rightarrow 0} \frac{\tan \delta_{\ell=1}}{k^3}$. In ultracold physics, e.g., relevant to Bose–Einstein condensation (BEC) and degenerate Fermi gases (DFG), it is particularly crucial to accurately describe the field-dependent Fano–Feshbach resonances, and this can be treated compactly using generalized MQDT [9, 10, 13, 35].

When quantum defect theory is generalized to handle a non-Coulombic long-range potential $v^{LR}(r)$, a first key step is to identify a pair of independent solutions $\{f_{\ell}^0(\varepsilon, r), g_{\ell}^0(\varepsilon, r)\}$ to the radial Schrödinger equation of that potential, which are analytic functions of the energy ε near the potential asymptote ($\varepsilon = 0$). These need not be {regular, irregular}, respectively. Analyticity in ε is usually achieved by choosing them to be energy independent in the small r limit. These issues, and other details such as the modifications of the usual Wigner threshold laws in the presence of long-range power law potentials, are discussed in [10]. Figure 50.4 gives one simple example of the power of MQDT in the context of ultracold atom–atom collisions, specifically for $^{85}\text{Rb} - ^{85}\text{Rb}$ s -wave collisions in the $f = 2, m_f = -2$ state. In the range of energies and magnetic fields shown, the

Fig. 50.4 The S -wave scattering length between two ^{85}Rb atoms, each in their $f = 2, m_f = -2$ state, is shown as a function of energy for three different magnetic fields, close to the broad Fano–Feshbach resonance at $B_{\text{res}} = 155\text{G}$. These curves are all computed using multi-channel quantum defect theory (MQDT), with a field-independent and energy-independent reaction matrix that was obtained using the methods described in [9]

physics can be described accurately using a 5 by 5 reaction matrix K that is independent of energy and field strength. The reaction matrix in this case was determined by solving the five coupled radial Schrödinger equations with a finite-element R-matrix method. Note that over the energy range shown, there is only one energetically open collision chan-

nel, and for this symmetry there are four closed channels, which are responsible for the Fano–Feshbach resonance apparent in Fig. 50.4.

Abstract

The positron is the antiparticle of the electron, having the same mass but opposite charge. Positrons undergo collisions with atomic and molecular systems in much the same way as electrons do. Thus, the standard scattering theory for electrons can also be applied to positron scatter-

ing. However, there are a number of important differences from electron scattering, which we outline below.

Since the positron is a distinct particle from the atomic electrons, it cannot undergo an exchange process with the bound electrons during a collision, as is possible with electrons. Thus, the nonlocal exchange terms that arise in the description of electron scattering are not present for positrons. This leads to a simplification of the scattering equations from those for electrons. However, there are scattering channels available with positron scattering that do not exist with electrons. These are dealt with in Sect. 51.1.

Historically, beams of low-energy positrons were difficult to obtain and, consequently, there is considerably less experimental data available for positrons than for electrons. This was particularly true for quantities that required large incident positron fluxes, such as differential scattering cross sections and coincidence parameters. The recent development of cold trap-based positron beams with high resolution and high brightness by the San Diego group [1] has enabled significant progress in experimental positron scattering, which is discussed in Sect. 51.3.

Throughout this chapter we will employ atomic units unless otherwise noted.

51.1 Scattering Channels

Positrons colliding with atomic and molecular systems have the same scattering channels available as for electrons, viz., elastic, excitation, ionization, and for molecules, dissociation. However, two channels exist for positrons that do not exist for electrons, viz., positronium formation and annihilation.

51.1.1 Positronium Formation

Positronium, a bound state of an electron–positron pair (Chap. 28), can be formed during the collision of a positron with an atomic or molecular target. The positronium *atom* (Ps) can escape to infinity leaving the target in an ionized state with a positive charge of 1. Thus, this process can be difficult to distinguish experimentally from direct ionization, where both the incident positron and the ionized electron are asymptotically free particles. The positronium atom can exist in its ground state or in any one of an infinite number of excited states after the collision. These states form two series; a singlet series ($S = 0$) referred to as parapositronium (*p*-Ps) and a triplet series ($S = 1$) referred to as orthopositronium (*o*-Ps). The level structure of both these series is, to order α^2 , where α is the fine-structure constant, identical to that of hydrogen, but with each level having half the energy of the corresponding hydrogenic state.

Positronium formation is a rearrangement channel, and thus, is a two-center problem. Because positronium is a light particle, having a reduced mass one-half that of an electron, the semiclassical type of approximations used in ion–atom collisions (Chap. 53) are not applicable here. We will discuss various theoretical approaches to this process in Sect. 51.2 and give references to experimental results in Sect. 51.3.

Positronium formation in the ground state has a threshold that is 1/4 of a Hartree (6.80285 eV) below the ionization threshold of the target. This means that it is normally the lowest inelastic channel in positron scattering from neutral atoms. For atoms with a small ionization potential, such as the alkalis, this channel is always open. The energy range between the positronium threshold and the first excited state of the atom is known as the Ore gap. In this range, positronium formation is the only possible inelastic process.

51.1.2 Annihilation

Annihilation is a process in which an electron–positron pair is converted into two or more photons. It can occur either directly with a bound atomic electron or after positronium formation has taken place. The direct annihilation cross section for a positron of momentum k colliding with an atomic or molecular target can be written as [2]

$$\sigma_a = \frac{\alpha^3 Z_{\text{eff}}}{k} (\pi a_0^2), \quad (51.1)$$

where Z_{eff} can be thought of as the effective number of electrons in the target with which the positron can annihilate. If $\Psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N, \mathbf{x})$ is the wave function for the system of a positron, with coordinate \mathbf{x} , colliding with an N -electron

target, then

$$Z_{\text{eff}} = \sum_{i=1}^N \int d\mathbf{r}_1 d\mathbf{r}_2 \dots d\mathbf{r}_N |\Psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N; \mathbf{r}_i)|^2. \quad (51.2)$$

While this formula can be naively derived by assuming that the positron can only annihilate with an electron if it is at the identical location, it actually follows from a quantum electrodynamical treatment of the process [3]. If the wave function Ψ is approximated by the product of the undistorted target wave function times a positron scattering function $F(\mathbf{x})$, then

$$Z_{\text{eff}} = \int d\mathbf{r} \rho(\mathbf{r}) |F(\mathbf{r})|^2, \quad (51.3)$$

where ρ is the electron number density of the target. Thus, in the Born approximation, where F is taken as a plane wave, Z_{eff} simply becomes the total number of electrons Z in the target. However, a pronounced enhancement of the annihilation rate in the vicinity of the Ps formation threshold due to virtual Ps formation was predicted [4, 5]. Subsequently, the Born approximation was shown to be grossly inadequate by the San Diego group, who found annihilation rates (Z_{eff}) at room temperature that are an order of magnitude larger for some atoms and even up to five orders of magnitude larger in large hydrocarbon molecules. Furthermore, there is evidence that only the outer shell of electrons takes part in the annihilation process. Two mechanisms have been proposed in order to explain these large values for Z_{eff} . One involves the enhancement of the direct annihilation process below the Ps formation threshold due to the attractive nature of the positron–electron interaction, which increases the overlap of positron and electron densities in the atom or molecule. The second mechanism is referred to as resonant annihilation, which occurs after the positron has been captured into a Feshbach resonance, where the positron is bound to a vibrationally excited molecule. A summary of the above results can be found in the review article by *Gribakin et al.* [6].

When a positron annihilates with an atomic electron, the most likely result is two 511 keV photons, if the positron–electron pair are in a singlet spin state (parapositronium). In the center-of-mass frame of the pair, the photons are emitted in opposite directions to conserve momentum. However, in the laboratory frame, the bound electron has a momentum distribution which is reflected in the photon directions not being exactly 180 degrees apart. This slight angular deviation, called the angular correlation, can be measured and gives information about the momentum distribution of the bound electrons. This quantity is given by [3]

$$S(\mathbf{q}) = \sum_{i=1}^N \int d\mathbf{r}_1 \dots d\mathbf{r}_{i-1} d\mathbf{r}_{i+1} \dots d\mathbf{r}_N \times \int d\mathbf{r}_i d\mathbf{x} e^{i\mathbf{q} \cdot \mathbf{x}} |\Psi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N; \mathbf{x}) \delta(\mathbf{r}_i - \mathbf{x})|^2, \quad (51.4)$$

where \mathbf{q} is the resultant momentum of the annihilating pair. In evaluating this quantity, the positron is assumed to be thermalized in the gas before undergoing annihilation. Experimentally, only one component of \mathbf{q} is measured, so that $S(\mathbf{q})$ is integrated over the other two components of the momentum to obtain the measured quantity. The spin triplet component of an electron–positron pair (ortho-positronium) can only decay with the emission of three or more photons that do not have well-defined energies. This is a much less probable process than the two-photon decay from the singlet component.

51.2 Theoretical Methods

The basic theoretical approaches to the calculation of positron scattering from atoms and molecules were originally developed for electron scattering and later applied to the positron case. Thus, we emphasize here only the differences that arise between the electron and positron cases, both in the theoretical formulations, and in later sections, in the nature of the results.

The lowest-order interaction between a free positron and an atomic or molecular target is the repulsive static potential of the target

$$V_s = \langle \psi_0 | V | \psi_0 \rangle, \quad (51.5)$$

where ψ_0 is the unperturbed target wave function, and V is the electrostatic interaction potential between the positron and the target. Since this interaction has the opposite sign from that for electron scattering, the static potential also has the opposite sign in these two cases. On the other hand, the next higher-order of interaction is polarization, which arises from the distortion of the atom by the incident particle. If we represent this distortion of the target to first order by the wave function ψ_1 , as in the polarized-orbital approximation, for example, then the polarization interaction can be represented by the potential

$$V_p = \langle \psi_0 | V | \psi_1 \rangle. \quad (51.6)$$

This potential is attractive for both positron and electron scattering and has an asymptotic form with leading term $-\alpha_d/2r^4$, where α_d is the static dipole polarizability (Sect. 24.2.3) of the target. Thus, the static and polarization potentials for positron scattering from ground state systems are of opposite sign and tend to cancel one another. This leads to very different behavior from the electron case where they are of the same sign. In particular, the elastic scattering cross sections for positron scattering from an atom are much smaller than for electron scattering, and the phase shifts (Sect. 49.1.1) have very different magnitudes and dependencies on energy. This is illustrated for the case of scattering from helium in Fig. 51.1, where the results of the highly ac-

Fig. 51.1 Total elastic cross sections for electron (*dashed line*) and positron (*solid line*) from helium atoms [8, 10, 11]. The higher-order phase shifts were calculated from effective range theory (Sect. 49.1.1)

curate variational calculations for scattering by electrons and positrons are shown. There is a corresponding difference in sign between the electron and positron s -wave phase shifts for very small values of the incident momentum. In fact, the positron phase shift goes through zero, which leads to the Ramsauer minimum in the positron total cross section, as shown in Fig. 51.1. The large difference in magnitudes between the electron and positron s and p -wave phase shifts leads to the large difference in the total elastic cross sections, as shown [7–9].

Higher-order terms in the interaction potential may also give important contributions to scattering cross sections. For a detailed discussion, see the article by *Drachman and Temkin* [12].

A simple potential scattering calculation using the sum of the static and polarization potentials, but without the exchange terms that are present for the electron case, can be applied to elastic scattering calculations for closed shell systems (Sects. 51.3.1, 51.3.2). The potentials defined above can also be used in a distorted-wave approximation (Chap. 49), which can be applied to excitation and ionization by positron impact. Once again, the complicated exchange terms that arise in electron scattering are absent here [13].

For positrons with high enough incident energies (≈ 1 keV), the first Born approximation will become valid (Chap. 49). Since the first Born approximation is independent of the sign of the charge of the incident particles, this indicates that as the incident energy increases, the corresponding cross sections for electron and positron scattering will eventually merge. From flux conservation arguments, this means that the positronium formation cross section will rapidly decrease as the incident energy increases. In

fact, from experimental measurements, the total cross sections (summed over all possible channels) for electron and positron scattering appear to merge at a much lower energy than the cross sections for individual channels [14]. More elaborate calculations for high energy scattering have been carried out in the eikonal-Born series [15] (Chap. 49). These approximations allow for both polarization and absorption (i.e., inelastic processes) and yield good agreement with elastic experimental measurements of differential cross sections at energies above 100 eV. A detailed analysis [9, 15] of the various contributions to the scattering indicates that absorption effects due to the various open inelastic channels play a much more important role here than for electron scattering.

A more elaborate treatment of positron scattering is based on the close-coupling approximation (Chap. 49), where the wave function for the total system of positron plus target is expanded using a basis set comprised of the wave functions of the target. Once again, there are no exchange terms involving the positron and, in principle, a complete expansion including the continuum states of the target would include the possibility of positronium formation. However, such an expansion is not practicable if one wants to calculate explicit cross sections for positronium formation. Even in cases where such cross sections are not required, the considerable effect that the positronium formation channels can have on the other scattering cross sections is best included by a close-coupling expansion that includes terms representing positronium states plus the residual target ion. There is a problem of double counting of states in such an expansion but, in practice, this does not appear to be a problem if the number of states in the expansion is not large. Also, in many cases, additional pseudo states have to be included in the expansion in order to correctly represent the long-range polarization interaction.

A close-coupling expansion including positronium states is a two-center problem, i.e., it includes the centers of mass of both the target and the positronium states. This means that one is faced with a problem of considerable computational complexity [16–21].

Another way to take into account the effects of open inelastic channels without the complications of a full close-coupling approach is to use optical potentials. These are often based on a close-coupling formalism [9, 22] and lead to a complex potential, the real part of which represents distortions of the target (such as polarization), while the imaginary part allows for absorption (i.e., flux into open channels not explicitly represented). Such an approach was developed by *Chen et al.* [23] and applied to the noble gases [24]. Recently, a simple approach based upon an optical potential model, yielded good results for the positronium formation cross section in the noble gases [25].

Bray and Stelbovics [26] applied the convergent close-coupling (CCC) method to the scattering of positrons from

atoms. This method includes contributions from the continuum states of the target and sufficient terms in the expansion are included to ensure numerical convergence. Positronium states have been included via pseudostates for positron scattering with helium [27]. A single-center adiabatic-nuclei version has been used for positron scattering with molecular hydrogen [28].

The variational method (Chap. 49) uses an analytic form of trial wave function to represent the total system. The parameters of this analytic function are determined as part of the method. Given a trial wave function with sufficient flexibility and a large enough number of parameters, essentially exact results can be obtained in the elastic energy range and the Ore gap. Because the complexity of the trial function increases as the square of the number of electrons in the target, only positron scattering from hydrogen, helium and lithium, and the hydrogen molecule have been treated by this method to date [10, 29, 30].

Many-body theory has been applied to positron scattering from the noble gases below the positronium formation threshold. Of particular importance is the ability of many-body theory to account for positron–atom and electron–positron correlations, which have a large influence on both the scattering dynamics and the annihilation rate. Many-body theory has produced very good agreement with the most recent experimental results for elastic differential scattering [31].

In the case of direct ionization, there appears to be quite distinct threshold behavior of the cross sections for electron and positron collisions. For electrons, the Wannier threshold law (Sect. 56.3.1) has an exponent of 1.127, while a similar analysis for positrons [32] yields an exponent of 2.651. However, the existence of the positronium formation channel leaves in question whether this analysis will give the dominant term at the threshold. For a fuller discussion, see [33] and references therein. An experimental investigation of the threshold ionization of helium [34] obtained a value 2.2. This was followed by a theoretical investigation that considered anharmonic corrections to the Wannier threshold law to explain the experimental results [35]. A recent measurement within 2 eV of the ionization threshold obtained a value of 1.1 [36].

There has been an investigation [37] of the behavior of the elastic cross sections at the positronium formation threshold, which predicts the occurrence of a Wigner cusp for the noble gases using R-matrix methods. A comprehensive set of measurements using a high-resolution trap-based beams of the elastic scattering cross section about the positronium formation threshold revealed a family of Wigner cusps in the noble gases [38]. Subsequent measurements of the elastic scattering cross section about the positronium formation threshold in molecules that are isoelectronic with helium and neon, and did not show a Wigner cusp [39].

51.3 Particular Applications

51.3.1 Atomic Hydrogen

Because of the difficulty of taking measurements in atomic hydrogen, the available experimental data has so far been restricted to total cross sections, as well as to total ionization and positronium formation cross sections. Essentially exact variational calculations have been carried out in the elastic energy regime and the Ore gap [10]. These calculations are used to benchmark many-body theory [40].

Ionization cross sections have been measured by both the Bielefeld and London groups ([41, 42] and references therein) and have been calculated in a number of approximations [24, 26, 43–45]. However, disagreements between the experimental measurements mean that there is at present no reliable way of assessing the various theoretical approximations used. More elaborate calculations with asymptotically correct wave functions have been used to determine triple differential cross sections for ionization [46, 47]. However, the task of integrating these to produce total cross sections is a formidable one.

The total positron–hydrogen cross section has also been measured by the Detroit group [48] and is in quite good agreement with calculations based upon the coupled-pseudostate [45] and the convergent close-coupling [49] methods, except at very low energies where the experimental uncertainties are the greatest.

In order to determine reliable positronium formation cross sections, the explicit positronium states have to be included. Several such calculations have been carried out [17–20]. These indicate the necessity of explicitly including positronium formation channels in the expansion of the total wave function in order to obtain accurate results, even for elastic scattering. The most recent calculations [45, 49, 50] are in quite good agreement with various experiments [41, 51] over the majority of the energy range.

As is the case for electron scattering, positron cross sections exhibit resonances (Sect. 49.1.3). These have been extensively studied by *Ho* [52], who used variational and complex rotation methods.

51.3.2 Noble Gases

Because the noble gases are convenient experimental targets, a good deal of effort has gone into calculations for these targets, particularly for elastic scattering, ionization, and Ps formation. In the purely elastic energy range, i.e., for energies below the positronium formation threshold, the simple potential scattering approach using the static and polarization potentials defined above yields quite good results. Since the long-range behavior of the sum of the potentials

is attractive, the scattering phase shifts for positrons must be positive for sufficiently low energies. However, as its incident energy increases, the positron probes the repulsive inner part of the potential, and the phase shifts become negative. This behavior leads to the well-known Ramsauer minimum in the integral elastic cross sections (Chap. 49). The Ramsauer minimum has been observed in helium and neon ([53, 54] and references therein). In the case of argon, no minimum is observed given a sufficiently high-quality beam [55]. In general, this differs from electron scattering, where some low-energy phase shifts can be negative (modulo π) because of the existence of bound orbitals of the same symmetry.

Another difference between positron and electron scattering is exhibited by the differential cross sections (Chap. 49). For electrons, the shape of the cross section is determined by a few dominant phase shifts, whereas for positrons, many phase shifts contribute to the final shape [56]. Because of this behavior, the differential cross sections for positron scattering have much less overall structure than for electron scattering. However, the differential cross sections for positrons for many of the noble gases have a single minimum at relatively small angles, both below and above the first inelastic channel [57, 58]. The earlier results have been reviewed by *Kaupilla et al.* [59]. At intermediate energies, the simple potential scattering approximation is no longer sufficient, and the inelastic channels have to be taken into account via, for example, the use of an optical potential [9, 15, 23, 60] or convergent close-coupling method ([61] and references therein). Furthermore, in the inelastic scattering regime, the existence of open channels has a much more marked effect on the shape of the differential cross sections for positron scattering than that for electrons [57].

Absolute elastic differential cross sections were measured for argon, krypton, and xenon at low energies using a magnetized beam of cold positrons [58, 61, 62]. Magnetized beam measurements generally do not distinguish between forward and backward scattered positrons (or electrons). In this case, the reported elastic cross section is folded about 90 degrees. As with electrostatic beams, a portion of the angular scatter is indistinguishable from the incident beam, which plays an important role in the comparison of experiment and theory [55]. These results are in general agreement with a variety of different theoretical predictions [63–65]. A method that allows the scattering phase shifts to be extracted from the folded elastic differential scattering cross section was developed recently [66].

There is relatively little experimental data for the excitation of the noble gases. Some experimental work has been carried out for the lighter noble gases, helium, neon, and argon ([67] and references therein), and there is satisfactory agreement between these measurements and close-coupling [68], as well as distorted-wave [69] calculations.

The first state-resolved absolute excitation cross sections for the $4s [1/2]_1^0$ and $4s [3/2]_1^0$ states of argon and the $6s [3/2]_1^0$ state of xenon have been measured by the San Diego group [6, 70]. Relativistic distorted-wave calculations are in satisfactory agreement with the experiment for argon [71] but less so for xenon [72]. Excitation of the $n = 2$ states of helium was measured by the ANU group [73]. Convergent close-coupling calculations are in good agreement for both the 2^1S and 2^1P states [27].

The total ionization and positronium cross sections have been measured extensively for all of the noble gases. In general, there is good agreement amongst the various experiments for the ionization cross section but much less so for the positronium formation cross section, with a recent exception [25]. A summary of the experimental work on the ionization and positronium cross sections for neon, argon, krypton, and xenon can be found in the article by Marler et al. ([74] and references therein). A summary of the corresponding theoretical work can be found in [24, 25].

Both double and triple-differential ionization cross sections have been measured for helium [75] and argon [76, 77]. Distorted wave Born (DWBA) and three-continuum approximation (3C model) have also been applied to these systems ([78, 79] and references therein).

The formation of excited-state positronium has been measured for positron scattering from helium, argon, and xenon and has been compared to a number of theoretical results [80].

There exist some measurements of Z_{eff} and angular correlation parameters for these gases [81], mainly at room temperature, and calculations for them have been made in the polarized-orbital approximation [82]. Measurements have been made at various temperatures and are in relatively good agreement with early calculations [83].

The combination of available gas-phase scattering cross sections for energies between 0 and 10 keV has been used to model a single track of a positron through argon [84].

51.3.3 Other Atoms

In the case of positron scattering from the alkali atoms, the positronium formation channel is always open, and the simple potential scattering approach does not yield reliable results. The Detroit group has measured the total cross section, as well as the upper and lower bounds to the positronium formation cross section for sodium, potassium, and rubidium [48]. Although early close-coupling calculations of the elastic and excitation cross sections [85–87] were in surprisingly good agreement with the experimental total cross section, these calculations did not include the positronium formation channel. Subsequently, much more sophisticated calculations were carried out by the Belfast group using the

coupled-pseudo-state method, which included both eigenstates of the target, as well as positronium [45, 88–90]. These calculations also showed the increasing importance of positronium formation in excited states for the alkalis: potassium, rubidium, and caesium. The overall agreement between experimental results and those from the coupled-pseudo-state method are quite good for both potassium and rubidium; however, for sodium, the experimental positronium formation cross section is significantly above these theoretical calculations. A summary of the experimental work on the alkalis can be found in [48], while a corresponding summary of theoretical work is given in [45].

Substantial resonance features have been found in these positron–alkali atom cross sections using close-coupling calculations [91, 92]. More recently, various theoretical methods have been applied to the positron–lithium system ([93, 94] and references therein).

The positronium formation threshold for magnesium is very low, only 0.844 eV, and hence, the elastic and positronium formation cross sections will dominate in the low-energy region. Upper and lower bounds to the Ps formation cross section in magnesium have been determined [48, 95] and are in agreement with both close-coupling calculations [96] and the results of many-body theory [97].

51.3.4 Molecular Hydrogen

By its fundamental nature, molecular hydrogen has attracted considerable attention both experimentally and theoretically. The total elastic cross section has been measured by the Detroit group [51], the London group [98], and the ANU group [99]. There have been several theoretical calculations of this cross section by a variety of methods: Kohn variational [100], R -matrix [101], distributed positron model [102], a Schwinger multichannel method [101–103], and convergent close-coupling calculations by the Curtin group [104].

Calculations have shown the elastic cross section is strongly influenced by the positronium formation channel near the threshold. However, a recent measurement did not show any feature in the integral elastic cross section about the positronium formation threshold [39].

The vibrational ($0 \rightarrow 1$) excitation cross section of molecular hydrogen has been measured between 0.55 and 4 eV and is in quite good agreement with theoretical calculations [105] (and reference therein). The San Diego group has also measured the electronic excitation of the $B^1\Sigma$ state from the threshold to 30 eV [70]. Their data are in reasonable agreement with the Schwinger multichannel calculation of Lino et al. [106]. The measured positron excitation cross section appears to be larger than that measured for electron excitation.

The ionization cross section has been determined over a wide range of energies by a number of different groups ([107–111] and references therein). Since all of the above measurements are relative, they must be normalized to one another at particular energies. Theoretical calculations are in satisfactory agreement with the measurements ([112] and references therein).

Electron capture to the continuum has been observed in triple-differential ionization measurements [113]. Reasonable agreement has been found between available experimental measurements and the distorted-wave Born approximation (with the Ward–Macek approximation; [79] and references therein).

The positronium formation cross section has also been measured by a number of different groups and has been compared to the first Born approximation and a coupled-channels calculation, see [99] and reference therein.

Differential elastic cross sections have been measured by the ANU group and compared to a number of calculations [99]. The shape of these measurements are in good agreement with the complex model potential calculation [114]. More recently, a single-center adiabatic-nuclei convergent close-coupling method [104] showed good agreement between experiment and theory for the differential elastic cross section below the positronium formation threshold.

Rotational excitation cross sections have been calculated using the Schwinger multichannel method with fixed nuclei and the adiabatic rotational approximation ([115] and references therein). Recent progress in cryogenic positron traps by the San Diego group [116] will enable an experimental investigation of the rotational excitation of molecular hydrogen.

51.3.5 Water

From a biological perspective, water is fundamental, and it was recently studied experimentally and theoretically. The total scattering cross has been measured by the ANU group and compared to previous measurements and calculations ([117] and references therein). The ionization cross section has been measured by the London group [118]. The total elastic cross section and total inelastic cross section less positronium formation have been measured by the ANU group [119]. These measurements were compared to R-matrix and the independent atom model (IAM) methods ([119] and references therein).

Differential ionization cross sections have been measured by the London group [120]. Triple-differential ionization has been calculated using a second-order distorted-wave Born approximation [121].

51.3.6 Other Molecules

For diatomic and triatomic molecules, most of the experimental and theoretical work has been carried out for CO, CO₂, O₂, and N₂. Total cross sections for O₂, N₂, and CO₂ have been measured from the threshold to several hundred eV ([98] and references therein). Recently, the independent atom model (IAM) was compared to measurements for C₂, N₂, and O₂ [122] (and references therein). A spherical complex optical potential was used to determine the total scattering cross section for positron scattering from a number of simple molecules [123].

Relative differential cross sections have been measured for CO, CO₂, O₂, N₂, as well as N₂O, on both sides of the positronium formation threshold [124]. At low energies, the gases N₂, O₂, and CO exhibit a minimum in the DCS at small angles, as with the heavier noble gases. This minimum gradually disappears as the energy increases.

Vibrational excitation cross sections for CO and CO₂ have been measured [105] and are in excellent agreement with the theoretical calculations of [125] for CO, and in satisfactory agreement with theory [126] for CO₂. Electron excitation of the $a^1\Pi$ and $a^1\Sigma$ states of N₂ have been measured from threshold to 20 eV [70]. Interestingly, the positron cross section near the threshold is approximately double that for electrons.

Impact ionization, positronium formation, and electronic excitation have been measured for N₂, CO, and O₂ [127]. Additionally, positronium formation has been measured for CO₂ [128].

For small polyatomic molecules, the majority of experimental and theoretical work was carried out for CH₄. This includes the total cross section and quasi-elastic (summed over vibration–rotational levels) differential cross sections [129]. At low energies, there is a minimum in these DCS at small angles, as for the heavier noble gases which, in turn, also disappears at higher energies [59]. The positronium formation cross section has also been measured [130].

Recently, a large number of total scattering cross section measurements of organic compounds were studied experimentally by the Trento group ([131] and references therein). This work has been extended to purine nucleobasis and other biologically relevant molecules [132] (and references therein). Additionally, a comparison of the total scattering cross section from chiral enantiomers was also made [133].

Positronium formation has been measured for methanol and ethanol [134]. Total and elastic differential scattering, and positronium formation cross sections for a number of biologically relevant molecules have been measured by the ANU group ([135, 136] and references therein). In these cases, the scattering cross sections are summed over rotational and vibrational states. Nucleobases that are solid at

room temperature require a vacuum oven to produce vapor of the molecules. In these cases, relative cross sections were determined experimentally, and IAM calculations set the absolute scale at 150 eV.

51.4 Binding of Positrons to Atoms

There have been many recent investigations of the possible binding of positrons to a variety of atoms. As was mentioned in Sect. 48.1.2, such binding could greatly enhance the annihilation cross section and help explain the large measured values of Z_{eff} for both atoms and molecules. It has been shown theoretically that a positron will bind to a large number of one-electron and two-electron atomic systems ([137] and references therein). For one-electron systems, where the ionization potential is less than 6.80285 eV, the dominant configuration is a polarized positronium (Ps) cluster moving in the field of the residual positive ion, while for two-electron systems, with an ionization potential greater than 6.80285 eV, the dominant configuration involves a positron orbiting a polarized neutral atom [138]. So far, there is no experimental evidence for these positronic atoms [139]. However, a significant amount of theoretical work has shown that many atoms can bind a positron ([140] and references therein).

Enhancement of the annihilation rate (Z_{eff}) is observed in polyatomic molecules. The mechanism has been identified as vibrational Feshbach resonances mediating positron binding to molecules ([6] and references therein). In the case of linear alcohols, the binding energy depends linearly upon the molecular polarizability [141].

51.5 Positronium Scattering

There has been interest in positronium (Ps) scattering from atomic and molecular targets for a considerable time; see the work of *Fraser* and coworkers [142] and reference therein, but only recently has this field seen much activity. This is a two-center problem with the Ps *atom* being a light particle, so semiclassical methods are not applicable. There was some theoretical work by *Drachman* and *Houston* [143, 144], and recently there has been close-coupling calculations for simple target systems [145]. This problem has also been studied by a pseudo-potential method ([146] and references therein). The long-range interactions in positron–hydrogen scattering have recently been investigated [147]. The London group has measured the total cross sections for positronium scattering from the noble gases and small molecules (H_2 , N_2 , O_2 , H_2O , CO_2 , SF_6). Unexpectedly, the total cross sections for positronium scattering have been found to be very similar to scattering by

electron of the same velocity [148]. This has been explained in part by the polarization of the incident Ps [149].

The formation of the positronium negative ion, Ps^- , has been observed [150], and resonance structure has also been observed in the photodetachment of Ps^- [151, 152].

The formation of molecular positronium (Ps_2) has been observed [153] using intense positron pulses at a metal surface. The scattering of positronium atoms by positronium atoms has been investigated theoretically [154, 155] with an investigation of exciton-like nature of positronium [156].

The positronium atom is a boson, and, thus, there is fundamental interest in the creation of a Bose–Einstein condensate of an antimatter–matter composite boson. A unique feature of a Ps-BEC is the possibility of stimulated annihilation or the creation of a gamma-ray laser [157, 158]. More detailed theoretical treatments have appeared more recently [159–161].

51.6 Antihydrogen

Positron and positronium scattering play an important role in efforts to form antihydrogen, the bound state of an antiproton and a positron. This antimatter atom is an ideal system to test CPT. In the past decade, antihydrogen has been trapped [162] with the first spectroscopic measurements made recently [163]. In addition, the formation of an antihydrogen beam has been postulated [164]. Excited-state positronium has been found to be extremely useful in the formation of antihydrogen using detailed CCC calculations [165].

51.7 Reviews

For a number of years, a Positron Workshop has been held as a satellite of the International Conference on the Physics of Electronic and Atomic Collisions. The Proceedings [166–182] give an excellent summary of the state of positron scattering research, both experimental and theoretical, and applications to astro and biophysics.

There are several review articles on positron scattering in gases, including the early historical development [183], more comprehensive articles [2, 184–186], as well as more recent reviews [131, 187–191]. There are a number of reviews of the various antihydrogen efforts [192–195] with a special issue on antihydrogen and positronium [196]. A review on positronium laser physics [197] discusses the future for positron physics.

The book [198] discusses various aspects of both experimental and theoretical positron physics.

Josh R. Machacek Josh Machacek received his PhD from the Australian National University. He was a postdoctoral scholar at JPL before returning to the ANU. He is a recipient of a DECRA Fellowship from the Australian Research Council and a US National Research Council Fellowship at the Air Force Institute of Technology. He is currently focused on quantum mechanically complete experiments involving positrons.

Allan D. Stauffer Allan Stauffer has published numerous papers in the field of electron and positron scattering from atoms and simple molecules. In collaboration with numerous colleagues, he has been involved with extensive scattering calculations and developed methods to carry out these investigations and has worked closely with groups involved in measuring these processes.

Robert P. McEachran Professor McEachran received his PhD from the University of Western Ontario, Canada. He spent 2 years at the University College London (England) before joining York University in Toronto in 1964. In 1997, he accepted an Adjunct Professorship at the Australian National University. His current research interests are the theoretical treatment of electron/positron scattering from heavy atoms within a relativistic framework.

Adiabatic and Diabatic Collision Processes at Low Energies

Abstract

Adiabatic and diabatic electronic states of a system of atoms are defined and their properties are described. Nonadiabatic interaction for slow quasi-classical motion

E. Nikitin (✉)

of atoms is discussed within the two-state approximation. Analytical formulae for nonadiabatic transition probabilities are presented for particular models with reference to single and double-passage of coupling regions. The generalization for multiple passages is described.

Keywords

potential energy surface · potential energy curve · Coriolis coupling · nonadiabatic transition · nonadiabatic coupling

52.1 Basic Definitions

52.1.1 Slow Quasi-Classical Collisions

Slow collisions of atoms or molecules (neutral or charged) are defined as collisions for which the velocity of the relative motion of colliding particles v is substantially lower than the velocity of valence electrons v_e

$$\frac{v}{v_e} \ll 1. \quad (52.1)$$

If v_e is estimated as $v_e \approx 1 \text{ a.u.} \approx 10^8 \text{ cm/s}$, then Eq. (52.1) is fulfilled for medium-mass nuclei ($\approx 10 \text{ amu}$) up to several keV.

Quasi-classical collisions are those for which the de Broglie wavelength λ_{dB} for relative motion is substantially smaller than the range parameter a of the interaction potential (the WKB (Wentzel–Kramers–Brillouin) condition [1–4])

$$\lambda_{dB} \ll a. \quad (52.2)$$

The two conditions in Eqs. (52.1) and (52.2) define the energy range within which collisions are slow and quasi classical. For medium-mass nuclei, this energy range covers collision energies above room temperature and below hundreds of eV. The parameter a should not be confused with

another important parameter, L_0 , which characterizes the extent of the interaction region. For instance, for the exchange interaction between two atoms, L_0 corresponds to the distance of closest approach of the colliding particles, while a is the range of the exponential decrease of the interaction. Typically, L_0 noticeably exceeds a .

52.1.2 Adiabatic and Diabatic Electronic States

Let r refer to a set of electronic coordinates in a body-fixed frame related to the nuclear framework of a colliding system and let \mathcal{R} refer to a set of nuclear coordinates determining the relative position of nuclei in this system. A configuration of electrons and nuclei in a frame fixed in space is completely determined by r , \mathcal{R} , and the set of Euler angles Ω , which relate the body-fixed frame to the space-fixed frame. With the total Hamiltonian of the system $\mathcal{H}(r, \mathcal{R}, \Omega)$, the stationary state wave function satisfies the equation

$$\mathcal{H}(r, \mathcal{R}, \Omega)\Psi_E(r, \mathcal{R}, \Omega) = E\Psi_E(r, \mathcal{R}, \Omega). \quad (52.3)$$

The electronic adiabatic Hamiltonian $H(r; \mathcal{R})$ is defined to be the part of $\mathcal{H}(r, \mathcal{R}, \Omega)$ in which the kinetic energy of the nuclei and certain weak interactions are ignored. Typically, $H(r; \mathcal{R})$ includes the electron–electron and electron–nuclear electrostatic interaction and, possibly, the spin–orbit interaction. The adiabatic electronic functions $\psi_n(r; \mathcal{R})$ are defined as eigenfunctions of $H(r; \mathcal{R})$ at a fixed nuclear configuration \mathcal{R} with set of electronic coordinates r

$$H(r; \mathcal{R})\psi_n(r; \mathcal{R}) = U_n(\mathcal{R})\psi_n(r; \mathcal{R}). \quad (52.4)$$

The eigenvalues $U_n(\mathcal{R})$ are called adiabatic potential energy surfaces (adiabatic PES). In the case of a diatom, the set \mathcal{R} collapses into a single coordinate, the internuclear distance R , and the PES become potential energy curves PEC, $U_n(R)$. The functions $\psi_n(r; \mathcal{R})$ depend explicitly on \mathcal{R} and implicitly on the Euler angles Ω . The significance of the adiabatic PES is related to the fact that in the limit of very low velocities, a system of nuclei will move across a single PES. In this approximation, called the adiabatic approximation, the function $U_n(\mathcal{R})$ plays the part of the potential energy, which drives the motion of the nuclei [1–4].

An electronic diabatic Hamiltonian is defined formally as a part of H , i.e., $H_0 = H + \Delta H$. The partitioning of H into H_0 and ΔH is dictated by the requirement that the eigenfunctions of H_0 , called diabatic electronic functions ϕ_n , depend weakly on the configuration \mathcal{R} . The physical meaning of this weak dependence is different for different problems. A perfect diabatic basis set $\phi_n(r)$ is \mathcal{R} independent; for practical purposes, one can use a diabatic set that is considered \mathcal{R} independent within a certain region of the configuration space \mathcal{R} .

Two basis sets ψ_n and ϕ_n generate the matrices

$$\begin{aligned} \langle \phi_m | H | \phi_n \rangle &= H_{mn}, \\ \langle \phi_m | \mathcal{H} | \phi_n \rangle &= H_{mn} + D_{mn}, \\ \langle \psi_m | \mathcal{H} | \psi_n \rangle &= U_n(\mathcal{R})\delta_{mn} + \mathcal{D}_{mn}. \end{aligned} \quad (52.5)$$

The eigenvalues of the matrix H_{mn} are U_n ; D_{mn} and \mathcal{D}_{mn} are the matrices of interactions ignored in the passage from the Hamiltonian \mathcal{H} to H . All the above matrices are, in principle, of infinite order. For low-energy collisions, the use of finite matrices of moderate dimension will usually suffice.

Diabatic PES are defined as the diagonal elements H_{nn} . The significance of the diabatic PES is that for velocities that are high [but still satisfy Eq. (52.1)] the system moves preferentially across diabatic PES, provided that the off-diagonal elements H_{mn} are small enough.

An adiabatic function $\psi_n(r; \mathcal{R})$ can be constructed as a linear combination of the diabatic functions $\phi_m(r)$ as

$$\psi_n(r; \mathcal{R}) = \sum_m C_{nm}(\mathcal{R})\phi_m(r). \quad (52.6)$$

52.1.3 Nonadiabatic Transitions: The Massey Parameter

Deviations from the adiabatic approximation manifest themselves in transitions between different PES, which are induced by the dynamic coupling matrix \mathcal{D} . At low energies, the transitions usually occur in localized regions of nonadiabatic coupling (NAR). In these regions, the motion of nuclei in different electronic states is coupled, and, in general, it cannot be interpreted as being driven by a single potential [3, 5–7].

An important simplifying feature of slow adiabatic collisions is that, typically, the distance between different NAR is substantially larger than the extents of each NAR. This makes it possible to formulate simple models for the coupling in isolated NAR, and, subsequently, to incorporate the solution for nonadiabatic coupling into the overall dynamics of the system.

For a system of s nuclear degrees of freedom, there are the following possibilities for the behavior of PES within NAR:

- (i) If two s -dimensional PES correspond to electronic states of different symmetry, they can cross along an $(s - 1)$ -dimensional line. For a system of two atoms, $s = 1$, and so two potential curves of different symmetry can cross at a point.
- (ii) If two s -dimensional PES correspond to electronic states of the same symmetry, they can cross along an $(s - 2)$ -dimensional line. For a system of two atoms, $s = 1$, and so two potential curves of different symmetry cannot cross.

- (iii) If two s -dimensional PES correspond to electronic states of the same symmetry in the presence of spin–orbit coupling, they can cross along an $(s - 3)$ -dimensional line.

Statement (ii) applied to a two-atom system is known as the Wigner–Witmer noncrossing rule. In applications to a system with $s > 1$, it is frequently discussed in terms of the conical intersection [8].

The efficiency of the nonadiabatic coupling between two adiabatic electronic states is determined according to the adiabatic principle of mechanics (both classical and quantum), by the value of the Massey (M) parameter ζ^M , which represents the product of the electronic transition frequency ω_{el} and the time τ_{nuc} that characterizes the rate of change of electronic function due to the nuclear motion. Putting $\omega_{el} \approx \Delta U(\mathcal{R})/\hbar$ and $\tau_{nuc} = \Delta L/v(\mathcal{R})$, we get

$$\zeta^M(\mathcal{R}) = \omega_{el}\tau_{nuc} = \Delta U(\mathcal{R})\Delta L/\hbar v(\mathcal{R}), \quad (52.7)$$

where ΔU is the spacing between any two adiabatic PES, and ΔL is a certain range that depends on the type of coupling. The nonadiabatic coupling is inefficient at those configurations \mathcal{R} where $\zeta^M(\mathcal{R}) \gg 1$. If $\zeta^M(\mathcal{R})$ is less than or of the order of unity, the nonadiabatic coupling is efficient, and a change in adiabatic dynamics of nuclear motion is very substantial.

The following relations usually hold for the parameters $\Delta L, a, L_0$ for slow collisions

$$\Delta L \ll a \ll L_0. \quad (52.8)$$

When the nonadiabatic coupling is taken into account, the total (electronic and nuclear) wave function, Ψ_E , can be represented as a series expansion in ψ_n or ϕ_n (the Euler angles Ω are suppressed for brevity)

$$\begin{aligned} \Psi_E(r, \mathcal{R}) &= \sum_n \psi_n(r; \mathcal{R})\chi_{nE}(\mathcal{R}) \\ &= \sum_n \phi_n(r)\kappa_{nE}(\mathcal{R}). \end{aligned} \quad (52.9)$$

Here, $\chi_{nE}(\mathcal{R})$ and $\kappa_{nE}(\mathcal{R})$ are the functions that have to be found as solutions to the coupled equations formulated in the adiabatic or diabatic electronic basis, respectively [3, 5–7, 9]. In general, different contributions to the first sum in Eq. (52.9) can be associated with nonadiabatic transition probabilities between different electronic states.

A practical means of calculating functions $\chi_{nE}(\mathcal{R})$ [or $\kappa_{nE}(\mathcal{R})$] consists of expanding them over certain basis functions $\mathcal{E}_{nv}(\mathcal{R}')$, where \mathcal{R}' denotes all coordinates \mathcal{R} save a single coordinate R . Writing

$$\chi_{nE}(\mathcal{R}) = \sum_v \mathcal{E}_{nv}(\mathcal{R}')\xi_{nvE}(\mathcal{R}), \quad (52.10)$$

one arrives at a set of coupled second-order equations for the unknown functions $\xi_{nvE}(\mathcal{R})$ (the scattering equations). In the adiabatic approximation, the total wave function is represented by a single term in the first sum of Eq. (52.9)

$$\Psi_E(r, \mathcal{R}) = \psi_n(r; \mathcal{R})\chi_{nE}(\mathcal{R}). \quad (52.11)$$

52.2 Two-State Approximation

52.2.1 Relation Between Adiabatic and Diabatic Basis Functions

In the two-state approximation, two adiabatic functions $\psi_k(r; \mathcal{R})$ are assumed to be expressed as a linear combination of two diabatic functions $\phi_k(r)$ via a rotation angle θ

$$\begin{aligned} \psi_1(r; \mathcal{R}) &= \cos \theta(\mathcal{R})\phi_1(r) + \sin \theta(\mathcal{R})\phi_2(r), \\ \psi_2(r; \mathcal{R}) &= -\sin \theta(\mathcal{R})\phi_1(r) + \cos \theta(\mathcal{R})\phi_2(r). \end{aligned} \quad (52.12)$$

The rotation angle, $\theta(\mathcal{R})$, is expressed via the diagonal and off-diagonal matrix elements of the adiabatic Hamiltonian H in the diabatic basis ϕ_1, ϕ_2

$$\tan 2\theta(\mathcal{R}) = \frac{2H_{12}(\mathcal{R})}{H_{11}(\mathcal{R}) - H_{22}(\mathcal{R})}. \quad (52.13)$$

The eigenvalues of H are

$$\begin{aligned} U_{1,2} &= \bar{U} \pm \Delta U, \\ \bar{U} &= (H_{11} + H_{22})/2 = \bar{H}, \\ \Delta U &= \frac{1}{2}\sqrt{(\Delta H)^2 + 4H_{12}^2}, \\ \Delta H &= H_{11} - H_{22}, \end{aligned} \quad (52.14)$$

implying

$$\begin{aligned} \Delta H &= \Delta U \cos 2\theta, \\ H_{12} &= (1/2)\Delta U \sin 2\theta. \end{aligned} \quad (52.15)$$

52.2.2 Coupled Equations and Transition Probabilities in the Common Trajectory Approximation

A two-state nonadiabatic wave function $\Psi(r, \mathcal{R})$ can be written as an expansion into either adiabatic or diabatic electronic wave functions

$$\begin{aligned} \Psi(r; \mathcal{R}) &= \psi_1(r; \mathcal{R})\alpha_1(\mathcal{R}) + \psi_2(r; \mathcal{R})\alpha_2(\mathcal{R}), \\ \Psi(r; \mathcal{R}) &= \phi_1(r)\beta_1(\mathcal{R}) + \phi_2(r)\beta_2(\mathcal{R}), \end{aligned} \quad (52.16)$$

in which the nuclear wave functions satisfy two coupled s -dimensional Schrödinger equations [1–3].

In the common trajectory (CT) approximation, the motion of the nuclei is described by the classical trajectory, i.e., by a one-dimensional manifold $Q(t)$ embedded in the s -dimensional manifold \mathcal{R} . A section of PES along this one-dimensional manifold determines a set of effective PEC. In the case of atomic collisions, Q coincides with the interatomic distance R , and the effective PEC are just ordinary PEC. A definition of a CT, or an effective potential that drives it, represents a challenging task which is not discussed here (e.g., references in the collection of notes [10, 11]).

A CT counterpart of Eq. (52.16) is

$$\begin{aligned}\Psi(r, t) &= \psi_1[r; Q(t)]a_1(t) + \psi_2[r; Q(t)]a_2(t), \\ \Psi(r; t) &= \phi_1(r)b_1(t) + \phi_2(r)b_2(t).\end{aligned}\quad (52.17)$$

The expansion coefficients $a_k(t)$ satisfy the set of equations

$$\begin{aligned}i\hbar \frac{da_1}{dt} &= U_1(Q)a_1 + i\dot{Q}g(Q)a_2, \\ i\hbar \frac{da_2}{dt} &= -i\dot{Q}g(Q)a_1 + U_2(Q)a_2.\end{aligned}\quad (52.18)$$

Here, the dynamical coupling function (defined in the adiabatic basis)

$$g(Q) = \langle \psi_1 | \frac{\partial}{\partial Q} | \psi_2 \rangle = -\langle \psi_2 | \frac{\partial}{\partial Q} | \psi_1 \rangle = \frac{d\theta}{dQ}, \quad (52.19)$$

arises from the action of the operator $i\hbar \partial / \partial t$ on the adiabatic functions and is expressed in terms of the angle $\theta(Q)$ (defined in the diabatic basis by Eq. (52.13)).

For low energies, function $g(Q)$ is localized near the NAR center, and Eqs. (52.18) decouple away from the NAR center. This property of coupled equations may be lost if they are formulated in the diabatic basis. The diabatic expansion coefficients $b_k(t)$ satisfy the set of equations

$$\begin{aligned}i\hbar \frac{db_1}{dt} &= H_{11}(Q)b_1 + H_{12}(Q)b_2, \\ i\hbar \frac{db_2}{dt} &= H_{21}(Q)b_1 + H_{22}(Q)b_2.\end{aligned}\quad (52.20)$$

Clearly, for a system of two atoms, $Q \equiv R$.

Solutions to Eqs. (52.18) and (52.20) are equivalent, provided that the initial conditions are matched, and the transition probability is properly defined with account taken for the coupling of the diabatic states away from the NAR center. It is customary to identify the center of the NAR with a value of $Q = Q_p$, which corresponds to the real part of the complex-valued coordinate Q_c at which two adiabatic PES cross and which possesses the smallest imaginary part [1].

The crossing conditions in the adiabatic and diabatic representations are

$$\begin{aligned}\Delta U(Q_c) &= 0, \\ [\Delta H(Q_c)]^2 + 4H_{12}^2(Q_c) &= 0.\end{aligned}\quad (52.21)$$

Since Q represents a one-dimensional manifold, the crossing condition Eq. (52.21) is satisfied for complex values of $Q = Q_c$, unless $H_{12} = 0$. Then, by definition, the location of the NAR center is identified with $Q_p = \text{Re } Q_c$. A characteristic width of an isolated NAR is determined by the width ΔQ_p of a peaked (at $\Delta Q = Q_p$) function $g(Q)$. Normally, ΔQ_p is about $\text{Im } Q_c$ [3]. A more general discussion of the crossing in the complex coordinate plane is given in the context of the hidden crossing [10].

For low energies, the Eq. (52.20) along a particular CT are partitioned into sets of adiabatic evolution and the sets of nonadiabatic transformation of the amplitudes. The spatial (or temporal) extension of the former is normally much larger compared to the latter, such that nonadiabatic transformation of the amplitudes can be described by Eq. (52.18) applied to an isolated NAR. Since the characteristic width of a NAR is small on the scale of the whole CT, the part of CT that is essential in describing the nonadiabatic transformation of $a_k(t)$ can be simplified in order to make Eq. (52.18) more easily handled. This simplification (to be called the local common trajectory, LCT) is a crux of the analytical solution for model cases of nonadiabatic coupling (Sect. 52.3) within an isolated NAR.

With the given functions $U_1(Q)$, $U_2(Q)$, $g(Q)$ (or $H_{11}(Q)$, $H_{22}(Q)$, and $H_{12}(Q)$), the Eq. (52.18) are completely defined by setting the LCT with $Q = Q_{\text{LCT}}(t)$. Equation (52.18) decouple on both sides of the NAR, say, at $t < t^{(-)}$ and $t > t^{(+)}$. At these values of t , the two-state function $\Psi(r, t)$ evolves adiabatically, and this behavior can be singled out by transformation ($t^{(-)} < t_p < t^{(+)}$)

$$a_k(t) = \bar{a}_k(t) \exp \left[-\frac{i}{\hbar} \int_{t_p}^t U_k[Q_{\text{LCT}}(t)] dt \right]. \quad (52.22)$$

The amplitudes $\bar{a}_k(t)$, which become time-independent outside NAR, satisfy equations

$$\begin{aligned}\frac{d\bar{a}_1}{dt} &= \bar{a}_2 \dot{Q}_{\text{LCT}} g(Q_{\text{LCT}}) \exp \left[\frac{i}{\hbar} \int_{t_p}^t \Delta U[Q_{\text{LCT}}(t)] dt \right], \\ \frac{d\bar{a}_2}{dt} &= -\bar{a}_1 \dot{Q}_{\text{LCT}} g(Q_{\text{LCT}}) \\ &\times \exp \left[-\frac{i}{\hbar} \int_{t_p}^t \Delta U[Q_{\text{LCT}}(t)] dt \right].\end{aligned}\quad (52.23)$$

Thus, the amplitudes $\bar{a}_k(t)$ are determined by two functions, $\Delta U(Q)$ and $g(Q)$, that evolve along a chosen LCT. These two functions are related to the two diabatic basis functions $H_{12}(Q)$ and $\Delta H(Q)$ by Eq. (52.14). It follows from Eq. (52.23) that \bar{a}_1 and \bar{a}_2 become time independent outside NAR. This property of the amplitudes in the adiabatic basis is lost for their counterparts in the diabatic basis.

A solution of the equations of the nonadiabatic coupling across an isolated maximum of $g(Q)$ within the time interval $t^{(-)} \leq t \leq t^{(+)}$ (LCT interval $Q_{\text{LCT}}^{(-)} \leq Q_{\text{LCT}} \leq Q_{\text{LCT}}^{(+)}$, accordingly) gives the single-passage (or one-way) matrix of the nonadiabatic evolution, $\mathcal{N}_{n,m}^{+,-}$, which connects the amplitudes $\{a_1^{(-)}, a_2^{(-)} \rightarrow a_1^{(+)}, a_2^{(+)}\}$ on both sides of NAR. In particular, the probability P_{12} of the nonadiabatic transition $1 \rightarrow 2$ and the probability $1 - P_{12}$ of the nonadiabatic survival $1 \rightarrow 1$ are

$$P_{12} = |\mathcal{N}_{2,1}^{+,-}|^2 \quad \text{and} \quad 1 - P_{12} = |\mathcal{N}_{1,1}^{+,-}|^2. \quad (52.24)$$

The efficiency of nonadiabatic coupling in crossing an isolated NAR can be estimated by the Landau formula for transition probability in the near-adiabatic limit when $P_{12} \ll 1$

$$P_{12} = \exp \left[-\frac{2}{\hbar} \left| \text{Im} \int_{t_r}^{t_c} \Delta U[Q_{\text{LCT}}(t)] dt \right| \right], \quad (52.25)$$

where t_c is a root of the equation $Q_{\text{LCT}}(t_c) = Q_c$, and t_r is any real-valued time. The single-passage transition probabilities are discussed in Sect. 52.3.

Once passage matrices $\mathcal{N}_{n,m}^{+,-}$ are known, they can be incorporated into the general scheme of nonadiabatic dynamics. In particular, the transition probabilities for the double passage of the same NAR are discussed in Sect. 52.4, and the nonadiabatic dynamics with multiple transitions is described in Sect. 52.5.

Table 52.1 Selection rules for the coupling between diabatic and adiabatic states of a diatomic quasi molecule ($w = g, u; \sigma = +, -$)

Interaction	$^{2S+1}A_w^{(\sigma)}$ nomenclature	$\Omega_w^{(\sigma)}$ nomenclature
Configuration interaction	$\Delta\Lambda = 0, \Delta S = 0$	$\Delta\Omega = 0$
(electrostatic)	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$
Spin-orbit interaction	$\Delta\Lambda = 0, \pm 1, \Delta S = 0, \pm 1$	$\Delta\Omega = 0$
	$g \not\rightleftharpoons u, + \rightleftharpoons -$	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$
Radial motion	$\Delta\Lambda = 0, \Delta S = 0$	$\Delta\Omega = 0$
	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$
Rotational motion	$\Delta\Lambda = \pm 1, \Delta S = 0$	$\Delta\Omega = \pm 1$
	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$	$g \not\rightleftharpoons u, + \not\rightleftharpoons -$
Hyperfine interaction	$\Delta\Lambda = 0, \pm 1, \Delta S = 0, \pm 1$	$\Delta\Omega = 0, \pm 1$
	$g \rightleftharpoons u, + \rightleftharpoons -$	$g \rightleftharpoons u, + \rightleftharpoons -$

52.2.3 Selection Rules for Nonadiabatic Coupling

In the general case, the coupling between adiabatic states or diabatic states is controlled by certain selection rules. The most detailed selection rules exist for a system of two colliding atoms, since this system possesses a high symmetry ($C_{\infty v}$ or, for identical atoms, $D_{\infty h}$ point symmetry in the adiabatic approximation). In the adiabatic representation, the coupling is due to the elements of the matrix \mathcal{D} . They fall into two different categories: those proportional to the radial nuclear velocity (coupling by radial motion or radial coupling) and those proportional to the angular velocity of rotation of the molecular axis (coupling by rotational motion or Coriolis coupling). Besides, \mathcal{D} includes the spin-orbit and other weak interactions if they are not included in the adiabatic Hamiltonian.

In a diabatic representation, the coupling is due to the parts of the interaction potential neglected in the definition of the diabatic Hamiltonian H_0 . In typical cases, these parts (besides the nuclear motion) are: the electrostatic interaction between different electronic states constructed as certain electronic configurations (H_0 corresponds to a self-consistent field Hamiltonian); spin-orbit interaction (H_0 corresponds to a nonrelativistic Hamiltonian); hyperfine interaction (H_0 ignores the magnetic interaction of electronic and nuclear spins); as well as the electrostatic interaction between electrons and quadrupole moments of nuclei. Different definitions of the adiabatic electronic states (i.e., different Hund coupling cases [1]) of a system of two atoms are discussed in [11]; the respective selection rules are summarized in [12]. The selection rules for the above interactions in this case are listed in Table 52.1 for two conventional nomenclatures for molecular states: Hund's case (a), $^{2S+1}A_w^{(\sigma)}$, and Hund's case (c), $\Omega_w^{(\sigma)}$.

For molecular systems with more than two nuclei, the selection rules cannot be put in a detailed form since, in general, the symmetry of the system is quite low. For the important case of three atoms, a general configuration is planar (C_s symmetry); particular configurations correspond to an isosceles triangle if two atoms are identical (C_{2v} symmetry),

Table 52.2 Selection rules for dynamic coupling between adiabatic states of a system of three atoms

C_s		A'		A''	
	C_{2v}	A_1	B_1	A_2	B_2
A'	A_1	z	y, R_x	R_z	R_y
	B_1	y, R_x	z	R_y	R_z
A''	A_2	R_z	R_y	z	y, R_x
	B_2	R_y	R_z	y, R_x	z

to an equilateral triangle for three identical atoms (D_{3h} symmetry), or to a linear configuration. For the last case, the selection rules are the same as for a system of two atoms. The selection rules for the dynamic coupling between adiabatic states classified according to the irreducible representations of the C_s and C_{2v} groups are listed in Table 52.2. In Table 52.2, z and y refer to two modes of the relative nuclear motion in the system plane, R_z and R_y refer to two rotations about principal axes of inertia lying in the system plane, and R_x refers to a rotation about the principal axis of inertia perpendicular to the system plane. In-plane motion of nuclei couples the state of the same reflection symmetry; rotation of the system plane couples the state of the different reflection symmetry. The spin-orbit interaction, if included in matrices D_{mn} and D_{mn} , couples the states of different reflection symmetry. For a more detailed discussion see [12].

52.3 Single-Passage Transition Probabilities in Common Trajectory Approximation

52.3.1 Transitions Between Noncrossing Adiabatic Potential Energy Curves

Single-passage transition probabilities between noncrossing adiabatic potential curves for different models can be classified by either diabatic or adiabatic Hamiltonians using the common trajectory with the NAR region. The following discussion refers to the cases of one-dimensional motion, when the transition probability can be expressed analytically. Here, a quite general model corresponds to exponential diabatic potentials and coupling (Nikitin (N) model [13]), with residual dynamical coupling neglected. It is formulated as

$$\begin{aligned} \Delta H^N(Q) &= -\Delta E [1 - \cos 2\vartheta e^{-\alpha(Q-Q_p)}], \\ H_{12}^N(Q) &= (\Delta E/2) \sin 2\vartheta e^{-\alpha(Q-Q_p)}. \end{aligned} \quad (52.26)$$

Here, ϑ is a parameter that defines the interplay between the off-diagonal element $H_{12}^N(Q)$ and the difference in the diagonal elements $\Delta H^N(Q)$. In addition, Eq. (52.26) includes asymptotic spacing ΔE of diabatic PEC (for $\alpha(Q-Q_p) \gg 1$) and characteristic scale $1/\alpha$ of the exponential interaction. The meaning of the characteristic coordinate Q_p is revealed,

when one passes to the adiabatic basis with the spacing $\Delta U(Q)$ and dynamical coupling $g(Q)$

$$\begin{aligned} \Delta U(Q) &= \Delta E \sqrt{1 - 2 \cos 2\vartheta e^{-\alpha(Q-Q_p)} + e^{-2\alpha(Q-Q_p)}}, \\ g(Q) &= \frac{\alpha}{2} \frac{\sin 2\vartheta e^{-\alpha(Q-Q_p)}}{1 - 2 \cos 2\vartheta e^{-\alpha(Q-Q_p)} + e^{-2\alpha(Q-Q_p)}}. \end{aligned} \quad (52.27)$$

As ϑ changes from very small values to $\pi/2$, the spacing of adiabatic PEC changes from the narrow avoided crossing to the wide one and ultimately displays strong divergence. The adiabatic PEC cross at

$$Q_c = Q_p \pm 2i\vartheta/\alpha. \quad (52.28)$$

This expression defines Q_p as the center of NAR, $Q_p = \text{Re } Q_c$, while the characteristic range of NAR is $\Delta Q_p = \text{Im } Q_c = 2\vartheta/\alpha$. The adiabatic states become uncoupled outside the NAR, while diabatic states remain coupled on the asymptotic side of NAR.

For this model, adiabatic wave functions coincide with diabatic functions before entering the coupling region (in the limit $\alpha(Q-Q_p) \gg 1$), but after exiting the coupling region (in the limit $\alpha(Q-Q_p) \ll -1$) they are ϑ -dependent linear combinations of the diabatic functions.

The definition of the exponential model within the LCT concept is completed once one specifies the LCT that crosses the NAR. It is taken to be a segment of a rectilinear trajectory,

$$Q(t) - Q_p = v_p(t - t_p), \quad (52.29)$$

where $v_p = \dot{Q}(t)|_{t=t_p}$ is additional parameter of the model, and t_p is the time corresponding to the center of NAR.

The solution of coupled equations yields the transition probability between adiabatic states

$$P_{12}^N = \frac{\sinh(\zeta \cos^2 \vartheta)}{\sinh \zeta} e^{-\zeta \sin^2 \vartheta}, \quad (52.30)$$

where $\zeta = \pi \Delta E / (\hbar \alpha v_p)$ is the asymptotic Massey parameter. Its value at the center of NAR is $\zeta_p = \zeta \sin^2 \vartheta$.

Special cases of the exponential model correspond to the linearly crossing diabatic potentials with the constant coupling (Landau-Zener (LZ) model [14–16]), parallel diabatic potentials with the exponential coupling (Demkov (D) model [17]), and the asymptotically degenerate diabatic potentials (resonance (R) model [13]).

The LZ model [14–16] is obtained from the exponential model by retaining Eq. (52.27) terms linear in ϑ and $\alpha(Q-Q_p)$ (i.e., for $\vartheta \ll 1$, $\zeta \gg 1$)

$$\begin{aligned} \Delta H^{LZ}(Q) &= \Delta E \alpha(Q-Q_p) \equiv \Delta F \alpha(Q-Q_p), \\ H_{12}^{LZ} &= \Delta E \vartheta \equiv V. \end{aligned} \quad (52.31)$$

Here, the right-hand-side corresponds to the standard parameterization of the LZ model, where $\Delta F = \Delta E \alpha$ denotes the difference in slopes of the diabatic crossing PEC at Q_p , and V is a constant. The pattern of the adiabatic PEC, with $\Delta U(Q_p)$ calculated from Eq. (52.31) as

$$\Delta U(Q) = \left| \sqrt{\Delta F^2 (Q - Q_p)^2 + 4V^2} \right|, \quad (52.32)$$

corresponds to an avoided crossing (or pseudo crossing). For this model, adiabatic wave functions coincide with diabatic functions on one side of the NAR, but on the other side, the former interchange with the latter accompanied by a sign reversal.

When $\vartheta \ll 1$ and $\zeta \gg 1$, Eq. (52.30) yields the LZ transition probability

$$P_{12}^{LZ} = \exp(-2\pi\zeta\vartheta^2) = \exp(-2\pi V^2/\Delta F v_p). \quad (52.33)$$

Remarkable properties of the Landau–Zener model are:

- (i) Expression Eq. (52.33) for the probability P_{12}^{LZ} is valid for arbitrary values of the exponent and not only for the large ones. In the latter case, the probability is very low, so that the system moves preferentially along a noncrossing adiabatic PEC.
- (ii) In the weak-coupling case (small value of the exponent in Eq. (52.33) termed narrow avoided crossing), the system moves preferentially along a crossing diabatic PES. The survival probability for a motion along the adiabatic PEC is then very low, $1 - P_{12}^{LZ} = 2\pi V^2/(\Delta F v_p)$.

The D model [17] is obtained from Eq. (52.27) by setting $\vartheta = \pi/4$

$$\begin{aligned} \Delta H^D(Q) &= \Delta E, \\ H_{12}^D(Q) &= (\Delta E/2) \exp[-\alpha(Q - Q_p)]. \end{aligned} \quad (52.34)$$

The transition probability in this case is

$$P_{12}^D = \frac{\exp(-\zeta)}{1 + \exp(-\zeta)}. \quad (52.35)$$

For this model, the adiabatic wave functions coincide with the diabatic functions on the one side of NAR, but on the other side, the former are expressed through the linear combinations of the latter with equal weights.

The R model is defined by the condition $\Delta E = 0$, i.e., $\zeta = 0$. For arbitrary ϑ , this case corresponds to the so-called accidental resonance (AR), and for $\vartheta = \pi/4$, it corresponds to the symmetric resonance (SR). In these two cases, the transition probabilities read

$$\begin{aligned} P_{12}^{AR} &= P_{12}^N|_{\zeta=0} = \cos^2 \vartheta, \\ P_{12}^{SR} &= P_{12}^N|_{\zeta=0, \vartheta=\pi/4} = 1/2. \end{aligned} \quad (52.36)$$

52.3.2 Transitions Between Crossing Adiabatic Potential Curves

The nomenclature of the adiabatic PEC within and outside a NAR differs for noncrossing and crossing adiabatic PES. For the former case, the assignment of the asymptotic states can be done according to their energies (e.g., $U_1(Q) > U_2(Q)$), while for the latter case, the inequality sign is reversed as a system passes the NAR. When applying the model for the noncrossing adiabatic PEC to the crossing PEC, one should take into account this reversal of the nomenclature. Then the transition probability P_{12} between the crossing adiabatic PEC can be recovered from the survival probability for the noncrossing adiabatic PEC with the proper modification of parameters.

A particular case of the linear crossing (LC) adiabatic potentials and the constant dynamical coupling corresponds to the Hamiltonian

$$\begin{aligned} \Delta U^{LC}(Q) &= \Delta F \alpha (Q - Q_c), \\ D_{12}^{LC} &= D = \text{const}. \end{aligned} \quad (52.37)$$

This Hamiltonian can be mapped onto the LZ Hamiltonian Eq. (52.31) by replacing the velocity v_p at the NAR center with the velocity v_c at the crossing point Q_c . Taking into account the reversal of the LZ nomenclature for the adiabatic and diabatic functions in crossing the NAR, the nonadiabatic transition probability for the LC P_{12}^{LC} is related to P_{12}^{LZ} as

$$\begin{aligned} P_{12}^{LC} &= 1 - P_{12}^{LZ}(V, v_p)|_{V \rightarrow D, v_p \rightarrow v_c} \\ &= 1 - \exp[-2\pi D^2/(\hbar \Delta F v_c)]. \end{aligned} \quad (52.38)$$

The matrix element D is often related to the Coriolis coupling between the adiabatic electronic states of different spatial symmetry. With D being proportional to the angular velocity of rotation of the molecular frame at the crossing point Q_c , this coupling is normally weak, and in this limit Eq. (52.38) reads

$$P_{12}^{LC} \approx 2\pi D^2/(\hbar \Delta F v_c). \quad (52.39)$$

With $P_{12}^{LC} \ll 1$, the system moves preferentially along the crossing PEC. However, sometimes the adiabatic PES are defined with the spin–orbit interaction neglected. In this case, the adiabatic electronic states are associated with different values of the electronic spin, and then the spin–orbit interaction is included into the coupling matrix element D . Then the approximation in Eq. (52.39) may not be valid, and one should use the general relation in Eq. (52.38) with the quantity D^2 in the exponent accounting for the contributions due to the dynamical (Coriolis) and static (spin–orbit) couplings.

52.4 Double-Passage Transition Probabilities

52.4.1 Transition Probabilities in the Classically-Allowed and Classically-Forbidden WKB Regimes: Interference and Tunneling

If a system traverses several NAR, its dynamics can be characterized by successive matching of the different \mathcal{N} matrices by the intermediate matrices of the adiabatic evolution. The latter have a simple expression when the system motion satisfies the standard WKB condition. In the case of an atomic collision, the set \mathcal{R} shrinks into a single coordinate, R , and $v_p = \sqrt{2(E - U_p)/\mu}$ is expressed through the radial energy, E , of the relative motion of the atoms having the reduced mass, μ , and the potential energy, $U_p = \bar{U}(R)|_{R=R_p}$. If there is only one NAR over the whole range of R , the colliding system traverses it twice, as the atoms approach and then recede, and there are two different paths between the center of the NAR, R_p , and the turning points, R_{t1} and R_{t2} , on the adiabatic potential curves, $U_1(R)$ and $U_2(R)$. The double-passage nonadiabatic event $1 \rightarrow 2$ consists of: (i) the single-passage transition $1 \rightarrow 2$, the adiabatic evolution $R_p \rightarrow R_{t2} \rightarrow R_p$ in the state $|2\rangle$, the single-passage survival $2 \rightarrow 2$; (ii) the single-passage survival $1 \rightarrow 1$, the adiabatic evolution $R_p \rightarrow R_{t1} \rightarrow R_p$ in state $|1\rangle$, and the single-passage transition $1 \rightarrow 2$. Accordingly, the double-passage nonadiabatic amplitude $\mathcal{A}_{12}^{\text{WKB}}$ for the transition $1 \rightarrow 2$ reads

$$\begin{aligned} \mathcal{A}_{12}^{\text{WKB}} &= \sqrt{P_{12}} \exp(2i\phi_2 + 2i\Delta\phi_{12}) \sqrt{P_{22}} \\ &+ \sqrt{P_{11}} \exp(2i\phi_1 + 2i\Delta\phi_{21}) \sqrt{P_{12}}, \end{aligned} \quad (52.40)$$

where $P_{22} = P_{11} = 1 - P_{12}$ are the survival probabilities, $2\phi_1$ and $2\phi_2$ are the WKB phases accumulated during the adiabatic motion of a diatom from the center of NAR to the turning points and back, and $2\Delta\phi_{12}$ and $2\Delta\phi_{21}$ are the so-called dynamical phases that originate from nonadiabatic dynamics in crossing the NAR. Then the double-passage transition probability, $\mathcal{P}_{12}^{\text{WKB}} = |\mathcal{A}_{12}^{\text{WKB}}|^2$, assumes the form

$$\begin{aligned} \mathcal{P}_{12}^{\text{WKB}}(E)|_{E>U_p} &= \\ 4P_{12}(1 - P_{12}) \sin^2(\Phi_{12}^{\text{WKB}} + \Delta\Phi_{12}). \end{aligned} \quad (52.41)$$

Here,

$$\begin{aligned} \hbar\Phi_{12}^{\text{WKB}}(E) &= \hbar(\phi_1 - \phi_2) \\ &= \int_{R_p}^{R_{t1}} p_1(R) dR - \int_{R_p}^{R_{t2}} p_2(R) dR, \\ \Delta\Phi_{12} &= \Delta\phi_{12} - \Delta\phi_{21}, \end{aligned} \quad (52.42)$$

where p_k are the classical moments for motion across adiabatic potentials $U_k(R)$. Equation (52.41) was first derived by Stückelberg [18] for an avoided crossing situation under assumption $\Delta\Phi_{12} = 0$.

If the single-passage transition probability is calculated in the LCT approximation, Eq. (52.41) represents a combination of LCT and WKB approximations. A further simplification of this expression corresponds to the replacement of the WKB phase, Φ_{12}^{WKB} , with its CT counterpart,

$$\Phi_{12}^{\text{CT}} = \frac{1}{\hbar} \int_{t_p}^{t_t} \Delta U(R(t)) dt, \quad (52.43)$$

where $\Delta U(R) = U_1(R) - U_2(R)$, $R(t)$ is a CT, and, t_p and t_t are the time moments corresponding to the NAR center and the turning points for the motion in the field of the CT potential, $U^{\text{CT}}(R)$, respectively. An ambiguity in the definition of $U^{\text{CT}}(R)$ shows up in the approximation for \mathcal{P}_{12} resulting from the passage $\Phi_{12}^{\text{WKB}} \rightarrow \Phi_{12}^{\text{LC}}$.

When P_{12} in Eq. (52.41) is considered within the LZ or D models, the respective expressions are called Landau–Zener–Stückelberg (LZS) probability and Rosen–Zener–Demkov probability (although the interference phase was calculated in Eq. [19] for a special case of time-dependent coupling). Analytical expressions for the dynamical phases for the models discussed in Sect. 52.3 are also available [3, 6].

A particular example of the LZS probability corresponds to the narrow avoided crossing between the adiabatic potentials (or to the weak coupling between the crossing diabatic curves). Here, one replaces the adiabatic potentials in Eq. (52.42) by their diabatic counterparts that define the phase, $\Phi_{12}^{\text{WKB-D}}$, with $\Delta\Phi_{12} = \pi/4$ [3]. Then Eq. (52.41), in the weak-coupling limit and with the LZS parameterization assumes the form derived by Landau (L) [14]

$$\begin{aligned} \mathcal{P}_{12}^{\text{L}}(E)|_{E>U_p} &= \frac{8\pi V^2}{\hbar\Delta F} \left[\frac{\mu}{2(E - U_p)} \right]^{1/2} \\ &\times \sin^2(\Phi_{12}^{\text{WKB-D}}(E) + \pi/4), \end{aligned} \quad (52.44)$$

which is valid for $\mathcal{P}_{12}^{\text{L}}(E)|_{E>U_p} \ll 1$. The unphysical divergence in Eq. (52.44) at $E \rightarrow U_p$ is due to the use of the WKB approximation, when turning points are close to the crossing point. For a correct expression in that case, see Sect. 52.4.2.

In many applications, one can use the mean transition probability $\langle \mathcal{P}_{12} \rangle$, which is obtained from \mathcal{P}_{12} , by averaging over several oscillations,

$$\langle \mathcal{P}_{12} \rangle = 2P_{12}(1 - P_{12}), \quad (52.45)$$

such that the double-passage transition probability $\langle \mathcal{P}_{12} \rangle$ is expressed only in terms of the single-passage transition probability, P_{12} . Equation (52.45) is a simple example of the

surface-hopping approximation [9], when one calculates the total transition probability as a results of two independent hop/survival events at the first and the second crossings of NAR: hop $1 \rightarrow 2$, (survival $2 \rightarrow 2$) + (survival $1 \rightarrow 1$), hop $2 \rightarrow 1$ (Sect. 52.5.2).

The main condition of applicability of Eqs. (52.40)–(52.45) is $\Phi_{12}^{\text{WKB}} \gg 1$, i.e., the energy, E , is well above the mean adiabatic potential at the NAR center, U_p . In this case, the NAR region is classically accessible, and the single-passage probabilities depend on the local kinetic energy $E - U_p$ at the NAR center. With decreasing collision energy, the condition $\Phi_{12}^{\text{WKB}} \gg 1$ for the WKB interference eventually breaks down, implying also the inapplicability of the LCT approximation for the single-passage transition probability. When the energy, E , drops well below U_p , one can again use the WKB approximation for the description of tunneling nonadiabatic transitions [1, 3]. Then the system reaches NAR by motion in the classically forbidden range of R , and this motion is characterized by the imaginary-value quantity $\Phi_{12}^{\text{WKB}}|_{E < U_p}$, which is obtained from the real-valued quantity, $\Phi_{12}^{\text{WKB}}|_{E > U_p}$, by the analytical continuation into the complex energy plane from the classically accessible to the classically forbidden WKB motion. Under the condition $|\text{Im} \Phi_{12}^{\text{WKB}}(E)|_{E < U_p} \gg 1$, the transition probability, $\mathcal{P}_{12}^{\text{WKB}}(E)|_{E < U_p}$, which is a classically forbidden counterpart of $\mathcal{P}_{12}^{\text{WKB}}(E)|_{E > U_p}$ in Eq. (52.41), is proportional to a small exponential factor

$$\mathcal{P}_{12}^{\text{WKB}}(E)|_{E < U_p} \propto \exp[-2|\text{Im} \Phi_{12}^{\text{WKB}}(E)|]. \quad (52.46)$$

The pre-exponential factor for Eq. (52.46) can be calculated either by specifying the integration contour for calculating the WKB transition amplitude or by the analytical continuation of Eq. (52.44) from the classically accessible to the classically forbidden WKB regions. In particular, the tunneling weak-coupling probability, $\mathcal{P}_{12}^{\text{L}}(E)|_{E < U_p}$, which is a counterpart of $\mathcal{P}_{12}^{\text{L}}(E)|_{E > U_p}$ in Eq. (52.44), reads

$$\mathcal{P}_{12}^{\text{L}}(E)|_{E < U_p} = \frac{2\pi V^2}{\hbar \Delta F} \left[\frac{2\mu}{E - U_p} \right]^{1/2} \times \exp[-2|\text{Im} \Phi_{12}^{\text{WKB-D}}(E)|]. \quad (52.47)$$

Another practically important example of the nonadiabatic transition that occurs in the deep tunneling region corresponds to the Landau–Teller [20] model of the vibrational relaxation of a diatomic molecule in a collision with atoms. The probability, P^{LT} , of the transition with the energy release, ΔE (which is induced by the relative motion in a field of a repulsive exponential potential of the range $1/\alpha$) is proportional to a small exponential factor with the expo-

nent that is different in the CT and WKB approximations

$$\begin{aligned} P^{\text{LT-CT}} &\propto \exp\left[-2\pi \Delta E \sqrt{\mu/2}/(\hbar \alpha \sqrt{E})\right], \\ P^{\text{LT-WKB}} &\propto \exp\left[-2\pi \frac{\sqrt{2\mu}(\sqrt{E + \Delta E} - \sqrt{E})}{\hbar \alpha}\right], \end{aligned} \quad (52.48)$$

where E is the initial collision energy. Since the LT-CT exponent in Eq. (52.48) is the first term of the expansion of the LT-WKB exponent in powers of the ratio $\Delta E/E$, the former provides a good approximation to the latter for $\Delta E/E \ll 1$.

52.4.2 Nonadiabatic Transitions near Turning Points

The effect of the turning points onto the double-passage probability shows itself in Eq. (52.41) through the phase Φ_{12}^{WKB} , assumed to be large enough. With E approaching U_p , the turning points become closer to the NAR center. In this situation, one can use a model of linearly crossing (LC) diabatic PEC.

In the CT approach, one keeps the LZ Hamiltonian Eq. (52.31) but introduces a CT that explicitly describes the incoming and outgoing motion within the NAR. For the case when the slopes, $-F_1$ and $-F_2$, of the diabatic potentials at R_c are of the same sign, the CT can be defined as the decelerated and accelerated motion in the field of the effective force \bar{F}

$$R(t) - R_p = \bar{F}t^2/(2\mu) - (E - U_p)/\bar{F}, \quad (52.49)$$

where \bar{F} is assumed to be a certain mean of F_1 and F_2 . For $E > U_p$, the trajectory $R(t)$ reaches the center of NAR twice at $t_p = \pm \sqrt{2\mu(E - U_p)}/\bar{F}$. For $E < U_p$, t_p is imaginary, and the center of NAR is classically inaccessible; then the trajectory $R(t)$ reaches the NAR center through the classically forbidden range of potentials. It turns out that when $\bar{F} = \sqrt{F_1 F_2}$, the semiclassical problem defined by the LZ Hamiltonian Eq. (52.31) and the CT Eq. (52.49) becomes equivalent to the quantum problem with the Hamiltonian Eq. (52.31) supplemented by the mean potential $\bar{U}(R) = U_p - (F_1 + F_2)(R - R_p)$ [3].

In the weak-coupling limit, the expression for the LC transition probability, $\mathcal{P}_{12}^{\text{LC}} \ll 1$, reads

$$\begin{aligned} \mathcal{P}_{12}^{\text{LC}}(E) &= 4\pi^2 V^2 \left(\frac{2\mu}{\hbar^2 \bar{F} \Delta F} \right)^{2/3} \\ &\times \text{Ai}^2 \left[(U_p - E) \left(\frac{2\mu \Delta F^2}{\hbar^2 \bar{F}^4} \right)^{1/3} \right], \end{aligned} \quad (52.50)$$

where A_i is the Airy function, and the difference $U_p - E$ can be of either sign.

The large absolute values of the argument of the Airy function correspond to the cases when the turning points are far from the NAR center; then Eq. (52.50) passes into the WKB expressions Eqs. (52.44) and (52.47), where the phases refer to the linear potentials

$$\mathcal{P}_{12}^{\text{LC}}(E) = \begin{cases} \mathcal{P}_{12}^{\text{LC}}(E)|_{E > U_p}, & \Phi_{12}^{\text{WKB-D}} \rightarrow \Phi_{12}^{\text{WKB-DL}} \gg 1, \\ \mathcal{P}_{12}^{\text{LC}}(E)|_{E < U_p}, & |\Phi_{12}^{\text{WKB-D}}| \rightarrow |\Phi_{12}^{\text{WKB-DL}}| \gg 1. \end{cases} \quad (52.51)$$

Here, the phase $\Phi_{12}^{\text{WKB-DL}}$, which is real for $E > U_p$ and imaginary for $E < U_p$, is

$$\Phi_{12}^{\text{WKB-DL}}(E) = \frac{2}{3}(E - U_p)^{3/2} \sqrt{\frac{2\mu}{\hbar^2} \frac{\Delta F}{F^2}}. \quad (52.52)$$

In the intermediate cases, when the Airy function cannot be approximated by its asymptotic expressions, Eq. (52.51) describes the situation when the center of NAR is close to the turning points. A further discussion on the transitions near turning points can be found in [3]. A review of different two-state models for single and double-passage nonadiabatic transitions is presented in [21].

52.5 Multiple-Passage Transition Probabilities

52.5.1 Multiple Passage in Atomic Collisions

In the case of atomic collisions, there is only one nuclear coordinate R . If there exist several NAR on the R -axis, those that are classically accessible (for given total energy, E , and total angular momentum, J) can be traversed several times. In the semiclassical approximation [22], the multiple-passage transition amplitude, A_{if} , for a given transition between initial state, i , and final state, f , can be calculated as a sum of transition amplitudes $A_{if}^{\mathcal{L}}$, over all possible classical paths, \mathcal{L} , which connect these states and which run along a one-dimensional manifold R

$$A_{if} = \sum_{\mathcal{L}} A_{if}^{\mathcal{L}}, \quad (52.53)$$

where each $A_{if}^{\mathcal{L}}$ can be expressed through the probability, $\mathcal{P}_{if}^{\mathcal{L}}$, and the phase, $\Phi_{if}^{\mathcal{L}}$, by [23]

$$A_{if}^{\mathcal{L}} = [\mathcal{P}_{if}^{\mathcal{L}}]^{1/2} \exp(i\Phi_{if}^{\mathcal{L}}). \quad (52.54)$$

The net transition probability is then

$$\begin{aligned} \mathcal{P}_{if} &= |A_{if}|^2 \\ &= \sum_{\mathcal{L}} \mathcal{P}_{if}^{\mathcal{L}} + \sum'_{\mathcal{L}, \mathcal{L}'} [\mathcal{P}_{if}^{\mathcal{L}} \mathcal{P}_{if}^{\mathcal{L}'}]^{1/2} \cos(\Phi_{if}^{\mathcal{L}} - \Phi_{if}^{\mathcal{L}'}). \end{aligned} \quad (52.55)$$

The first sum runs over all different paths and the second (primed) over all different pairs of paths. The primed sum usually yields a contribution to the transition probability, which oscillates rapidly with a change of the parameters entering into \mathcal{P}_{if} (i.e., E and J) and represents a multiple-passage counterpart to the Stückelberg oscillations.

If the Stückelberg oscillations are neglected, \mathcal{P}_{if} is equivalent to a mean transition probability $\langle \mathcal{P}_{if} \rangle$

$$\langle \mathcal{P}_{if} \rangle = \sum_{\mathcal{L}} \mathcal{P}_{if}^{\mathcal{L}}. \quad (52.56)$$

For one NAR, there are two equivalent paths, and $\mathcal{P}_{if}^{(1)} = \mathcal{P}_{if}^{(2)} = P_{if}(1 - P_{if})$. Then Eq. (52.56) yields Eq. (52.45).

52.5.2 Surface Hopping

For molecular collisions, Eqs. (52.53) and (52.54) apply as well. However, the manifold of \mathcal{R} to which a trajectory $\mathcal{Q}(t)$ belongs now comprises $3N - 5$ (for a linear arrangement of nuclei) or $3N - 6$ (for a nonlinear arrangement) degrees of freedom, where N is the number of atoms in the system. The approximation Eq. (52.56) is called, in the context of inelastic molecular collisions, the surface-hopping approximation [5, 24]. Each time a trajectory reaches a NAR, it bifurcates, and the system makes a hop from one PES to another with a certain probability. Keeping track of all the bifurcations and associated probabilities, one calculates $\mathcal{P}_{if}^{\mathcal{L}}$ along a path \mathcal{L} made up of different portions of trajectories running across different PES. Because of the complicated sequence of nonadiabatic events leading from the initial state to the final state, each $\mathcal{P}_{if}^{\mathcal{L}}$ is a complicated function of different single-passage transition probabilities, P_{nm} , and survival probabilities, $1 - P_{nm}$. Even if all P_{nm} are known in analytical form, the calculation of $\langle \mathcal{P}_{if} \rangle$ requires numerical computations to keep track of individual nonadiabatic events [24].

In order to formulate the approach implementing the surface-hopping approximation, often referred to as molecular dynamics with electronic transitions, it is convenient to rewrite Eqs. (52.18) for the time evolution of the wave function expansion coefficients in the more general density matrix notation. The diagonal density matrix elements in the adiabatic representation, $\rho_{11} = a_1 a_1^*$ and $\rho_{22} = a_2 a_2^*$, determining the electronic state populations then satisfy the following equations

$$\frac{d\rho_{22}}{dt} = -\frac{d\rho_{11}}{dt} = \dot{Q}g(\mathcal{Q})(\rho_{12} + \rho_{21}), \quad (52.57)$$

and the coherence defined by $\rho_{12} = a_1 a_2^*$ satisfies

$$\frac{d\rho_{12}}{dt} = i\hbar^{-1} \Delta U(\mathcal{Q})\rho_{12} + \dot{Q}g(\mathcal{Q})(\rho_{11} - \rho_{22}). \quad (52.58)$$

Equation (52.57) shows that it is the dynamical coupling function $g(Q)$ that promotes the changes in the electronic state populations, i.e., the electronic transitions. Due to these transitions the trajectory bifurcates, and the surface-hopping approach can be considered a procedure for selection of the proper branch for the system to evolve. The most popular version of that approach, fewest-switches surface hopping (FSSH) [25], proposed by *J. C. Tully* is considered here. Its key feature is the algorithm maintaining the statistical distribution of electronic state populations in agreement with those obtained by numerically integrating the system of differential equations (52.57) and (52.58). Let the system be at time t on a trajectory Q_1 corresponding to the state 1 with population $\rho_{11}(t)$. According to Eq. (52.57) the nonadiabatic coupling $g(Q)$ induces the electronic transitions in a small time interval δt , leading to the change of the state 1 population, $\delta\rho_1 = \rho_{11}(t + \delta t) - \rho_{11}(t)$. If $\delta\rho_1 \geq 0$, i.e., there is a gain in the state 1 population, then the probability of the switch is set to zero, and the system remains on the trajectory $Q_1(t)$. If, in contrast, $\delta\rho_1 < 0$, there exists a nonzero probability P_{12} for the trajectory to switch to the trajectory branch Q_2 corresponding to the state 2

$$P_{12}(t, \delta t) = -\frac{\delta\rho_1}{\rho_{11}(t)} \approx \frac{\lambda(t)\delta t}{\rho_{11}(t)}, \quad (52.59)$$

where $\lambda(t)$ denotes the right-hand side of Eq. (52.57). The decision to switch from state 1 to state 2 is made when the switch probability P_{12} is larger than a random number between 0 and 1 generated from the uniform distribution.

The FSSH algorithm automatically incorporates a number of important properties: (i) as P_{12} is proportional to dynamic coupling $g(Q)$, the transitions between electronic states can occur at any location and time, not only in the NAR specified by some predefined conditions like was done in Sect. 52.2.2 or in the earlier version of surface hopping, which makes the method applicable to any number of passages through NAR; (ii) for the large number of trajectories, their fraction located on the state i branch approaches $\rho_{ii}(t)$ at any t , thus reproducing the electronic state populations; (iii) the electronic coherences are propagated properly with Eq. (52.58) enabling the reproducing of quantum interference effects; (iv) the generalization for any number of coupled electronic states is straightforward, and FSSH was recently implemented to study the nonadiabatic dynamics of an open-shell molecule at a metal surface [26].

At the same time, surface hopping is not free from some *ad hoc* adjustments, which can limit its validity. For example, when a switch between state 1 and state 2 PES occurs, the velocities of classical degrees of freedom have to be rescaled to preserve the total energy, which leads to discontinuities in the classical trajectory, $Q(t)$, defined on the many-dimensional manifold, \mathcal{R} . Moreover, the amount of classical kinetic energy is not always sufficient to fill the gap between electronic

states (classically forbidden transitions). In that case, the switch is rejected (a so-called “frustrated hop”), which introduces artificial distortions in the state populations.

The manifold \mathcal{R} can be reduced in size if one treats other degrees of freedom, besides electronic ones, on the same footing. In this way one introduces adiabatic vibronic (vibrational + electronic) states and adiabatic vibronic PES, and considers nonadiabatic transitions between them [27]. In the vibronic representation, the formal theory remains the same; however its implementation is more difficult since there are many more possibilities for trajectory branching. Finally, under certain conditions, one can use a fully adiabatic description of all degrees of freedom, save one – the intermolecular distance R . This approach provides a basis for the statistical adiabatic channel model (SACM) of unimolecular reactions [28] where the receding fragments are scattered adiabatically in the exit channels after leaving the region of a statistical complex.

For a recent review of the theory of molecular nonadiabatic dynamics, see [7] and papers in [9], as well as the recent book [29].

Abstract

This chapter summarizes the principal features of theoretical treatments of intermediate-energy ion–atom and atom–atom collisions. Here, intermediate means that the relative velocity between the projectile and target is on the order of, or larger than, the orbital speed of the active electron(s) but not large enough for relativistic effects to play a significant role. In this range, the semiclassical approximation in which the scattering problem is described by a time-dependent Schrödinger equation for the electronic motion in the field of classically moving nuclei is usually appropriate. The main goal of this chapter is to introduce the basic concepts, terminology, and methods to discuss ion–atom and atom–atom collisions in this framework.

53.1 Introduction

Ion–atom and atom–atom collisions are the subject of several chapters in this Handbook. The wide range of experimentally accessible impact energies, the variety of processes that can occur, and the long and rich history of the field translate into a large number of theoretical approaches and computational methods that are in use to describe the physics at play. The emphasis of the present chapter is on general approaches to deal with this problem. There are several review articles and monographs, e.g., [1–4], which provide comprehensive and in-depth accounts of the many methods and techniques that have been developed and applied over the years.

53.2 General Considerations and Formulation of the Problem

The collisions considered in this chapter involve a projectile ion or atom A and a target atom B . The collision kinematics can be described in the laboratory frame, where B is assumed to be initially at rest, and the collision energy is the kinetic energy of A when it is far from B prior to the collision, or in the center of mass frame. The primary quantities of interest are the cross sections for producing various final states of the system for given initial states of the target and projectile.

A few examples for a projectile with charge q in the initial state are

where A^* and B^* denote excited states. Variants of the above list would involve initially excited projectile and/or target species or the special case of a neutral projectile ($q = 0$).

For a multielectron collision system, combinations of the above processes may occur. A few representative examples are

One class of collision problems that has received much theoretical attention involves an initially bare projectile ion and a neutral target atom with one or several electrons in the initial (ground) state. Obviously, this represents a simpler problem than that of a collision system in which electrons are bound to both the target and the projectile initially. The simplest scenario is a bare ion colliding with the one-electron hydrogen atom. In this case, the single-electron processes target excitation, and target ionization and e^- charge transfer are the only inelastic collision channels that can occur. Figure 53.1 shows total cross sections for these channels for the p-H system as functions of the collision energy E_p ; $E_p = 25$ keV corresponds to a velocity of one atomic unit, i.e., the (average) orbital speed associated with the kinetic energy of the H(1s) electron and $E_p = 100$ keV to two atomic units of velocity. The three cross sections shown in Fig. 53.1 are of comparable magnitude in this energy interval. This illustrates a competition of collisional processes, or in more technical terms, the occurrence of coupled-channel dynamics, which calls for a nonperturbative solution of the scattering problem.

For the cross sections and the impact energy interval of Fig. 53.1, the semiclassical approximation (SCA), in which the motion of the nuclei is described classically and only the electron is described in terms of quantum-mechanical wave functions, is essentially exact [3, 5]. At $E_p \geq 10$ keV

Fig. 53.1 Total cross sections for target excitation, e^- charge transfer (capture), and target ionization in p-H collisions as functions of impact energy. Curves correspond to theoretical results obtained from the two-center basis generator method [11, 12]

the projectile can be safely assumed to follow a straight-line path with constant speed v . At somewhat lower energies the deflection and change in speed of the projectile due to the projectile–target interaction are often incorporated. One can determine curved trajectories by considering the nonadiabatic coupling of the electronic and nuclear motions [6, 7], or one can use predetermined Coulomb trajectories due to the nucleus–nucleus interaction [8, 9] or trajectories corresponding to model potentials that account for electronic screening effects in addition [10]. For a bare positive ion projectile, such as the proton in p-H collisions, the Coulomb trajectory effects increase the distance of the closest approach for a given impact parameter b and reduce the projectile speed v in the interaction region.

In the SCA, the vector $\mathbf{R}(b, t)$ that locates the projectile relative to the target nucleus is a function of the impact parameter b and time t . The specific functional dependence is determined by the trajectory being used. For a straight-line, constant velocity v path, $\mathbf{R} = \mathbf{b} + \mathbf{v}t$. For the case of a bare projectile ion and a one-electron target, the time-dependent projectile–target interaction is given by

$$V(\mathbf{r}, b, t) = \frac{-Z_P e^2}{4\pi\epsilon_0 |\mathbf{r} - \mathbf{R}(b, t)|} + \frac{Z_P Z_T e^2}{4\pi\epsilon_0 R(b, t)}, \quad (53.1)$$

where Z_P and Z_T are the projectile and target nuclear charge numbers, e is the elementary charge, ϵ_0 the electric permittivity of the vacuum, and \mathbf{r} the position vector of the electron

relative to the target nucleus, which is chosen here as the origin of the (inertial) reference frame.

Using atomic units characterized by $\hbar = m_e = e = 4\pi\epsilon_0 = 1$ from here on, the full Hamiltonian for the one-electron ion–atom collision problem reads

$$\hat{H}(t) = -\frac{1}{2}\nabla^2 - \frac{Z_T}{|\mathbf{r}|} + V(\mathbf{r}, b, t), \quad (53.2)$$

and the time-dependent Schrödinger equation (TDSE)

$$(\hat{H}(t) - i\partial_t)\psi(\mathbf{r}, t) = 0 \quad (53.3)$$

has to be solved subject to the initial condition $\psi(\mathbf{r}, t = t_i) = \phi_i(\mathbf{r})$, where ϕ_i denotes, e.g., the hydrogen ground state. Exploiting cylindrical symmetry, the total cross section for a transition from the initial state ϕ_i to a final state ϕ_f is given by

$$\sigma_{i \rightarrow f} = 2\pi \int_0^\infty b |a_{fi}(b)|^2 db, \quad (53.4)$$

where $a_{fi} = \langle \phi_f | \psi(t_f) \rangle$ is the electronic transition amplitude for the process of interest taken at a final time t_f , which formally should approach infinity and in practice has to be large enough to ensure that when it is varied the transition probability does not change appreciably. As a consequence of the unitarity of the TDSE one has $\sum_f |a_{fi}|^2 = 1$, if the sum over the final states is complete.

It is noteworthy that the nuclear repulsion term in Eq. (53.1) does not involve the electronic coordinates and can be eliminated by a phase transformation. It thus makes no contribution to total cross sections for anything other than elastic scattering for which the total cross section does depend on the phase information in the amplitude

$$\sigma_{\text{elastic}} = 2\pi \int_0^\infty b |a_{f=i}(b) - 1|^2 db. \quad (53.5)$$

One might think that the framework of the SCA precludes the calculation of cross sections differential in the scattering angle Θ of the projectile. However, this is not the case. If the collision energy is high, and the projectile is scattered primarily by the static potential of the target, a classical treatment of the scattering can be used to relate b to Θ . Even when straight-line, constant speed projectile paths are used to calculate the transition probabilities, differential cross sections can be extracted by relating b to Θ . At lower energies, where the de Broglie wavelength of the projectile is not small compared with the range of the interaction, eikonal methods can be used to convert impact parameter dependent transition amplitudes to differential cross sections (e.g., [3, 13, 14] and references therein). These methods establish a two-dimensional Fourier-transform-like relation

between $a_{fi}(b)$ and the T -matrix of stationary scattering theory. Given that they involve *amplitudes* the calculated differential cross sections are sensitive to phase information and, as a consequence, to the nuclear repulsion term in Eq. (53.1).

53.3 Approximate Versus Full Many-Electron Treatments

In the semiclassical impact parameter method, as described in Sect. 53.2, for a one-electron collision system one has to calculate a single-particle wave function and from it single-electron transition amplitudes. For an N -electron collision problem, the situation is, in general, much more complicated since the Hamiltonian involves one-particle and two-particle terms

$$\hat{H}(t) = \sum_{i=1}^N \left(-\frac{1}{2}\nabla_i^2 - \frac{Z_T}{|\mathbf{r}_i|} + V(\mathbf{r}_i, b, t) \right) + \sum_{i < j}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|}. \quad (53.6)$$

The latter introduce electron correlations and prevent the TDSE from being separable.

However, a full account of the correlated many-electron problem is not always necessary. Consider a collision system in which a bare ion interacts with an alkali atom such as lithium. In such a case, it is often reasonable to assume that the inner-shell electrons are frozen to their initial state and merely provide an effective potential in which the active valence electron moves. This scenario corresponds to a single-particle Hamiltonian like the one in Eq. (53.2) with the electron–target Coulomb potential replaced by an effective atomic ground-state potential. Formally, one can derive this single active electron approximation by averaging the two-particle Hamiltonian Eq. (53.6) over the coordinates of the passive electrons [14, 15].

In the independent particle model (IPM), the two-particle electron–electron terms in Eq. (53.6) are approximated by effective one-body operators. The many-electron collision problem then reduces to a set of single-electron problems which, depending on the level of approximation used, may be coupled or uncoupled. An example of the former is the time-dependent Hartree–Fock (TDHF) method, which involves nonlinear single-particle equations and a nonlocal (Fock) exchange operator [16–18]. An example of the latter is an IPM, in which single-active-electron-model ground-state potentials are used, and the problems associated with the nonlocality of the Fock exchange term and the nonlinearity of the TDHF equations are avoided [14]. In either case, the solution of the single-particle equations at each impact parameter and energy gives single-electron transition amplitudes a_{fi} , which, when combined in an appropriate way, yield cross sections for multielectron transitions [19, 20].

The most sophisticated method of combining the single-particle solutions starts with the assumption that the initial and final many-electron states are represented by single Slater determinants. Transition probabilities for multielectron processes can then be written as combinations of determinants of reduced density matrices [21]. The determinantal structure of these expressions reflects the antisymmetry of the problem and has often been associated with so-called Pauli correlations [22]. If the Pauli correlations are neglected and the final-state analysis is based on simple product states instead of Slater determinants, the multielectron transition probabilities simplify to multinomial combinations of single-electron probabilities [23–25].

The effective single-particle character of the IPM equations is a consequence of an approximation, the replacement of the two-particle electron–electron interactions in Eq. (53.6) by one-body operators. By contrast, the Kohn–Sham scheme of time-dependent density functional theory (TDDFT) asserts that one can map the interacting many-body problem to a set of effective single-particle equations *exactly* [26, 27]. This seemingly contradictory statement is based on the insight that the electron density determines the state of a many-body system. More precisely, one can show (provided that certain conditions are met) that the solution Ψ of the TDSE for the Hamiltonian Eq. (53.6) is a unique functional of the density n , i.e., $\Psi = \Psi[n](t)$ and that n can be calculated from orbitals

$$n(\mathbf{r}, t) = \sum_{i=1}^N |\psi_i(\mathbf{r}, t)|^2, \quad (53.7)$$

which solve single-particle equations of the form

$$i \partial_t \psi_i(\mathbf{r}, t) = \left(-\frac{1}{2} \nabla^2 + v_{\text{TDKS}}[n](\mathbf{r}, t) \right) \psi_i(\mathbf{r}, t) \\ i = 1, \dots, N. \quad (53.8)$$

The effective potential v_{TDKS} in Eq. (53.8) is called the time-dependent Kohn–Sham (TDKS) potential and is itself a unique functional of the density. The problem is that the exact form of this functional is not known and has to be approximated in practical calculations. One usually starts by decomposing v_{TDKS} into different pieces associated with the external Coulomb interactions and with electronic screening, exchange, and correlation effects and then introduces different levels of approximation or models for the electronic pieces. In particular, the correlation portion is often neglected, which amounts to an IPM-like (“exchange-only”) treatment. For a two-electron spin-singlet system such as a bare-ion helium-atom collision problem exchange can be treated exactly without added difficulty [28, 29] or can be approximated in various ways [30, 31]. For more complex problems the Krieger–Li–Iafraite approximation [32] can be used to construct an almost exact exchange potential [33].

Similarly to the TDKS potential, most multielectron probabilities of interest in an ion–atom or atom–atom collision problem have to be approximated. These probabilities are readily expressed in terms of integrals that involve the many-electron wave function at an asymptotic time after the collision. Hence, they are functionals of n because $\Psi(t_f)$ is, but their exact functional form is normally not known because the exact $\Psi[n](t_f)$ is not available.

Some progress has been made in recent years in developing and implementing approximate density functionals that improve on IPM predictions for certain collision processes [34]. This parallels successes in the application of TDDFT to the somewhat related problem of the excitation and ionization of atoms (and molecules) by strong laser fields (Chap. 78). However, there is room for further improvement, and it remains to be seen whether the TDDFT approach will be capable of explaining well-known signatures of correlated electron dynamics in collisions.

A famous example of the latter is an observed factor-of-2 difference in the total double-ionization cross section of helium in the MeV/amu collision energy region, when the impacting projectile is either a proton ($Z_p = +1$) or an antiproton ($Z_p = -1$). The IPM fails to produce this difference, which can be qualitatively understood using arguments based on perturbation theory and by differentiating between externally and internally induced two-electron processes [35, 36].

In an externally induced two-electron process, the projectile interacts with both electrons and induces the transition of each. In the internal process, energy is transferred to just one electron; this energy is then shared with the other electron through the internal action of the correlating electron–electron force. At sufficiently high energies, the external reaction has an amplitude proportional to Z_p^2 . To lowest order, the reaction proceeds through two consecutive first-order Born collisions, perhaps more correctly described as a two-particle second-order Born collision. This is called the two-step two (TS2) mechanism. The internal reaction amplitude, again at sufficiently high energies, is proportional to Z_p , as a first-order Born reaction initiates the process. The sharing of energy with the second electron can be thought of in two ways. If the first electron is ejected without interacting with the second, there is a change in the screening that can be thought of as being responsible for shaking the second electron off. The main role of the electron–electron force here is to introduce correlation into the initial ground-state wave function. A second way for both electrons to be ionized is for the first electron to strike the second on the way out. This has been variously called interception or two-step one (TS1) [23, 37–39]. The role of the electron–electron force here is to introduce correlation into the final two-electron wave function.

At asymptotic energies the first Born term eventually dominates, and the internal correlated mechanism is solely responsible for double ionization. At lower energies, the ex-

ternal and internal amplitudes are of the same order, and thus they interfere. The interference produces terms in the transition probability that are proportional to odd powers of Z_P , and therefore leads to a cross section that changes when the sign of the projectile charge changes. This phenomenon has been observed for proton versus antiproton impact-induced double ionization [40].

Accounting for electron correlations directly by solving the nonseparable TDSE involving the Hamiltonian Eq. (53.6) is computationally costly. In coupled-channel calculations (Sect. 53.4), this brute-force approach becomes intractable if the number of electrons exceeds two or three, and more than a few coupled channels are important, which is usually the case at intermediate collision energies. Some full two-electron calculations have been carried out nevertheless [41–46], especially for antiproton-impact collisions ([40, 47] and references therein). In low-energy collisions where molecular basis expansions are appropriate, it is more likely that only a few channels are important, i.e., those involved in potential curve crossings or near crossings, and full electron calculations are more feasible (Chap. 55).

Some alternatives to full electron quantum calculations have been developed. In the nonperturbative regime they include the independent event model [48], classical dynamics calculations (Chap. 62), the frozen-correlation approximation (FCA) [49], and the forced impulse method (FIM) [38, 39]. The FCA distinguishes between static and dynamic correlation and takes into account the former, but neglects the latter. The FIM uses similar ideas of static and dynamic correlation and divides the collision time into short sequential segments such that an impulse approximation becomes valid. The system is allowed to collapse back into a fully correlated eigenstate at the end of each segment, but the electrons propagate independently during each segment. Provided that the number of segments is large enough, the FIM solution should be equivalent to the full electron solution.

Similarly to full electron approaches, the vast majority of calculations that use one of these alternative methods were carried out for two-electron systems. The most promising first-principles approach to deal with collision systems that involve more than two electrons is probably TDDFT. A recent work has addressed the three-electron He^+-He system, in which an active projectile electron has to be taken into account in addition to two active target electrons [33]. This approach holds promise to be extended to atom–atom collisions, which always involve (active) electrons on both centers. TDDFT methods have also been used to study low to intermediate energy ion collisions from (small) molecules [50–52]. This problem has attracted considerable attention in recent years but is, of course, even harder to address in terms of full electron approaches or one of the alternative methods described above than ion–atom or atom–atom collisions.

53.4 Computational Techniques

There is a wide variety of techniques used for computing cross sections for ion–atom and atom–atom collisions. One class uses approximate analytical methods. The expressions and the wave functions that enter into them may be sufficiently complicated that they must be evaluated on a computer, but they can be written down as closed-form expressions. One important example is the first Born approximation (FBA), in which the projectile–target interaction is treated in first order. Hence, the FBA is the most accurate for weak interactions, for example for small projectile charge and large collision energy (e.g., [5] and Chap. 57).

Higher-order Born calculations should extend the range of applicability of the FBA but are difficult to implement and, in practice, usually restricted to second order [53]. Distorted-wave methods are viable alternatives within the framework of perturbation theory; particularly variants of the continuum distorted-wave (CDW) model (Chap. 56) have been widely and successfully applied to ion–atom collision problems. Other approximate methods that lead to simple analytic expressions include the Glauber approximation [54–56] and the binary encounter approximation (BEA, Chap. 60).

A difficulty with these methods is that they normally do not admit to a sequence of successive improvements; there is no procedure for systematically driving them to convergence. This is to be contrasted with methods that solve the semiclassical TDSE, or even the full quantum-mechanical scattering problem, fully nonperturbatively. This class of largely numerical methods does allow for systematic convergence studies and, given the ever increasing availability of computational resources, highly accurate solutions.

53.4.1 Coupled-Channel Methods

The standard approach to solving the semiclassical TDSE nonperturbatively is to expand the electronic wave function in some basis set [2, 3, 57]. This procedure is called the coupled-channel or close-coupling method. It is convenient to diagonalize the target and projectile systems in the chosen basis to produce matrix eigenfunctions for the target and projectile. Putting this expansion into the TDSE leads to a set of coupled first-order equations for the time-dependent expansion coefficients. This set of equations is solved subject to the boundary condition that long before the collision, the expansion coefficient for the initial state wave function is unity and all other coefficients are zero. Then a long time after the collision, the expansion coefficients give the amplitudes for transitions into those states.

Several types of expansions are used. The notation appropriate to a single-electron problem will be used for simplicity in the following. In the single-centered expansion [58, 59],

the wave function is expanded in a set of target centered basis functions. Diagonalization of the target Hamiltonian in this basis yields a set of target eigenfunctions $\phi_j^T(\mathbf{r})$ and energies E_j . The expansion of the time-dependent wave function for the collision system is then

$$\psi_i(\mathbf{r}, b, t) = \sum_j a_{ji}(b, t) e^{-i(E_j - E_i)t} \phi_j^T(\mathbf{r}). \quad (53.9)$$

If the electron is initially in the target state i , the initial boundary condition is $a_{ji}(b, t_i \rightarrow -\infty) = \delta_{ji}$. At times long after the collision, the expansion coefficients, $a_{ji}(b, t_f \rightarrow +\infty)$, give the amplitudes for transitions from target state i to j . Ionization probabilities and the description of the ionization continuum will be discussed in Sect. 53.5. It suffices to say here that some of the $\phi_j(\mathbf{r})$ represent ionized states and account for transitions that leave the electron no longer in a target bound state.

This single-centered expansion is the natural approach to describing a collision system that involves antiproton projectiles that do not support bound electron states [40, 60]. It can also be used for positively charged projectile ions, although it does not directly allow for calculation of charge transfer amplitudes. However, it has been shown that if the number of angular momenta included in the set of $\phi_j(\mathbf{r})$ is large enough, the basis can accurately describe electron loss from the target bound states, i.e., the sum of electron capture and ionization events, even in cases where the charge transfer probability is large [59].

In a two-centered expansion [2, 61–65], the time-dependent wave function for the collision system is expanded in two sets of functions: a set of eigenfunctions centered on the target $\phi_j^T(\mathbf{r})$ and a set of projectile centered eigenfunctions $\phi_k^P(\mathbf{r} - \mathbf{R})$

$$\begin{aligned} \psi_i(\mathbf{r}, b, t) = & \sum_j a_{ji}^T(b, t) \exp[-i(E_j - E_i)t] \phi_j^T(\mathbf{r}) \\ & + \sum_k a_{ki}^P(b, t) \exp[-i(E_k - E_i)t] \\ & \times \exp[i\mathbf{p} \cdot \mathbf{r}] \phi_k^P(\mathbf{r} - \mathbf{R}). \end{aligned} \quad (53.10)$$

Here, $\exp[i\mathbf{p} \cdot \mathbf{r}]$ is an electron translation factor that accounts for the momentum \mathbf{p} that the electron has relative to the target when it moves with the projectile. The energies E_k also contain the kinetic energy in the target frame that the electron has when it moves with the projectile. The problem of electron translation factors when a two-centered molecular basis is used instead of the atomic basis has been extensively addressed [2, 3, 66].

The coefficients $a_{ji}^T(b, t_f \rightarrow +\infty)$ and $a_{ki}^P(b, t_f \rightarrow +\infty)$ are the amplitudes for transitions into target and projectile states. The two-centered expansion allows for charge transfer amplitudes to be calculated directly and is capable of an accurate description of the electron flux loss from the target

due to charge transfer, but the computational difficulty is significantly greater than in a single-centered expansion. One reason is that the projectile and target basis states are not orthogonal, and computational linear dependence can arise when both centers are close during the collision. This problem is most apparent in a symmetric collision system such as p-H, where the projectile-centered basis states will become nearly identical to the target-centered states at small internuclear distances [67, 68]. Very high numerical precision in the solution of the coupled-channel equations is required to deal with this situation.

There are other basis methods. To account for flux loss from the target region due to charge transfer, while retaining the computational efficiency of the single-centered expansion, a hybrid method called the one-and-a-half centered expansion was developed and applied to several collision problems with good success some time ago [69, 70]. Calculations have also been done with a triple-centered expansion [71, 72], in which bound atomic states are centered on each nucleus and on a third center (the center of charge) in order to simulate the molecular character of slow collisions. The orbitals on this third center represent the united-atom character of the wave function. These and other expansion techniques proposed and applied before the early 1990s are described in some detail in [3]. A somewhat more recent approach that is in active use is the basis generator method (BGM). In the BGM, a single-centered [73] or a two-centered [11] basis of bound states is augmented by pseudo states that are constructed by operating with a regularized potential operator on target states or on target and projectile states. At low impact energies these BGM pseudo states play a role that is similar to the center-of-charge states in a triple-center expansion. They also overlap with the continuum and, when orthogonalized to the bound states of both centers, allow for a description of ionization events.

53.4.2 Numerical Grid Methods

In grid-based approaches, the electronic wave function is represented on a spatial lattice and time-evolved fully numerically. A variety of methods can be used to this end, e.g., finite difference and Fourier collocation techniques [74–78]. The latter are based on splitting the time-evolution operator \hat{U} for a small time step into factors associated with kinetic (T) and potential (W) energy terms according to

$$\begin{aligned} \hat{U}(t + \Delta t, t) \approx & \exp[-i\hat{H}(t)\Delta t] \approx \exp[-iT\Delta t/2] \\ & \times \exp[-iW(t)\Delta t] \exp[-iT\Delta t/2] \end{aligned} \quad (53.11)$$

and switching back and forth between coordinate and momentum space using a fast Fourier transform algorithm when

applying \hat{U} to the wave function. The benefit of switching between representations is that each propagation step involves multiplicative operators only, either in coordinate space ($W(t) = W(\mathbf{r}, t)$) or in momentum space ($T = \mathbf{p}^2/2$).

In most lattice methods, the Coulomb singularities are avoided by using soft-core potentials and the wave function is prevented from being reflected at the boundaries of the numerical box by using mask functions or (complex) absorbing potentials. The bound-state contributions of the wave function at the final time are extracted by projection techniques to calculate charge transfer and target excitation probabilities. An appealing feature of lattice solutions is that they provide a direct view of the unbound part of the wave function, i.e., they appear to be well suited to describe differential ionization patterns.

There are also methods that one can view as hybrids of basis-expansion and lattice techniques; if one expands the electronic wave function into spherical harmonics, one obtains a set of coupled partial differential equations for time-dependent radial functions $R_{lm}(r, t)$ that can be solved by grid-based or other numerical techniques [47, 79]. A somewhat similar method to address the semiclassical scattering problem in momentum space is described in [80].

53.5 Description of the Ionization Continuum

In ion–atom and atom–atom collision calculations, the description of the ionization continuum presents particular difficulties. For hydrogenic systems, the exact continuum wave functions are known analytically, and these may be used in analytic approximations such as the FBA. For non-hydrogenic systems, screened hydrogenic wave functions or numerical wave functions computed from some local effective potential, such as the Hartree–Fock–Slater approximation, can be used [81, 82]. However, for coupled-channel calculations that involve expansion of the system wave function in terms of a discrete set of functions some discretization of the continuum must be performed.

A simple procedure for generating a discrete representation of the continuum is to diagonalize the target (or projectile) Hamiltonian in a finite basis of square integrable basis functions. Some commonly used basis functions are Sturmian [65], Gaussian [46, 68], Laguerre [83–85], or Slater-type orbitals [86]. The diagonalization produces a set of discrete matrix eigenvalues and eigenvectors. For a one-electron or effective one-electron system, the exact energy spectrum of the Hamiltonian consists of an infinite set of discrete bound states and an ionization continuum, and the interpretation of the matrix eigenvectors is straightforward. Those whose eigenvalues are below the first ionization threshold represent bound states. Let us assume that there are M such vectors. By the Hylleraas–Undheim theorem, their

eigenvalues are upper bounds to the first M exact energies (Sect. 12.3.1). The matrix eigenvectors with positive eigenvalues are usually called pseudo states and provide a discrete representation of the ionization continuum [87], similarly to the BGM pseudo states mentioned in Sect. 53.4.1. In contrast to the latter, they are related to the true continuum states in a direct way. Each positive energy pseudo state is accurately proportional to the exact continuum wave function at the pseudo-state energy for radial distances r out to the range of the basis. The proportionality constant gives the energy width of the pseudo state – the energy region of the continuum represented by that pseudo state [88, 89]. These widths are approximately equal to the energy spacing between pseudo states. The pseudo states represent the continuum in the sense that the total ionization cross section is equal to the sum of the continuum pseudo-state cross sections. For example, the total p-H ionization cross section shown in Fig. 53.1 has been obtained by summing up the BGM pseudo-state continuum contributions.

Driven by experimental advances, the description of differential ionization patterns has become a major objective of ion–atom collision calculations. Cross sections differential in the ionized electron’s energy [90, 91], cross sections differential in the electron’s emission angle, and cross sections differential in both energy and angle have been extracted from discretized continuum [83, 84] and numerical lattice [75] calculations. Ejected electron momentum distributions have also been studied [75, 80, 92–94]. It is even possible to extract triply differential cross sections, i.e., cross sections that are differential in the electron energy, electron emission angle, and in the projectile scattering angle Θ from semiclassical coupled-channel calculations [83, 84]. The eikonal methods mentioned in Sect. 53.2 are used in those works to convert impact parameter-dependent to Θ -dependent ionization amplitudes [95]. Alternatively, a close-coupling approach to the fully quantum-mechanical scattering problem has been developed to calculate total [85, 96] and differential [97] scattering cross sections.

Coupled-channel calculations have also been carried out with wave packets constructed at discrete energies from the exact continuum wave functions [98, 99]. This method has the advantage that the density of the continuum discretization can be made arbitrarily high, thereby improving the accuracy of calculated differential cross sections and allowing for the observation of features that are difficult to resolve in standard pseudo-state calculations [99].

Figure 53.2 shows a comparison of triply differential ionization cross sections in antiproton–hydrogen collisions obtained by using different methods. The geometry is chosen such that the momenta of all three particles in the final state are in the same plane. The electron ejection energy and the momentum transfer vector (whose transverse component determines Θ) are fixed, and the electron ejection angle is

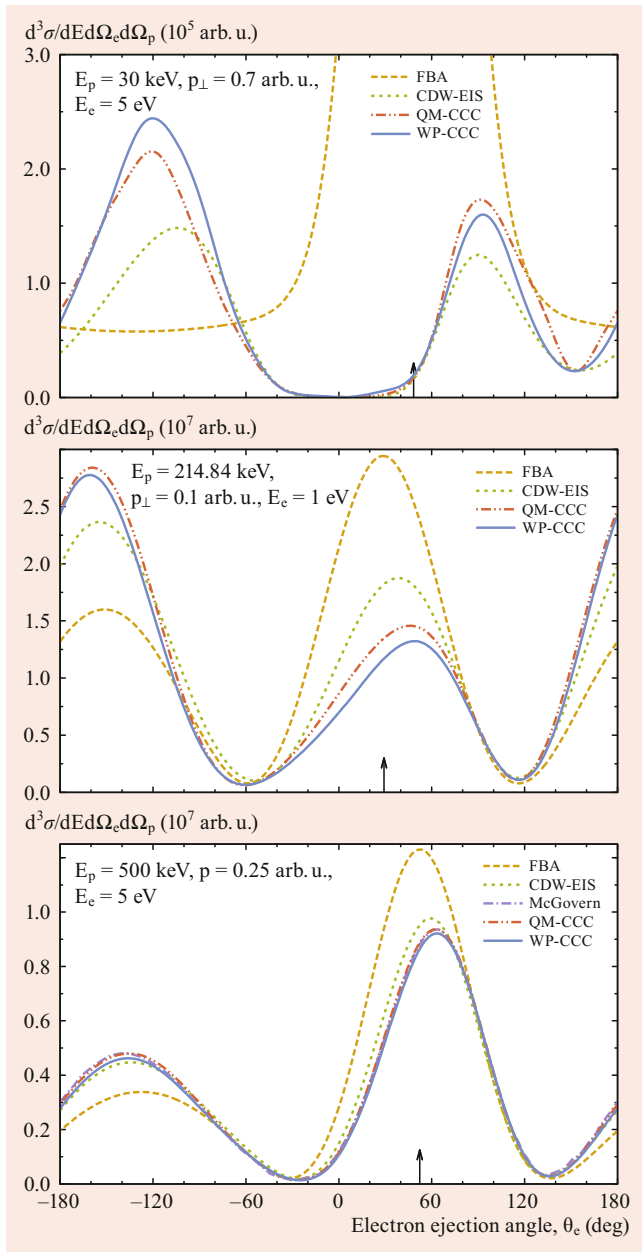

Fig. 53.2 Triply differential cross sections for antiproton-impact ionization of ground-state atomic hydrogen at various impact energies E_p , electron ejection energies E_e , and (perpendicular) momentum transfers $p_{(\perp)}$ plotted as functions of the electron ejection angle. Arrows indicate the direction of the momentum transfer vector. CDW-EIS: continuum distorted-wave eikonal initial-state [100], McGovern: coupled pseudo state [83], QM-CCC: quantum-mechanical convergent close-coupling [97], FBA and WP-CCC: first Born and wave-packet convergent close-coupling [99] calculations. After [99] by permission

measured with respect to the direction of the incident antiproton. All theories predict the familiar two-lobe structure of this cross section except for the FBA at $E_p = 30$ keV. This is a clear indication that first-order perturbation theory is not valid at such a relatively low impact energy. The continuum distorted-wave eikonal initial-state (CDW-EIS,

Chap. 56) model fares much better and qualitatively agrees with the fully nonperturbative calculations, which are either based on the SCA [83, 99] or a fully quantum-mechanical close-coupling method [97]. At $E_p = 500$ keV the level of agreement of all those calculations is very good with only the FBA deviating by more than a few percent from the other theories. At the lower impact energies the wave packet approach is deemed to be the most accurate one [99].

The coupled-channel calculations shown in Fig. 53.2 are based on single-centered expansions. Two-centered variants have also been developed in order to deal with differential ionization in p-H collisions at intermediate impact energy [101, 102]. It was noted that an ambiguity appears to arise in this case and that one had two choices to compute differential ionization cross sections: either by adding the scattering amplitude corresponding to the positive-energy target states to that corresponding to the projectile-centered states coherently or by adding them incoherently [101]. The ambiguity is related to the nonorthogonality problem of two-centered expansions discussed in Sect. 53.4.1. However, if the final-state analysis is carried out at a truly asymptotic distance where the target- and projectile-centered states do not overlap, formal arguments favor the coherent version.

As mentioned above, lattice methods give access to differential ionization patterns in a direct fashion. Once the bound-state parts of the wave function have been properly subtracted, the time evolution of the continuum wave packet can be monitored either in coordinate space or in momentum space. In recent work, scaled coordinates and a transformation of the wave function that removes a diverging phase factor have been employed to follow the density and current density distributions to truly asymptotic distances [103]. This has been key to the discovery of vortices in atomic collision systems and the investigation of their role in transferring angular momentum from nuclear to electronic motions [104].

Analyzing the continuum content of two-electron or multi-electron wave functions is more complex than for one-electron systems. The energy spectrum of a two-electron atom consists of an infinite set of bound states, an infinite set of overlapping single ionization continua that correspond to different residual ion states, and overlapping the higher energy part of these single-ionization continua, a double-ionization continuum where both electrons are unbound. The exact wave function for two electrons in the continuum of an ion is not known, but there are a number of approximate forms [105–107].

The interpretation of two-electron pseudo states is also complicated. For energies below the second single-ionization threshold, the energy of a pseudo state clearly identifies whether it represents a bound state or an ionized state. However, in the energy region where there are overlapping continua there are ambiguities. For example, a pseudo state with energy above the double-ionization threshold can rep-

resent a doubly ionized state, a singly ionized state of the same total energy, or some admixture of the two. A method to solve this pseudo-state interpretation problem was proposed some time ago [38, 39], but subsequent work suggested that the question is not completely settled [86]. In a number of calculations (for antiproton-impact ionization of helium), the more pragmatic approach to use uncorrelated product states to project out single and double-ionization transition amplitudes was followed [108–110]. This proved to be successful in practice but can be criticized on fundamental grounds since these simple product states do not diagonalize the two-electron Hamiltonian. A clustering analysis to sort pseudo-continuum states into singly and doubly ionized states based on a set of ad-hoc criteria was proposed in [111].

To conclude this chapter, all theory described here assumes (implicitly or explicitly) that the projectile momentum is sharp, i.e., that the impinging particles can be described by momentum-space wave packets with negligible spread. Recent work suggests that the conditions for this assumption to be correct are not always met in highly differential experiments. The consequence then is that the degree of coherence of the projectiles need to be considered in theoretical calculations to explain those measurements [112]. This topic is discussed in Chap. 69.

Acknowledgment One of us (T.K.) has been supported by the Natural Sciences and Engineering Research Council of Canada under Grant No. RGPIN-2019-06305. This chapter is based on a previous version written by A.L.F and J.F.R. for the first edition of the Handbook. It is hoped that the clear presentation of the subject matter in that original work shines through the substantial modifications and additions made.

Tom Kirchner Tom Kirchner is a Professor of Physics at York University, Toronto, Canada. He received his PhD from Goethe University Frankfurt in 1999 and joined the York faculty in 2009 after postdoctoral stints at York and the Max Planck Institute for Nuclear Physics, and a junior professorship at TU Clausthal (Germany). His research is concerned with the quantum dynamics of multi-particle Coulomb systems, in particular atomic and molecular scattering processes. He is a Fellow of the American Physical Society.

A. Lewis Ford Dr Ford's research interests lie in theoretical atomic and molecular physics: inner-shell excitation, ionization, charge transfer, and electronic properties of diatomic molecules. He joined the Texas A&M faculty in 1973. After receiving his BA degree from Rice University, he completed his PhD at the University of Texas at Austin in 1972 and did post-doctoral work at Harvard. Professor Ford is a member of the American Physical Society, Division of Electron, Atomic, and Optical Physics.

John F. Reading Professor Reading earned his PhD from the University of Birmingham, UK in 1964. His current research interests are in theoretical calculations of cross sections for excitation and ionization following fast ion-atom collisions, the role of Pauli correlation in inner-shell vacancy production, and the role of dynamic electronic correlation, the latter especially in comparison of proton and antiproton-induced single and double ionization of helium.

Abstract

Rydberg excitations have had a substantial impact on the development of atomic and molecular physics. Advances in cooling and trapping of atoms and molecules have allowed for precise interrogation of quantum processes in such atomic systems with Rydberg excitation as a probe. In this chapter, the reader is familiarized with extension of Rydberg spectral line broadening concepts to quantum collision of Rydberg electrons with atoms and molecules and how the Rydberg spectra reveal molecular oligomeric formation and the emergence of ozonic and fermionic polaron features. It is shown that with fermions as the gas particles, the Pauli exclusion principle suppresses molecular formation.

Much of the information gleaned from the quantum world comes to us via scattering of particles over a wide range of energies. At large collisional energies, compared with typical energies in the target particles, perturbative methods are employed with efficiency and efficacy to probe weak coupling. At the other end of the energy scale, strong coupling emerges at low energies. This new physics is consequential.

In 1934, *Edoardo Amaldi* and *Emilio Segre* performed absorption spectroscopy of sodium ($3s-np$) Rydberg lines in high-pressure nitrogen and hydrogen chambers [1]. They observed two unexpected results: (1) that the highly excited sodium lines survived in the N_2 and H_2 mixtures, and (2) that the lines in the presence of H_2 gas were blue shifted (“violet”). We will return to the first discovery as it becomes relevant to studies of Rydberg excitations in high-density quantum gases. The second crucial discovery became the foundation for Enrico Fermi’s exploration of what effectively is the birth of low-energy quantum physics.

When a free charge (or weakly bound electron) is immersed in a gas, it interacts with the nearby atoms or molecules, and if the neighboring gas species do not possess a permanent electric dipole moment, then the interaction of the charge with the surrounding ground-state atoms is, in the first-order perturbation theory, via the polarization potential

$$W(q_i) = - \sum_i \frac{e^2 \alpha}{2q_i^4}, \quad (54.1)$$

where α is the polarizability of the ground state particles, and q_i is the charge position from the i -th perturber core.

The shift of the Rydberg lines due to dielectric screening is obtained in cm^{-1} as in [2, Eq. 23],

$$\Delta_\epsilon \approx 2.6 \left(\frac{4\pi}{3} \right)^{4/3} \left[\frac{(\epsilon - 1)}{16\pi^2 \hbar c} \right] e^2 \rho^{1/3}, \quad (54.2)$$

where ϵ is the dielectric constant, normalized to vacuum permittivity, and ρ is the gas density.

The immediate observation is that all spectral lines shift to the red. For the Na Rydberg excitation in H_2 , this was clearly not true. The flaw that Fermi discovered in this argument was to note that the quasi-bound Rydberg electrons scatter from the perturber atoms or molecules.

In the low-energy scattering of a Rydberg electron from perturber particles, the wave function will be slowly varying, except near the perturbers. To circumvent this fast oscillation, Fermi wrote down another wave function, $\bar{\psi}$, as the mean value of ψ around the perturbers, whose extent was to be small compared with the electron de Broglie wavelength but still have a volume large enough to contain a sizable number of perturber atoms.

This wave function, regular at the origin, can be written as

$$u(r) = r\psi(r) = (r - a_S(0))\bar{\psi}. \quad (54.3)$$

The parameter $a_S(0)$ is of dimension length called the scattering length and is the intercept at zero momentum ($k = 0$) of $k \cot \delta_S(k)$, i.e., $a_S(0) = -\lim_{k \rightarrow 0} \frac{1}{k} \tan(\delta_S(k))$, of the s-wave phase shift, $\delta_S(k)$.

The spectral energy shift in the long-wavelength limit becomes [2], in units of cm^{-1} ,

$$\Delta_a = \frac{\hbar a_S(0)\rho}{m_e c}, \quad (54.4)$$

with m_e the mass of the electron. When $a_S(0) > 0$, the spectral line shift can be to the blue if $\Delta_a > \Delta_\epsilon$, but when $a_S(0) < 0$, the shift is always to the red.

This description of spectral line broadening and shift, where the interaction is described as a zero-range interaction [2]

$$V_S(\mathbf{r} - \mathbf{R}) = 2\pi a_S(k)\delta(\mathbf{r} - \mathbf{R}), \quad (54.5)$$

is able to account for the peculiar line shifts in the experiment of *Amaldi and Segre* [1]. In the above expression, \mathbf{R} refers to the interparticle separation between the Rydberg core and the perturber atom. The concept of the pseudopotential, as in Eq. (54.5) is familiar and crucial in chemistry, condensed matter, and surface physics, where effective Hamiltonians need to be constructed for structure calculations of many-body systems [3].

Schwinger [4, Sects. 2 and 3] showed that the phase shift in triplet neutron-proton scattering can be written as

$$k \cot \delta = -\gamma + \frac{1}{2}(\gamma^2 + k^2)r_0 + \mathcal{O}(k^4 r_0^2), \quad (54.6)$$

where γ is related to the deuteron binding energy as $(\hbar^2 \gamma^2 / M)$, r_0 is the effective range of the nuclear forces, and the scattering length is $\frac{1}{a} = \gamma(1 - \frac{1}{2}\gamma r_0)$. This is the first proof that experiments can determine the effective range of the interaction. In deuteron triplet scattering, the scattering length is positive and a bound state forms, whereas in the singlet channel, the scattering length is negative and binding fails.

Bethe [5] first wrote down the fundamental expression of low-energy scattering,

$$k \cot \delta = -\frac{1}{a} + \frac{1}{2}k^2 r_0. \quad (54.7)$$

The scattering cross section, $\sigma = \frac{4\pi}{k^2} \left[\frac{1}{1 + \cot^2 \delta} \right]$ reaches unitarity when $k^2 = \frac{2}{ar_0}$. When the effective range term is small, at very low temperatures, the unitarity is achieved at $|a| \rightarrow \infty$. At zero energy, the cross section becomes $\sigma = 4\pi a^2$. When the atoms are indistinguishable, such as in a Bose-Einstein condensate, the cross section is $\sigma = 8\pi a^2$.

54.1 Zero/Short-Range Neutral Collisions

While many of the early applications of the zero-range scattering were in nuclear and condensed matter physics, the advent of low-temperature atomic traps in the last few decades has shifted the focus of research and application to cold and ultracold atomic and molecular collisions [6].

At low temperatures, the collision between two spherically symmetric ground state atoms, say alkali metal atoms, is mediated by the interaction at large separations, where in the lowest order of active perturbation, the interaction is

$$V(R) = \frac{C_6}{R^6} + \frac{C_8}{R^8} + \frac{C_{10}}{R^{10}} + \dots \quad (54.8)$$

where the successively shorter-range terms contain the van der Waals (vdW) coefficients, dictating the interatomic interaction [7]. Much of the work on the modification to the zero-range effective range theory due to short-range interactions (polarization, vdW, etc.) was done by *Spruch* [8], *Fabrikant* [9], and *Gao* [10–12].

In a quantum gas, the de Broglie wavelength $\lambda_{\text{dB}} = \left[\frac{2\pi\hbar^2}{mk_B T} \right]^{3/2} \sim 100 \mu\text{m}$ is larger than any interaction length, $R_{\text{vdW}} = \left[\frac{2\mu C_p}{\hbar^2} \right]^{1/p-2} \sim 10 \text{nm}$. In the above, m stands for the single particle mass, μ is the reduced binary mass, T is temperature, and R_{vdW} is the van der Waals length. For a polynomial in $1/R$ interaction of order p - the most common of all vdW interactions is with $p = 6$. In such circumstances, the interaction among the gas particles is no longer a product of pair interactions, and the wave function for the gas particles

Fig. 54.1 Magnetically tuned Fano–Feshbach resonances in the collision of two atoms. A broad and a narrow resonance, a consequence of interacting potential curves correlating to different atomic hyperfine levels, are shown

in a cold trap obeys the Gross–Pitaevski (GP) equation

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + V_{\text{trap}} + N U_0 |\Psi|^2 \right] \Psi = \mu \Psi, \quad (54.9)$$

where the trap potential is usually approximated as a harmonic well, $U_0 = \frac{4\pi\hbar^2 a}{m}$ is the strength the two-body short-range interaction between any pairs of N particles of mass m , and μ is the chemical potential, the energy needed to add one particle to the gas. The strength of the interaction is determined by the zero-momentum s-wave scattering length (a), whose sign also determines the stability of the trapped gas. For $a > 0$, as more atoms are added to the gas, the energy goes up, and so goes the density, until the critical value for condensation in the limit of noninteracting particles, i.e., $\rho\lambda_{\text{dB}}^3 \geq 2.612$ [13] is reached. Conversely, for $a < 0$, the aggregate energy decreases as more particles are added, leading to instability and the eventual collapse of the many-body state. The GP or the nonlinear Schrödinger equation (NLSE) has a quadratic nonlinearity, typical of quantum N -body Hamiltonians.

It is important to recognize that the nonlinear term in Eq. (54.9) is precisely that of the Fermi pseudopotential (Eq. (54.5)); the additional factor of 2 in Eq. (54.9) accounts for the indistinguishability of bosons.

The short-range pair interaction can be engineered nearly at will. A large body of literature now exists on how to tailor the scattering length between two atoms to a desired accuracy. All such techniques depend on engineering a form of resonant interaction [14, 15]. The workhorse method is via magnetic tuning of the pair interaction, the so-called magnetic Fano–Feshbach resonance, in which magnetic fields are used to couple atoms in different Zeeman sublevels. When

the coupling of two atomic Zeeman manifolds are different, rovibrational levels in one Born–Oppenheimer (BO) potential energy form in the continuum of the other manifold BO potential energy and, therefore, appear as resonances. One one side of this resonance, the scattering length is positive, leading to positive infinity, and on the other side, the scattering length becomes progressively negative; see Fig. 54.1. The crossover is the unitarity limit for strong interactions.

54.2 Low-Energy Phase Shift and Zero-Energy Scattering Length

Large spin-exchange cross sections for electrons scattering from alkali metal atoms [16] imply large differences between singlet ($S = 0$) and triplet ($S = 1$) $L = 0$ scattering phase shifts. The elastic phase shifts were calculated with coupled channel solutions [17], relativistic R-matrix with inclusion of fine structure splitting for heavier alkali metal atoms [18–21], and the pseudopotential method for electron interaction with the perturber atom [22].

The behavior of the $L = 0$ phase shift is markedly different at low momentum. The singlet phase shift has a negative slope resulting in a positive scattering length, i.e., positive electron affinity for the 1S_0 scattering, while the triplet scattering length is large and negative. This trend is observed for all alkali metal atoms. For electron scattering from heavy alkali-metal atoms, inner shell electron–electron repulsion

Fig. 54.2 The e^- –Cs(6s) scattering phase shifts as a function of the electron momentum for different scattering partial waves. The $^S L_J = ^1 P_1$ phase shift is from Thumm [23]. The $^{1,3}S_0$ and $^3 P_{J=0,1,2}$ resonant phase shifts are obtained by matching at short distances to observed scattering resonance positions and widths [7, 24]. The $^3 S_1$ phase shift has a positive slope near $k = 0$, which extrapolates to a scattering length of $a_S(0) = -16.5 a_0$ in Eq. (54.10). Reprinted by permission from [25]

pushes the $L = 1, S = 1$ bound states into the continuum, resulting in resonant 3P_J scattering states. These scattering resonances, e.g., Fig. 54.2, have been calculated and observed [18, 24]. The negative 3S scattering length allows for the formation of Rydberg molecule states in ultracold magneto-optical traps (MOT), e.g., Eq. (54.5), and the 3P_J resonances hugely distort the BO potential energy curves, e.g., Fig. 54.4, and affect the dynamics of molecular formation and fragmentation into neutral and ionic species.

54.3 Ultralong-Range Rydberg Molecules: Fermi's Idea Redux

The Fermi pseudopotential (Eq. (54.5)) made a debut in quantum electron collision physics in 2000, when Greene and coworkers realized that this widely used formalism for Rydberg line broadening and shift can be utilized to calculate realistic BO potential energy curves, albeit at large separations between atoms [26].

When one atom, say an alkali-metal atom, for simplicity as well as practicality because most ultracold species are of this variety, is excited into a Rydberg state, $\phi(\mathbf{r})$, where \mathbf{r} specify the radial degrees of freedom for the Rydberg electron, its excitation spectrum will be influenced, as Fermi formulated [2], by the surrounding atoms, which are at separation \mathbf{R} and are assumed to be in their ground state. The form of the BO potential energy is then

$$\begin{aligned} U_{\text{BO}}(R) &= E_{nl} - 2\pi a_S(0) |\langle \phi(\mathbf{r}) | \delta(\mathbf{r} - \mathbf{R}) | \phi(\mathbf{r}) \rangle| \\ &= E_{nl} - 2\pi a_S(0) |\phi_{nlm}(R)|^2. \end{aligned} \quad (54.10)$$

In this expression, the Rydberg states are at energies E_{nl} and have eigenwave functions ϕ_{nlm} . When a bath atom is at a distance near the minima in the potential wells, e.g., the red and green balls in Fig. 54.3, and provided that the Rydberg electron scattering from the atom has a negative scattering length, it may bind inside the Rydberg orbit and form a diatomic molecule at large separations R .

The original Fermi expression for spectral shift in Eq. (54.4) has a linear dependence on the atom number density. The Rydberg molecular shift in Eq. (54.10) offers a reinterpretation of density as the quantum mechanical electron probability density, i.e., the modulus of the wave function squared at the position of the perturber atom.

Equation 54.10 indicates that $U_{\text{BO}}(R)$ will oscillate with R because the Rydberg wave function oscillates, see Fig. 54.3. When $a_S(0)$ is negative, the potentials will possess localized wells at extremely large separations and scale with n^2 . These wells may support bound vibrational levels. The undulations in the BO potential energy curves are not unique to the Fermi model and have been confirmed with detailed quantum chemical calculations of ground atom and Rydberg atom interactions; e.g., [27].

Fig. 54.3 BO potentials resulting from s -wave zero energy scattering of a Rydberg electron from a ground polarizable atom, as a function of internuclear separation. This illustrates the two most salient features of an ultracold, ultralong-range Rydberg molecule: the oscillatory behavior of the potential energy curve and the vibrational binding of the interaction

Given the energy resolution of discrete vibrational bound states of the Rydberg molecules, much below 1 cm^{-1} , ensures that they could only be found in conditions of ultracold atomic traps. However, the influence of Rydberg quasi-molecular interactions on the Rydberg satellite lines of alkali metal atoms was already proposed by *Niemax* in 1972 [28]. Subsequent measurements and interpretations of the spectral features in the wings of Rydberg lines showed strong correlation with the minima of the BO potential energy curves, as illustrated in Fig. 54.3 [29].

Nearly a decade after their prediction, ultralong-range Rydberg molecules were realized in an ultracold rubidium gas, where a fraction of atoms were excited into $\text{Rb}(ns)$ states [30]. A two-color excitation process was used to photoassociate $^3\Sigma$ Rydberg molecules. Several vibrational bound states were observed as peaks to the red of the atomic Rydberg $\text{Rb}(35s\text{--}37s)$ lines. Subsequent measurements observed ultralong-range Rydberg molecules in other species and in different initial atomic angular momentum states [31–38].

54.4 Fermi Extended: Do Elastic Collisions Result in Inelastic Chemical Reactions?

The natural extension of the Fermi pseudopotential to higher-order partial wave scattering, e.g., P-wave scattering, was done by *Omont* [39], more than 40 years after Fermi. *Omont*'s insight was that for low n excitations, when the electron kinetic energy $\text{KE} = E + e^2/R$, varies as a function of the perturber position R , a proper account of the electron-neutral interaction would have to include the energy dependence of the S-wave scattering length, $a_S(k) = -\tan(\delta_S(k))/k$, where $k = \sqrt{2 \text{KE}}$ is the electron momentum in atomic units.

The P-wave electron–atom interaction has the form [39],

$$V_P(\mathbf{r}) = 6\pi a_P^3(k) \delta(\mathbf{r}) \overleftarrow{\nabla} \cdot \overrightarrow{\nabla}, \quad (54.11)$$

where $a_P^3(k) = -\tan(\delta_P(k))/k^3$ is the energy-dependent P-wave scattering volume, with $\delta_P(k)$ the energy-dependent

Fig. 54.4 BO potentials resulting from P-wave and P-wave zero energy scattering of a Rydberg electron from a ground polarizable atom as a function of internuclear separation. In **a**, the S-wave scattering curves at different levels of approximation, with just the Rb(35s) wave function (*dot-dashed line*), diagonalization in a manifold of s states (*dashed line*), including P-wave scattering (Eq. (54.11)) (*solid line*). In **b**, avoided crossings due to S-wave and P-wave resonant interactions occur. The effect of P-wave resonances is evident on the BO potential energy curves as they crash through several Rb(n l) atomic energies. Reprinted with permission from [40]

P-wave scattering phase shift. The arrows over the ∇ operators indicate the direction in which the operator acts. In the above expression, when $\delta_p(k) = \pi/2$, i.e., at resonant energy of a metastable state of an electron interacting with a neutral perturber, the P-wave contact interaction diverges. This is precisely what happens for the triple ($S = 1$) scattering of an electron with unit angular momentum from a heavy alkali-metal atom (Na, K, Rb, Cs). For e^-A interaction, where A is any of these atoms, the $L = 1, S = 1$ scattering contains a low-energy P-wave resonance [19, 41]; see also Fig. 54.4b.

An immediate observation from Fig. 54.4 is the imprint of the resonant P-wave scattering on the BO potential energy curves. The potential energy curves correlating to ground and excited atomic states crash through a manifold of Rydberg states due to interaction at and near the position of P-wave scattering resonances, mixing different l states and forming large numbers of avoided crossings within the same molecular symmetry. The influence of P-wave resonances, in different J quantum numbers, with the BO potential curves, has consequences for the lifetime of vibrational levels. In particular, excited levels can tunnel through the barriers, therefore inducing shorter lifetimes [42]. Change in kinetic energy of the Rydberg atoms, as they undergo l -changing collisions can be measured [43]. The threshold ionization field directly exploits the angular momentum change of the Rydberg atom, and the rate of l -changing collisions is obtained by monitoring the Landau–Zener probabilities through the manifold of crossings in Fig. 54.4b. Throughout, L refers to the electron scattering angular momentum, while l refers to the Rydberg orbital angular momentum.

As the collisions proceed to shorter distances, neutral atom–ion interaction, where the electronic distributions be-

tween the Rydberg atom and the ground neutral perturber overlap, dominates, leading to associative ionization

Indeed, through primarily elastic electron scattering collision with a neutral perturber at extreme low kinetic energy, it becomes possible to induce novel chemical reactions such as the above. The n -dependent branching ratio for production of the molecular ion, $P_{\text{Rb}_2^+}(n) = N_{\text{Rb}_2^+} / [N_{\text{Rb}_2^+} + N_{\text{Rb}^+}]$ can also be measured through the l -changing and short-range collisions [43, 44]. The high branching ratio, which depends on the density of the ultracold perturber atoms, at intermediate principal quantum numbers, is likely the result of l -changing collisions.

54.5 Ion-Pair Molecules

Electron hopping from one atomic center to another, induced in avoided crossings between the covalent potential energy curves correlating to Rydberg–neutral ground state atoms and the anion–cation potential energy curve of the same symmetry, leads to formation of long-range ion-pair molecules. These molecules are bound by ion-pair interaction: both have an infinite number of bound rovibrational states that obey the Rydberg formula with a heavy mass and large permanent electric dipole moments [25, 45].

The ion-pair molecules can be produced by excitation into Rydberg butterfly molecular states [37, 41] and transitioning into most Franck–Condon (FC) favorable ion-pair vibrational states [46].

54.6 Few-Body Short-Range Scattering

54.6.1 Additivity of Binary Interactions

The form of Eq. (54.10) suggests that for an isotropic Rydberg excitation, i.e., $l = 0$ state excitation, the BO potential energy is additive in the number of perturber interactions with the Rydberg atom,

$$U_{\text{BO}}(R) = \sum_k^N U_{\text{BO}}(R_k), \quad (54.13)$$

where the index k runs over the N number of perturber atoms, and R_k denotes the location of each perturber from the Rydberg core. The molecular binding energy of an oligomer is then combinatorially obtained from dimer energies. A series of theoretical and experimental efforts on Rb and Sr atoms [43, 47–49] identified and observed successive formation of oligomeric s-orbital angular momentum molecules (trimers, tetramers, pentamers, ...) whose energies are combinatorially determined from the dimer energies, see Fig. 54.5.

54.6.2 Three-Body Effective Interactions

The great additivity feature that facilitates oligomeric molecule formation is interrupted when Rydberg excitations are instead made to states with nonzero angular momenta, e.g., Rb(np , nd) states. Spectral Rydberg molecule lines in excitation in a Cs ultracold gas to Cs(nd) states were recently

Fig. 54.5 The Rydberg absorption spectrum $A(\omega)$ for excitation in a Sr Bose gas. The peak at zero detuning is the atomic Rydberg line and D_j peaks refer to the formation of Rydberg dimers in ground and excited vibrational levels, T_{ij} trimer, T_{ijk} tetramer levels. Courtesy of Richard Schmidt

observed [50]. A number of red-detuned spectral features could not be ascribed to any two-body dimer (or three-body additive trimer) interactions.

A three-body effective Hamiltonian [50],

$$U_{\pm}(R, \theta) = U_{\text{dim}}(R) \left[1 \pm \left(-\frac{1}{2} + \frac{3}{2} \cos^2 \theta \right) \right], \quad (54.14)$$

where $U_{\text{dim}}(R)$ is the diatomic molecular energy, and θ is the angular degree of freedom between the internuclear distances from the Rydberg core to the perturber atoms, was able to in the first order describe the presence of nonadditive Rydberg trimers. In this scenario, each perturber atom sits in the different lobes of the Cs(nd) electron density. The effective three-body Hamiltonians, which here arises from the intrinsic anisotropy of the initial Rydberg excitation, are in vogue for simulations of various quantum many-body and quantum information systems, including quantum loop models and adiabatic quantum computing.

A natural question now arises: would this Lego-like molecular stack continue unabated with the addition of successive bath atoms inside a Rydberg orbit, or would some new and manifestly quantum behavior emerge?

54.7 Collective Quantum Many-Body Effects

54.7.1 Bose and Fermi Polarons

When the number of atoms inside the Rydberg orbit increases, either with increasing gas density or increasing the principal quantum number, the Rydberg spectral lines broaden and for extreme excitations approach the classical broadening [51], producing a density-dependent broadening, $\Delta = \frac{2\pi\hbar^2 a_s}{m} \int |\Psi(R)|^2 \rho(R) dR = \frac{2\pi\hbar^2 a_s}{m} \bar{\rho}$, where $\rho(R)$ is the local density and $\bar{\rho}$ the weighted average density.

Can quantum behavior, including quantum statistics and many-body effects, ever become evident in these spectra? The short answer is yes.

In the second quantization notation, the Hamiltonian for an impurity with mass M at position and momentum $\hat{\mathbf{R}}, \hat{\mathbf{p}}$, interacting with gas bosons is

$$\hat{H} = \frac{\hat{\mathbf{p}}^2}{2M} + \sum_{\mathbf{k}} \epsilon_{\mathbf{k}} a_{\mathbf{k}}^{\dagger} a_{\mathbf{k}} + \frac{1}{\mathcal{V}} \sum_{\mathbf{k}\mathbf{q}} V(\mathbf{q}) e^{-i\mathbf{q}\hat{\mathbf{R}}} a_{\mathbf{k}+\mathbf{q}}^{\dagger} a_{\mathbf{k}}, \quad (54.15)$$

where \mathcal{V} is the quantization volume, and $a_{\mathbf{k}}$ ($a_{\mathbf{k}}^{\dagger}$) are the annihilation (creation) operators for the bosons with dispersion $\epsilon_{\mathbf{k}} = \frac{\hbar^2 \mathbf{k}^2}{2m}$ [48, 52]. The last term contains the Rydberg impurity-boson interaction, the Fermi pseudopotential, in

the momentum-representation, i.e., $V(\mathbf{q})$ in Eq. (54.5). The widely used Fröhlich Hamiltonian is obtained by employing the Bogoliubov approximation and keeping interactions linear in the bosonic field operators [53]. The Fröhlich Hamiltonian cannot account for particle–particle scattering and the formation of bound states correctly. By including all impurity–boson interaction terms, an extended Fröhlich Hamiltonian [52] which accounts for the formation of dimers, trimers, and higher order oligomers can be obtained.

54.7.2 Linear Response Absorption

The polaron dynamics can be probed by absorption spectroscopy. In the ground state, a bosonic atom contact interaction with the surrounding Bosons is negligible compared to the Rydberg excited interaction $V(\mathbf{q})$ with the gas Bosons. In the linear response, the absorption amplitude at frequency ν is written in Fermi’s Golden rule,

$$\mathcal{A}(\nu) = 2\pi \sum_{if} w_i \left| \langle f | \hat{V}_L | i \rangle \right|^2 \times \delta(\nu - (E_i - E_f)). \quad (54.16)$$

In the above expression, all initial and final states of impurity and bath Bosons satisfy the eigen equations, $\hat{H}_0 |i\rangle = E_i |i\rangle$ and $\hat{H} |f\rangle = E_f |f\rangle$. Formally, the initial state of the impurity plus gas bosons is written at zero temperature as, $|i\rangle = |\text{BEC}\rangle \otimes |\mathbf{p} = 0\rangle_I \otimes |g\rangle_I$. The notation indicates that the Bose–Einstein condensate (BEC) atoms and the Rydberg impurity (I) are initially at zero momentum ($\mathbf{p} = 0$) in ground electronic state. At finite temperatures, the weights of the initial states are obtained from the initial density matrix, $\rho = e^{-\beta H_0} / Z$, with β the inverse temperature and Z the partition function. The laser operator $\hat{V}_L = |e\rangle\langle g| + \text{h.c.}$ connects the ground state to an excited state.

The absorption spectrum can be obtained in a way that formally encapsulates the non-equilibrium evolution of the system after a quantum quench at $t = 0$ by excitation of a Rydberg impurity,

$$\mathcal{A}(\nu) = 2 \text{Re} \int_0^\infty dt e^{i\nu t} S(t). \quad (54.17)$$

The many-body overlap, also called Loschmidt echo, is

$$S(t) = \text{tr}[e^{i\hat{H}_0 t} e^{-i\hat{H} t} \hat{\rho}], \quad (54.18)$$

where $\hat{\rho}$ represents the density matrix of the initial state; \hat{H}_0 is the Hamiltonian without the excitation. At $T = 0$, this density matrix is simply written as $\hat{\rho} = |\Psi_0\rangle\langle\Psi_0|$, where $|\Psi_0\rangle$ is the Fock state of the macroscopic occupation of bosons, $|\Psi_0\rangle = \frac{1}{\sqrt{N!}} (a_0^\dagger)^N |\text{vac}\rangle$, with N the particle number [48].

The Rydberg spectrum exhibiting the oligomeric molecule formation can be obtained from the Fourier transform of the above equation,

$$A(\omega) = 2 \text{Re} \int_0^\infty dt e^{i\omega t} S(t). \quad (54.19)$$

The full description of solving the overlap integral, known also as the Loschmidt echo, is given in [52]. The Loschmidt echo bears resemblance to the autocorrelation function in wave packet dynamics but for the application of interacting and noninteracting Hamiltonians.

An spectrum obtained from a Rydberg excitation in a Sr BEC (Sr(5s38s) excitation) is shown in Fig. 54.5, illustrating in intricate detail the formation of ground and excited vibrational dimers (D_i), trimers (T_{ik}), tetramers (T_{ijk}), pentamers (P_{ijklm}), . . . levels. At still higher quantum excitation and higher gas density, where the average number of gas atoms that fit into a Rydberg orbit approaches macroscopic numbers, a new phenomenon emerges, the so-called Bose polaron [48, 52]. Such Rydberg Bose polarons are characterized by localized states with discrete negative energies, which are bound to the Rydberg impurity. They can be contrasted to the usual Bose polarons in condensed matter systems that are dressed by the continuum phonon modes. The broad spectral tails, which match the Gaussian profile expected of polarons, progressively narrow with increasing local density, and have an n^{-3} analytical scaling with the Rydberg principal quantum number [49, 52].

In a degenerate Fermi gas, a Rydberg excitation leads to the formation of dimer Rydberg molecules, as with excitations in a Bose gas. However, fermions obey the Dirac–Fermi statistics, and unlike bosons, which can macroscopically occupy one quantum state, say the ground rovibrational state in the outer well in Fig. 54.3, spin-polarized fermions will occupy successively excited rotational levels, up to the Fermi energy. In addition, the nonlocal correlations in the fermionic wave function ensure that molecular reactivity beyond dimer formation is suppressed, i.e., formation of fermionic trimers, tetramers, etc., is greatly inhibited. This is termed Pauli-enforced rotational blockade [54]. In the high-density limit, the Fermi Rydberg polarons form, but their spectral width is narrowed due to Fermi compression [54].

The interaction of a Rydberg atom with a ground state atom is at the core of atomic physics. At extreme low kinetic energies, this interaction takes a deceptively simple form, e.g., the Fermi contact interaction, which allows for unique binding mechanisms, few-body and nonperturbative many-body states, and correlations. New vistas into several topical condensed matter problems, the Kondo singlet, the Bose polaron, and the central spin problems, are opening, aided by the low-energy electron scattering in quantum gases [55].

Just as magnetic tuning of the atom–atom scattering length [15] has tremendously advanced tailoring of interactions at will, it may become possible to also control the electron–atom scattering length in the near future.

Abstract

In this chapter, we review the over-the-barrier, Langevin-orbiting, Landau–Zener–Rosen, and molecular orbital close-coupling (MOCC), models used in calculations for low-energy ion–atom charge transfer reactions in which both the incident and exit configurations include at least one positively charged ion. We summarize theoretical descriptions for both radiative and nonradiative charge transfer processes.

Introduction

Consider a positively charged ion that slowly approaches a neutral atom. As the distance of approach R becomes comparable to the size of the atom, a tug of war ensues and, at a critical value of R , there is a finite probability that one, or more, electrons escape from the atom and attach to the interloper. In other words, a charge transfer reaction has occurred. We distinguish two classes: endoergic and exothermic reactions. In the first, the binding energy of the electron on the ion is less than that of the atom. Energy conservation requires that a portion of the kinetic energy of the approaching ion supplies the extra energy. However, for slow approaches in which an ion kinetic energy surplus is not available, charge transfer can only occur if the final electron binding energy is greater than or equal to its binding energy on the atom. If it is equal, the reaction is called resonant charge transfer; if not, a reaction proceeds either with the emission of a photon, radiation-less charge transfer, or both. The latter belong to the exothermic class of reactions. If radiation is emitted, we call the reaction radiative charge transfer/association and, if not, direct charge transfer.

Charge exchange reactions play an essential role in a diverse range of environments. They are an efficient generator of X-rays in astrophysical processes, and fuel X-ray sources in cometary and planetary atmospheres, the heliosphere, stars, and the interstellar medium [1]. Spectroscopy of atomic spectral lines, arising from ion–atom collisions, is a valuable diagnostic probe of those environments [2].

Charge transfer reaction rates are essential ingredients for the accurate modeling of low-temperature edge plasmas in laboratory fusion devices [3]. The latter enables diagnostic capabilities in studies of the physical evolution and life cycle of laboratory plasmas.

We use atomic units throughout the discussion.

55.1 Classical and Semiclassical Treatments

55.1.1 Over the Barrier Models

The classical “over the barrier” model (COB) [4, 5] offers a simple qualitative understanding of the charge transfer mechanism when the kinetic energy of the collision partners can be ignored. Figure 55.1 provides a plot of the function

$$V(x) = -q/x - 1/|R - x|, \quad (55.1)$$

where x is the distance of a bound electron from the projectile; R is the distance between the two positive charges, and q is the charge of the ion. At its local maximum, the potential has the value

$$V_{\max} = -(\sqrt{q} + 1)^2/R, \quad (55.2)$$

and the electron attaches to the projectile if its binding energy, perturbed by the electron–ion Coulomb energy $-1/2 - q/R$, becomes greater than V_{\max} . Also, assuming that the binding energy of the electron at the projectile site is given by $E_n = -q^2/2n^2$, where n denotes a principal quantum number, energy conservation requires that

$$-1/2 - q/R = E_n - 1/R. \quad (55.3)$$

Fig. 55.1 Plot of potential (55.1) as function of the ion–electron distance x . Panels from upper left to lower right illustrate how the bound state energy of the electron, shown by the solid red line, varies as a function of the internuclear distance R . The charge transfer is precipitated when that energy surmounts the local barrier as shown in the right-most lower panel

Together these relations predict [5]

$$R_n = \frac{2(q-1)}{q^2/n^2 - 1}, \quad (55.4)$$

for the largest value of the internuclear distance in which an electron is transferred to the projectile with binding energy E_n . Assuming a transfer probability of 1/2, for projectile impact parameters $\leq R_n$, the COB model predicts a total charge transfer cross section [5]

$$\sigma_{CT} = \frac{\pi}{2} R_{n^*}^2, \quad (55.5)$$

where n^* is the value of n in Eq. (55.4) in which the equality holds. Comparison of prediction in Eq. (55.5) with experimental data for collisions of ions with charges $q = 3, 4, 5$ shows a fair qualitative agreement in the collision energy range $1 < k^2 < 6$ keV/amu [5]. In this notation, the relative kinetic energy of the approaching fragments is given by $E = k^2/2\mu$, where μ is the reduced mass of the system.

55.1.2 Langevin Orbiting

At very low collision energies, on the order of $k^2 < 0.1$ keV/amu, the COB picture fails in predicting the correct $1/v$, where v is the relative velocity of the collision partners, behavior observed in experimental studies [6]. That behavior was first predicted in a classical orbiting theory, the Langevin model [7], after P. Langevin who pioneered the study of ionized gases. In the Langevin picture, the approach of the ion induces, via polarization of the electron cloud, an energy shift of the ground state s-wave electron given by [8]

$$\Delta E = -\frac{1}{2}\alpha|\mathbf{E}|^2. \quad (55.6)$$

Here, α is called the polarizability of the atom [9] and $|\mathbf{E}| = q/R^2$ is the magnitude of the electric field impressed on the electron by the projectile. The collision partners follow a trajectory governed by this mutual attractive force or potential

$$V_{\text{pol}} = -\frac{C_4}{R^4} \quad C_4 = \frac{\alpha}{2}q^2, \quad (55.7)$$

in addition to a centripetal effect described by an effective potential

$$V_L = \frac{L(L+1)}{2\mu R^2}; \quad (55.8)$$

$L = \mu v b$ is an angular momentum and b is an impact parameter. For a given b , the effective potential, the sum of Eqs. (55.7) and (55.8) possesses a local maximum $V_{\max}(b)$ at

Fig. 55.2 Trajectories displaying Langevin orbiting. The panel on left is a plot of the effective potential, as a function of R , for various impact parameters. The red lines correspond to impact parameters below the critical value b_c , obtained by equating $V_{\max}(b)$ with the total kinetic energy shown by the solid black line. The panel on the right illustrates classical trajectories for the corresponding impact parameters

a critical value R_c . The first panel in Fig. 55.2 depicts the effective potentials for various values of b as a function of the internuclear distance. The location and values for V_{\max} depend on the impact parameter. At a given collision energy E , all impact parameters in which $V_{\max} > E$ beget the trajectories shown in blue on the right panel of Fig. 55.2. For values of b in which $E < V_{\max}$, the collision partners overcome the repulsive barrier and engage in orbiting before returning to their asymptotic trajectories. The latter are shown in red in the second panel of that figure. Orbiting provides ample opportunity for the electron, being in close proximity to the ion, to “jump ship” and precipitate a charge transfer reaction. Solving for the impact parameter b_c for which that equality is satisfied, gives

$$b_c = \frac{1}{\sqrt{v}} \left(\frac{8C_4}{\mu} \right)^{1/4}. \quad (55.9)$$

Assuming a 100% charge transfer probability for all impact parameters $< b_c$,

$$\begin{aligned} \sigma_{CT} &= 2\pi \int_0^{b_c} db b \\ &= \pi b_c^2 = \frac{\pi}{v} \sqrt{\frac{8C_4}{\mu}} = \frac{2\pi q}{v} \sqrt{\frac{\alpha}{\mu}}. \end{aligned} \quad (55.10)$$

55.1.3 Landau–Zener–Rosen Theories

Classical descriptions invoke gross simplifying assumptions and lack quantum features observed in the laboratory. In a more nuanced analysis, for the case where the collisions partners approach slowly, it is convenient to assume adiabatic evolution. In that description, for a given nuclear separation, electrons equilibrate to an energy eigenstate of the electronic

Hamiltonian

$$\begin{aligned} H(\mathbf{R}_j, \mathbf{r}_i) &= - \sum_i \frac{1}{2} \nabla_i^2 \\ &\quad - \sum_i \sum_{j=1,2} \frac{q_j}{|\mathbf{R}_j - \mathbf{r}_i|} + \sum_{i < k} \frac{1}{|\mathbf{r}_i - \mathbf{r}_k|}. \end{aligned} \quad (55.11)$$

Here, \mathbf{R}_j are coordinates for the nuclei of charge q_j , and \mathbf{r}_i are the electronic coordinates. Factoring out the center of mass, and ignoring small isotopic couplings, the eigenstates of Eq. (55.11) are typically written in the form $\phi_n(\mathbf{r}, \mathbf{R})$, where \mathbf{r} is a collective coordinate for the electrons and \mathbf{R} a parameter that denotes the vector joining the two nuclei. The energy eigenstates $E_n(R)$ corresponding to these eigenstates are functions of the distance $R \equiv |\mathbf{R}|$. In an ion–atom collision scenario it is useful to focus on the pair of eigenstates whose asymptotic limits describe the pre and postcollision ion–atom configurations. For example, in the collision of a projectile A^{q+} on a neutral atom B in its ($1s$) ground state, we invoke the correlation rule

$$\begin{aligned} \phi_2(\mathbf{r}, \mathbf{R}) &\rightarrow A^{q+} + B(1s) \\ \phi_1(\mathbf{r}, \mathbf{R}) &\rightarrow A^{(q-1)+} + B^+. \end{aligned} \quad (55.12)$$

In Eq. (55.12), the arrow suggests that eigenstates ϕ_i approach, as $R \rightarrow \infty$, direct product eigenstates of the separated ion/atom configurations as shown in Fig. 55.3, which illustrates the electronic energy eigenvalues $E_n(R)$ for the states itemized in Eq. (55.12). Note that at a critical value of the internuclear distance R_c , the pair of curves share an avoided crossing, i.e., the energy defect $\Delta E = E_2(R) - E_1(R)$ has a local minimum at R_c . In a semiclassical description, the system evolves adiabatically on the potential surface that correlates asymptotically to the initial ion–atom configuration. As it reaches R_c , for a given impact parameter,

Fig. 55.3 An avoided crossing among Born–Oppenheimer energies. The *dashed lines* correspond to the diabatic couplings $V_{11}(R)$, $V_{22}(R)$ defined in Eq. (55.14)

there is a finite probability [4]

$$P(b) = \exp(-2\pi \Gamma)$$

$$\Gamma = \frac{V_{12}^2(R_c)}{|V'_{11}(R_c) - V'_{22}(R_c)| v_c} \quad (55.13)$$

of a transition to the neighboring electronic state. In Eq. (55.12) v_c , is the relative velocity of the collision partners at the crossing distance R_c , and $V_{11}(R)$, $V_{22}(R)$ are the, so-called, diabatic energy curves shown by the dashed lines in Fig. 55.3. They are related to the eigenvalues $E_1(R)$, $E_2(R)$ via

$$V_{11}(R) = E_1(R) \cos^2(\Omega(R)) + E_2(R) \sin^2(\Omega(R)) ,$$

$$V_{22}(R) = E_1(R) \sin^2(\Omega(R)) + E_2(R) \cos^2(\Omega(R)) , \quad (55.14)$$

where

$$\Omega(R) = -i \int^R A(R') dR' ,$$

$$A(R) \equiv i \langle \phi_1 | d/dR | \phi_2 \rangle , \quad (55.15)$$

and the $\langle | \rangle$ notation implies integration over all electronic coordinates. The diabatic coupling matrix element is

$$V_{12} = \frac{E_2(R) - E_1(R)}{2} \sin(2\Omega(R)) . \quad (55.16)$$

Summing the transition probabilities over all impact parameters one obtains [4] an expression for the total charge transfer cross section

$$\sigma_{CT} = 4\pi \int_0^{R_c} P(b)(1 - P(b)) b db . \quad (55.17)$$

In deriving expression in Eq. (55.17) we allowed for the possibility that the system traverses the crossing distance R_c twice. Once during the initial approach and again in the exit channel.

The Landau–Zener model provides fair estimates of charge transfer cross sections in the collision of ion projectiles C^{3+} , O^{2+} , O^{3+} , Ne^{3+} with atomic hydrogen at low energies [10]. Those estimates arrive at the correct order of magnitude, when compared to the results of more accurate fully quantal methods [2, 10].

Not all direct charge transfer reactions are precipitated by an avoided crossing. For example, in the $He^+ + Ne$ [11] collision system, the coupling term $A(R)$ is not localized near a crossing. Instead, its influence persists over a wide range of internuclear distances in which the pair of potential surfaces has a nearly constant energy defect. In that case, the Rosen–Zener–Demkov [12, 13] model is relevant. In that theory, one assumes that the diabatic coupling has the form $V_{12}(R) = V_0 \exp(-\lambda R)$, and a transition occurs at R_c , for which, $V_{12}(R_c) = 1/2 \Delta E(R_c)$, where ΔE is the energy defect between the two potential surfaces. An expression for the cross sections of the latter is given by

$$\sigma_{CT} = 2\pi \int_0^{R_c} b P(b) db$$

$$P(b) = \frac{1}{2} \operatorname{sech}^2 \left(\frac{\pi \Delta E(R_c)}{2 \lambda v(b)} \right) . \quad (55.18)$$

In the collision energy range $27.2 \text{ eV} < E < 8.2 \text{ keV}$, the predictions based on this model are in good agreement with the results of a fully quantal calculation [11], as well as with laboratory measurements [14].

55.2 The Molecular Orbital Approach

In the molecular orbital close-coupling (MOCC) approach, the total system amplitude is expressed as a sum of electronic eigenstates, whose expansion coefficients describe the motion of the nuclear coordinate \mathbf{R} . There are two versions of this theory. In the first, the nuclear motion is treated classically, but the electronic degrees of freedom are treated quantum mechanically. This approach, the method of perturbed stationary states (PSS), was first advocated by Massey and Smith in 1932 [15]. A quantum version of the PSS method was developed by David Bates and co-workers in the 1950s. But it was not until the 1980s, with the advent and availability of powerful supercomputers and vector machines, that the fully quantum MOCC calculations [10, 16, 17] became commonplace.

The quantum mechanical theory of resonant charge transfer [18] offers a compelling example of the predictive power

of the MOCC approach. In it, the charge cross section is given by the expression

$$\sigma_{CT} = \frac{\pi}{k^2} \sum_l (2l+1) \sin^2(\delta_1(l) - \delta_2(l)), \quad (55.19)$$

where $\delta_i(l)$ is the phase shift of the l -th partial wave of the scattering amplitude that evolves on the molecular potential surface that correlates to the i -th fragment. This expression is sensitive to the values of the adiabatic molecular potentials and is a stringent test of the molecular orbital paradigm. The results of laboratory measurements [19] for the near resonant charge transfer reaction

rate coefficients corresponding to collision energies below 1 eV, compare favorably with the results of calculations using the molecular elastic scattering expression (55.19).

55.2.1 A Gauge Theoretic Framework for the PSS Equations

In a fully quantal description of the PSS equations, the total (excluding the center of mass motion) system amplitude by an MOCC expansion

$$\psi(\mathbf{R}, \mathbf{r}) = \sum_n^N \phi_n(\mathbf{R}, \mathbf{r}) F_n(\mathbf{R}). \quad (55.20)$$

Here, $F_n(\mathbf{R})$ are quantal amplitudes that predict the probability for the system to occupy the n -th electronic states at \mathbf{R} . The index N is arbitrary but typically includes all states (channels) that are energetically open, i.e., if E is the collision energy, $E_N \leq E$. Of course, an unrestricted sum provides an exact description as the adiabatic states ϕ_n are complete for all \mathbf{R} , i.e.,

$$\sum_n \phi_n^\dagger(\mathbf{R}, \mathbf{r}) \phi_n(\mathbf{R}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}').$$

In practice, an exact description is not feasible. However, with a finite but sufficiently large value of N , the PSS equations are believed to provide an accurate description. Inserting the above expansion into the eigenvalue equation $(H - E)\psi = 0$, and projecting the latter onto the adiabatic basis vectors $|\phi_n\rangle$, we arrive at a set of coupled second-order partial differential equations

$$\begin{aligned} \nabla^2 F_i - 2i \sum_j^N (\nabla F_j) \cdot \mathbf{A}_{ij} - \sum_j^N B_{ij} F_j \\ - 2\mu \sum_j^N V_{ij} F_j + 2\mu E F_i = 0, \end{aligned} \quad (55.21)$$

where ∇ the nuclear gradient operator, and

$$\begin{aligned} \mathbf{A}_{ij}(\mathbf{R}) &\equiv i \langle \phi_i | \nabla | \phi_j \rangle \\ B_{ij}(\mathbf{R}) &\equiv -\langle \phi_i | \nabla \cdot \nabla | \phi_j \rangle \\ V_{ij}(R) &= \delta_{ij} E_j(R). \end{aligned} \quad (55.22)$$

Equation (55.21) is the quantal expression of the PSS equations and a starting point for all modern computational efforts; \mathbf{A}_{ij} are nonadiabatic matrix elements, B_{ij} constitute the Born-Huang-Dalgarno adiabatic corrections, and V_{ij} is the Born-Oppenheimer energy matrix of the system. With relation [11]

$$B_{ij} = \sum_k \mathbf{A}_{ik} \cdot \mathbf{A}_{kj} + i \nabla \cdot \mathbf{A}_{ij},$$

it is useful [11, 20] to rearrange Eq. (55.22) into the matrix form

$$-\frac{1}{2\mu} (\nabla - i\mathbf{A})^2 \underline{\mathbf{F}}(\mathbf{R}) + (\underline{\mathbf{V}}(\mathbf{R}) - E) \underline{\mathbf{F}}(\mathbf{R}) = 0, \quad (55.23)$$

where $\underline{\mathbf{F}}(\mathbf{R})$ is a column matrix whose entries are the amplitudes $F_i(\mathbf{R})$, and \mathbf{A} is an $N \times N$ matrix whose entries are the components defined in Eq. (55.22). The components of the scalar $N \times N$ matrix are given by [11]

$$\underline{\mathbf{V}}_{ij}(\mathbf{R}) = \delta_{ij} E_i(R) + \sum_{k \neq i,j} \mathbf{A}_{ik} \cdot \mathbf{A}_{kj}. \quad (55.24)$$

In the form of Eq. (55.23), the PSS equations manifest as a non-Abelian gauge theory [20, 21]. That is, the multichannel amplitude $\underline{\mathbf{F}}(\mathbf{R})$ is minimally coupled to vector \mathbf{A} and scalar $\underline{\mathbf{V}}$ gauge potentials, so that under the transformation $\underline{\mathbf{F}}(\mathbf{R}) \rightarrow \underline{\mathbf{U}}(\mathbf{R}) \underline{\mathbf{F}}(\mathbf{R})$, where $\underline{\mathbf{U}}$ is a unitary $N \times N$ matrix, the gauge potentials transform covariantly, i.e.,

$$\begin{aligned} \mathbf{A}(\mathbf{R}) &\rightarrow U^{-1} \mathbf{A}(\mathbf{R}) U + i U^{-1} \nabla U \\ \underline{\mathbf{V}}(\mathbf{R}) &\rightarrow U^{-1} \underline{\mathbf{V}}(\mathbf{R}) U - i U^{-1} \partial U \partial t. \end{aligned} \quad (55.25)$$

There are several advantages in expressing the PSS equations as a gauge theory [20, 21]. Not least is the recognition [20, 22, 23] of the fact that once an adiabatic truncation of channel states is imposed, one cannot, in general, “transform away” the diagonal components of the vector gauge potential \mathbf{A} . The latter fact leads to the phenomenon of geometric magnetism [20, 24], also known as artificial or synthetic magnetism [25–27]. The standard PSS approach, in which the eigenfunctions of Hamiltonian Eq. (55.11) are employed has been modified to accommodate so-called translation factors [28]. The latter was first introduced into the classical version of the PSS paradigm [15] in order to allow for “traveling” orbitals. In the quantum version, translation factors

modify the nonadiabatic coupling matrix \mathbf{A} appearing in Eq. (55.23). They have been introduced in order to correct perceived anomalies, including fictitious origin-dependent and long-range couplings, in the standard MOCC expansion. However, other efforts [29–31] have argued for the fidelity of the standard PSS expansion.

55.3 Cold and Ultracold Charge Exchange and Association

In a study [17] of the direct charge transfer reaction $\text{He}^+ + \text{H} \rightarrow \text{He} + \text{H}^+$ at low collision energies, it was found that the competing processes

corresponding to radiative charge transfer and association, respectively, dominate direct charge transfer. At a collision energy of about 8 eV/amu the radiative and direct charge transfer cross sections are comparable. However, at lower collision energies the former exhibit Langevin behavior, whereas the latter cross sections are decreasing. Theories of radiative charge transfer [17, 32] exploit the fact that the coupling of radiation with matter is weak, thus allowing for a perturbative analysis. In the past decade or so, there has been renewed interest in understanding charge transfer at ultralow collision energies [33–35]. The development of hybrid ion traps [36, 37] has allowed researchers to explore this novel and uncharted energy regime. At ultralow collision energies, the speed associated with the approach of collision partners is typically on the order of a few mm or cm per second. In this regime, it is convenient to express the collision energy in terms of an effective temperature, so that $\mu v^2/2$ is proportional to $k_B T$, where k_B is the Boltzmann constant, and T is a temperature in units of Kelvin. At temperatures on the order of mK, centripetal repulsion prevents close ion–atom encounters, and so only a few partial waves contribute to the total cross section. In that limit, Langevin behavior, which requires the participation of many partial waves, is no longer effective. Instead, s-wave scattering dominates, and dynamics is dictated by Wigner threshold [8] behavior. For example, the s-wave cross section for association to a molecular ion, following charge transfer in an approach of an ion with a neutral atom, is given by the expression [35]

$$\sigma = \sum_n \frac{16\mu\pi\omega_n^3}{3c^3k} \left| \int_0^{R_0} dR \phi(R) D(R) \phi_{J=1}^n(R) \right|^2, \quad (55.27)$$

In Eq. (55.27), c is the speed of light, k the wavenumber corresponding to the kinetic energy of the initial approach, $\phi_{J=1}^n$

Fig. 55.4 Radiative association into the rovibrational levels in the $X^2\Sigma^+$ electronic state of the YbCa^+ ion, following initial approach in the $\text{Yb}^+ + \text{Ca}$ channel. A similar description (not shown) allows radiative decay in the continuum states of the YbCa^+ ion and corresponds to radiative charge transfer into the $\text{Yb} + \text{Ca}^+$ exit channel

are the $J = 1, n$, rovibrational states of the molecular ion, ω_n is the angular frequency of the photon emitted into the n -th rovibrational state, and $D(R)$ is a coupling element proportional to the transition dipole moment between the molecular states; $\phi(R)$ is the radial s-wave elastic scattering wavefunction normalized so that $d\phi(R)/dR|_{R_0} = 1$, and where R_0 is a sufficiently large internuclear distance in which $\phi(R)$ exhibits asymptotic behavior. In a study [35] of the radiative processes (see Fig. 55.4)

it was found that Langevin behavior persists to temperatures as low as a few micro-Kelvin. Below this threshold, s-wave scattering becomes more important. Figure 55.5 presents plots of the thermal average $\langle v\sigma \rangle$, or the rate constant, for the reaction in Eq. (55.28). Figure 55.5 shows a dramatic transition from Langevin behavior, in which the rate tends to a constant value, for temperatures above $\approx 10^{-6}$ K, to a rapid, isotope-dependent, variation in the rate. At ultralow temperatures, the rate again assumes a constant value, as predicted by expression Eq. (55.27), in which σ is a product of a constant with the $1/k$ kinematic factor. The large isotope dependence is explained by appealing to Wigner theory. In the latter, the s-wave S-matrix is expressed as the ratio of the Jost functions [38] for amplitude $\phi(R)$. If the system possesses a bound state near the zero-collision energy threshold, the denominator of that ratio exhibits a zero in the complex k -plane. That zero begets a singularity in the ratio of Jost functions and leads to a large enhancement factor [38]. In other words, the amplitude for $\phi(R)$ near its overlap with $\phi_{J=1}^n$ is large and leads to an enhanced value for the integral

Fig. 55.5 Isotopic dependence of radiative association into the YbCa^+ molecular ion

in Eq. (55.27). As different isotopes possess bound states of differing energy defects from the zero energy threshold, the isotopic dependence of σ follows. A similar analysis holds for the radiative charge transfer reaction, although these reaction rates [35] are only a small fraction of the radiative association rates.

Other methods, such as the impression of external fields, pioneered in laboratory studies of ultracold neutral gases, can also be employed to adjust the energy defect of a bound state, or Feshbach-like resonances, in ion–atom systems. According to expression (55.27), this offers the possibility for external control of ion–atom reactions.

55.4 New Developments and Future Prospects

Even at the low collision energies of several milli-electron volts, corresponding to near room temperature, a typical charge transfer reaction involves the participation of hundreds of partial waves. Although quantum effects are important in this energy regime, it is still useful to adopt classical, or semiclassical, models to describe the latter. In order to flesh out quantum features, the de-Broglie wavelength corresponding to the ion–atom relative motion should be on the order of the distance of the closest approach for the colliding partners. In the related discipline of atom–atom collisions, this has been achieved due to laboratory advances in trapping and laser cooling of atoms. It has allowed researchers unprecedented access in investigations of collision phenomena in which quantum mechanics plays the leading role.

Several efforts, in the past decade or so, have been directed to probing ion–atom interactions where classical Langevin behavior breaks down and quantum effects dominate. Although there has been tremendous progress, using sympathetic cooling techniques, to reach the milli-Kelvin

regime [36, 37], access to nano-Kelvin temperatures has been hindered due to the strong coupling of the ion’s charge with the trapping potential. A novel, recent advance [39] promises to achieve the ultralow temperatures that are necessary to allow the conditions in which only a few partial waves participate in a charge transfer reaction. The ability to study partial wave-dependent charge transfer will provide stringent tests on theories that are based on the MOCC paradigm. In particular, such studies could assess the fidelity of theories that require the application of electronic translation factors.

Abstract

The continuum distorted wave model has been extensively applied to charge transfer and ionization processes. We present both the perturbative and variational capture theories as well as highlighting the suitability of this model in describing the continuum final states in both heavy and light particle ionization for both atomic and molecular targets. Particular emphasis will be put in the application of distorted wave theories to the description of recent complete experiments. We then develop the Wannier theory for threshold ionization and further theoretical work

that led to the modern quantal semiclassical approximation. This very successful theory has provided the first absolute cross sections that are in good agreement with experiment. The present work is based on the previous one conceived by *Crothers* et al. [1]. Only a few minor modifications in the text have been introduced, and a complete subsection has been added in order to take into account the state of art of the subject.

total cross section · semiclassical theory · triple differential cross section · bound-state wave function · classical turning point

56.1 Introduction

The development here presented includes third-order continuum distorted wave double scattering $1s-1s$ transitions (Sect. 56.2.1), relativistic continuum distorted waves (Sect. 56.2.2), a theory on magnetically quantized continuum distorted waves [2, 3] (Sect. 56.2.4), and single ionization of molecular targets (Sect. 56.2.5). A theory for low energies (below 80 keV) is also reported in which the target is considered as a one-electron atom, and the interactions between this active electron and the remaining target electrons are treated by a model potential including both short and long-range effects. In the final channel, the usual product of two continuum distorted wave functions, each associated with a distinct electron–nucleus interaction, is used [4].

In addition, Sect. 56.3 on the Wannier method reports the major progress made over the last years. These major advances include (a) the development of below-threshold semiclassical theory for the study of doubly excited states [5–8] (b) a more accurate variant of the semiclassical quantum-mechanical treatment of *Crothers* [9].

56.2 Continuum Distorted Wave Method

56.2.1 Perturbation Theory

Continuum distorted wave theory (CDW) is one of the most advanced and complete perturbative theories of heavy-particle collisions formulated to date. It was originally introduced by *Cheshire* [10] to model the process of charge transfer during the collision of an atom/ion with an ion (specifically, the resonant process of $p + \text{H}(1s) \rightarrow \text{H}(1s) + p$). These types of three-body collisions are made amenable to the perturbative approach when the ratio of the projectile impact velocity v to the electron initial bound-state mean velocity v_b satisfies

$$\frac{v}{v_b} \gtrsim 3. \quad (56.1)$$

The criterion for nonrelativistic collisions, in which electron capture is a dominant process, is that both v and v_b are small compared with the speed of light c . The theoretical description of collisions that involve the disturbance of a bound electron of mass m_e by the field of a fast moving heavy particle of mass M can be greatly simplified by exploiting the fact that, since the ratio m_e/M is so small, the heavy particle follows a straight-line trajectory throughout the collision.

This allows the parametrization of the internuclear vector \mathbf{R} in terms of an impact parameter \mathbf{b} , such that

$$\mathbf{R} = \mathbf{b} + \mathbf{v}t. \quad (56.2)$$

This impact parameter picture (IPP) of the collision is equivalent to the full quantal or wave treatment when the eikonal criterion for small angle scattering is satisfied [11].

It has become standard to work in a generalized nonorthogonal coordinate system in which the vectors \mathbf{r}_T (\mathbf{r}_P) from the target (projectile) to the electron are treated, along with \mathbf{R} , as independent variables [12]. Working in the frame centered on the target nucleus and using atomic units, the Lagrangian is given by

$$\begin{aligned} H - i \frac{d}{dt} \Big|_{\mathbf{r}_T} &= -\frac{1}{2} \nabla_{\mathbf{r}_T}^2 + V_T(\mathbf{r}_T) - i \frac{\partial}{\partial t} - \frac{1}{2} \nabla_{\mathbf{r}_P}^2 \\ &+ V_P(\mathbf{r}_P) + i\mathbf{v} \cdot \nabla_{\mathbf{r}_P} \\ &+ V_{TP}(\mathbf{R}) - \nabla_{\mathbf{r}_P} \cdot \nabla_{\mathbf{r}_T}, \end{aligned} \quad (56.3)$$

where $d/dt|_{\mathbf{r}_T}$ refers to differentiation with respect to t , keeping \mathbf{r}_T fixed, and where

$$V_T = -\frac{Z_T}{r_T}, \quad V_P = -\frac{Z_P}{r_P}, \quad V_{TP} = \frac{Z_T Z_P}{R}. \quad (56.4)$$

Since these potentials are pure Coulomb potentials, they continue to affect the relevant wave functions even at infinity. These long-range Coulomb boundary conditions are defined in Eqs. (56.10) and (56.11). The $+i\mathbf{v} \cdot \nabla_{\mathbf{r}_P}$ term gives rise to

the Bates–McCarroll electron translation factors, which are required to satisfy Galilean invariance.

The Lagrangian above has been written in such a way as to highlight the three two-body decompositions exploited in CDW, with the $-\nabla_{\mathbf{r}_P} \cdot \nabla_{\mathbf{r}_T}$ term, the so-called nonorthogonal kinetic energy, coupling the systems. The essence of CDW is to treat the bound electron as simultaneously being in the continuum of the other heavy particle.

The initial wave function can be written as

$$\xi_i^\pm = D_{-v}^\pm(\mathbf{r}_P) \Phi_i(\mathbf{r}_T, t) C(\mathbf{R}, t), \quad (56.5)$$

where D_{-v}^\pm is the distortion from the projectile, and C is a function that accounts for the internuclear potential, V_{TP} . The bound state $\Phi_i = \phi_i(\mathbf{r}_T) \exp(-i\epsilon_i t)$, where $\phi_i(\mathbf{r}_T)$ is the initial eigenstate, and ϵ_i is the initial eigenenergy.

In this form, the action of the Lagrangian can be split into three separate differential equations plus a residual interaction. This gives the following solutions: for the distortion D ,

$$\begin{aligned} D_{-v}^+ &= N(\zeta_P)_1 F_1(i\zeta_P; 1; i\mathbf{v} \cdot \mathbf{r}_P + ivr_P), \\ D_{-v}^- &= (D_{-v}^+)^*, \end{aligned} \quad (56.6)$$

with

$$N(\zeta) = \exp(\pi\zeta/2) \Gamma(1 - i\zeta), \quad \zeta_{T,P} = Z_{T,P}/v; \quad (56.7)$$

and for the internuclear function C ,

$$C(\mathbf{R}, t) = \exp\left[i \frac{Z_P Z_T}{v} \ln(vR - v^2 t) \right]. \quad (56.8)$$

Similarly, it can be shown that

$$\begin{aligned} \xi_f^\pm &= D_v^\pm(\mathbf{r}_T) \Phi_f(\mathbf{r}_P, t) C^*(\mathbf{R}, -t) \\ &\times \exp\left(i\mathbf{v} \cdot \mathbf{r}_T - i \frac{v^2}{2} t \right), \end{aligned} \quad (56.9)$$

where $i\mathbf{v} \cdot \mathbf{r}_T - i \frac{v^2}{2} t$ results from the Galilean transformation to the target frame. The superscripts plus and minus refer to outgoing and incoming Coulomb boundary conditions, respectively. These are determined by the asymptotic form of the wave functions

$$\begin{aligned} \lim_{t \rightarrow -\infty} \xi_i^+ &\approx \Phi_i(\mathbf{r}_T, t) \\ &\times \exp\left[i \frac{Z_P(Z_T - 1)}{v} \ln(vR - v^2 t) \right], \end{aligned} \quad (56.10)$$

and

$$\begin{aligned} \lim_{t \rightarrow +\infty} \xi_f^- &\approx \Phi_f(\mathbf{r}_P, t) \exp\left(i\mathbf{v} \cdot \mathbf{r}_T - i \frac{v^2}{2} t \right) \\ &\times \exp\left[-i \frac{Z_T(Z_P - 1)}{v} \ln(vR + v^2 t) \right]. \end{aligned} \quad (56.11)$$

Of course, ξ_i^+ and ξ_f^- are not exact solutions of the three-body Schrödinger equation; in fact,

$$\left(H - i\frac{d}{dt_{r_T}}\right)\xi_i^+ = W_i\xi_i^+ = -\nabla_{r_P}D_v^+ \cdot \nabla_{r_T}\Phi_i, \quad (56.12)$$

and

$$\begin{aligned} \left(H - i\frac{d}{dt_{r_T}}\right)\xi_f^- &= W_f\xi_f^- \\ &= -e^{i\mathbf{v}\cdot\mathbf{r}_T - i\frac{v^2}{2}t} \nabla_{r_T}D_v^- \cdot \nabla_{r_P}\phi_f. \end{aligned} \quad (56.13)$$

The CDW transition amplitude is written as

$$A_{if} = -i \int_{-\infty}^{+\infty} dt \langle \xi_f^- | T_{\text{CDW}} | \xi_i^+ \rangle. \quad (56.14)$$

A perturbative expansion via the distorted wave Lippmann–Schwinger equation can be made for T_{CDW} , either in the post form

$$T_{\text{CDW}}^+ = W_f^\dagger(1 + G_V W_i) + T_{\text{CDW}}^+ G_i V G_V W_i, \quad (56.15)$$

or in the prior form

$$T_{\text{CDW}}^- = (1 + W_f^\dagger G_V) W_i + W_f^\dagger G_V V G_f T_{\text{CDW}}^-, \quad (56.16)$$

where the Green functions are given by

$$G_{i,f} = \left(i\frac{d}{dt_{r_T}} - H + W_{i,f} + i\epsilon\right)^{-1}, \quad (56.17)$$

$$G_V = \left(i\frac{d}{dt_{r_T}} - H + V + i\epsilon\right)^{-1}, \quad (56.18)$$

and V is any potential which ensures that the kernels of the integral equations for T_{CDW} are continuous [13].

By taking the first term in the expansions in Eqs. (56.15) and (56.16), we get the post and prior forms of the CDW1 amplitude as used by Cheshire. When calculating these amplitudes, the separable nature of the CDW wave function is best exploited by using Fourier transforms to move to the time-independent wave picture. A similar transformation is not suitable in the coupled channel approach discussed in Sect. 56.2.3.

Crothers [13], working in the wave treatment, has calculated the second-order CDW2 amplitude using various approximations for the Green functions and showed that the CDW perturbation series converged very well to first order in most parts of the differential cross section. This is in contrast to the standard Born or Brinkman–Kramers approximations, which do not start to converge until expanded to second order. CDW1 is the only first-order perturbation theory, apart from asymmetric hybrid models derived from it, that produces the Thomas peak. Unfortunately, due to

Fig. 56.1 Differential cross sections for electron capture in the collision $\text{H}^+ + \text{H}(1s) \rightarrow \text{H}(1s) + \text{H}^+$ as a function of laboratory scattering angle (θ_{lab}) for impact energy of 5 MeV: *solid line* TCDW, folded over the experimental resolution of Vogt et al. [15]. *Unfolded theoretical results: dashed line* TCDW; *dotted line* CDW1. *Experimental data; circles*, Vogt et al. [15]

the cancellation of the leading order terms, which are associated with the interference of contributions coming from two different mechanisms, corresponding to the intermediate excitation of the electron to a target continuum and to the intermediate capture to a projectile continuum state, CDW1 has an extreme dip at the Thomas angle [14]. This is illustrated in Fig. 56.1, which also includes both folded and unfolded versions of the asymmetric target CDW (TCDW) theory discussed below, as well as experimental data [15].

Further work in this area has included the development of the Thomas double-scattering electron capture at asymptotically high velocity within the third-order continuum distorted wave perturbation theory for 1s–1s transitions in proton hydrogen collisions. It has been shown [16] that at the critical proton scattering angles, namely the forward peak, Thomas double encounter peak, small angles, and the interference minimum, the CDW series has converged at second order. Moreover, it is proven that the third-order correction makes no contribution to the velocity-dependent v^{-11} and v^{-12} behavior of the Thomas double-scattering total cross section at the leading angles. In contrast, it may be seen in [16] that the Oppenheimer–Brinkman–Kramers (OBK) traveling atomic orbital theory (which, in general, suffers from a common phase factor that embraces intermediate elastic divergences [17] in the first and higher-order terms) does not converge at second order. It remains an open question as to whether fourth-order terms or higher in the OBK approximation contribute to various differential cross sections. It is concluded that the CDW model gives a superior description of the Thomas double-scattering mechanism when compared with the OBK model.

Anomalously large cross sections are obtained at low energies if the CDW wave function is not normalized at all times throughout the collision [12]. This is best demonstrated by the presence of the $N(\zeta)$ terms in

$$\lim_{t \rightarrow +\infty} \xi_i^+ = N(\zeta_P) \Phi_i(\mathbf{r}_T, t) \times \exp \left[i \frac{Z_P Z_T}{v} \ln(vR - v^2 t) \right] \quad (56.19)$$

and

$$\lim_{t \rightarrow -\infty} \xi_f^- = N^*(\zeta_T) \Phi_f(\mathbf{r}_P, t) \exp \left(i \mathbf{v} \cdot \mathbf{r}_T - i \frac{v^2 t}{2} \right) \times \exp \left[-i \frac{Z_T Z_P}{v} \ln(vR + v^2 t) \right]. \quad (56.20)$$

Using

$$\lim_{v \rightarrow 0} |N(Z/v)|^2 \approx \frac{2\pi Z}{v} \quad (56.21)$$

it is clear that the problem gets worse as v decreases. It can be corrected by defining

$$\hat{\xi}_{i,f}^\pm = \xi_{i,f}^\pm \left\langle \xi_{i,f}^\pm \left| \xi_{i,f}^\pm \right. \right\rangle^{-1/2}. \quad (56.22)$$

Simpler distorted wave models can be generated through further approximations. Two of the most popular are target CDW [$D_{-v}(\mathbf{r}_P) \rightarrow 1$] and projectile CDW [$D_v(\mathbf{r}_T) \rightarrow 1$]. These approximations are justified when $Z_T > Z_P$ and $Z_P > Z_T$, respectively, and are particularly simple to calculate when the simple Born-like residual interaction is used rather than the full CDW form.

The asymptotic forms of the CDW wave functions can be used throughout the collision, ensuring normalization, and this leads to the continuum distorted wave-eikonal initial state [18] or symmetric eikonal [19] models, which are among the most successful ones to describe experimental data.

56.2.2 Relativistic Continuum Distorted Waves

The CDW model can be naturally extended to the two-center time-dependent Dirac equation, so that a Lorentz invariant theory is obtained. When the electron orbital velocity αZc , or the collision velocity v , approaches the speed of light c , the kinematics are modified by time dilation. In addition, the particle interactions change because of retardation and the fact that spin-orbit effects are now important. Moreover, vacuum interactions such as radiative emissions and electron-positron pair production begin to play a role. A comprehensive account of atomic processes in relativistic heavy-particle collisions can be found in the books [11, 20, 21]. At high collision energies, $\gamma \equiv (1 - v^2/c^2)^{-1/2} \gg 1$, and high-charge states of the ions, the Dirac sea of negative energy states

becomes energetically accessible and strongly coupled. The process of electron capture, for example, may be mediated by spin-flip transitions [22], or spontaneous X-ray emission (radiative electron capture) [23] and even electron capture via pair production [24–27]. Although the importance of vacuum processes diminishes with energy, these mechanisms dominate in the extreme relativistic regime. Indeed, the last of these processes was used to produce antihydrogen in the laboratory [28] at GeV amu⁻¹ energies.

At relativistic energies, the principal inelastic process is collisional ionization [20, 21]. The extensions of the distorted wave theory to accommodate Lorentz invariance was developed by Rivarola and Deco [29, 30] and Crothers and coworkers [22] over the basis of previous works on the Born series [31] and impulse approximation [32]. In practical applications to electron capture cross sections, the symmetric semirelativistic CDW theory of Glass et al. [22] was found to be in very good agreement with experiments in the GeV amu⁻¹ energy range with charges $Z_{P,T} \approx 6-80$. For nonradiative electron capture, it was found that second-order retardation dominates at extreme relativistic velocities so that $\sigma \approx \gamma^{-1} (\ln \gamma)^2$ [33]. However, the momentum transfer kinematics for this process is unfavorable, and a more efficient mechanism based on electron-positron pair production with capture of the created electron is more strongly coupled. Theoretical estimates of this process using relativistic CDW [34] compared with experiments [35] are in very good agreement.

The same model has been applied to estimate yields of antihydrogen following antiproton impact with neutral high- Z atoms [28] following experiments at CERN and Fermilab. The virtual photon model of Baur [35] gives cross sections that agree well with the limited data [28]. However, these estimates are roughly ten times larger than the relativistic CDW results [20] and one hundred times the first Born estimate [36]. It appears that additional studies, both experimental and theoretical, would be worthwhile in order to understand this process more fully.

56.2.3 Variational CDW

As the ratio of v/v_b decreases, perturbation theory starts to fail. This is due to the effective interaction time between the projectile and target atoms being long enough for strong three-body coupling. In this environment, variational methods have proved successful. This procedure ensures both gauge invariance and unitarity – two fundamental attributes that perturbation theory usually cannot guarantee. Continuing in the IPP, we use the Sil variational principle, which gives

$$\delta \int_{-\infty}^{+\infty} dt \langle \Psi | H - i \frac{d}{dt} | \Psi \rangle = 0. \quad (56.23)$$

In the two-state CDW approximation, we may assume

$$\Psi_{\text{CDW}} = c_0(t)\xi_i^+ + c_1(t)\xi_f^-, \quad (56.24)$$

subject to the boundary conditions $c_0(-\infty) = 1$ and $c_1(-\infty) = 0$. Variation of c_0^* and c_1^* gives the standard coupled equations

$$iN_{00}\dot{c}_0 + iN_{01}\dot{c}_1 = H_{00}c_0 + H_{01}c_1, \quad (56.25)$$

$$iN_{10}\dot{c}_0 + iN_{11}\dot{c}_1 = H_{10}c_0 + H_{11}c_1, \quad (56.26)$$

where

$$\begin{aligned} N_{00} &= \left\langle \xi_i^+ \left| \xi_i^+ \right. \right\rangle, \\ N_{11} &= \left\langle \xi_f^- \left| \xi_f^- \right. \right\rangle, \\ N_{01} &= \left\langle \xi_i^+ \left| \xi_f^- \right. \right\rangle = N_{10}^*, \end{aligned} \quad (56.27)$$

and

$$\begin{aligned} H_{00} &= \left\langle \xi_i^+ \left| H - i \frac{d}{dt} \right| \xi_i^+ \right\rangle, \\ H_{01} &= \left\langle \xi_i^+ \left| H - i \frac{d}{dt} \right| \xi_f^- \right\rangle, \\ H_{10} &= \left\langle \xi_f^- \left| H - i \frac{d}{dt} \right| \xi_i^+ \right\rangle, \\ H_{11} &= \left\langle \xi_f^- \left| H - i \frac{d}{dt} \right| \xi_f^- \right\rangle. \end{aligned} \quad (56.28)$$

Equations (56.25) and (56.26) can clearly be written as a matrix equation,

$$iN\dot{c} = Hc, \quad (56.29)$$

which is then easily generalized for larger expansions of Ψ . By using an orthogonalized basis set of normalized functions in the manner of *Löwdin* [37, 38], the N matrix reduces to the unit matrix. This will be understood when considering expansions for Ψ from now on.

Another interesting, but potentially ruinous, result of the asymptotic forms in Eqs. (56.19) and (56.20) is their failure to obey the correct long-range Coulomb boundary conditions; compare this with their expressions at the opposite time extreme in Eqs. (56.10) and (56.11). This has no consequence until second-order VCDW is calculated in which divergent integrals arise as a direct result of this feature of the wave functions. These terms are analogous to the well-known intermediate elastic divergences that occur in Born-type expansions, which do not have the correct Coulomb phases.

A novel way to avoid this problem [39, 40] is to split the time plane into two parts, allowing the well-behaved set $\{\xi^+\}$ to be used exclusively for $t \leq 0$, while the set $\{\xi^-\}$ forms the basis for $t \geq 0$. This phase integral halfway house VCDW is based on the factorization of the scattering matrix S into a product of two Møller matrices,

$$S = \Omega_-^\dagger \Omega_+, \quad (56.30)$$

where Ω_-^\dagger represents the propagation of the initial state from $t = -\infty$ to $t = 0_-$, while Ω_+ represents the propagation of the final state from $t = +\infty$ to $t = 0_+$.

The total wave function is similarly split into two expansions over an orthogonal basis ψ , with

$$\Psi^- = c^- \psi^+, \quad t < 0, \quad (56.31)$$

$$\Psi^+ = c^+ \psi^-, \quad t > 0, \quad (56.32)$$

where the superscripts on the Ψ correspond to the respective heavy-particle motion. This, in turn, divides the coupled equations into two sets

$$i\dot{c}^- = H^{++}c^-, \quad t < 0, \quad (56.33)$$

$$i\dot{c}^+ = H^{--}c^+, \quad t > 0, \quad (56.34)$$

where

$$H^{\pm\pm} = \langle \Psi^\pm | H - i \frac{d}{dt} | \Psi^\pm \rangle. \quad (56.35)$$

The coefficients c^\pm then have to be matched over a local discontinuity in the total wave function at $t = 0$, such that $c^+(0) = c^-(0)$. Halfway house VCDW has all the appealing attributes of a variational theory but, by explicitly satisfying the long-range Coulomb boundary conditions, it is divergence free.

56.2.4 Ionization

CDW, by treating the Coulomb interactions to such a high degree, has obvious attractions for modeling the ionization process. Single ionization of an electron from an atom by a high-energy projectile is a perturbative process, and the Born approximation will match experimental total cross sections rather well. However, CDW-like representations of the initial and final states generate better results at lower energies, as well as producing features in the differential cross sections that are beyond the reach of the first Born approximation.

In full CDW ionization theory, the initial state is given by the usual charge transfer wave function ξ_i in Eq. (56.5), while the final state takes the form

$$\begin{aligned} \xi_f^- &= (2\pi)^{-2/3} \exp\left(i\mathbf{k} \cdot \mathbf{r}_T - i\frac{k^2}{2}t\right) \\ &\times \exp\left[-i\frac{Z_T Z_P}{v} \ln(vR + \mathbf{v} \cdot \mathbf{R})\right] \\ &\times N^*(Z_T/k) {}_1F_1(-iZ_T/k; 1; -i\mathbf{k} \cdot \mathbf{r}_T - ikr_T) \\ &\times N^*(Z_P/p) {}_1F_1(-iZ_P/p; 1; -i\mathbf{p} \cdot \mathbf{r}_P - ipr_P), \end{aligned} \quad (56.36)$$

where \mathbf{k} ($\mathbf{p} = \mathbf{k} - \mathbf{v}$) is the momentum of the electron relative to the target (projectile) nucleus.

CDW ionization theories presented prior to 1982 produced spuriously large results due to the unnormalized initial state. Since the matrix element $\langle \xi_i^+ | \xi_i^+ \rangle$ is computationally expensive to calculate as a function of \mathbf{b} and t , a very successful alternative is to take the initial state as an eikonal distorted state [41], thus ensuring normalization. The initial state in this CDW-EIS theory is thus taken to be

$$\xi_i^{\text{EIS}} = \hat{D}_{-v}^+(\mathbf{r}_P)\Phi_i(\mathbf{r}_T, t)C(\mathbf{R}, t), \quad (56.37)$$

where now

$$\hat{D}_{-v}^+(\mathbf{r}_P) = \exp\left[-i\frac{Z_P}{v}\ln(vr_P + \mathbf{v} \cdot \mathbf{r}_P)\right]. \quad (56.38)$$

The final state remains as in Eq. (56.36).

The CDW final state is most effective when differential cross sections are studied. The most interesting features are in the forward $\theta = 0$ ejection angle; i.e., the soft collision peak ($k \simeq 0$), the electron capture to the continuum peak ECC ($k \simeq v$) and the binary encounter peak ($k \simeq 2v$). CDW theories are especially suited to the description of the ECC peak that, theoretically, results from the presence of the $N(Z_P/p)$ factor in the wave function. This peak can be analyzed in detail via a multipole expansion, and much theoretical work has been centered on the dipole parameter β . A negative β is strongly suggested by both experiment and physical intuition. CDW, CDW-EIS, and halfway house VCDW all predict different values for β , with the last theory being the only one that gives the high energy limit, in which it remains negative [42].

Magnetically quantized continuum distorted wave theory also has been considered [2] in the description of ionization in ion-atom collisions. This generalizes the CDW-EIS theory of Crothers and McCann [3] to incorporate the azimuthal angle dependence of each CDW in the final state wave function. This is accomplished by the analytic continuation of hydrogenic-like wave functions from below to above threshold, using parabolic coordinates and quantum numbers, including magnetic quantum numbers, thus providing a more complete set of states. The continuation applies to excitation, charge transfer, ionization, and double and hybrid events for both light and heavy-particle collisions. It has successfully been applied to the calculation of double differential cross sections for the single ionization of the hydrogen atom and for a hydrogen molecule by a proton for electrons ejected in the forward direction at a collision energy of 50 keV and 100 keV, respectively.

It is well known that the CDW-EIS models are the best suited to the intermediate and high-energy regions. Recent results for proton-argon total ionization cross sections [43] highlight large discrepancies between CDW-EIS theory and experiment for energies below 80 keV. This problem has been addressed in [4]. Here, following the theory of [44], the authors in [4] use a Born initial state wave function. In the final channel, the usual product of two continuum distorted

Fig. 56.2 Total ionization cross section for the proton-impact single ionization of Ar: *solid line* theoretical results of [4], *dashed line* theoretical results of OPM [43], and *dotted line* HFS [43]. Experimental data: *circles*, Rudd et al. [45]

wave functions, each associated with a distinct electron-nucleus interaction, is used. In their treatment, the target is considered as a one-electron atom, and the interactions between this active electron and remaining target electrons are treated by a model potential including both short and long-range effects. The success of this new theory for low energies is shown in Fig. 56.2. Here it is clear that the calculation in [4] gives good agreement for the total cross sections in the energy range 10–300 keV with the measurements of Rudd et al. [45].

Double ionization in general remains an extremely difficult area for theoretical models based on perturbative expansions – even those with explicit distortions built in. In this process, the explicit correlation between the electrons in the target atom is vitally important. However, one example where CDW theory can overcome these problems is in the bound-state wave function of *Pluvinage* [46]. This very successful treatment, which also includes a variationally determined parameter, is just the CDW analogy in bound-state theory, although this appeared well before Cheshire’s paper on scattering. The Pluvinage wave function for the ground state of a two-electron atom is given by

$$\begin{aligned} \phi = c(\kappa) & \left(\frac{Z_T^3}{\pi}\right) \exp[-Z_T(r_1 + r_2) + i\kappa r_{12}] \\ & \times {}_1F_1\left(1 + \frac{1}{2i\kappa}; 2; 2i\kappa r_{12}\right), \end{aligned} \quad (56.39)$$

where $r_{1,2}$ are the distances of the two electrons from the target nucleus, and r_{12} is the interelectron separation. The constant κ is variationally determined to be 0.41, giving the normalization constant $c = (0.36405)^{1/2}$.

An analogous wave function for two electrons in the target continuum was derived [12] and implemented later in a successful CDW treatment of ionization by electrons and positrons [47]. This BBK theory, so named in deference to the authors, demonstrates the high resolution CDW final states obtained, right down to triply differential cross sections (TDCS). However, this model suffers from the low-energy normalization problems associated with CDW and is also unable to describe the threshold effects that are in the domain of Wannier theory.

56.2.5 Ionization of Molecular Targets

The CDW-EIS model can be extended to treat single ionization of simple molecular targets by fast bare ions. Fast heavy ions in our framework implies that the projectile velocity is much larger, but still within the nonrelativistic range, than the typical electron velocity of bound electrons. At these high collision energies, for which the collision time is smaller than the relaxation one, corresponding to those electrons that remain bound to the molecule acting as spectators, the so-called passive electrons, we can assume in an acceptable approximation that they stay frozen in their respective molecular orbitals during the collision process. Additionally, we could also consider that the collision time is also shorter than the vibrational and rotational molecular times. In this way, the orientation of the molecule remains fixed in the space until the direct interaction of the projectile with the target ends. Specifically, for the projectile velocities we use and considering small molecules, the collision time τ is within the sub-fs to the -as domain ($1 \text{ fs} = 10^{-15} \text{ s}$, $1 \text{ as} = 10^{-18} \text{ s}$), while the typical vibration and rotational frequencies are in the range of $10^{13} \sim 10^{14} \text{ Hz}$ and $10^{10} \sim 10^{12} \text{ Hz}$, respectively (e.g., [48]).

An interesting set of phenomena can be related with the single ionization of simple molecules: the coherent superposition of quantum objects emitted from spatially separated positions. This process is often cited as the molecular double-slit scenario [49] in which a homonuclear diatomic molecule such as molecular hydrogen [50] or nitrogen [51] is ionized by irradiation with light or by impact of charged particles such as electrons or heavy ions. For decades particular attention has been paid to these phenomena due to their intrinsic importance in areas such as astrophysics and biology (see, e.g., the present book for more details). For the first time in 1966, *Howard Cohen* and *Ugo Fano*, in theoretical studies of photoionization of N_2 and O_2 molecules, recognized the existence of interference effects for these reactions [52]. They showed that an oscillating pattern appeared in the partial photoionization cross sections (PCS) when a two-center electron wave function was employed to model the coherent electron emission from both atomic center. Electrons can be emit-

ted coherently from both of the atoms in these molecules, in such a way that the electron waves could be either in phase or out of phase. In this way, these systems should exhibit an interference behavior equivalent to that seen in macroscopic double-slit experiments. Nevertheless, the first experimental confirmation for these interference phenomena appeared three decades later, in 2001, in the single ionization of H_2 molecules by impact of Kr^{34+} projectiles. Starting from this seminal work by *Stolterfoht* et al. [50], about coherent electron emission from H_2 molecules by impact of highly charged ions impact, there has been a true deluge of papers in the field (e.g., [53] and references therein).

Let us focus our interest here on the single ionization of diatomic molecules by impact of heavy ion projectiles. They possess a charge Z_p and incoming velocity v , and the beam is directed along the z -axis. In this way, we designate the $x-z$ plane as the scattering plane. The momentum transfer \mathbf{q} is defined as $\mathbf{q} = \mathbf{K}_i - \mathbf{K}_f$, where \mathbf{K}_i (\mathbf{K}_f) is the initial (final) momentum of the incident (scattered) particle, whereas \mathbf{k} is the momentum of the ionized electron, represented in usual spherical coordinates by the polar θ_e and azimuthal ϕ_e angles, respectively. Finally, the polar angle θ_ρ sets the orientation of the internuclear axis ρ with respect to the z -axis, and ϕ_ρ is the azimuthal angle, i.e., the angle of the internuclear axis with respect to the x -axis.

In the final channel of the reaction, we use the two-effective center (TEC) approximation introduced by *Wang* et al. [54] (also *Corchs* et al. [55]). This model was applied to the study of electron capture by impact of bare ions on homonuclear and heteronuclear molecules. Later, the TEC approximation was employed by *Galassi* et al. [56, 57] to describe single ionization of H_2 molecules by the impact of fast bare ions. In this approximation, the scattering matrix for the active electron can be written as

$$\begin{aligned} \tilde{T}_{fi}(\boldsymbol{\eta}, \boldsymbol{\rho}) = & \tilde{T}_{fi}^{(1)}(\boldsymbol{\eta}) \exp(i(1-\mu)\mathbf{q} \cdot \boldsymbol{\rho}) \\ & + \tilde{T}_{fi}^{(2)}(\boldsymbol{\eta}) \exp(-i\mu\mathbf{q} \cdot \boldsymbol{\rho}), \end{aligned} \quad (56.40)$$

where the atomic centers are displaced from the center of mass of the target by $(1-\mu)\boldsymbol{\rho}$ for the center 1 and $\mu\boldsymbol{\rho}$ for the center 2, $\mu \approx M_1/(M_1 + M_2)$ being the reduced mass, with M_1 and M_2 the masses of both centers, and $\tilde{T}_{fi}^{(1)}$ and $\tilde{T}_{fi}^{(2)}$ the corresponding effective atomic scattering matrix elements. In (56.40), $\boldsymbol{\eta}$ is the transversal component of \mathbf{q} , i.e., $\boldsymbol{\eta} \cdot \mathbf{v} = 0$.

For the case of homonuclear molecules, it is possible to demonstrate that

$$|\tilde{T}_{fi}(\boldsymbol{\eta}, \boldsymbol{\rho})|^2 = \{1 + \cos[(\mathbf{k} - \mathbf{q}) \cdot \boldsymbol{\rho}]\} |\tilde{T}_{fi}^{\text{eff}}(\boldsymbol{\eta})|^2, \quad (56.41)$$

with $\tilde{T}_{fi}^{\text{eff}}(\boldsymbol{\eta}) = \tilde{T}_{fi}^{(1)}(\boldsymbol{\eta}) = \tilde{T}_{fi}^{(2)}(\boldsymbol{\eta})$, an *effective* one-center scattering T -matrix element. The oscillatory factor in (56.41) is the signature of interference patterns coming from the electron emission of each of the two effective centers.

In the case of randomly oriented molecules, (56.41) should be averaged over all molecular orientations, so that

$$|\tilde{T}_{fi}(\boldsymbol{\eta}, \boldsymbol{\rho})|^2 = 4\pi \left[1 + \frac{\sin(|\mathbf{k} - \mathbf{q}|\rho)}{|\mathbf{k} - \mathbf{q}|\rho} \right] |\tilde{T}_{fi}^{\text{eff}}(\boldsymbol{\eta})|^2. \quad (56.42)$$

Furthermore, doubly differential cross sections (DDCS) as a function of the final energy and solid angle subtended by the ejected electron, averaged over all molecular orientations, can be obtained using (56.41) and (56.42)

$$\begin{aligned} \frac{d^2\sigma}{dE_k d\Omega_k} &= N_e (2\pi)^4 \frac{4\pi k}{v^2} \\ &\times \int d\boldsymbol{\eta} \left[1 + \frac{\sin(|\mathbf{k} - \mathbf{q}|\rho)}{|\mathbf{k} - \mathbf{q}|\rho} \right] |\tilde{T}_{fi}^{\text{eff}}(\boldsymbol{\eta})|^2 \\ &= S_{\text{dir}}(E_k, \Omega_k) + S_{\text{int}}(E_k, \Omega_k), \end{aligned} \quad (56.43)$$

with $S_{\text{dir}}(E_k, \Omega_k)$ being the contribution to the DDCS given by the effective atomic center and $S_{\text{int}}(E_k, \Omega_k)$ the interference contribution that corresponds to considering only the oscillatory part of the integrand in (56.43). The relevant physical quantity to observe interference patterns for oriented (fixed) molecules is the product $(\mathbf{k} - \mathbf{q}) \cdot \boldsymbol{\rho}$. On the other hand, for randomly oriented species, $|\mathbf{k} - \mathbf{q}|\rho$ is the factor that dominates the interference picture. Moreover, in order to get DDCS we should sum up over all the transverse momentum transfer values so that, depending on the molecular orientation, the interference traces may be washed out.

In Fig. 56.3, contributions to the ratio between DDCS for molecular H_2 and twice the atomic H is shown for the case of impact of $60 \text{ MeV amu}^{-1} \text{ Kr}^{34+}$ projectiles on H_2 targets. The direct $S_{\text{dir}}(E_k, \Omega_k)$ and interference $S_{\text{int}}(E_k, \Omega_k)$ terms are considered for the $\theta_e = 20^\circ$ emission angle. This ratio could be expected to be close to unity at the high impact energy considered. However, some differences are observed due to the different binding energies of H_2 and H, the corresponding effective charges Z_{eff} , and the normalization of the respective bound-state wave functions. While $S_{\text{dir}}(E_k, \Omega_k)$ increases monotonically, $S_{\text{int}}(E_k, \Omega_k)$ presents a damped oscillatory behavior as a function of the ejected electron velocity, demonstrating that interference patterns arise from coherent electron emission from the molecular centers.

Further experimental investigations, proving the existence of coherent electron emission, have been carried out. For instance, single ionization of H_2 molecules by impact of $68 \text{ MeV amu}^{-1} \text{ Kr}^{33+}$ [58] and 1, 3, and 5 MeV H^+ [59, 60] projectiles have been presented. Additionally, Misra et al. [61] measured DDCS for the cases of $1.5 \text{ MeV amu}^{-1} \text{ F}^{9+}$ and $1.0 \text{ MeV amu}^{-1} \text{ C}^{6+}$ ions impinging on atomic H and molecular H_2 targets. Cross section ratios were, thus, obtained by dividing both experimental results and compared with fully theoretical CDW-EIS calculations employing the model introduced by Galassi et al. [56]. Once again, the presence of interference patterns due to coherent electron emission from

Fig. 56.3 Experimental-to-theoretical cross section ratios for the single ionization of H_2 molecules by $60 \text{ MeV amu}^{-1} \text{ Kr}^{34+}$ projectiles. The electron emission angle is $\theta_e = 20^\circ$. Solid circles: experiment from [50]. Theory: solid line, CDW-EIS calculation; dashed line, contribution from $S_{\text{dir}}(E_k, \Omega_k)$; dot-dashed line, contribution from $S_{\text{int}}(E_k, \Omega_k)$ [56]

the molecular centers was found, confirming the previous results.

Other distorted wave-based methods have been applied to single ionization of H_2 molecules by ion impact at intermediate energies. For instance, the molecular version of the three-body distorted wave-eikonal initial state (3DW-EIS), named M3DW-EIS, was introduced by Chowdhury et al. [62] to calculate triply differential cross sections (TDCS) and DDCS for single ionization of H_2 by 75-keV proton impact. For the initial state, the 3DW-EIS method uses a Hartree-Fock wave function for the bound electron and an eikonal wave for the heavy ion projectile. For the final state, a distorted wave is used for the ejected electron, a Coulomb wave is used for the projectile in the field of a point charge, and the Coulomb distortion between the projectile and the ejected electron is also included. The asymptotic Coulomb interactions between the projectile and target are contained in the eikonal approximation for the initial state. Given the two-center nature of the hydrogen molecule, the projectile can scatter from either center, which leads to the possibility of observing interference effects, and this feature is, indeed, captured by M3DW-EIS.

Let us extend our analysis now to the case of diatomic molecules formed by a few electron orbitals. In order to

model its initial fundamental state the corresponding wave functions are written as linear combinations of Slater-type orbitals (STO) centered on each one of the nuclei of the molecule, and both the exponents and the weight coefficients are variationally optimized by employing the quantum chemistry program Gaussian [63]. In turn, each STO is written as a combination of Gaussian-type orbitals by employing a minimal STO-6G basis set. The equilibrium distance ρ and each of the orbital energies ε_i are then calculated with a higher precision by means of the larger HF/6-311 G* basis set.

The scattering matrix element $T_{fi,MO}(\boldsymbol{\eta}, \boldsymbol{\rho})$ per electron corresponding to a definite molecular orbital may be expressed as a linear combination of effective one-center scattering matrix elements $T_{hj,MO}^{\text{eff}}(\boldsymbol{\eta}, \boldsymbol{\rho})$ associated with a basis of STO centered on the h -target nucleus, given by

$$T_{h,MO}^{\text{eff}}(\boldsymbol{\eta}, \boldsymbol{\rho}) = \sum_j \omega_{h,j} T_{hj,MO}^{\text{eff}}(\boldsymbol{\eta}, \boldsymbol{\rho}), \quad (56.44)$$

where $h = 1, 2$ indicates the nucleus of the molecules in which the STO is centered, and the subscript j denotes the corresponding quantum numbers nlm . The coefficients $\omega_{h,j}$ are determined by means of the above-mentioned program Gaussian [63].

The case of 1 MeV protons impacting on N_2 molecules was studied by *Tachino et al.* [64]. They considered two different orientations of the internuclear axis, i.e., parallel and perpendicular to the incident projectile velocity, and electrons emitted with an energy of 100 eV. The structures present in the TDCS for parallel orientation give evidence of the presence of interference patterns. At variance, these patterns are washed out for perpendicular orientation due to the contribution of different transverse momentum transfers, in this way erasing the signatures of the coherent electron emission. It must be remarked that the phase of the structures for parallel orientation is shifted with respect to the others, depending on the orbital considered. Consequently, it has, indeed, been verified that the TDCS for the complete molecule do not present oscillations coming from interference effects. This also explains the suppression of primary electron interferences in the experimental results by *Baran et al.* [65, 66], where DDCS were measured for impact of N_2 molecules by protons. These authors suggest that the delocalization of several molecular orbitals could be responsible for the suppression mentioned. Moreover, a similar behavior for impact of H^+ and $\text{O}^{5+,8+}$ projectile beams on O_2 targets was observed [67, 68].

Further experiments confirmed the theoretical predictions showing the absence of interference effects on single ionization DDCS of O_2 [69, 70] and N_2 [71] by fast bare carbon ions. In all these cases, the DDCS ratios for ionization of the molecular target and twice the corresponding atomic compounds were considered.

The CDW-EIS model was also able to describe successfully experimental differential and total cross sections for ionization of water vapor. Two different representations for the ground state molecular orbitals of the target were used [72]. One of them was the the complete neglect of differential overlap (CNDO) approximation, originally implemented by *Pople* [73–75], where the molecular orbitals for the valence electrons were described by means of a linear combination of atomic orbitals (LCAO), and the basis set employed was a minimal one formed by Slater-type functions (STF) with fixed characteristic exponents. Moreover, all inner shells were considered as a part of an unpolarized core. However, some complications appear to compute DDCS due to the fact that all the crossed terms between different atomic orbitals should be evaluated. To make the computations easier, *Senger* [76, 77] introduced a usually applied method in which all the overlapping integrals are disregarded, thus reducing the final DDCS for any MO to a weighted sum of atomic DDCS, for each of the atomic components of the molecule. The other one is a monocentric approach developed by *R. Moccia* [78–80], where the ground state orbitals of molecules of the type XH_n are constructed through a linear combination of STF described with reference to a common origin. In the mentioned molecules, this origin is placed at the location of the nucleus of the heaviest atom labeled X, i.e., where the electronic density is concentrated. Moreover, wave functions are obtained for fixed-in-space molecules. In order to compare with most experiments where the molecular target is randomly oriented, an average over all possible molecular orientations is required.

To circumvent the complexities of using numerical three-center molecular continuum wave functions, an additional assumption is introduced: the active electron-residual target potential in the final channel is accounted for through an effective Coulomb one with an effective charge chosen in close relation with the binding energy of the molecular orbital from which ionization is produced.

The prior version of the CDW-EIS approximation exhibited a very good accord with the available experimental DDCS as a function of the angular distribution of ejected electrons, corresponding to fixed final electron energies, for impact of fast H^+ , He^{2+} , C^{6+} , and O^{8+} ([72] and references therein). The results were quite insensitive to the theoretical descriptions of the initial state. Moreover, this theoretical model was also applied with success not only to describe the above-mentioned DDCS but also to electron energy spectra for fixed angle emission, as well as for single differential cross sections [81–83].

In addition, it should be noted that a molecular version of the CDW-EIS within a three-body description – active electron, residual target, and projectile – labeled CDW-EIS MO, was employed. In this version, the molecular orbitals were obtained through a contraction of Gaussian-type func-

tions, using the STO-3G basis set, based on an HF approach, and the associated orbital energies were determined. The target molecular continuum wave functions were approximated by means of a spherical averaged potential created by the nuclei and the residual electrons, where effective nuclear potentials are used. It was again shown that the results for both single-electron ionization and single-electron capture by proton impact were quite insensitive to the description of the initial state, by comparing DDCS with the ones obtained with the CNDO model.

Finally, the CDW and CDW-EIS approximations were also employed to investigate single-electron capture and single-electron ionization DDCS, SDSCS- and TCS of larger molecules like the nucleobases, namely adenine, cytosine, thymine, and guanine, and the sugar phosphate backbone composing the double-stranded deoxyribonucleic acid (DNA) as well as uracil [84, 85]. A similar description to that employed by *Tachino et al.* [72] for DNA and uracil total-energy calculations for all targets were performed in the gas phase with the Gaussian 09 software at the RHF/3-21G level of theory. The equilibrium geometries of the nucleobases were obtained without symmetry constraints [63]. The results were compared with the scarce experimental data that was available in those days. Those results stimulated the development of further experiments, which were successfully compared with CDW-EIS calculations [86–88].

56.3 Wannier Method

56.3.1 The Wannier Threshold Law

In 1953, *Wannier* [89] deduced the relationship between the cross section at the threshold of a reaction and the excess-of-threshold energy of the incident particle for a three-body ionization problem, where the final state consists of a residual unit positive charge and two electrons, with each body moving in the continuum of the other two. This extended the earlier two-body threshold law derived by *Wigner* [90] to three bodies (Sect. 64.2.2).

For final states with $L = 0$, *Wannier* employed hyperspherical coordinates $(\rho, \alpha, \theta_{12})$, where

$$\begin{aligned} \rho^2 &= r_1^2 + r_2^2, \quad \alpha = \tan^{-1}\left(\frac{r_2}{r_1}\right), \\ \theta_{12} &= \cos^{-1}(\hat{\mathbf{r}}_1 \cdot \hat{\mathbf{r}}_2). \end{aligned} \quad (56.45)$$

Here, we assume that the residual ion is infinitely massive and at rest with respect to the two electrons. By converting the two-electron problem to the case of motion of a single point in six-dimensional space, we can take the hyperradius ρ as the *size* of the hypersphere, α as the radial correlation of the electrons, and θ_{12} as their angular correlation. This allows

the Schrödinger equation for the final state to be written (in a.u.) as

$$\begin{aligned} \left(h_0 - \frac{l^2(\hat{\mathbf{r}}_1)}{\rho^2 \cos^2 \alpha} - \frac{l^2(\hat{\mathbf{r}}_2)}{\rho^2 \sin^2 \alpha} + 2E \right. \\ \left. + \frac{2Z(\alpha, \theta_{12})}{\rho} \right) \Psi(\mathbf{r}_1, \mathbf{r}_2) = 0, \end{aligned} \quad (56.46)$$

where

$$\begin{aligned} h_0 &= \frac{1}{\rho^5} \frac{\partial}{\partial \rho} \left(\rho^5 \frac{\partial}{\partial \rho} \right) + \frac{1}{\rho^2 \sin^2 \alpha \cos^2 \alpha} \frac{\partial}{\partial \alpha} \\ &\times \left(\sin^2 \alpha \cos^2 \alpha \frac{\partial}{\partial \alpha} \right), \end{aligned} \quad (56.47)$$

and

$$Z(\alpha, \theta_{12}) = \frac{1}{\cos \alpha} + \frac{1}{\sin \alpha} - \frac{1}{(1 - \cos \theta_{12} \sin 2\alpha)^{\frac{1}{2}}} \quad (56.48)$$

is the potential surface on which the particle is moving [91].

The most likely configuration of the electrons leading to double escape at threshold corresponds to the region $\mathbf{r}_1 = -\mathbf{r}_2$, i.e., the two electrons escape in opposite directions from the reaction zone, corresponding to the saddle point of the potential surface $Z(\alpha, \theta_{12})$ and defined as the Wannier ridge. Also, dynamic screening between the two electrons means there would be equal partitioning of the energy available for the two particles, and so they would have equal but opposite velocities on escape. In hyperspherical coordinates, the most important region for double escape is, therefore, $\alpha = \pi/4$, and $\theta_{12} = \pi$.

The main conclusion of *Wannier's* theory is that the total cross section for electron impact single ionization scales as

$$\sigma = kE^{m_{12}}, \quad (56.49)$$

where E is the excess-of-threshold energy,

$$m_{12} = -\frac{1}{4} + \frac{1}{4} \left(\frac{100Z - 9}{4Z - 1} \right)^{\frac{1}{2}}, \quad (56.50)$$

and Z the residual charge; m_{12} is 1.127 for a unit residual charge, with $m_{12} \rightarrow 1$ as $Z \rightarrow \infty$.

56.3.2 Peterkop's Semiclassical Theory

The Wannier threshold law has been verified both semiclassically [92] and quantum mechanically [93]. *Peterkop* [92]

adopted a semiclassical JWKB approach to the problem by using the three-dimensional WKB ansatz

$$\Psi_0 = P^{\frac{1}{2}} \exp\left(\frac{iS}{\hbar}\right), \quad (56.51)$$

for the final-state wave function, where S and P are, respectively, the solutions of the Hamilton–Jacobi equation,

$$(\nabla_1 S)^2 + (\nabla_2 S)^2 = 2(E - V), \quad (56.52)$$

and the continuity equation,

$$\nabla_1(P \nabla_1 S) + \nabla_2(P \nabla_2 S) = 0. \quad (56.53)$$

In hyperspherical coordinates, these equations become

$$\begin{aligned} & \left(\frac{\partial S}{\partial \rho}\right)^2 + \frac{1}{\rho^2} \left(\frac{\partial S}{\partial \alpha}\right)^2 + \frac{4}{\rho^2 \sin^2 2\alpha} \left(\frac{\partial S}{\partial \theta_{12}}\right)^2 \\ & = 2E + \frac{2Z}{\rho}, \end{aligned} \quad (56.54)$$

and

$$\begin{aligned} & D_0 \left(P \frac{\partial S}{\partial \rho} \right) + \frac{1}{\rho^2} \\ & \times \left[D_1 \left(P \frac{\partial S}{\partial \alpha} \right) + D_2 \left(\frac{\partial S}{\partial \theta_{12}} \right) \right] = 0, \end{aligned} \quad (56.55)$$

where

$$D_0 f = \frac{1}{\rho^5} \frac{\partial}{\partial \rho} (\rho^5 f), \quad (56.56)$$

$$D_1 f = \frac{1}{\sin^2 2\alpha} \frac{\partial}{\partial \alpha} (f \sin^2 2\alpha), \quad (56.57)$$

$$D_2 f = \frac{4}{\sin^2 2\alpha} \frac{1}{\sin \theta_{12}} \frac{\partial}{\partial \theta_{12}} (f \sin \theta_{12}). \quad (56.58)$$

Following Wannier's hypothesis, solutions of these equations are found in the region $\alpha = \pi/4$, $\theta_{12} = \pi$. Taking the Taylor expansion for $Z(\alpha, \theta_{12})$ as

$$Z(\alpha, \theta_{12}) = Z_0 + \frac{1}{2} Z_1 (\Delta\alpha)^2 + \frac{1}{8} Z_2 (\Delta\theta_{12})^2 + \dots, \quad (56.59)$$

where $\Delta\alpha = \alpha - \pi/4$ and $\Delta\theta_{12} = \theta_{12} - \pi$, it follows from Eq. (56.48) that

$$Z_0 = \frac{3}{\sqrt{2}}, \quad Z_1 = \frac{11}{\sqrt{2}}, \quad Z_2 = -\frac{1}{\sqrt{2}}. \quad (56.60)$$

Similarly, taking the solution of Eq. (56.54) in the form

$$S = S_0(\rho) + \frac{1}{2} S_1(\rho) (\Delta\alpha)^2 + \frac{1}{8} S_2(\rho) (\Delta\theta_{12})^2 + \dots \quad (56.61)$$

gives

$$\frac{dS_0}{d\rho} = \omega, \quad (56.62)$$

$$\omega \frac{dS_i}{d\rho} + \frac{S_i^2}{\rho^2} = \frac{Z_i}{\rho}, \quad i = 1, 2, \quad (56.63)$$

where $\omega = (2E + 2Z_0/\rho)^{\frac{1}{2}}$. The solutions are

$$S_0 = \rho\omega + \frac{Z_0}{\chi} \ln \frac{\rho(\chi + \omega)^2}{2Z_0}, \quad (56.64)$$

$$S_i = \rho^2 \omega \frac{1}{u_i} \frac{du_i}{d\rho}, \quad i = 1, 2, \quad (56.65)$$

where $\chi = (2E)^{\frac{1}{2}}$, and

$$u_i = C_{i1} u_{i1} + C_{i2} u_{i2}, \quad (56.66)$$

$$u_{ij} = \rho^{m_{ij}} {}_2F_1 \left(m_{ij}, m_{ij} + 1; 2m_{ij} + \frac{3}{2}; \frac{-E\rho}{Z_0} \right), \quad (56.67)$$

$$m_{i1} = -\frac{1}{4} - \frac{1}{2} \mu_i, \quad m_{i2} = -\frac{1}{4} + \frac{1}{2} \mu_i, \quad (56.68)$$

$$\mu_i = \frac{1}{2} \left(1 + \frac{8Z_i}{Z_0} \right)^{\frac{1}{2}}, \quad (56.69)$$

where, for $i = 2$, the principal branch is understood.

Expanding P in the same form as S , and restricting the solution to finding P_0 , gives

$$P_0 = \frac{C}{\rho^5 \omega u_1 u_2^2}, \quad (56.70)$$

where $C \approx C_{12} E^{1-m_{12}}$. By solving these equations, Peterkop extracted the Wannier cross section behavior by matching the exact wave function with an approximate one for which the energy dependence is known at some arbitrarily finite value r_0 of ρ , giving the total cross section as

$$\sigma_{\text{tot}} \approx E^{1.127}, \quad (56.71)$$

as required. However, neither this method of Peterkop nor the quantum mechanical approach of [93] were able to deduce the constant of proportionality.

56.3.3 The Quantal Semiclassical Approximation

As can be seen from the form of Eq. (56.70) for P_0 , u_2 vanishes in the double limit $\rho \rightarrow +\infty$, $E \rightarrow 0$, and so, the semiclassical theory breaks down at every configuration of importance. To avoid this problem, Crothers [9] adopted a change of the dependent variable to obtain a uniform

JWKB approximation. Taking $\alpha = \pi/4$, (i.e., $\Delta\alpha = 0$) as the natural barrier, he set the final-state wave function as

$$\psi^{-*} = \frac{x |\sin(\alpha - \pi/4)|^{1/2}}{\rho^{5/2} \sin \alpha \cos \alpha (\sin \theta_{12})^{1/2}}, \quad (56.72)$$

so that

$$\left[\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho^2 \sin |\Delta\alpha|} \frac{\partial}{\partial \alpha} \left(\sin |\Delta\alpha| \frac{\partial}{\partial \alpha} \right) + \frac{1}{\rho^2 \sin^2 \alpha \cos^2 \alpha} \frac{\partial^2}{\partial \theta_{12}^2} + 2E + \frac{2Z}{\rho} + \frac{(\frac{1}{4} + \frac{1}{4} \csc^2 \Delta\theta_{12})}{\rho^2 \sin^2 \alpha \cos^2 \alpha} - \frac{\csc^2 |\Delta\alpha|}{4\rho^2} \right] x = 0, \quad (56.73)$$

where $|\Delta\alpha|$ and θ_{12} are, respectively, the polar and azimuthal angles. Near $\theta_{12} = \pi$ and $\alpha = \pi/4$ (i.e., at $\Delta\theta_{12} = \Delta\alpha = 0$), the term $(4\rho^2)^{-1}$ is negligible compared with $\csc^2 \theta_{12}/(4\rho^2)$. Also, the θ_{12} pseudopotential is clearly attractive, while the α potential is repulsive, and both potentials are large just at the region of importance, i.e., at $\Delta\alpha = 0 = \Delta\theta_{12}$.

Again, following the method of Peterkop, the final state wave function is written in the form of Eqs. (56.51), (56.54), and (56.55), where now the action perturbation expression S must be generalized to

$$S = s_0 \ln |\Delta\alpha| + s_1 \ln(\Delta\theta_{12}) + S_0(\rho) + \frac{1}{2} S_1(\rho)(\Delta\alpha)^2 + \frac{1}{8} S_2(\rho)(\Delta\theta_{12})^2 + \dots, \quad (56.74)$$

where the extra logarithmic phases indicate long-range Coulomb potentials. By applying the Kohn variational principle perturbatively and invoking Jeffreys' [94] connection formula on the Wannier ridge with $\rho = 0$ as the classical turning point, the final state wave function is [9]

$$\begin{aligned} \psi_f^{-*} = & \frac{c^{1/2} E^{m_{12}/2} \rho^{m_{12}/2 + 1/4} r (2Z_0)^{1/4} (-\chi/2\pi)^{1/2}}{(2Z_0/\rho)^{1/4} \rho^{5/2} \sin \alpha \cos \alpha} \\ & \times \delta(\hat{\mathbf{k}}_1 - \hat{\mathbf{r}}_1) \delta(\hat{\mathbf{k}}_2 - \hat{\mathbf{r}}_2) \\ & \times \exp\left[4i(8Z_0\rho)^{-1/2}(\Delta\theta_{12})^{-2}\right] \\ & \times \left\{ \exp\left[-i(8Z_0\rho)^{1/2} - \frac{1}{2}i(\Delta\alpha)^2\right] \right. \\ & \quad \times (2Z_0\rho)^{1/2} m_{12} - \frac{1}{8}i(\Delta\theta_{12})^2 \\ & \quad \left. \times (2Z_0\rho)^{1/2} m_{21} - \frac{1}{4}i\pi \right] - \text{c.c.} \left. \right\}, \quad (56.75) \end{aligned}$$

where $\chi = 2\pi \text{Im}(m_{21})$.

Taking the total cross section for distinguishable particles as

$$\begin{aligned} \sigma = & \frac{\pi^2 a_0^2}{k_0} \iint d\hat{\mathbf{k}}_1 d\hat{\mathbf{k}}_2 \frac{\pi Z_2 \tanh \chi}{(2E)^{1/2}} \left| f(\hat{\mathbf{k}}_1, \hat{\mathbf{k}}_2) \right|^2 \\ & \times \exp\left[\frac{-Z_2}{4(2E)^{1/2}} (\Delta\theta_{12})^2 \pi \tanh \chi \right], \quad (56.76) \end{aligned}$$

where f is the scattering amplitude, then the corresponding TDCS is

$$\begin{aligned} & \frac{d^3\sigma}{d\hat{\mathbf{k}}_1 d\hat{\mathbf{k}}_2 d(\frac{1}{2}k_1^2)} \\ & = \frac{2\pi^2 a_0^2}{k_0} \frac{d}{dE} \frac{\pi Z_2 \tanh \chi}{(2E)^{1/2}} \\ & \quad \times \exp\left[\frac{-Z_2}{4(2E)^{1/2}} (\Theta_{12} - R\pi)^2 \pi \tanh \chi \right] \\ & \quad \times \left| f(\hat{\mathbf{k}}_1, \hat{\mathbf{k}}_2) \right|^2. \quad (56.77) \end{aligned}$$

Assuming that the contribution from triplet states is negligible, $|f|^2$ can be written as

$$\frac{1}{4} \left| f(\hat{\mathbf{k}}_1, \hat{\mathbf{k}}_2) + f(\hat{\mathbf{k}}_2, \hat{\mathbf{k}}_1) \right|^2, \quad (56.78)$$

where $f(\hat{\mathbf{k}}_1, \hat{\mathbf{k}}_2)$ (and by permutation $f(\hat{\mathbf{k}}_2, \hat{\mathbf{k}}_1)$, hereafter referred to as f and g , respectively) is given by

$$\begin{aligned} f \simeq & \frac{2i}{\pi} \int d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 \Psi_f^{-*} \phi_f(2, \mathbf{r}_3) \\ & \times (H - E) \exp(i\mathbf{k}_0 \cdot \mathbf{r}_1) \psi_i(\mathbf{r}_2, \mathbf{r}_3). \quad (56.79) \end{aligned}$$

As a test of the above formulation for the process $e^- + \text{He} \rightarrow \text{He}^+ + 2e^-$ near the ionization threshold, Crothers [9] used an independent-electron open-shell wave function for the initial bound-state helium target, written as

$$\psi_i(\mathbf{r}_2, \mathbf{r}_3) = \frac{\phi(\mathbf{r}_2, z_0)\phi(\mathbf{r}_3, \beta) + \phi(\mathbf{r}_3, z_0)\phi(\mathbf{r}_2, \beta)}{[2(1 + S)]^{1/2}}, \quad (56.80)$$

where

$$\phi(\mathbf{r}, z_0) = z_0^{3/2} \pi^{-1/2} \exp(-z_0 r), \quad (56.81)$$

$$\begin{aligned} S = & \left[\int \phi(\mathbf{r}, z_0)\phi(\mathbf{r}, \beta) d\mathbf{r} \right]^2 \\ & = \left(\frac{4z_0\beta}{(z_0 + \beta)^2} \right)^3, \quad (56.82) \end{aligned}$$

and z_0 and β take the physical values $z_0 = 1.8072^{1/2}$, and $\beta = 2$. The total singlet cross section was found to be (in atomic units)

$$\sigma = 2.37 E^{m_{12}} a_0^2, \quad (56.83)$$

in line with Wannier's threshold law and with experiments [95], while the corresponding absolute TDCS were expressed as

$$\frac{d^3\sigma}{d\hat{k}_1 d\hat{k}_2 d(\frac{1}{2}k_1^2)} = \frac{70cz_0^2 2^{1/2} \chi \tanh \chi}{\pi R_\infty Z_0^{1/2} m_{12}} |f + g|^2 \times \left[\frac{d}{dE} E^{m_{12}-1/2} \exp\left(\frac{-Z_2(\Theta_{12} - \pi)^2 \pi \tanh \chi}{4(2E)^{1/2}}\right) \right] \quad (56.84)$$

in units of $10^{-19} \text{ cm}^2 \text{ sr}^{-2} \text{ eV}^{-1}$, where

$$c = \frac{\Gamma(m_{12} + 3/2)\Gamma(m_{12} + 1)}{2\pi Z_0^{m_{12}} \Gamma(2m_{12} + 3/2)}, \quad (56.85)$$

and where f (and similarly g for Θ_2) is given by

$$f = \int_0^\infty d\rho \rho^{3/2+m_{21}/2+1/4} \sum_{L=0}^{L_{\max}} i^L (2L+1) j_L\left(\frac{\rho z_0}{2^{1/2}}\right) \times P_L(\cos \Theta_1) \exp\left\{\frac{1}{8} \times \text{Im}[m_{21}(\Theta_{12}-\pi)^2 (2Z_0\rho)^{1/2}]\right\} \times 2 \cos\left\{(8Z_0\rho)^{1/2} + \frac{1}{8}\right\} \times \text{Re}[m_{21}(\Theta_{12}-\pi)^2 (2Z_0\rho)^{1/2}]\right\} \times r(\rho, \Theta_{12}) \quad (56.86)$$

with

$$(1+S)^{1/2} r(\rho, \Theta_{12}) = \exp\left(-\frac{\rho z_0}{2^{1/2}}\right) \left(2^{1/2} z_0 - \frac{1}{(1-\cos \Theta_{12})^{1/2}}\right) + \exp(-2^{1/2}\rho) \left[\frac{64(2)^{1/2}(z_0-1)}{(z_0+2)^3} + \frac{32}{(z_0+2)^3} [2(2)^{1/2} + (z_0+2)\rho] \exp\left(\frac{-\rho(z_0+2)}{2^{1/2}}\right)\right]. \quad (56.87)$$

These results have been found to compare favorably with both the relative experimental results of [96] and the absolute experimental results of [97]. The Crothers quantal semiclassical approximation has been successfully applied to other threshold (e, 2e) and (photon, 2e) collisions, namely two-electron photodetachment from H^- [98], $\text{He}(^4\text{P}_{5/2}^0)$ [99], and K^- [100]. Further investigations of the TDCS for helium at threshold have been since then carried out. The $^3\text{P}^0$ triplet contribution to the TDCS was studied in [101], where small

but notable improvements in the comparison with experimental results [96] and [97] were achieved for most configurations of the angles θ_1 and θ_2 . The inclusion of contributions from $^3\text{D}^{e,0}$ or $^3\text{F}^0$ to the absolute TDCS were found to be negligible in comparison with the effect of the $^3\text{P}^0$ [102], although the admittedly non-Wannier effective-charge investigation of $\theta_{12} = \pi$ by Pan and Starace [103] suggests that $^3\text{F}^0$ may be important at $\theta_1 = \pi/6$ or $5\pi/6$, in line with the experiment of Rösler et al. [97]. Another aspect that is thought to contribute to the TDCS is explicit correlation in the initial bound-state wave function for the helium target, in which the interelectronic distance r_{23} is explicitly contained. Absolute singlet TDCS have been obtained [104], using a helium ground state wave function developed by Le Sech [105]. Again, excellent agreement with the singlet results of [9] has been achieved, and, in most configurations, notable improvements with the corresponding experimental data are obtained, as shown in Fig. 56.4 for scattering angle $\theta_1 = 60^\circ$ (a) and 90° (b), indicating that electron correlation should also be considered if a full picture of threshold ionization is to be achieved.

Several significant new developments and contributions to the Wannier theory have also been presented. One notable achievement has been the analytical continuation of the uniform semiclassical wave function [9] to below the energy threshold to calculate the complex eigenenergies for doubly excited states of helium using a complex Bohr–Sommerfeld quantization rule with at least one complex transition point [5, 6]. The real parts of the eigenvalues were found to be in good agreement with the experimental results of Buckman et al. [106, 107] for the resonance positions, while the imaginary parts give the explicit widths of the resonances from which the intensities have been estimated. The theory in [5] was initially considered for the inaugural case of $L = 0$. Further investigation [6–8] extended the theory to include resonant states for $L = 1$ and $L = 2$. In the case of $L = 1$, an irrational quantum number was obtained, and attosecond lifetimes were obtained. Excellent results were obtained for the resonance positions, lifetimes, intensities, and scaling rules in comparison with the experimental data [106]. This success persuaded Deb and Crothers [108] to revisit the problem of quantal near-threshold ionization of He by electron impact. In particular, they reexamined the problem of above threshold ionization of He by electron impact by retaining the term $2L(L+1)/\rho^2$ in the hyperspherical equation

$$\left(\frac{1}{\rho^5} \frac{\partial}{\partial \rho} \rho^5 \frac{\partial}{\partial \rho} + \frac{1}{\rho^2 \sin^2 2\alpha} \frac{\partial}{\partial \alpha} \sin^2 2\alpha \frac{\partial}{\partial \alpha} + \frac{4}{\rho^2 \sin \theta_{12}} \frac{\partial}{\partial \theta_{12}} \sin \theta_{12} \frac{\partial}{\partial \theta_{12}} + 2E + \frac{2\zeta(\alpha, \theta_{12}) 2L(L+1)}{\rho^2}\right) \Psi = 0. \quad (56.88)$$

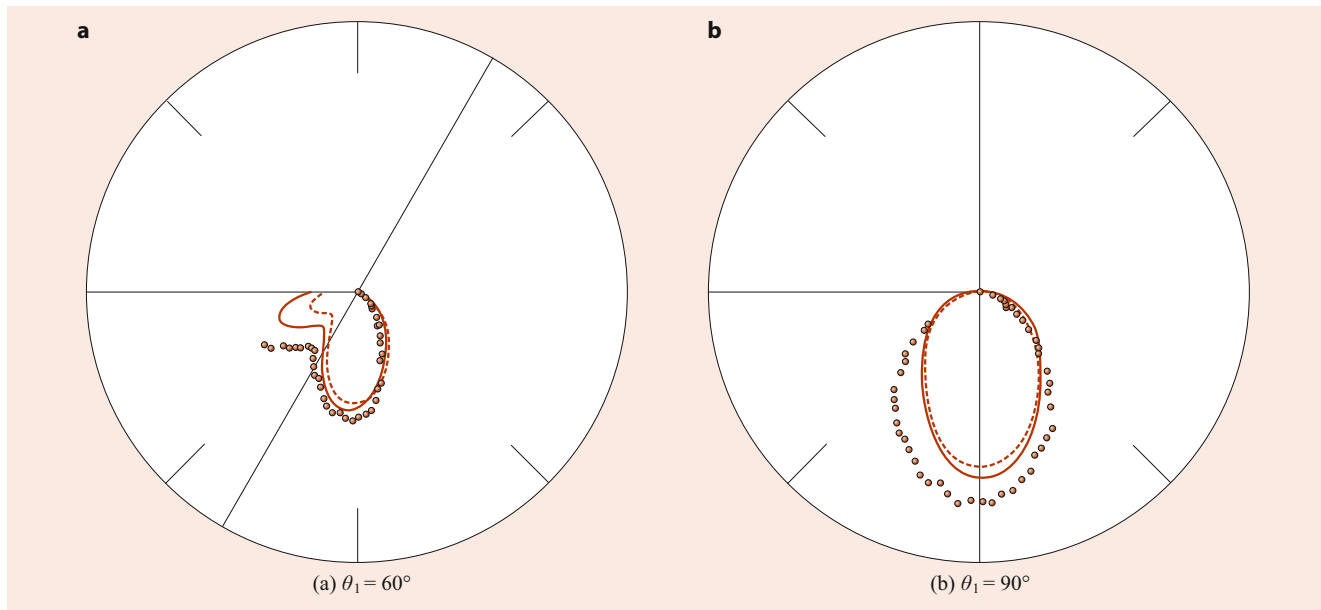

Fig. 56.4 Helium triply differential ionization cross section for coplanar geometry, $E_1 = E_2 = 1$ eV and $E = 2$ eV, calculated (full curve) TDCS of Copeland and Crothers [104] in polar coordinates, with polar coordinates as θ_2 , for scattering angles $\theta_1 = 60^\circ$ (a) and $\theta_1 = 90^\circ$ (b), in comparison with absolute experimental (circles) data of Rösel et al. [97], and theoretical results (broken curve) of Crothers [9]. The radius of each circle is $1.0 \times 10^{-19} \text{ cm}^2 \text{ sr}^{-2} \text{ eV}^{-1}$

Following the procedure of Crothers [9], they obtained

$$\begin{aligned} \Psi_f^{-*} = & \frac{c^{1/2} E^{m_{12}/2} u_1^{1/2}}{\tilde{\omega}^{1/2} \rho^{5/2} \sin \alpha \cos \alpha} \delta(\hat{\mathbf{k}}_1 - \hat{\mathbf{r}}_1) \\ & \times \delta(\hat{\mathbf{k}}_2 - \hat{\mathbf{r}}_2) \exp[4i(8Z_0\rho)^{-1/2}(\Delta\theta_{12})^{-2}] \\ & \times \exp\left\{-i\left[S_0 + \frac{1}{2}S_1(\Delta\alpha)^2\right.\right. \\ & \left.\left.+ \frac{1}{8}S_2(\Delta\theta_{12})^2 + \frac{\pi}{4}\right] - \text{conjugate}\right\}, \end{aligned} \quad (56.89)$$

where the classical action variables are given by

$$S_0 = \int_0^\rho d\tilde{\rho} \tilde{\omega}, \quad (56.90)$$

$$S_i = \rho^2 \omega (\ln u_i)', \quad i = 1, 2, \quad (56.91)$$

with

$$\tilde{\omega} = [\omega^2 - \omega(\ln u_2 - i \ln u_1)']^{1/2}, \quad (56.92)$$

$$\omega^2 = 2E + 2Z_0/\rho - 2L(L+1)/\rho^2. \quad (56.93)$$

The primes in Eqs. (56.91) and (56.92) denote derivatives with respect to ρ and $\tilde{\rho}$, respectively. It is to be noted here that the original work used the approximated form of ω by dropping the L -dependent term in Eq. (56.93). The inclusion

of this angular momentum term moves the classical turning point from the origin to ρ_+ , where

$$\rho_+ = \frac{-Z_0 + \sqrt{Z_0^2 + 4EL(L+1)}}{2E}. \quad (56.94)$$

As a result, the lower limit of ρ integration will be replaced by ρ_+ . The classical action variables S_1 and S_2 are now evaluated without introducing the limit $E\rho \rightarrow 0$. Using the final state wave function in Eq. (56.89) we first calculated the direct ionization amplitude. The exchange ionization amplitudes for the two indistinguishable atomic electrons were then obtained by interchanging the angles θ_1 and θ_2 in the direct amplitude. Singlet and triplet contributions are then accounted for in the usual ratio of 1 : 3.

Equation (56.89) is a more accurate variant of Eq. (56.75) used in the original theory of Crothers [9]. Using this refinement of the wave function, all partial wave contributions for singlets and triplets are accounted for up to $L = 6$ for the case of He by electron impact at an excess of 2 eV above threshold. It was found that within the coplanar geometry, both the symmetric and asymmetric triple differential cross sections, peaking at and near the Wannier ridge, are greatly improved when compared with experiment [109]. However, far away from the Wannier ridge, the TDCS tend to show qualitative differences from measurement [109].

The improved theory [108] has also been successfully applied to the calculation of total cross sections of positron impact ionization of helium for energies 0.5–10 eV above

threshold [110]. Excellent agreement with available experimental data [111] was obtained for the absolute theoretical calculation of positron impact ionization [110].

Roberto D. Rivarola Roberto D. Rivarola born in Rosario, Argentina. He received his PhD from the Université de Bordeaux I (France) in 1984. He has been Full Professor of Physics at the Universidad Nacional de Rosario since 1990 and is Superior Researcher at the National Research Council (CONICET). At present, he is Vice President of CONICET and Chair of Commission on Atomic, Molecular and Optical Physics of IUPAP.

Omar A. Fojón Omar A. Fojón received his PhD from the National University of Rosario (UNR) in Argentina in 1994. He has held several postdoctoral positions at universities in France and in Spain. At present, he is Researcher at the National Research Council of Argentina and Professor at the UNR. His areas of interest include attosecond science and atomic collisions.

Marcelo Ciappina M. Ciappina received his PhD from the Balseiro Institute at Argentina in 2005 and a Research Professor degree from the Czech Academy of Sciences in 2019. His academic training includes postdoctoral stays at renowned institutions in Germany, Singapore, USA, Spain and Czechia. At present, he is Associate Professor at the Guangdong Technion – Israel Institute of Technology (GTIIT), Shantou, China. His areas of interest include attosecond science and atomic collisions.

Derrick Crothers Derrick Crothers is Professor of Theoretical Physics (Personal Chair). He research interests lie in atomic, molecular, optical, and condensed matter physics. The topics include heavy-particle collisions, threshold phenomena, dielectrics, and ferromagnetism. He was awarded an Honorary Professorship in Physics by St Petersburg State University in 2003. He passed away on January 15, 2021.

Basic Atomic Processes in High-Energy Ion–Atom Collisions

Abstract

This chapter gives an overview of basic atomic physics processes occurring in a high-energy collision of an ion with an atom. These processes include ionization of the atom, electron loss from the ion, nonradiative and radiative electron transfer from the atom to the ion, as well as electron–positron pair production. Atomic units ($e = m_e = \hbar = 1$, where e is the elementary charge, m_e is the electron mass, and \hbar Planck’s constant) are used throughout unless otherwise stated.

Keywords

ionization · electron transfer · projectile-electron loss · electron–positron pair production · born approximation · doubly differential cross section · target electron · total ionization cross section · binary encounter

57.1 Introduction

In a collision between an ion (projectile) and a neutral atom (target), a multitude of atomic physics processes may occur. Their strength, importance, and even their very existence essentially depend on the colliding species and the impact velocity (energy). They range from relatively simple processes, in which a minimum possible number of “active” electrons (leptons) participate and which can be termed *basic*, to very complex ones involving many “active” electrons (leptons). In this chapter, we shall deal with basic atomic processes occurring in high-energy ion–atom collisions.

The definition “high-energy” means that the impact velocity v greatly exceeds the typical orbiting velocities v_0 of outer-shell atomic electrons: $v \gg v_0$, where $v_0 \simeq e^2/\hbar$. Thus, in terms of the impact velocity, the high-energy collisions refer to the interval $v_0 \ll v < c$, where $c = v_0/\alpha$ is the speed of light in vacuum ($\alpha = e^2/\hbar c \approx 1/137$ is the fine-structure constant). In terms of the impact energy, the lower boundary of the range of high-energy collisions can, somewhat arbitrarily, be defined as $\simeq 1$ MeV/u (corresponding to $v \simeq 6v_0$), whereas its upper boundary is formally infinite.

Three basic atomic physics processes can occur in collisions between a bare projectile nucleus and a target atom. (i) An atomic electron can be ejected (or excited) due to the interaction with the projectile. (ii) An atomic electron can be transferred to the projectile forming a bound state of the corresponding projectile ion. The transfer can proceed without or with emission of radiation and is called nonradiative or radiative electron capture, respectively. (iii) In relativistic collisions, electron–positron pair production becomes possible.

If initially the projectile has an electron, then in a collision with an atom it can be ejected (lost) or excited. In the rest frame of the projectile this can be viewed as “ionization” or excitation of the ion by the incident atom. In addition to the nucleus, the atom has electrons, which also interact with the electron of the ion. As a result, the physics of “ionization” of the ion by the impact of a neutral atom will, in general, differ

very substantially from that of atomic ionization in collisions with a bare nucleus. Thus, in collisions of partially stripped ions with neutral atoms, a new process – (iv) projectile electron loss (or excitation) – becomes possible.

In ion–atom collisions nuclear processes may also take place. However, compared to atomic processes, they are normally characterized by much smaller cross sections. Therefore, the nuclei of the colliding particles will be regarded as structureless point-like charges that cannot be excited or broken in the collision.

A theoretical consideration of processes (i)–(iv) exploits a huge difference between masses of electrons and nuclei. Because of this the nuclei move in the collision practically undeflected and can be regarded as the source of an *external field* in which the electrons move undergoing transitions. In the *semiclassical* (or *impact parameter*) approximation only the electrons are treated as quantum particles, whereas the nuclei are supposed to move along classical trajectories (e.g. [1, Chap. 4]). One often chooses a reference frame in which one of the nuclei is at rest and takes its position as the origin. The other nucleus moves in this frame along a straight-line trajectory $\mathbf{R}(t) = \mathbf{b} + \mathbf{v}t$, where \mathbf{b} is the impact parameter, \mathbf{v} the particle (collision) velocity, and t the time.

Using the semiclassical approximation one obtains the semiclassical transition amplitude $a_{fi}(\mathbf{b})$. The transition amplitude $S_{fi}(\mathbf{q}_\perp)$, obtained using a fully quantum treatment, is related to $a_{fi}(\mathbf{b})$ by the Fourier transformation

$$S_{fi}(\mathbf{q}_\perp) = \frac{1}{2\pi} \int d^2\mathbf{b} a_{fi}(\mathbf{b}) \exp(i\mathbf{q}_\perp \cdot \mathbf{b}), \quad (57.1)$$

where \mathbf{q}_\perp is the transverse part ($\mathbf{q}_\perp \cdot \mathbf{v} = 0$) of the momentum transfer in the collision.

57.2 Atomic Ionization and Projectile-Electron Loss

Let us consider collisions of two atomic particles, which we denote by labels 1 and 2 (see for an illustration Fig. 57.1). At the moment, we do not specify whether particle 1 (2) is the ion (the atom) or the atom (the ion). Since we are interested in electronic transitions caused by the collision we shall suppose that at least one of the particles changes its internal state. Let this be particle 1.

The transition amplitude $a_{fi}(\mathbf{b})$ can be written as ([2, Chap. 5])

$$a_{fi}(\mathbf{b}) = \left(-\frac{i}{c^2} \int d^4x J_{1\mu}(x) A_2^\mu(x) \right)_{fi}. \quad (57.2)$$

Here, $J_{1\mu}(x)$ ($\mu = 0, 1, 2, 3$) is the electromagnetic four-current of particle 1 at a space-time point x , and $A_2^\mu(x)$

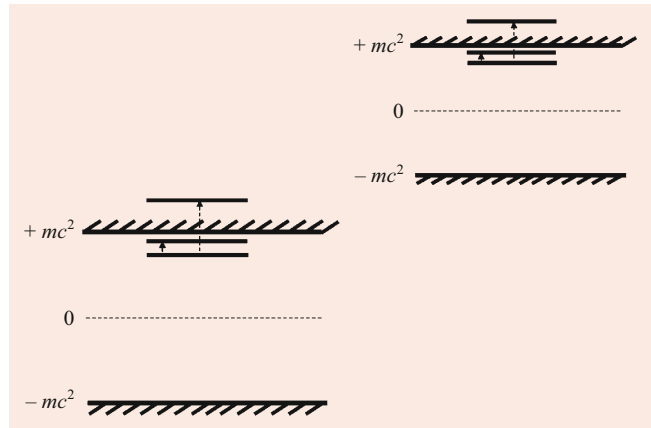

Fig. 57.1 Collision of an ion carrying (initially) electron(s) with an atom. Simultaneous electron transitions in both colliding species are possible

is the four-potential of the electromagnetic field created by particle 2 at the same point x . The summation over repeated Greek indices is implied.

The simplest consideration of the collisions is based on first-order perturbation theory in the interaction between the particles – *the (first) Born approximation* – which is valid provided that the colliding particles represent comparatively weak perturbations for each other. The latter is (overall) the case provided

$$\frac{Z}{v} \ll 1 \left(\frac{Ze^2}{\hbar v} \ll 1 \right), \quad (57.3)$$

where $Z = \max\{Z_1, Z_2\}$, and Z_1 and Z_2 are the atomic numbers of particles 1 and 2, respectively.

The condition Eq. (57.3) also means that the overlap in *the phase space* between the electrons of particles 1 and 2 will, in general, be quite small, and these two groups of electrons can be regarded as distinguishable.

In the Born approximation, the initial and final states of the particles are approximated by their unperturbed states, which are used to determine the four-current and the four-potential in Eq. (57.2). The amplitude Eq. (57.2) can be calculated by evaluating the current $J_{1\mu}$ of particle 1 in the reference frame K_1 (where its nucleus rests) and the potential A_2^μ of particle 2 in the reference frame K_2 (where its nucleus is at rest). Then this potential is transformed to the frame K_1 , where it is combined with $J_{1\mu}(x)$ in the amplitude Eq. (57.2). The result is (for its detailed derivation see [2, Chap. 5] and references therein)

$$\begin{aligned} a_{fi}(\mathbf{b}) &\equiv a_{0 \rightarrow n}^{0 \rightarrow m}(\mathbf{b}) \\ &= \frac{-i}{\pi v \gamma} \int d^2\mathbf{q}_\perp \exp(-i\mathbf{q}_\perp \cdot \mathbf{b}) \\ &\quad \times \frac{F_{1\mu}(n0; \mathbf{q}_1) \Lambda_v^\mu F_2^\nu(m0; -\mathbf{q}_2)}{-q_\lambda q^\lambda - i\zeta}. \end{aligned} \quad (57.4)$$

In Eq. (57.4) $\gamma = 1/\sqrt{1-v^2/c^2}$ is the collisional Lorentz factor, $\zeta \rightarrow +0$ gives the prescription to handle a (possible) singularity, the integration runs over the two-dimensional vector \mathbf{q}_\perp ($\mathbf{q}_\perp \cdot \mathbf{v} = 0, 0 \leq q_\perp < \infty$),

$$\begin{aligned} \mathbf{q}_1 &= (\mathbf{q}_\perp, q_{1\min}) \\ q_{1\min} &= \frac{\varepsilon_n - \varepsilon_0}{v} + \frac{\varepsilon_m - \varepsilon_0}{v\gamma}, \end{aligned} \quad (57.5)$$

and

$$\begin{aligned} \mathbf{q}_2 &= (\mathbf{q}_\perp, q_{2\min}), \\ q_{2\min} &= \frac{\varepsilon_m - \varepsilon_0}{v} + \frac{\varepsilon_n - \varepsilon_0}{v\gamma}. \end{aligned} \quad (57.6)$$

The four quantities,

$$\begin{aligned} F_{1_0}(n0; \mathbf{k}) &= - \int d^3\mathbf{r} \psi_n^\dagger \exp(i\mathbf{k} \cdot \mathbf{r}) \psi_0, \\ F_{1_l}(n0; \mathbf{k}) &= \int d^3\mathbf{r} \psi_n^\dagger \exp(i\mathbf{k} \cdot \mathbf{r}) \alpha_l \psi_0 \quad (l = 1, 2, 3), \end{aligned} \quad (57.7)$$

are the *inelastic* ($n \neq 0$) *form factors* of particle 1, where $\psi_0 = \psi_0(\mathbf{r})$ ($\psi_n = \psi_n(\mathbf{r})$) is the initial (final) state of the electron of particle 1 in the frame K_1 with an energy ε_0 (ε_n), α_l are the Dirac matrices, and \mathbf{r} is the electron coordinate (for simplicity, we assume that particle 1 has only one electron). Further, $\Lambda_{\mu\nu}$ is the Lorentz transformation matrix [3] from the frame K_2 to the frame K_1 , and F_{2_μ} are the form factors of particle 2 (given in K_2)

$$\begin{aligned} F_{2_0}(m0; \mathbf{k}) &= Z_2 \delta_{m0} - \int \prod_{i=1}^{N_2} d^3\xi_i u_m^\dagger \sum_{i=1}^{N_2} \exp(i\mathbf{k} \cdot \xi_i) u_0; \\ F_{2_l}(m0; \mathbf{k}) &= \int \prod_{i=1}^{N_2} d^3\xi_i u_m^\dagger \sum_{i=1}^{N_2} \alpha_{l(i)} \exp(i\mathbf{k} \cdot \xi_i) u_0, \end{aligned} \quad (57.8)$$

where N_2 is the number of the electrons of particle 2, $\alpha_{l(i)}$ are the Dirac matrices for the i -th electron, $u_0 = u_0(\xi_1, \dots, \xi_{N_2})$ ($u_m = u_m(\xi_1, \dots, \xi_{N_2})$) is the initial (final) electron state of particle 2 in the frame K_2 , ε_0 (ε_m) is its energy, and ξ_i is the coordinate of the i -th electron.

Using Eqs. (57.1) and (57.4) one can derive the quantum transition amplitude $S_{\text{fi}}(\mathbf{q}_\perp)$:

$$S_{\text{fi}}(\mathbf{q}_\perp) = - \frac{2i}{v\gamma} \frac{F_{1_\mu}(n0; \mathbf{q}_1) \Lambda_\nu^\mu F_{2_\nu}^v(m0; -\mathbf{q}_2)}{-q_\lambda q^\lambda - i\zeta}. \quad (57.9)$$

The quantity \mathbf{q}_1 (\mathbf{q}_2) has a physical meaning of the momentum transferred in the collision to particle 1 (2) in the frame K_1 (K_2). Further, $q_\lambda q^\lambda = (\varepsilon_n - \varepsilon_0)^2/c^2 - \mathbf{q}_1^2 \equiv (\varepsilon_m -$

$\varepsilon_0)^2/c^2 - \mathbf{q}_1^2$ is the square of the four-momentum of the (virtual) photon, which transmits the interaction between particles 1 and 2. Its explicit form is given by

$$\begin{aligned} -q_\lambda q^\lambda &= q_\perp^2 + \frac{(\varepsilon_n - \varepsilon_0 + \varepsilon_m - \varepsilon_0)^2}{v^2 \gamma^2} \\ &+ 2(\gamma - 1) \frac{(\varepsilon_n - \varepsilon_0)(\varepsilon_m - \varepsilon_0)}{v^2 \gamma^2}. \end{aligned} \quad (57.10)$$

If the photon is an on-mass-shell, $q_\mu q^\mu = 0$, the singularity appears in the amplitude Eq. (57.9) (and in the integrand of Eq. (57.4)). However, if $(\varepsilon_n - \varepsilon_0)(\varepsilon_m - \varepsilon_0) \geq 0$, then $q_\mu q^\mu = 0$ only provided that q_\perp , $(\varepsilon_m - \varepsilon_0)$ and $(\varepsilon_n - \varepsilon_0)$ are all equal to zero meaning the absence of any collision. Therefore, if $(\varepsilon_n - \varepsilon_0)(\varepsilon_m - \varepsilon_0) \geq 0$, then the restrictions imposed by the energy-momentum conservation in the collision do not permit the electromagnetic interaction between the particles to be transmitted by an on-mass-shell photon. In what follows, we assume that $(\varepsilon_n - \varepsilon_0)(\varepsilon_m - \varepsilon_0) \geq 0$, and the term $i\zeta$ in the amplitudes may be omitted.

The nonzero elements of the matrix Λ_ν^μ are [3]: $\Lambda_0^0 = \Lambda_3^3 = \gamma$, $\Lambda_1^1 = \Lambda_2^2 = 1$, and $\Lambda_3^0 = \Lambda_0^3 = (v/c)\gamma$. Hence, the explicit form of the form-factor coupling in Eqs. (57.4) and (57.9) reads

$$\begin{aligned} F_{1_\mu} \gamma^{-1} \Lambda_\nu^\mu F_2^v &= \left(F_{1_0} + \frac{v}{c} F_{1_3} \right) \left(F_2^0 + \frac{v}{c} F_2^3 \right) \\ &+ \frac{F_{1_3} F_2^3}{\gamma^2} + \frac{F_{1_1} F_2^1 + F_{1_2} F_2^2}{\gamma}. \end{aligned} \quad (57.11)$$

Taking into account Eqs. (57.10) and (57.11) we see that the form of the amplitudes Eqs. (57.4) and (57.9) is remarkably symmetric with respect to the quantities of the colliding particles.

For a collision in which particle 1 and particle 2 undergo transitions $\psi_0 \rightarrow \psi_n$ and $u_0 \rightarrow u_m$, respectively, the cross section differential in the transverse momentum transfer is given by

$$\frac{d^2\sigma_{0 \rightarrow n}^{0 \rightarrow m}}{d\mathbf{q}_\perp^2} = |S_{\text{fi}}(\mathbf{q}_\perp)|^2. \quad (57.12)$$

The total cross section can be expressed in two equivalent forms

$$\begin{aligned} \sigma_{0 \rightarrow n}^{0 \rightarrow m} &= \int d^2\mathbf{q}_\perp |S_{\text{fi}}(\mathbf{q}_\perp)|^2 \\ &= \int d^2\mathbf{b} |a_{\text{fi}}(\mathbf{b})|^2. \end{aligned} \quad (57.13)$$

The nonrelativistic limit. The amplitudes Eqs. (57.4) and (57.9) are obtained by using a fully relativistic treatment and can describe relativistic effects caused by high collision velocity and large values of the orbiting electron velocities

inside particles 1 and 2. The nonrelativistic limit of these amplitudes is obtained by setting $c \rightarrow \infty$, which yields

$$a_{0 \rightarrow n}^{0 \rightarrow m}(\mathbf{b}) = \frac{-i}{\pi v} \int d^2 \mathbf{q}_\perp \exp(-i \mathbf{q}_\perp \cdot \mathbf{b}) \times \frac{F_{1_0}(n0; \mathbf{q}) F_{2_0}(m0; -\mathbf{q})}{q^2}, \quad (57.14)$$

and

$$S_{0 \rightarrow n}^{0 \rightarrow m}(\mathbf{q}_\perp) = \frac{-2i}{v} \frac{F_{1_0}(n0; \mathbf{q}) F_{2_0}(m0; -\mathbf{q})}{q^2}, \quad (57.15)$$

where

$$\mathbf{q} = \left(\mathbf{q}_\perp, \frac{\varepsilon_n - \varepsilon_0 + \varepsilon_m - \varepsilon_0}{v} \right), \quad (57.16)$$

and the form factors F_{1_0} and F_{2_0} of the particles have to be evaluated with the nonrelativistic (Schrödinger) wave functions of the electrons. The application of the nonrelativistic Born approximation to atomic ionization and projectile-electron loss has a long history ([1, 4, 5] and references therein).

57.2.1 Atomic Ionization in Collisions with a Bare Nucleus

Let us now consider ionization of an atom (particle 1), assuming for simplicity that it has just one “active” electron, by collisions with a bare projectile nucleus (particle 2). The form factors of particle 2 are given by $F_{2_0} = Z_2$ and $F_{2_1} = F_{2_2} = F_{2_3} = 0$ (Eq. (57.8)), and $\varepsilon_m - \varepsilon_0 = 0$. Therefore, the form-factor coupling Eq. (57.11) reduces to $Z_2(F_{1_0} + (v/c)F_{1_3}) = -Z_2 \langle \psi_n | \exp(i \mathbf{q} \cdot \mathbf{r}) (1 - (v/c)\alpha_3) | \psi_0 \rangle$, and in the rest frame of the atom the quantum transition amplitude is given by

$$S_{\text{fi}}(\mathbf{q}_\perp) = \frac{2iZ_2 \langle \psi_p | \exp(i \mathbf{q} \cdot \mathbf{r}) (1 - \frac{v}{c}\alpha_3) | \psi_0 \rangle}{v \left(q_\perp^2 + \frac{(\varepsilon_p - \varepsilon_0)^2}{v^2 \gamma^2} \right)}. \quad (57.17)$$

Here, ψ_0 is the initial state of the atom with energy ε_0 , ψ_p describes the emitted electron with an asymptotic momentum \mathbf{p} , and energy ε_p (bound and continuum states in a Coulomb potential are considered in details in [6] and [7–9] for nonrelativistic and relativistic electrons, respectively), and

$$\mathbf{q} = \left(\mathbf{q}_\perp, \frac{\varepsilon_p - \varepsilon_0}{v} \right) \quad (57.18)$$

is the momentum transferred to the atom in its rest frame.

The semiclassical transition amplitude reads (e.g. [2, p. 189])

$$a_{\text{fi}}(\mathbf{b}) = \frac{2iZ_2}{v} \langle \psi_p | \exp(iq_z z) \left(1 - \frac{v}{c}\alpha_3 \right) \times K_0 \left(\frac{\omega_{n0}}{v\gamma} |\mathbf{r}_\perp - \mathbf{b}| \right) | \psi_0 \rangle, \quad (57.19)$$

where $q_z = (\varepsilon_p - \varepsilon_0)/v$, $\omega_{p0} = \varepsilon_p - \varepsilon_0$, and K_0 is a modified Bessel function [10].

Assuming that the electron continuum states ψ_p are normalized as $\langle \psi_{p'} | \psi_p \rangle = \delta^{(3)}(\mathbf{p}' - \mathbf{p})$ the ionization cross section differential in the momentum \mathbf{p} of the emitted electron in the rest frame of the atom is given by

$$\frac{d\sigma}{d^3 \mathbf{p}} = \int d^2 \mathbf{q}_\perp |S_{\text{fi}}(\mathbf{q}_\perp)|^2 = \frac{4Z_2^2}{v^2} \times \int d^2 \mathbf{q}_\perp \frac{|\langle \psi_p | \exp(i \mathbf{q} \cdot \mathbf{r}) (1 - \frac{v}{c}\alpha_3) | \psi_0 \rangle|^2}{\left(q_\perp^2 + \frac{\omega_{p0}^2}{v^2 \gamma^2} \right)^2}. \quad (57.20)$$

Since $d^3 \mathbf{p} = p^2 d p d\Omega_p = (p \varepsilon_p / c^2) d\varepsilon_p d\Omega_p$, where Ω_p is the solid angle for the emitted electron, the cross section Eq. (57.20) can be converted into the cross section $(d\sigma)/(d\varepsilon_p d\Omega_p)$ differential in the electron emission energy and emission angles. This cross section can be recalculated to any other inertial reference frame K' by using the transformation formula (see e.g. [11])

$$\frac{d\sigma'}{d\varepsilon_p' d\Omega_p'} = \frac{p'}{p} \frac{d\sigma}{d\varepsilon_p d\Omega_p}, \quad (57.21)$$

where the primed quantities refer to K' .

The Born approximation is “overall” valid if $Z_2/v \ll 1$. However, in the case of ionization an additional precaution is necessary. Let an unbound electron move in a Coulomb field of a nucleus with an atomic number Z . The influence of the field on the electron can be characterized by the Sommerfeld parameter $\eta_e = Z/v_e$, where v_e is the electron velocity relative to the nucleus. An electron emitted in ion–atom collision moves in the presence of two fields whose influence is characterized by $\eta_{1,e} = Z_1/v_e$ and $\eta_{2,e} = Z_2/|\mathbf{v}_e - \mathbf{v}|$, where \mathbf{v}_e and $\mathbf{v}_e - \mathbf{v}$ are the velocities of the emitted electron with respect to the atomic residue and the ionic projectile, respectively (for simplicity, here we neglect relativistic effects). It is obvious that the condition $Z_2/v \ll 1$ does not necessarily lead to $\eta_{1,e} \gg \eta_{2,e}$ and, hence, does not guarantee that the field of the atomic residue dominates the motion of the emitted electron.

Fig. 57.2 The energy spectrum of soft electrons emitted in single ionization of He by 1 MeV p^+

In particular, if the emitted electron has a velocity close to that of the projectile, then the field of the latter strongly affects the electron motion invalidating the Born approximation. Such electrons, which correspond to *electron capture to the projectile continuum*, are observed in experiments ([12] and references therein) and can be described by continuum-distorted-wave models and two-center coupled-channel methods.

Provided that $Z_2/v \ll 1$, the Born approximation is applicable to the emission of electrons with velocities v_e substantially smaller than v . In collisions where the impact velocity v greatly exceeds the typical orbiting velocity v_0 of the electron in its initial state ($v_0 \simeq Z_1$), electrons emitted with velocities $v_e \ll v$ constitute the *soft-electron peak*. This peak consists of electrons with kinetic energies in the range $(0, E_{\max})$, where E_{\max} is of the order of the binding energy of the electron in its initial state and contributes most to the total ionization cross section. The energy distribution of these electrons decreases very rapidly with an increase in the emission energy (Fig. 57.2).

One more prominent emission feature is represented by *binary-encounter electrons*. They originate in collisions with vanishingly small momentum transfers to the atomic nucleus, from the *Bethe ridge* (e.g. [13]) and have kinetic energies ranging from 0 up to $2c^2(\gamma^2 - 1)$.

Expressions (Eqs. (57.17)–(57.20)) take into account relativistic effects related to the collision velocity and the velocities of the electron in its initial and final states. They are successfully applied to calculate electron emission from the *K*-shell of very heavy atoms by high-energy collisions

with protons and other light nuclei where both types of the relativistic effects are of importance.

However, the fully relativistic description of ionization is not always necessary, even if $v \rightarrow c$. For instance, in soft-electron emission from light atoms, the motion of the electrons in the initial and final states is nonrelativistic (in the rest frame of the atom), and the description can be simplified by replacing in Eqs. (57.17), (57.19), and (57.20)

$$\begin{aligned} \alpha_3 \exp(i\mathbf{q} \cdot \mathbf{r}) &\rightarrow \frac{1}{2c} (\hat{p}_z \exp(i\mathbf{q} \cdot \mathbf{r}) + \exp(i\mathbf{q} \cdot \mathbf{r}) \hat{p}_z) \\ \alpha_3 \exp(iq_z z) &\rightarrow \frac{1}{2c} (\hat{p}_z \exp(iq_z z) + \exp(iq_z z) \hat{p}_z) \\ \psi_0(\psi_p) &\rightarrow \varphi_0(\varphi_p), \end{aligned} \quad (57.22)$$

where φ_0 and φ_p are the corresponding nonrelativistic (Schrödinger) wave functions, and $\hat{p}_z = \hat{\mathbf{p}} \cdot \mathbf{v}/v$ ($\hat{\mathbf{p}}$ is the electron momentum operator). The resulting expressions describe only relativistic effects dependent on the collision velocity v .

If not only the motion of the electron is nonrelativistic but also $v \ll c$, then a further simplification is obtained by setting $c \rightarrow \infty$, which results in the fully nonrelativistic description of the collision.

The total cross section for ionization is obtained by integrating the cross section $d\sigma/d^3\mathbf{p}$ over the momenta of the emitted electrons. If for the overwhelming majority of ionization events the minimum momentum transfer $q_{\min} = (\varepsilon_p - \varepsilon_0)/v \approx Z_1^2/v$ is much smaller than the typical orbiting momentum of the electron in its initial state $\approx Z_1$ (which is the case provided that $Z_1/v \ll 1$), then one can derive a simple expression for the total cross section [4]

$$\sigma_t = a \frac{Z_2^2}{v^2} \left(\ln(bv\gamma) - \frac{v^2}{2c^2} \right), \quad (57.23)$$

where $a \approx Z_1^{-2}$ and $b \approx Z_1^{-1}$ are the quantities dependent on the properties of the target. As an estimate, Eq. (57.23) can also be used when the condition $Z_1/v \ll 1$ ($Z_1/c \ll 1$) is not fulfilled, but the impact energy is so high that $\gamma \gg 1$ [14].

At $v \rightarrow c$, the cross section Eq. (57.23) grows with an increase in the impact energy. The growth is caused by the Lorentz contraction, owing to which the range of the field produced by a point-like charge is reduced by a factor of γ in the direction along its velocity and is increased by the same factor in the plane perpendicular to it. As a result, when the impact energy increases, there appear contributions to the cross section given by larger and larger impact parameters. At $\gamma \rightarrow \infty$, the cross section Eq. (57.23) diverges. This divergence is, however, rather formal since all calculable quantities remain finite due to the target density effect (e.g. [15]) and/or the finite sizes of the target and projectile beam.

Beyond the Born approximation

As has already been stressed, the application of the Born approximation is restricted by the condition $Z_2/v \ll 1$. Moreover, even if it is fulfilled, this approximation may still break down when applied to the emission of fast electrons. Therefore, we now very briefly consider a few more advanced treatments for ionization.

- *Coupled-channel methods.* The wave function satisfying the equation

$$i \frac{\partial \psi(t)}{\partial t} = \hat{H}(t) \psi(t), \quad (57.24)$$

where $\hat{H} = \hat{H}_0 + \hat{V}$ is the full Hamiltonian, \hat{H}_0 is the Hamiltonian for the free (noninteracting) atom, and $\hat{V}(t)$ is the interaction with the projectile ion, can be expanded into a complete set of the eigenstates of \hat{H}_0 . By inserting this expansion into Eq. (57.24) we obtain a set of coupled equations for the expansion coefficients. Then this set is reduced to a tractable number of equations by taking into account only the “most essential” eigenstates of \hat{H}_0 . The remaining equations are solved rigorously (numerically).

- *Distorted-wave models.* In a distorted-wave approach, the full Hamiltonian is also split into two parts. However, one now tries to include as much of the ion–atom interaction as possible already into the definition of the initial and final states treating the remaining part of the Hamiltonian as a perturbation. Since this perturbation is weaker than the ion–atom interaction \hat{V} , a distorted-wave series has a better convergence, and it often suffices to consider just its first term.

Distorted-wave models for the ionization of atoms in non-relativistic collisions with bare nuclei are considered in Chap. 56 of this Handbook. For relativistic collisions they were reviewed in [16, Chap. 6] (see also [2, Chap. 6]).

- *The light-cone approximation.* Let us suppose that the projectile ion moves with such high energy that its velocity (the collision velocity) is almost equal to the speed of light. Then, by assuming that the projectile velocity is equal to the speed of light it is possible [17] to derive an exact expression for the transition amplitude in the impact parameter space, which reads

$$a_{fi}^{LC}(\mathbf{b}) = \langle \psi_p | \exp \frac{i\omega_{n0}z}{c} (1 - \alpha_3) \exp(iG_0) | \psi_0 \rangle, \quad (57.25)$$

where $G_0 = (2Z_2/c) \ln(|\mathbf{r}_\perp - \mathbf{b}|/b)$. Unlike the Born amplitude Eq. (57.19), the amplitude Eq. (57.25) contains the projectile’s charge Z_2 in the exponent, reflecting the fact that the interaction with the projectile is taken into account to all orders of perturbation theory. By comparing Eq. (57.25) with Eq. (57.19) we see that the exact and

Born amplitudes will, in general, differ even at $\gamma \rightarrow \infty$.

There exists an intimate link between the light-cone approximation and some of the distorted-wave models, which at $\gamma \rightarrow \infty$ yield the transition amplitude in the form of Eq. (57.25) [18].

- *Numerical solutions on a lattice.* Yet another nonperturbative – and fully numerical – treatment is the direct numerical solution of the time-dependent Dirac (or Schrödinger) equation on a lattice in position or momentum space (e.g. [19, Chap. 7], [2, Chap. 6] and references therein).
- *Classical trajectory Monte Carlo calculations.* This method is based on a purely classical description of ion–atom collisions. It is reviewed in Chap. 62 of this Handbook.

Basic Collision Dynamics

Most detailed and basic information about the collision dynamics is contained in the fully differential cross section (given by $|S_{fi}(\mathbf{q}_\perp)|^2$). The advent of reaction microscopes has enabled us to accurately measure such cross sections for the ionization of simple atoms (He, Li) by fast ions. In order to describe the experimental results, theory has to properly treat the behavior of the electron in the simultaneous presence of the fields of the atomic core and the projectile ion and address the role of the interaction between the projectile ion and the target nucleus. All this is missing in the Born approximation but can be successfully implemented within distorted-wave models and coupled-channel methods. Moreover, there are some indications that the coherence properties of the projectile should be also taken into account [20].

57.2.2 Projectile-Electron Loss

Let us consider collisions of a projectile ion with a target atom assuming that the ion carries initially one electron and focusing on its transitions. Now particle 1 is the ion ($n \neq 0$), particle 2 is the atom, and we can again apply Eq. (57.4) and/or Eq. (57.9).

For collisions of very simple atomic systems (like a hydrogen-like projectile ion on an atomic hydrogen) the cross sections can be calculated relatively easily for any particular reaction channel (e.g., for mutual ionization in which both the ion and the atom lose electron(s)). However, in collision experiments with a focus on transitions in the projectile ion, the final state of the target is often not observed, and one then has to deal with the cross section

$$\sigma_{0 \rightarrow n} = \sum_m \sigma_{0 \rightarrow n}^{0 \rightarrow m}, \quad (57.26)$$

where the sum runs over all possible final states of the target, including its continuum. In the case of atoms with more than one electron, rigorous calculations become infeasible,

and one has to use some simplifications [2]. The first of these consists of reducing the relativistic form-factor coupling according to

$$\frac{F_{1\mu} A_\nu^\mu F_2^\nu}{\gamma} \rightarrow F_2^0 \left(F_{1_0} + \frac{v}{c} F_{1_3} \right) = -Z_{2,\text{eff}}^{0 \rightarrow m} \times \langle \psi_n | \exp(i\mathbf{q} \cdot \mathbf{r}) \left(1 - \frac{v}{c} \alpha_3 \right) | \psi_0 \rangle, \quad (57.27)$$

where the quantity

$$Z_{2,\text{eff}}^{0 \rightarrow m} = F_2^0 = Z_2 \delta_{m0} - \langle u_m | \sum_{j=1}^{Z_2} \exp(i\mathbf{q}_2 \cdot \boldsymbol{\xi}_j) | u_0 \rangle \quad (57.28)$$

is the effective charge of the atom “seen” by the electron of the ion. This charge depends on the momentum transfer in the collision and also on the initial and final states of the atom.

It is customary to split the cross section Eq. (57.26) into two parts and discuss them separately.

Elastic Target Mode. Screening

One part represents the contribution to the cross section Eq. (57.26) from collisions in which the target remains in its initial internal state ($m = 0$). In this collision mode, the effective atomic charge

$$Z_{2,\text{eff}}^{0 \rightarrow 0}(\mathbf{q}_0) = Z_2 - \int d^3\xi \rho_{\text{el}}(\boldsymbol{\xi}) \exp(i\mathbf{q}_0 \cdot \boldsymbol{\xi}), \quad (57.29)$$

where $\mathbf{q}_0 = (-\mathbf{q}_\perp; -(\varepsilon_n - \varepsilon_0)/v\gamma)$ is the momentum transferred to the atom (in its rest frame), can be cast into a convenient form by using a parametrization

$$\rho_{\text{el}}(\boldsymbol{\xi}) = \frac{Z_2}{4\pi\xi} \sum_{j=1}^3 A_j \kappa_j^2 \exp(-\kappa_j \xi) \quad (57.30)$$

for the electron charge density $\rho_{\text{el}}(\boldsymbol{\xi})$ in the atomic ground state. The parameters A_j and κ_j ($j = 1, 2, 3$, $\sum_j^3 A_j = 1$) are tabulated in [21, 22]. This yields

$$Z_{2,\text{eff}}^{0 \rightarrow 0}(\mathbf{q}_0) = Z_2 q_0^2 \sum_{j=1}^3 \frac{A_j}{\kappa_j^2 + q_0^2}. \quad (57.31)$$

The effective atomic charge Eq. (57.31) varies between 0 (at $q_0 \rightarrow 0$) and Z_2 (at $q_0 \gg \kappa_j$). Such behavior is not related to a particular form used to parametrize the electron density and actually already follows from the analysis of Eq. (57.28) showing that the effective atomic charge vanishes in collisions in which the momentum transfer to the atom is much smaller than the typical momenta of the atomic electrons,

increases monotonously with the increase in q_0 and reaches a plateau ($Z_{2,\text{eff}}^{0 \rightarrow 0} = Z_2$) in collisions where the momentum transfer to the atom is large on the atomic scale. Thus, the effect of the target electrons in collisions where the target remains in its initial internal state is to partially or even fully *screen* the atomic nucleus that reduces the force acting on the electron of the ion compared to that in collisions with bare nucleus Z_2 .

With the effective charge in the form Eq. (57.31), the expressions for the amplitude and the cross sections are simplified substantially. In particular, the cross section for the electron-loss differential in the momentum of the emitted electron is given by an expression similar to Eq. (57.20), in which the constant charge Z_2 should be replaced by $Z_{2,\text{eff}}^{0 \rightarrow 0}(\mathbf{q}_0)$ from Eq. (57.31).

The projectile-target collision mode, in which the target does not change its internal state (while the projectile does), is often called the *elastic mode*, implying that it is elastic only for the target.

Inelastic Target Mode. Antiscreening

The remaining part of the cross section Eq. (57.26) describes collisions in which not only the electron of the ion but also the atomic electrons are “active” in the collision. This collision mode is called *doubly inelastic* or simply *inelastic*.

According to the Born approximation, the inelastic mode is not influenced by the interaction between the electron of the projectile and the nucleus of the target, and the projectile electron undergoes a transition solely due to its interaction with the target electrons ([2, 5, 23]).

The contributions from collisions in which the target changes its initial internal state increase the total cross section for electron loss. This action of the target electrons is exactly opposite to their effect in the elastic mode and is called *antiscreening*.

The relative role of the antiscreening mode is maximal for collisions with hydrogen decreasing with the increase in the atomic number Z_2 . In particular, in collisions with large momentum transfers, the contributions of the screening and antiscreening mode scale approximately as $\approx Z_2^2$ and $\approx Z_2$, respectively (Eq. (57.32)).

Beyond the Born Approximation

If the condition Eq. (57.3) is violated, the Born approximation becomes invalid, and more sophisticated theoretical methods have to be used.

In collisions of very highly charged projectiles with heavy atoms occurring at not too high impact energies only the impact parameters, which are quite small on the scale of a neutral atom, contribute noticeably to the loss process ([2, Chap. 6] and references therein). In such collisions, the field of the atomic nucleus becomes too strong to be described within the Born approximation, but the role of the atomic

electrons is of minor importance. Therefore, the problem of projectile-electron loss in collisions with a neutral atom can be reduced to the problem of “ionization” in a three-body system (the electron, the nuclei of the ion and atom) and then treated by using, for instance, *three-body distorted-wave models* ([2, Chap. 6], [16, Chap. 6], Chap. 56 of the present Handbook and references therein) or coupled-channel methods ([19, Chap. 2, 7, 8] and references therein).

For collisions with heavy atoms at noticeably higher impact energies, where the role of larger impact parameters increases and the screening effect of the atomic electrons can no longer be neglected [2], a *symmetric eikonal model*, in which the effect of the strong field of the neutral atom on the electron of the projectile is described by eikonal distortion factors, can be used [18]. In the limit $\gamma \rightarrow \infty$, this model goes over into the light-cone approximation and is expected to yield good results also for finite but large γ .

A different kind of *symmetric eikonal model* was developed for projectile-electron loss in nonrelativistic and relativistic collisions with very light atoms like hydrogen and helium ([2, Chap. 6] and references therein). In such collisions, the role of the atomic electrons is comparable to that of the atomic nucleus. In collisions with highly charged ions, the motion of the atomic electrons is influenced by the field of the ion, which may, in turn, affect their interaction with the electron of the ion. The model takes this influence into account by introducing eikonal distortion factors for the initial and final state of the target atom. Surprisingly, the model shows noticeable deviations from the predictions of the Born approximation even when the parameter Z_1/v is as small as 0.1. With its increase, the model itself eventually becomes invalid when the motion of the atomic electrons in the collision is already governed mainly by the field of the ion.

An electron in a highly charged ion is very tightly bound and, in order to remove it from the ion, the momentum transfers in the collision have to be sufficiently large. In particular, it may happen that the momentum transfers to the atom (Eq. (57.6)) will be much larger than the typical orbiting momenta of all atomic electrons. Then the motion of the atomic electrons in the collision is governed by the field of the ion, and the cross section for electron loss from (or excitation of) the ion is given by [24, 25]

$$\sigma = Z_2^2 \sigma_p + Z_2 \sigma_e, \quad (57.32)$$

where Z_2 is the atomic number of the atom, and σ_p and σ_e are the cross sections for electron loss in collisions with equivelocity incident protons and electrons, respectively (σ_e should be averaged over the atomic Compton profile, if necessary). In calculating σ_e it is of crucial importance to take into account the effect of the field of the highly charged ion on the incident and scattered electrons as well as on the emitted electron. Equation (57.32) was applied to excita-

tion of 212.9 MeV/u $U^{91+}(1s)$ in collisions with hydrogen, and a very good agreement with experiment was found [26]. Equation (57.32) was also applied to electron loss from $U^{91+}(1s)$ in collisions with hydrogen and helium [25]. However, available experimental data is not sufficiently accurate to test the theory.

Projectile-electron loss in nonrelativistic collisions with many-electron atoms was also considered by using *coupled-channel methods* (for the elastic mode only) and the *sudden approximation* ([2, Chap. 3] and references therein).

57.3 Electron Transfer Processes

In this section, we consider electron transfer processes in the basic situation when a bare ion Z_i collides with an atomic system consisting of one (“active”) electron and a nucleus Z_a .

57.3.1 Nonradiative Electron Capture

A starting point in our discussion of nonradiative capture will be the following two expressions for the transition amplitude,

$$\begin{aligned} a_{fi}^{(+)}(\mathbf{b}) &= -i \int_{-\infty}^{+\infty} dt \left\langle \left(\hat{H} - i \frac{\partial}{\partial t} \right) \chi_f(t) \middle| \psi_i^{(+)}(t) \right\rangle, \\ a_{fi}^{(-)}(\mathbf{b}) &= -i \int_{-\infty}^{+\infty} dt \left\langle \psi_f^{(-)}(t) \middle| \left(\hat{H} - i \frac{\partial}{\partial t} \right) \varphi_i(t) \right\rangle, \end{aligned} \quad (57.33)$$

where $a_{fi}^{(+)}$ and $a_{fi}^{(-)}$ represent the *post* and *prior* forms, respectively, of the amplitude. In Eq. (57.33), $\varphi_i(t)$ and $\chi_f(t)$ are the initial and final exact asymptotic states of the electron, respectively, and $\psi_i^{(+)}(t)$ and $\psi_f^{(-)}(t)$ are solutions of the full (two-center) Dirac equation

$$i \frac{\partial \psi^{(\pm)}(t)}{\partial t} = \hat{H} \psi^{(\pm)}(t), \quad (57.34)$$

with the “in” ($\psi_i^{(+)}$) and “out” ($\psi_f^{(-)}$) boundary conditions. The two-center Hamiltonian reads

$$\begin{aligned} \hat{H} &= c \boldsymbol{\alpha} \cdot \hat{\mathbf{p}} + \beta c^2 - [\Phi_a(\mathbf{r}, t) - \boldsymbol{\alpha} \cdot \mathbf{A}_a(\mathbf{r}, t)] \\ &\quad - [\Phi_i(\mathbf{r}, t) - \boldsymbol{\alpha} \cdot \mathbf{A}_i(\mathbf{r}, t)], \end{aligned} \quad (57.35)$$

where $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \alpha_3)$, β are the Dirac matrices, and (Φ_i, \mathbf{A}_i) and (Φ_a, \mathbf{A}_a) are two sets of the scalar and vector potentials, which describe the fields of the atomic and ionic nuclei, respectively.

These potentials are normally taken as follows. The field of that nucleus, which is chosen to be at rest, is fully described by its scalar potential. The field of the moving

nucleus is described in a gauge where its vector and scalar potentials are related by $\mathbf{A} = (\mathbf{v}/c)\Phi$. In the rest frame of the ion, *which is used throughout this section* and where the coordinate of the atomic nucleus is given by $\mathbf{R} = \mathbf{b} + \mathbf{v}t$ with $\mathbf{b} = (b_x, b_y, 0)$ and $\mathbf{v} = (0, 0, v)$, these potentials read

$$\begin{aligned}\Phi_a(\mathbf{r}, t) &= \frac{-\gamma Z_a}{s}, & A_a(\mathbf{r}, t) &= \frac{\mathbf{v}}{c}\Phi_a(\mathbf{r}, t), \\ \Phi_i(\mathbf{r}) &= \frac{-Z_i}{r}, & A_i(\mathbf{r}, t) &= 0,\end{aligned}\quad (57.36)$$

where $\mathbf{s} = (x - b_x, y - b_y, \gamma(z - vt))$, and $\mathbf{r} = (x, y, z)$ are the coordinates of the electrons with respect to the nuclei of the atom and ion, respectively (the atom is supposed to move along the z -axis).

The post and prior amplitudes Eq. (57.33) employing exact solutions of Eq. (57.34) are identical. However, such solutions are not known, and the amplitudes are evaluated using approximations for $\psi^{(\pm)}$. Then they will, in general, differ (the so-called *post–prior discrepancy*).

The nonrelativistic limit. If the collision velocity and the orbiting velocities of the electron in its initial and final bound states are all much less than the speed of light, then a nonrelativistic treatment of capture suffices. It is based on the Schrödinger equation with the two-center nonrelativistic Hamiltonian

$$\hat{H} = \frac{\hat{\mathbf{p}}^2}{2m} - \frac{Z_a e^2}{s} - \frac{Z_i e^2}{r}, \quad (57.37)$$

where $\mathbf{s} = (x - b_x, y - b_y, (z - vt))$.

Born Approximation

The simplest approach to capture – which is often called the Born approximation – consists of the following steps. In the post form, the state $\psi_i^{(+)}$ is replaced by the undistorted initial atomic state $\phi_a(t)$, and the state $\chi_f(t)$ is taken as the undistorted final state $\zeta_f(t)$ of the electron in the ion that leads to the residual interaction $(\hat{H} - i(\partial/\partial t))\zeta_f(t) = -(\gamma Z_a/s)(1 - (v/c)\alpha_3)\zeta_f(t)$. In the prior form, the approximations are similar: $\psi_f^{(-)} \rightarrow \zeta_f(t)$, $\varphi_i(t) \rightarrow \phi_a(t)$, and the residual interaction is $-Z_i/r$. Although the Born amplitudes are not exact, this approximation is free of post–prior discrepancy:

$$\begin{aligned}a_{\text{fi}}^{(BA,+)}(\mathbf{b}) &= -i \int_{-\infty}^{+\infty} dt \left\langle \left(\hat{H} - i \frac{\partial}{\partial t} \right) \zeta_f(t) \middle| \phi_a(t) \right\rangle, \\ &\equiv -i \int_{-\infty}^{+\infty} dt \left\langle \zeta_f(t) \middle| \left(\hat{H} - i \frac{\partial}{\partial t} \right) \phi_a(t) \right\rangle \\ &= a_{\text{fi}}^{(BA,-)}(\mathbf{b}),\end{aligned}\quad (57.38)$$

where in the transition from the first to the last expression in Eq. (57.38), we took into account that the Hamiltonian \hat{H} is hermitian, and the states $\phi_i(t)$ and $\zeta_f(t)$ at $t \rightarrow \pm\infty$ have a zero overlap in space.

States of a moving atom. Let $\phi'_a(\mathbf{r}', t') = \phi'_0(\mathbf{r}') \times \exp(-i\epsilon_i t')$ be the initial electron state in the atom given in the atomic rest frame, where \mathbf{r}' and t' are the electron coordinates and time in this frame. This state can be transformed to the rest frame of the ion according to (e.g. [27, Chap. 3, 6])

$$\begin{aligned}\phi_a(\mathbf{r}, t) &= \sqrt{\frac{1+\gamma}{2}} \left(I + \frac{v}{c} \frac{\gamma}{\gamma+1} \alpha_3 \right) \\ &\times \phi'_0(x - b_x, y - b_y, \gamma(z - vt)) \\ &\times \exp\left[-i\epsilon_i \gamma \left(t - \frac{v}{c^2} z \right)\right],\end{aligned}\quad (57.39)$$

where I is a unit 4×4 matrix, $\mathbf{r} = (x, y, z)$, and t are the electron coordinates and time in the rest frame of the ion ($x' = x - b_x$, $y' = y - b_y$, $z' = \gamma(z - vt)$, $t' = \gamma(t - vz/c^2)$).

In the nonrelativistic limit ($c \rightarrow \infty$), the state of an electron bound in the moving atom reads

$$\begin{aligned}\phi_a(\mathbf{r}, t) &= \phi'_0(x - b_x, y - b_y, z - vt) \exp(-i\epsilon_i t) \\ &\times \exp\left(imvz - i \frac{mv^2}{2} t \right),\end{aligned}\quad (57.40)$$

where $\exp[i(mvz - mv^2/2t)]$ is the *electron translational factor* (first obtained in [28]), and ϕ_a and ϕ'_0 are understood as the corresponding Schrödinger states.

The Born amplitudes for electron capture were evaluated for nonrelativistic and relativistic collisions ([16, Chap. 2] and [19, Chap. 9], as well as references therein). One of the main results obtained for the nonrelativistic domain is that at asymptotically high impact energies (where the collision velocity greatly exceeds the typical orbiting velocities of the electron in its initial and final bound states), the capture is dominated by the $1s \rightarrow 1s$ transition, and the cross section possesses a strong dependence on the impact energy E (the collision velocity v)

$$\sigma \approx \frac{Z_i^5 Z_a^5}{E^6} \approx \frac{Z_i^5 Z_a^5}{v^{12}}, \quad (57.41)$$

which is related to a very rapidly vanishing overlap between the initial and final states of the electron in the momentum space with the increase in the collision energy/velocity. In the relativistic domain, the dependence of the Born cross section on the impact energy becomes much steeper and at $\gamma \gg 1$, where the capture is dominated by the $1s \rightarrow 1s$ transition, is given by

$$\sigma \approx \frac{Z_i^5 Z_a^5}{E} \approx \frac{Z_i^5 Z_a^5}{\gamma}. \quad (57.42)$$

Because of the Lorentz contraction of the electron wave function in the position space along the collision velocity, the electron wave function in the momentum space becomes broader along this direction. This relativistic effect gives rise to a less steeper decrease in the overlap between the initial and final electron states in the momentum space, which, in turn, leads to a much slower decrease of the cross section with an increase in the impact energy than the nonrelativistic treatment suggests.

Electron transfer in high-energy collisions is characterized by the change in electron momentum much larger than the typical orbiting momenta of the electron in its initial and final bound states, and the $Z_{a,i}^5$ -dependences in Eq. (57.41) and Eq. (57.42) reflect the crucial role played in capture by the high-momentum components of these states.

Boundary-Corrected Born Approximation

Being strongly gauge-dependent the Born approximation is not very accurate even at asymptotically high impact energies. Better results for capture are yielded by the boundary-corrected Born approximation in which the initial and final states of the electron (considered in the rest frame of the ion) are taken as

$$\begin{aligned}\tilde{\phi}_a(t) &= \exp\left(-i\frac{Z_i}{v}\ln(R-vt)\right)\phi_a(t), \\ \tilde{\zeta}_f(t) &= \exp\left(i\frac{Z_a}{v}\ln(R'+vt')\right)\zeta_f(t),\end{aligned}\quad (57.43)$$

where

$$\begin{aligned}R &= \sqrt{b^2 + v^2t^2}, \\ R' &= \sqrt{b^2 + v^2t'^2}\end{aligned}\quad (57.44)$$

and t (t') is the time in the rest frame of the ion (atom) (e.g. [19, Chap. 9]). Compared to the Born approximation, the difference is that within its boundary-corrected version the account is taken of the long-range Coulomb field of the ion in the initial state and of the field of the atomic residue in the final state by solving the wave equations for these states, assuming asymptotically large distances between the nuclei (e.g. [19], Sect. 7.4). The residual interactions in the post and prior forms are given, respectively, by

$$\begin{aligned}\left(\hat{H} - i\frac{\partial}{\partial t}\right)\tilde{\zeta}_f(t) &= -\gamma Z_a f(s, R') \mathcal{E} \tilde{\zeta}_f(t), \\ \left(\hat{H} - i\frac{\partial}{\partial t}\right)\tilde{\phi}_a(t) &= -Z_i f(r, R) \tilde{\phi}_a(t),\end{aligned}\quad (57.45)$$

where $f(a, b) = 1/a - 1/b$ and $\mathcal{E} = (1 - v\alpha_3/c)$.

Impulse Approximation

Suppose that the momentum transferred to the electron in the collision is much larger than the typical momentum of

this electron in its bound state. Then one can neglect the action of the corresponding binding force during the collision to a good approximation. This is the physical essence of the impulse approximation.

In applications of the impulse approximation to nonradiative capture, it is assumed that the electron motion during the collision is driven mainly by the field of one of the nuclei, whereas the role of the other nucleus is to produce the electron momentum distribution in the initial (or final) bound state and to serve as the perturbation resulting in electron transfer. Such an approach is not symmetric with respect to the treatment of the nuclei and is, therefore, best suited to when the charges of the nuclei substantially differ.

Let a highly charged bare nucleus capture an electron from a light atom. In the impulse approximation, the transition amplitude in the rest frame of the ion is given by

$$a_{fi}^{(+)}(\mathbf{b}) = -i \int_{-\infty}^{+\infty} dt \langle \chi_f | \hat{W}_a | \psi_i^{(+)} \rangle. \quad (57.46)$$

Here, $\hat{W}_a = -(\gamma Z_a/s)(1 - (v/c)\alpha_3)$ is the interaction between the electron and the nucleus of the atom, $\chi_f(t)$ is the undistorted final bound state of the electron in the ion, and the initial state can be approximated [29] by

$$\begin{aligned}\psi_i^{(+)}(\mathbf{r}, t) &= \frac{\exp(-i\epsilon_a t/\gamma)}{\gamma} \int d^3\mathbf{p} \exp(-i\mathbf{p} \cdot \mathbf{R}) \\ &\times C_a \left(\mathbf{p}_\perp, -\frac{v\epsilon_a}{c^2} + \frac{p_z}{\gamma} \right) \chi_p^{(+)}(\mathbf{r}),\end{aligned}\quad (57.47)$$

where ϵ_a is the electron energy in the initial atomic state, $\chi_p^{(+)}(\mathbf{r})$ is the Coulomb continuum “in” state of the electron in the field of the highly charged nucleus with momentum $\mathbf{p} = (\mathbf{p}_\perp, p_z)$, and

$$C_a(\mathbf{k}) = \frac{1}{(2\pi)^{3/2}} \int d^3\mathbf{r}' \phi_0'(\mathbf{r}') \exp(-i\mathbf{k} \cdot \mathbf{r}') \quad (57.48)$$

is the Fourier transform of the initial (nonrelativistic) atomic state. According to Eqs. (57.47) and (57.48) the initial state of the electron is represented by a superposition of continuum states of the electron in the field of the ionic nucleus, where the coefficients in this superposition are related to the momentum decomposition of the initial atomic state.

The impulse approximation is expected to yield good results provided that the change in the momentum of the electron in the capture process greatly exceeds its typical orbiting momentum in the lighter of the colliding nuclei.

Various models for electron capture in nonrelativistic collisions based on the impulse approximation have been used for a long time ([1, 30, 31] and references therein). The impulse approximation was introduced to nonradiative capture in relativistic collisions in [32]. Its discussion from the perspective of distorted-wave models can be found in [16].

Other Distorted-Wave Models

Other very frequently used distorted-wave models for nonradiative electron capture include the asymmetric and symmetric eikonal approximations [19] and continuum-distorted-wave models [16].

Two-Center Coupled-Channel Methods

Coupled-channel methods for electron capture in ion–atom collisions are similar to those for atomic excitation or ionization. However, unlike ionization, in the case of capture, the wave function of the electron is always expanded simultaneously into two sets of eigenstates referring to the initial and final channel Hamiltonians [19].

We conclude this section with two remarks. First, in nonradiative electron transfer occurring in high-energy collisions ($Z_a/v \ll 1$ or $\gamma \gg 1$), the electron is captured mainly from the K -shell of the atom. In multielectron atoms, the presence of a vacancy in the K -shell leads to a multitude of atomic reactions driven by the interaction of the remaining atomic electrons with the radiation field and with each other, which results in emission of photons and electrons.

Second, an interesting peculiarity of nonradiative electron transfer in nonrelativistic collisions is that at asymptotically high impact energies this process is dominated by the *Thomas capture mechanism*. According to this mechanism, electron capture proceeds via a binary collision of the projectile ion with one of (quasi free) atomic electrons and a consequent re-scattering of this electron on the atomic nucleus, after which it moves with a vector velocity equal to that of the projectile ion. This mechanism is considered in Chap. 61 of this Handbook.

57.3.2 Radiative Electron Capture

In the process of radiative capture, the interaction of the electron with the radiation field plays a crucial role, and the electron transfer proceeds with emission of a photon. The interaction with the radiation field is also responsible for radiative recombination of an electron with an ion – a process that, under certain conditions, is very closely related to radiative electron capture.

We shall describe the radiation field by using a gauge in which the scalar potential is set to zero and the vector potential \hat{A} is transverse, $\nabla \cdot \hat{A} = 0$, and reads

$$\hat{A} = \sum_{\mathbf{k}, \lambda} \sqrt{\frac{2\pi c^2}{V\omega_k}} \mathbf{e}_{\mathbf{k}, \lambda} \times \{ \hat{a}_{\mathbf{k}, \lambda} \exp[i(\mathbf{k} \cdot \mathbf{r} - \omega_k t)] + \hat{a}_{\mathbf{k}, \lambda}^+ \exp[-i(\mathbf{k} \cdot \mathbf{r} - \omega_k t)] \}. \quad (57.49)$$

Here, $\hat{a}_{\mathbf{k}, \lambda}$ and $\hat{a}_{\mathbf{k}, \lambda}^+$ are the annihilation and creation operators, respectively, for a photon with momentum \mathbf{k} ($\hbar\mathbf{k}$), unit

polarization vectors $\mathbf{e}_{\mathbf{k}, \lambda}$ ($\lambda = 1, 2$, $\mathbf{e}_{\mathbf{k}, \lambda} \cdot \mathbf{k} = 0$, $\mathbf{e}_{\mathbf{k}, \lambda} \cdot \mathbf{e}_{\mathbf{k}, \lambda'} = \delta_{\lambda \lambda'}$) and frequency $\omega_k = c k$, V is the normalization volume for the radiation field, and the sum in Eq. (57.49) runs over all possible modes of the field.

The transition amplitude, calculated in the first-order perturbation theory in the interaction with the radiation field, is given by

$$a_{\text{fi}}(\mathbf{b}) = -i \int_{-\infty}^{+\infty} dt \langle \psi_f^{(-)}; \mathbf{k} \lambda | \hat{W} | \psi_i^{(+)}; 0 \rangle, \quad (57.50)$$

where

$$\hat{W} = -e\boldsymbol{\alpha} \cdot \hat{A} \quad (57.51)$$

is the interaction of the electron with the radiation field, $|\psi_i^{(+)}; 0\rangle$ and $|\psi_f^{(-)}; \mathbf{k} \lambda\rangle$ represent the initial and final states, respectively, of the quantum (sub)system involving the electron and the radiation field. The latter is initially in the vacuum state, $|0\rangle$, undergoing a transition into a state $|\mathbf{k} \lambda\rangle$ with one photon having momentum \mathbf{k} and polarization λ . Inserting Eqs. (57.49) and (57.51) into Eq. (57.50) we obtain

$$a_{\text{fi}}(\mathbf{b}) = -i \sqrt{\frac{2\pi c^2}{V\omega_k}} \int_{-\infty}^{+\infty} dt \langle \psi_f^{(-)} | \boldsymbol{\alpha} \cdot \mathbf{e}_{\mathbf{k}, \lambda} \times \exp[-i(\mathbf{k} \cdot \mathbf{r} - \omega_k t)] | \psi_i^{(+)} \rangle. \quad (57.52)$$

The nonrelativistic limit. Suppose that the collision velocity and the initial and final orbiting velocities of the electron are all much less than the speed of light. Then the electron can be treated using the Schrödinger equation with the nonrelativistic Hamiltonian Eq. (57.37), and the interaction with the radiation field reads

$$\hat{W} = -\frac{e}{mc} \hat{A} \cdot \hat{\mathbf{p}}. \quad (57.53)$$

In the treatment of radiative capture, which is of first order in the interaction with the radiation field but otherwise exact, the states $\psi_i^{(+)}(t)$ and $\psi_f^{(-)}(t)$ would have to be solutions of Eq. (57.34) with the two-center Hamiltonian Eq. (57.35) (or of the corresponding Schrödinger equation with the Hamiltonian Eq. (57.37)). Since such solutions are not known, in practice, the transition amplitude Eq. (57.50) is evaluated by using various approximations.

Born Approximation

The simplest approach to radiative capture – the Born approximation – consists of replacing the state $\psi_i^{(+)}(t)$ by the undistorted initial atomic state $\phi_a(t)$ and the state $\psi_f^{(-)}(t)$ by the undistorted final bound state $\zeta_f(t)$. The Born approximation is covariant under the transformation of a reference frame. Moreover, when the gauge Eq. (57.49) is employed, the Born approximation yields reasonable results provided

that $Z_{a(i)} \ll v$ and the basic consideration is given in the rest frame of the ion. The differential cross sections obtained in this frame can be recalculated to the laboratory frame similarly as is done for electron emission (see Eq. (57.21)).

At asymptotically high impact energies in the nonrelativistic domain ($Z_{a(i)} \ll v \ll c$), the Born approximation predicts that radiative capture proceeds mainly into the 1s-state of the ion, yielding for the total cross section

$$\sigma_{\text{rec}} \approx N_a \frac{Z_i^5}{E^{2.5}} \approx N_a \frac{Z_i^5}{v^5}, \quad (57.54)$$

where N_a is the number of the electrons in the atom, Z_i is the charge of the ion, and E is the impact energy. The cross section Eq. (57.54) strongly depends on the charge of the ion but is independent of the charge of the atomic nucleus, suggesting that the latter is just a *spectator* in this process and, thus, pointing to the connection between radiative capture in ion–atom collisions and radiation recombination of a free electron with an ion. Comparing Eq. (57.54) with Eq. (57.41) we see that, owing to a much weaker dependence on the impact energy, radiative capture can become more probable than nonradiative capture in collisions with light atoms, provided that the impact energy is high enough. For instance, in collisions of protons with atomic hydrogen, radiative capture becomes the dominant channel for electron transfer at impact energies $E \gtrsim 10$ MeV.

At high impact energies in the relativistic domain ($\gamma \gg 1$), the Born approximation predicts that

$$\sigma \approx N_a \frac{Z_i^5}{E} \approx N_a \frac{Z_i^5}{\gamma}, \quad (57.55)$$

with the capture also mainly proceeding into the 1s state of the ion.

In the Born approximation, the initial and final states of the electron are states of the different channel Hamiltonians. This does not affect its Lorentz (or Galilean) covariance but leads to a strong gauge-dependence of the calculated cross sections. Reference-frame and gauge transformations can become so intimately interrelated that gauge dependence is sometimes incorrectly interpreted as the lack of covariance under the transformation of a reference frame (for an in-depth discussion of this point see part A4 of [2] and references therein).

Impulse Approximation

The impulse approximation for radiative capture is formulated similarly as for nonradiative transfer. Since it is the interaction with the radiation field that leads to the electron transition, the “minor” nucleus now plays an even lesser role restricted to merely producing the initial momentum distribution of the electron. The impulse approximation is well suited for asymmetric collisions in which the electron is transferred from a light atom to a highly charged ion. Moreover, since in

radiative capture the symmetry between the initial and final states is already broken by the emitted photon, the impulse approximation can also be applied to more symmetric collisions.

The impulse approximation enables one to establish a close relation between radiative electron capture in ion–atom collisions and radiative recombination of a free electron with an ion. Therefore, in practice, the cross sections for radiative capture are often calculated by averaging the corresponding cross sections for radiative recombination over the Compton profile of the atomic electron(s) [33].

Continuum-Distorted-Wave Model

Theoretical models for radiative capture in which, unlike the impulse approximation, the nuclei of the ion and atom are considered on equal footing are also of great interest. One of these is the continuum-distorted-wave model. This was considered in detail for radiative capture in relativistic collisions in [16]. Some merits of this model in nonrelativistic collisions are discussed in part A4 of [2].

57.4 Electron–Positron Pair Production

Electron–positron pair production is one of the most fascinating predictions of quantum electrodynamics. In this process, the presence of electromagnetic fields makes the “empty space” (vacuum) unstable, resulting in the conversion of “energy into matter”. In general, one can speak about two qualitatively different limiting regimes of this process.

In one of them, an external electric field is almost time independent (on the time scale of the pair production process) but is so strong that it can provide an energy of the order of the electron rest energy mc^2 on a distance of the order of the electron Compton wave length $\lambda_C = \hbar/mc$. The strength E_{cr} of such a field, which is called *critical*, can be estimated according to $e E_{\text{cr}} \lambda_C = mc^2$, which results in $E_{\text{cr}} = m^2 c^3 / (\hbar e)$. The critical field is $\alpha^{-3} = (\hbar c/e^2)^3 \approx 2.57 \times 10^6$ times larger than the typical electric field $E_0 = m^2 e^5 / \hbar^4$ acting on the electron in the ground state of atomic hydrogen. This regime of pair production can, for instance, be encountered in comparatively slow collisions of two very heavy bare nuclei; when these nuclei closely approach each other their combined electric field may become close to the critical value.

In the other limiting regime of pair production, the fields may be not that strong but vary so rapidly in time that their characteristic frequencies multiplied by \hbar are larger than $2mc^2$. Possible realizations of this regime include a conversion of a high-energy photon into a pair in the field of a heavy nucleus and pair production in relativistic ion–atom (ion–ion) collisions. In the rest of this section, we shall discuss the latter in some detail.

A rigorous treatment of electron–positron pair production is possible within quantum electrodynamics. However,

Fig. 57.3 Pair production in a strong constant electric field can be viewed as electron tunneling from the “negative-energy” to the “positive-energy” continuum

Fig. 57.4 Free and bound–free pair production in a rapidly time-varying electromagnetic field

very often, accurate results for this process can already be obtained using *relativistic quantum mechanics* (RQM) and the *Dirac sea* picture. Like *relativistic classical mechanics* (RCM), RQM predicts the existence of states with positive and negative total energies. However, in contrast to RCM, RQM also predicts the possibility of transitions between these states. In order to avoid electron transitions into negative-energy states (which would make even the ground states of atoms unstable due to spontaneous decay into the negative-energy states) P. Dirac assumed that under normal conditions all electron states with negative total energies are already occupied (*the Dirac “sea”*). Then, as a consequence of the Pauli exclusion principle, no more electrons can be added into the negative-energy continuum. In this picture, pair production is viewed as a transition of an electron from a state with a negative total energy to a state with a positive total energy. The absence of a negative-energy electron – a hole in the Dirac sea – is interpreted as a positron.

In Figs. 57.3 and 57.4 the Dirac sea picture is used to illustrate pair production in a strong constant electric field and a rapidly time-varying electromagnetic field, respectively.

Pair production in relativistic collisions can be subdivided into free, bound–free, and bound–bound pair production, which possess different dependences on the impact energy and the charges of the colliding particles.

57.4.1 Free Pair Production

In this process, the ion–atom (or ion–ion) collision results in the creation of free electrons and positrons. It was studied in much detail in a vast number of theoretical and experimental

papers (e.g., [34] for a review). Two theoretical methods are frequently used to describe this process.

In the first (and simplest) method, the lepton states are approximated by Dirac plane waves, and the interaction with the colliding heavy particles is treated within the second order of perturbation theory (see Fig. 57.5). The corresponding amplitude reads

$$a_{\text{fi}} = a_{\text{fi}}^{(\alpha)} + a_{\text{fi}}^{(\beta)}, \quad (57.56)$$

where

$$\begin{aligned} a_{\text{fi}}^{(\alpha)} &= - \sum_{p, \pm} \int_{-\infty}^{+\infty} dt \langle \varphi_{p_f}(t) | \hat{W}_1(t) | \varphi_p(t) \rangle \\ &\quad \times \int_{-\infty}^t dt' \langle \varphi_p(t') | \hat{W}_2(t') | \varphi_{p_i}(t') \rangle \\ a_{\text{fi}}^{(\beta)} &= - \sum_{p, \pm} \int_{-\infty}^{+\infty} dt \langle \varphi_{p_f}(t) | \hat{W}_2(t) | \varphi_p(t) \rangle \\ &\quad \times \int_{-\infty}^t dt' \langle \varphi_p(t') | \hat{W}_1(t') | \varphi_{p_i}(t') \rangle. \end{aligned} \quad (57.57)$$

Here, $\varphi_{p_i}(t)$ ($\varphi_{p_f}(t)$) refers to the initial (final) state of a free electron with momentum \mathbf{p}_i (\mathbf{p}_f) and total energy $\varepsilon_i = -\sqrt{p_i^2 c^2 + m^2 c^4}$ ($\varepsilon_f = +\sqrt{p_f^2 c^2 + m^2 c^4}$). (The created electron and positron have momenta and energies given by $\mathbf{p}_e = \mathbf{p}_f$, $\varepsilon_e = \varepsilon_f$ and $\mathbf{p}_p = -\mathbf{p}_i$, $\varepsilon_p = -\varepsilon_i$, respectively.) The sum in Eq. (57.57) runs over all intermediate plane-wave states with positive and negative total energies, and \hat{W}_1 (\hat{W}_2) denotes the interaction with the first (second) nucleus.

Within this method, pair production can be also viewed as a conversion of two virtual photons representing the fields of the colliding particles into an electron–positron pair. In extreme relativistic collisions, virtual photons closely resemble real photons, and one may relate pair production in collisions to photo pair production (the Weizsäcker–Williams approximation; e.g., [3, 35]).

At high impact energies ($\gamma \gg 1$), the total cross section for pair production in nucleus–nucleus collisions can be well approximated by

$$\sigma_{\text{ff}} = \frac{28}{27\pi} \lambda_C^2 (\alpha Z_1)^2 (\alpha Z_2)^2 \ln^3 \left(\frac{\gamma}{4} \right), \quad (57.58)$$

where Z_1 and Z_2 are the atomic numbers of the colliding nuclei.

In the second method, the interaction between the lepton field and one of the heavy particles is taken into account exactly, by describing electron states with negative and positive total energies by the corresponding solutions of the Dirac equation in the field of this heavy particle. The action of the other heavy particle is accounted for by using first-

Fig. 57.5 Free pair production according to the second Born approximation. The nuclei and the leptons are indicated by *bold* and *thin solid lines*, respectively. *Wavy lines* show virtual photons representing the fields of the nuclei

order perturbation theory. Thus, pair production is regarded as a transition between negative-energy and positive-energy states in the field of one heavy particle induced by a single interaction with the field of the other (Fig. 57.4). Such a treatment is well suited for pair production in asymmetric collisions where the atomic numbers of the colliding particles differ substantially. At very high impact energies ($\gamma \rightarrow \infty$), it can also be applied to (more) symmetric collisions by performing two calculations: in one of them the initial and final states are states in the field of particle 1, whereas particle 2 represents the perturbation; in the other the roles of these particles are interchanged.

It is not difficult to realize that in the second method, the description of pair production in ion–atom (or ion–ion) collisions is actually given by the formalism discussed in Sect. 57.2. Indeed, in order to adapt it for pair production, we just need to replace bound–bound (or bound–positive-energy-continuum) electron transitions in one of the colliding particles (say particle 1) by transitions between its negative- and positive-energy states.

57.4.2 Bound–Free Pair Production

Unlike free pair production, in bound–free pair production, the electron is created in a bound state. In collisions between two bare nuclei, the created electron can be bound by either nucleus, whereas in ion(nucleus)–atom collisions, the electron will be most likely created in a bound state of the ion. Bound–free pair production can be regarded as *electron*

capture from vacuum. The capture mainly proceeds into the ground state of the ion.

This process can be viewed as a collision-induced transition of a negative-energy electron into a bound state (Fig. 57.4). In its simplest treatment, the interaction with that heavy particle, which binds the created electron, is taken into account exactly, whereas the action of the other heavy particle is described by using the first-order perturbation theory. Such a description is obviously equivalent to the second of the two methods discussed in Sect. 57.4.1, and the formalism presented in Sect. 57.2 can again be used. It is adapted to bound–free pair production by replacing bound–bound (or bound–positive-energy-continuum) electron transitions in one of the colliding particles (say particle 1) by transitions between its negative-energy continuum and a bound state.

Suppose, for instance, that electron–positron pair production occurring in the field of a bare nucleus (particle 1) is induced by collisions with another bare nucleus (particle 2). Then in the rest frame of particle 1, the corresponding quantum transition amplitude reads

$$S_{fi}(\mathbf{q}_\perp) = \frac{2iZ_2}{v} \frac{\langle \psi_f | \exp(i\mathbf{q} \cdot \mathbf{r}) (1 - \frac{v}{c}\alpha_3) | \psi_i \rangle}{\mathbf{q}_\perp^2 + \frac{(\varepsilon_f - \varepsilon_i)^2}{v^2\gamma^2}}. \quad (57.59)$$

Here, $\psi_i \equiv \psi_p$ is the state of a negative-energy electron with momentum $-\mathbf{p}$ and energy $\varepsilon_i = -\varepsilon_p \leq -mc^2$ (the created positron has momentum \mathbf{p} and energy $\varepsilon_p \geq mc^2$), $\psi_f = \psi_b$ is the bound state of the created electron with an energy $\varepsilon_f = \varepsilon_b$, and

$$\mathbf{q} = \left(\mathbf{q}_\perp, \frac{\varepsilon_f - \varepsilon_i}{v} \right) = \left(\mathbf{q}_\perp, \frac{\varepsilon_b + \varepsilon_p}{v} \right) \quad (57.60)$$

is the momentum transferred to particle 1 in its rest frame.

If particle 2 is a neutral atom, its electrons will influence pair production via the screening and antiscreening effects, and this can also be taken into account by using the formalism discussed in Sect. 57.2. Since the momentum transfers characteristic for pair production are very large, the screening effect of atomic electrons may remain modest even in extreme relativistic collisions (Fig. 57.6).

At high impact energies ($\gamma \gg 1$), the total cross section for bound–free pair production in collisions between two bare nuclei with the atomic numbers Z_1 and Z_2 can be approximated by

$$\sigma_{bf} \simeq a_1 \lambda_C^2 (\alpha Z_1)^5 (\alpha Z_2)^2 \ln(a_2 \gamma). \quad (57.61)$$

Here, the created electron forms a bound state with the nucleus Z_1 , and the parameters a_1 and a_2 depend on Z_1 . The cross section Eq. (57.61) increases with increasing impact energy. The increase, however, is weaker than in the case of free pair production (Eq. (57.58)). In Eq. (57.61), the dependence on Z_2 is similar to that for free pair production, but

Fig. 57.6 Total cross section for bound–free pair production in collisions of 160 GeV/u Pb^{82+} nuclei with gas and solid-state targets as a function of the target atomic number. Circles represent experimental data for Be, C, Al, Cu, Ar, Kr, Sn, Xe, and Au targets [36–38]. Solid triangles connected by a solid curve and open triangles connected by dash curve are calculations for collisions with atoms of Be, C, Al, Ar, Cu, Kr, Ag, Sn, Xe, and Au and with the corresponding bare nuclei. The curves are just to guide the eye

the dependence on Z_1 is much steeper because the nucleus Z_1 accommodates the created electron.

Unlike electron transfer, in which the initial and final electron states belong to the different colliding particles, in bound–free pair production at high collision energies, the transition occurs between states of the same particle. However, similarly to electron transfer, pair production is characterized by large momentum transfers ($\simeq 2mc > Z_1$) due to large energies ($\simeq 2mc^2$) imparted to the vacuum. Because of this, the Z_1 -dependence in Eq. (57.61) is similar to the charge dependence of the capture cross sections (compare Eq. (57.61) with Eqs. (57.42) and (57.55)). At the same time, since bound–free pair production in high-energy collisions is essentially a single-center process, the increase in the impact energy just makes bound–free pair production more probable due to the increase of the range of the impact parameters contributing to this process. This is very similar to what takes place in ionization by high-energy charged particles, which is also essentially a single-center process (but characterized by much smaller momentum transfers). As a result, the dependences of the cross sections for bound–free pair production and ionization on the impact energy are similar (compare Eq. (57.61) with Eq. (57.23)).

If bound–free pair production occurs in collisions between a bare nucleus and a neutral atom, then at sufficiently high impact energies, the total cross section for this process “saturates” becoming independent of the impact energy ([2,

Fig. 57.7 Bound–bound pair production in relativistic collisions of a nucleus and an antinucleus

Chap. 8]). This is caused by the presence of atomic electrons that makes the field of the atom short ranged.

With an increase in the impact energy, the cross section for bound–free pair production increases (or saturates), whereas the cross sections for nonradiative and radiative electron transfer decrease. Therefore, in ion–atom collisions at high impact energies ($\gamma \gg 1$), bound–free pair production represents the main mechanism for the ion to change its charge.

57.4.3 Bound–Bound Pair Production

When the colliding nuclei possess charges of different signs, yet another pair production process becomes possible, in which not only the electron but also the positron is created in a bound state. This process is called bound–bound pair production [39] and, in the simplest picture, can be viewed as collision-induced electron transition between two bound states (Fig. 57.7). The initial bound state is formed by a negative-energy electron and the antinucleus, whereas the final bound state consists of a positive-energy electron and the nucleus. This picture suggests that bound–bound pair production has an important similarity with nonradiative electron capture (nonradiative capture is discussed in Sect. 57.3.2).

The cross section σ_{bb} for bound–bound pair production nonmonotonously depends on the impact energy (Fig. 57.8). The reasons for this are discussed in [39], where it is also shown that at $\gamma \gg 1$

$$\sigma_{bb} \approx \lambda_C^2 \frac{(\alpha Z_1)^5 (\alpha |Z_2|)^5}{\gamma}, \quad (57.62)$$

where the atomic numbers $Z_1 > 0$ and $Z_2 < 0$ refer to the nucleus and the antinucleus, respectively. The dependencies of the cross section Eq. (57.62) on Z_1 , $|Z_2|$ and γ turn out to be similar to those on Z_1 , Z_2 and γ for nonradiative electron transfer (see Eq. (57.42)) and have basically the same origin. In particular, the γ^{-1} -dependence of the cross section Eq. (57.62) reflects the decrease in the momentum overlap

Fig. 57.8 Formation of antihydrogen via bound–bound, $p^- + U^{92+} \rightarrow \bar{H}(1s) + U^{91+}(1s)$ (solid curve), and bound–free, $p^- + U^{92+} \rightarrow \bar{H}(1s) + U^{92+} + e^-$ (dashed curve), pair production. For more information, the dotted curve displays the cross section for nonradiative capture, $H(1s) + U^{92+} \rightarrow p^+ + U^{91+}(1s)$, multiplied by 2

between the initial and final states with an increase in the impact energy.

57.4.4 More Advanced Theoretical Methods

In addition to the simplest theoretical methods, discussed in the previous sections, also more sophisticated models for pair production have been developed. In particular, they include one and two-center coupled-channel methods [19], direct numerical solutions of the time-dependent Dirac equation on a lattice [19], continuum-distorted-wave models [16], various eikonal approximations including the symmetric eikonal model [18], and the light-cone approximation [17].

Abstract

This chapter collects together the formulae, expressions, and specific equations that cover various aspects, approximations, and approaches to electron–ion, ion–ion and neutral–neutral recombination processes. The primary focus is on recombination processes in the gas phase, both at thermal energies and in ultracold regimes.

Recombination processes are ubiquitous in nature. These reactions occur in a wide variety of applications and are an important formation or loss mechanism of atoms and molecules. To illustrate the types of problems where recombination is important, we enumerate six broad areas in which recombination processes occur: (a) collisional-radiative recombination processes, involving hydrogen

and helium, which are important in understanding the cosmic microwave background in cosmology [1–3]; (b) radio recombination lines involving electrons and ions, which are central to understanding the observed spectra from interstellar clouds and planetary nebulae [4, 5]; (c) recombination processes, involving electrons and holes are important in semiconductors [6, 7]; (d) electron–ion and ion–ion recombination processes, which are important in understanding the properties of plasmas, whether they are in the upper atmosphere, the solar corona, or industrial reactors on earth [8–10]; (e) atom–molecule recombination involving oxygen, which are important mechanism for forming ozone [11]; and, finally, (f) three-body recombination processes, involving neutral bosons, which are an important loss mechanism in ultracold Rydberg atom collisions, leading to the depletion of the Bose Einstein condensate (BEC) [12–14].

Keywords

radiative recombination · mutual neutralization · dielectronic recombination · dissociative recombination · vibrational wave function

58.1 Recombination Processes

58.1.1 Electron–Ion Recombination

This proceeds via the following four processes:

(a) Radiative recombination (RR)

(b) Three-body collisional-radiative recombination

where the third body can be an electron or a neutral gas.

(c) Dielectronic recombination (DLR)

(d) Dissociative recombination (DR)

Electron recombination with bare ions can proceed only via (a) and (b), while (c) and (d) provide additional pathways for ions with at least one electron initially or for molecular ions AB^+ . Electron radiative capture denotes the combined effect of RR and DLR.

Field-assisted:

Electron–ion recombination can also occur by application of a laser field,

leading to high-order harmonic generation (HHG).

58.1.2 Positive–Ion Negative–Ion Recombination

This proceeds via the following three processes:

(e) Mutual neutralization

(f) Three-body (termolecular) recombination

(g) Tidal recombination

where M is some third species (atomic, molecular, or ionic). Although (e) always occurs when no gas M is present, it is greatly enhanced by coupling to (f). The dependence of the rate $\hat{\alpha}$ on density N of background gas M is different for all three cases, (e)–(g).

Processes (a), (c), (d), and (e) are elementary processes in that microscopic detailed balance (proper balance) exists with their true inverses, i.e., with photoionization (both with and without autoionization) as in (c) and (a), associative ionization and ion-pair formation as in (d) and (e), respectively. Processes (b), (f), and (g) in general involve a complex sequence of elementary energy-changing mechanisms as collisional and radiative cascade and their overall rates are determined by an input–output continuity equation involving microscopic continuum–bound and bound–bound collisional and radiative rates.

58.1.3 Balances

Proper Balances

Proper balances are detailed microscopic balances between forward and reverse mechanisms that are direct inverses of one another, as in

where the kinetic energy of the particles is redistributed;

between direct ionization from and direct recombination into a given level $n\ell$;

between excitation and deexcitation among bound levels;

which involves interaction between radiation and atoms in photoionization/recombination to a given level $n\ell$.

Improper Balances

Improper balances maintain constant densities via production and destruction mechanisms that are not pure inverses of each other. They are associated with flux activity on a macroscopic level as in the transport of particles into the system for recombination and net production and transport of particles (i.e. e^- , A^+) for ionization. Improper balances can then exist between dissimilar elementary production–depletion processes as in (a) coronal balance between electron-excitation into and radiative decay out of level n . (b) Radiative balance between radiative capture into and radiative cascade out of level n . (c) Excitation saturation balance between upward collisional excitations $n-1 \rightarrow n \rightarrow n+1$ between adjacent levels. (d) Deexcitation saturation balance between downward collisional de-excitations $n+1 \rightarrow n \rightarrow n-1$ into and out of level n .

58.1.4 Neutral–Neutral Recombination

Neutral–neutral reactions, leading to recombination or dissociation, generally proceed via resonances involving transitions among molecular electronic states. At thermal energies, these reactions are studied via transition state theory, reaction rate theory, and a wide range of semiclassical techniques. See Chap. 37 of this Handbook and [15–19] for a general introduction to this vast literature in chemical physics and chemistry.

Distinguishable Particles [3]

When one or more reactants in the process are distinguishable, the thermal reactions proceed via two broad pathways, *direct* and *indirect*:

Direct pathway

where k_{direct} is the reaction rate (cm^3/s) for the formation of molecule AB and reactant C.

Indirect pathways

where $(A \cdots B)$ indicates an intermediate collision complex formed between atoms A and B, and k_{indirect}^{ET} , k_{indirect}^{Ex} are the reaction rates (cm^3/sec) for the transfer and exchange reactions in Eq. (58.14) (upper/lower), respectively. Prediction of rates k , in both the direct and indirect pathways, depends upon detailed knowledge of the molecular potential energy surfaces, curve-crossings, and tunneling probabilities for specific reactants.

LTE effective rate equation

For systems in local thermodynamic equilibrium (LTE), the effective rate equations are

$$\frac{1}{[C]} \frac{d}{dt} [AB] = k_r [A][B] - k_d [AB], \quad (58.15)$$

where the square brackets indicate the number density of the enclosed species, and k_r denotes the rate constant for three-body recombination, while k_d the rate constant for collision-induced dissociation

$$k_r = \sum_{b,u} k_{u \rightarrow b} \frac{[AB(u)]}{[A][B]}, \quad (58.16a)$$

$$k_d = \sum_{b,u} k_{b \rightarrow u} \frac{[AB(b)]}{[AB]}, \quad (58.16b)$$

with b and u representing bound and unbound states of the indicated collision complex, respectively. The state-to-state rate coefficients are defined by

$$k_{i \rightarrow j} = \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} (k_B T)^{-2} \int_0^\infty \sigma_{i \rightarrow j}(E_T) \times \exp(-E_T/k_B T) E_T dE_T, \quad (58.17)$$

where μ is the reduced mass, $E_T = E - E_i$ is the translational energy of the i -th state of the atom, and σ is the cross section for the indicated transition $i \rightarrow j$.

NLTE effective rate equations

For systems not in local thermodynamic equilibrium (NLTE) the effective rate equations are

$$\begin{aligned} 6 \frac{d}{dt} [AB(b)] = & [C] \sum_u (k_{u \rightarrow b} [AB(u)] - k_{b \rightarrow u} [AB(b)]) \\ & + [C] \sum_{b'} (k_{b' \rightarrow b} [AB(b')] - k_{b \rightarrow b'} [AB(b)]), \end{aligned} \quad (58.18a)$$

$$\begin{aligned} \frac{d}{dt}[\text{AB}(u)] = & [\text{C}] \sum_b (k_{b \rightarrow u}[\text{AB}(b)] - k_{u \rightarrow b}[\text{AB}(u)]) \\ & + [\text{C}] \sum_{u'} (k_{u' \rightarrow u}[\text{AB}(u')] - k_{u \rightarrow u'}[\text{AB}(u)]) \\ & + k_{f \rightarrow u}^{\text{elastic}}[\text{A}][\text{B}] - \frac{[\text{AB}(u)]}{\tau_u}, \end{aligned} \quad (58.18b)$$

where τ_u is the lifetime of the unbound state u , and $k_{f \rightarrow u}^{\text{elastic}}$ is the elastic two-body rate constant.

Identical Particles

At thermal energies, reactions involving identical particles proceed as detailed above. In ultracold regimes, collisions involving identical bosons proceed via Fano–Feshbach or Föster resonances [20–22]. These resonances can be exploited by varying the applied magnetic or electric fields used in traps to create and control Bose–Einstein condensates (BEC).

At thermal and higher energies, the rate-limiting step [23] is generally either collisional or radiative capture into high-lying Rydberg states ($n \gg 1$), followed by radiative decay into lower lying states via n and n, ℓ mixing collisions. In contrast, at ultracold regimes, the rate-limiting step is collisional ℓ mixing, wherein rapid collisional capture into very high-lying Rydberg states ($n > 200$) is followed by slow collisional-radiative decay. The result is a cloud of Rydberg atoms that has condensed into a long-lived macroscopic BEC, which can be controlled via the applied fields used in the trap.

For three identical particles, this proceeds as

Time-dependent equation

$$\frac{dn_A}{dt} = \begin{cases} -3\alpha n_A^3 & \text{before onset of BEC} \\ -\frac{1}{2}\alpha n_A^3 & \text{at BEC} \end{cases}, \quad (58.20)$$

where α is the recombination rate coefficient (number of dimers $\text{cm}^{-3} \text{s}^{-1}$), and n_A is the number density of atoms A. At the onset of BEC in ultracold traps, the recombination rate is reduced by the factor $1/3!$ because of the symmetry of the macroscopic quantum state the atoms A are then in. See Sect. 58.4 for explicit closed-form expressions for α .

Heteronuclear Mixtures

For heteronuclear mixtures of particles, this proceeds as

for distinct atoms A and B.

At thermal energies this is analyzed as above using either LTE or NLTE formulations involving the relevant molecular potential surfaces. At ultracold regimes [24] the mixtures are

composed of heavy and light bosons, or bosons and fermions, or of a boson together with heavy and light fermions, and are analyzed using zero-range methods. See Table 1 of [25] for details on the various cases where the Efimov effect occurs in such systems and Sect. 58.4 for explicit expressions for α . For details on the Efimov effect, see Sects. 58.4 and 60.6 in this Handbook and [25, 26].

Time-dependent equation

$$\frac{dn_A}{dt} = -\alpha n_A n_B^2. \quad (58.22)$$

58.1.5 N-Body Recombination [27]

This proceeds, for four identical particles, as

and has been observed [28] in an ultracold sample of Cs atoms at 30 nK. See Fig. 58.1 for an illustration of the allowed regimes for the various reactant branches in (58.23) as a function of energy and inverse scattering length.

The general problem of N-body recombination is challenging both experimentally and theoretically. Samples involving alkali atoms at ultracold temperatures currently provide the best conditions for observing N-body recombination. At present, the hyperspherical method of solving the N-body Schrödinger equation has been used most extensively on the problem. See Sect. 58.5 for closed-form expressions for N-body recombination rates α .

Fig. 58.1 Illustration of allowed regions for 4 bosons ($\text{A}+\text{A}+\text{A}+\text{A}$), Dimers + 2 bosons ($\text{D}+\text{A}+\text{A}$), 2 Dimers ($\text{D}+\text{D}$) and Trimers + bosons ($\text{T}+\text{A}$). See [28] for details

58.2 Collisional-Radiative Recombination

Radiative recombination

Process Eq. (58.1) involves a free-bound electronic transition with radiation spread over the recombination continuum. It is the inverse of photoionization without autoionization and favors high-energy gaps with transitions to low $n \approx 1, 2, 3$ and low angular momentum states $\ell \approx 0, 1, 2$ at higher electron energies.

Three-body electron–ion recombination

Processes Eq. (58.2a,b) favor free-bound collisional transitions to high levels n , within a few $k_B T$ of the ionization limit of $A(n)$ and collisional transitions across small energy gaps. Recombination becomes stabilized by collisional-radiative cascade through the lower-bound levels of A . Collisions of the $e^- - A^+$ pair with third bodies become more important for higher levels of n , and radiative emission is important down to and among the lower levels of n . In optically thin plasmas this radiation is lost, while in optically thick plasmas it may be reabsorbed. At low electron densities, radiative recombination dominates with predominant transitions taking place to the ground level. For process Eq. (58.2a) at high electron densities, three-body collisions into high Rydberg levels dominate, followed by cascade, which is collision dominated at low electron temperatures T_e and radiation dominated at high T_e . For process Eq. (58.2b) at low gas densities N , the recombination is collisionally radiatively controlled while, at high N , it eventually becomes controlled by the rate of diffusional drift Eq. (58.73) through the gas M .

Collisional-radiative recombination [29]

Here, the cascade collisions and radiation are coupled via the continuity equation. The population n_i of an individual excited level i of energy E_i is determined by the rate equations

$$\frac{dn_i}{dt} = \frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \mathbf{v}_i) \quad (58.24)$$

$$= \sum_{i \neq f} [n_f v_{fi} - n_i v_{if}] = P_i - n_i D_i, \quad (58.25)$$

which involve temporal and spatial relaxation in Eq. (58.24) and collisional-radiative production rates P_i and destruction frequencies D_i of the elementary processes included in Eq. (58.25). The total collisional and radiative transition frequency between levels i and f is v_{if} and the f -sum is taken over all discrete and continuous (c) states of the recombining species. The transition frequency v_{if} includes all contributing elementary processes that directly link states i and f , e.g., collisional excitation and deexcitation, ionization ($i \rightarrow c$) and recombination ($c \rightarrow i$) by electrons and heavy particles, radiative recombination ($c \rightarrow i$), radiative decay ($i \rightarrow f$), possibly radiative absorption for optically thick plasmas, autoionization, and dielectronic recombination.

Production rates and processes

The production rate for a level i is

$$P_i = \sum_{f \neq i} n_e n_f K_{fi}^c + n_e^2 N^+ k_{ci}^R + \sum_{f > i} n_f (A_{fi} + B_{fi} \rho_\nu) + n_e N^+ (\hat{\alpha}_i^{RR} + \beta_i \rho_\nu), \quad (58.26)$$

where the terms in the above order represent (1) collisional excitation and deexcitation by $e^- - A(f)$ collisions, (2) three-body $e^- - A^+$ collisional recombination into level i , (3) spontaneous and stimulated radiative cascade, and (4) spontaneous and stimulated radiative recombination.

Destruction rates and processes

The destruction rate for a level i is

$$n_i D_i = n_e n_i \sum_{f \neq i} K_{if}^c + n_e n_i S_i + n_i \sum_{f < i} (A_{if} + B_{if} \rho_\nu) + n_i \sum_{f > i} B_{if} \rho_\nu + n_i B_{ic} \rho_\nu, \quad (58.27)$$

where the terms in the above order represent (1) collisional destruction, (2) collisional ionization, (3) spontaneous and stimulated emission, (4) photoexcitation, and (5) photoionization.

58.2.1 Saha and Boltzmann Distributions

Collisions of $A(n)$ with third bodies such as e^- and M are more rapid than radiative decay above a certain excited level n^* . Since each collision process is accompanied by its exact inverse the principle of detailed balance determines the population of levels $i > n^*$.

Saha Distribution

This connects equilibrium densities \tilde{n}_i , \tilde{n}_e , and \tilde{N}^+ of bound levels i , of free electrons at temperature T_e , and of ions by

$$\frac{\tilde{n}_i}{\tilde{n}_e \tilde{N}^+} = \left(\frac{g(i)}{g_e g_A^+} \right) \frac{h^3}{(2\pi m_e k T_e)^{3/2}} \exp(I_i / k_B T_e), \quad (58.28)$$

where the electronic statistical weights of the free electron, the ion of charge $Z + 1$, and the recombined $e^- - A^+$ species of net charge Z and ionization potential I_i are $g_e = 2$, g_A^+ , and $g(i)$, respectively. Since $n_i \leq \tilde{n}_i$ for all i , then the Saha–Boltzmann distributions imply that $n_1 \gg n_i$ and $n_e \gg n_i$ for $i \neq 1, 2$, where $i = 1$ is the ground state.

Boltzmann Distribution

This connects the equilibrium populations of bound levels i of energy E_i by

$$\tilde{n}_i/\tilde{n}_j = [g(i)/g(j)] \exp[-(E_i - E_j)/k_B T_e]. \quad (58.29)$$

58.2.2 Quasi-Steady State Distributions

The reciprocal lifetime of level i is the sum of radiative and collisional components, and this lifetime is, therefore, shorter than the pure radiative lifetime $\tau_R \approx 10^{-7} Z^{-4}$ s. The lifetime τ_1 for the ground level is collisionally controlled and depends on n_e , and, generally, is within the range of 10^2 and 10^4 s for most laboratory plasmas and the solar atmosphere. The excited level lifetimes τ_i are then much shorter than τ_1 . The (spatial) diffusion or plasma decay (recombination) time is then much longer than τ_i , and the total number of recombined species is much smaller than the ground-state population n_1 . The recombination proceeds on a timescale much longer than the time for population/destruction of the excited levels. The condition for quasi-steady state, or QSS-condition, $dn_i/dt = 0$ for the bound levels $i \neq 1$, therefore, holds. The QSS distributions n_i , therefore, satisfy $P_i = n_i D_i$.

58.2.3 Ionization and Recombination Coefficients

Under QSS, the continuity Eq. (58.25) then reduces to a finite set of simultaneous equations $P_i = n_i D_i$. This gives a matrix equation that is solved numerically for $n_i (i \neq 1) \leq \tilde{n}_i$ in terms of n_1 and n_e . The net ground-state population frequency per unit volume ($\text{cm}^{-3} \text{s}^{-1}$) can then be expressed as

$$\frac{dn_1}{dt} = n_e N^+ \hat{\alpha}_{\text{CR}} - n_e n_1 S_{\text{CR}}, \quad (58.30)$$

where $\hat{\alpha}_{\text{CR}}$ and S_{CR} , respectively, are the overall rate coefficients for recombination and ionization via the collisional-radiative sequence. The determined $\hat{\alpha}_{\text{CR}}$ equals the direct ($c \rightarrow 1$) recombination to the ground level supplemented by the net collisional-radiative cascade from that portion of bound-state population that originated from the continuum. The determined S_{CR} equals direct depletion (excitation and ionization) of the ground state reduced by the deexcitation collisional radiative cascade from that portion of the bound levels accessed originally from the ground level. At low n_e , $\hat{\alpha}_{\text{CR}}$ and S_{CR} reduce, respectively, to the radiative recombination coefficient summed over all levels and to the collisional ionization coefficient for the ground level.

C, \mathcal{E} , and S Blocks of Energy Levels

For the recombination processes in Eqs. (58.2a), (58.2b), and (58.7), which involve a sequence of elementary reactions,

the $e^- - A^+$ or $A^+ - B^-$ continuum levels and the ground $A(n=1)$ or the lowest vibrational levels of AB are, therefore, treated as two large particle reservoirs of reactants and products. These two reservoirs act as reactant and sink blocks C and S, which are, respectively, drained and filled at the same rate via a conduit of highly excited levels, which comprise an intermediate block of levels \mathcal{E} . This C draining and S filling proceeds, via block \mathcal{E} , on a timescale large compared with the short time for a small amount from the reservoirs to be redistributed within block \mathcal{E} . This forms the basis of QSS.

58.2.4 Working Rate Formulae

For electron-atomic-ion collisional-radiative recombination Eq. (58.2a), detailed QSS calculations can be fitted by the rate [30]

$$\hat{\alpha}_{\text{CR}} = (3.8 \times 10^{-9} T_e^{-4.5} n_e + 1.55 \times 10^{-10} T_e^{-0.63} + 6 \times 10^{-9} T_e^{-2.18} n_e^{0.37}) \text{ cm}^3 \text{ s}^{-1}, \quad (58.31)$$

which agrees with experiment for a Lyman α optically thick plasma with n_e and T_e in the range $10^9 \text{ cm}^{-3} \leq n_e \leq 10^{13} \text{ cm}^{-3}$ and $2.5 \text{ K} \leq T_e \leq 4000 \text{ K}$. The first term is the pure collisional rate Eq. (58.61), the second term is the radiative cascade contribution, and the third term arises from collisional-radiative coupling.

For ($e^- - \text{He}_2^+$), recombination in a high-pressure (5–100 Torr) helium afterglow, the rate for Eq. (58.2b) is [31]

$$\hat{\alpha}_{\text{CR}} = [(4 \pm 0.5) \times 10^{-20} n_e] (T_e/293)^{-(4 \pm 0.5)} + [(5 \pm 1) \times 10^{-27} n(\text{He}) + (2.5 \pm 2.5) \times 10^{-10}] \times (T_e/293)^{-(1 \pm 1)} \text{ cm}^3/\text{s}. \quad (58.32)$$

The first two terms are in accord with the purely collisional rates Eqs. (58.61) and (58.64b), respectively.

58.2.5 Computer Codes

A large number of computer codes for solving the collisional-radiative equations in astrophysical plasmas and fusion plasmas are available. See Table 58.1 for details.

58.3 Macroscopic Methods

58.3.1 Resonant Capture-Stabilization Model: Dissociative and Dielectronic Recombination

The electron is captured dielectronically, Eq. (58.53), into an energy-resonant long-lived intermediate collision complex of

superexcited states d , which can autoionize or be stabilized irreversibly into the final product channel f either by molecular fragmentation

as in direct dissociative recombination (DR), or by emission of radiation as in dielectronic recombination (DLR)

Production Rate of Superexcited States d

$$\frac{dn_d^*}{dt} = n_e N^+ k_c(d) - n_d^* [\nu_A(d) + \nu_S(d)]; \quad (58.35)$$

$$\nu_A(d) = \sum_{i'} \nu_a(d \rightarrow i'), \quad (58.36a)$$

$$\nu_S(d) = \sum_{f'} \nu_s(d \rightarrow f'). \quad (58.36b)$$

Steady-State Distribution

For a steady-state distribution, the capture volume is

$$\frac{n_d^*}{n_e N^+} = \frac{k_c(d)}{\nu_A(d) + \nu_S(d)}. \quad (58.37)$$

Recombination Rate and Stabilization Probability

The recombination rate to channel f is

$$\hat{\alpha}_f = \sum_d \left(\frac{k_c(d) \nu_s(d \rightarrow f)}{\nu_A(d) + \nu_S(d)} \right), \quad (58.38a)$$

and the rate to all product channels is

$$\hat{\alpha} = \sum_d \frac{k_c(d) \nu_S(d)}{\nu_A(d) + \nu_S(d)}. \quad (58.38b)$$

In the above, the quantities

$$P_f^S(d) = \nu_s(d \rightarrow f) / [\nu_A(d) + \nu_S(d)], \quad (58.39)$$

$$P^S(d) = \nu_S(d) / [\nu_A(d) + \nu_S(d)], \quad (58.40)$$

represent the corresponding stabilization probabilities.

Macroscopic Detailed Balance and Saha Distribution

$$K_{di}(T) = \frac{\tilde{n}_d^*}{\tilde{n}_e \tilde{N}^+} = \frac{k_c(d)}{\nu_a(d \rightarrow i)} = k_c(d) \tau_a(d \rightarrow i) \quad (58.41a)$$

$$= \frac{h^3}{(2\pi m_e k_B T)^{3/2}} \left(\frac{\omega(d)}{2\omega^+} \right) \exp(-E_{di}^* / k_B T), \quad (58.41b)$$

where E_{di}^* is the energy of superexcited neutral levels AB^{**} above that for ion level $AB^+(i)$, and ω are the corresponding statistical weights.

Alternative Rate Formula

$$\hat{\alpha}_f = \sum_d K_{di} \left(\frac{\nu_a(d \rightarrow i) \nu_s(d \rightarrow f)}{\nu_A(d) + \nu_S(d)} \right). \quad (58.42)$$

Normalized Excited-State Distributions

$$\rho_d = n_d^* / \tilde{n}_d^* = \frac{\nu_a(d \rightarrow i)}{[\nu_A(d) + \nu_S(d)]}, \quad (58.43)$$

$$\hat{\alpha} = \sum_d k_c(d) P^S(d) = \sum_d K_{di} \rho_d \nu_S(d) \quad (58.44a)$$

$$= \sum_d k_c(d) [\rho_d \nu_S(d) \tau_a(d \rightarrow i)]. \quad (58.44b)$$

Although equivalent, Eqs. (58.38a) and (58.42) are normally invoked for Eqs. (58.33) and (58.34), respectively, since $P^S \leq 1$ for DR, so that $\hat{\alpha}_{\text{DR}} \rightarrow k_c$; and $\nu_A \gg \nu_S$ for DLR with $n \ll 50$ so that $\hat{\alpha} \rightarrow K_{di} \nu_s$. For $n \gg 50$, $\nu_S \gg \nu_A$ and $\hat{\alpha} \rightarrow k_c$. The above results Eqs. (58.38a) and (58.42) can also be derived from microscopic Breit–Wigner scattering theory for isolated (nonoverlapping) resonances.

58.3.2 Reactive Sphere Model: Three-Body Electron–Ion and Ion–Ion Recombination

Since the Coulomb attraction cannot support quasi-bound levels, three body electron–ion and ion–ion recombination

do not, in general, proceed via time-delayed resonances but rather by reactive (energy-reducing) collisions with the third body M. This is particularly effective for A–B separations $R \leq R_0$, as in the sequence

In contrast to Eqs. (58.33) and (58.34), where the stabilization is irreversible, the forward step in Eq. (58.45b) is reversible. The sequence Eqs. (58.45a) and (58.45b) represents a closed system where thermodynamic equilibrium is eventually established.

Steady-State Distribution of AB^* Complex

$$n^* = \left(\frac{k_c}{\nu_s + \nu_d} \right) n_A(t) n_B(t) + \left(\frac{\nu_{-s}}{\nu_s + \nu_d} \right) n_s(t). \quad (58.46)$$

Saha and Boltzmann balances

$$\begin{aligned} \text{Saha:} \quad & \tilde{n}_A \tilde{n}_B k_c = \tilde{n}^* \nu_d, \\ \text{Boltzmann:} \quad & \tilde{n}_s \nu_{-s} = \tilde{n}^* \nu_s; \end{aligned} \quad (58.47)$$

\tilde{n}^* is in Saha balance with reactant block C and in Boltzmann balance with product block S .

Normalized Distributions

$$\rho^* = \frac{n^*}{\tilde{n}^*} = P^D \gamma_c(t) + P^S \gamma_s(t), \quad (58.48a)$$

$$\gamma_c(t) = \frac{n_A(t) n_B(t)}{\tilde{n}_A \tilde{n}_B}, \quad \gamma_s(t) = \frac{n_s(t)}{\tilde{n}_s}. \quad (58.48b)$$

Stabilization and Dissociation Probabilities

$$P^S = \frac{\nu_s}{(\nu_s + \nu_d)}, \quad P^D = \frac{\nu_d}{(\nu_s + \nu_d)}. \quad (58.49)$$

Time-Dependent Equations

$$\frac{dn_c}{dt} = -k_c P^S \tilde{n}_A \tilde{n}_B [\gamma_c(t) - \gamma_s(t)], \quad (58.50a)$$

$$\frac{dn_s}{dt} = -\nu_{-s} P^D \tilde{n}_s [\gamma_s(t) - \gamma_c(t)], \quad (58.50b)$$

$$\frac{dn_c}{dt} = -\hat{\alpha}_3 n_A(t) n_B(t) + k_d n_s(t), \quad (58.51)$$

where the recombination rate coefficient (cm^3/s) and dissociation frequency are, respectively,

$$\hat{\alpha}_3 = k_c P^S = \frac{k_c \nu_s}{(\nu_s + \nu_d)}, \quad (58.52)$$

$$k_d = \nu_{-s} P^D = \frac{\nu_{-s} \nu_d}{(\nu_s + \nu_d)}, \quad (58.53)$$

which also satisfy the macroscopic detailed balance relation

$$\hat{\alpha}_3 \tilde{n}_A \tilde{n}_B = k_d \tilde{n}_s. \quad (58.54)$$

Time-Independent Treatment

The rate $\hat{\alpha}_3$ given by the time-dependent treatment can also be deduced by viewing the recombination process as a source block C kept fully filled with dissociated species A and B maintained at equilibrium concentrations \tilde{n}_A, \tilde{n}_B (i.e., $\gamma_c = 1$) and draining at the rate $\hat{\alpha}_3 \tilde{n}_A \tilde{n}_B$ through a steady-state intermediate block \mathcal{E} of excited levels into a fully absorbing sink block S of fully associated species AB kept fully depleted with $\gamma_s = 0$, so that there is no backward redissociation from block S . The frequency k_d is deduced as if the reverse scenario, $\gamma_s = 1$ and $\gamma_c = 0$, holds. This picture uncouples $\hat{\alpha}$ and k_d and allows each coefficient to be calculated independently. Both dissociation (or ionization) and association (recombination) occur within block \mathcal{E} .

If $\gamma_c = 1$ and $\gamma_s = 0$, then

$$\rho^* = n^*/\tilde{n}^* = \nu_d/(\nu_s + \nu_d), \quad (58.55a)$$

$$K = \tilde{n}^*/\tilde{n}_A \tilde{n}_B = k_c/\nu_d = k_c \tau_d, \quad (58.55b)$$

$$P^S = \nu_s/(\nu_s + \nu_d) = \rho^* \nu_s \tau_s, \quad (58.55c)$$

and the recombination coefficient is

$$\hat{\alpha} = k_c P^S = k_c (\rho^* \nu_s \tau_d) = K \rho^* \nu_s. \quad (58.56)$$

Microscopic Generalization

From Eq. (58.206), the microscopic generalizations of rate in Eq. (58.52) and probability in Eq. (58.55c) are, respectively,

$$\hat{\alpha} = \bar{\nu} \int_0^\infty \varepsilon e^{-\varepsilon} d\varepsilon \int_0^{b_0} 2\pi b db P^S(\varepsilon, b; R_0), \quad (58.57a)$$

$$P^S(\varepsilon, b; R_0) = \oint_{R_i}^{R_0} \rho_i(R) v_i^b(R) dt \equiv \langle \rho \nu_s \rangle \tau_d, \quad (58.57b)$$

where $\rho_i(R) = n(\varepsilon, b; R)/\tilde{n}(\varepsilon, b; R)$; $v_i^{(b)}$ is the frequency Eq. (58.203a) of (A–B)–M continuum-bound collisional transitions at fixed A–B separation R , R_i is the pericenter of the orbit, ($i \equiv \varepsilon, b$), and

$$b_0^2 = R_0^2 [1 - V(R_0)/E], \quad \varepsilon = E/k_B T, \quad (58.57c)$$

$$\hat{\alpha} \equiv k_c \langle P^S \rangle_{\varepsilon, b}, \quad \bar{\nu} = (8k_B T/\pi M_{AB})^{1/2}, \quad (58.57d)$$

$$k_c = \{ \pi R_0^2 [1 - V(R_0)/k_B T] \bar{\nu} \}, \quad (58.57e)$$

where M_{AB} is the reduced mass of A and B.

Low Gas Densities

Here $\rho_i(R) = 1$ for $E > 0$,

$$P^S(\varepsilon, b; R_0) = \oint_{R_i}^{R_0} v(t) dt = \oint_{R_i}^{R_0} ds/\lambda_i; \quad (58.58)$$

$\lambda_i = (N\sigma)^{-1}$ is the microscopic path length towards the (A–B)–M reactive collision with frequency $\nu = N\nu\sigma$. For λ_i

constant, the rate in Eq. (58.57a) reduces at low N to

$$\hat{\alpha} = (v\sigma_0 N) \int_0^{R_0} \left(1 - \frac{V(R)}{k_B T}\right) 4\pi R^2 dR, \quad (58.59)$$

which is linear in the gas density N .

58.3.3 Working Formulae for Three-Body Collisional Recombination at Low Density

For three-body ion-ion collisional recombination of the form $A^+ + B^- + M$ in a gas at low density N , set $V(R) = -e^2/R$. Then Eq. (58.59) yields

$$\hat{\alpha}^c(T) = \left(\frac{8k_B T}{\pi M_{AB}}\right)^{1/2} \frac{4}{3} \pi R_0^3 \left(1 + \frac{3R_e}{2R_0}\right) (\sigma_0 N), \quad (58.60)$$

where $R_e = e^2/k_B T$, and the trapping radius R_0 , determined by the classical variational method, is $0.41R_e$, in agreement with detailed calculation. The special cases are the following.

(a) $e^- + A^+ + e^-$

Here, $\sigma_0 = \frac{1}{9}\pi R_e^2$ for ($e^- - e^-$) collisions for scattering angles $\theta \geq \pi/2$, so that

$$\hat{\alpha}_{ee}^c(T) = 2.7 \times 10^{-20} \left(\frac{300}{T}\right)^{4.5} n_e \text{ cm}^3 \text{ s}^{-1} \quad (58.61)$$

in agreement with *Mansbach* and *Keck* [32].

(b) $A^+ + B^- + M$

Here, $\sigma_0 \bar{v} \approx 10^{-9} \text{ cm}^3 \text{ s}^{-1}$, which is independent of T for polarization attraction. Then

$$\hat{\alpha}_3(T) = 2 \times 10^{-25} \left(\frac{300}{T}\right)^{2.5} N \text{ cm}^3 \text{ s}^{-1}. \quad (58.62)$$

(c) $e^- + A^+ + M$

Only a small fraction $\delta = 2m/M$ of the electron's energy is lost upon ($e^- - M$) collision, so that Eq. (58.57a) for constant λ is modified to

$$\hat{\alpha}_{eM} = \sigma_0 N \int_0^{R_0} 4\pi R^2 dR \int_0^{E_m} \tilde{n}(R, E) v dE \quad (58.63a)$$

$$= \bar{v}_e \sigma_0 N \int_0^{R_0} 4\pi R^2 dR \int_0^{\varepsilon_m} \left(1 - \frac{V(R)}{E}\right) \varepsilon e^{-\varepsilon} d\varepsilon, \quad (58.63b)$$

where $\varepsilon = E/k_B T$, and $E_m = \delta e^2/R = \varepsilon_m k_B T$ is the maximum energy for collisional trapping. Hence,

$$\hat{\alpha}_{eM}(T_e) = 4\pi \delta \left(\frac{8k_B T_e}{\pi m_e}\right)^{1/2} R_e^2 R_0 [\sigma_0 N] \quad (58.64a)$$

$$\approx \frac{10^{-26}}{M} \left(\frac{300}{T}\right)^{2.5} N \text{ cm}^3 \text{ s}^{-1}, \quad (58.64b)$$

where the mass M of the gas atom is now in a.m.u. This result agrees with the energy diffusion result of *Pitaevskii* [33] when R_0 is taken as the Thomson radius $R_T = \frac{2}{3}R_e$.

58.3.4 Recombination Influenced by Diffusional Drift at High Gas Densities

Diffusional-Drift Current

The drift current of A^+ towards B^- in a gas under an $A^+ - B^-$ attractive potential $V(R)$ is

$$\mathbf{J}(R) = -D \nabla n(R) - \left[\frac{K}{e} \nabla V(R)\right] n(R) \quad (58.65a)$$

$$= -\left(D \tilde{N}_A \tilde{N}_B e^{-V(R)/k_B T} \frac{\partial \rho}{\partial R}\right) \hat{\mathbf{R}}. \quad (58.65b)$$

Relative Diffusion and Mobility Coefficients

$$D = D_A + D_B,$$

$$K = K_A + K_B, \quad De = K(k_B T), \quad (58.66)$$

where the D_i and K_i are, respectively, the diffusion and mobility coefficients of species i in gas M .

Normalized Ion-Pair R -Distribution

$$\rho(R) = \frac{n(R)}{\tilde{N}_A \tilde{N}_B \exp[-V(R)/k_B T]}. \quad (58.67)$$

Continuity Equations for Currents and Rates

$$\frac{\partial n}{\partial t} + \nabla \cdot \mathbf{J} = 0, \quad R \geq R_0, \quad (58.68a)$$

$$\hat{\alpha}_{RN}(R_0) \rho(R_0) = \hat{\alpha} \rho(\infty). \quad (58.68b)$$

The rate of reaction for ion pairs with separations $R \leq R_0$ is $\alpha_{RN}(R_0)$. This is the recombination rate that would be obtained for a thermodynamic equilibrium distribution of ion pairs with $R \geq R_0$, i.e., for $\rho(R \geq R_0) = 1$.

Steady-State Rate of Recombination

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{R_0}^{\infty} \left(\frac{\partial n}{\partial t}\right) d\mathbf{R} = -4\pi R_0^2 J(R_0). \quad (58.69)$$

Steady-State Solution

$$\rho(R) = \rho(\infty) \left(1 - \frac{\hat{\alpha}}{\hat{\alpha}_{TR}(R)}\right), \quad R \geq R_0 \quad (58.70a)$$

$$\rho(R_0) = \rho(\infty) [\hat{\alpha}/\hat{\alpha}_{RN}(R_0)]. \quad (58.70b)$$

Recombination Rate

$$\hat{\alpha} = \frac{\hat{\alpha}_{\text{RN}}(R_0)\hat{\alpha}_{\text{TR}}(R_0)}{\hat{\alpha}_{\text{RN}}(R_0) + \hat{\alpha}_{\text{TR}}(R_0)} \quad (58.71a)$$

$$\rightarrow \begin{cases} \hat{\alpha}_{\text{RN}}, & N \rightarrow 0 \\ \hat{\alpha}_{\text{TR}}, & N \rightarrow \infty. \end{cases} \quad (58.71b)$$

Diffusional-Drift Transport Rate

$$\hat{\alpha}_{\text{TR}}(R_0) = 4\pi D \left(\int_{R_0}^{\infty} \frac{e^{V(R)/k_B T}}{R^2} dR \right)^{-1}. \quad (58.72)$$

With $V(R) = -e^2/R$,

$$\hat{\alpha}_{\text{TR}}(R_0) = 4\pi K e [1 - \exp(-R_e/R_0)]^{-1}, \quad (58.73)$$

where $R_e = e^2/k_B T$ provides a natural unit of length.

Langevin Rate

For $R_0 \ll R_e$, the transport rate

$$\hat{\alpha}_{\text{TR}} \rightarrow \hat{\alpha}_L = 4\pi K e \quad (58.74)$$

tends to the Langevin rate which varies as N^{-1} .

Reaction Rate

When R_0 is large enough that R_0 -pairs are in (E, L^2) equilibrium Eq. (58.206),

$$\hat{\alpha}_{\text{RN}}(R_0) = \bar{v} \int_0^{\infty} \varepsilon e^{-\varepsilon} d\varepsilon \int_0^{b_0} 2\pi b db P^S(\varepsilon, b; R_0) \quad (58.75a)$$

$$\equiv \bar{v} \int_0^{\infty} \varepsilon e^{-\varepsilon} d\varepsilon [\pi b_0^2 P^S(\varepsilon; R_0)] \quad (58.75b)$$

$$\equiv \bar{v} \pi b_{\text{max}}^2 P^S(R_0), \quad (58.75c)$$

where

$$b_{\text{max}}^2 = R_0^2 \left(1 - \frac{V(R_0)}{k_B T} \right), \quad (58.76)$$

and b_0 and ε are given by Eq. (58.57c) and \bar{v} by Eq. (58.57d).

The probability P^S and its averages over b and (b, E) for reaction between pairs with $R \leq R_0$ is determined in Eq. (58.75a–58.75c) from solutions of coupled master equations; P^S increases linearly with N initially and tends to unity at high N . The recombination rate in Eq. (58.71a) with Eq. (58.75a) and Eq. (58.73), therefore, increases linearly with N initially, reaches a maximum when $\hat{\alpha}_{\text{TR}} \approx \hat{\alpha}_{\text{RN}}$, and then decreases eventually as N^{-1} , in accord with Eq. (58.74).

Reaction Probability

The classical absorption solution of Eq. (58.196) is

$$P^S(E, b; R_0) = 1 - \exp\left(-\oint_{R_i}^{R_0} \frac{ds_i}{\lambda_i}\right). \quad (58.77)$$

With the binary decomposition $\lambda_i^{-1} = \lambda_{iA}^{-1} + \lambda_{iB}^{-1}$,

$$P^S = P_A + P_B - P_A P_B. \quad (58.78)$$

Exact b^2 -Averaged Probability

With $V_c = -e^2/R$ for the A^+B^- interaction in Eq. (58.75b), and at low gas densities N ,

$$P_{A,B}(E, R_0) = \frac{4R_0}{3\lambda_{A,B}} \left(1 - \frac{3V_c(R_0)}{2E_i} \right) \frac{1}{[1 - V_c(R_0)/E_i]}, \quad (58.79)$$

appropriate for constant mean free path λ_i .

(E, b^2) -Averaged Probability

$P^S(R_0)$ in Eq. (58.75c) at low gas density is

$$P_{A,B}(R_0) = P_{A,B}(E = k_B T, R_0). \quad (58.80)$$

Thomson Trapping Distance

When the kinetic energy gained from Coulomb attraction is assumed lost upon collision with third bodies, then bound (A, B) pairs are formed with $R \leq R_T$. Since $E = \frac{3}{2}k_B T - e^2/R$, then

$$R_T = \frac{2}{3} \left(\frac{e^2}{k_B T} \right) = \frac{2}{3} R_e. \quad (58.81)$$

Thomson Straight-Line Probability

The $E \rightarrow \infty$ limit of Eq. (58.77) is

$$P_{A,B}^T(b; R_T) = 1 - \exp[-2(R_T^2 - b^2)/\lambda_{A,B}]. \quad (58.82)$$

The b^2 -average is the Thomson probability

$$P_{A,B}^T(R_T) = 1 - \frac{1}{2X^2} [1 - e^{-2X}(1 + 2X)] \quad (58.83a)$$

for reaction of (A–B) pairs with $R \leq R_T$. As $N \rightarrow 0$

$$P_{A,B}^T(R_T) \rightarrow \frac{4}{3} X \left(1 - \frac{3}{4} X + \frac{2}{5} X^2 - \frac{1}{6} X^3 + \dots \right) \quad (58.83b)$$

and tends to unity at high N ; $X = R_T/\lambda_{A,B} = N(\sigma_0 R_T)$. These probabilities have been generalized [34] to include hyperbolic and general trajectories.

Thomson Reaction Rate

$$\hat{\alpha}_T = \pi R_T^2 \bar{v} (P_A^T + P_B^T - P_A^T P_B^T) \rightarrow \begin{cases} \frac{4}{3} \pi R_T^3 (\lambda_A^{-1} + \lambda_B^{-1}), & N \rightarrow 0 \\ \pi R_T^2 \bar{v}, & N \rightarrow \infty. \end{cases} \quad (58.84)$$

58.4 Zero-Range Methods

Zero-range methods refer to scattering models that make use of the scattering length to characterize the collision. Zero-range methods are used in ultracold collisions where the de Broglie wavelength of the atoms is much larger than the range of their interactions, and hence the scattering is well described by the S-wave scattering length, a .

The T-matrix element for S-wave scattering of two identical particles, mass m and energy $E = k^2/m$, is

$$T(k) = \frac{8\pi}{m} \frac{1}{k \cot \delta_0(k) - ik}, \quad (58.85)$$

where $\delta_0(k)$ is the S-wave phase shift. In general, one would solve numerically a couple-channel problem to compute the phase shifts for all the states of interest. In ultracold collisions, the low-energy effective range expansion of the S-wave phase shift can be utilized

$$k \cot \delta_0(k) = -1/a + \frac{1}{2}r_s k^2 + \dots \quad (58.86)$$

to simplify the scattering calculation. The effective range expansion serves to define the scattering length a and the effective range r_s . See Sect. 47.5.5 and Eq. (47.46b) in this Handbook, and [35] for details on the scattering length and effective range. For the typical ultracold collision involving alkali atoms in specific hyperfine states, the van der Waals length, ℓ_{vdW} , and energy E_{vdW} , provide natural length and energy scales, respectively

$$\ell_{\text{vdW}} = (mC_6/\hbar^2)^{1/4}, \quad (58.87a)$$

$$E_{\text{vdW}} = (m^3C_6/\hbar^6)^{-1/2}, \quad (58.87b)$$

for atom of mass m and van der Waals constant C_6 . For alkali atom collisions, the scattering lengths are [35]:

	${}^6\text{Li}(a_t)$	${}^{85}\text{Rb}(a_s)$	${}^{133}\text{Cs}(a_t)$
$a(a_0)$	-2160	2800	2400

where the subscript s or t refer to singlet or triplet states, respectively.

Contrast these large values for alkali atom collisions with the much smaller values for $e^- + \text{Rg}$ atom collisions in Sect. 47.5.5 ($\text{Rg} = \text{He} - \text{Xe}$). See Table 1 of [26] for a more complete tabulation. The elastic scattering cross section for two bosonic atoms in the same spin state is

$$\sigma_{\text{elastic}}(E) = \frac{8\pi a^2}{1 + ma^2 E}, \quad (58.88)$$

where a is the scattering length.

Shallow dimers

When $a > 0$, there is a single bound state with binding energy $E_D = 1/(ma^2)$, referred to as a shallow dimer state.

The three-body recombination rate α_s into a shallow dimer state is [26, 36]

$$\alpha_s = \frac{128\pi^2(4\pi - 3\sqrt{3})}{\sinh^2(\pi s_0) + \cosh^2(\pi s_0) \tan^2[s_0 \ln(a\kappa_*) + \gamma]} \frac{\hbar a^4}{m}, \quad (58.89)$$

where κ_* is the wave number of the shallow dimer state n_* , γ is a constant, and s_0 is the root of the transcendental equation

$$s_0 \cosh \frac{\pi s_0}{2} = \frac{8}{\sqrt{3}} \sinh \frac{\pi s_0}{6}, \quad (58.90)$$

with approximate numerical solution of $s_0 \sim 1.00624$. The phase constant γ has been computed in [37, 38] and is of order unity.

The three-body collision, at low energies in reaction Eq. (58.19), that results in the formation of dimers A_2 exhibits a universal property, wherein the spacing between adjacent energy levels of the dimer, $E_T^{(n)}$ follows an exponential scaling independent of system

$$E_T^{(n)} \rightarrow (e^{-2\pi/s_0})^{n-n_*} \frac{\hbar^2 \kappa_*^2}{m}, \quad (58.91)$$

as $n \rightarrow \infty$, and where κ_* is the wave number associated with the dimer state labeled by the integer n_* . The scaling relationship Eq. (58.91) was first described by *Efimov* [39, 40]. Further details on the universal scaling property Eq. (58.91) called the *Efimov effect* can be found in Sect. 60.6 of this Handbook, and [20, 25, 26, 41].

Deep dimers

Depending on the details of the short-range part of the dimer molecular potential, governed by the parameters a , κ_* , and the inelasticity parameter η_* , the dimer may support multiple states below threshold, called deep dimer states. See [26], and references therein, for a complete discussion of these parameters.

The three-body recombination rate α_d into a deep dimer state is [26]

$$\alpha_d = \frac{C_{\text{max}} \cosh(\pi s_0) \sinh(\pi s_0) \cosh \eta_* \sinh \eta_* \hbar a^4}{\sinh^2(\pi s_0 + \eta_*) + \sin^2[s_0 \ln(a\kappa_*) + \gamma]} \frac{\hbar a^4}{m}, \quad (58.92)$$

where η_* is the inelasticity parameter, and C_{max} is defined

$$C_{\text{max}} = \frac{128\pi^2(4\pi - 3\sqrt{3})}{\sinh^2(\pi s_0)}, \quad (58.93)$$

while s_0 and γ retain their meaning as in Eq. (58.89).

Expressions for scattering lengths and effective ranges for shallow and deep dimers can be found in Sect. 60.6.

58.5 Hyperspherical Methods

Hyperspherical methods are techniques of solving the N-body Schrödinger equation where the coupled partial differential equations are reformulated in terms of hyperspherical coordinates. See Chap. 56 of this Handbook and [20] for details on hyperspherical methods.

d-dimensional coordinates [42]

$$R = \sqrt{x_1^2 + x_2^2 + x_3^2 + \cdots + x_d^2}. \quad (58.94)$$

$$x_d = R \cos \alpha_{d-1},$$

$$x_{d-1} = R \sin \alpha_{d-1} \cos \alpha_{d-2},$$

$$x_{d-2} = R \sin \alpha_{d-1} \sin \alpha_{d-2} \cos \alpha_{d-3},$$

...

$$x_2 = R \prod_{j=1}^{d-1} \sin \alpha_j,$$

$$x_1 = R \prod_{j=2}^{d-1} \sin \alpha_j \cos \alpha_1, \quad (58.95a)$$

where R is the hyperradius, x_i the coordinates of the particles, and α_j the corresponding hyperangles. The set Eq. (58.95a) is usually termed the canonical choice and have the ranges

$$0 \leq \alpha_1 \leq 2\pi, \quad 0 \leq \alpha_i \leq \pi, \quad i = 2, \dots, d-1. \quad (58.96)$$

The nonrelativistic kinetic energy operator is then separable

$$\hat{T} = T_R + \frac{\hbar^2 \Lambda^2}{2\mu R}, \quad (58.97a)$$

$$T_R = -\frac{\hbar^2}{2\mu} \frac{1}{R^{d-1}} R^{d-1} \frac{\partial}{\partial R}, \quad (58.97b)$$

where μ is the N-body reduced mass

$$\mu = (\mu_{12}\mu_{12,3}\cdots)^{1/(N-1)}, \quad (58.98)$$

and,

$$\mu_{12} = \frac{m_1 m_2}{m_1 + m_2}, \quad (58.99a)$$

$$\mu_{12,3} = \frac{(m_1 + m_2)m_3}{m_1 + m_2 + m_3}, \quad (58.99b)$$

the usual reduced masses, while Λ is the isotropic Casimir operator

$$\Lambda^2 = -\sum_{i>j} \Lambda_{ij}^2, \quad \Lambda_{ij} = x_i \frac{\partial}{\partial x_j} - x_j \frac{\partial}{\partial x_i}. \quad (58.100)$$

Three-particle case

$$R^2 = \rho_1^2 + \rho_2^2, \quad 0 \leq R < \infty. \quad (58.101)$$

$$\vec{\rho}_1 = (\vec{r}_2 - \vec{r}_1)/\Delta, \quad (58.102a)$$

$$\vec{\rho}_2 = \Delta \left[\vec{r}_3 - \frac{m_1 \vec{r}_1 + m_2 \vec{r}_2}{m_1 + m_2} \right], \quad (58.102b)$$

with,

$$\Delta^2 = \frac{1}{\mu} \frac{m_3(m_1 + m_2)}{m_1 + m_2 + m_3}, \quad (58.103a)$$

$$\mu^2 = \frac{m_1 m_2 m_3}{m_1 + m_2 + m_3}, \quad (58.103b)$$

for particles i with mass m_i and position vector \vec{r}_i , $i = 1-3$. The mass-scaled Jacobi coordinates, $\vec{\rho}_1$ and $\vec{\rho}_2$ determine the hyperangles θ and φ in the body frame x - y plane, yielding a rescaled Schrödinger equation for three identical particles

$$\left(-\frac{1}{2\mu} \frac{\partial^2}{\partial R^2} + \frac{15}{8\mu R^2} + \frac{\Lambda^2}{2\mu R^2} + V(R, \theta, \varphi) \right) \Psi_E = E \Psi_E, \quad (58.104)$$

where the full three-particle interaction potential V is expressed in terms of the hyperradius R and hyperangles θ and φ , and the angular momentum operator Λ is given in [20, equations (22–25)].

Coupled-channel expansion
