$$\Psi_{E\nu'} = \sum_{\nu} \frac{\Phi_{\nu}(R; \tilde{\omega})}{R^{(d-1)/2}} [f_{E\nu}(R) \delta_{\nu\nu'} - g_{E\nu}(R) K_{\nu\nu'}], \quad (58.105)$$

where $f_{E\nu}(R)$ and $g_{E\nu}(R)$ are the regular and irregular radial functions, respectively; $K_{\nu\nu'}$ is the real symmetric reaction matrix, and $\tilde{\omega}$ represents the set of hyperangles, while d is the dimension.

The usual technique is to solve numerically the set of coupled equations and matching to linear combinations of regular and irregular functions at a large hyperradius R_0 to obtain the reaction matrix K .

58.5.1 Three-Body Recombination Rate (Identical Particles)

$$\alpha(E) = \frac{\hbar k}{\mu} \frac{192\pi^2}{k^5} \sum_{\nu'\nu} |S_{\nu'\nu}|^2, \quad (58.106)$$

where $k = \sqrt{2\mu E/\hbar^2}$, and the S-matrix is determined from the reaction matrix using the standard expression Eq. (49.17). The sum includes all entrance channel ν three-body continuum states and exit channel ν' two-body bound states of A_2 .

58.5.2 N-Body Recombination Rate (Identical Particles)

$$\alpha_N(E) = N! \frac{\hbar k}{\mu} \left(\frac{2\pi}{k} \right)^{d-1} \frac{\Gamma(d/2)}{2\pi^{d/2}} \sum_{v'v} |S_{v'v}|^2, \quad (58.107)$$

where $\Gamma(x)$ is the Gamma function and d is the dimension.

58.6 Field-Assisted Methods

Field-assisted methods is a general term to encompass techniques used to compute recombination rates in cases where the reaction is assisted by the application of an external field. Currently, the most commonly applied field is laser-assisted recombination Eq. (58.5) in studying the spectrum in high-order harmonic generation (HHG). See Sects. 78.3, 78.4 and 80.6 in this Handbook for further details on HHG.

Differential cross section [43]

$$\frac{d\sigma_{\text{len}}^R}{d\Omega_k d\Omega_n} = \frac{4\pi^2 \omega^3}{c^3 k} |a_{\text{len}}^{\text{sc}}(k)|^2, \quad (58.108a)$$

$$\frac{d\sigma_{\text{acn}}^R}{d\Omega_k d\Omega_n} = \frac{4\pi^2 \omega}{c^3 k} |a_{\text{acn}}^{\text{sc}}(k)|^2, \quad (58.108b)$$

where σ^R is the differential cross section for Eq. (58.5), the subscripts *len* and *acn* refer to the length and acceleration form of the matrix elements, respectively; ω is the angular frequency of the released photon, k the momentum of the recombining electron, Ω_n, Ω_k the corresponding solid angles, and c the speed of light.

He

$$a_{\text{len}}^{\text{sc}}(k) = a_1 c_1 e^{i(\delta_1 + \sigma_1)} \langle u_g r \rangle u_{k1}^{\text{sc}}, \quad (58.109a)$$

$$a_{\text{acn}}^{\text{sc}}(k) = -a_1 c_1 Z_N e^{i(\delta_1 + \sigma_1)} \langle u_g \frac{1}{r^2} \rangle u_{k1}^{\text{sc}}. \quad (58.109b)$$

Rg (Ar–Xe)

$$a_{\text{len}}^{\text{sc}}(k) = a_0 c_0 e^{i(\delta_0 + \sigma_0)} \langle u_g r \rangle u_{k0}^{\text{sc}} + a_2 c_2 e^{i(\delta_2 + \sigma_2)} \langle u_g r \rangle u_{k2}^{\text{sc}} \quad (58.110a)$$

$$a_{\text{acn}}^{\text{sc}}(k) = -a_0 c_0 Z_N e^{i(\delta_0 + \sigma_0)} \langle u_g \frac{1}{r^2} \rangle u_{k0}^{\text{sc}} - a_2 c_2 Z_N e^{i(\delta_2 + \sigma_2)} \langle u_g \frac{1}{r^2} \rangle u_{k2}^{\text{sc}}, \quad (58.110b)$$

where the constants a_ℓ and c_ℓ are defined

$$a_\ell = \frac{t^\ell}{2k} \sqrt{\frac{2\ell + 1}{\pi}}, \quad (58.111a)$$

$$c_\ell = \langle Y_{\ell_g}^{m=0} \cos \theta \rangle Y_\ell^{m=0}, \quad (58.111b)$$

with Y_ℓ^m the spherical harmonics and Z_N the atomic number.

Detailed balance

$$\frac{d^2 \sigma^R}{\omega^2 d\Omega_n d\Omega_k} = \frac{d^2 \sigma^I}{k^2 c^2 d\Omega_k d\Omega_n}, \quad (58.112)$$

where the superscripts R and I refer to recombination and ionization, respectively.

58.7 Dissociative Recombination

58.7.1 Curve-Crossing Mechanisms

Direct Process

Dissociative recombination (DR) for diatomic ions can occur via a crossing at R_X between the bound and repulsive potential energy curves $V^+(R)$ and $V_d(R)$ for AB^+ and AB^{**} , respectively. Here, DR involves the two-stage sequence

The first stage is dielectronic capture whereby the free electron of energy $\epsilon = V_d(R) - V^+(R)$ excites an electron of the diatomic ion AB^+ with internal separation R and is then resonantly captured by the ion, at rate k_c , to form a repulsive state d of the doubly excited molecule AB^{**} , which in turn can either autoionize at probability frequency ν_a , or else in the second stage, predissociate into various channels at probability frequency ν_d . This competition continues until the (electronically excited) neutral fragments accelerate past the crossing at R_X . Beyond R_X , the increasing energy of relative separation reduces the total electronic energy to such an extent that autoionization is essentially precluded, and the neutralization is then rendered permanent past the stabilization point R_X . This interpretation [44] has remained intact and robust in the current light of ab initio quantum chemistry and quantal scattering calculations for the simple diatomics (O_2^+ , N_2^+ , Ne_2^+ , etc.). Mechanism Eq. (58.113) is termed the direct process, which, in terms of the macroscopic frequencies in Eq. (58.113), proceeds at the rate

$$\hat{\alpha} = k_c P_S = k_c [\nu_d / (\nu_a + \nu_d)], \quad (58.114)$$

where P_S is probability for AB^* survival against autoionization from the initial capture at R_c to the crossing point R_X . Configuration mixing theories of this direct process are available in the quantal [45] and semiclassical-classical path formulations [46].

Indirect Process

In the three-stage sequence

the so-called indirect process [45] might contribute. Here, the accelerating electron loses energy by vibrational excitation ($v_i^+ \rightarrow v_f$) of the ion and is then resonantly captured into a Rydberg orbital of the bound molecule AB^* in vibrational level v_f , which then interacts one way (via configuration mixing) with the doubly excited repulsive molecule AB^{**} . The capture initially proceeds via a small effect – vibronic coupling (the matrix element of the nuclear kinetic energy) induced by the breakdown of the Born–Oppenheimer approximation – at certain resonance energies $\varepsilon_n = E(v_f) - E(v_i^+)$ and, in the absence of the direct channel Eq. (58.113), would therefore be manifest by a series of characteristic very narrow Lorentz profiles in the cross section. Uncoupled from Eq. (58.113) the indirect process would augment the rate. Vibronic capture proceeds more easily when $v_f = v_i^+ + 1$, so that Rydberg states with $n \approx 7-9$ would be involved [for $H_2^+(v_i^+ = 0)$], so that the resulting longer periods of the Rydberg electron would permit changes in nuclear motion to compete with the electronic dissociation. Recombination then proceeds as in the second stage of Eq. (58.113), i.e., by electronic coupling to the dissociative state d at the crossing point. A multichannel quantum defect theory [47] has combined the direct and indirect mechanisms.

Interrupted Recombination

The process

proceeds via the first (dielectronic capture) stage of Eq. (58.113) followed by a two-way electronic transition with frequency ν_{dn} and ν_{nd} between the d and n states. All (n, v) Rydberg states can be populated, particularly those in low n and high v since the electronic $d-n$ interaction varies as $n^{-1.5}$ with broad structure. Although the dissociation process proceeds here via a second-order effect (ν_{dn} and ν_{nd}), the electronic coupling may dominate the indirect vibronic capture and interrupt the recombination, in contrast to Eq. (58.115) which, as written in the one-way direction, feeds the recombination. Both dip and spike structure has been observed [48].

58.7.2 Quantal Cross Section

The cross section for direct dissociative recombination

of electrons of energy ε , wavenumber k_e , and spin statistical weight 2, for a molecular ion $AB^+(v_i^+)$ of electronic statistical weight ω_{AB}^+ in vibrational level v_i^+ is

$$\begin{aligned} \sigma_{DR}(\varepsilon) &= \frac{\pi}{k_e^2} \left(\frac{\omega_{AB}^*}{2\omega^+} \right) |a_Q|^2 \\ &= \left(\frac{h^2}{8\pi m_e \varepsilon} \right) \left(\frac{\omega_{AB}^*}{2\omega^+} \right) |a_Q|^2. \end{aligned} \quad (58.118)$$

Here, ω_{AB}^* is the electronic statistical weight of the dissociative neutral state of AB^* whose potential energy curve V_d crosses the corresponding potential energy curve V^+ of the ionic state. The transition T-matrix element for autoionization of AB^* embedded in the (moving) electronic continuum of $AB^+ + e^-$ is the quantal probability amplitude

$$a_Q(v) = 2\pi \int_0^\infty V_{d\varepsilon}^*(R) [\psi_v^{+*}(R) \psi_d(R)] dR \quad (58.119)$$

for autoionization. Here, ψ_v^+ and ψ_d are the nuclear bound and continuum vibrational wave functions for AB^+ and AB^* , respectively, while

$$\begin{aligned} V_{d\varepsilon}(R) &= \langle \phi_d | \mathcal{H}_{el}(\mathbf{r}, R(t)) | \phi_\varepsilon(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}, \hat{\varepsilon}} \\ &= V_{\varepsilon d}^*(R) \end{aligned} \quad (58.120)$$

are the bound-continuum electronic matrix elements coupling the diabatic electronic bound state wave functions $\psi_d(\mathbf{r}, \mathbf{R})$ for AB^* with the electronic continuum state wave functions $\phi_\varepsilon(\mathbf{r}, \mathbf{R})$ for $AB^+ + e^-$. The matrix element is an average over electronic coordinates \mathbf{r} and all directions $\hat{\varepsilon}$ of the continuum electron. Both continuum electronic and vibrational wave functions are energy normalized (Sect. 58.11.3), and

$$\Gamma(R) = 2\pi |V_{d\varepsilon}^*(R)|^2 \quad (58.121)$$

is the energy width for autoionization at a given nuclear separation R . Given $\Gamma(R)$ from quantum chemistry codes, the problem reduces to evaluation of continuum vibrational wave functions in the presence of autoionization. The rate associated with a Maxwellian distribution of electrons at temperature T is

$$\hat{\alpha} = \bar{v}_e \int \varepsilon \sigma_{DR}(\varepsilon) e^{-\varepsilon/k_B T} d\varepsilon / (k_B T)^2, \quad (58.122)$$

where \bar{v}_e is the mean speed (Sect. 58.12).

Maximum Cross Section and Rate

Since the probability for recombination must remain less than unity, $|a_Q|^2 \leq 1$, so that the maximum cross section and

rates are

$$\sigma_{\text{DR}}^{\text{max}}(\varepsilon) = \frac{\pi}{k_e^2} \left(\frac{\omega_{\text{AB}}^*}{2\omega^+} \right) = \left(\frac{h^2}{8\pi m_e \varepsilon} \right) (2\ell + 1), \quad (58.123)$$

where ω_{AB}^* has been replaced by $2(2\ell + 1)\omega^+$ under the assumption that the captured electron is bound in a high-level Rydberg state of angular momentum ℓ , and

$$\hat{\alpha}_{\text{max}}(T) = \bar{v}_e \sigma_{\text{DR}}^{\text{max}}(\varepsilon = k_B T) \quad (58.124a)$$

$$\approx 5 \times 10^{-7} \left(\frac{300}{T} \right)^{1/2} (2\ell + 1) \text{ cm}^3/\text{s}. \quad (58.124b)$$

Cross section maxima of $5(2\ell + 1)(300/T) \times 10^{-14} \text{ cm}^2$ are therefore possible, being consistent with the rate Eq. (58.124b).

First-Order Quantal Approximation

When the effect of autoionization on the continuum vibrational wave function $\psi_d(R)$ for AB^* is ignored, then a first-order undistorted approximation to the quantal amplitude Eq. (58.119) is

$$T_{\text{B}}(v^+) = 2\pi \int_0^\infty V_{d\varepsilon}^*(R) [\psi_v^{+*}(R) \psi_d^{(0)}(R)] dR, \quad (58.125)$$

where $\psi_d^{(0)}$ is ψ_d in the absence of the back reaction of autoionization. Under this assumption, Eq. (58.118) reduces to

$$\sigma_c(\varepsilon, v^+) = \frac{\pi}{k_e^2} \left(\frac{\omega_{\text{AB}}^*}{2\omega^+} \right) |T_{\text{B}}(v^+)|^2, \quad (58.126)$$

which is then the cross section for initial electron capture since autoionization has been precluded. Although the Born T -matrix Eq. (58.125) violates unitarity, the capture cross section Eq. (58.126) must remain less than the maximum value

$$\sigma_c^{\text{max}} = \frac{\pi}{k_e^2} \left(\frac{\omega_{\text{AB}}^*}{2\omega^+} \right) = \left(\frac{h^2}{8\pi m_e \varepsilon} \right) \left(\frac{\omega_{\text{AB}}^*}{2\omega^+} \right), \quad (58.127)$$

since $|a_Q|^2 \leq 1$. So as to acknowledge after the fact the effect of autoionization, assumed small, and neglected by Eq. (58.125), the DR cross section can be approximated as

$$\sigma_{\text{DR}}(\varepsilon, v^+) = \sigma_c(\varepsilon, v^+) P_{\text{S}}, \quad (58.128)$$

where P_{S} is the probability of survival against autoionization on the V_d curve until stabilization takes place at some crossing point R_X .

Approximate Capture Cross Section

With the energy-normalized Winans–Stückelberg vibrational wave function

$$\psi_d^{(0)}(R) = |V_d'(R)|^{-1/2} \delta(R - R_c), \quad (58.129)$$

where R_c is the classical turning point for $(\text{A}-\text{B}^*)$ relative motion, Eq. (58.126) reduces to

$$\sigma_c(\varepsilon, v^+) = \frac{\pi}{k_e^2} \left(\frac{\omega_{\text{AB}}^*}{2\omega^+} \right) [2\pi \Gamma(R_c)] \left\{ \frac{|\psi_v^+(R_c)|^2}{|V_d'(R_c)|} \right\}, \quad (58.130)$$

where the term inside the braces in Eq. (58.130) is the effective Franck–Condon factor.

Six Approximate Stabilization Probabilities

(1)

A unitarized T -matrix is

$$T = \frac{T_{\text{B}}}{1 + \frac{1}{2}|T_{\text{B}}|^2}, \quad (58.131)$$

so that $P_{\text{S}} = |T|^2/|T_{\text{B}}|^2$ to give

$$\begin{aligned} P_{\text{S}}(\text{low } \varepsilon) &= \left(1 + \frac{1}{4}|T_{\text{B}}|^2 \right)^{-2} \\ &= \left\{ 1 + \pi^2 \left| \int_0^\infty V_{d\varepsilon}^*(R) [\psi_v^{+*}(R) \psi_d^{(0)}(R)] dr \right|^2 \right\}^{-2}, \end{aligned} \quad (58.132a)$$

which is valid at low ε when only one vibrational level v^+ , i.e., the initial level of the ion is repopulated by autoionization.

(2)

At higher ε , when population of many other ionic levels v_f^+ occurs, then

$$P_{\text{S}}(\varepsilon) = \left[1 + \frac{1}{4} \sum_f |T_{\text{B}}(v_f^+)|^2 \right]^{-2}, \quad (58.132b)$$

where the summation is over all the open vibrational levels v_f^+ of the ion. When no intermediate Rydberg $\text{AB}^*(v)$ states are energy resonant with the initial $e^- + \text{AB}^+(v^+)$ state, i.e., coupling with the indirect mechanism is neglected, then Eq. (58.128), with Eq. (58.132b), is the direct DR cross section normally calculated.

(3)

In the high- ε limit, when an infinite number of v_f^+ levels are populated following autoionization, the survival probability, with the aid of closure, is then

$$P_S = \left[1 + \pi^2 \int_{R_c}^{R_X} |V_{d\varepsilon}^*(R)|^2 |\psi_d^{(0)}(R)|^2 dR \right]^{-2}. \quad (58.133)$$

(4)

On adopting in Eq. (58.133) the JWKB semiclassical wave function for $\psi_d^{(0)}$,

$$\begin{aligned} P_S(\text{high } \varepsilon) &= \left[1 + \frac{1}{2\hbar} \int_{R_c}^{R_X} \frac{\Gamma(R)}{v(R)} dR \right]^{-2} \\ &= \left[1 + \frac{1}{2} \int_{t_c}^{t_X} v_a(t) dt \right]^{-2}, \end{aligned} \quad (58.134)$$

where $v(R)$ is the local radial speed of A–B relative motion, and where the frequency $v_a(t)$ of autoionization is Γ/\hbar .

(5)

A classical path local approximation for P_S yields

$$P_S = \exp\left(-\int_{t_c}^{t_X} v_a(t) dt\right), \quad (58.135)$$

which agrees to first order for small v with the expansion of Eq. (58.134).

(6)

A partitioning of Eq. (58.113) yields

$$P_S = v_d/(v_a + v_d) = (1 + v_a\tau_d)^{-1}, \quad (58.136)$$

on adopting macroscopic averaged frequencies v_i and associated lifetimes $\tau_i = v_i^{-1}$. The six survival probabilities in Eqs. (58.132a), (58.132b), (58.132a), (58.133)–(58.136) are all suitable for use in the DR cross section Eq. (58.128).

58.7.3 Noncrossing Mechanism

The dissociative recombination (DR) processes

at low electron energy ε , and

have spurred renewed theoretical interest because they both proceed at respective rates of $(2 \times 10^{-7}$ to $2 \times 10^{-8}) \text{ cm}^3 \text{ s}^{-1}$ and $10^{-8} \text{ cm}^3 \text{ s}^{-1}$ at 300 K. Such rates are generally associated with the direct DR, which involves favorable curve crossings between the potential energy surfaces, $V^+(R)$ and $V_d(R)$ for the ion AB^+ and neutral dissociative AB^{**} states. The difficulty with Eqs. (58.137) and (58.138) is that there are no such curve crossings, except at $\varepsilon \geq 8 \text{ eV}$ for Eq. (58.137). In this instance, the previous standard theories would support only extremely small rates when electronic resonant conditions do not prevail at thermal energies. Theories [49–53] have been developed for application to processes such as Eq. (58.137).

58.8 Mutual Neutralization

Diabatic potentials

$V_i^{(0)}(R)$ and $V_f^{(0)}(R)$ for initial (ionic) and final (covalent) states are diagonal elements of

$$V_{if}(R) = \langle \Psi_i(\mathbf{r}, \mathbf{R}) | \mathcal{H}_{\text{el}}(\mathbf{r}, \mathbf{R}) | \Psi_f(\mathbf{r}, \mathbf{R}) \rangle_r, \quad (58.140)$$

where $\Psi_{i,f}$ are diabatic states, and \mathcal{H}_{el} is the electronic Hamiltonian at fixed internuclear distance R .

Adiabatic potentials for a two-state system

$$V^\pm(R) = V_0(R) \pm \left[\Delta^2(R) + |V_{if}(R)|^2 \right]^{1/2}, \quad (58.141a)$$

$$V_0(R) = \frac{1}{2} \left[V_i^{(0)}(R) + V_f^{(0)}(R) \right], \quad (58.141b)$$

$$\Delta(R) = \left[V_i^{(0)}(R) - V_f^{(0)}(R) \right]. \quad (58.141c)$$

For a single crossing of diabatic potentials at R_X , $V_i^{(0)}(R_X) = V_f^{(0)}(R_X)$ and the adiabatic potentials at R_X are

$$V^\pm(R_X) = V_i^{(0)}(R_X) \pm V_{if}(R_X), \quad (58.142)$$

with energy separation $2V_{if}(R_X)$.

58.8.1 Landau–Zener Probability for Single Crossing at R_X

On assuming $\Delta(R) = (R - R_X)\Delta'(R_X)$, where $\Delta'(R) = d\Delta(R)/dR$, the probability for single crossing is

$$P_{if}(R_X) = \exp[\eta(R_X)/v_X(b)], \quad (58.143a)$$

$$\eta(R_X) = \left(\frac{2\pi}{\hbar} \right) \frac{|V_{if}(R_X)|^2}{\Delta'(R_X)}, \quad (58.143b)$$

$$v_X(b) = \left[1 - V_i^{(0)}(R_X)/E - b^2/R_X^2\right]^{1/2}. \quad (58.143c) \quad (\mathbf{R}, E, L^2)\text{-distribution}$$

Overall Charge-Transfer Probability

From the incoming and outgoing legs of the trajectory,

$$P^X(E) = 2P_{if}(1 - P_{if}). \quad (58.144)$$

58.8.2 Cross Section and Rate Coefficient for Mutual Neutralization

$$\begin{aligned} \sigma_M(E) &= 4\pi \int_0^{b_X} P_{if}(1 - P_{if})b \, db \\ &= \pi b_X^2 P_M, \\ \pi b_X^2 &= \pi \left(1 - \frac{V_i^{(0)}(R_X)}{E}\right) R_X^2 \\ &= \pi \left(1 + \frac{14.4}{R_X(\text{\AA})E(\text{eV})}\right) R_X^2; \end{aligned} \quad (58.145a)$$

P_M is the b^2 -averaged probability Eq. (58.144) for charge-transfer reaction within a sphere of radius R_X .

The rate is

$$\hat{\alpha}_M = (8k_B T/\pi M_{AB})^{1/2} \int_0^\infty \epsilon \sigma_M(\epsilon) e^{-\epsilon} d\epsilon, \quad (58.146)$$

where $\epsilon = E/k_B T$.

58.9 One-Way Microscopic Equilibrium Current, Flux, and Pair Distributions

All quantities on the RHS in the Cases (a)–(e) below are to be multiplied by $\tilde{N}_A \tilde{N}_B [\omega_{AB}/\omega_A \omega_B]$, where the ω_i denote the statistical weights of species i that are not included by the density of states associated with the E, L^2 orbital degrees of freedom.

Case (a)

($i \equiv \mathbf{R}, E, L^2$).

$$\text{Current: } j_i^\pm(\mathbf{R}) = n^\pm(\mathbf{R}, E, L^2) v_R \equiv n_i^\pm v_R.$$

$$\text{Flux: } 4\pi R^2 j_i^\pm(\mathbf{R}) dE dL^2 = \frac{4\pi^2 e^{-E/k_B T}}{(2\pi M_{AB} k_B T)^{3/2}} dE dL^2. \quad (58.147)$$

This flux is independent of R . For dissociated pairs $E > 0$,

$$4\pi R^2 j_i^\pm(\mathbf{R}) dE dL^2 = [\bar{v} \epsilon e^{-\epsilon} d\epsilon] [2\pi b db]. \quad (58.148)$$

$$\begin{aligned} n(\mathbf{R}, E, L^2) d\mathbf{R} dE dL^2 \\ = \frac{(8\pi^2/v_R) e^{-E/k_B T}}{(2\pi M_{AB} k_B T)^{3/2}} \left(\frac{d\mathbf{R}}{4\pi R^2}\right) dE dL^2. \end{aligned} \quad (58.149)$$

Case (b)

($i \equiv \mathbf{R}, E, L^2$)-integrated quantities.

$$\text{Current: } j_i^\pm(\mathbf{R}) = \frac{1}{2} v n^\pm(\mathbf{R}, E) \equiv \frac{1}{2} v n_i^\pm. \quad (58.150)$$

$$\text{Flux: } 4\pi R^2 j_i^\pm(\mathbf{R}) dE = [\bar{v} \epsilon e^{-\epsilon} d\epsilon] \pi b_0^2, \quad (58.151a)$$

$$\pi b_0^2 = \pi R^2 [1 - V(R)/E]. \quad (58.151b)$$

(\mathbf{R}, E)-Distribution:

$$\begin{aligned} n(\mathbf{R}, E) d\mathbf{R} dE \\ = \frac{2}{\sqrt{\pi}} \left[\frac{E - V(R)}{k_B T}\right]^{1/2} e^{-\epsilon} d\epsilon d\mathbf{R} \\ \equiv G_{MB}(E, R) d\mathbf{R}, \end{aligned} \quad (58.151c)$$

which defines the Maxwell–Boltzmann velocity distribution G_{MB} in the presence of the field $V(R)$.

Case (c)

(E, L^2)-integrated quantities.

$$\text{Current: } j^\pm(\mathbf{R}) = \frac{1}{4} \bar{v} e^{-V(R)/k_B T}. \quad (58.152)$$

$$\text{Flux: } 4\pi R^2 j^\pm(\mathbf{R}) = \pi R^2 \bar{v} e^{-V(R)/k_B T}. \quad (58.153)$$

$$\text{Distribution: } n(R) = e^{-V(R)/k_B T}. \quad (58.154)$$

When E -integration is only over dissociated states ($E > 0$), the above quantities are

$$j_d^\pm(\mathbf{R}) = \frac{1}{4} \bar{v} [1 - V(R)/k_B T], \quad (58.155)$$

$$4\pi R^2 j_d^\pm(\mathbf{R}) = \pi R^2 \left(1 - \frac{V(R)}{k_B T}\right) \bar{v} \equiv \pi b_{\max}^2 \bar{v}, \quad (58.156)$$

$$n(R) = [1 - V(R)/k_B T]. \quad (58.157)$$

Case (d)

(E, L^2)-distribution. For bound levels

$$n(E, L^2) dE dL^2 = \frac{4\pi^2 \tau_R(E, L)}{(2\pi M_{AB} k_B T)^{3/2}} e^{-E/k_B T} dE dL^2, \quad (58.158)$$

where $\tau_R = \oint dt = (\partial J_R / \partial E)$ is the period for bounded radial motion of energy E and radial action $J_R(E, L) = M_{AB} \oint v_R dR$.

Case (e)

E -distribution. For bound levels

$$n(E)dE = \frac{2e^{-\varepsilon}}{\sqrt{\pi}} d\varepsilon \int_0^{R_A} \left(\frac{E-V}{k_B T} \right)^{1/2} dR, \quad (58.159)$$

where R_A is the turning point $E = V(R_A)$.

Example

For electron-ion bounded motion, $V(R) = -Ze^2/R$, $R_A = Ze^2/|E|$, $R_e = Ze^2/k_B T$, $\varepsilon = E/k_B T$. Then $\tau_R = 2\pi(m/Ze^2)^{1/2}(R_A/2)^{3/2}$,

$$\int_0^{R_A} \left(\frac{R_e}{R} - |\varepsilon| \right)^{1/2} dR = \frac{\pi^2}{4} R_A^{5/2} R_e^{1/2}, \quad (58.160)$$

and

$$n^s(E)dE = \left(\frac{2e^{-\varepsilon}}{\sqrt{\pi}} d\varepsilon \right) \frac{\pi^2}{4} R_A^{5/2} R_e^{1/2} \quad (58.161)$$

$$= \left(\frac{2e^{-\varepsilon}}{\sqrt{\pi}} d\varepsilon \right) \left(\frac{\pi^2 R_e^3}{4|\varepsilon|^{5/2}} \right). \quad (58.162)$$

For closely spaced levels in a hydrogenic $e^- - A^{Z+}$ system,

$$n^s(p, \ell) = n(E, L^2) \left(\frac{dE}{dp} \right) \left(\frac{dL^2}{d\ell} \right), \quad (58.163a)$$

$$n^s(p) = n(E) \left(\frac{dE}{dp} \right). \quad (58.163b)$$

Using $E = -(2p^2)^{-1}(Z^2e^2/a_0)$ and $L^2 = (\ell + 1/2)^2\hbar^2$ for level (p, ℓ) then

$$\tau_R(E, L) \frac{dE}{dp} \left(\frac{dL^2}{d\ell} \right) = \left(\frac{dJ_R}{dp} \right) \left(\frac{dL^2}{d\ell} \right) \quad (58.164)$$

$$= h((2\ell + 1)\hbar^2), \quad (58.165)$$

$$\frac{n^s(p, \ell)}{n_e N^+} = \frac{2(2\ell + 1)}{2\omega_A^+} \frac{h^3}{(2\pi m_e k_B T)^{3/2}} e^{I_p/k_B T}, \quad (58.166a)$$

$$\frac{n^s(p)}{n_e N^+} = \frac{2p^2}{2\omega_A^+} \frac{h^3}{(2\pi m_e k_B T)^{3/2}} e^{I_p/k_B T}, \quad (58.166b)$$

in agreement with the Saha ionization formula Eq. (58.28), where N^+ is the equilibrium concentration of A^{Z+} ions in their ground electronic states. The spin statistical weights are $\omega_{eA} = \omega_e = 2$.

Notation:

M_{AB} reduced mass $M_A M_B / (M_A + M_B)$

R internal separation of A–B

E orbital energy $\frac{1}{2}Mv^2 + V(R)$

L orbital angular momentum

L^2 $2MEb^2$ for $E > 0$

v_R radial speed $|\dot{R}|$

\bar{v} mean relative speed $(8kT/\pi M_{AB})^{1/2}$

ε normalized energy $E/k_B T$

n_i pair distribution function $n_i^+ + n_i^-$

n_i^\pm component of n_i with $\dot{R} > 0$ (+) and $\dot{R} < 0$ (-).

58.10 Microscopic Methods for Termolecular Ion–Ion Recombination

At low gas density, the basic process

is characterized by nonequilibrium with respect to E . Dissociated and bound $A^+ - B^-$ ion pairs are in equilibrium with respect to their separation R , but bound pairs are not in E -equilibrium with each other; L^2 -equilibrium can be assumed for ion–ion recombination but not for ion–atom association reactions.

At higher gas densities N , there is nonequilibrium in the ion-pair distributions with respect to R , E , and L^2 . In the limit of high N , there is only nonequilibrium with respect to R . See [54] for full details.

58.10.1 Time-Dependent Method: Low Gas Density

Energy levels E_i of $A^+ - B^-$ pairs are so close that they form a quasi continuum with a nonequilibrium distribution over E_i determined by the master equation

$$\frac{dn_i(t)}{dt} = \int_{-D}^{\infty} (n_i v_{if} - n_f v_{fi}) dE_f, \quad (58.168)$$

where $n_i dE_i$ is the number density of pairs in the interval dE_i about E_i , and $v_{if} dE_f$ is the frequency of i -pair collisions with M that change the i -pair orbital energy from E_i to between E_f and $E_f + dE_f$. The greatest binding energy of the $A^+ - B^-$ pair is D .

Association Rate

$$R^A(t) = \int_{-D}^{\infty} P_i^S \left(\frac{dn_i}{dt} \right) dE_i \quad (58.169a)$$

$$= \hat{\alpha} N_A(t) N_B(t) - k n_s(t), \quad (58.169b)$$

where P_i^S is the probability for collisional stabilization (recombination) of i -pairs via a sequence of energy changing collisions with M. The coefficients for $C \rightarrow S$ recombination out of the C -block with ion concentrations $N_A(t)$, $N_B(t)$ (in cm^{-3}) into the S block of total ion-pair concentrations $n_s(t)$ and for $S \rightarrow C$ dissociation are $\hat{\alpha}$ ($\text{cm}^3 \text{s}^{-1}$) and k (s^{-1}), respectively.

One-Way Equilibrium Collisional Rate and Detailed Balance

$$C_{if} = \tilde{n}_i v_{if} = \tilde{n}_f v_{fi} = C_{fi} , \quad (58.170)$$

where the tilde denotes equilibrium (Saha) distributions.

Normalized Distribution Functions

$$\gamma_i(t) = n_i(t)/\tilde{n}_i^S , \quad \gamma_s(t) = n_s(t)/\tilde{n}_s^B(t) , \quad (58.171)$$

$$\gamma_c(t) = N_A(t)N_B(t)/\tilde{N}_A\tilde{N}_B , \quad (58.172)$$

where \tilde{n}_i^S and \tilde{n}^B are the Saha and Boltzmann distributions.

Master Equation for $\gamma_i(t)$

$$\frac{d\gamma_i(t)}{dt} = - \int_{-D}^{\infty} [\gamma_i(t) - \gamma_f(t)] v_{if} dE_f . \quad (58.173)$$

Quasi-Steady State (QSS) Reduction

Set

$$\gamma_i(t) = P_i^D \gamma_c(t) + P_i^S \gamma_s(t) \xrightarrow{t \rightarrow \infty} 1 , \quad (58.174)$$

where P_i^D and P_i^S are the respective time-independent portions of the normalized distribution γ_i , which originate, respectively, from blocks C and S . The energy separation between the C and S blocks is so large that $P_i^S = 0$ ($E_i \geq 0$, C block), $P_i^S \leq 1$ ($0 > E_i \geq -S$, \mathcal{E} block), and $P_i^S = 1$ ($-S \geq E_i \geq -D$, S block). Since $P_i^S + P_i^D = 1$, then

$$\frac{d\gamma_i(t)}{dt} = -[\gamma_c(t) - \gamma_s(t)] \int_{-D}^{\infty} (P_i^D - P_f^D) C_{if} dE_f . \quad (58.175)$$

Recombination and Dissociation Coefficients

Equation (58.174) in Eq. (58.169a) enables the recombination rate in Eq. (58.169b) to be written as

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-D}^{\infty} P_i^D dE_i \int_{-D}^{\infty} (P_i^D - P_f^D) C_{if} dE_f . \quad (58.176)$$

The QSS condition ($dn_i/dt = 0$ in block \mathcal{E}) is then

$$P_i^D \int_{-D}^{\infty} v_{if} dE_f = \int_{-D}^E v_{if} P_f^D dE_f , \quad (58.177)$$

which involves only time-independent quantities. Under QSS, Eq. (58.176) reduces to the net downward current across bound level $-E$,

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-E}^{\infty} dE_i \int_{-D}^{-E} (P_i^D - P_f^D) C_{if} dE_f , \quad (58.178)$$

which is independent of the energy level ($-E$) in the range $0 \geq -E \geq -S$ of block \mathcal{E} .

The dissociation frequency k in Eq. (58.169b) is

$$k \tilde{n}_s = \int_{-D}^{-E} dE_i \int_{-E}^{\infty} (P_i^S - P_f^S) C_{if} dE_f , \quad (58.179)$$

and macroscopic detailed balance $\hat{\alpha} \tilde{N}_A \tilde{N}_B = k \tilde{n}_s$ is automatically satisfied; $\hat{\alpha}$ is the direct ($C \rightarrow S$) collisional contribution (small) plus the (much larger) net collisional cascade downward contribution from that fraction of bound levels that originated in the continuum C ; k_d is the direct dissociation frequency (small) plus the net collisional cascade upward contribution from that fraction of bound levels that originated in block S .

58.10.2 Time-Independent Methods: Low Gas Density

QSS rate

Since recombination and dissociation (ionization) involve only that fraction of the bound state population that originated from the C and S blocks, respectively, recombination can be viewed as time independent with

$$N_A N_B = \tilde{N}_A \tilde{N}_B , \quad n_s(t) = 0 , \quad (58.180a)$$

$$\rho_i = n_i / \tilde{n}_i \equiv P_i^D \quad (58.180b)$$

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-E}^{\infty} dE_i \int_{-D}^{-E} (\rho_i - \rho_f) C_{if} dE_f . \quad (58.180c)$$

QSS integral equation

$$\rho_i \int_{-D}^{\infty} v_{if} dE_f = \int_{-S}^{\infty} \rho_f v_{if} dE_f \quad (58.181)$$

is solved subject to the boundary condition

$$\rho_i = 1 (E_i \geq 0) , \quad \rho_i = 0 (-S \geq E_i \geq -D) . \quad (58.182)$$

Collisional energy-change moments

$$D^{(m)}(E_i) = \frac{1}{m!} \int_{-D}^{\infty} (E_f - E_i)^m C_{if} dE_f, \quad (58.183)$$

$$D_i^{(m)} = \frac{1}{m!} \frac{d}{dt} \langle (\Delta E)^m \rangle. \quad (58.184)$$

Averaged energy-change frequency

For an equilibrium distribution \tilde{n}_i of E_i -pairs per unit interval dE_i per second,

$$D_i^{(1)} = \frac{d}{dt} \langle \Delta E \rangle.$$

Averaged energy-change per collision

$$\langle \Delta E \rangle = D_i^{(1)} / D_i^{(0)}.$$

Time-independent dissociation

The time-independent picture corresponds to

$$n_s(t) = \tilde{n}_s, \quad \gamma_c(t) = 0, \quad \rho_i = n_i / \tilde{n}_i \equiv P_i^S, \quad (58.185)$$

in analogy to the macroscopic reduction of Eqs. (58.50a,58.50b).

Variational Principle

The QSS condition Eq. (58.174) implies that the fraction P_i^D of bound levels i with precursor C are so distributed over i that Eq. (58.176) for $\hat{\alpha}$ is a minimum. Hence P_i^D or ρ_i are obtained either from the solution of Eq. (58.181) or from minimizing the variational functional

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-D}^{\infty} n_i dE_i \int_{-D}^{\infty} (\rho_i - \rho_f) v_{if} dE_f \quad (58.186a)$$

$$= \frac{1}{2} \int_{-D}^{\infty} dE_i \int_{-D}^{\infty} (\rho_i - \rho_f)^2 C_{if} dE_f, \quad (58.186b)$$

with respect to variational parameters contained in a trial analytic expression for ρ_i . Minimization of the quadratic functional Eq. (58.186b) has an analogy with the principle of least dissipation in the theory of electrical networks.

Diffusion-in-Energy-Space Method

Integral Eq. (58.181) can be expanded in terms of energy-change moments, via a Fokker–Planck analysis to yield the differential equation

$$\frac{\partial}{\partial E_i} \left(D_i^{(2)} \frac{\partial \rho_i}{\partial E_i} \right) = 0, \quad (58.187)$$

with the QSS analytical solution

$$\rho_i(E_i) = \left(\int_{E_i}^0 \frac{dE}{D^{(2)}(E)} \right) \left(\int_{-S}^0 \frac{dE}{D^{(2)}(E)} \right)^{-1} \quad (58.188)$$

of *Pitaevskii* [33] for ($e^- + A^+ + M$) recombination where collisional energy changes are small. This distribution does not satisfy the exact QSS condition Eq. (58.181). When inserted in the exact non-QSS rate Eq. (58.186b), highly accurate $\hat{\alpha}$ for heavy-particle recombination are obtained.

Bottleneck Method

The one-way equilibrium rate ($\text{cm}^{-3} \text{s}^{-1}$) across $-E$, i.e., Eq. (58.180c) with $\rho_i = 1$ and $\rho_f = 0$, is

$$\hat{\alpha}(-E) \tilde{N}_A \tilde{N}_B = \int_{-E}^{\infty} dE_i \int_{-D}^{-E} C_{if} dE_f. \quad (58.189)$$

This is an upper limit to Eq. (58.180c) and exhibits a minimum at $-E^*$, the bottleneck location. The least upper limit to $\hat{\alpha}$ is then $\hat{\alpha}(-E^*)$.

Trapping Radius Method

Assume that pairs with internal separation $R \leq R_T$ recombine with unit probability so that the one-way equilibrium rate across the dissociation limit at $E = 0$ for these pairs is

$$\hat{\alpha}(R_T) \tilde{N}_A \tilde{N}_B = \int_0^{R_T} dR \int_{V(R)}^0 C_{if}(R) dE_f, \quad (58.190)$$

where $V(R) = -e^2/R$, and $C_{if}(R) = \tilde{n}_i(R) v_{if}(R)$ is the rate per unit interval ($dR dE_i$) dE_f for the $E_i \rightarrow E_f$ collisional transitions at fixed R in

$$(A^+ - B^-)_{E_i,R} + M \rightarrow (A^+ - B^-)_{E_f,R} + M. \quad (58.191)$$

The concentration (cm^{-3}) of pairs with internal separation R and orbital energy E_i in the interval $dR dE_i$ about (R, E_i) is $\tilde{n}_i(R) dR dE_i$. Agreement with the exact treatment [54] is found by assigning $R_T = (0.48 - 0.55)(e^2/k_B T)$ for the recombination of equal mass ions in an equal mass gas for various ion–neutral interactions.

58.10.3 Recombination at Higher Gas Densities

As the density N of the gas M is raised, the recombination rate $\hat{\alpha}$ increases initially as N to such an extent that there are increasingly more pairs $n_i^-(R, E)$ in a state of contraction in

R than there are those $n_i^+(R, E)$ in a state of expansion; i.e., the ion-pair distribution densities $n_i^\pm(R, E)$ per unit interval $dE dR$ are not in equilibrium with respect to R in blocks C and \mathcal{E} . Those in the highly excited block \mathcal{E} , in addition, are not in equilibrium with respect to energy E . Basic sets of coupled master equations have been developed [54] for the microscopic nonequilibrium distributions $n^\pm(R, E, L^2)$ and $n^\pm(R, E)$ of expanding (+) and contracting (−) pairs with respect to A–B separation R , orbital energy E , and orbital angular momentum L^2 . With $n(\mathbf{R}, E_i, L_i^2) \equiv n_i(R)$ and using the notation defined at the beginning of Sect. 58.6, the distinct regimes for the master equations discussed in Sect. 58.10.4 are:

Low N equilibrium in R , but not in E, L^2
 → master equation for $n(E, L^2)$.

Pure Coulomb equilibrium in L^2

Attraction → master equation for $n(E)$.

High N nonequilibrium in R, E, L^2

→ master equation for $n_i^\pm(R)$.

Highest N equilibrium in (E, L^2) but not in R

→ macroscopic transport equation

Eq. (58.68a) in $n(R)$.

Normalized Distributions

For a state $|i \Rightarrow E, L^2$,

$$\begin{aligned} \rho_i(R) &= \frac{n_i(R)}{\tilde{n}_i(R)}, & \rho_i^\pm(R) &= \frac{n_i^\pm(R)}{\tilde{n}_i^\pm(R)}, \\ \rho_i(R) &= \frac{1}{2}(\rho_i^+ + \rho_i^-). \end{aligned} \quad (58.192)$$

Orbital Energy and Angular Momentum

$$E_i = \frac{1}{2}M_{AB}v^2 + V(R), \quad (58.193a)$$

$$E_i = \frac{1}{2}M_{AB}v_R^2 + V_i(R), \quad (58.193b)$$

$$V_i(R) = V(R) + \frac{L_i^2}{2M_{AB}R^2}, \quad (58.193c)$$

$$\begin{aligned} L_i &= |\mathbf{R} \times M_{AB}\mathbf{v}|, \\ L_i^2 &= (2M_{AB}E_i)b^2, \quad E_i > 0. \end{aligned} \quad (58.193d)$$

Maximum Orbital Angular Momenta

(1) A specified separation R can be accessed by all orbits of energy E_i with L_i^2 between 0 and

$$L_{im}^2(E_i, R) = 2M_{AB}R^2[E_i - V(R)]. \quad (58.194a)$$

(2) Bounded orbits of energy $E_i < 0$ can have L_i^2 between 0 and

$$L_{ic}^2(E_i) = 2M_{AB}R_c^2[E_i - V(R_c)], \quad (58.194b)$$

where R_c is the radius of the circular orbit determined by $\partial V_i/\partial R = 0$, i.e., by $E_i = V(R_c) + \frac{1}{2}R_c(\partial V/\partial R)_{R_c}$.

58.10.4 Master Equations

Master Equation for $n_i^\pm(R) \equiv n^\pm(R, E_i, L_i^2)$ [54]

$$\begin{aligned} &\pm \frac{1}{R^2} \frac{\partial}{\partial R} [R^2 n_i^\pm(R) |v_R|]_{E_i, L_i^2} \\ &= - \int_{V(R)}^{\infty} dE_f \int_0^{L_{fm}^2} dL_f^2 [n_i^\pm(R) v_{if}(R) \\ &\quad - n_f^\pm(R) v_{fi}(R)]. \end{aligned} \quad (58.195)$$

The set of master equations [54] for n_i^+ is coupled to the n_i^- set by the boundary conditions $n_i^-(R_i^\mp) = n_i^+(R_i^\mp)$ at the pericenter R_i^- for all E_i and apocenter R_i^+ for $E_i < 0$ of the E_i, L_i^2 -orbit.

Master Equations for Normalized Distributions [54]

$$\begin{aligned} \pm |v_R| \frac{\partial \rho_i^\pm}{\partial R} &= - \int_{V(R)}^{\infty} dE_f \int_0^{L_{fm}^2} dL_f^2 \\ &\quad \times [\rho_i^\pm(R) - \rho_f^\pm(R)] v_{if}(R). \end{aligned} \quad (58.196)$$

Corresponding master equations for the L^2 integrated distributions $n^\pm(R, E)$ and $\rho^\pm(R, E)$ have been derived [54].

Continuity Equations

$$J_i = [n_i^+(R) - n_i^-(R)] |v_R| = (\rho_i^+ - \rho_i^-) \tilde{j}_i^\pm, \quad (58.197)$$

$$\begin{aligned} \frac{1}{R^2} \frac{\partial}{\partial R} (R^2 J_i) &= - \int_{V(R)}^{\infty} dE_f \int_0^{L_{fm}^2} dL_f^2 \\ &\quad \times [n_i(R) v_{if}(R) - n_f(R) v_{fi}(R)], \end{aligned} \quad (58.198)$$

$$\begin{aligned} \frac{1}{2} |v_R| \frac{\partial [\rho_i^+(R) - \rho_i^-(R)]}{\partial R} \\ &= - \int_{V(R)}^{\infty} dE_f \int_0^{L_{fm}^2} dL_f^2 [\rho_i(R) - \rho_f(R)] v_{if}(R). \end{aligned} \quad (58.199)$$

58.10.5 Recombination Rate

Flux Representation

The $R_0 \rightarrow \infty$ limit of

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = -4\pi R_0^2 J(R_0) \quad (58.200)$$

has the microscopic generalization

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{V(R_0)}^{\infty} dE_i \int_0^{L_{ic}^2} dL_i^2 [4\pi R_0^2 \tilde{j}_i^{\pm}(R_0)] \times [\rho_i^-(R_0) - \rho_i^+(R_0)], \quad (58.201)$$

where L_{ic}^2 is given by Eq. (58.194b) with $R_c = R_0$ for bound states and is infinite for dissociated states, and where

$$\rho_i^-(R_0) - \rho_i^+(R_0) = \oint_{R_i}^{R_0} \rho_i(R) [v_i^b(R) + v_i^c(R)] dt, \quad (58.202)$$

with

$$\begin{aligned} \rho_i(R) v_i^b(R) &= \int_{V(R)}^{V(R_0)} dE_f \int_0^{L_{fm}^2} dL_f^2 [\rho_i(R) - \rho_f(R)] \\ &\quad \times v_{if}(R), \\ \rho_i(R) v_i^c(R) &= \int_{V(R_0)}^{\infty} dE_f \int_0^{L_{fm}^2} dL_f^2 [\rho_i(R) - \rho_f(R)] \\ &\quad \times v_{if}(R). \end{aligned} \quad (58.203a)$$

Collisional Representation

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{V(R_0)}^{\infty} dE_i \int_0^{L_{ic}^2} dL_i^2 \int_{R_i}^{R_0} \tilde{n}_i(R) dR \times [\rho_i(R) v_i^b(R)], \quad (58.204)$$

which is the microscopic generalization of the macroscopic result $\hat{\alpha} = K \rho^* v_s = \alpha_{RN}(R_0) \rho(R_0)$.

The flux for dissociated pairs $E_i > 0$ is

$$4\pi R^2 |v_R| \tilde{n}_i^{\pm}(R) dE dL^2 = [\bar{v} \varepsilon e^{-\varepsilon} d\varepsilon] [2\pi b db] \tilde{N}_A \tilde{N}_B, \quad (58.205)$$

so the rate Eq. (58.204) as $R_0 \rightarrow \infty$ is

$$\hat{\alpha} = \bar{v} \int_0^{\infty} \varepsilon e^{-\varepsilon} d\varepsilon \int_0^{b_0} 2\pi b db \oint_{R_i}^{R_0} \rho_i(R) v_i^b(R) dt, \quad (58.206)$$

which is the microscopic generalization Eq. (58.57b) of the macroscopic result $\hat{\alpha} = k_c P^S$ of Eq. (58.56).

Reaction Rate $\alpha_{RN}(R_0)$

On solving Eq. (58.196) subject to $\rho(R_0) = 1$, according to Eq. (58.68b), $\hat{\alpha}$ determined by Eq. (58.201) is the rate $\hat{\alpha}_{RN}$ of recombination within the (A – B) sphere of radius R_0 . The overall rate of recombination $\hat{\alpha}$ is then given by the full diffusional-drift reaction rate Eq. (58.71b) where the rate of transport to R_0 is determined uniquely by Eq. (58.72).

58.11 Radiative Recombination

In the radiative recombination (RR) process

the accelerating electron e^- with energy and angular momentum (E, ℓ') is captured, via coupling with the weak quantum electrodynamic interaction $(e/m_e c) \mathbf{A} \cdot \mathbf{p}$ associated with the electromagnetic field of the moving ion, into an excited state $n\ell$ with binding energy $I_{n\ell}$ about the parent ion A^{Z+} (initially in an electronic state c). The simultaneously emitted photon carries away the excess energy $h\nu = E + I_{n\ell}$ and angular momentum difference between the initial and final electronic states. The cross section $\sigma_R^{n\ell}(E)$ for RR is calculated (a) from the Einstein A coefficient for free-bound transitions or (b) from the cross section $\sigma_I^{n\ell}(h\nu)$ for photoionization (PI) via the detailed balance (DB) relationship appropriate to Eq. (58.207).

The rates $\langle v_e \sigma_R \rangle$ and averaged cross sections $\langle \sigma_R \rangle$ for a Maxwellian distribution of electron speeds v_e are then determined from either

$$\begin{aligned} \hat{\alpha}_R^{n\ell}(T_e) &= \bar{v}_e \int_0^{\infty} \varepsilon \sigma_R^{n\ell}(\varepsilon) \exp(-\varepsilon) d\varepsilon \\ &= \bar{v}_e \langle \sigma_R^{n\ell}(T_e) \rangle, \end{aligned} \quad (58.208)$$

where $\varepsilon = E/k_B T_e$, or from the Milne DB relation Eq. (58.281) between the forward and reverse macroscopic rates of Eq. (58.207). Using the hydrogenic semiclassical σ_f^j of *Kramers* [34], together with an asymptotic expansion [55] for the g -factor of *Gaunt* [56], the quantal/semiclassical cross section ratio in Eq. (58.287), *Seaton* [57] calculated $\hat{\alpha}_R^{n\ell}$.

The rate of electron energy loss in RR is

$$\left\langle \frac{dE}{dt} \right\rangle_{n\ell} = n_e \bar{v}_e (k_B T_e) \int_0^{\infty} \varepsilon^2 \sigma_R^{n\ell}(\varepsilon) e^{-\varepsilon} d\varepsilon, \quad (58.209)$$

and the radiated power produced in RR is

$$\left\langle \frac{d(h\nu)}{dt} \right\rangle_{n\ell} = n_e \bar{v}_e \int_0^{\infty} \varepsilon h\nu \sigma_R^{n\ell}(\varepsilon) e^{-\varepsilon} d\varepsilon. \quad (58.210)$$

Standard conversions

$$E = p_e^2/2m_e = \hbar^2 k_e^2/2m_e = k_e^2 a_0^2 (e^2/2a_0) \quad (58.211a)$$

$$= \kappa^2 (Z^2 e^2/2a_0) = \varepsilon (Z^2 e^2/2a_0), \quad (58.211b)$$

$$E_v = h\nu = \hbar\omega = \hbar k_\nu c = (I_n + E) \quad (58.211c)$$

$$\equiv (1 + n^2 \varepsilon) (Z^2 e^2/2n^2 a_0), \quad (58.211d)$$

$$h\nu/I_n = 1 + n^2 \varepsilon, \quad k_e^2 a_0^2 = 2E/(e^2/a_0), \quad (58.211e)$$

$$k_\nu a_0 = (h\nu)\alpha/(e^2/a_0), \quad (58.211f)$$

$$k_\nu^2/k_e^2 = (h\nu)^2/(2Em_e c^2) \quad (58.211g)$$

$$= \alpha^2 (h\nu)^2/[2E(e^2/a_0)], \quad (58.211h)$$

$$I_H = e^2/2a_0, \quad \alpha = e^2/\hbar c = 1/137.0359895,$$

$$\alpha^{-2} = m_e c^2/(e^2/a_0), \quad I_n = (Z^2/n^2)I_H. \quad (58.211i)$$

The electron and photon wavenumbers are k_e and k_ν , respectively.

58.11.1 Detailed Balance and Recombination-Ionization Cross Sections

Cross sections $\sigma_R^{n\ell}(E)$ and $\sigma_I^{n\ell}(h\nu)$ for radiative recombination (RR) into and photoionization (PI) out of level $n\ell$ of atom A are interrelated by the detailed balance relation

$$g_e g_A^+ k_e^2 \sigma_R^{n\ell}(E) = g_\nu g_A k_\nu^2 \sigma_I^{n\ell}(h\nu), \quad (58.212)$$

where $g_e = g_\nu = 2$. Electronic statistical weights of A and A^+ are g_A and g_A^+ , respectively. Thus, using Eq. (58.211g) for k_ν^2/k_e^2 ,

$$\sigma_R^{n\ell}(E) = \left(\frac{g_A}{2g_A^+} \right) \left(\frac{(h\nu)^2}{Em_e c^2} \right) \sigma_I^{n\ell}(h\nu). \quad (58.213)$$

The statistical factors are:

(a) For $(A^+ + e^-)$ state $c[S_c, L_c; \varepsilon, \ell', m']$:

$$g_A^+ = (2S_c + 1)(2L_c + 1).$$

(b) For $A(n\ell)$ state $b[S_c, L_c; n, \ell]SL$

$$g_A = (2S + 1)(2L + 1).$$

(c) For $n\ell$ electron outside a closed shell

$$g_A^+ = 1, \quad g_A = 2(2\ell + 1).$$

Cross sections are averaged over initial and summed over final degenerate states. For case (c),

$$\sigma_I^n = \frac{1}{n^2} \sum_{\ell=0}^{n-1} (2\ell + 1) \sigma_I^{n\ell}; \quad (58.214a)$$

$$\sigma_R^n = \sum_{\ell=0}^{n-1} 2(2\ell + 1) \sigma_R^{n\ell}. \quad (58.214b)$$

58.11.2 Kramers Cross Sections, Rates, Electron Energy-Loss Rates, and Radiated Power for Hydrogenic Systems

These are all calculated from application of the detailed balance Eq. (58.212) to the original $\sigma_I^n(h\nu)$ of *Kramers* [34].

Semiclassical (Kramers) Cross Sections

For hydrogenic systems,

$$I_n = \frac{Z^2 e^2}{2n^2 a_0}, \quad h\nu = I_n + E. \quad (58.215)$$

The results below are expressed in terms of the quantities

$$b_n = \frac{I_n}{k_B T_e}, \quad (58.216)$$

$$\sigma_{10}^n = \frac{64\pi a_0^2 \alpha}{3\sqrt{3}} \left(\frac{n}{Z^2} \right) = 7.907071 \times 10^{-18} (n/Z^2) \text{ cm}^2, \quad (58.217)$$

$$\sigma_{R0}(E) = \left(\frac{8\pi a_0^2 \alpha^3}{3\sqrt{3}} \right) \frac{(Z^2 e^2/a_0)}{E}, \quad (58.218)$$

$$\hat{\alpha}_0(T_e) = \bar{v}_e \left(\frac{8\pi a_0^2 \alpha^3}{3\sqrt{3}} \right) \frac{(Z^2 e^2/a_0)}{k_B T_e}. \quad (58.219)$$

PI and RR cross sections for level n

In the Kramer (K) semiclassical approximation,

$$\kappa \sigma_I^n(h\nu) = \left(\frac{I_n}{h\nu} \right)^3 \sigma_{10}^n = \kappa \sigma_I^{n\ell}(h\nu), \quad (58.220)$$

$$\begin{aligned} \kappa \sigma_R^n(E) &= \sigma_{R0}(E) \left(\frac{2}{n} \right) \left(\frac{I_n}{I_n + E} \right) \\ &= 3.897 \times 10^{-20} \\ &\quad \times [n\varepsilon(13.606 + n^2\varepsilon^2)]^{-1} \text{ cm}^2, \end{aligned} \quad (58.221)$$

where ε is in units of eV and is given by

$$\varepsilon = E/Z^2 \equiv (2.585 \times 10^{-2}/Z^2)(T_e/300). \quad (58.222)$$

Equation (58.221) illustrates that RR into low n at low E is favored.

Cross section for RR into level $n\ell$

$$\kappa\sigma_{\text{R}}^{n\ell} = [(2\ell + 1)/n^2] \kappa\sigma_{\text{R}}^n. \quad (58.223)$$

Rate for RR into level n

$$\hat{\alpha}_{\text{R}}^n(T_e) = \hat{\alpha}_0(T_e)(2/n)b_n e^{b_n} E_1(b_n), \quad (58.224a)$$

which for large b_n (i.e., $k_{\text{B}}T_e \ll I_n$) tends to

$$\begin{aligned} \hat{\alpha}_{\text{R}}^n(T_e \rightarrow 0) &= \hat{\alpha}_0(T_e)(2/n) \\ &\times (1 - b_n^{-1} + 2b_n^{-2} - 6b_n^{-3} + \dots). \end{aligned} \quad (58.224b)$$

The Kramers cross section for photoionization at threshold is $\sigma_{\text{R}0}^n$, and

$$\sigma_{\text{R}0}^n = 2\sigma_{\text{R}0}/n; \quad \hat{\alpha}_0^n = 2\hat{\alpha}_0/n \quad (58.225)$$

provide the corresponding Kramers cross section and rate for recombination as $E \rightarrow 0$ and $T_e \rightarrow 0$, respectively.

RR Cross sections and rates into all levels $n \geq n_f$

$$\begin{aligned} \sigma_{\text{R}}^{\text{T}}(E) &= \int_{n_f}^{\infty} \sigma_{\text{R}}^n(E) dn \\ &= \sigma_{\text{R}0}(E) \ln(1 + I_f/E), \end{aligned} \quad (58.226a)$$

$$\hat{\alpha}_{\text{R}}^{\text{T}}(T_e) = \hat{\alpha}_0(T_e)[\gamma + \ln b_f + e^{b_f} E_1(b_f)]. \quad (58.226b)$$

Useful integrals

$$\int_0^{\infty} e^{-x} \ln x dx = \gamma, \quad (58.227a)$$

$$\int_b^{\infty} x^{-1} e^{-x} dx = E_1(b), \quad (58.227b)$$

$$\int_0^b e^x E_1(x) dx = \gamma + \ln b + e^b E_1(b), \quad (58.227c)$$

$$\begin{aligned} \int_0^b [1 - x e^x E_1(x)] dx \\ = \gamma + \ln b + e^b(1 - b)E_1(b), \end{aligned} \quad (58.227d)$$

where $\gamma = 0.5772157$ is Euler's constant, and $E_1(b)$ is the first exponential integral such that

$$\begin{aligned} b e^b E_1(b) \\ \xrightarrow{b \gg 1} 1 - b^{-1} + 2b^{-2} - 6b^{-3} + 24b^{-4} + \dots \end{aligned}$$

Electron Energy Loss Rate**Energy loss rate for RR into level n**

$$\left\langle \frac{dE}{dt} \right\rangle_n = n_e \hat{\alpha}_{\text{R}}^n(T_e) k_{\text{B}} T_e \left(\frac{1 - b_n e^{b_n} E_1(b_n)}{e^{b_n} E_1(b_n)} \right), \quad (58.228a)$$

which for large b_n (i.e. $(k_{\text{B}}T_e) \ll I_n$) tends to

$$n_e \hat{\alpha}_{\text{R}}^n(T_e) k_{\text{B}} T_e (1 - b_n^{-1} + 3b_n^{-2} - 13b_n^{-3} + \dots), \quad (58.228b)$$

with Eq. (58.224a) for $\hat{\alpha}_{\text{R}}^n$.

Energy loss rate for RR into all levels $n \geq n_f$

$$\begin{aligned} \left\langle \frac{dE}{dt} \right\rangle \\ = n_e k_{\text{B}} T_e \hat{\alpha}_0(T_e) [\gamma + \ln b_f + e^{b_f} E_1(b_f)(1 - b_f)] \end{aligned} \quad (58.229a)$$

$$= n_e (k_{\text{B}} T_e) [\hat{\alpha}_{\text{R}}^{\text{T}}(T_e) - \hat{\alpha}_0(T_e) b_f e^{b_f} E_1(b_f)], \quad (58.229b)$$

with Eqs. (58.226b) and (58.219) for $\hat{\alpha}_{\text{R}}^{\text{T}}$ and $\hat{\alpha}_0$.

Radiated Power**Radiated power for RR into level n**

$$\left\langle \frac{d(h\nu)}{dt} \right\rangle_n = n_e \hat{\alpha}_{\text{R}}^n(T_e) I_n [b_n e^{b_n} E_1(b_n)]^{-1}, \quad (58.230a)$$

which for large b_n (i.e. $(k_{\text{B}}T_e) \ll I_n$) tends to

$$n_e \hat{\alpha}_{\text{R}}^n(T_e) I_n (1 + b_n^{-1} - b_n^{-2} + 3b_n^{-3} + \dots). \quad (58.230b)$$

Radiated power for RR into all levels $n \geq n_f$

$$\left\langle \frac{d(h\nu)}{dt} \right\rangle = n_e \hat{\alpha}_0(T_e) I_f. \quad (58.231)$$

To allow n -summation, rather than integration as in Eq. (58.226a), $1/2\sigma_{\text{R}}^{n_f}$, $1/2\hat{\alpha}_{\text{R}}^{n_f}$, $1/2\langle dE/dt \rangle_{n_f}$, and $1/2\langle d(h\nu)/dt \rangle_{n_f}$, respectively, are added to each of the above expressions. The expressions valid for bare nuclei of charge Z are also fairly accurate for recombination to a core of charge Z_c and atomic number Z_A , provided that Z is identified as $1/2(Z_A + Z_c)$.

Differential cross sections for Coulomb elastic scattering

$$\sigma_{\text{c}}(E, \theta) = \frac{b_0^2}{4 \sin^4 \frac{1}{2}\theta}, \quad b_0^2 = (Ze^2/2E)^2. \quad (58.232)$$

The integral cross section for Coulomb scattering by $\theta \geq \pi/2$ at energy $E = (3/2)k_{\text{B}}T$ is

$$\sigma_{\text{c}}(E) = \pi b_0^2 = \frac{1}{9} \pi R_{\text{e}}^2, \quad R_{\text{e}} = e^2/k_{\text{B}}T. \quad (58.233)$$

Photon emission probability

$$P_\nu = \sigma_R^n(E)/\sigma_c(E). \quad (58.234a)$$

This is small and increases with decreasing n as

$$P_\nu(E) = \left(\frac{8\alpha^3}{3\sqrt{3}}\right) \frac{8}{n} \frac{E}{(e^2/a_0)} \left(\frac{I_n}{h\nu}\right). \quad (58.234b)$$

58.11.3 Basic Formulae for Quantal Cross Sections**Radiative Recombination and Photoionization Cross Sections**

The cross section $\sigma_R^{n\ell}$ for recombination follows from the continuum-bound transition probability P_{if} per unit time. It is also provided by the detailed balance relation Eq. (58.212) in terms of $\sigma_I^{n\ell}$, which follows from P_{fi} . The number of radiative transitions per second is

$$\begin{aligned} & \left[g_e g_A^+ \rho(E) dE d\hat{\mathbf{k}}_e \right] P_{if} \left[\rho(E_\nu) dE_\nu d\hat{\mathbf{k}}_\nu \right] \\ &= g_e g_A^+ v_e \frac{d\mathbf{p}_e}{(2\pi\hbar)^3} \sigma_R(\mathbf{k}_e) = g_\nu g_A c \frac{d\mathbf{k}_\nu}{(2\pi)^3} \sigma_I(\mathbf{k}_\nu), \end{aligned} \quad (58.235)$$

where the electron current ($\text{cm}^{-2} \text{s}^{-1}$) is

$$\frac{v_e d\mathbf{p}_e}{(2\pi\hbar)^3} = \left(\frac{2mE}{h^3}\right) dE d\hat{\mathbf{k}}_e, \quad (58.236)$$

and the photon current ($\text{cm}^{-2} \text{s}^{-1}$) is

$$c \frac{d\mathbf{k}_\nu}{(2\pi)^3} = c \frac{(h\nu)^2}{(2\pi\hbar c)^3} dE_\nu d\hat{\mathbf{k}}_\nu. \quad (58.237)$$

Time-dependent quantum electrodynamical interaction

$$\begin{aligned} V(\mathbf{r}, t) &= \frac{e}{mc} \mathbf{A} \cdot \mathbf{p} = ie \left(\frac{2\pi h\nu}{\mathcal{V}}\right)^{1/2} (\hat{\mathbf{e}} \cdot \mathbf{r}) e^{-i(\mathbf{k}_\nu \cdot \mathbf{r} - \omega t)} \\ &\equiv V(\mathbf{r}) e^{i\omega t}. \end{aligned} \quad (58.238)$$

In the dipole approximation, $e^{-i\mathbf{k}_\nu \cdot \mathbf{r}} \approx 1$.

Continuum-bound state-to-state probability

$$\begin{aligned} P_{if} &= \frac{2\pi}{\hbar} |V_{fi}|^2 \delta[E_\nu - (E + I_n)] \\ V_{fi} &= \langle \Psi_{n\ell m}(\mathbf{r}) V(\mathbf{r}) \Psi_i(\mathbf{r}, \mathbf{k}_e) \rangle. \end{aligned} \quad (58.239)$$

Number of photon states in volume \mathcal{V}

$$\rho(E_\nu, \hat{\mathbf{k}}_\nu) dE_\nu d\hat{\mathbf{k}}_\nu = \mathcal{V} (h\nu)^2 / (2\pi\hbar c)^3 dE_\nu d\hat{\mathbf{k}}_\nu \quad (58.240a)$$

$$= \mathcal{V} [\omega^2 / (2\pi c)^3] d\omega d\hat{\mathbf{k}}_\nu. \quad (58.240b)$$

Continuum-bound transition rate

On summing over the two directions ($g_\nu = 2$) of polarization, the rate for transitions into all final photon states is

$$\begin{aligned} A_{n\ell m}(E, \hat{\mathbf{k}}_e) &= \int P_{if} \rho(E_\nu) dE_\nu d\hat{\mathbf{k}}_\nu \\ &= \frac{4e^2}{3\hbar} \frac{(h\nu)^3}{(3\hbar c)^3} |\langle \Psi_{n\ell m} | \mathbf{r} | \Psi_i(\mathbf{k}_e) \rangle|^2. \end{aligned} \quad (58.241)$$

Transition frequency: alternative formula

$$A_{n\ell m}(E, \hat{\mathbf{k}}_e) = (2\pi/\hbar) |D_{fi}|^2, \quad (58.242)$$

where the dipole atom–radiation interaction coupling is

$$D_{fi}(\mathbf{k}_e) = \left(\frac{2\omega^3}{3\pi c^3}\right)^{1/2} \langle \Psi_{n\ell m} | e \mathbf{r} | \Psi_i(\mathbf{k}_e) \rangle. \quad (58.243)$$

RR cross section into level (n, ℓ, m)

$$\begin{aligned} \sigma_R^{n\ell m}(E) &= \frac{1}{4\pi} \int \sigma_R^{n\ell m}(\mathbf{k}_e) d\hat{\mathbf{k}}_e \\ &= \frac{h^3 \rho(E)}{8\pi m_e E} \int A_{n\ell m}(E, \hat{\mathbf{k}}_e) d\hat{\mathbf{k}}_e. \end{aligned} \quad (58.244)$$

RR cross section into level (n, ℓ)

$$\begin{aligned} \sigma_R^{n\ell}(E) &= \frac{8\pi^2}{3} \left(\frac{\alpha h\nu}{2(e^2/a_0)E}\right) \rho(E) R_I^{n\ell}(E), \\ R_I^{n\ell}(E) &= \int d\hat{\mathbf{k}}_e \sum_m |\langle \Psi_{n\ell m} | \mathbf{r} | \Psi_i(\mathbf{k}_e) \rangle|^2. \end{aligned} \quad (58.245)$$

Transition T-matrix for RR

$$\sigma_R^{n\ell}(E) = \frac{\pi a_0^2}{(ka_0)^2} |T_R|^2 \rho(E), \quad (58.246)$$

$$|T_R|^2 = 4\pi^2 \int \sum_m |D_{fi}|^2 d\hat{\mathbf{k}}_e. \quad (58.247)$$

Photoionization cross section

From the detailed balance in Eq. (58.235), $\sigma_I^{n\ell}$ is

$$\sigma_I^{n\ell}(h\nu) = \left(\frac{8\pi^2}{3}\right) \alpha h\nu \left(\frac{g_A^+}{g_A}\right) \rho(E) R_I^{n\ell}(E). \quad (58.248)$$

Continuum wave function expansion

$$\Psi_i(\mathbf{k}_e, \mathbf{r}) = \sum_{\ell' m'} i^{\ell'} e^{i\eta_{\ell'}} R_{E\ell'}(r) Y_{\ell' m'}(\hat{\mathbf{k}}_e) Y_{\ell' m'}(\hat{\mathbf{r}}). \quad (58.249)$$

Energy normalization

With $\rho(E) = 1$,

$$\int \Psi_i(\mathbf{k}_e; \mathbf{r}) \Psi_i^*(\mathbf{k}'_e; \mathbf{r}) d\mathbf{r} = \delta(E - E') \delta(\hat{\mathbf{k}}_e - \hat{\mathbf{k}}'_e). \quad (58.250)$$

Plane wave expansion

$$e^{i\mathbf{k}\cdot\mathbf{r}} = 4\pi \sum_{\ell=0}^{\infty} i^{\ell} j_{\ell}(kr) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}}), \quad (58.251)$$

$$j_{\ell}(kr) \approx \sin\left(kr - \frac{1}{2}\ell\pi\right) / (kr). \quad (58.252)$$

For bound states,

$$\Psi_{n\ell m}(\mathbf{r}) = R_{n\ell}(r) Y_{\ell m}(\hat{\mathbf{r}}). \quad (58.253)$$

RR and PI cross sections and radial integrals

$$\sigma_{\text{R}}^{n\ell}(E) = \frac{8\pi^2}{3} \left(\frac{(\alpha h\nu)^3}{2(e^2/a_0)E} \right) \rho(E) R_{\text{I}}(E; n\ell). \quad (58.254)$$

For an electron outside a closed core,

$$g_{\text{A}}^+ = 1, \quad g_{\text{A}} = 2(2\ell + 1),$$

$$\sigma_{\text{I}}^{n\ell}(h\nu) = \frac{4\pi^2 \alpha h\nu \rho(E)}{3(2\ell + 1)} R_{\text{I}}(E; n\ell), \quad (58.255a)$$

$$R_{n\ell}^{e,\ell'} = \int_0^{\infty} (R_{e\ell'} r R_{n\ell}) r^2 dr, \quad (58.255b)$$

$$R_{\text{I}}(E; n\ell) = \ell \left| R_{n\ell}^{e,\ell-1} \right|^2 + (\ell + 1) \left| R_{n\ell}^{e,\ell+1} \right|^2. \quad (58.255c)$$

For an electron outside an unfilled core (c) in the process $(\text{A}^+ + e^-) \rightarrow \text{A}(n\ell)$, the weights are

State i : $[\text{S}_{\text{c}}, L_{\text{c}}; \varepsilon]$, $g_{\text{A}}^+ = (2\text{S}_{\text{c}} + 1)(2L_{\text{c}} + 1)$.

State f : $[(\text{S}_{\text{c}}, L_{\text{c}}; n\ell)S, L]$, $g_{\text{A}} = (2S + 1)(2L + 1)$.

$$R_{\text{I}}(E; n\ell) = \frac{(2L + 1)}{(2L_{\text{c}} + 1)} \times \sum_{\ell'=\ell\pm 1} \sum_{L'} (2L' + 1) \left\{ \begin{matrix} \ell & L & L_{\text{c}} \\ L' & \ell' & 1 \end{matrix} \right\}^2 \times \ell_{\text{max}} \left| \int_0^{\infty} (R_{e\ell'} r R_{n\ell}) r^2 dr \right|^2. \quad (58.256)$$

This reduces to Eq. (58.255c) when the radial functions $R_{i,f}$ do not depend on $(\text{S}_{\text{c}}, L_{\text{c}}, S, L)$.

Cross Section for Dielectronic Recombination

$$\sigma_{\text{DLR}}^{n\ell}(E) = \frac{\pi a_0^2}{(ka_0)^2} |T_{\text{DLR}}(E)|^2 \rho(E),$$

$$|T_{\text{DLR}}(E)|^2 = 4\pi^2 \int d\hat{\mathbf{k}}_e \times \sum_j \left| \frac{\langle \Psi_f D \rangle \Psi_j \langle \Psi_j V \rangle \Psi_i(\mathbf{k}_e)}{(E - \varepsilon_j + i\Gamma_j/2)} \right|^2, \quad (58.257)$$

which is the generalization of the T -matrix Eq. (58.247) to include the effect of intermediate doubly excited autoionizing states $\langle \Psi_j$ in energy resonance to within width Γ_j of the initial continuum state Ψ_i . The electrostatic interaction $V = e^2 \sum_{i=1}^N (\mathbf{r}_i - \mathbf{r}_{N+1})^{-1}$ initially produces dielectronic capture by coupling the initial state i with the resonant states j , which become stabilized by coupling via the dipole radiation field interaction $\mathbf{D} = (2\omega^3/3\pi c^3)^{1/2} \sum_{i=1}^{N+1} (e\mathbf{r}_i)$ to the final stabilized state f . The above cross section for Eq. (58.3) is valid for isolated, nonoverlapping resonances.

Continuum Wave Normalization and Density of States

The basic formulae Eq. (58.245) for $\sigma_{\text{R}}^{n\ell}$ depends on the density of states $\rho(E)$, which in turn varies according to the particular normalization constant N adopted for the continuum radial wave,

$$R_{E\ell}(r) \approx N \sin\left(kr - \frac{1}{2}\ell\pi + \eta_{\ell}\right) / r, \quad (58.258)$$

in Eq. (58.249) where the phase is

$$\eta_{\ell} = \arg \Gamma(\ell + 1 + i\beta) - \beta \ln 2kr + \delta_{\ell}. \quad (58.259)$$

The phase corresponding to the Hartree–Fock short-range interaction is δ_{ℓ} . The Coulomb phase shift for electron motion under $(-Ze^2/r)$ is $(\eta_{\ell} - \delta_{\ell})$ with $\beta = Z/(ka_0)$.

For a plane wave $\phi_{\mathbf{k}}(\mathbf{r}) = N' \exp(i\mathbf{k} \cdot \mathbf{r})$,

$$\begin{aligned} \langle \phi_{\mathbf{k}}(\mathbf{r}) | \phi_{\hat{\mathbf{k}}'}(\mathbf{r}) \rangle d\mathbf{k} &= (2\pi)^3 |N'|^2 \rho(\mathbf{k}) d\mathbf{k} \delta(\mathbf{k} - \mathbf{k}') \\ &\equiv \left(\frac{h^3}{mp} \right) |N'|^2 \rho(E, \hat{\mathbf{k}}) dE d\hat{\mathbf{k}} \delta(E - E') \delta(\hat{\mathbf{k}} - \hat{\mathbf{k}}'). \end{aligned} \quad (58.260)$$

On integrating Eq. (58.260) over all E and $\hat{\mathbf{k}}$ for a single particle distributed over all $|E, \hat{\mathbf{k}}\rangle$ states, N' and ρ are then interrelated by

$$|N'|^2 \rho(E, \hat{\mathbf{k}}) = mp/h^3. \quad (58.261)$$

The incident current is

$$j dE d\hat{\mathbf{k}}_e = v |N'|^2 \rho(E, \hat{\mathbf{k}}) dE d\hat{\mathbf{k}}_e \quad (58.262a)$$

$$= (2mE/h^3) dE d\hat{\mathbf{k}}_e = v d\mathbf{p}_e/h^3. \quad (58.262b)$$

Radial wave connection

From Eqs. (58.249) and (58.251), $N = (4\pi N'/k)$, so that the connection between N of Eq. (58.258) and $\rho(E)$ is

$$|N|^2 \rho(E, \hat{\mathbf{k}}) = \frac{(2m/\hbar^2)}{\pi k} = \frac{(2/\pi)}{ka_0 e^2}. \quad (58.263)$$

RR Cross Sections for Common Normalization Factors of Continuum Radial Functions (Four Choices)

Choice a

$$N = 1; \quad \rho(E) = \frac{(2m/\hbar^2)}{\pi k} = \frac{(2/\pi)}{(ka_0)e^2}, \quad (58.264)$$

$$\sigma_{\text{R}}^{n\ell}(E) = \frac{8\pi^2 a_0^2}{(ka_0)^3} \int \sum_m |D_{fi}|^2 d\hat{\mathbf{k}}_e, \quad (58.265)$$

where D_{fi} of Eq. (58.243) is dimensionless.

Choice b

$$N = k^{-1}; \quad \rho(E) = (2m/\hbar^2)(k/\pi), \quad (58.266)$$

$$\sigma_{\text{R}}^{n\ell}(E) = \frac{16\pi a_0^2}{3\sqrt{2}} \left(\frac{\alpha h\nu}{e^2/a_0} \right)^3 \sqrt{\frac{(e^2/a_0)}{E}} \left(\frac{R_1}{a_0^5} \right), \quad (58.267)$$

where Eqs. (58.255b) and (58.255c) for R_1 have dimension $[L^5]$.

Choice c

$$N = k^{-1/2}; \quad \rho(E) = \frac{(2m/\hbar^2)}{\pi}, \quad (58.268)$$

$$\sigma_{\text{R}}^{n\ell}(E) = \frac{8\pi a_0^2}{3} \left(\frac{\alpha^3 (h\nu)^3}{(e^2/a_0)^2 E} \right) \left(\frac{R_1}{a_0^4} \right), \quad (58.269)$$

where R_1 has dimensions of $[L^4]$.

Choice d

$$N = (2m/\hbar^2 \pi^2 E)^{1/4}; \quad \rho(E) = 1, \quad (58.270)$$

$$\sigma_{\text{R}}^{n\ell}(E) = \frac{4(\pi a_0)^2}{3} \left(\frac{\alpha^3 (h\nu)^3}{(e^2/a_0)^2 E} \right) \left(\frac{R_1}{e^2 a_0} \right), \quad (58.271)$$

where R_1 has dimensions of $[L^2 E^{-1}]$.

58.11.4 Bound–Free Oscillator Strengths

For a transition $n\ell \rightarrow E$ to $E + dE$,

$$\frac{df_{n\ell}}{dE} = \frac{2}{3} \frac{(h\nu)}{(e^2/a_0)} \frac{1}{(2\ell + 1)} \sum_m \sum_{\ell'm'} \left| \mathbf{r}_{n\ell m}^{\ell' m'} \right|^2, \quad (58.272)$$

$$\begin{aligned} R_1(\varepsilon; n\ell) &= \int d\hat{\mathbf{k}}_e \sum_m |\langle \Psi_{n\ell m} | \mathbf{r} | \Psi_i(\mathbf{k}_e) \rangle E|^2 \\ &= \sum_{m, \ell', m'} \left| \mathbf{r}_{n\ell m}^{\ell' m'} \right|^2, \end{aligned} \quad (58.273)$$

$$\sigma_{\text{R}}^{n\ell}(E) = 2\pi^2 \alpha a_0^2 g_{\text{A}} \left(\frac{k_{\text{v}}^2}{k_{\text{e}}^2} \right) \left(\frac{e^2}{a_0} \right) \frac{df_{n\ell}}{dE}, \quad (58.274a)$$

$$\sigma_{\text{I}}^{n\ell}(h\nu) = 2\pi^2 \alpha a_0^2 g_{\text{A}}^+ \left(\frac{e^2}{a_0} \right) \frac{df_{n\ell}}{dE}. \quad (58.274b)$$

Semiclassical Hydrogenic Systems

$$g_{\text{A}} = g_{n\ell} = 2(2\ell + 1), \quad g_{\text{A}}^+ = 1,$$

$$\sigma_{\text{R}}^n(E) = \sum_{\ell=0}^{n-1} \sigma_{\text{R}}^{n\ell}(E) = 2\pi^2 \alpha a_0^2 \left(\frac{k_{\text{v}}^2}{k_{\text{e}}^2} \right) \frac{dF_n}{dE}, \quad (58.275)$$

$$\frac{dF_n}{dE} = \sum_{\ell=0}^{n-1} g_{n\ell} \frac{df_{n\ell}}{dE} = 2 \sum_{\ell, m} \frac{df_{n\ell m}}{dE}. \quad (58.276)$$

Bound–bound absorption oscillator strength

For a transition $n \rightarrow n'$,

$$F_{nn'} = 2 \sum_{\ell m} \sum_{\ell' m'} f_{n\ell m}^{n' \ell' m'} \quad (58.277a)$$

$$= \frac{2^6}{3\sqrt{3}\pi} \left[\left(\frac{1}{n^2} - \frac{1}{n'^2} \right)^{-3} \right] \frac{1}{n^3} \frac{1}{n'^3}, \quad (58.277b)$$

$$\frac{dF_n}{dE} = \frac{2^5}{3\sqrt{3}\pi} n \frac{I_n^2}{(h\nu)^3} = 2n^2 \frac{df_{n\ell}}{dE}, \quad (58.277c)$$

$$\sigma_{\text{R}}^n(E) = \frac{2^5 \alpha^3}{3\sqrt{3}} \left(\frac{n I_n^2}{E(h\nu)} \right) \pi a_0^2, \quad (58.277d)$$

$$\sigma_{\text{I}}^{n\ell}(h\nu) = \frac{2^6 \alpha}{3\sqrt{3}} \frac{n}{Z^2} \left(\frac{I_n}{h\nu} \right)^3 \pi a_0^2, \quad (58.277e)$$

$$= 7.907071 \left(\frac{n}{Z^2} \right) \left(\frac{I_n}{h\nu} \right)^3 \text{ Mb}. \quad (58.277f)$$

This semiclassical analysis yields exactly Kramers PI and associated RR cross sections in Sect. 58.8.2.

58.11.5 Radiative Recombination Rate

$$\hat{\alpha}_{\text{R}}^{n\ell}(T_e) = \bar{v}_e \int_0^{\infty} \varepsilon \sigma_{\text{R}}^{n\ell}(\varepsilon) e^{-\varepsilon} d\varepsilon \quad (58.278a)$$

$$\equiv \bar{v}_e \langle \sigma_{\text{R}}^{n\ell}(T_e) \rangle, \quad (58.278b)$$

where ε is given in Eq. (58.57c), and $\langle \sigma_{\text{R}}^{n\ell}(T_e) \rangle$ is the Maxwellian-averaged cross section for radiative recombination.

In terms of the continuum-bound $A_{n\ell}(E)$,

$$\hat{\alpha}_{\text{R}}^{n\ell}(T_e) = \frac{h^3}{(2\pi m_e k_{\text{B}} T)^{3/2}} \int_0^{\infty} \left(\frac{dA_{n\ell}}{d\varepsilon} \right) e^{-\varepsilon} d\varepsilon, \quad (58.279)$$

$$\frac{dA_{n\ell}}{dE} = \rho(E) \sum_m \int A_{n\ell m}(E, \hat{\mathbf{k}}_e) d\hat{\mathbf{k}}_e. \quad (58.280)$$

Milne Detailed Balance Relation

In terms of $\sigma_I^{n\ell}(h\nu)$,

$$\begin{aligned} \hat{\alpha}_R^{n\ell}(T_e) &= \bar{v}_e \left(\frac{g_A}{2g_A^+} \right) \left(\frac{k_B T_e}{mc^2} \right) \left(\frac{I_n}{k_B T_e} \right)^2 \langle \sigma_I^{n\ell}(T_e) \rangle, \quad (58.281) \end{aligned}$$

where, in reduced units $\omega = h\nu/I_n$, $T = k_B T_e/I_n = b_n^{-1}$, the averaged PI cross section corresponding to Eq. (58.213) is

$$\langle \sigma_I^{n\ell}(T) \rangle = \frac{e^{1/T}}{T} \int_1^\infty \omega^2 \sigma_I^{n\ell}(\omega) e^{-\omega/T} d\omega. \quad (58.282)$$

When $\sigma_I^{n\ell}(\omega)$ is expressed in Mb (10^{-18} cm²),

$$\begin{aligned} \hat{\alpha}_R^{n\ell}(T_e) &= 1.508 \times 10^{-13} \left(\frac{300}{T_e} \right)^{1/2} \left(\frac{I_n}{I_H} \right)^2 \left(\frac{g_A}{2g_A^+} \right) \\ &\times \langle \sigma_I^{n\ell}(T) \rangle \text{ cm}^3 \text{ s}^{-1}. \quad (58.283) \end{aligned}$$

When σ_I can be expressed in terms of the threshold cross section σ_0^n Eq. (58.217) as

$$\sigma_I^{n\ell}(h\nu) = (I_n/h\nu)^p \sigma_0(n); \quad (p = 0, 1, 2, 3), \quad (58.284)$$

then $\langle \sigma_I^{n\ell}(T) \rangle = S_p(T) \sigma_0(n)$, where

$$S_0(T) = 1 + 2T + 2T^2, \quad S_1(T) = 1 + T, \quad (58.285a)$$

$$S_2(T) = 1, \quad (58.285b)$$

$$S_3(T) = (e^{1/T}/T) E_1(1/T) \quad (58.285c)$$

$$\stackrel{T \ll 1}{\approx} 1 - T + 2T^2 - 6T^3. \quad (58.285d)$$

The case $p = 3$ corresponds to Kramers PI cross section Eq. (58.220) so that

$$\kappa \hat{\alpha}_R^{n\ell}(T_e) = \frac{(2\ell + 1)}{n^2} \frac{2}{n} \hat{\alpha}_0(T_e) S_3(T) \quad (58.286a)$$

$$\equiv \kappa \hat{\alpha}_R^{n\ell}(T_e \rightarrow 0) S_3(T), \quad (58.286b)$$

such that $\kappa \hat{\alpha}_R^{n\ell} \approx Z^2/(n^3 T_e^{1/2})$ as $T = (k_B T_e/I_n) \rightarrow 0$.

58.11.6 Gaunt Factor, Cross Sections, and Rates for Hydrogenic Systems

The Gaunt factor $G_{n\ell}$ is the ratio of the quantal to Kramers (K) semiclassical PI cross section such that

$$\begin{aligned} \sigma_I^{n\ell}(h\nu) &= \kappa \sigma_I^n(h\nu) G_{n\ell}(\omega); \\ \omega &= h\nu/I_n = 1 + E/I_n. \quad (58.287) \end{aligned}$$

(a) Radiative Recombination Cross Section

$$\sigma_R^{n\ell}(E) = \left(\frac{g_A}{g_A^+} \right) \left(\frac{\alpha^2 (h\nu)^2}{2E(e^2/a_0)} \right) G_{n\ell}(\omega) \kappa \sigma_I^n(h\nu) \quad (58.288a)$$

$$= G_{n\ell}(\omega) \kappa \sigma_R^{n\ell}(E) \quad (58.288b)$$

$$= \left[\frac{(2\ell + 1)}{n^2} G_{n\ell}(\omega) \right]_{\text{K}} \sigma_R^n(E), \quad (58.288c)$$

$$\sigma_R^n(E) = G_n(\omega) \kappa \sigma_R^n(E), \quad (58.288d)$$

where the quantum mechanical correction, or Gaunt factor, to the semiclassical cross sections

$$G_{n\ell}(\omega) \rightarrow \begin{cases} 1, & \omega \rightarrow 1 \\ \omega^{-(\ell+1/2)}, & \omega \rightarrow \infty \end{cases} \quad (58.289)$$

favors low $n\ell$ -states. The ℓ -averaged Gaunt factor is

$$G_n(\omega) = (1/n^2) \sum_{\ell=0}^{n-1} (2\ell + 1) G_{n\ell}(\omega). \quad (58.290)$$

Approximations for G_n : as ε increases from zero,

$$G_n(\varepsilon) = \left[1 + \frac{4}{3}(a_n + b_n) + \frac{28}{18} a_n^2 \right]^{-3/4} \quad (58.291a)$$

$$\simeq 1 - (a_n + b_n) + \frac{7}{3} a_n b_n + \frac{7}{6} b_n^2 \quad (58.291b)$$

where $E = \varepsilon(Z^2 e^2/2a_0)$, $\omega = 1 + n^2 \varepsilon$, and

$$a_n(\varepsilon) = 0.172825(1 - n^2 \varepsilon) c_n(\varepsilon), \quad (58.292a)$$

$$b_n(\varepsilon) = 0.04959 \left(1 + \frac{4}{3} n^2 \varepsilon + n^4 \varepsilon^2 \right) c_n^2(\varepsilon), \quad (58.292b)$$

$$c_n(\varepsilon) = n^{-2/3} (1 + n^2 \varepsilon)^{-2/3}. \quad (58.292c)$$

Radiative Recombination Rate

$$\hat{\alpha}_R^{n\ell}(T_e) = \kappa \hat{\alpha}_R^{n\ell}(T_e \rightarrow 0) F_{n\ell}(T), \quad (58.293)$$

$$\hat{\alpha}_R^{n\ell}(T_e \rightarrow 0) = \frac{(2\ell + 1)}{n^2} \left(\frac{2}{n} \right) \hat{\alpha}_0(T_e), \quad (58.294)$$

in accordance with Eq. (58.224b).

$$F_{n\ell}(T) = \frac{e^{1/T}}{T} \int_1^\infty \frac{G_{n\ell}(\omega)}{\omega} e^{-\omega/T} d\omega. \quad (58.295)$$

The multiplicative factors F and G convert the semiclassical (Kramers) $T_e \rightarrow 0$ rate and cross section to their quantal values. Departures from the scaling rule ($Z^2/n^3 T_e^{1/2}$) for RR rates is measured by $F_{n\ell}(T)$.

58.11.7 Exact Universal Rate Scaling Law and Results for Hydrogenic Systems

$$\hat{\alpha}_R^{n\ell}(Z, T_e) = Z \hat{\alpha}_R^{n\ell}(1, T_e/Z^2) \quad (58.296)$$

as exhibited by Eq. (58.281) with Eqs. (58.277e) and (58.282).

Recombination rates are greatest into low n levels and the $\omega^{-\ell-1/2}$ variation of $G_{n\ell}$ preferentially populates states with low $\ell \approx 2-5$. Highly accurate analytical fits for $G_{n\ell}(\omega)$ have been obtained for $n \leq 20$ so that Eq. (58.287) can be expressed in terms of known functions of fit parameters [58]. This procedure (which does not violate the S_2 sum rule) has been extended to nonhydrogenic systems of neon-like Fe XVII, where $\sigma_I^{n\ell}(\omega)$ is a monotonically decreasing function of ω .

The variation of the ℓ -averaged values

$$n^{-2} \sum_{\ell=0}^{n-1} (2\ell+1) F_{n\ell}(T)$$

is close in both shape and magnitude to the corresponding semiclassical function $S_3(T)$, given by Eq. (58.295) with $G_{n\ell}(\omega) = 1$. Hence the ℓ -averaged recombination rate is

$$\hat{\alpha}_R^n(Z, T) = (300/T)^{1/2} (Z^2/n) F_n(T), \\ \times 1.1932 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1},$$

where F_n can be calculated directly from Eq. (58.295) or be approximated as $G_n(1)S(T)$. A computer program based on a three-term expansion of G_n is also available [59]. From a three-term expansion for G , the rate of radiative recombination into all levels of a hydrogenic system is

$$\hat{\alpha}(Z, T) = 5.2 \times 10^{-14} Z \lambda^{1/2} \\ \times \left(0.43 + \frac{1}{2} \ln \lambda + 0.47/\lambda^{1/2} \right), \quad (58.297)$$

where $\lambda = 1.58 \times 10^5 Z^2/T$ and $[\hat{\alpha}] = \text{cm}^3/\text{s}$. Tables [60] exist for the effective rate

$$\hat{\alpha}_E^{n\ell}(T) = \sum_{n'=n}^{\infty} \sum_{\ell'=0}^{n'-1} \hat{\alpha}_R^{n'\ell'} C_{n'\ell', n\ell} \quad (58.298)$$

of populating a given level $n\ell$ of H via radiative recombination into all levels $n' \geq n$ with subsequent radiative cascade ($i \rightarrow f$) with probability $C_{i,f}$ via all possible intermediate paths. Tables [60] also exist for the full rate

$$\hat{\alpha}_F^N(T) = \sum_{n=N}^{\infty} \sum_{\ell=0}^{n-1} \hat{\alpha}_R^{n\ell} \quad (58.299)$$

of recombination, into all levels above $N = 1, 2, 3, 4$ of hydrogen. They are useful in deducing time scales of radiative recombination and rates for complex ions.

58.12 Useful Quantities

(a) Mean speed

$$\bar{v}_e = \left(\frac{8k_B T}{\pi m_e} \right)^{1/2} = 1.076042 \times 10^7 \left(\frac{T}{300} \right)^{1/2} \text{ cm/s} \\ = 6.69238 \times 10^7 T_{\text{eV}}^{1/2} \text{ cm/s}, \\ \bar{v}_i = 2.51116 \times 10^5 \left(\frac{T}{300} \right)^{1/2} (m_p/m_i)^{1/2} \text{ cm/s},$$

where $(m_p/m_e)^{1/2} = 42.850352$, and $T = 11604.45 T_{\text{eV}}$ relates the temperature in K and in eV.

(b) Natural radius

$$|V(R_e)| = e^2/R_e = k_B T. \\ R_e = \frac{e^2}{k_B T} = 557 \left(\frac{300}{T} \right) \text{ \AA} = \left(\frac{14.4}{T_{\text{eV}}} \right) \text{ \AA}.$$

(c) Boltzmann average momentum

$$\langle p \rangle = \int_{-\infty}^{\infty} e^{-p^2/2mk_B T} dp = (2\pi m_e k_B T)^{1/2}.$$

(d) De Broglie wavelength

$$\lambda_{\text{dB}} = \frac{h}{\langle p \rangle} = \frac{h}{(2\pi m_e k_B T)^{1/2}} \\ = \frac{7.453818 \times 10^{-6} \text{ cm}}{T_e^{1/2}} \\ = 43.035 \left(\frac{300}{T_e} \right)^{1/2} \text{ \AA} = \frac{6.9194}{T_{\text{eV}}^{1/2}} \text{ \AA}.$$

Abstract

Dielectronic recombination (DR) is a two-step process that greatly increases the efficiency for electrons and ions to recombine in a plasma. The process, therefore, plays an important role in the theoretical modeling of plasmas, whether in the laboratory or in astrophysical sources such as the solar corona. The purpose of this chapter is to present the theoretical formulation for DR and the principal methods for calculating rate coefficients. The results are compared with experiment over a broad range of low- Z ions and high- Z ions where relativistic effects become important.

Keywords

dielectronic recombination · plasmas · Rydberg series · distorted-wave approximation · autoionization rate

59.1 Introduction

Electron-ion recombination into a particular final recombined state may be schematically represented as

$$e^- + A_i^{q+} \rightarrow A_f^{(q-1)+} + \hbar\omega, \quad (59.1)$$

and

$$e^- + A_i^{q+} \rightarrow [A_j^{(q-1)+}] \rightarrow A_f^{(q-1)+} + \hbar\omega, \quad (59.2)$$

where q is the charge on the atomic ion A , ω is the frequency of the emitted light, and the brackets in Eq. (59.2) indicate a doubly excited resonance state. The first process is called radiative recombination (RR), while the second is called dielectronic recombination (DR). Both recombination mechanisms are the inverse of photoionization. At sufficiently high electron density, three-body recombination becomes possible. The three-body mechanism is the inverse of electron impact ionization.

The review article by *Seaton and Storey* [1] includes an interesting history of the theoretical work on dielectronic recombination. The process was first referred to as dielectronic recombination by *Massey and Bates* [2], after a suggestion of its possible importance in the ionosphere by *Sayers* in 1939. However, estimates of the rate coefficient for this process indicated that DR is not an important process in the ionosphere, where the temperatures are too low to excite anything but the lower energy resonance states.

In 1961, *Unsold*, in a letter to *Seaton*, suggested that DR might account for a well-known temperature discrepancy in the solar corona. *Seaton* initially concluded that DR would not significantly increase recombination in the solar corona. However, he had only included the lower energy resonance states in his analysis; *Burgess* [3] showed that when one includes the higher members of the Rydberg series of resonance states that are populated at coronal temperatures, DR can indeed explain this discrepancy.

Dielectronic recombination has since received much theoretical attention due, in part, to its importance in modeling

high-temperature plasmas. Various approaches to the theory are discussed in a review by *Hahn* [4] and in [5]. Recently, there have been various projects aimed at the generation of large quantities of DR data for use in astrophysical and fusion plasma modeling. One such project is based on the results of the AUTOSTRUCTURE code, with both the total and partial (i.e., resolved by recombined level) DR rate coefficients being archived. The methodology is outlined in *Badnell et al.* [6]. Data are calculated for all members of an isoelectronic sequence from H to Ar, along with various ions relevant to astrophysics or fusion, namely Ca, Ti, Cr, Fe, Ni, Zn, Kr, Mo, and Xe. Work has been completed for the hydrogen [7], helium [8], lithium [9], beryllium [10], boron [11], carbon [12], nitrogen [13], oxygen [14], fluorine [15], neon [16], sodium [17], magnesium [18], aluminum [19], and argon [20] isonuclear sequences. There has also been a large quantity of data generated using a fully relativistic Dirac–Fock code [21]. These data include calculations of Na-like ions [22] and H-like through to Ne-like [23] ions of certain astrophysically important elements.

Interest in dielectronic recombination has increased dramatically in the last 20 years. *Mitchell et al.* [24] published the DR cross section for C⁺ using a merged electron–ion beams apparatus, and *Belic et al.* [25] reported on a crossed beams measurement of the DR cross section for Mg⁺. Also, *Dittner et al.* [26] published merged beams measurements of the DR cross section for the multiply charged ions B²⁺ and C³⁺. Since that time, atomic physics experiments carried out using heavy-ion traps, accelerators, and storage-cooler rings have produced high-resolution mappings of the resonance structures associated with electron–ion recombination. The experiments have been carried out using a wide range of facilities and technologies, such as the test storage ring (TSR) at Heidelberg, the experimental storage ring (ESR) at Darmstadt, the accelerator-cooler ring facility at Aarhus, the electron beam ion trap (EBIT) at Livermore, and the electron beam ion source (EBIS) at Kansas State. A good review of the dramatic experimental progress in DR measurements is again found in the NATO proceedings [5].

59.2 Theoretical Formulation

In the independent-processes approximation, the two paths for recombination are summed incoherently. The radiative recombination cross section for Eq. (59.1), in lowest-order of perturbation theory, is given by

$$\sigma_{\text{RR}} = \frac{8\pi^2}{k^3} \times \sum_{\ell_j} \sum_{JM} \sum_{M_0} \frac{1}{2g_1} \left| \langle \alpha_0 J_0 M_0 | D | \alpha_1 J_1 \ell_j J M \rangle \right|^2. \quad (59.3)$$

The set $(\alpha_1 J_1)$ represents the quantum numbers for the N -electron target ion state, $(\alpha_0 J_0 M_0)$ represents the quantum numbers for the $(N+1)$ -electron recombined ion state, $(k \ell_j)$ represents the quantum numbers for the continuum electron state, (JM) represents the quantum numbers for the $(N+1)$ -electron system of target plus free electron state, and g_1 is the statistical weight of a J_1 level. The dipole radiation field operator is given by

$$D = \sqrt{\frac{2\omega^3}{3\pi c^3}} \sum_{s=1}^{N+1} \mathbf{r}_s. \quad (59.4)$$

Continuum normalization is chosen as one times a sine function, and atomic units ($e = \hbar = m = 1$) are used. In the isolated-resonance approximation, the dielectronic recombination cross section for Eq. (59.2), in lowest-order perturbation theory, is given by

$$\sigma_{\text{DR}} = \frac{8\pi^2}{k^3} \sum_{\ell_j} \sum_{JM} \sum_{M_0} \frac{1}{2g_1} \times \sum_{\alpha_i J_i M_i} \left| \frac{\langle \alpha_0 J_0 M_0 | D | \alpha_i J_i M_i \rangle \langle \alpha_i J_i M_i | V | \alpha_1 J_1 \ell_j J M \rangle}{E_0 - E_i + i\Gamma_i/2} \right|^2, \quad (59.5)$$

where the set $(\alpha_i J_i M_i)$ represents the quantum numbers for a resonance state with energy E_i and total width Γ_i , and the electrostatic interaction between electrons is given by

$$V = \sum_{s=1}^N |\mathbf{r}_s - \mathbf{r}_{N+1}|^{-1}. \quad (59.6)$$

By the principle of detailed balance, σ_{RR} of Eq. (59.3) is proportional to the photoionization cross section from the bound state, while the energy-averaged σ_{DR} may be written as

$$\langle \sigma_{\text{DR}} \rangle = \frac{2\pi^2}{\Delta\epsilon k^2} \sum_{\alpha_i J_i M_i} \frac{1}{2g_1} \frac{A_a A_r}{\Gamma_i}, \quad (59.7)$$

where the autoionization decay rate A_a is given by

$$A_a = \frac{4}{k} \sum_{\ell_j} \sum_{JM} |\langle \alpha_1 J_1 \ell_j J M | V | \alpha_i J_i M_i \rangle|^2, \quad (59.8)$$

the radiative decay rate A_r is given by

$$A_r = 2\pi \sum_{M_0} |\langle \alpha_0 J_0 M_0 | D | \alpha_i J_i M_i \rangle|^2, \quad (59.9)$$

and $\Delta\epsilon$ is the energy bin width. Each resonance level in Eq. (59.7) makes a contribution at a fixed continuum energy $k^2/2$; thus $\langle \sigma_{\text{DR}} \rangle$ plotted as a function of energy is a histogram.

59.3 Comparisons with Experiment

59.3.1 Low-Z Ions

For the most part, the agreement between the recent high-resolution measurements and theoretical calculations based on the independent-processes and isolated-resonance (IPIR) approximations is quite good [27–45]. We illustrate the agreement with experiment obtained by calculations employing the IPIR approximations with three examples from the Li isoelectronic sequence. The pathways for dielectronic capture, in terms of specific levels, are given by

where a $1s^2$ core is assumed to be present. Both Rydberg series autoionize by the reverse of the paths in Eq. (59.10), while for sufficiently high n , the $2p_{3/2}nlj$ levels may autoionize to the $2p_{1/2}$ continuum. Both series radiatively stabilize by either a $2p \rightarrow 2s$ core orbital transition or by a $nlj \rightarrow n'l'j'$ valence orbital transition, where $2p_j n'l'j'$ with $j = (1/2), (3/2)$ is a bound level.

Dielectronic recombination cross section calculations [35] in the IPIR approximation for O^{5+} are compared with experiment in Fig. 59.1. Fine-structure splitting of the two series of Eq. (59.10) is minimal for this light ion, so there appears only one Rydberg series. The $2p\ 6\ell$ resonances are located at 2.5 eV, the $2p\ 7\ell$ at 5.0 eV, and so on, accumulating at the series limit around 11.3 eV. Electric field effects on the high- n resonances are strong in O^{5+} , so that calculations were done for fields of 0, 3, 5, and 7 V/cm. Since the precise electric

Fig. 59.1 Dielectronic recombination for O^{5+} . Calculations were performed for fields of 0 V/cm (dotted curve), 3 V/cm (dashed curve), 5 V/cm (chain curve), and 7 V/cm (solid curve)

field strength in the experiment is not known, the accuracy of an electric field-dependent theory, in this case, has yet to be determined. However, the effects of state mixing by extrinsic fields in the collision region for the dielectronic recombination of Mg^+ have been investigated both experimentally [46] and theoretically [47].

There have been a significant number of recent experiments on low- Z ions. These experiments, in general, show good agreement with theory, see *Fogle et al.* [44] and *Schnell et al.* [45]. However, it is also clear that discrepancies remain between theory and experiment for certain low-energy resonances, due to the difficulty in calculating the energy positions of such resonances. As has been pointed out in *Savin et al.* [48] and *Schippers et al.* [49], this can lead to significant uncertainties in low-temperature DR rate coefficients. Calculating such low-energy resonances to sufficient accuracy for low-temperature DR rate coefficients remains a significant challenge for theory. Some success in this area has been achieved using relativistic many-body perturbation theory, obtaining very good agreement with low-energy resonance positions for a range of systems, see, for example, *Lindroth et al.* [50], *Fogle et al.* [51], and *Tokman et al.* [52].

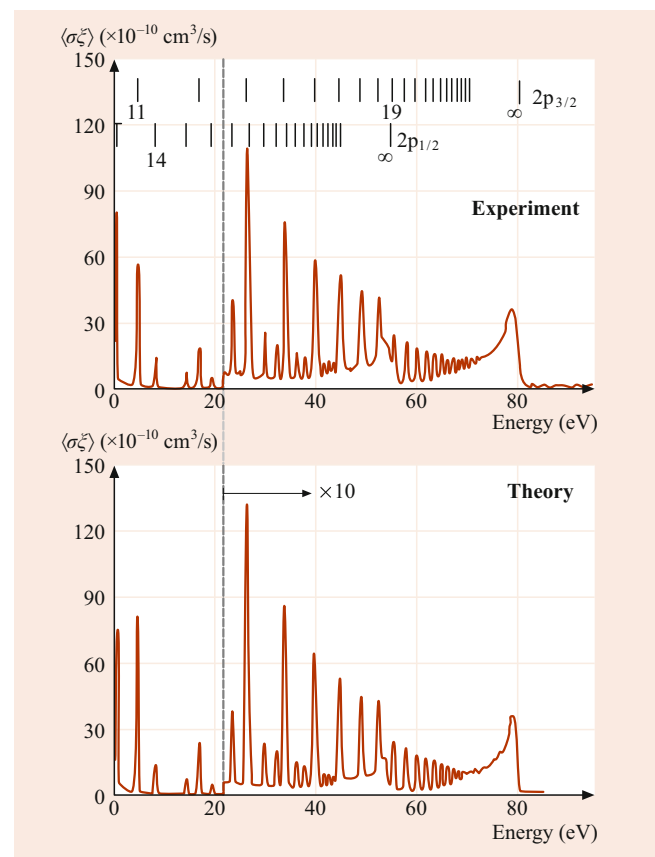

Fig. 59.2 Dielectronic recombination for Cu^{26+}

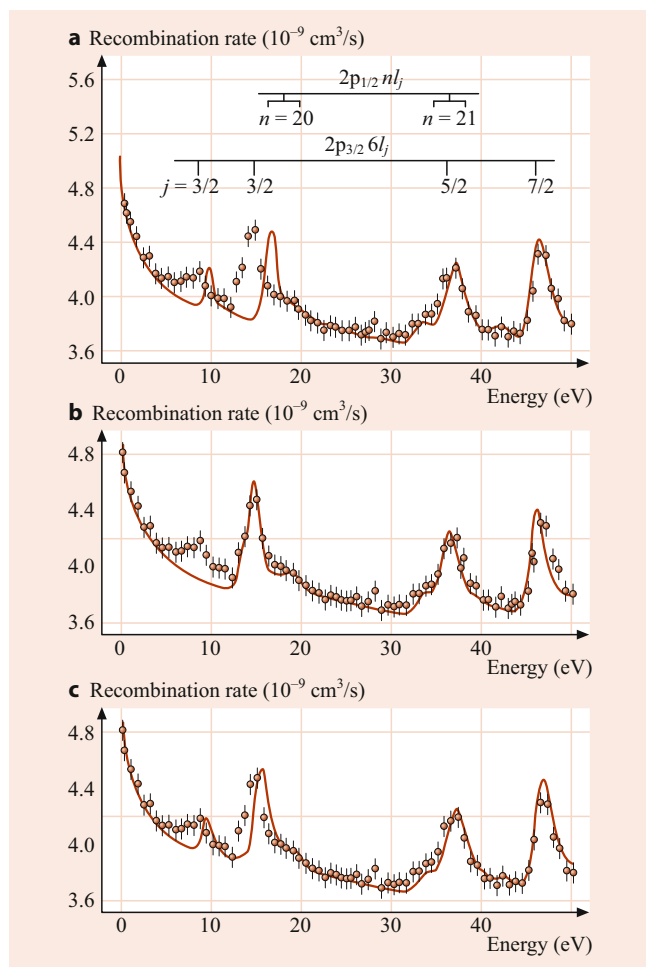

Fig. 59.3 Dielectronic recombination for Au^{76+} . The curves show (a) perturbative relativistic, (b) semirelativistic, and (c) fully relativistic calculations for the dielectronic recombination cross section

59.3.2 High- Z Ions and Relativistic Effects

Dielectronic recombination cross section calculations [38] in the IPIR approximation for Cu^{26+} are compared with experiment in Fig. 59.2. The two fine-structure Rydberg series are now clearly resolved; the fine-structure splitting is about 27 eV for Cu^{26+} . The $2p_{1/2} 13\ell$ resonances are just above threshold, while the $2p_{3/2} 11\ell$ resonances are found around 5.0 eV. Electric fields in the range 0–50 V/cm have little effect on the Cu^{26+} spectrum. Overall, the agreement between theory and experiment is excellent.

Electron–ion recombination cross section calculations [39] in the IPIR approximation for low-lying resonances in Au^{76+} are compared with experiment in Fig. 59.3. The $2p_{1/2} nlj$ series limit is at 217 eV, while the $2p_{3/2} nlj$ series limit is at 2.24 keV, yielding a fine structure splitting of 2.03 keV. QED effects alone shift the $2p_{3/2} nlj$ series limit by 22.0 eV. Thus, accurate atomic structure calculations must be made to locate the $2p_{3/2} 6lj$ resonances in the 0–50 eV

energy range of the experiment. Figure 59.3 shows that the perturbative relativistic, semirelativistic, and fully relativistic calculations for the dielectronic recombination cross section ride on top of a strong radiative recombination background. In principle, the fully relativistic theory contains the most physics, and thus it is comforting that on the whole it is in good agreement with the experiment. It is instructive, however, to see how well the computationally simpler perturbative relativistic and semirelativistic theories do for such a highly charged ion.

There have been several recent experimental measurements on high- Z ions, in particular, for astrophysically abundant species. In general, there is good agreement between theory and experiment. Examples of high- Z element DR studies include those done on Fe^{21+} and Fe^{22+} by Savin et al. [48], and on Fe^{20+} by Savin et al. [53]. There have also been recent comparisons between experiment and theory for heavy metal ions, for example W^{18+} [54], W^{19+} [55], W^{20+} [56–59], and Au^{20+} [60, 61]. Many calculations of electron–ion recombination rate coefficients and photoionization cross sections for astrophysically important species, and especially in connection with the iron project, have been carried out by Nahar et al. For recent work, see [62, 63].

59.4 Radiative–Dielectronic Recombination Interference

There has been a great deal of effort in recent years to develop a more general theory of electron–ion recombination that would go beyond the IPIR approximation to include radiative–dielectronic recombination interference and overlapping (and interacting) resonance structures [64–71]. In almost all cases, the interference between a dielectronic recombination resonance and the radiative recombination background is quite small and difficult to observe. The best possibility for observation of RR–DR interference appears to be in highly charged atomic ions. In the cases studied to date, the combination of electron and photon continuum coupling selection rules and the requirement of near energy degeneracy make the overlapping (and interacting) resonance effects small and difficult to observe. Heavy ions in relatively low stages of ionization are the best place to look, since there are resonance series attached to the large numbers of LS terms or fine structure levels.

The distorted-wave approximation (Chap. 56) has been so successful in describing dielectronic recombination cross sections for most atomic ions because, for low charged ions, the DR cross section is proportional to the radiative rate, while for highly charged ions the DR cross section is proportional to the autoionization rate. Thus, the weakness of the distorted-wave method in calculating accurate autoionization rates for low charged ions is masked by a DR cross section

that is highly dependent on radiative atomic structure. As one moves to more highly charged ions, the DR cross section becomes more sensitive to the autoionization rates, but at the same time, the distorted-wave method becomes increasingly more accurate.

59.5 Dielectronic Recombination in Plasmas

Dielectronic recombination is an important atomic process that is included in the theoretical modeling of the ionization state and emission of radiating ions, which is fundamental to the interpretation of spectral emission from both fusion and astrophysical plasmas (Chap. 86). The dielectronic recombination rate coefficient, into a particular final recombined state, is given by

$$\alpha_{\text{DR}} = \sqrt{\frac{2}{\pi T^3}} k^2 \Delta \epsilon \langle \sigma_{\text{DR}}(i \rightarrow f) \rangle \exp\left(\frac{-k^2}{2T}\right), \quad (59.11)$$

where T is the electron temperature. Dielectronic recombination rate coefficients, from the ground and metastable states of a target ion into fully resolved low-lying states and bundled high-lying states of a recombined ion, are required for a generalized collisional radiative treatment [72, 73] of highly populated metastable states, the influence of finite plasma density on excited state populations, and of ionization in dynamic plasmas. We also note that contributions to recombination in plasmas may come from high Rydberg states just below the ionization threshold [74, 75].

Abstract

Collisions involving atoms or molecules in Rydberg orbitals are important in understanding a wide range of phenomena from the spectra of astrophysical objects, such as planetary nebulae and interstellar gas clouds, and industrial plasmas on Earth, to Bose-Einstein condensates and multi-qubit logic gates in quantum computing. This Chapter collects together many of the equations used to study theoretically the collisional properties of both charged and neutral particles with atoms and molecules in Rydberg states or orbitals, from thermal energies to ultracold temperatures, including the impulse approximation, binary encounter approximation and the Born approximation. Also covered are many new asymptotic methods and working formulae suitable for numerical computation, as well as models using scattering lengths and effective ranges. Readers interested in the basic quantum mechanical properties of Rydberg states may consult Chap. 15.

The theoretical techniques used to study Rydberg collisions complement and supplement the eigenfunction expansion approximations used for collisions with target atoms and molecules in their ground ($n = 1$) or first few excited states ($n > 1$), as discussed in Chap. 49. Direct application of eigenfunction expansion techniques to Rydberg collisions, wherein the target particle can be in a Rydberg orbital with principal quantum number in the range $n \geq 100$, is prohibitively difficult due to the need

to compute numerically and store wave functions with n^3 , or more, nodes. For $n = 100$ this amounts to $\approx 10^6$ nodes for each of the wave functions represented in the eigenfunction expansion. Therefore, a variety of approximate scattering theories have been developed to deal specifically with the peculiarities of Rydberg collisions.

Experiments in the ultracold regime, via the use of lasers and magnetic traps, has allowed access to aspects of many-body physics using collisions of Rydberg atoms in a gas that were previously inaccessible in condensed matter and nuclear physics. For the second edition of the Handbook we have changed the title of the chapter to reflect the broader array of theories now being used, in particular, in ultra-cold collisions of Rydberg atoms and the study of their universal properties.

binary encounter · Born approximation · impulse approximations · line strengths · correspondence principles · form factors · universality properties

60.1 Rydberg Collision Processes

(A) State-changing collisions Quasi-elastic ℓ -mixing collisions

$$A^*(n\ell) + B \rightarrow A^*(n\ell') + B. \quad (60.1)$$

Quasi-elastic J -mixing collisions: fine structure transitions with $J = |\ell \pm 1/2| \rightarrow J' = |\ell \pm 1/2|$ are

$$A^*(n\ell J) + B \rightarrow A^*(n\ell J') + B. \quad (60.2)$$

Energy transfer n -changing collisions

$$A^*(n) + B(\beta) \rightarrow A^*(n') + B(\beta'), \quad (60.3)$$

where, if B is a molecule, the transition $\beta \rightarrow \beta'$ represents an inelastic energy transfer to the rotational-vibrational degrees of freedom of the molecule B from the Rydberg atom A^* .

Elastic scattering

$$A^*(\gamma) + B \rightarrow A^*(\gamma) + B, \quad (60.4)$$

where the label γ denotes the set of quantum numbers n, ℓ or n, ℓ, J used.

Depolarization collisions

$$A^*(n\ell m) + B \rightarrow A^*(n\ell m') + B, \quad (60.5a)$$

$$A^*(n\ell JM) + B \rightarrow A^*(n\ell JM') + B. \quad (60.5b)$$

(B) Ionizing collisions Direct and associative ionization

Penning ionization

$$A^*(\gamma) + B \rightarrow A + B^+ + e^-. \quad (60.7)$$

Ion-pair formation

$$A^*(\gamma) + B \rightarrow A^+ + B^-. \quad (60.8)$$

Dissociative attachment

$$A^*(\gamma) + BC \rightarrow A^+B^- + C. \quad (60.9)$$

60.2 General Properties of Rydberg States

Figure 60.1 illustrates the range of physical phenomena where collisions of Rydberg atoms play a role from thermal molecular beams down to the ultracold regime of the Bose-Einstein condensates (BEC) and degenerate Fermi gases. The types of theories required to understand Rydberg atom collisions range from Born, binary-encounter and impulse approximations at thermal energies to hyperspherical, zero-range, and many-body theories in the cold and ultracold regimes. A good general introduction to Rydberg atom collision theories can be found in [1] and [2].

Table 60.1 displays the general n -dependence of a number of key properties of Rydberg states and some specific representative values for hydrogen.

60.2.1 Dipole Moments

Definition $D_{i \rightarrow f} = -eX_{i \rightarrow f}$, where

$$X_{i \rightarrow f} = \langle \phi_f | \sum_j e^{ik \cdot r_j} \mathbf{r}_j | \phi_i \rangle. \quad (60.10)$$

Hydrogenic dipole moments See *Bethe and Salpeter* [5] and the references by *Khandelwal* and coworkers [6–9] for details and tables.

Exact expressions In the limit $|k| \rightarrow 0$, the dipole allowed transitions summed over final states are

$$|X_{1s \rightarrow n}|^2 = \frac{2^8}{3} n^7 \frac{(n-1)^{2n-5}}{(n+1)^{2n+5}}, \quad (60.11a)$$

$$|X_{2s \rightarrow n}|^2 = \frac{2^5}{3n^3} \frac{(\frac{1}{2} - \frac{1}{n})^{2n-7}}{(\frac{1}{2} + \frac{1}{n})^{2n+7}} \left(\frac{1}{4} - \frac{1}{n^2} \right) \left(1 - \frac{1}{n^2} \right), \quad (60.11b)$$

$$|X_{2p \rightarrow n}|^2 = \frac{2^5}{144} \frac{1}{n^3} \frac{(\frac{1}{2} - \frac{1}{n})^{2n-7}}{(\frac{1}{2} + \frac{1}{n})^{2n+7}} \left(11 - \frac{12}{n^2} \right). \quad (60.11c)$$

Fig. 60.1 The world of ultracold atomic, molecular, and cluster systems [3]

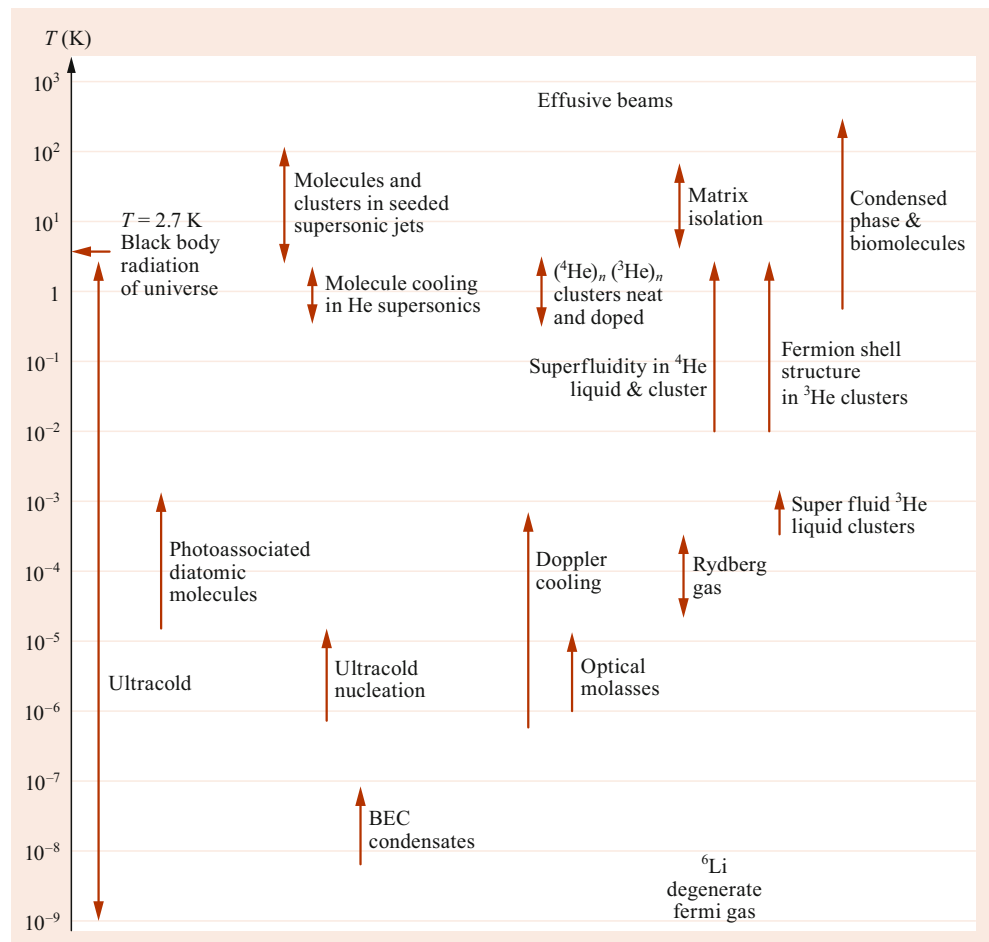

Table 60.1 General n -dependence of characteristic properties of Rydberg states. After [4]

Property	n -dependence	$n = 10$	$n = 100$	$n = 500$	$n = 1000$
Radius (cm)	$n^2 a_0 / Z$	5.3×10^{-7}	5.3×10^{-5}	1.3×10^{-3}	5.3×10^{-3}
Velocity (cm/s)	$v_B Z / n$	2.18×10^7	2.18×10^6	4.4×10^5	2.18×10^5
Area (cm ²)	$\pi a_0^2 n^4 / Z^2$	8.8×10^{-13}	8.8×10^{-9}	5.5×10^{-6}	8.8×10^{-5}
Ionization potential (eV)	$Z^2 R_\infty / n^2$	1.36×10^{-1}	1.36×10^{-3}	5.44×10^{-5}	1.36×10^{-6}
Radiative lifetime (s) ^a	$n^5 [3 \ln n - (1/4)] / (A_0 Z^4)$	8.4×10^{-5}	17	7.3×10^4	7.22 hours
Period of classical motion (s)	$2\pi / \omega_{n,n\pm 1} = \hbar n^3 / (2Z^2 R_\infty)$	1.5×10^{-13}	1.5×10^{-10}	1.9×10^{-8}	1.5×10^{-7}
Transition frequency (s ⁻¹)	$\omega_{n,n\pm 1} = 2Z^2 R_\infty / (\hbar n^3)$	4.1×10^{13}	4.1×10^{10}	3.3×10^8	4.1×10^7
Wavelength (cm)	$\lambda_{n,n\pm 1} = 2\pi c / \omega_{n,n\pm 1}$	4.6×10^{-3}	4.6	570	4.5609×10^3

^a $A_0 = [8\alpha^3 / (3\sqrt{3}\pi)] (v_B / a_0)$

Asymptotic expressions For $n \gg 1$,

$$n^3 |X_{1s \rightarrow n}|^2 \approx 1.563 + \frac{5.731}{n^2} + \frac{13.163}{n^4} + \frac{24.295}{n^6} + \frac{39.426}{n^8} + \frac{58.808}{n^{10}}, \quad (60.12a)$$

$$n^3 |X_{2s \rightarrow n}|^2 \approx 14.658 + \frac{180.785}{n^2} + \frac{1435.854}{n^4} + \frac{9341.634}{n^6} + \frac{54,208.306}{n^8} + \frac{292,202.232}{n^{10}}, \quad (60.12b)$$

$$n^3 |X_{2p \rightarrow n}|^2 \approx 13.437 + \frac{218.245}{n^2} + \frac{2172.891}{n^4} + \frac{17,118.786}{n^6} + \frac{117,251.682}{n^8} + \frac{731,427.003}{n^{10}}. \quad (60.12c)$$

60.2.2 Interaction Potentials

H(n)-H(n) long-range interactions [10]

$$V_{\rightarrow,\rightarrow}(R) = -\frac{2}{R^3}Q_1^2 - \frac{2}{R^5}[4Q_1Q_3 - 3Q_2^2] - \frac{2}{R^7}[6Q_1Q_5 - 15Q_2Q_4 + 10Q_3^2] - O(R^{-9}), \quad (60.13)$$

for parallel-aligned dipoles; and,

$$V_{\leftarrow,\rightarrow}(R) = \frac{2}{R^3}Q_1^2 + \frac{6}{R^4}Q_1Q_2 + \frac{2}{R^5}[4Q_1Q_3 + 3Q_2^2][Q_1Q_4 + 2Q_2Q_3] + \frac{2}{R^7}[6Q_1Q_5 + 15Q_2Q_4 + 10Q_3^2] - O(R^{-8}), \quad (60.14)$$

for antiparallel-aligned dipoles.

Analytical expressions for the Q_L multipole moments for $L = 0 - 5$ are provided in Table 60.2. Full expressions for L up to 10 are provided in [10].

He(2^{1,3}P)-He(2^{1,3}P) Long-range dispersion coefficients [11] Expressions for the second-order potential, $V^{(2)}$, for the first three molecular states are:

Σ molecular states

$$V^{(2)}(\Sigma, \beta; \lambda_i) = -\sum_{n \geq 3} \frac{C_{2n}(\Sigma, \beta; \lambda_i)}{R^{2n}} \quad (60.15a)$$

$$C_{2n}(\Sigma, \beta; \lambda_i) = \sum_{\substack{\ell, L, \ell', L' \geq 1 \\ \ell + L + \ell' + L' + 2 = 2n}} D_{\lambda_i}(\ell, L, \ell', L'), \quad (60.15b)$$

where the D_{λ_i} are defined

$$D_{\lambda_i}(\ell, L, \ell', L') = \frac{3\alpha^2}{8} \sum_{L_s, L_t} f_{\lambda_i}(\ell, L, L_s; L_t, \ell', L') \times (G_1 + (2-i)^{(2-i)}G_2). \quad (60.16)$$

Table 60.2 Multipoles Q_L for the Stark states $|\pm\rangle$ of H(n)

Multipole	Value	Asymptotic value
$Q_0(+)=Q_0(-)$	1	
$Q_1(+)= -Q_1(-)$	$(3/2)n(n-1)$	$(3/2)n^2$
$Q_2(+)=Q_2(-)$	$(2/2^2)n^2(n-1)(5n-7)$	$(5/2)n^4$
$Q_3(+)= -Q_3(-)$	$(5/2^3)n^3(n-1)(n-2)(7n-9)$	$(35/8)n^6$
$Q_4(+)=Q_4(-)$	$(6/2^4)n^4(n-1)(n-2)(21n^2-77n+62)$	$(63/8)n^8$
$Q_5(+)= -Q_5(-)$	$(42/2^5)n^5(n-1)(n-2)(n-3)(11n^2-39n+30)$	$(231/16)n^{10}$

Π molecular states

$$V^{(2)}(\Pi, \beta; \gamma) = -\sum_{n \geq 3} \frac{C_{2n}(\Pi, \beta; \gamma)}{R^{2n}} \quad (60.17a)$$

$$C_{2n}(\Pi, \beta; \gamma) = \sum_{\substack{\ell, L, \ell', L' \geq 1 \\ \ell + L + \ell' + L' + 2 = 2n}} D_{\beta\gamma}(\ell, L, \ell', L'), \quad (60.17b)$$

where the $D_{\beta\gamma}$ are defined

$$D_{\beta\gamma}(\ell, L, \ell', L') = \frac{9\alpha^2}{16} \sum_{L_s, L_t} [f_{1\gamma}(\ell, L, L_s; L_t, \ell', L')G_1 + f_{2\gamma}(\ell, L, L_s, L_t, \ell', L')G_2]. \quad (60.18)$$

Δ molecular states

$$V^{(2)} = -\sum_{\ell\ell'LL'} \frac{D_1(\ell, L, \ell', L')}{R^{\ell+L+\ell'+L'+2}}, \quad (60.19)$$

where the D_1 are defined

$$D_1(\ell, L, \ell', L') = \frac{1}{2\pi} \sum_{L_s, L_t} G_1(\ell, L, \ell', L', L_s, L_t) \times F_1(\ell, L, \ell', L', L_s, L_t). \quad (60.20)$$

See [11] for detailed tabulations of the dispersion coefficients C and for the (lengthy) expressions for the various $f_{\lambda_i}, f_1, f_2, F_1, G_1, G_2$ functions appearing in Eqs. (60.16), (60.18), and (60.20).

Cs-Cs and Rb-Rb pseudo-potentials [12] $V_{LS}(r)$ for $L = 0, 1$

$$V_{0S}(r) = -\frac{A}{r}e^{-\gamma r} - \frac{\alpha}{2r^4} \left(1 - e^{-(r/r_c)^6}\right) \quad (60.21a)$$

$$V_{1S}(r) = -\frac{Z_c}{r}e^{-\lambda r} - Ae^{-\gamma r} - \frac{\alpha}{2r^4} \left(1 - e^{-(r/r_c)^6}\right), \quad (60.21b)$$

where the fitted parameters for Cs and Rb are given in Table 60.3. For the case of Sr-Sr, see [13], while for e⁻-Ne, see [14].

Table 60.3 Fit parameters for Cs-Cs and Rb-Rb pseudo-potentials (from [12])

	r_0	α	λ	State	A	γ	r_c

60.2.3 Radial Integrals

Definition

$$R_{n\ell}^{n'\ell'} \equiv \int_0^\infty R_{n\ell}(r)rR_{n'\ell'}(r)r^2dr, \quad (60.22)$$

where $R_{n\ell}(r)$ are solutions to the radial Schrödinger equation. See Chap. 9 for specific representations of $R_{n\ell}$ for hydrogen.

Exact results for hydrogen For $\ell' = \ell - 1$ and $n \neq n'$ [15],

$$\begin{aligned} R_{n\ell}^{n'\ell-1} &= \frac{a_0}{Z} \frac{(-1)^{n'-\ell} (4nn')^{\ell+1} (n-n')^{n+n'-2\ell-2}}{4(2\ell-1)!(n+n')^{n+n'}} \\ &\times \left[\frac{(n+\ell)!(n'+\ell-1)!}{(n'+\ell')!(n-\ell-1)!} \right]^{1/2} \\ &\times \left\{ {}_2F_1(-n+\ell+1, -n'+\ell; 2\ell; Y) \right. \\ &\quad \left. - \left(\frac{n-n'}{n+n'} \right)^2 \right. \\ &\quad \left. \times {}_2F_1(-n+\ell-1, -n'+\ell; 2\ell; Y) \right\}, \quad (60.23) \end{aligned}$$

where $Y = -4nn'/(n-n')^2$. For $n = n'$,

$$R_{n\ell}^{n\ell-1} = \left(\frac{a_0}{Z} \right) \frac{3}{2} n \sqrt{n^2 - \ell^2}. \quad (60.24)$$

The hypergeometric functions ${}_2F_1$ in Gordon's formulae above are increasingly difficult to compute numerically due to unavoidable roundoff errors. See Sect. 60.8 for working formulae suitable for numerical computations.

Semiclassical quantum defect representation [16]

$$\begin{aligned} |R_{n\ell}^{n'\ell'}|^2 &= \left(\frac{a_0}{Z} \right)^2 \\ &\times \left| \frac{n_c^2}{2\Delta} \left[\left(1 - \frac{\Delta\ell\ell_{>}}{n_c} \right) J_{\Delta-1}(-x) \right. \right. \\ &\quad \left. \left. - \left(1 + \frac{\Delta\ell\ell_{>}}{n_c} \right) J_{\Delta+1}(-x) \right. \right. \\ &\quad \left. \left. + \frac{2}{\pi} \sin(\pi\Delta)(1-e) \right] \right|^2, \quad (60.25) \end{aligned}$$

where

$$n_c = 2n^*n'^*/(n^* + n'^*), \quad (60.26a)$$

$$\Delta = n'^* - n^*, \quad (60.26b)$$

$$\Delta\ell = \ell' - \ell, \ell_{>} = \max(\ell, \ell'), \quad (60.26c)$$

$$x = e\Delta, e = \sqrt{1 - (\ell_{>}/n_c)^2}, \quad (60.26d)$$

and $J_n(y)$ is the Anger function.

The energies of the states $n\ell$ and $n'\ell'$ are given in terms of the quantum defects δ by

$$E_{n\ell} = -Z^2 R_\infty / n^{*2}, n^* = n - \delta_\ell, \quad (60.27a)$$

$$E_{n'\ell'} = -Z^2 R_\infty / n'^{*2}, n'^* = n' - \delta_{\ell'}. \quad (60.27b)$$

Sum rule For hydrogen

$$\sum_{n'} |R_{n\ell}^{n'\ell-1}|^2 = \sum_{n'} |R_{n\ell}^{n'\ell+1}|^2 \quad (60.28a)$$

$$= \frac{n^2 a_0^2}{2Z^2} [5n^2 + 1 - 3\ell(\ell+1)]. \quad (60.28b)$$

See §61 of [5] for additional sum rules.

Zéldovich effect [17]

$$\frac{a_B}{2\pi a_s} = -\cot \pi\delta - \frac{2}{\pi} \ln \frac{2}{\gamma x_0}, \quad (60.29)$$

where a_B is the Bohr radius of the Coulomb field, δ is the quantum defect, $\ln \gamma$ is Euler's constant, $x_0 = \sqrt{8r_0/a_B}$, and r_0 is the radius of the short-range field.

60.2.4 Line Strengths

Definition

$$S(n'\ell', n\ell) = e^2 (2\ell+1) |r_{n'\ell', n\ell}|^2 \quad (60.30a)$$

$$= e^2 \max(\ell, \ell') |R_{n\ell}^{n'\ell'}|^2, \quad (60.30b)$$

where $\ell' = \ell \pm 1$. For hydrogen,

$$S(n', n) = 32 \left(\frac{ea_0}{Z} \right)^2 (nn')^6 \frac{(n-n')^{2(n+n')-3}}{(n+n')^{2(n+n')+4}} \times \left\{ \left[{}_2F_1(-n', -n+1; 1; Y) \right]^2 - \left[{}_2F_1(-n'+1, -n; 1; Y) \right]^2 \right\}, \quad (60.31)$$

where $Y = -4nn'/(n-n')^2$.

Semiclassical representation [18]

$$S(n', n) = \frac{32}{\pi\sqrt{3}} \left(\frac{ea_0}{Z} \right)^2 \frac{(\varepsilon\varepsilon')^{3/2}}{(\varepsilon - \varepsilon')^4} G(\Delta n), \quad (60.32)$$

where $\varepsilon = 1/n^2$, $\varepsilon' = 1/n'^2$, and the Gaunt factor $G(\Delta n)$ is given by

$$G(\Delta n) = \pi\sqrt{3} |\Delta n| \mathbf{J}_{\Delta n}(\Delta n) \mathbf{J}'_{\Delta n}(\Delta n), \quad (60.33)$$

where the prime on the Anger function denotes differentiation with respect to the argument Δn . Equation (60.33) can be approximated to within 2% by the expression

$$1 - \frac{1}{4|\Delta n|}. \quad (60.34)$$

Relation to oscillator strength

$$S(n', n) = \sum_{\ell, \ell'} S(n'\ell', n\ell) = 3e^2 a_0^2 \frac{R_\infty}{\hbar\omega} \sum_{\ell, \ell'} f_{n'\ell', n\ell}. \quad (60.35)$$

Connection with radial integrals

$$-f_{n'\ell', n\ell} = \frac{\hbar\omega}{3R_\infty} \frac{\max(\ell, \ell')}{(2\ell+1)} |R_{n\ell}^{n'\ell'}|. \quad (60.36)$$

Density of line strengths For bound-free $n\ell \rightarrow E\ell'$ transitions in a Coulomb field, the semiclassical representation [4] is

$$\frac{d}{dE} S(n\ell, E) = 2n(2\ell+1) \left(\frac{R_\infty}{\hbar\omega} \right)^2 \times \left[\mathbf{J}'_{\Delta}(\mathbf{e}\Delta)^2 + \left(1 - \frac{1}{\mathbf{e}^2} \right) \mathbf{J}_{\Delta}(\mathbf{e}\Delta)^2 \right] \times \frac{e^2 a_0^2}{R_\infty}, \quad (60.37)$$

where $\Delta = \hbar\omega n^3/2R_\infty$ and $\mathbf{e} = \sqrt{1 - (\ell + (1/2))^2/n^2}$. The asymptotic expression for $\Delta \gg 1$

$$\frac{d}{dE} S(n\ell, E) = \frac{2(2\ell+1)}{3\pi^2} \left(\frac{R_\infty}{\hbar\omega} \right)^2 \frac{(\ell + \frac{1}{2})^4}{n^3} \times \left[K_{1/3}^2(\eta) + K_{2/3}^2(\eta) \right] \frac{e^2 a_0^2}{R_\infty}, \quad (60.38)$$

where $\eta = (E/R_\infty)(\ell + 1/2)^3/6$, and $K_\nu(x)$ are Bessel functions of the third kind.

Line strength of line n

$$S_n \equiv S(n) = \sum_{k \neq 0} S(n+k, n) \frac{1}{k^3}. \quad (60.39)$$

Born approximation to line strength S_n [4]

$$S_n^B = \frac{Z^2 R_\infty}{E} \left[\frac{1}{2} \ln(1 + \varepsilon_e/\varepsilon) \sum_{k \neq 0} \left(1 - \frac{1}{4k} \right) \frac{1}{k^4} + \frac{4}{3} \frac{\varepsilon_e}{\varepsilon + \varepsilon_e} \sum_{k \neq 0} \left(1 - \frac{0.60}{k} \right) \frac{1}{k^3} \right] = \frac{Z^2 R_\infty}{E} \left[0.82 \ln \left(1 + \frac{\varepsilon_e}{\varepsilon} \right) + \frac{1.47\varepsilon_e}{\varepsilon + \varepsilon_e} \right], \quad (60.40)$$

where $\varepsilon = |E_n|Z^2/R_\infty$ and $\varepsilon_e = \varepsilon/Z^2 R_\infty$.

60.2.5 Form Factors

$$F_{n'n}(Q) = \sum_{\ell, m} \sum_{\ell', m'} | \langle n\ell m | e^{i\mathbf{Q}\cdot\mathbf{r}} | n'\ell' m' \rangle |^2. \quad (60.41)$$

Connection with generalized oscillator strengths

$$f_{n'n}(Q) = \frac{Z^2 \Delta E}{n^2 Q^2 a_0^2} F_{n'n}(Q). \quad (60.42)$$

Semiclassical limit

$$\lim_{Q \rightarrow 0} f_{n'n}(Q) = \frac{32}{3n^2} \left(\frac{nn'}{\Delta n(n+n')} \right)^3 \times \Delta n \mathbf{J}_{\Delta n}(\Delta n) \mathbf{J}'_{\Delta n}(\Delta n), \quad (60.43)$$

where $J_m(y)$ denotes the Bessel function.

Representation as microcanonical distribution

$$F_{n'n\ell}(Q) = (2\ell+1) \frac{2Z^2 R_\infty}{n^3} \int d\mathbf{p} |g_{n\ell}(p)|^2 \times \delta \left(\frac{(\mathbf{p} - \hbar\mathbf{Q})^2}{2m} - \frac{p^2}{2m} - E_{n'} - E_{n\ell} \right), \quad (60.44)$$

$$F_{n'n}(Q) = \frac{4Z^2 R_\infty^2}{(nn')^3} \int \frac{d\mathbf{p} d\mathbf{r}}{(2\pi\hbar)^3} \delta \left(\frac{p^2}{2m} - \frac{Ze^2}{r} - E_n \right) \times \delta \left(\frac{(\mathbf{p} - \hbar\mathbf{Q})^2}{2m} - \frac{Ze^2}{r} - E_{n'} \right), \quad (60.45)$$

$$= \frac{2^9}{3\pi (nn')^3} \frac{\kappa^5}{(\kappa^2 + \kappa_+^2)^3 (\kappa^2 + \kappa_-^2)^3}, \quad (60.46)$$

where $\kappa = Qa_0/Z$, and $\kappa_\pm = |1/n \pm 1/n'|$.

60.2.6 Impact Broadening

The total broadening cross section of a level n is

$$\sigma_n = (\pi a_0^2 / Z^4) n^4 S_n. \quad (60.47)$$

The width of a line $n \rightarrow n+k$ is [19]

$$\gamma_{n,n+k} = n_e [\langle v\sigma_n \rangle + \langle v\sigma_{n+k} \rangle], \quad (60.48)$$

where n_e is the number density of electrons, and

$$\langle v\sigma_n \rangle = \sum_{k \neq 0} \langle v\sigma_{n+k,n} \rangle = \frac{n^4}{Z^3} K_n \quad (60.49a)$$

$$= \frac{n^4 \pi a_0^2 v_B}{Z^3 \theta^{3/2}} \int_0^\infty e^{-E/k_B T} S_n \frac{E dE}{(Z^2 R_\infty)^2}, \quad (60.49b)$$

where $\theta = k_B T / Z^2 R_\infty$. See Chap. 63 for collisional line broadening.

60.2.7 Effective Lifetimes and Depopulation Rates

Black-body radiation (BBR) depopulation rates [20]

$$\Gamma_{\text{BBR}} = \frac{1}{n_{\text{eff}}^5} \frac{2.14 \times 10^{10}}{\exp(315,780/n_{\text{eff}}^3 T) - 1} (s^{-1}), \quad (60.50)$$

where n_{eff} represents an effective quantum number for $n > 15$.

Effective sum rule

$$\sum_{n'} \omega_{nn'} f(nL \rightarrow n'L') = \frac{2}{3n_{\text{eff}}^2}. \quad (60.51)$$

For nP and nD states, Eq. (60.50) overestimates the lifetimes for intermediate quantum numbers $n \sim 20$. For those states a generalization of Eq. (60.50) using fitted parameters A , B , C , and D is appropriate,

$$\Gamma_{\text{BBR}} = \frac{A}{n_{\text{eff}}^D} \frac{2.14 \times 10^{10}}{\exp(315,780B/n_{\text{eff}}^C T) - 1} (s^{-1}). \quad (60.52)$$

Semiempirical radiative lifetimes [21]

$$\tau_0 = \tau_s n_{\text{eff}}^\delta (ns.) \quad (60.53)$$

Effective lifetimes [20]

$$\tau_{\text{eff}} = \left(\frac{1}{\tau_s n_{\text{eff}}^\delta} \frac{A}{n_{\text{eff}}^D} \frac{21.4}{\exp(315,780B/n_{\text{eff}}^C T) - 1} \right)^{-1} (ns.) \quad (60.54)$$

See [20] for extensive tables of the effective lifetimes and fitted parameters A , B , C , D , τ_s , and δ for the alkali atoms.

Depopulation rates for trapped Rydberg states [22]

$$\Gamma_{n'\ell'm\pm 1}^{n\ell m}(B) = \left(1 \mp \frac{n^2 n'^2}{n^2 - n'^2} \frac{\mu_B B}{R_\infty \hbar c} \right)^3 \Gamma_{n'\ell'm\pm 1}^{n\ell m}(0), \quad (60.55)$$

where B is the external magnetic field, μ_B is the Bohr magneton, and $\Gamma(0)$ is the field-free depopulation rate.

60.3 Correspondence Principles

Correspondence principles are used to connect quantum mechanical observables with the corresponding classical quantities in the limit of large n . See [23] for details on the equations in this section.

60.3.1 Bohr-Sommerfeld Quantization

$$A_i = J_i \Delta w_i \oint p_i dq_i = 2\pi \hbar (n_i + \alpha_i), \quad (60.56)$$

where $n_i = 0, 1, 2, \dots$ and $\alpha_i = 0$ if the generalized coordinate q_i represents rotation, and $\alpha_i = 1/2$ if q_i represents a libration.

60.3.2 Bohr Correspondence Principle

$$E_{n+s} - E_n = h\nu_{n+s,n} \approx s\hbar\omega_n, \quad s = 1, 2, \dots \ll n, \quad (60.57)$$

where $\nu_{n+s,n}$ is the line emission frequency, and ω_n is the angular frequency of classical orbital motion. The number of states with quantum numbers in the range Δn is

$$\begin{aligned} \Delta N &= \prod_{i=1}^D \Delta n = \prod_{i=1}^D (\Delta J_i \Delta w_i) / (2\pi \hbar)^D \\ &= \prod_{i=1}^D (\Delta p_i \Delta q_i) / (2\pi \hbar)^D, \end{aligned} \quad (60.58)$$

for systems with D degrees of freedom, and the mean value \bar{F} of a physical quantity $F(q)$ in the quantum state Ψ is

$$\bar{F} = \langle \Psi | F(q) | \Psi \rangle = \sum_{n,m} a_m^* a_n F_{mn}^{(q)} e^{i\omega_{mn} t}, \quad (60.59)$$

where the $F_{mn}^{(q)}$ are the quantal matrix elements between time-independent states.

The first order S -matrix is

$$S_{fi} = -\frac{i\omega}{2\pi \hbar} \int_{-\infty}^{\infty} dt \int_0^{2\pi/\omega} V[\mathbf{R}(t), r(t_1)] e^{is\omega(t_1-t)} dt_1, \quad (60.60)$$

where \mathbf{R} denotes the classical path of the projectile and r the orbital of the Rydberg electron.

60.3.3 Heisenberg Correspondence Principle

For one degree of freedom [23],

$$F_{mn}^{(q)}(\mathbf{R}) = \int_0^\infty \phi_m^*(r) F(r, \mathbf{R}) \phi_n(r) dr \quad (60.61)$$

$$= \frac{\omega}{2\pi} \int_0^{2\pi/\omega} F^{(c)}[r(t)] e^{is\omega t} dt. \quad (60.62)$$

The three-dimensional generalization is [23]

$$F_{n,n'}^{(q)} \approx F_s^{(c)}(\mathbf{J}) = \frac{1}{8\pi^3} \int F^c[\mathbf{r}(\mathbf{J}, \mathbf{w})] e^{is \cdot \mathbf{w}} d\mathbf{w}, \quad (60.63)$$

where \mathbf{n}, \mathbf{n}' denotes the triple of quantum numbers (n, ℓ, m) , (n', ℓ', m') , respectively, and $s = \mathbf{n} - \mathbf{n}'$.

The correspondence between the three-dimensional quantum and classical matrix elements in Eq. (60.63) follows from the general Fourier expansion for any classical function $F^{(c)}(\mathbf{r})$ periodic in \mathbf{r} ,

$$F^{(c)}[\mathbf{r}(t)] = \sum_s F_s^{(c)}(\mathbf{J}) \exp(-is \cdot \mathbf{w}), \quad (60.64)$$

where \mathbf{J}, \mathbf{w} denotes the action-angle conjugate variables for the motion. For the three-dimensional Coulomb problem, the action-angle variables are

$$\begin{aligned} J_n &= n\hbar, & w_n &= \left(\frac{\partial E}{\partial J_n} \right) t + \delta, \\ J_\ell &= \left(\ell + \frac{1}{2} \right) \hbar, & w_\ell &= \psi_E, \\ J_m &= m\hbar, & w_m &= \phi_E, \end{aligned} \quad (60.65)$$

where ψ_E is the Euler angle between the line of nodes and a direction in the plane of the orbit (usually taken to be the direction of the perihelion or perigee), and is constant for a Coulomb potential. The Euler angle ϕ_E is the angle between the line of nodes and the fixed x -axis. See [23] for details.

The first-order S -matrix is

$$S_{fi} = -\frac{i\omega}{2\pi\hbar} \int_0^{2\pi/\omega} dt_e \int_{-\infty}^\infty dt V[\mathbf{R}(t), r(t+t_e)] e^{is\omega t_e}, \quad (60.66)$$

with $s = i - f$, \mathbf{R} is the classical path of the projectile, and $r(t_e)$ is the classical internal motion of the Rydberg electron.

60.3.4 Strong Coupling Correspondence Principle

The S -matrix is

$$S_{fi} = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} dt_e \times \exp \left\{ i(s\omega t_e) - \frac{i}{\hbar} \int_{-\infty}^\infty V[\mathbf{R}(t), r(t+t_e)] dt \right\}. \quad (60.67)$$

See [23–26] for additional details.

60.3.5 Equivalent Oscillator Theorem

$$\sum_n^f a_n(t) V_{fn}(t) e^{i\omega_f t} = \sum_{d=-f}^f a_{d+f}(t) V_d(t) e^{-id\omega t}. \quad (60.68)$$

The S -matrix is

$$\begin{aligned} S_{n',n} &= a_{n'}(t \rightarrow \infty) \\ &= \int_0^{2\pi} \frac{d\mathbf{w}}{8\pi^3} \exp \left[is \cdot \mathbf{w} - \frac{i}{\hbar} \int_{-\infty}^\infty V(\mathbf{w} + \omega t, t) dt \right]. \end{aligned} \quad (60.69)$$

60.4 Distribution Functions

The function $W_\alpha(x)dx$ characterizes the probability (distribution) of finding an electron in a Rydberg orbital α within a volume dx centered at the point x in phase space. Integration of the distribution function W_α over all phase space volumes dx yields, depending upon the normalization chosen, either unity or the density of states appropriate to the orbital α .

60.4.1 Spatial Distributions

Distribution over n, ℓ, m [4]

$$\begin{aligned} W_{n\ell m}(r, \theta) r^2 \sin \theta dr d\theta \\ = \frac{r^2 \sin \theta dr d\theta}{\pi^2 a^2 r \{ [e^2 - (1 - r/a)^2] [\sin^2 \theta - (m/\ell)^2] \}^{1/2}}, \end{aligned} \quad (60.70)$$

where $a = Ze^2/2|E| = n^2\hbar^2/mZe^2\hbar^2$ is the semimajor axis, and $e^2 = 1 - (\ell/n)^2$ is the eccentricity.

Distribution over n, ℓ

$$W_{n\ell}(r, \theta)r^2 \sin \theta dr d\theta = g(n\ell) \frac{r^2 \sin \theta dr d\theta}{2\pi a^2 r [e^2 - (1 - r/a)^2]^{1/2}}, \quad (60.71)$$

where $g(n\ell) = 2\ell$.

Distribution over n

$$W_n(r)r^2 dr = g(n) \frac{2}{\pi} \left[1 - \left(1 - \frac{r}{a} \right)^2 \right]^{1/2} \frac{r dr}{a^2}, \quad (60.72)$$

with $g(n) = n^2$.

60.4.2 Momentum Distributions

Distribution over n, ℓ [4]

$$W_{n\ell}(p)p^2 dp = g(n\ell) \frac{4}{\pi} \frac{dx}{(1+x^2)^2}, \quad (60.73)$$

where $x = p/p_n$ and $p_n^2 = 2m|E|$.

Distribution over n

$$W_n(p)p^2 dp = g(n) \frac{32}{\pi} \frac{x^2 dx}{(1+x^2)^4}. \quad (60.74)$$

Sum rules

$$\frac{1}{n^2} \sum_{\ell, m} |G_{n\ell m}(\mathbf{k})|^2 = \left(\frac{na_0}{Z} \right)^3 \frac{8}{\pi^2 (x^2 + 1)^4}, \quad (60.75a)$$

$$\frac{1}{n^2} \sum_{\ell=0}^{n-1} (2\ell + 1) |g_{n\ell}(k)|^2 k^2 = \frac{32na_0 x^2}{\pi Z (x^2 + 1)^4}, \quad (60.75b)$$

where $x = nka_0/Z$, and

$$G_{n\ell m}(\mathbf{k}) = g_{n\ell}(k) Y_{\ell m}(\hat{\mathbf{k}}), \quad (60.76a)$$

$$g_{n\ell}(k) = \left(\frac{2}{\pi} \frac{(n-\ell-1)!}{(n+\ell)!} \right)^{1/2} \left(\frac{a_0}{Z} \right)^{3/2} 2^{2(\ell+1)} n^2 \ell! \times \frac{(-ix)^\ell}{(x^2+1)^{\ell+2}} C_{n-\ell-1}^{(\ell+1)} \left(\frac{x^2-1}{x^2+1} \right), \quad (60.76b)$$

where $C_i^{(j)}(y)$ is the associated Gegenbauer polynomial. See Chap. 9 for additional details on hydrogenic wave functions.

Quantum defect representation [27]

$$g_{n\ell}(k) = - \left(\frac{2}{\pi} \frac{\Gamma(n^* - 1)}{\Gamma(n^* + \ell + 1)} \right)^{1/2} n^* (a_0/Z)^{3/2} 2^{2(\ell+1)} \times \frac{(\ell+1)! (-ix)^\ell}{(x^2+1)^{\ell+2}} J(n^*, \ell+1; X), \quad (60.77)$$

where $n^* = n - \delta$, δ being the quantum defect, and $x = n^*ka_0/Z$. The function J is given by the recurrence relation

$$J(n^*, \ell+1; X) = - \frac{1}{2(2\ell+2)} \frac{\partial}{\partial X} J(n^*, \ell; X),$$

$$J(n^*, 0; X) = - \frac{n^* \sin[n^*(\beta - \pi)]}{\sin(\beta - \pi)} - \frac{\sin n^* \pi}{\pi} \int_0^1 \frac{(1-s^2)s^{n^*}}{(1-2Xs+s^2)} ds, \quad (60.78)$$

where $X = (x^2 - 1)/(x^2 + 1)$, and $\beta = \cos^{-1} X$. In the limit $\ell \ll n^*$, Eq. (60.77) becomes

$$|g_{n\ell}(k)|^2 = 4 \left(\frac{n^* a_0}{Z} \right)^3 \frac{1 - (-1)^\ell \cos[2n^*(\beta - \pi)]}{\pi x^2 (x^2 + 1)^2}. \quad (60.79)$$

Classical density of states

$$\rho(E) = \int \delta[E - H(\mathbf{p}, \mathbf{r})] \frac{d\mathbf{p}d\mathbf{r}}{(2\pi\hbar)^3} = \frac{n^5 \hbar^2}{mZ^2 e^4}. \quad (60.80)$$

60.5 Classical Theory

The classical cross section for energy transfer ΔE between two particles, with arbitrary masses m_1, m_2 , and charges Z_1, Z_2 , is given by [28]

$$\sigma_{\Delta E}(\mathbf{v}_1, \mathbf{v}_2) = \frac{2\pi(Z_1 Z_2 e^2 V)^2}{v^2 |\Delta E|^3} \times \left(1 + \cos^2 \bar{\theta} + \frac{\Delta E}{\mu v V} \cos \bar{\theta} \right), \quad (60.81)$$

valid for $-1 \leq \cos \bar{\theta} - \Delta E/(\mu v V) \leq 1$, and $\sigma_{\Delta E}(\mathbf{v}_1, \mathbf{v}_2) = 0$ otherwise, where

$$\mathbf{v} = \mathbf{v}_1 - \mathbf{v}_2, \quad (60.82a)$$

$$\mathbf{V} = (m_1 \mathbf{v}_1 + m_2 \mathbf{v}_2)/M, \quad (60.82b)$$

$$\cos \bar{\theta} = \frac{1}{vV} \mathbf{v} \cdot \mathbf{V}, \quad (60.82c)$$

and $\mu = m_1 m_2 / M$, $M = m_1 + m_2$. If particle 2 has an isotropic velocity distribution in the lab frame, the effective cross section averaged over the direction $\hat{\mathbf{n}}_2$ of \mathbf{v}_2 is

$$v_1 \sigma_{\Delta E}^{(\text{eff})}(\mathbf{v}_1, \mathbf{v}_2) = \frac{1}{4\pi} \int d\hat{\mathbf{n}}_2 |\mathbf{v}_1 - v_2 \hat{\mathbf{n}}_2| \sigma_{\Delta E}(\mathbf{v}_1, \mathbf{v}_2). \quad (60.83)$$

If v_1 is also isotropic, then the average of Eq. (60.83), together with Eq. (60.81), gives for the special case of a Coulomb potential

$$\begin{aligned} \sigma_{\Delta E}^{(\text{eff})}(\mathbf{v}_1, \mathbf{v}_2) &= \frac{\pi(Z_1 Z_2 e^2)^2}{4|\Delta E|3v_1^2 v_2} \left[(v_1^2 - v_2^2)(v_2^2 - v_1^2)(v_l^{-1} - v_u^{-1}) \right. \\ &\quad \left. + (v_1^2 + v_2^2 + v_1^2 + v_2^2)(v_u - v_l) - \frac{1}{3}(v_u^3 - v_l^3) \right], \end{aligned} \quad (60.84)$$

where

$$v'_1 = (v_1^2 - 2\Delta E/m_1)^{1/2}, \quad (60.85)$$

$$v'_2 = (v_2^2 + 2\Delta E/m_2)^{1/2}, \quad (60.86)$$

and v_u, v_l are defined below for cases 1–4. With the definitions

$$\Delta\varepsilon_{12} = 4m_1 m_2 (E_1 - E_2)/M^2, \quad \Delta m_{12} = |m_1 - m_2|,$$

$$\Delta\tilde{\varepsilon}_{12} = \frac{4m_1 m_2}{M^2} \left(E_1 \frac{v_2}{v_1} - E_2 \frac{v_1}{v_2} \right),$$

the four cases are

1. $\Delta E \geq \Delta\varepsilon_{12} + |\Delta\tilde{\varepsilon}_{12}| \geq 0$, and $2m_2 v_2 \geq \Delta m_{12} v_1$

$$v_l = v'_2 - v'_1, \quad v_u = v'_1 + v'_2, \quad \Delta E \geq 0; \quad (60.87a)$$

$$v_l = v_2 - v_1, \quad v_u = v_1 + v_2, \quad \Delta E \leq 0. \quad (60.87b)$$

If $2m_2 v_2 < \Delta m_{12} v_1$, then $\sigma_{\Delta E}^{(\text{eff})}(v_1, v_2) = 0$,

2. $\Delta\varepsilon_{12} - \Delta\tilde{\varepsilon}_{12} \leq \Delta E \leq \Delta\varepsilon_{12} + \Delta\tilde{\varepsilon}_{12}$, and $m_1 > m_2$

$$v_l = v'_2 - v'_1, \quad v_u = v_1 + v_2, \quad \Delta E \geq 0; \quad (60.87c)$$

$$v_l = v_2 - v_1, \quad v_u = v'_1 + v'_2, \quad \Delta E \leq 0. \quad (60.87d)$$

3. $\Delta E \leq \Delta\varepsilon_{12} - |\Delta\tilde{\varepsilon}_{12}| \leq 0$, and $2m_1 v_1 \geq \Delta m_{12} v_2$

$$v_l = v_1 - v_2, \quad v_u = v_1 + v_2, \quad \Delta E \geq 0; \quad (60.87e)$$

$$v_l = v'_1 - v'_2, \quad v_u = v'_1 + v'_2, \quad \Delta E \leq 0. \quad (60.87f)$$

If $2m_1 v_1 < \Delta m_{12} v_2$, then $\sigma_{\Delta E}^{(\text{eff})}(v_1, v_2) = 0$,

4. $\Delta\varepsilon_{12} + \Delta\tilde{\varepsilon}_{12} \leq \Delta E \leq \Delta\varepsilon_{12} - \Delta\tilde{\varepsilon}_{12}$, and $m_1 < m_2$

$$v_l = v_1 - v_2, \quad v_u = v'_1 + v'_2, \quad \Delta E \geq 0; \quad (60.87g)$$

$$v_l = v'_1 - v'_2, \quad v_u = v_1 + v_2, \quad \Delta E \leq 0. \quad (60.87h)$$

If $2m_1 v_1 < \Delta m_{12} v_2$, then $\sigma_{\Delta E}^{(\text{eff})}(v_1, v_2) = 0$.

Since v'_1 and v'_2 , given by Eqs. (60.85) and (60.86), respectively, must be real, $\sigma_{\Delta E}(\mathbf{v}_1, \mathbf{v}_2) = 0$ for ΔE outside the range

$$-\frac{1}{2}m_2 v_2^2 \leq \Delta E \leq \frac{1}{2}m_1 v_1^2, \quad (60.88)$$

which simply expresses the fact that the particle losing energy in the collision cannot lose more than its initial kinetic energy.

The cross section Eq. (60.84) must be integrated over the classically allowed range of energy transfer ΔE and averaged over a prescribed speed distribution $W(v_2)$ before a comparison with experiment can be made. See [28, 29] for details.

Classical removal cross section [30] The cross section for removal of an electron from a shell is given by

$$\sigma_r(V) = \int_0^\infty f(v) \sigma_{\Delta E}(\mathbf{v}_1, \mathbf{v}_2) dv. \quad (60.89)$$

Total removal cross section [30] In an independent electron model,

$$\sigma_r^{\text{total}}(V) = N_{\text{shell}} \sigma_r(V), \quad (60.90)$$

where N_{shell} is the number of equivalent electrons in a shell. In a shielding model,

$$\sigma_r^{\text{total}}(V) = \left[1 - \frac{(N_{\text{shell}} - 1)}{4\pi \bar{r}^2} \sigma_r(V) \right] N_{\text{shell}} \sigma_r(V), \quad (60.91)$$

where \bar{r}^2 is the root mean square distance between electrons within a shell. Experiment [31] favors Eq. (60.91) over Eq. (60.90). See Fig. 4a–e of [30] for details.

Classical trajectory and Monte-Carlo methods are covered in Chap. 62.

60.6 Universality Properties

Universality properties [32, 33] have been observed in all the alkalis' atoms in ultracold Rydberg collisions where the scattering length, a , is very much greater than the effective range of the interaction, R_{eff} . The result is that details of the two-body collision are characterized by a single parameter, a , the scattering length, that is universal and independent of the details of the short-range interaction at such low energies.

In the case of three-body collisions, a universal property, first predicted in 1970 by *Efimov* [34], is that there is an infinite number of shallow three-body bound states with binding energies $E_T^{(n)}$ that has an accumulation point at $E = 0$. The *Efimov effect* of the occurrence of an infinite number of three-body bound states is present for both the case of three identical bosons, and more generally for three bodies where at least two of the three have large S-wave scattering lengths.

In the general case, the bound states appear in the spectrum at critical values of a that differ by multiplicative factors of e^{π/s_0} , where s_0 only depends on the masses and spin statistics of the particles and is the solution of the transcendental equation,

$$s_0 \cosh \frac{\pi s_0}{2} = \frac{8}{\sqrt{3}} \sinh \frac{\pi s_0}{6}. \quad (60.92)$$

The solution of Eq. (60.92) yields $s_0 \sim 1.00624$.

Asymptotic number of bound states

$$N \longrightarrow \frac{s_0}{\pi} \ln \frac{|a|}{r_0}, \quad (60.93)$$

for scattering length a and hard-core radius r_0 .

$$E_T^{(n+1)}/E_T^{(n)} \longrightarrow 1/515.03 \quad (60.94)$$

as $n \rightarrow +\infty$ and with the scattering length $a = \pm\infty$.

Asymptotic spectrum: general case

$$E_T^{(n)} \longrightarrow (e^{-2\pi/s_0})^{n-n_*} \frac{\hbar^2 \kappa_*^2}{m}. \quad (60.95)$$

60.6.1 Equal Mass Case**Asymptotic spectrum: three identical bosons**

$$E_T^{(n)} \longrightarrow \left(\frac{1}{515.03} \right)^{n-n_*} \frac{\hbar^2 \kappa_*^2}{m}, \quad (60.96)$$

with $n \rightarrow +\infty$, the scattering length $a = \pm\infty$, and where κ_* is a three-body parameter that is the zeros of

$$\sin\left(\frac{1}{2}s_0 \ln[mE_T/(\hbar^2 \kappa_*^2)]\right) = 0, \quad (60.97)$$

with s_0 being the solution of Eq. (60.92). See Table 1 of [32] for useful tabulations of scattering lengths for the alkali atoms. See §III.F of [33] for details on the ultracold experiments of the alkali atoms.

Atom-dimer scattering length (shallow dimers)

$$a_{AD} = (b_1 - b_0 \tan[s_0 \ln(a\kappa_*) + \beta])a, \quad (60.98)$$

where b_0, b_1 , and β are universal parameters, and κ_* is the three-body parameter in Eq. (60.96). The parameters in Eq. (60.98) are universal in that they hold for all identical bosons, independent of the details of their short-range interactions.

Atom-dimer scattering length a and effective range r_s (deep dimers)

$$a_{AD} = (1.46 + 2.15 \cot[s_0 \ln(a/a_*) + i\eta_*])a, \quad (60.99a)$$

$$r_{s,AD} = (1.13 + 0.73 \cot[s_0 \ln(a/a_*) + 0.98 + i\eta_*])^2 a, \quad (60.99b)$$

where a_* is the scattering length when the Efimov resonance is at the atom-dimer threshold, and is related to the three-body parameter, κ_* ; and η_* is an inelasticity parameter, generally ~ 0.1 . See §6 and 7 of [32] for a full discussion. Atom and dimer here refer to one boson scattering with a pair of bosons (dimer) in either a shallow or a deep well.

Atom-dimer cross section (deep dimers)

$$\sigma_{AD} = 84.9 \frac{\sin^2[s_0 \ln(a/a_*) - 0.97] + \sinh^2 \eta_*}{\sin^2[s_0 \ln(a/a_*)] + \sinh^2 \eta_*} \quad (60.100)$$

at $E = -E_D$, where E_D is the atom-dimer threshold Efimov resonance in which S-wave scattering dominates.

60.6.2 Unequal Mass Case

The two heavy masses are M , and the one light mass is m .

Asymptotic spectrum: two heavy – one light [35]

$$\frac{\Gamma_T^{(n)}}{E_T^{(n)}} \longrightarrow 103.0 \exp(-1.260 \sqrt{M/m}) \times \sin^2 \left[\frac{1}{2} s_0 \ln(4E_{\text{deep}}/E_T^{(n)}) \right], \quad (60.101a)$$

$$s_0 \sim 0.567142 \sqrt{M/m}, \quad (60.101b)$$

as $n \rightarrow \infty$ with $a = \pm\infty$ and $M \gg m$; $\Gamma_T^{(n)}$ and E_{deep} are the width of the Efimov trimer resonance and the binding energy of the dimer well, respectively.

60.7 Many-Body and Multiparticle Effects**60.7.1 Many-Body Theory**

Gross–Pitaevskii Equation [36, 37]

$$[T(x) - \mu]\Psi(x) + \int d^3x' V(x - x') |\Psi(x')|^2 \Psi(x) = 0, \quad (60.102)$$

where Ψ is the Bose condensate wavefunction; T and V are the kinetic and potential energy operators (respectively), and μ is the chemical potential. See the standard monographs [38–41], on many-body theory for more general details.

60.7.2 Dilute Bose Gas

The Lee-Huang-Yang equation for the second correction to the thermodynamic ground state of a dilute Bose gas has been proven in a mathematically rigorous manner [42],

$$E(\rho) \geq 4\pi\rho^2 a \left(1 + \frac{128}{15\sqrt{\pi}} \sqrt{\rho a^3} + O(\sqrt{\rho a^3}) \right), \quad (60.103)$$

where $E(\rho)$ is the energy density of the Bose gas with density ρ , and scattering length a .

Further details on the use of Rydberg states in quantum information can be found in Chap. 85 of this handbook, and [43–46].

60.8 Working Formulae for Rydberg Collisions

60.8.1 Inelastic n, ℓ -Changing Transitions

$$A^*(n\ell) + B \rightarrow A^*(n') + B + \Delta E_{n',n\ell}, \quad (60.104)$$

where $\Delta E_{n',n\ell} = E_{n'} - E_{n\ell}$ is the energy defect. The cross section for Eq. (60.104) in the quasi-free electron model [47] is

$$\sigma_{n',n\ell}(V) = \frac{2\pi a_s^2}{(V/v_B)^2 n^3} f_{n',n\ell}(\lambda), \quad \ell \ll n, \quad (60.105)$$

where a_s is the scattering length for $e^- + B$ scattering, $\lambda = n^* a_0 \omega_{n',n\ell} / V$, $\omega_{n',n\ell} = |\Delta E_{n',n\ell}| / \hbar$, $E_{n'} = -R_\infty / n'^2$, and $E_{n\ell} = -R_\infty / n^*$, with $n^* = n - \delta_\ell$. Also, v_B is the atomic unit of velocity (Chap. 1), and

$$f_{n',n\ell}(\lambda) = \frac{2}{\pi} \left[\tan^{-1} \left(\frac{2}{\lambda} \right) - \frac{\lambda}{2} \ln \left(1 + \frac{4}{\lambda^2} \right) \right]. \quad (60.106)$$

Limiting cases: $f_{n',n\ell}(\lambda) \rightarrow 1$ as $\lambda \rightarrow 0$, and $f_{n',n\ell}(\lambda) \approx 8 / (3\pi\lambda^3)$ for $\lambda \gg 1$. Then

$$\sigma_{n',n\ell} \approx \begin{cases} \frac{2\pi a_s^2}{(V/v_B)^2 n^3}, & \lambda \rightarrow 0, \\ \frac{16a_s^2 V n^3}{3v_B |\delta_\ell + \Delta n|^3}, & \lambda \gg 1. \end{cases} \quad (60.107)$$

Rate coefficients

$$\langle \sigma_{n',n\ell}(V) \rangle \equiv \langle V \sigma_{n',n\ell}(V) \rangle / \langle V \rangle \quad (60.108a)$$

$$= \frac{2\pi a_s^2}{(V_T/v_B)^2 n^3} \varphi_{n',n\ell}(\lambda_T), \quad (60.108b)$$

where $V_T = \sqrt{2k_B T / \mu}$, $\lambda_T = n^* a_0 \omega_{n',n\ell} / V_T$, $\Delta n = n' - n$, and μ is the reduced mass of A–B. The function $\varphi_{n',n\ell}(\lambda_T)$ in Eq. (60.108a) is given by

$$\varphi_{n',n\ell}(\lambda_T) = e^{\lambda_T^2/4} \operatorname{erfc} \left(\frac{1}{2} \lambda_T \right) - \frac{\lambda_T}{\pi} \int_0^\infty \frac{du}{\sqrt{u}} e^{-u} \ln \left(1 + \frac{4}{\lambda_T^2} \right) \quad (60.109a)$$

$$= \begin{cases} 1 - \frac{\lambda_T}{\sqrt{\pi}} \ln(1/\lambda_T^2), & \lambda_T \rightarrow 0, \\ 2 / (\sqrt{\pi} \lambda_T^3), & \lambda_T \gg 1, \end{cases} \quad (60.109b)$$

and $\operatorname{erfc}(x)$ is the complementary error function.

Hydrogenic For the case of hydrogen, Dewangan [48] reformulated the hypergeometric functions appearing in Gordon's formulae in terms of Jacobi polynomials $P_i^{(\alpha,\beta)}(\phi)$, a form more suitable for numerical computation

$$R_{n,\ell}^{n',\ell-1} = C_J \left[\frac{(n-\ell+1)(n-\ell)}{(n+\ell)(n+\ell-1)} P_{n-\ell+1}^{(\Delta-1, 2\ell-1)}(\cos\phi) - \sin^2 \left(\frac{1}{2} \phi \right) P_{n-\ell-1}^{(\Delta+1, 2\ell-1)}(\cos\phi) \right], \quad (60.110)$$

where the constant C_J is,

$$C_J = \left(\frac{1}{4} \sqrt{\frac{(n+\ell)!(n'+\ell-1)!}{(n-\ell-1)!(n'-\ell)!}} \cot^{2\ell+2} \left(\frac{1}{2} \phi \right) \times \sin^{\Delta+2\ell} \left(\frac{1}{2} \phi \right) \Gamma(n+\ell-1) \right)^{-1},$$

and $\Delta = n' - n \geq 1$.

Asymptotic Expressions [48]: Two Cases

(a) $n \gg n' \gg 1$ near continuum threshold The exact expression Eq. (60.110) has the following asymptotic form in terms of Airy functions $Ai(x)$

$$R_{n,\ell}^{n',\ell-1} \simeq \frac{4^\ell (n')^{\ell+1}}{n^{3/2}} \sqrt{\frac{(n'+\ell-1)!}{(n'-\ell)!}} \times \left[\frac{4n'(n'+\ell)}{(2n'+1)^{2\ell+1/3}} Ai \left(-\frac{1}{(2n'+1)^{1/3}} \right) + \frac{(2\ell-1)}{2^{2\ell-2/3}} \frac{Ai(0)}{(n')^{2\ell-2/3}} - \frac{1}{(2n'-1)^{2\ell-5/3}} Ai \left(\frac{1}{(2n'-1)^{1/3}} \right) \right] \quad (60.111)$$

suitable for practical computations, and where $\ell \ll n'$.

(b) $\Delta = n - n' \geq 1$ nearby Rydberg states

$$R_{n,\ell}^{n',\ell-1} \simeq B_J \left[J_{\Delta-1}(A_1\phi) - (n-\ell+1)(n-\ell) \frac{A_1^{\Delta-1}}{A_2^{\Delta+1}} J_{\Delta+1}(A_2\phi) \right], \quad (60.112)$$

for small Δ/n , $J_\alpha(x)$ is a Bessel function of order α , and the constants are defined

$$B_J = \sqrt{\frac{\phi}{2}} \left(\frac{1}{4} \sqrt{\frac{(n+\ell)!(n-\ell-1)!}{(n'-\ell)!(n'+\ell-1)!}} \cos^{5/2} \left(\frac{1}{2} \phi \right) \times \sin^{-3/2} \left(\frac{1}{2} \phi \right) \frac{1}{A_1^{\Delta-1}} \right) \quad (60.113a)$$

$$A_1^2 = \left(\frac{(n+n'-1)^2 - (2\ell-1)^2}{4} \right) \times \left[1 - \frac{\Delta(\Delta-2)}{3[(n+n'-1)^2 - (2\ell-1)^2]} \right], \quad (60.113b)$$

$$A_2^2 = \left(\frac{(n+n'+1)^2 - (2\ell-1)^2}{4} \right) \times \left[1 - \frac{\Delta(\Delta+2)}{3[(n+n'+1)^2 - (2\ell-1)^2]} \right]. \quad (60.113c)$$

See §4 of [48] for an extensive discussion of the numerical evaluations of both the Jacobi, and the Airy and Bessel function formulations.

Form factors for $ns \rightarrow n's$ transitions [48] The full expression from Eq. (60.41), in terms of an integral over a pair of hypergeometric functions ${}_1F_1$, is computationally difficult for large n, n' . Recast in terms of Jacobi polynomials it results in an expression that is much more suitable for practical computation

$$F_{n's,ns}(Q) = \frac{4}{Q n^{5/2} n'^{3/2}} \left(\frac{1}{\sin^2(\frac{\phi}{2})} \right)^{n-1} \times P_{n-1}^{(\Delta,1)}(\cos \phi) \operatorname{Im}(u) \quad (60.114a)$$

$$= \frac{1}{Q n^{1/2} n'^{3/2}} \sin \Theta \left(\sin \frac{1}{2} \phi \right)^\Delta \times \left(\cos \frac{1}{2} \phi \right)^2 P_{n-1}^{(\Delta,1)}(\cos \phi), \quad (60.114b)$$

where $\Delta = n' - n$, and u and Θ are defined,

$$u = \frac{(\frac{1}{n} - \frac{1}{n'} + iQ)^{n-1} (\frac{1}{n} - \frac{1}{n'} - iQ)^{n'-1}}{(\frac{1}{n} + \frac{1}{n'} - iQ)^{n+n'}} \quad (60.115)$$

$$\Theta = (n+n') \arctan \frac{Qnn'}{(n+n')} - \Delta \arctan \frac{Qnn'}{\Delta}.$$

60.8.2 Inelastic $n \rightarrow n'$ Transitions

$$A^*(n) + B \rightarrow A^*(n') + B + \Delta E_{n'n}. \quad (60.116)$$

(A) Cross sections

$$\sigma_{n'n} = \sum_{\ell\ell'} \frac{(2\ell+1)}{n^2} \sigma_{n'\ell',n\ell}, \quad (60.117)$$

$$\sigma_{n',n}(V) = \frac{2\pi a_s^2}{(V/v_B)^2 n'^3} F_{n'n}(\lambda), \quad (60.118)$$

where $\lambda = na_0\omega_{n'n}/V = |\Delta n|v_B/(n^2V)$, and

$$F_{n'n}(\lambda) = \frac{2}{\pi} \left[\tan^{-1} \left(\frac{2}{\lambda} \right) - \frac{2\lambda(3\lambda^2 + 20)}{3(4 + \lambda^2)^2} \right]. \quad (60.119)$$

Limiting cases

$$\sigma_{n'n} \approx \begin{cases} \frac{2\pi a_s^2}{(V/v_B^2 n'^3)}, & \lambda \ll 1, \\ \frac{256\sigma_{e^-B}^{\text{elastic}}(V/v_B)^3 n^7}{15\pi|\Delta n|5}, & \lambda \gg 1, \end{cases} \quad (60.120)$$

where $\sigma_{e^-B}^{\text{elastic}}$ is the elastic cross section for $e^- + B$ -scattering.

(B) Rate coefficients

$$K_{n'\ell',n\ell}(T) = \langle V\sigma_{n'\ell',n\ell} \rangle, \quad (60.121a)$$

$$K_{n'n}(T) = \sum_{\ell,\ell'} \frac{(2\ell+1)}{n^2} K_{n'\ell',n\ell}, \quad (60.121b)$$

$$K_{n'n}(T) = \frac{v_B\sigma_{e^-B}^{\text{elastic}}}{\sqrt{\pi}n^3(V_T/v_B)} \Phi_{n'n}(\lambda_T), \quad (60.121c)$$

where

$$\Phi_{n'n}(\lambda_T) = e^{\lambda_T^2/8} \left[e^{\lambda_T^2/8} \operatorname{erfc} \left(\frac{1}{2} \lambda_T \right) - \frac{\lambda_T^2}{\sqrt{2\pi}} D_{-3} \left(\frac{\lambda_T}{2} \right) - \frac{5\lambda_T}{\sqrt{\pi}} D_{-4} \left(\frac{\lambda_T}{\sqrt{2}} \right) \right] \quad (60.122a)$$

$$\approx \begin{cases} 1 - 8\lambda_T/3\sqrt{\pi}, & \lambda_T \ll 1 \\ 2^6/(\sqrt{\pi}\lambda_T^5), & \lambda_T \gg 1 \end{cases}, \quad (60.122b)$$

where $D_{-v}(y)$ denotes the parabolic cylinder function.

Limiting cases

$$K_{n'n}(T) \approx \begin{cases} \left(\frac{\mu R_\infty}{\pi m_e k_B T} \right)^{1/2} \frac{v_B\sigma_{e^-B}^{\text{elastic}}}{n^3}, & \lambda_T \rightarrow 0, \\ \frac{2^6 v_B\sigma_{e^-B}^{\text{elastic}} n^7}{\pi|\Delta n|5} \left(\frac{2k_B T}{\mu v_B^2} \right)^2, & \lambda_T \gg 1. \end{cases} \quad (60.123)$$

Born Results

$$\sigma_{n'n} = \frac{8\pi}{k^2} \frac{1}{n^2} \int_{|k-k'|}^{k+k'} F_{n'n}(Q) \frac{d(Qa_0)}{(Qa_0)^3}. \quad (60.124)$$

(A) Electron–Rydberg atom collision

$$\sigma_{n'n} = \frac{8\pi a_0^2 R_\infty}{Z^2 E n^2} \left[\left(1 - \frac{1}{4\Delta n} \right) \frac{(\varepsilon\varepsilon')^{3/2}}{(\Delta\varepsilon)^4} \ln(1 + \varepsilon_e/\varepsilon) + \left(1 - \frac{0.6}{\Delta n} \right) \frac{\varepsilon_e}{\varepsilon + \varepsilon_e} \frac{(\varepsilon')^{3/2}}{(\Delta\varepsilon)^2} \left(\frac{4}{3\Delta n} + \frac{1}{\varepsilon} \right) \right], \quad (60.125)$$

for $n' > n$, where $\varepsilon_e = E/(Z^2 R_\infty)$, $\varepsilon = 1/n^2$, $\varepsilon' = 1/n'^2$, and $\Delta\varepsilon = \varepsilon - \varepsilon'$.

(B) Heavy-particle–Rydberg atom collision

$$\sigma_{n'n} = \frac{8\pi a_0^2 Z^2}{Z^4 n^2 \varepsilon_e} \left[\left(1 - \frac{1}{4\Delta n} \right) \frac{(\varepsilon \varepsilon')^{3/2}}{(\Delta \varepsilon)^4} \ln(1 + \varepsilon_e/\varepsilon) + \left(1 - \frac{0.6}{\Delta n} \right) \frac{\varepsilon_e}{\varepsilon + \varepsilon_e} \frac{(\varepsilon')^{3/2}}{(\Delta \varepsilon)^2} \left(\frac{4}{3\Delta n} + \frac{1}{\varepsilon} \right) \right], \quad (60.126)$$

where $\varepsilon_e = m\varepsilon/MZ^2R_\infty$ with heavy-particle mass and charge denoted above by M and Z , respectively, and all other terms retain their meaning as in Eq. (60.125).

60.8.3 Quasi-Elastic ℓ -Mixing Transitions

$$\sigma_{n\ell}^{(\ell\text{-mixing})} \equiv \sum_{\ell' \neq \ell} \sigma_{n\ell', n\ell} \quad (60.127a)$$

$$\approx \begin{cases} \sigma_{\text{geo}} = 4\pi a_0^2 n^4, & n \ll n_{\text{max}}, \\ 2\pi a_s^2 v_B^2 / V^2 n^3, & n \gg n_{\text{max}}. \end{cases} \quad (60.127b)$$

The two limits correspond to strong (close) coupling for $n \ll n_{\text{max}}$ and weak coupling for $n \gg n_{\text{max}}$, and expressions Eq. (60.127b) are valid when the quantum defect δ_ℓ of the initial Rydberg orbital $n\ell$ is small; n_{max} is the principal quantum number, where the ℓ -mixing cross section reaches a maximum [49],

$$n_{\text{max}} \approx \left(\frac{v_B |a_s|}{V a_0} \right)^{2/7}. \quad (60.128)$$

For Rydberg atom–noble gas atom scattering, $n_{\text{max}} = 8$ to 20, while for Rydberg atom–alkali atom scattering $n_{\text{max}} = 15$ to 30.

60.8.4 Elastic $n\ell \rightarrow n\ell'$ Transitions

$$A^*(n\ell) + B \rightarrow A^*(n\ell') + B. \quad (60.129)$$

(A) Cross sections

$$\sigma_{ns}^{\text{elastic}}(V) = \frac{2\pi C_{ss} a_s^2}{(V/v_B)^2 n^{*4}}, \quad (60.130)$$

valid for $n^* \gg [v_B |a_s| / (4V a_0)]^{1/4}$ with

$$C_{ss} = \frac{8}{\pi^2} \int_0^{1/\sqrt{2}} [K(k)]^2 dk, \quad (60.131)$$

where $K(k)$ denotes the complete elliptic integral of the first kind.

(B) Rate coefficients [50] (three cases) With the definitions

$$v_B = v_B/v_{\text{rms}}, \quad v_{\text{rms}} = \sqrt{(8k_B T)/\mu\pi}, \quad (60.132)$$

$$f(y) = y^{-1/2}(1 - (1 - y)e^{-y}) + y^{3/2}\text{Ei}(y), \quad (60.133)$$

$$y = (v_B a_s)^2 / (4\pi a_0^2 n^{*8}), \quad (60.134)$$

$$n_1 = (|a_s| v_B / 4a_0)^{1/4}, \quad (60.135)$$

$$n_2 = 0.7 \left[|a_s| v_B^{5/6} / (\alpha_d a_0^3)^{1/6} \right]^{1/3}, \quad (60.136)$$

where α_d is the dipole polarizability of A^* , then

$$\langle \sigma_{ns}^{\text{el}} \rangle \approx \begin{cases} 8\pi a_0^2 n^{*4}, & n^* \leq n_1, \\ 4\pi^{1/2} a_0 |a_s| v_B f(y), & n_1 \leq n^* \leq n_2, \\ \begin{cases} 7(\alpha_d v_B)^{2/3} + \frac{4a_s^2 v_B^2}{n^{*4}} \\ - \frac{2.7a_s^2 v_B^2 (\alpha_d v_B)^{1/3}}{a_0 n^{*6}}, \end{cases} & n^* \geq n_2. \end{cases} \quad (60.137)$$

60.8.5 Inelastic $n\ell \rightarrow n\ell'$ Transitions**(A) Impact Parameter Theory with cutoffs [51, 52]**

$$\langle \sigma_{n\ell} \rangle = 9.93 \cdot 10^{-6} \left(\frac{\mu}{m} \right)^{1/2} \frac{D_{n\ell}}{T_e^{1/2}} \times \left\{ 11.54 + \log_{10} \left(\frac{T_e m}{D_{n\ell} \mu} \right) + 2 \log_{10} R_c \right\} \text{cm}^3/\text{sec}. \quad (60.138)$$

where μ is the reduced mass of the system, m is the electron mass, T_e is the temperature in K and,

$$D_{n\ell} = \left(\frac{Z_p}{Z_t} \right)^2 6n^2(n^2 - \ell^2 - \ell - 1) \quad (60.139)$$

with Z_p and Z_t denoting the charge of the projectile and target, respectively.

Pengelly and Seaton's expression Eq. (60.138) includes a sum over $\ell' = \ell \pm 1$, and therefore only includes the contribution of dipole transitions. See [53] and [54] for further details on the contribution of multipole transitions to the rate coefficients and line emissivities. See also [54] and [55] for tabulations of rate coefficients and line emissivities, and Eq. (14) of [54] for a modified version of Pengelly and Seaton's expression which includes more accurately the contribution from small energies.

The cutoff parameter, R_c is defined,

$$R_c = \min\{R_c^{\text{d}}, R_c^{\text{nd}}, R_D\} \quad (60.140)$$

with,

$$R_c^{\text{d}} = 0.72v\tau \quad (60.141a)$$

$$R_c^{\text{nd}} = 1.12\hbar v / \Delta E \quad (60.141b) \quad \text{where,}$$

$$R_D = \left[\frac{k_B T_e}{4\pi e^2 n_e} \right]^{1/2} \quad (60.141c)$$

where v is the projectile speed, τ , the lifetime of the initial state and ΔE is the energy difference between non-degenerate initial and final states.

The individual cutoffs R_c^{d} and R_c^{nd} for degenerate and non-degenerate states, respectively, are introduced to avoid the logarithmic divergence at large impact parameters. The third cutoff, R_D is the Debye screening length, is used to model the effect of screening at large impact parameters.

(B) Exact Classical Theory for hydrogenic collisions [56, 57] Exploiting the dynamical SO(4) symmetry of the hydrogen atom, Vranceanu and Flannery solved exactly the time-dependent classical equations for the transition probability,

$$P_{\ell'\ell}^n(\chi) = \frac{2\ell'/n^2}{\pi\hbar \sin^2(\chi/2)} \begin{cases} 0 & \mathcal{B} < 0 \\ \frac{K[\mathcal{B}/(\mathcal{B}-\mathcal{A})]}{\sqrt{\mathcal{B}-\mathcal{A}}} & \mathcal{B} > 0, \mathcal{A} < 0 \\ \frac{K[(\mathcal{B}-\mathcal{A})/\mathcal{B}]}{\sqrt{\mathcal{B}}} & \mathcal{B} > 0, \mathcal{A} > 0 \end{cases} \quad (60.142)$$

where χ is the rotation angle,

$$\cos \frac{\chi}{2} = \frac{1 + \alpha^2 \cos(\sqrt{1 + \alpha^2} \Delta\Phi)}{(1 + \alpha^2)}, \quad (60.143)$$

with $K(k)$ denoting the complete elliptic integral of the first kind, $\alpha = 3Z_p a_n v_n / 2bv$ is the Stark parameter, $\Delta\Phi$ is the polar angle swept out during the collision, and,

$$\mathcal{A}(\ell/n, \ell'/n; \chi) = \frac{\cos(u_1 + u_2) - \cos \chi}{1 - \cos \chi} \quad (60.144a)$$

$$\mathcal{B}(\ell/n, \ell'/n; \chi) = \frac{\cos(u_1 - u_2) - \cos \chi}{1 - \cos \chi} \quad (60.144b)$$

where the angles u_1 and u_2 only depend on the initial and final states, respectively,

$$\cos u_1 = 2\ell^2/n^2 - 1 \quad (60.145a)$$

$$\cos u_2 = 2\ell'^2/n^2 - 1 \quad (60.145b)$$

(C) Semiclassical Transition Probability [58]

$$P^{\text{SC}}(\ell/n, \ell'/n; \chi) = \frac{2\ell'}{\pi\hbar n^2 \sin \chi} \times \begin{cases} 0 & |\sin \chi| < |\sin(\eta_1 - \eta_2)| \\ \frac{K[\mathcal{B}/\mathcal{A}]}{\sqrt{\mathcal{A}}} & |\sin \chi| > |\sin(\eta_1 + \eta_2)| \\ \frac{K[\mathcal{A}/\mathcal{B}]}{\sqrt{\mathcal{B}}} & |\sin \chi| < |\sin(\eta_1 + \eta_2)| \end{cases} \quad (60.146)$$

$$A = \sin^2 \chi - \sin^2(\eta_1 - \eta_2) \quad (60.147a)$$

$$B = \sin^2(\eta_1 + \eta_2) - \sin^2(\eta_1 - \eta_2) \quad (60.147b)$$

and,

$$\cos \eta_1 = \ell/n \quad (60.148a)$$

$$\cos \eta_2 = \ell'/n \quad (60.148b)$$

(D) Exact Quantal Theory for hydrogenic collisions [57, 59, 60] Vranceanu and Flannery made use of the isomorphism between SO(4) and SO(3) \oplus SO(3) to solve the Schrödinger equation in the interaction picture, under assumptions of an adiabatic, dipole and classical path, to yield the transition probability on the energy shell

$$P_{\ell'\ell}^{(n)} = \frac{2\ell' + 1}{n} \sum_{L=|\ell'-\ell|}^{n-1} (2L+1) \begin{bmatrix} \ell' & \ell & L \\ j & j & j \end{bmatrix}^2 H_{jL}^2(\eta) \quad (60.149)$$

where $\{\dots\}$ denotes the 6- j symbol, and,

$$H_{jL}(\eta) = (2L)!! \sqrt{\frac{(2j+1)(2j-L)!}{(2j+L+1)!}} \left(\sin \frac{\eta}{2}\right)^L \times C_{2j-L}^{(1+L)}\left(\cos \frac{\eta}{2}\right) \quad (60.150)$$

is a standard result from group theory [61, 62], and with,

$$\cos \frac{\eta}{2} = \frac{1 + \alpha^2 \cos \sqrt{1 + \alpha^2} \Delta\Phi}{1 + \alpha^2} \quad (60.151)$$

where α and $\Delta\Phi$ have the same meanings as in (B) above. $C_n^{(\alpha)}(x)$ is the ultraspherical, or Gegenbauer polynomials of index n and order α [63]. See Table 1 of [60] for a list of exact expressions for $P_{\ell'\ell}^{(n)}$ for $n = 1-5$.

60.8.6 Fine Structure $n\ell J \rightarrow n\ell J'$ Transitions

$$A^*(n\ell J) + B \rightarrow A^*(n\ell J') + B + \Delta E_{J'J}. \quad (60.152)$$

(A) Cross sections (two cases)

$$\sigma_{n\ell J}^{n\ell J'}(V) = \frac{2J' + 1}{2(2\ell + 1)} c_{\text{norm}} 4\pi a_0^2 n^{*4}, \quad (60.153)$$

valid for $n^* \leq n_0(V)$, and

$$\sigma_{n\ell J}^{n\ell J'}(V) = \frac{2\pi C_{J'J}^{(\ell)} a_s^2 v_B^2}{V^2 n^{*4}} \varphi_{J'J}^{(\ell)}(v_{J'J}) \left(1 - \frac{n_0^8(V)}{2n^{*8}}\right), \quad (60.154)$$

valid for $n^* \geq n_0(V)$, where the quantity $n_0(V)$ is the effective principal quantum number such that the impact parameter ρ_0 of B (moving with relative velocity V) equals the radius $2n^{*2}a_0$ of the Rydberg atom A^* ; $n_0(V)$ is given by the solution to the following transcendental equation

$$n_0^8(V) = \frac{(2\ell + 1)C_{J'J}^{(\ell)}}{2(2J' + 1)c_{\text{norm}}} \left(\frac{v_B a_s}{V a_0} \right)^2 \varphi_{J'J}^{(\ell)}(v_{J'J}[n_0(V)]) . \quad (60.155)$$

The constant c_{norm} in Eq. (60.153) is equal to $5/8$ if $\sigma_{\text{geo}} = \pi \langle r^2 \rangle_{n\ell}$, or 1 if $\sigma_{\text{geo}} = 4\pi a_0^2 n^{*4}$. The function $\varphi_{J'J}^{(\ell)}(v_{J'J})$ in Eq. (60.154) is given, in general, by [64, 65]

$$\varphi_{J'J}^{(\ell)}(v_{J'J}) = \xi_{J'J}^{(\ell)}(v_{J'J}) / \xi_{J'J}^{(\ell)}(0) , \quad (60.156a)$$

$$\xi_{J'J}^{(\ell)}(v_{J'J}) = \sum_{s=0}^{\ell} A_{\ell J', \ell J}^{(2s)} \int_{v_{J'J}}^{\infty} j_s^2(z) J_s^2(z) z dz , \quad (60.156b)$$

$$v_{J'J} = |\delta_{\ell J'} - \delta_{\ell J}| \frac{v_B}{V n^*} , \quad (60.156c)$$

where $j_s(z)$ is the spherical Bessel function, and the coefficients $C_{J'J}^{(\ell)}$ and $A_{\ell J', \ell J}^{(2s)}$ in Eqs. (60.154) and (60.156b), respectively, are given in Table 5.1 of *Beigman and Lebedev* [4]. The quantum defect of Rydberg state $n\ell J$ is $\delta_{\ell J}$. For elastic scattering, $v_{JJ} = 0$, and $\varphi_{JJ}^{(\ell)}(0) = 1$.

Symmetry relation

$$\xi_{J'J}^{(\ell)}(v_{J'J}) = \frac{2J + 1}{2J' + 1} \xi_{J'J}^{(\ell)}(v_{J'J}) . \quad (60.157)$$

(B) Rate coefficients

$$\begin{aligned} \langle \sigma_{n\ell J'}^{n\ell J} \rangle &= \left(\frac{c_{\text{norm}}(2J' + 1)C_{J'J}^{(\ell)}}{2(2\ell + 1)} \right)^{1/2} \\ &\times \pi a_0^2 F(\zeta) \left(\frac{v_B |a_s|}{V_{\text{T}} a_0} \right) , \end{aligned} \quad (60.158)$$

where $\zeta = n_0^8(V_{\text{T}})/n^{*8}$, and

$$F(\zeta) \equiv \sqrt{\zeta} \left[E_2(\zeta) + \frac{1}{\zeta} (1 - e^{-\zeta}) \right] , \quad (60.159)$$

where $E_2(x)$ is an exponential integral.

Limiting cases

$$\langle \sigma_{n\ell J'}^{n\ell J} \rangle = \begin{cases} \frac{2J' + 1}{2(2\ell + 1)} c_{\text{norm}} 4\pi a_0^2 n^{*4} , & n^* \ll n_{\text{max}}^* , \\ \frac{2\pi C_{J'J}^{(\ell)} a_s^2 v_B^2}{V_{\text{T}}^2 n^{*4}} , & n^* \gg n_{\text{max}}^* , \end{cases} \quad (60.160)$$

where $n_{\text{max}}^* = (3/2)^{1/8} n_0(V)$ if $v_{J'J} \ll 1$.

60.9 Impulse Approximation

60.9.1 Quantal Impulse Approximation

Basic Formulation [66]

Consider a Rydberg collision between a projectile (1) of charge Z_1 and a target with a valence electron (3) in orbital ψ_i bound to a core (2). The full three-body wave function for the system of projectile + target is denoted by Ψ_i . The relative distance between 1 and the center-of-mass of 2–3 is denoted by σ , while the separation of 2 from the center-of-mass of 1–3 is ρ .

Formal scattering theory

$$\Psi_i^{(+)} = \Omega^{(+)} \psi_i , \quad (60.161)$$

where the Möller scattering operator $\Omega^{(+)} = 1 + G^+ V_i$, and $V_i = V_{12} + V_{13}$.

Let χ_m be a complete set of free-particle wave functions satisfying

$$(H_0 - E_m) \chi_m = 0 \quad (60.162)$$

and define operators $\omega_{ij}^+(m)$ by

$$\omega_{ij}^+(m) \chi_m = \left(1 + \frac{1}{E_m - H_0 - V_{ij} + i\epsilon} V_{ij} \right) \chi_m , \quad (60.163)$$

where V_{ij} denotes the pairwise interaction potential between particles i and j ($i, j = 1, 2, 3$). Then the action of the full Green's function G^+ on the two-body potential V_{ij} is

$$\begin{aligned} G^+ V_{ij} &= \left[\omega_{ij}^+(m) - 1 \right] \\ &+ G^+ [(E_m - E) + V_{12} + V_{13} + V_{23} - V_{ij}] \\ &\times \left[\omega_{ij}^+(m) - 1 \right] . \end{aligned} \quad (60.164)$$

Projection operators

$$b_{ij}^+(m) = \omega_{ij}^+(m) - 1 , \quad (60.165a)$$

$$b_{ij}^+ = \sum_m b_{ij}^+(m) |\chi_m\rangle \langle \chi_m| , \quad \omega_{ij}^+ = b_{ij}^+ + 1 . \quad (60.165b)$$

$$G^+ V_{ij} |\psi_i\rangle = \sum_m G^+ V_{ij} |\chi_m\rangle \langle \chi_m | \psi_i\rangle \quad (60.166a)$$

$$\begin{aligned} &= \left[b_{ij}^+ + G^+ [V_{23}, b_{ij}^+] \right. \\ &\left. + G^+ [V_{12} + V_{13} - V_{ij}] b_{ij}^+(m) \right] |\psi_i\rangle . \end{aligned} \quad (60.166b)$$

Möller scattering operator

$$\Omega^+ = (\omega_{13}^+ + \omega_{12}^+ - 1) + G^+[V_{23}, (b_{13}^+ + b_{12}^+)] + G^+(V_{13}b_{12}^+ + V_{12}b_{13}^+). \quad (60.167)$$

Exact T -matrix

$$T_{if} = \langle \psi_f | V_f | (\omega_{13}^+ + \omega_{12}^+ - 1) \psi_i \rangle + \langle \psi_f | V_f | G^+[V_{23}, (b_{13}^+ + b_{12}^+)] \psi_i \rangle + \langle \psi_f | V_f | G^+(V_{13}b_{12}^+ + V_{12}b_{13}^+) \psi_i \rangle. \quad (60.168)$$

The impulse approximation to the exact T -matrix element Eq. (60.168) is obtained by ignoring the second term involving the commutator of V_{23} ,

$$\Psi_i \longrightarrow \Psi_i^{\text{imp}} = (\omega_{13}^+ + \omega_{12}^+ - 1) \psi_i. \quad (60.169)$$

Impulse approximation: post form

$$T_{if}^{\text{imp}} = \langle \psi_f | V_f | (\omega_{13}^+ + \omega_{12}^+ - 1) \psi_i \rangle. \quad (60.170)$$

The impulse approximation can also be expressed using incoming-wave boundary conditions by making use of the prior operators

$$\omega_{ij}^-(m) \chi_m = \left(1 + \frac{1}{E_m - H_0 - V_{ij} - i\epsilon} V_{ij} \right) \chi_m, \quad (60.171a)$$

$$\omega_{ij}^- = \sum_m \omega_{ij}^-(m) |\chi_m\rangle \langle \chi_m|. \quad (60.171b)$$

The impulse approximation Eq. (60.170) is exact if V_{23} is a constant since the commutator of V_{23} vanishes in that case.

Applications [66]

(1) Electron capture $X^+ + H(i) \rightarrow X(f) + H^+$.

$$T_{if}^{\text{imp}} = \langle \psi_f | V_{12} + V_{23} (\omega_{12}^+ + \omega_{13}^+ - 1) \psi_i \rangle. \quad (60.172)$$

Wave functions: $\psi_i = e^{i\mathbf{k}_i \cdot \boldsymbol{\rho}} \varphi_i(\mathbf{r})$, $\psi_f = e^{i\mathbf{k}_f \cdot \boldsymbol{\rho}} \varphi_f(\mathbf{x})$, $\chi_m = (2\pi)^{-3} \exp[i(\mathbf{K} \cdot \mathbf{x} + \mathbf{k} \cdot \boldsymbol{\rho})]$, where the φ_n are hydrogenic wave functions.

If X above is a heavy particle, the V_{12} term in Eq. (60.172) may be omitted due to the difference in mass between the projectile 1 and the bound Rydberg electron 3. See [66] and

references therein for details. With the definitions

$$\begin{aligned} z &= \frac{4\alpha\delta^2}{(T-2\delta)(T-2\alpha\delta)}, & T &= \beta^2 + P^2, \\ \delta &= i\beta\mathbf{K} - \mathbf{p} \cdot \mathbf{K}, & v &= aZ_1/K, \\ \mathbf{t}_1 &= \mathbf{K}/a + \mathbf{v}, & N(v) &= e^{\pi v/2} \Gamma(1-iv), \\ a &= \frac{M_1}{M_1 + m_e}, & b &= \frac{M_2}{M_2 + m_e}, \\ \mathbf{k} &= a\mathbf{k}_2 - (1-a)\mathbf{k}_f, & \mathbf{K} &= a\mathbf{k}_1 - (1-a)\mathbf{k}_i, \\ \mathbf{t} &= (\mathbf{K} - \mathbf{p})/a, & \mathbf{p} &= a\mathbf{k}_f - \mathbf{k}_i, \\ \beta &= aZ_1/n, \end{aligned}$$

and n is the principal quantum number, the impulse approximation to the T -matrix becomes, in this case,

$$T_{if}^{\text{imp}} \approx \langle \psi_f | V_{23} | \omega_{13}^+ \psi_i \rangle \quad (60.173)$$

$$= \frac{-1}{2\pi^2 a^3} \int \frac{d\mathbf{K}}{t^2} N(v) g_i(\mathbf{t}_1) \mathcal{F}(f, \mathbf{K}, \mathbf{p}), \quad (60.174)$$

where, for a general final s -state,

$$\begin{aligned} \mathcal{F}(f, \mathbf{K}, \mathbf{p}) &= \int \varphi_f^*(\mathbf{x}) e^{i\mathbf{p} \cdot \mathbf{x}} \\ &\times {}_1F_1[iv, 1; i(Kx - \mathbf{K} \cdot \mathbf{x})] d\mathbf{x}, \quad (60.175) \end{aligned}$$

and $g_i(\mathbf{t}_1)$ denotes the Fourier transform of the initial state. The normalization of the Fourier transform is chosen such that momentum and coordinate space hydrogenic wave functions are related by $\varphi_n(\mathbf{r}) = (2\pi)^{-3} \int \exp(i\mathbf{t}_1 \cdot \mathbf{r}) g_n(\mathbf{t}_1) d\mathbf{t}_1$. For the case $f = 1s$,

$$\begin{aligned} \mathcal{F}(1s, \mathbf{K}, \mathbf{p}) &= -\frac{\beta^{3/2}}{\sqrt{\pi}} \frac{\partial}{\partial \beta} \mathcal{I}(v, 0, \beta, -\mathbf{K}, \mathbf{p}) \\ &= 8\sqrt{\pi} \beta^{3/2} \left[\frac{(1-iv)\beta}{T^2} \right. \\ &\quad \left. + \frac{iv(\beta - iK)}{T(T-2\delta)} \left(\frac{T}{T-2\delta} \right)^{iv} \right] \quad (60.176) \end{aligned}$$

evaluated at $\beta = aZ_1$. For the case $f = 2s$,

$$\mathcal{F}(2s, \mathbf{K}, \mathbf{p}) = -\frac{\beta^{3/2}}{\sqrt{\pi}} \left[\left(\frac{\partial}{\partial \beta} + \beta \frac{\partial^2}{\partial \beta^2} \right) \mathcal{I}(v, 0, \beta, -\mathbf{K}, \mathbf{p}) \right] \quad (60.177)$$

evaluated at $\beta = aZ_1/2$. For a general final ns -state f ,

$$\begin{aligned} \mathcal{I}(v, \alpha, \beta, \mathbf{K}, \mathbf{p}) &= \frac{4\sqrt{\pi}}{T} \left(\frac{T-2\alpha\delta}{T-2\delta} \right)^{iv} \\ &\times (U \cosh \pi v \pm iV \sinh \pi v), \quad (60.178) \end{aligned}$$

where the complex quantity $U + iV$ is

$$U + iV = (4z)^{iv} \frac{\Gamma(\frac{1}{2} + iv)}{\Gamma(1 + iv)} \times {}_2F_1(-iv, -iv; 1 - 2iv; 1/z). \quad (60.179)$$

(2) Electron impact excitation

Neglecting V_{12} and exchange yields the approximate T -matrix element

$$\begin{aligned} T_{if}^{\text{imp}} &\approx \langle \psi_f | V_{13} | \omega_{13}^+ \psi_i \rangle \\ &= \frac{-Z_1}{(2\pi a)^3} \int d\mathbf{x} \int d\mathbf{r} e^{iq \cdot \sigma} \phi_f^*(\mathbf{r}) \frac{1}{x} \\ &\quad \times \int d\mathbf{K} N(\nu) g_i(\mathbf{t}_1) e^{i\mathbf{t}_1 \cdot \mathbf{r}} {}_1F_1(iv, 1; i\mathbf{K}x - i\mathbf{K} \cdot \mathbf{x}) \end{aligned} \quad (60.181)$$

$$\begin{aligned} &= \frac{-Z_1}{(2\pi a)^3} \int d\mathbf{K} N(\nu) g_i(\mathbf{t}_1) g_f^*(\mathbf{t}_2) \\ &\quad \times \mathcal{I}(\nu, 0, 0, -\mathbf{K}, -\mathbf{q}), \end{aligned} \quad (60.182)$$

where

$$\begin{aligned} \mathcal{I}(\nu, 0, 0, -\mathbf{K}, -\mathbf{q}) &= \lim_{\beta \rightarrow 0} \frac{4\pi}{\beta^2 + q^2} \left(\frac{\beta^2 + q^2}{\beta^2 + q^2 + 2\mathbf{q} \cdot \mathbf{K} - 2i\beta\mathbf{K}} \right)^{iv} \\ &= \frac{4\pi}{q^2} \left| 1 + \frac{2\mathbf{K}}{q} \cos \theta \right|^{-iv} A(\cos \theta), \end{aligned} \quad (60.183)$$

$$= \frac{4\pi}{q^2} \left| 1 + \frac{2\mathbf{K}}{q} \cos \theta \right|^{-iv} A(\cos \theta), \quad (60.184)$$

with

$$A(\cos \theta) = \begin{cases} 1, & \cos \theta > -q/2K, \\ e^{-\pi\nu}, & \cos \theta < -q/2K, \end{cases} \quad (60.185)$$

and $\cos \theta = \hat{\mathbf{K}} \cdot \hat{\mathbf{q}}$, $\mathbf{t}_2 = \mathbf{t}_1 + b\mathbf{q}$ and $\mathbf{q} = \mathbf{k}_i - \mathbf{k}_f$.

(3) Heavy-particle excitation [67]

$$\begin{aligned} T_{if}^{\text{imp}} &= -\frac{Z_1 2^{15/2} b^5}{\pi a^3 q^2} \int_0^\infty dK N(K) K^2 \int_{-1}^1 d(\cos \theta) \\ &\quad \times \left| 1 + \frac{2\mathbf{K}}{q} \cos \theta \right|^{-iv} \tilde{A}(\cos \theta), \end{aligned} \quad (60.187)$$

where

$$\begin{aligned} \tilde{A}(\cos \theta) &= \frac{2\pi}{D^4} \left(\frac{\alpha D(D - 2b^2)}{(\alpha^2 - \beta^2)^{3/2}} + \frac{8(3b^2 - D)}{(\alpha^2 - \beta^2)^{1/2}} \right. \\ &\quad - \frac{48\gamma^2 D^2 b^2}{(\gamma^2 - \delta^2)^{5/2}} + \frac{16D[\gamma D - (3\gamma + 4\alpha)b^2]}{(\gamma^2 - \delta^2)^{3/2}} \\ &\quad \left. + \frac{32(D - 3b^2)}{(\gamma^2 - \delta^2)^{1/2}} \right) A(\cos \theta), \end{aligned} \quad (60.188)$$

with $A(\cos \theta)$ given by Eq. (60.185), and

$$\alpha = b^2 + v^2 + \frac{K^2}{a^2} + \frac{K}{aq} \left(\frac{q^2}{\mu} + \Delta E \right) \cos \theta, \quad (60.189a)$$

$$\beta = \frac{K}{aq} \sin \theta \left[4v^2 q^2 - \left(\frac{q^2}{\mu} + \Delta E \right)^2 \right]^{1/2}, \quad (60.189b)$$

$$\delta = 4\beta, \quad \gamma = 4\alpha + D, \quad (60.189c)$$

$$D = \frac{4bq}{a} (q + 2K \cos \theta), \quad (60.189d)$$

while ν and $N(\nu)$ retain their meaning from Eq. (60.173).

(4) Ionization $e^- + H(i) \rightarrow e^- + H^+ + e^-$.

$$T_{if}^{\text{imp}} \approx -\frac{4\pi}{q^2} N(\nu) g_i(\mathbf{k} - b\mathbf{q}) \left(\frac{q^2}{q^2 - 2\mathbf{q} \cdot \mathbf{K}} \right)^{iv}, \quad (60.190)$$

where $\mathbf{K} = a(\mathbf{k} - b\mathbf{q} - \mathbf{v})$ and $\mathbf{q} = \mathbf{k}_i - \mathbf{k}_f$ and exchange and V_{12} are neglected.

(5) Rydberg atom collisions [23, 68]

Consider a Rydberg collision between a projectile (3) and a target with an electron (1) bound in a Rydberg orbital to a core (2) [23, 68].

Full T -matrix element

$$T_{fi}(\mathbf{k}_3, \mathbf{k}'_3) = \langle \phi_f(\mathbf{r}_1) e^{i\mathbf{k}'_3 \cdot \mathbf{r}_3} | V(\mathbf{r}_1, \mathbf{r}_3) | \Psi_i^{(+)}(\mathbf{r}_1, \mathbf{r}_3; \mathbf{k}_3) \rangle, \quad (60.193)$$

with primes denoting quantities after the collision, and where the potential V is

$$V(\mathbf{r}_1, \mathbf{r}_3) = V_{13}(\mathbf{r}) + V_{3C}(\mathbf{r}_3 + a\mathbf{r}_1), \quad \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_3, \quad (60.194)$$

with $a = M_1/(M_1 + M_2)$, while the subscript C labels the core. The impulse approximation to the full, outgoing wave function $\Psi_i^{(+)}$ is written as

$$\Psi_i^{\text{imp}} = (2\pi)^{3/2} \int g_i(\mathbf{k}_1) \Phi(\mathbf{k}_1, \mathbf{k}_3; \mathbf{r}_1, \mathbf{r}_3) d\mathbf{k}_1, \quad (60.195)$$

$$g_i(\mathbf{k}_1) = \frac{1}{(2\pi)^{3/2}} \int \phi_i(\mathbf{r}_1) e^{-i\mathbf{k}_1 \cdot \mathbf{r}_1} d\mathbf{r}_1. \quad (60.196)$$

Impulse approximation

$$T_{fi}^{\text{imp}}(\mathbf{k}_3, \mathbf{k}'_3) = \int d\mathbf{k}_1 \int d\mathbf{k}'_1 g_f^*(\mathbf{k}'_1) g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}') \times \delta[\mathbf{P} - (\mathbf{k}'_1 - \mathbf{k}_1)], \quad (60.197)$$

where T_{13} is the exact off-shell T -matrix for 1–3 scattering,

$$T_{13}(\mathbf{k}, \mathbf{k}') = \langle \exp(i\mathbf{k}' \cdot \mathbf{r}) | V_{13}(\mathbf{r}) | \psi(\mathbf{k}, \mathbf{r}) \rangle. \quad (60.198)$$

The delta function in Eq. (60.197) ensures linear momentum, $\mathbf{K} = \mathbf{k}_1 + \mathbf{k}_3 = \mathbf{k}'_1 + \mathbf{k}'_3$, is conserved in 1–3 collisions, with

$$\mathbf{k}'_1 = \mathbf{k}_1 + (\mathbf{k}_3 - \mathbf{k}'_3) \equiv \mathbf{k}_1 + \mathbf{P}, \quad (60.199a)$$

$$\mathbf{k}' = \frac{M_3}{M_1 + M_3} (\mathbf{k}_1 + \mathbf{k}_3) - \mathbf{k}'_3 = \mathbf{k} + \mathbf{P}. \quad (60.199b)$$

Elastic scattering

$$T_{ii}(\mathbf{k}_3, \mathbf{k}_3) = \int g_f^*(\mathbf{k}_1) g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}) d\mathbf{k}_1, \quad (60.200)$$

where $\mathbf{k} = (M_3/M)\mathbf{k}_1 + (M_1/M)\mathbf{k}_3$, and $M = M_1 + M_3$.

Integral cross section: for 3–(1,2) scattering,

$$\sigma_{if}(k_3) = \left(\frac{M_{AB}}{M_{13}} \right)^2 \frac{k'_3}{k_3} \int | \langle g_f(\mathbf{k}_1 + \mathbf{P}) | \times f_{13}(\mathbf{k}, \mathbf{k}') g_i(\mathbf{k}_1) \rangle |^2 d\hat{\mathbf{k}}'_3, \quad (60.201)$$

where M_{AB} is the reduced mass of the 3–(1,2) system, and M_{13} the reduced mass of 1–3. The 1–3 scattering amplitude f_{13} is given by

$$f_{13}(\mathbf{k}, \mathbf{k}') = -\frac{1}{4\pi} \left(\frac{2M_{13}}{\hbar^2} \right) T_{13}(\mathbf{k}, \mathbf{k}'). \quad (60.202)$$

Six Approximations to Eq. (60.197)

(1) Optical theorem

$$\begin{aligned} \sigma_{\text{tot}}(k_3) &= \frac{1}{k_3} \frac{2M_{AB}}{\hbar^2} T_{ii}(\mathbf{k}_3, \mathbf{k}'_3) \\ &= \frac{1}{v_3} \int |g_i(\mathbf{k}_1)|^2 [v_{13} \sigma_{13}^T(v_{13})] d\mathbf{k}_1, \end{aligned} \quad (60.203)$$

where σ_{13}^T is the total cross section for 1–3 scattering at relative speed v_{13} . The resultant cross section Eq. (60.203) is an upper limit and contains no interference terms.

(2) Plane-wave final state

$$\phi_f(\mathbf{r}_1) = (2\pi)^{-3/2} \exp(i\mathbf{k}'_1 \cdot \mathbf{r}_1), \quad (60.204)$$

$$g_f(\mathbf{k}'_1) = \delta(\mathbf{k}'_1 - \boldsymbol{\kappa}'_1), \quad (60.205)$$

$$T_{fi}(\mathbf{k}_3, \mathbf{k}'_3) = g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}'), \quad \mathbf{k}_1 = \boldsymbol{\kappa}_1 - \mathbf{P}, \quad (60.206)$$

$$\frac{d\sigma_{if}}{d\hat{\mathbf{k}}'_3 d\mathbf{k}'_1} = \left(\frac{M_{AB}}{M_{13}} \right)^2 \frac{k'_3}{k_3} |g_i(\mathbf{k}_1)|^2 |f_{13}(\mathbf{k}, \mathbf{k}')|^2. \quad (60.207)$$

(3) Closure

$$\sum_f g_f(\mathbf{k}'_1) g_f^*(\mathbf{k}''_1) = \delta(\mathbf{k}'_1 - \mathbf{k}''_1), \quad (60.208)$$

$$\frac{d\sigma_{if}^T}{d\hat{\mathbf{k}}'_3} = \frac{\bar{k}'_3}{k_3} \left(\frac{M_{AB}}{M_{13}} \right)^2 \int |g_i(\mathbf{k}_1)|^2 |f_{13}(\mathbf{k}, \mathbf{k}')|^2 d\mathbf{k}_1, \quad (60.209)$$

where $\mathbf{k}'_1 = (M_3/M)(\mathbf{k}_1 + \mathbf{k}_3) - \mathbf{k}'_3$.

Conditions for validity of Eq. (60.209): (a) k_3 is high enough to excite all atomic bound and continuum states, and (b) $k_3^2 = (k_3^2 - 2\varepsilon_{fi}/M_{AB})$ can be approximated by k_3 , or by an averaged wavenumber $\bar{k}'_3 = (k_3^2 - 2\bar{\varepsilon}_{fi}/M_{AB})^{1/2}$, where the averaged excitation energy is

$$\bar{\varepsilon}_{fi} = \ln\{\varepsilon_{fi}\} = \sum_j f_{ij} \ln \varepsilon_{ij} \left(\sum_j f_{ij} \right)^{-1}, \quad (60.210)$$

and the f_{ij} are the oscillator strengths.

(4) Peaking approximation

$$T_{fi}^{\text{peak}}(\mathbf{k}_3, \mathbf{k}'_3) = F_{fi}(\mathbf{P}) T_{13}(\mathbf{k}, \mathbf{k}'), \quad (60.211)$$

where F_{fi} is the inelastic form factor

$$F_{fi}(\mathbf{P}) = \int g_f^*(\mathbf{k}_1 + \mathbf{P}) g_i(\mathbf{k}_1) d\mathbf{k}_1 \quad (60.212)$$

$$= \langle \psi_f(\mathbf{r}) \exp(i\mathbf{P} \cdot \mathbf{r}) | \psi_i(\mathbf{r}) \rangle. \quad (60.213)$$

(5) $T_{13} = T_{13}(\mathbf{P})$

$$T_{fi}(\mathbf{k}_3, \mathbf{k}'_3) = T_{13}(\mathbf{P}) F_{fi}(\mathbf{P}). \quad (60.214)$$

(6) $T_{13} = \text{constant}$ $f_{13} \equiv a_s = \text{constant}$ scattering length.

$$\sigma_{if}(k_3) = \frac{2\pi a_s^2}{k_3^2} \left(\frac{M_{AB}}{M_{13}} \right)^2 \int_{k_3 - k'_3}^{k_3 + k'_3} |F_{fi}(\mathbf{P})|^2 P dP, \quad (60.215)$$

$$\sigma_{\text{tot}}(k_3) = \begin{cases} 4\pi a_s^2, & v_3 \gg v_1 \\ \langle v_1 \rangle 4\pi a_s^2 / v_3, & v_3 \ll v_1. \end{cases} \quad (60.216)$$

Validity Criteria

(A) Intuitive formulation [68]

- (i) Particle 3 scatters separately from 1 and 2, i.e., $r_{12} \gg A_{1,2}$; the relative separation of (1,2) \gg the scattering lengths of 1 and 2.
- (ii) $\lambda_{13} \ll r_{12}$, i.e., the reduced wavelength for 1–3 relative motion $\ll r_{12}$. Interference effects of 1 and 2 can be ignored and 1, 2 treated as *independent* scattering centers.
- (iii) 2–3 collisions do not contribute to inelastic 1–3 scattering.
- (iv) Momentum impulsively transferred to 1 during collision (time τ_{coll}) with $3 \gg$ momentum transferred to 1 due to V_{12} , i.e.,

$$P \gg \langle \psi_{n\ell} | -\nabla V_{12} | \psi_{n\ell} \rangle \tau_{\text{coll}}. \quad (60.217)$$

For a precise formulation of validity criteria based upon the two-potential formula, see the Appendix of [68].

Two classes of interaction in A – $B(n)$ Rydberg collisions justify use of the impulse approximation for the T -matrix for 1–3 collisions: (i) quasi-classical binding with $V_{\text{core}} = \text{const.}$, and (ii) weak binding with

$$E_3 \gg \Delta E_c \approx \langle \psi_n(\mathbf{r}) | V_{1C}(\mathbf{r}) | \psi_n(\mathbf{r}) \rangle, \quad (60.218a)$$

$$\langle \psi_n(\mathbf{r}_1) | -\frac{\hbar^2}{2M_{12}} \nabla_1^2 | \psi_n(\mathbf{r}_1) \rangle \approx |\varepsilon_n|, \quad (60.218b)$$

where E_3 is the kinetic energy of relative motion of 3, and ΔE_c is the energy shift in the core. The fractional error is [69]

$$\frac{f_{13}}{\lambda} \frac{\Delta E_c}{\hbar} \left(\frac{\hbar}{E_3} + \tau_{\text{delay}} \right) \ll 1, \quad (60.219)$$

where $\lambda \approx k_3^{-1}$ is the reduced wavelength of 3, f_{13} is the scattering amplitude for 1–3 collisions, and τ_{delay} is the time delay associated with 1–3 collisions.

Special case: for nonresonant scattering with $\tau_{\text{delay}} = 0$,

$$\frac{f_{13}}{\lambda} \frac{|\varepsilon_n|}{E_3} \ll 1, \quad (60.220)$$

which follows from Eq. (60.219) upon identifying the shift in the core energy ΔE_c with the binding energy $|\varepsilon|$.

Condition Eq. (60.220) is less restrictive than Eq. (60.218a) or Eq. (60.218b) since f_{13} can be either less than or greater than λ .

60.9.2 Classical Impulse Approximation

(A) **Ionization** For electron impact on heavy particles [70], the cross section for ionization of a particle moving with velocity t by a projectile with velocity s is

$$Q(s, t) = \frac{1}{u^2} \frac{2s}{m_2} \int_1^{s^2} \frac{dz}{z^2} \left[\frac{A(z)}{z} + B(z) \right], \quad (60.221)$$

where

$$A(z) = \frac{1}{2st^3} \left[\frac{1}{3} (x_{02}^{3/2} - x_{01}^{3/2}) - 2(s^2 + t^2)(x_{02}^{1/2} - x_{01}^{1/2}) - \frac{(s^2 - t^2)^2}{2ts^3} (x_{02}^{-1/2} - x_{01}^{-1/2}) \right], \quad (60.222a)$$

$$B(z) = \frac{1}{2m_2st^3} \left[(m_1 + m_2)(s^2 - t^2)(x_{02}^{-1/2} - x_{01}^{-1/2}) - (m_2 - m_1)(x_{02}^{1/2} - x_{01}^{1/2}) \right]. \quad (60.222b)$$

For electron impact, Eq. (60.222b) is evaluated at $m_1 = 1$. The remaining terms above are given by

$$s^2 = v_2^2/v_0^2, \quad t^2 = v_1^2/v_0^2 = E_1/u,$$

$$E_2 = m_2 v_2^2,$$

$$u = v_0^2 = \text{Ionization potential of target},$$

$$x_{0i} = (s^2 + t^2 - 2st \cos \theta_i), \quad i = 1, 2,$$

$$\cos \theta_i = \begin{cases} \kappa_0 \pm \kappa_1, & |\kappa_0 \pm \kappa_1| \leq 1 \\ 1, & \kappa_0 \pm \kappa_1 > 1 \\ -1, & \kappa_0 \pm \kappa_1 < -1 \end{cases},$$

$$\kappa_0 \pm \kappa_1 = -\frac{1}{2} \left(1 - \frac{m_1}{m_2} \right) \frac{z}{st} \pm \sqrt{\left(1 + \frac{z}{t^2} \right) \left(1 - \frac{z}{s^2} \right)}.$$

Equal mass case: ($m_1 = m_2$)

$$Q(s, t) = \begin{cases} \frac{4}{3s^2} \frac{1}{u^2} \frac{2(s^2 - 1)^{3/2}}{t}, & 1 \leq s^2 \leq t^2 + 1, \\ \frac{4}{3s^2} \frac{1}{u^2} \left(2t^2 + 3 - \frac{3}{s^2 - t^2} \right), & s^2 \geq t^2 + 1. \end{cases} \quad (60.223)$$

Integrating over the speed distribution (Sect. 60.4),

$$Q(s) = \frac{32}{\pi} \frac{1}{u^2} \int_0^\infty \frac{Q(s, t) t^2 dt}{(t^2 + 1)^4}, \quad (60.224)$$

which is then numerically evaluated. For electrons, the integral can be done analytically with the result

$$Q(y) = \frac{8}{3\pi y^2(y+1)^4} \times \left[(5y^4 + 15y^3 - 3y^2 - 7y + 6)(y-1)^{1/2} + (5y^5 + 17y^4 + 15y^3 - 25y^2 + 20y) \times \tan^{-1}(y-1)^{1/2} - 24y^{3/2} \ln \left| \frac{\sqrt{y} + \sqrt{y-1}}{\sqrt{y} - \sqrt{y-1}} \right| \right],$$

with $y = s^2$.

Thomson's result

$$Q_T(y) = \frac{4}{y} \frac{1}{u^2} \left(1 - \frac{1}{y} \right). \quad (60.225)$$

(B) Electron-loss cross section [30]

$$A(V) + B(u) \rightarrow A^+ + e^- + B(f), \quad (60.226)$$

where $B(f)$ denotes that the target B is left in any state (either bound or free) after the collision with the projectile A . The initial velocity of the projectile is V , while the velocity of the Rydberg electron relative to the core is u , and the ionization potential of the target B is I .

$$\sigma_{\text{loss}} = \frac{1}{3\pi v^2} \int_{\tau/4v}^{\infty} dx \sigma_T(x\bar{u}) + \left(\frac{8vx - 1 - (v-x)^2 - 2\tau}{[1 + (v-x)^2]^3} + \frac{1}{[1 + (v+x)^2 - \tau]^2} \right), \quad (60.227)$$

where $v = V/\bar{u}$, $\tau = I/(1/2)m_e\bar{u}^2$, $\bar{u} = \sqrt{2I/m_e}$, and σ_T is the total electron scattering cross section at speed $x\bar{u}$. The cross section Eq. (60.227) is valid only for particles being stripped (or lost from the projectile), which are not strongly bound. See [30, 71, 72] for details and numerous results.

(C) Capture cross section from shell i [30]

$$\sigma_{\text{capture}}^i(V) = \frac{2^{5/2} N_i \pi}{3V^7} \int_0^{r_i} dr \int_{C(-1)}^{C(+1)} d(\cos \eta') [P_i(r)]^2 \times \frac{\sqrt{1+y^2} [4\varepsilon^2 - (\varepsilon^2 - y^2)(1 + \varepsilon^2 + a^2 - y^2)]}{r^{3/2} \varepsilon^{9/2} (1 + a^2)^3 \sqrt{y^2 - a^2}}, \quad (60.228)$$

where C denotes that the integration range $[-1, +1]$ is restricted such that the integrand is real and positive and that $|1 - \varepsilon| < \sqrt{y^2 - a^2}$. The dimensionless variables a and y above are defined as

$$y^2 = \frac{2}{m_e} |V(R)| V^2, \quad a^2 = \frac{2}{m_e} I_i V^2, \quad (60.229)$$

and with $P_i(r)/r$ representing the Hartree–Fock–Slater radial wave function for shell i , with normalization

$$\int_0^{r_i} [P_i(r)]^2 dr = 1. \quad (60.230)$$

The ionization potential and number of electrons in shell i are denoted above, respectively, by I_i and N_i .

(D) Total capture cross section [30]

$$\sigma_{\text{capture}}^{\text{total}}(V) = \sum_i \sigma_{\text{capture}}^i. \quad (60.231)$$

(E) Universal capture cross section [30] A universal curve independent of projectile mass M and charge Z is obtained from the above expressions for the capture cross section by plotting the scaled cross section

$$\tilde{\sigma}_{\text{capture}}^{\text{total}} = \frac{E^{11/4}}{M^{11/4} Z^{7/2} \lambda^{3/4}} \sigma_{\text{capture}}^{\text{total}} \quad (60.232)$$

versus the scaled energy

$$\tilde{E} = \frac{m_e E}{M I}, \quad (60.233)$$

where m_e is the mass of the particle captured, which is usually taken to be a single electron, and I is the ionization potential of the target. The term λ in Eq. (60.232) is the coupling constant in the target potential, $V(R) = m_e \lambda / R^2$, which the electron being captured experiences during the collision. See [30, Fig. 11] for details.

60.9.3 Semiquantal Impulse Approximation

Basic expression [68, 73, 74]

$$\frac{d\sigma}{d\varepsilon dP dk_1 dk d\phi_1} = \frac{k_1'^2 k_3'}{J_{55} k_3} \left(\frac{M_3}{M_{13}} \right)^2 |g_i(\mathbf{k}_1)|^2 \times |f_{13}(\mathbf{k}, \mathbf{k}')|^2. \quad (60.234)$$

J_{55} is the five-dimensional Jacobian of the transformation

$$(P, \varepsilon, k_1, k, \phi_1) \rightarrow (\hat{\mathbf{k}}_3', \mathbf{k}_1'), \quad (60.235a)$$

$$J_{55} = \frac{\partial(P, \varepsilon, k_1, k, \phi_1)}{\partial(\cos \theta_3' \phi_3', k_1', \cos \theta_1', \phi_1')}. \quad (60.235b)$$

Expression for elemental cross section [68] In the $(P, \varepsilon, k_1, k, \phi_1)$ representation,

$$d\sigma = \frac{d\varepsilon dP}{M_{13}^2 v_3^2} \left[\frac{|g_i(\mathbf{k}_1)|^2 k_1^2 dk_1 d\phi_1}{v_1} \right] \times \frac{|f_{13}(\mathbf{k}, \mathbf{k}')|^2 dg^2}{\sqrt{(g_+^2 - g^2)(g^2 - g_-^2)}}, \quad (60.236)$$

where $g_{\pm}^2 = (1/2)B \pm \sqrt{(1/4)B^2 - C}$, and

$$B = B(\varepsilon, P, v_1; v_3) = \frac{a}{(1+a)^2} \frac{P^2}{M_{13}^2} + \left(v_1^2 + v_1'^2 + v_3^2 + v_3'^2 + \frac{2\Delta_3}{M_{13}} \right) - \frac{4\varepsilon(\varepsilon + \Delta_3)}{P^2},$$

$$C = C(\varepsilon, P, v_1; v_3) = \frac{v_1^2 + av_3^2}{1+a} \frac{P^2}{M_{13}^2} + (v_1^2 - v_3^2)(v_1'^2 - v_3'^2) + \frac{2\Delta_3}{M_{13}}(v_1^2 + v_3^2) + \frac{4\Delta_3}{P^2} [v_1^2(\varepsilon + \Delta_3) - \varepsilon v_3^2],$$

$$a = \frac{M_2 M_3}{M_1(M_1 + M_2 + M_3)},$$

$$\widetilde{M}_1 = M_1(1 + M_1/M_2),$$

$$v_1'^2 = v_1^2 + \frac{2\varepsilon}{\widetilde{M}_1}, \quad v_3'^2 = v_3^2 - \frac{2(\varepsilon + \Delta_3)}{M_{AB}},$$

and Δ_3 is the change in internal energy of particle 3, while ε denotes the energy change in the target 1–2.

Hydrogenic systems $g_i(\mathbf{k}_1) = g_{nl}(\mathbf{k}_1)Y_{\ell m}(\theta_1, \phi_1)$ The g_{nl} are the hydrogenic wave functions in momentum space. See Chap. 9 for details on hydrogenic wave functions.

Elemental cross sections (m -averaged and ϕ_1 -integrated)

$$d\sigma = \frac{d\varepsilon dP}{M_{13}^2 v_3^2} \frac{W_{nl}(v_1)dv_1}{2v_1} \frac{|f_{13}(P, g)|^2 dg^2}{\sqrt{(g_+^2 - g^2)(g^2 - g_-^2)}}, \quad (60.237)$$

where the speed distribution W_{nl} is given by Eq. (60.73).

Two representations for 1–3 scattering amplitude [68]

(i) $f_{13} = f_{13}(P, g)$ is a function of momentum transferred and relative speed. Then

$$\sigma(v_3) = \frac{1}{M_{13}^2 v_3^2} \int_{\varepsilon_1}^{\varepsilon_2} d\varepsilon \int_{v_{10}}^{\infty} \frac{W_{nl}(v_1)dv_1}{v_1} \int_{P^-}^{P^+} dP \times \int_{g^-}^{g^+} \frac{|f_{13}(P, g)|^2 dg^2}{\sqrt{(g_+^2 - g^2)(g^2 - g_-^2)}}, \quad (60.238)$$

where $v_{10}^2(\varepsilon) = \max[0, (2\varepsilon/M)]$, and the limits to the P integral are

$$P^+ = P^+(\varepsilon, v_1; v_3) = \min[M(v_1' + v_1), M_{AB}(v_3' + v_3)], \quad (60.239a)$$

$$P^- = P^-(\varepsilon, v_1; v_3) = \max[M|v_1' - v_1|, M_{AB}|v_3' - v_3|], \quad (60.239b)$$

and unless $P^+ > P^-$, the P integral is zero.

(ii) $f_{13} = f_{13}(g, \psi)$ is a function of relative speed and scattering angle. Then

$$\sigma(v_3) = \frac{1}{v_3^2} \int_{\varepsilon_1}^{\varepsilon_2} d\varepsilon \int_{v_{10}}^{\infty} \frac{W_{nl}(v_1)dv_1}{v_1} \int_{g^-}^{g^+} \frac{g dg}{S(v_1, g; v_3)} \times \int_{\psi^-}^{\psi^+} \frac{|f_{13}(g, \psi)|^2 d(\cos \psi)}{\sqrt{(\cos \psi^+ - \cos \psi)(\cos \psi - \cos \psi^-)}}, \quad (60.240)$$

where

$$S(v_1, g; v_3) = \frac{M_{13}}{1+a} [(1+a)(v_1^2 + av_3^2) - ag^2]^{1/2}. \quad (60.241)$$

Scattering angle ψ -limits,

$$\cos \psi^{\pm} = \cos \psi^{\pm}(\varepsilon, v_1, g; v_3) \quad (60.242)$$

$$= \frac{g}{g' \alpha^2 + \beta^2} \left\{ \alpha(\alpha + \tilde{\varepsilon}) \pm \beta[\omega^2(\alpha^2 + \beta^2) - (\alpha + \tilde{\varepsilon})^2]^{1/2} \right\}, \quad (60.243)$$

where

$$\alpha = \alpha(v_1, g; v_3)$$

$$= \frac{1}{2} M_{13} \left[v_1^2 - v_3^2 + \left(\frac{1-a}{1+a} \right) g^2 \right],$$

$$\beta = \beta(v_1, g; v_3)$$

$$= \frac{1}{2} M_{13} \left[(2v_1^2 + 2v_3^2 - g^2)g^2 - (v_1^2 - v_3^2)^2 \right]^{1/2},$$

$$\omega = g'/g, \quad \tilde{\varepsilon} = \varepsilon + \frac{a}{1+a} \Delta_3.$$

Special case: $f_{13} = f_{13}(P)$

$$\sigma(v_3) = \frac{\pi}{M_{13}^2 v_3^2} \int_{\varepsilon_1}^{\varepsilon_2} d\varepsilon \int_{v_{10}}^{\infty} \frac{W_{nl}(v_1)dv_1}{v_1} \times \int_{P^-}^{P^+} |f_{13}(P)|^2 dP. \quad (60.244)$$

60.10 Binary Encounter Approximation

The basic assumption of the binary encounter approximation is that an excitation or ionization process is caused solely by the interaction of the incoming charged or neutral projectile with the Rydberg electron bound to its parent ion. If, for example, the cross section depends only on the momentum transfer P to the Rydberg electron (as in the Born approximation), then the total cross section is obtained by integrating σ_P over the momentum distribution of the Rydberg electron. The basic cross sections required are given in Sect. 60.10.1. For further details see [75] and references therein.

60.10.1 Differential Cross Sections

Cross Section per Unit Momentum Transfer

Let the masses, velocities, and charges of the particles be $(m_1, \mathbf{v}_1, Z_1, e)$ and $(m_2, \mathbf{v}_2, Z_2, e)$, with $\mathbf{v} = |\mathbf{v}_1 - \mathbf{v}_2|$ denoting the relative velocity, and quantities *after* the collision are denoted by primes. Then for distinguishable particles,

$$\sigma_P = \frac{8\pi Z_1^2 Z_2^2 e^4 P}{v^2} \left| \frac{\exp(i\eta_P)}{P^2} \right|^2, \quad (60.245)$$

where the phase shift η_P is

$$\eta_P = -2\gamma \ln(P/2\mu v) + 2\eta_0 + \pi, \quad (60.246)$$

and with

$$\mu = \frac{m_1 m_2}{m_1 + m_2}, \quad \gamma = \frac{Z_1 Z_2 e^2}{\hbar v}, \quad e^{2i\eta_0} = \frac{\Gamma(1 + i\gamma)}{\Gamma(1 - i\gamma)}. \quad (60.247)$$

For identical particles,

$$\sigma_P^\pm = \frac{8\pi Z_1^2 Z_2^2 e^4 P}{v^2} \left| \frac{e^{i\eta_P}}{P^2} \pm \frac{e^{i\eta_S}}{S^2} \right|^2, \quad (60.248)$$

where η_P is given by Eq. (60.246), and η_S is

$$\eta_S = -2\gamma \ln(S/2\mu v) + 2\eta_0 + \pi, \quad (60.249)$$

while η_0 is given by Eq. (60.247). The momenta \mathbf{P} and \mathbf{S} transferred by direct and exchange collisions, respectively, are given by

$$\mathbf{P} = m_1(\mathbf{v}_1 - \mathbf{v}'_1) = m_2(\mathbf{v}_1 - \mathbf{v}'_2), \quad (60.250a)$$

$$\mathbf{S} = m_1(\mathbf{v}_1 - \mathbf{v}'_2) = m_2(\mathbf{v}'_1 - \mathbf{v}_2). \quad (60.250b)$$

The collision rates (in cm^3/s) are

$$\hat{\alpha}_P = v_1 \sigma_P, \quad \hat{\alpha}_P^\pm = v_1 \sigma_P^\pm. \quad (60.251)$$

Cross Section per Unit Momentum Transferred per Unit Steradian

Differential relationships

$$\alpha_{E,P} = \frac{d^2\alpha}{dP dE} = \frac{d^2\alpha}{dP d\varphi} \frac{d\varphi}{dE} = \alpha_{P,\varphi} \frac{d\varphi}{dE}. \quad (60.252)$$

For distinguishable particles,

$$\alpha_P = 2\pi v_1 \sigma_{P,\varphi} = 2\pi \alpha_{P,\varphi}, \quad (60.253a)$$

$$\alpha_{P,\varphi} = \frac{4Z_1^2 Z_2^2 e^4 P}{v} \left| \frac{e^{i\eta_P}}{P^2} \right|^2, \quad (60.253b)$$

$$\alpha_{E,P} = v_1 \sigma_{E,P} = \frac{8Z_1^2 Z_2^2 e^4}{v_1 v_2 \sqrt{X}} \left| \frac{e^{i\eta_P}}{P^2} \right|^2. \quad (60.253c)$$

For identical particles,

$$\alpha_{P,\varphi}^\pm = \frac{4Z_1^2 Z_2^2 e^4 P}{v} \left| \frac{e^{i\eta_P}}{P^2} \pm \frac{e^{i\eta_S}}{S^2} \right|^2, \quad (60.254a)$$

$$\alpha_{E,P}^\pm = v_1 \sigma_{E,P}^\pm = \frac{8Z_1^2 Z_2^2 e^4}{v_1 v_2 \sqrt{X}} \left| \frac{e^{i\eta_P}}{P^2} \pm \frac{e^{i\eta_S}}{S^2} \right|^2, \quad (60.254b)$$

where

$$X = -\cos^2 \phi + 2(\hat{\mathbf{v}}_1 \cdot \hat{\mathbf{P}})(\hat{\mathbf{v}}_2 \cdot \hat{\mathbf{P}}) \cos \phi + 1 - (\hat{\mathbf{v}}_1 \cdot \hat{\mathbf{P}})^2 - (\hat{\mathbf{v}}_2 \cdot \hat{\mathbf{P}})^2 \quad (60.255a)$$

$$= (\cos \phi_{\min} - \cos \phi)(\cos \phi - \cos \phi_{\max}) \quad (60.255b)$$

$$= \left(\frac{v}{v_1 v_2 P} \right)^2 (E_{\max} - E)(E - E_{\min}), \quad (60.255c)$$

with ϕ being the angle between the velocity vectors \mathbf{v}_1 and \mathbf{v}_2 .

For the special case of electron impact, $M_2 = m_e$, $Z_2 = -1$, and

$$\sigma_{E,P}(\phi) = \frac{8Z_1^2 e^4}{v_1^2 v_2 P^4 \sqrt{X}}, \quad (60.256)$$

$$\sigma_{E,P}^\pm(\phi) = 8e^4 v_1^2 v_2 \sqrt{X} \times \left(\frac{1}{P^4} + \frac{1}{S^4} \frac{2 \cos(\eta_P - \eta_S)}{P^2 S^2} \right), \quad (60.257)$$

where $\eta_P - \eta_S = -2\gamma \ln(P/S) = (2e^2/\hbar v) \ln(S/P)$, and X is given by Eq. (60.255a).

Integrated Cross Sections

For incident heavy particles

$$\sigma_{E,P} = \int_0^\pi \sigma_{E,P}(\phi) \frac{1}{2} \sin \phi d\phi = \frac{4\pi Z_1^2 e^4}{v_1^2 v_2 P^4}. \quad (60.258)$$

For incident electrons

$$q\sigma_{E,P}^{\pm} = \int_0^{\pi} \sigma_{E,P}^{\pm}(\phi) \frac{1}{2} \sin \phi d\phi \quad (60.259a)$$

$$= \frac{4\pi e^4}{v_1^2 v_2} \left(\frac{1}{P^4} + \frac{v_1^2 + v_2^2 - P^2/2m_e^2 - 2E^2/P^2}{m_e^4 |v_1^2 - v_2^2 - 2E/m_e|^3} \right. \\ \left. \pm \frac{2\Phi}{m_e^2 P^2 |v_1^2 - v_2^2 - 2E/m_e|} \right), \quad (60.259b)$$

where Φ can be approximated [76] by

$$\Phi \approx \cos \left(\left| \frac{R_{\infty}}{E_3 - E_2} \right|^{1/2} \ln \left| \frac{E}{E_3 - E_2 - E} \right| \right), \quad (60.260)$$

and E_3 is defined in [76].

Cross Sections per Unit Energy

For incident heavy particles (three cases)

$$\sigma_E = \frac{2\pi Z_1^2 e^4}{m_e v_1^2} \left(\frac{1}{E^2} + \frac{2m_e v_2^2}{3E^2} \right), \quad (60.261)$$

which is valid for $2v_1 \geq v_2 + v_2'$, $E \leq 2m_e v_1(v_1 - v_2)$, or

$$\sigma_E = \frac{\pi Z_1^2 e^4}{3v_1^2 v_2 E^3} \left(4v_1^3 - \frac{1}{2}(v_2' - v_2)^2 \right), \quad (60.262)$$

which is valid for $v_2' - v_2 \leq 2v_1 \leq v_2' + v_2$, $2m_e v_1(v_1 - v_2) \leq E \leq 2m_e v_1(v_1 + v_2)$, or otherwise, $\sigma_E = 0$ for $E \geq m_e v_1(v_2' + v_2)$.

For incident electrons (two cases)

$$\sigma_E^{\pm} = \frac{2\pi e^4}{m_e v_1^2} \left(\frac{1}{E^2} + \frac{2m_e v_2^2}{3E^3} + \frac{1}{D^2} + \frac{2m_e v_2^2}{3D^3} \pm \frac{2\Phi}{ED} \right), \quad (60.263)$$

which is valid for $m_e(v_2 - v_2') \leq m_e(v_1' - v_1)$, $m_e(v_2' + v_2) \leq m_e(v_1 + v_1')$, $D \geq 0$, or

$$\sigma_E = \frac{2\pi e^4}{m_e v_1^2} \left(\frac{1}{E^2} + \frac{2m_e v_1'^2}{3E^3} + \frac{1}{D^2} \right. \\ \left. + \frac{2m_e v_1'^2}{3|D|^3} \pm \frac{2\Phi}{E|D|} \right) \frac{v_1'}{v_1}, \quad (60.264)$$

which is valid for $m_e(v_2' - v_2) \leq m_e(v_1 - v_1')$, $m_e(v_1 + v_1') \leq m_e(v_2' + v_2)$, $D \leq 0$. In the expressions above, the exchange energy D transferred during the collision is

$$D = \frac{1}{2}m_e v_1^2 - \frac{1}{2}m_e v_2^2 = \frac{1}{2}m_e v_1^2 - \frac{1}{2}m_e v_2^2 - E. \quad (60.265)$$

60.10.2 Integral Cross Sections

$$e^-(T) + A(E_2) \rightarrow e^-(E) + A^+ + e^-, \quad (60.266)$$

where T is the initial kinetic energy of the projectile electron, while the Rydberg electron, initially bound in potential U_i to the core A^+ , has kinetic energy E_2 . The cross section per unit energy E is denoted below by σ_E . See the review by *Vriens* [75] for details.

For electron impact, there are two collision models: the *unsymmetrical collision model* of Thomson and Gryzinski assumes that the incident electron has zero potential energy, and the *symmetrical collision model* of Thomas and Burgess assumes that the incident electron is accelerated initially by the target (and thereby gains kinetic energy) while losing an equal amount of potential energy.

Unsymmetrical model (two cases)

$$\sigma_E = \frac{\pi e^4}{T} \left(\frac{1}{E^2} + \frac{4E_2}{3E^3} + \frac{1}{D^2} + \frac{4E_2}{3D^3} - \frac{\Phi}{ED} \right), \quad (60.267)$$

which is valid for $D = T - E_2 - E \geq 0$, or

$$\sigma_E = \frac{\pi e^4}{T} \left(\frac{1}{E^2} + \frac{4T'}{3E^3} + \frac{1}{D^2} + \frac{4T'}{3|D|^3} - \frac{\Phi}{E|D|} \right) \\ \times \left(\frac{T'}{E_2} \right)^{1/2}, \quad (60.268)$$

which is valid for $D \leq 0$ and $T \geq E$; and where $T' \equiv T - E$.

Symmetrical model (two cases)

$$\sigma_E = \frac{\pi e^4}{T_i} \left(\frac{1}{E^2} + \frac{4E_2}{3E^3} + \frac{1}{X_i^2} + \frac{4E_2}{3X_i^3} - \frac{\Phi}{EX_i} \right), \quad (60.269)$$

which is valid for $X_i \equiv T + U_i - E \geq 0$, with $T_i \equiv T + U_i + E_2$, and

$$\sigma_E = \frac{\pi e^4}{T_i} \left(\frac{1}{E^2} + \frac{4T'_i}{3E^3} + \frac{1}{X_i^2} + \frac{4T'_i}{3|X_i|^3} - \frac{\Phi}{E|X_i|} \right) \\ \times \left(\frac{T'_i}{E_2} \right)^{1/2}, \quad (60.270)$$

which is valid for $0 \leq T'_i \leq E_2$, $T \geq 0$, with $T'_i \equiv T_i - E$, and where Φ is given by Eq. (60.260).

For incident heavy particles, the unsymmetrical model in Eq. (60.267) should be used.

Single-Particle Ionization

The total ionization cross section per atomic electron for incident heavy particles is

$$Q_i = \frac{2\pi Z_1^2 e^4}{m_e v_1^2} \left(\frac{1}{U_i} + \frac{m_e v_2^2}{3U_i^2} - \frac{1}{2m_e(v_1^2 - v_2^2)} \right), \quad (60.271)$$

which is valid for $U_i \leq 2m_e v_1(v_1 - v_2)$, or

$$Q_i = \frac{\pi Z_1^2 e^4}{m_e v_1^2} \left\{ \frac{1}{2m_e v_2(v_1 + v_2)} + \frac{1}{U_i} + \frac{m_e}{3v_2 U_i^2} \left[2v_1^3 + v_2^3 - (2U_i/m_e + v_2^2)^{3/2} \right] \right\}, \quad (60.272)$$

which is valid for $2m_e v_1(v_1 - v_2) \leq U_i \leq 2m_e v_1(v_1 + v_2)$, or otherwise $Q_i = 0$ for $U_i \geq 2m_e v_1(v_1 + v_2)$.

For electron impact,

$$Q_i = \frac{1}{2}(Q_i^{\text{dir}} + Q_i^{\text{ex}} + Q_i^{\text{int}}). \quad (60.273)$$

In the unsymmetrical model, Q_i^{ex} diverges, hence the exchange and interference terms above are omitted in the unsymmetrical model for electrons to obtain

$$Q_i^{\text{dir}} = \frac{\pi e^4}{T} \left(\frac{1}{U_i} + \frac{2E_2}{3U_i^2} - \frac{1}{T - E_2} \right), \quad (60.274)$$

which is valid for $T \geq E_2 + U_i$, or

$$Q_i^{\text{dir}} = \frac{2\pi e^4}{3T} \frac{(T - U_i)^{3/2}}{U_i^2 \sqrt{E_2}}, \quad (60.275)$$

which is valid for $U_i \leq T \leq E_2 + U_i$.

In the symmetrical model,

$$Q_i^{\text{dir}} = Q_i^{\text{ex}} = \frac{\pi e^4}{T_i} \left[\frac{1}{U_i} - \frac{1}{T} + \frac{2}{3} \left(\frac{E_2}{U_i^2} - \frac{E_2}{T^2} \right) \right], \quad (60.276)$$

$$Q_i^{\text{int}} = -\frac{\pi e^4}{T_i} \left(\frac{2\Phi'}{T + U_i} \ln \frac{T}{U_i} \right), \quad (60.277)$$

where Φ' can be approximated by [76]

$$\Phi' = \cos \left[\left(\frac{R_\infty}{E_1 + U_i} \right)^{1/2} \ln \frac{E_1}{U_i} \right], \quad (60.278)$$

and E_1 is defined in [76].

The sum of Eqs. (60.276) and (60.277) yields

$$Q_i = \frac{\pi e^4}{T_i} \left[\frac{1}{U_i} - \frac{1}{T} + \frac{2}{3} \left(\frac{E_2}{U_i^2} - \frac{E_2}{T^2} \right) - \frac{\Phi'}{T + U_i} \ln \frac{T}{U_i} \right], \quad (60.279)$$

which is also obtained by integrating the expression in Eq. (60.270) for σ_E ,

$$Q_i = \int_{U_i}^{\frac{1}{2}(T+U_i)} \sigma_E dE. \quad (60.280)$$

Ionization rate coefficients For heavy-particle impact [70],

$$\langle Q \rangle = \frac{a_0^2}{\kappa^2} \left\{ \frac{128}{9} (\kappa^3 b^3 - b^{3/2}) + \frac{1}{3} \lambda b \left(35 - \frac{58}{3} b \frac{8}{3} b^2 \right) + \frac{2}{3} \kappa a b \left[(5 - 4\kappa^2) \left(3a^2 + \frac{3}{2} a b + b^2 \right) - \lambda \kappa \left(\frac{15}{2} + 9a + 5b \right) \right] - 16\kappa a^4 \ln(4\kappa^2 1) + \theta \left[\frac{35}{6} - \kappa^2 a \left(\frac{5}{2} + 3a + 4a^2 + 8a^3 \right) \right] \right\}, \quad (60.281)$$

where

$$\begin{aligned} \kappa &= v_1/v_0, \\ \lambda &= \kappa - (4\kappa)^{-1}, \\ \theta &= \pi + 2 \tan^{-1} \lambda, \\ a &= (1 + \kappa^2)^{-1}, \\ b &= (1 + \lambda^2)^{-1}. \end{aligned}$$

$$\langle \sigma_{E,P} dP dE \rangle = \frac{64e^4 v_0^5}{3v_1^2 P^4} \left(\left| \frac{E}{P} - \frac{P}{2m_e} \right|^2 v_0^2 \right)^{-3} dP dE,$$

where $(1/2)m_e v_0^2$ is the ionization energy of H(1s).

Scaling laws Given the binary encounter cross section for ionization by protons of energy E_1 of an atom with binding energy u_a , the cross section for ionization of an atom with different binding energy u_b and scaled proton energy E'_1 can be determined to be [30]

$$\sigma_{\text{ion}}(E'_1, u_b) = \left(\frac{u_a^2}{u_b^2} \right) \sigma_{\text{ion}}(E_1, u_a), \quad (60.282)$$

$$E'_1 = (u_b/u_a) E_1, \quad (60.283)$$

where $\sigma_{\text{ion}}(E, u)$ is the ionization cross section for removal of a single electron from an atom with binding energy u by impact with a proton with initial energy E .

Double ionization See [77] for binary encounter cross section formulae for the direct double ionization of two-electron atoms by electron impact.

Excitation Excitation is generally less violent than ionization, and hence binary encounter theory is less applicable. Binary encounter theory can be applied to exchange excitation transitions, e.g., $e^- + \text{He}(n^1L) \rightarrow e^- + \text{He}(n^3L)$, with

the restriction of large incident electron velocities. The cross section is

$$\begin{aligned} Q_e^{\text{ex}} &= \int_{U_n}^{U_{n+1}} \sigma_{E,\text{ex}} dE \\ &= \frac{\pi e^4}{T_i} \left[\frac{1}{\mathcal{T}_{n+1}} - \frac{1}{\mathcal{T}_n} + \frac{2}{3} \left(\frac{E_2}{\mathcal{T}_{n+1}^2} - \frac{E_2}{\mathcal{T}_n^2} \right) \right], \end{aligned} \quad (60.284)$$

valid for $T \geq U_{n+1}$, with $\mathcal{T}_n \equiv T + U_i - U_n$ and $\mathcal{T}_{n+1} \equiv T + U_i + U_{n+1}$, or

$$\begin{aligned} Q_e^{\text{ex}} &= \int_{U_n}^T \sigma_{E,\text{ex}} dE \\ &= \frac{\pi e^4}{T_i} \left[\frac{1}{U_i} - \frac{1}{\mathcal{T}_n} + \frac{2}{3} \left(\frac{E_2}{U_i^2} - \frac{E_2}{\mathcal{T}_n^2} \right) \right], \end{aligned} \quad (60.285)$$

valid for $U_n \leq T \leq U_{n+1}$; U_n and U_{n+1} denote the excitation energies for levels n and $n + 1$, respectively.

60.10.3 Classical Ionization Cross Section

Applying the classical energy-change cross section result in Eq. (60.84) of *Gerjuoy* [28] to the case of electron-impact ionization yields the four cases [29]

$$\begin{aligned} \sigma_{\text{ion}}(v_1, v_2) &\approx \int_{\Delta E_\ell}^{\Delta E_u} \sigma_{\Delta E}^{\text{eff}}(v_1, v_2; m_1/m_2) d(\Delta E) \\ &= \frac{\pi(Z_1 Z_2 e^2)^2}{3v_1^2 v_2} \left(\frac{-2v_2^3}{(\Delta E)^2} - \frac{6v_2}{m_2 \Delta E} \right), \end{aligned} \quad (60.286)$$

which is valid for $0 < \Delta E < b$, or

$$\begin{aligned} \sigma_{\text{ion}}(v_1, v_2) &= \frac{\pi(Z_1 Z_2 e^2)^2}{3v_1^2 v_2} \\ &\times \left(\frac{4(v_1 - 2v_1')}{m_1^2 (v_1 - v_1')^2} + \frac{4(v_2 - 2v_2')}{m_2^2 (v_2 - v_2')^2} \right), \end{aligned} \quad (60.287)$$

which is valid for $b < \Delta E < a$, or

$$\sigma_{\text{ion}}(v_1, v_2) = \frac{\pi(Z_1 Z_2 e^2)^2}{3v_1^2 v_2} \left(\frac{-2v_1^3}{(\Delta E)^2} \right), \quad (60.288)$$

which is valid for $\Delta E > a$, $2m_2 v_2 > |m_1 - m_2|v_1$, or otherwise is zero for $\Delta E > a$, $2m_2 v_2 < |m_1 - m_2|v_1$.

The limits $\Delta E_{\ell,u}$ to the ΔE integration in each of the four cases is indicated in the appropriate validity conditions. The constants a and b above are given by

$$\begin{aligned} a &= \frac{4m_1 m_2}{(m_1 + m_2)^2} \left[E_1 - E_2 + \frac{1}{2} v_1 v_2 (m_1 - m_2) \right], \\ b &= \frac{4m_1 m_2}{(m_1 + m_2)^2} \left[E_1 - E_2 - \frac{1}{2} v_1 v_2 (m_1 - m_2) \right]. \end{aligned}$$

The expressions above for $\sigma_{\text{ion}}(v_1, v_2)$ must be averaged over the speed distribution of v_2 before comparison with experiment. See [29] for explicit formulae for the case of a delta function speed distribution.

60.10.4 Classical Charge Transfer Cross Section

Applying the classical energy-change cross section result in Eq. (60.84) of *Gerjuoy* [28] to the case of charge-transfer yields the four cases [29]

$$\begin{aligned} \sigma_{\text{CX}}(v_1, v_2) &\approx \int_{\Delta E_\ell}^{\Delta E_u} \sigma_{\Delta E}^{\text{(eff)}}(v_1, v_2) d\Delta E \\ &= \frac{\pi e^4}{3v_1^2 v_2} \left(-\frac{2v_2^3}{(\Delta E)^2} - \frac{6v_2/m_2}{\Delta E} \right), \end{aligned} \quad (60.289)$$

which is valid for $0 < \Delta E < b$, or

$$\begin{aligned} \sigma_{\text{CX}}(v_1, v_2) &= \frac{\pi e^4}{3v_1^2 v_2} \left(3 \frac{v_1/m_1 - v_2/m_2}{\Delta E} \right. \\ &\left. + \frac{(v_2^3 - v_1^3) - (v_1^3 + v_2^3)}{(\Delta E)^2} \right), \end{aligned} \quad (60.290)$$

which is valid for $b < \Delta E < a$, or

$$\sigma_{\text{CX}}(v_1, v_2) = \frac{\pi e^4}{3v_1^2 v_2} \left(-\frac{2v_1^2}{(\Delta E)^2} \right), \quad (60.291)$$

which is valid for $\Delta E > a$, $m_e v_2 > (m_1 - m_e)v_1$, or otherwise $\sigma_{\text{CX}} = 0$ when $\Delta E > a$, $m_e v_2 < (m_1 - m_e)v_1$. The above expressions for $\sigma_{\text{CX}}(v_1, v_2)$ must be averaged over the speed distribution $W(v_2)$ before comparison with experiment. See [29] for details. The constants a and b above are as defined in Sect. 60.10.3, and the limits $\Delta E_{\ell,u}$ are given by

$$\Delta E_\ell = \frac{1}{2} m_e v_1^2 + U_A - U_B, \quad (60.292a)$$

$$\Delta E_u = \frac{1}{2} m_e v_1^2 + U_A + U_B, \quad (60.292b)$$

$$v_2 = \sqrt{2U_A/m_e}, \quad (60.292c)$$

where $U_{A,B}$ are the binding energies of atoms A and B . The expressions above for σ_{CX} diverge for some $v_1 > 0$ if $U_A < U_B$. If $U_A = U_B$, then σ_{CX} diverges at $v_1 = 0$. To avoid the divergence, employ Gerjuoy's modification, $\Delta E_\ell = (1/2)m_e v_1^2 + U_A$.

60.11 Born Approximation

See the reviews in [78, 79], as well as any standard textbook on scattering theory, for background details on the Born approximation, and [80–85] for extensive tables of Born cross sections.

60.11.1 Form Factors

The basic formulation of the first Born approximation for high-energy heavy-particle scattering is discussed in Sect. 57.1. For the general atom–atom or ion–atom scattering process

$$A(i) + B(i') \rightarrow A(f) + B(f'), \quad (60.293)$$

with nuclear charges Z_A and Z_B , respectively, let $\hbar \mathbf{K}_i$ and $\hbar \mathbf{K}_f$ be the initial and final momenta of the projectile A , and $\hbar \mathbf{q} = \hbar \mathbf{K}_f - \hbar \mathbf{K}_i$ be the momentum transferred to the target. Then Eq. (57.4) can be written in the generalized form

$$\begin{aligned} \sigma_{if}^{i'f'} &= \frac{8\pi a_0^2}{s^2} \int_{t_-}^{t_+} \frac{dt}{t^3} \left| Z_A \delta_{if} - F_{if}^A(t) \right|^2 \\ &\times \left| Z_B \delta_{i'f'} - F_{i'f'}^B(t) \right|^2, \end{aligned} \quad (60.294)$$

where the momentum transfer is $t = qa_0$, and $s = v/v_B$ is the initial relative velocity in units of v_B . The form factors are

$$F_{if}^A(t) = \langle \Phi_f^A | \sum_{k=1}^{N_A} \exp(it \cdot \mathbf{r}_a/a_0) | \Phi_i^A \rangle, \quad (60.295)$$

where N_A is the number of electrons associated with atom A and similarly for $F_{if}^B(t)$. The limits of integration are $t_{\pm} = |K_f \pm K_i|a_0$. For heavy-particle collisions, $t_{\pm} \approx \infty$ and

$$\begin{aligned} t_- &= (K_i - K_f)a_0 \\ &\simeq \frac{\Delta E_{if}}{2s} \left(1 + \frac{m_e \Delta E_{if}}{4Ms^2} \right), \end{aligned} \quad (60.296)$$

where $M = M_A M_B / (M_A + M_B)$.

Limiting cases As discussed in Sect. 57.1, for the case $i = f$, $F_{if}^A(t) \rightarrow N_A$ as $t \rightarrow 0$, so that $Z_A - F_{if}^A(t) \rightarrow Z_A - N_A$. For the case $i \neq f$, $F_{if}^A(t) \rightarrow 0$ as $t \rightarrow 0$ and $t \rightarrow \infty$.

60.11.2 Hydrogenic Form Factors

Bound–bound transitions In terms of $\tau = t/Z$,

$$|F_{1s,1s}| = \frac{16}{(4 + \tau^2)^2}, \quad (60.297a)$$

$$|F_{1s,2s}| = 2^{17/2} \frac{\tau^2}{(4\tau^2 + 9)^3}, \quad (60.297b)$$

$$|F_{1s,2p}| = 2^{15/2} \frac{3\tau}{(4\tau^2 + 9)^3}, \quad (60.297c)$$

$$|F_{1s,3s}| = 2^4 3^{7/2} \frac{(27\tau^2 + 16)\tau^2}{(9\tau^2 + 16)^4}, \quad (60.297d)$$

$$|F_{1s,3p}| = 2^{11/2} 3^3 \frac{(27\tau^2 + 16)\tau}{(9\tau^2 + 16)^4}, \quad (60.297e)$$

$$|F_{1s,3d}| = 2^{17/2} 3^{7/2} \frac{\tau^2}{(9\tau^2 + 16)^4}. \quad (60.297f)$$

Bound–continuum transitions In terms of the scaled wave vector $\kappa = \mathbf{k}a_0/Z$ for the ejected electron,

$$|F_{1s,\kappa}|^2 = \frac{2^8 \kappa \tau^2 (1 + 3\tau^2 + \kappa^2) \exp(-2\theta/\kappa)}{3 [1 + (\tau - \kappa)^2]^3 [1 + (\tau + \kappa)^2]^3 (1 - e^{-2\pi/\kappa})}, \quad (60.298)$$

where $\theta = \tan^{-1}[2\kappa/(1 + \tau^2 - \kappa^2)]$. Expressions for the bound–continuum form factors for the L-shell ($2\ell \rightarrow \kappa$) and M-shell ($3\ell \rightarrow \kappa$) transitions can be found in [86] and [87], respectively. See also §4 of [88] for further details.

General Expressions and Trends

For final ns states

$$\begin{aligned} |F_{1s,ns}|^2 &= \frac{2^4 n [(n-1)^2 + n^2 \tau^2]^{n-1}}{\tau^2 [(n+1)^2 + n^2 \tau^2]^{n+1}} \\ &\times \sin^2(n \tan^{-1} x + \tan^{-1} y), \end{aligned} \quad (60.299)$$

where

$$x = \frac{2\tau}{n(\tau^2 + 1 - n^{-2})}, \quad y = \frac{2\tau}{\tau^2 - 1 + n^{-2}}. \quad (60.300)$$

For final $n\ell$ states [89]

$$\begin{aligned} &F_{1s,n\ell}(\tau) \\ &= (i\tau)^\ell 2^{3(\ell+1)} \sqrt{2\ell+1} (\ell+1)! \left(\frac{(n-\ell-1)!}{(n+\ell)!} \right)^{1/2} \\ &\times n^{\ell+1} \frac{[(n-1)^2 + n^2 \tau^2]^{(n-\ell-3)/2}}{[(n+1)^2 + n^2 \tau^2]^{(n+\ell+3)/2}} \\ &\times \left[a_{n\ell} C_{n-\ell-1}^{(\ell+2)}(x) - b_{n\ell} C_{n-\ell-2}^{(\ell+2)}(x) + c_{n\ell} C_{n-\ell-3}^{(\ell+2)}(x) \right], \end{aligned} \quad (60.301)$$

with coefficients $a_{n\ell}$, $b_{n\ell}$ and $c_{n\ell}$ given by

$$\begin{aligned} a_{n\ell} &= (n+1)[(n-1)^2 + n^2\tau^2], \\ b_{n\ell} &= 2n\sqrt{[(n-1)^2 + n^2\tau^2][(n+1)^2 + n^2\tau^2]}, \\ c_{n\ell} &= (n-1)[(n+1)^2 + n^2\tau^2], \end{aligned}$$

and the argument

$$x = \frac{n^2 - 1 + n^2\tau^2}{\sqrt{[(n+1)^2 + n^2\tau^2][(n-1)^2 + n^2\tau^2]}}.$$

Summation over final ℓ states

$$\begin{aligned} |F_{1s,n}|^2 &= \sum_{\ell} |F_{1s,n\ell}|^2 \\ &= 2^8 n^7 \tau^2 \left[\frac{1}{3}(n^2 - 1) + n^2\tau^2 \right] \\ &\quad \times \frac{[(n-1)^2 + n^2\tau^2]^{n-3}}{[(n+1)^2 + n^2\tau^2]^{n+3}} \end{aligned} \quad (60.302)$$

which for large n becomes

$$|F_{1s,n}|^2 \approx \frac{2^8 \tau^2 (3\tau^2 + 1)}{3n^3 (\tau^2 + 1)^6} \exp\left(\frac{-4}{(\tau^2 + 1)}\right). \quad (60.303)$$

For initial $2s$ and $2p$ states,

$$\begin{aligned} |F_{2s,n}|^2 &= 2^4 n^7 \tau^2 \left[-\frac{1}{3} + \frac{1}{2}n^2 - \frac{3}{16}n^4 + \frac{1}{48}n^6 \right. \\ &\quad \left. + n^2\tau^2 \left(\frac{1}{3} - \frac{2}{3}n^2 + \frac{19}{48}n^4 \right) \right. \\ &\quad \left. + n^4\tau^4 \left(\frac{5}{3} - \frac{7}{6}n^2 \right) + n^6\tau^6 \right] \\ &\quad \times \frac{[(\frac{1}{2}n - 1)^2 + n^2\tau^2]^{n-4}}{[(\frac{1}{2}n + 1)^2 + n^2\tau^2]^{n+4}}, \end{aligned} \quad (60.304)$$

$$\begin{aligned} |F_{2p,n}|^2 &= \frac{2^4 n^9 \tau^2}{3} \left[\frac{1}{4} - \frac{7}{24}n^2 + \frac{11}{192}n^4 \right. \\ &\quad \left. - n^2\tau^2 \left(\frac{5}{6} - \frac{23}{24}n^2 \right) + \frac{1}{4}n^4\tau^4 \right] \\ &\quad \times \frac{[(\frac{1}{2}n - 1)^2 + n^2\tau^2]^{n-4}}{[(\frac{1}{2}n + 1)^2 + n^2\tau^2]^{n+4}}. \end{aligned} \quad (60.305)$$

Power series expansion $\tau^2 \ll 1$ [7]

$$|F_{1s,ns}(\tau)|^2 = A(n)\tau^4 + B(n)\tau^6 + C(n)\tau^8 + \dots, \quad (60.306) \quad \text{with } t_-^2 = [9/(16s^2)][1 + 3m_e/(4Ms^2) + \dots].$$

where

$$\begin{aligned} A(n) &= \frac{2^8 n^9 (n-1)^{2n-6}}{3^2 (n+1)^{2n+6}}, \\ B(n) &= -\frac{2^9 n^{11} (n^2 + 11)(n-1)^{2n-8}}{3^2 5 (n+1)^{2n+8}}, \\ C(n) &= -\frac{2^8 n^{13} (313n^4 - 1654n^2 - 2067)}{3^2 5^2 7 (n+1)^{2n+10}} (n-1)^{2n-10}. \end{aligned}$$

For analytical expressions for $A(n)$, $B(n)$, and $C(n)$ for final np and nd states, see [90, 91].

General trends in hydrogenic form factors [92] The inelastic form factor $|F_{n\ell \rightarrow n'\ell'}|$ oscillates with ℓ' on an increasing background until the value

$$\ell'_{\max} = \min\left(n' - 1, n \left(\frac{2(n+3)}{(n+1)}\right)^{1/2} - \frac{1}{2}\right) \quad (60.307)$$

is reached, after which a rapid decline for $\ell > \ell'_{\max}$ occurs. See [92] for illustrative graphs.

60.11.3 Excitation Cross Sections

Atom-Atom Collisions [93, 94]

Single excitation For the process

Eq. (60.294) reduces to

$$\sigma_{if} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{if}^A|^2 |Z_B - F_{i'i'}^B|^2. \quad (60.309)$$

Double excitation For the process

$$\sigma_{1s,n\ell}^{1s,n'\ell'} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{1s,n\ell}|^2 |F_{1s,n'\ell'}|^2. \quad (60.311)$$

Special cases are [95]

$$\sigma_{1s,2s}^{1s,2s} = \frac{2^{30} \pi a_0^2 (880t_-^4 + 396t_-^2 + 81)}{495s^2 (4t_-^2 + 9)^{11}}, \quad (60.312a)$$

$$\sigma_{1s,2p}^{1s,2p} = \frac{2^{30} 3^4 \pi a_0^2}{11s^2 (4t_-^2 + 9)^{11}}, \quad (60.312b)$$

$$\sigma_{1s,2s}^{1s,2p} = \frac{2^{29} 3^2 (44t_-^2 + 9)}{55s^2 (4t_-^2 + 9)^{11}}, \quad (60.312c)$$

Ion–atom collisions For the proton impact process

Eq. (60.294) reduces to

$$\sigma_{1s,n\ell} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{1s,n\ell}(t)|^2, \quad (60.314)$$

with $t_- = (1 - n^{-2})/(2s)$.

Asymptotic Expansions

$$\sigma_{1s,ns} = \frac{4\pi a_0^2 (n^2 - 1) |X_{1s \rightarrow ns}|^2}{24s^2 n^2} \times \left[C_s(n) - \frac{1}{s^2} + \frac{n^2 + 11}{20n^2 s^4} + \frac{313n^4 - 1654n^2 - 2067}{8400n^4 s^6} \right], \quad (60.315)$$

$$\sigma_{1s,np} = \frac{2^{10} \pi a_0^2 n^7 (n-1)^{2n-5}}{3s^2 (n+1)^{2n+5}} \times \left[C_p(n) + \ln s^2 + \frac{n^2 + 11}{10n^2 s^2} + \frac{313n^4 - 1654n^2 - 2067}{5600n^4 s^4} \right], \quad (60.316)$$

$$\sigma_{1s,nd} = \frac{2^{11} \pi a_0^2 (n^2 - 4)n^5 (n^2 - 1)^2 (n-1)^{2n-7}}{3^2 5s^2 (n+1)^{2n+7}} \times \left[C_d(n) - \frac{1}{s^2} + \frac{11n^2 + 13}{28n^2 s^4} \right], \quad (60.317)$$

where $C_s(2) = 16/5$, $C_s(3) = 117/32$, $C_s(4) \approx 3.386$, and

$$\gamma_n C_p(n) = \frac{1.3026}{n^3} + \frac{1.7433}{n^5} + \frac{16.918}{n^7}, \quad (60.318)$$

$$\gamma_n C_d(n) = \frac{2.0502}{n^3} + \frac{7.6125}{n^5}, \quad (60.319)$$

with

$$\gamma_n \equiv \frac{2^8 n^7 (n-1)^{(2n-5)}}{3(n+1)^{(2n+5)}}. \quad (60.320)$$

Further asymptotic expansion results can be found in [6–9].

A general expression for Born excitation and ionization cross sections for hydrogenic systems in terms of a parabolic coordinate representation (Chap. 9) is given in [96, 97].

Number of independent transitions \mathcal{N}_i between levels n and n' [96, 97]

$$\mathcal{N}_i = n^2 \left[n' - \left(\frac{n}{3} \right) \right] + \left(\frac{n}{3} \right). \quad (60.321)$$

Validity criterion The Born approximation is valid provided that [98]

$$nE \gg \ln \left(\frac{4E}{J_n} \right) \quad (60.322)$$

for transitions $n \rightarrow n'$ when $n, n' \gg 1$ and $|n - n'| \approx 1$. The constant J_n is undetermined (see [98] for details) but is generally taken to be the ionization potential of level n .

60.11.4 Ionization Cross Sections

The general expression for the Born differential ionization cross section can be evaluated in closed form using screened hydrogenic wave functions. The differential cross section per incident electron scattered into solid angle $d\Omega_{k'}$, integrated over directions κ for the ejected electron (treated as distinguishable) is [99–101]

$$I(\theta, \phi) d\Omega_{k'} d\kappa' = \frac{4k'}{kq^4 a_0 \tilde{Z}_B^4} |F_{n\ell, \kappa'}|^2(q) d\Omega_{k'} d\kappa', \quad (60.324)$$

where the form factor is given by Eq. (60.299) for the case $n\ell = 1s$, with the ejected electron wavenumber κ and momentum transferred q in the collision, $\kappa' = \kappa a_0 / \tilde{Z}_B$, $\mathbf{q} = (\mathbf{k}' - \mathbf{k}) a_0 / \tilde{Z}_B$, being scaled by the screened nuclear charge \tilde{Z}_B appropriate to the $n\ell$ -shell from which the electron is ejected. The total Born ionization cross section per electron is

$$\sigma_{\text{ion}}^{\text{B}} = \int_0^{\kappa_{\text{max}}} d\kappa' \int_{k-k'}^{k+k'} I(q, \kappa') dq, \quad (60.325)$$

which is generally evaluated numerically.

60.11.5 Capture Cross Sections

Electron capture

In the Oppenheimer–Brinkman–Kramers (OBK) approximation [102],

$$\sigma_{n\ell, n'\ell'} = \frac{M^2}{2\pi \hbar^3} \frac{v_f}{v_i} \int_{-1}^1 d(\cos \theta) |F_{n\ell \rightarrow n'\ell'}|^2, \quad (60.327)$$

where $\mathbf{v}_i = v_i \hat{\mathbf{n}}_i$, $\mathbf{v}_f = v_f \hat{\mathbf{n}}_f$, θ is the angle between $\hat{\mathbf{n}}_i$ and $\hat{\mathbf{n}}_f$, $M = M_A M_B / (M_A + M_B)$, and

$$|F_{n\ell, n'\ell'}| = \iint d\mathbf{r} ds \varphi_i(\mathbf{r}) \varphi_f^*(s) \left(\frac{Z_A e^2}{r} \right) \times e^{i(\alpha \cdot \mathbf{r} + \beta \cdot \mathbf{s})}, \quad (60.328)$$

with

$$\begin{aligned} \alpha &= k_f \hat{\mathbf{n}}_f + k_i \hat{\mathbf{n}}_i \frac{M_A}{M_A + m_e}, \\ \beta &= -k_i \hat{\mathbf{n}}_i - k_f \hat{\mathbf{n}}_f \frac{M_B}{M_B + m_e}, \\ k_i &= \frac{v_f}{\hbar} \frac{M_B (M_A + m_e)}{(M_A + M_B + m_e)}, \\ k_f &= \frac{v_f}{\hbar} \frac{(M_B + m_e) M_A}{(M_A + M_B + m_e)}. \end{aligned}$$

The Jackson–Schiff correction factor [103] is

$$\begin{aligned} \gamma_{\text{JS}} &= \frac{1}{192} \left(127 + \frac{56}{p^2} + \frac{32}{p^4} \right) \\ &\quad - \frac{\tan^{-1} \frac{1}{2} p}{48 p} \left(83 + \frac{60}{p^2} + \frac{32}{p^4} \right) \\ &\quad + \frac{(\tan^{-1} \frac{1}{2} p)^2}{24 p^2} \left(31 + \frac{32}{p^2} + \frac{16}{p^4} \right), \end{aligned} \quad (60.329)$$

and the capture cross section is

$$\begin{aligned} \sigma(n_i \ell_i, n_f \ell_f) &= \frac{\gamma_{\text{JS}} \pi a_0^2}{p^2} C(n_i \ell_i, n_f \ell_f) \\ &\quad \times \int_x^\infty F(n_i \ell_i, n_f \ell_f; x) dx, \end{aligned} \quad (60.330)$$

with

$$\begin{aligned} p &= \frac{m v_i}{\hbar}, \quad a = \frac{Z_A}{n_i}, \quad b = \frac{Z_B}{n_f}, \\ x &= [p^2 + (a + b)^2][p^2 + (a - b)^2] / 4 p^2. \end{aligned}$$

The coefficients C in Eq. (60.330) are given in Table 60.4, while the functions F are given in Table 60.5 [102]. In Table 60.5, the appropriate values of a and b are indicated by the quantum numbers n_i , ℓ_i and n_f , ℓ_f .

Table 60.4 Coefficients $C(n_i \ell_i \rightarrow n_f \ell_f)$ in the Born capture cross section formula in Eq. (60.330)

$n_f \ell_f$	$C(1s \rightarrow n_f \ell_f)$
1s	$2^8 Z_A^5 Z_B^5$
2s	$2^5 Z_A^5 Z_B^5$
3s	$2^8 Z_A^5 Z_B^5 / 3^3$
2p	$2^5 Z_A^5 Z_B^7$
3p	$2^{13} Z_A^5 Z_B^7 / 3^6$
3d	$2^{15} Z_A^5 Z_B^9 / 3^9$
4s	$2^2 Z_A^5 Z_B^5$
4p	$5 Z_A^3 Z_B^7$
4d	$Z_A^5 Z_B^9$
4f	$Z_A^5 Z_B^{11} / 20$

$$C(2s \rightarrow n_f \ell_f) = C(1s \rightarrow n_f \ell_f) / 8$$

$$C(2p \rightarrow n_f \ell_f) = C(1s \rightarrow n_f \ell_f) / 24$$

Table 60.5 Functions $F(n_i \ell_i \rightarrow n_f \ell_f; x)$ in the Born capture cross section formula in Eq. (60.330)

$n_f \ell_f$	$F(n_i \ell_i, n_f \ell_f; x)$
1s	x^{-6}
2s	$(x - 2b^2)^2 x^{-8}$
2p	$(x - b^2) x^{-8}$
3s	$[x^2 - (16/3)b^2 x + (16/3)b^4]^2 x^{-10}$
3p	$(x - b^2)(x - 2b^2)^2 x^{-10}$
3d	$(x - b^2)^2 x^{-10}$
4s	$(x - 2b^2)^2 (x^2 - 8b^2 x + 8b^4)^2 x^{-12}$
4p	$(x - b^2)[x^2 - (24/5)b^2 x + (24/5)b^4]^2 x^{-12}$
4d	$(x - b^2)^2 (x - 2b^2)^2 x^{-12}$
4f	$(x - b^2)^3 x^{-12}$

$$F(2s, n_f \ell_f; x) = (x - 2a^2)^2 x^{-2} F(1s, n_f \ell_f; x)$$

$$F(2p, n_f \ell_f; x) = (x - a^2) x^{-2} F(1s, n_f \ell_f; x)$$

Abstract

Thomas peaks correspond to singular second-order quantum effects whose location may be determined by classical two-step kinematics. The widths of these peaks (or ridges) may be estimated using the uncertainty principle. A second-order quantum calculation is required to obtain the magnitude of these peaks. Thomas peaks and ridges have been observed in various reactions in atomic and molecular collisions involving mass transfer and also ionization.

Transfer of mass is a quasi-forbidden process. Simple transfer of a stationary mass M_2 to a moving mass M_1 is forbidden by conservation of energy and momentum. If $M_1 < M_2$, then M_1 rebounds; if $M_1 = M_2$, then M_1 stops, and M_2 continues on; and if $M_1 > M_2$, then M_2 leaves faster than M_1 . In none of these cases do M_1 and M_2 leave

together. *Thomas* [1] understood this in 1927 and further realized that transfer of mass occurs only when a third mass is present, and all three masses interact. The simplest allowable process is a two-step process now called a Thomas process [2, 3].

Quantum mechanically [4], the second Born term at high energies is the largest Born term and corresponds to the simplest allowed classical process, namely the Thomas process. While the classically forbidden first Born term is not zero (saved by the uncertainty principle), the first Born cross section varies at high v as v^{-12} , in contrast to the second Born cross section, which varies as v^{-11} , thus dominating. Higher Born terms correspond to multistep processes that are unlikely in fast collisions where there is not enough time for complicated processes. The higher Born terms ($n > 2$) are also smaller than the second Born term.

61.1 The Classical Thomas Process

The basic Thomas process is shown in Fig. 61.1. Here, the entire collision is coplanar since particles 1 and 2 go off together (that is what is meant by mass transfer). We assume that all the masses and the incident velocities \mathbf{v} are known. Thus, there are six unknowns, \mathbf{v}' , \mathbf{v}_f , and \mathbf{v}_3 , each with two components. Conservation of momentum gives two equations of constraint for each collision. Conservation of overall energy gives a fifth constraint, and conservation of energy in the intermediate state (which only holds classically) gives a sixth constraint. With six equations of constraint, all six unknowns may be completely determined. The allowed values of \mathbf{v}' , \mathbf{v}_f , and \mathbf{v}_3 depend on the masses M_1 , M_2 , and M_3 . For example, in the case of the transfer of an electron from

Fig. 61.1 Diagram for mass transfer via a Thomas two-step process

atomic hydrogen to a proton, i.e., $p^+ + H \rightarrow H + p^+$, it is easily verified that the angles are $\alpha = (M_2/M_1) \sin 60^\circ$, $\beta = 60^\circ$ and $\gamma = 120^\circ$, where $m' = M_2 = m_f$, and $M_1 = M_3 = M_p = 1836 m_e$. For the case $e^+ + H \rightarrow Ps + p^+$, it may be verified that $\alpha = 45^\circ$, $\beta = 45^\circ$ and $\gamma = 90^\circ$.

In general, the intermediate mass m' may be equal to M_1 , M_2 , or M_3 . We shall regard these as different Thomas processes and label them B, A, and C, respectively. The standard Thomas process (the one actually considered by Thomas in 1927) is case A and corresponds to the first example given above. Lieber diagrams for the Thomas processes A, B, and C [5] are illustrated in Fig. 61.2. In the Lieber diagram, mass regions in which solutions exist for processes A, B, and C are shown. (An equivalent diagram was given earlier by Detmann and Liebfried [3].) There are some regions in which two-step processes are forbidden. In these regions, the theory of mass transfer is not fully understood at present.

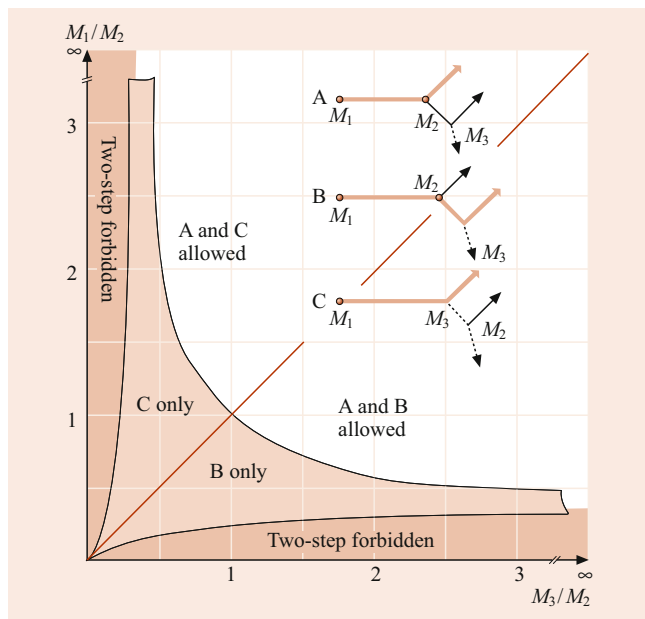

Fig. 61.2 Lieber diagram for mass transfer

61.2 Quantum Description

61.2.1 Uncertainty Effects

In quantum mechanics, energy conservation in the intermediate states may be violated within the limits of the uncertainty principle, $\Delta E \geq \hbar/\Delta t$, where Δt is the uncertainty in time of mass transfer. It is not possible to determine if mass transfer actually occurs at the beginning, in the middle, or at the end of the collision. Thus, we choose $\Delta t = \bar{r}/\bar{v}$, where \bar{r} is the size of the collision region, and \bar{v} is the mean collision velocity. Taking $\bar{r} \approx a_0/Z_{\text{target}}$ and $\bar{v} \approx v$, the projectile velocity, we have

$$\Delta E \approx \frac{\hbar}{\Delta t} = \frac{\hbar \bar{v}}{\bar{r}} = \frac{\hbar v}{a_0/Z_{\text{target}}} = \frac{\hbar Z_{\text{target}}}{a_0}. \quad (61.1)$$

Here, a_0 is the Bohr radius, and Z_{target} is the nuclear charge of the target in units of the electron charge. Within this range of energy ΔE , the constraint of energy conservation in the intermediate state does not apply.

61.2.2 Conservation of Overall Energy and Momentum

Conservation of overall energy and momentum then gives three equations of constraint on the four unknowns v_f and v_3 [6], namely,

$$M_1 v = (M_f + \tilde{M}_f) v_f + M_3 v_3, \quad (61.2)$$

$$M_1 v^2 = (M_f + \tilde{M}_f) v_f^2 + M_3 v_3^2, \quad (61.3)$$

where M_f (\tilde{M}_f) is the mass of the upper (lower) particle in the final state of the bound system shown in Fig. 61.1, in which m' is the mass of the intermediate particle M_1 , M_2 or M_3 . From Eqs. (61.2) and (61.3) it may be shown that the velocity of the recoil particle is constrained by the condition

$$2v_3 \cdot \hat{v} = 2 \cos \gamma = \frac{M_1 + M_2 + M_3}{M_1} \frac{v_3}{v} - \frac{M_2}{M_3} \frac{v}{v_3}. \quad (61.4)$$

Thus, the magnitude and the direction of v_3 are not independent. Specifying either v_3 or \hat{v}_3 is sufficient, together with the equations of constraint, to determine the energies and directions of all particles in the final state. Similarly, one may express the equations of constraint in terms of v_f and \hat{v}_f .

61.2.3 Conservation of Intermediate Energy

In a classical two-step process, the projectile hits a particle in the target, and the intermediate mass m' then propagates and subsequently undergoes a second collision. Quantum

Fig. 61.3 Counting rate (or cross section) on the vertical axis versus recoil speed v_3 and recoil angle γ for a Thomas process in which a proton (projectile) picks up an electron from helium (target). The captured electron bounces off the second target electron

mechanically, this corresponds to a second Born term represented by $V_1 G_0 V_2$, where V represents an interaction and G_0 is the propagator of the intermediate state, namely,

$$G_0 = (E - H_0 + i\epsilon)^{-1} = -i\pi\delta(E - H_0) + \wp \frac{1}{E - H_0}, \quad (61.5)$$

where \wp is the Cauchy principal value of G_0 , which excludes the singularity at $E = H_0$. This singularity corresponds to conservation of energy in the intermediate state. It is this singularity that gives rise to the weaker secondary ridge in Fig. 61.3 at $v_3 = v$. The width of the secondary ridge is given approximately by $\Delta E = \hbar/\Delta t$, as discussed above. The intersection of the ridges is the Thomas peak. At very high collision velocities, the Thomas peak dominates the total cross section for mass transfer.

The constraint imposed by conservation of intermediate energy may be expressed by replacing the speed of the recoil particle v_3 by the scaled variable $K = M_3 v_3 / m'v$. Then it may be shown that the conservation of intermediate energy may be expressed in the form [6]:

$$\left(\frac{M_3 v_3}{m'v} \right)^2 \equiv K^2 = 1. \quad (61.6)$$

The constraints of conservation of overall energy and momentum, i.e., Eq. (61.4), may be easily written in terms of K as

$$2 \cos \gamma = r \frac{m'}{M_2} K - \frac{M_2}{m'} \frac{1}{K}, \quad (61.7)$$

where $r = (M_1 + M_2 + M_3)M_2 / (M_1 M_3)$.

61.2.4 Example: Proton–Helium Scattering

The effect of the constraints of conservation of overall energy and momentum may be seen in Fig. 61.3, where a sharp ridge is evident in the reaction

and $M_1 = M_p$, $M_2 = M_3 = m_e$. Here, v_3 is the speed of the recoiling ionized target electron, and the target nucleus is not directly involved in the reaction. The width of the sharp ridge is due to the momentum spread of the electrons in helium and may be regarded as being caused by the uncertainty principle since this momentum (or velocity) spread corresponds to $\Delta p = \hbar/\Delta r$, where Δr is taken as the radius of the helium atom.

The locus of the sharp ridge in Fig. 61.3, corresponding to conservation of overall energy and momentum, is given by Eq. (61.8). The locus of the weaker ridge, corresponding to the conservation of energy in the intermediate state, is given by Eq. (61.7). The intersection of these two loci gives the unique classical result suggested by Thomas. The width of these ridges may be estimated from the uncertainty principle as described above.

Experimental evidence for the double ridge structure has been reported by *Palinkas et al.* [7], corresponding to the calculations given in Fig. 61.3, but at a collision energy of 1 MeV, as shown below.

The data in Fig. 61.4 corresponds to a slice across the sharp ridge of Fig. 61.3 at $v = v_3$. The solid line is a second

Fig. 61.4 Observation of a slice of the Thomas ridge structure in $p^+ + \text{He} \rightarrow \text{H} + \text{He}^{++} + e^-$ at 1 MeV by *Palinkas et al.* [7]

Fig. 61.5 Energy-conserving (on-shell) and energy-nonconserving contributions to the second Born scattering amplitude

Born calculation [8, 9] at 1 MeV. The bump of data above a smooth background is the indication of the ridge structure.

61.3 Off-Energy-Shell Effects

In Eq. (61.6), the Green's function G_0 contains an energy-conserving term $i\pi\delta(E - H_0)$, which is imaginary, and a real energy-nonconserving term $\wp[1/(E - H_0)]$. The latter does not occur classically; it is permitted by the uncertainty principle and represents the contribution of virtual (off-the-energy-shell or energy-nonconserving) states within $\pm\Delta E = \hbar/\Delta t$ about the classical value $E = H_0$. This quantum term also represents the effect of time-ordering in the second Born amplitude [10]. In plane wave second-Born calculations, the off-energy-shell term gives the real part of the scattering amplitude f_2 , while the on-shell (energy conserving) term gives the imaginary part of f_2 . These two contributions are shown in Fig. 61.5.

Half of the Thomas peak comes from energy-nonconserving contributions that are not included in a classical description. Also, the energy-nonconserving contribution plays a significant role in determining the shape of the standard Thomas peak, which has been observed [11].

61.4 Dispersion Relations

Because of the form of the Green's function of Eq. (61.6), the second Born contribution f_2 to the scattering amplitude has a single pole in the lower half of the complex plane. Con-

sequently, it obeys the dispersion relation

$$\begin{aligned} \operatorname{Re}[f_2(\lambda)] &= -\frac{1}{\pi} \wp \int_{-\infty}^{+\infty} \frac{\operatorname{Im}[f_2(\lambda')]}{\lambda - \lambda'} d\lambda', \\ \operatorname{Im}[f_2(\lambda)] &= \frac{1}{\pi} \wp \int_{-\infty}^{+\infty} \frac{\operatorname{Re}[f_2(\lambda')]}{\lambda - \lambda'} d\lambda', \end{aligned} \quad (61.9)$$

where $\operatorname{Re} f_2$ and $\operatorname{Im} f_2$ denote the real and imaginary parts of f_2 . Thus, the energy-nonconserving part of f_2 is related to an integral over the energy-conserving part and vice versa. In the case of the dielectric constant it is well known that the real and imaginary parts of ϵ are also related by a dispersion relation, namely the Kramers–Kronig relation [12].

Resonances are usually a function of energy E . The width of a resonance gives the lifetime τ of the resonance. Classically, τ is how long the projectile orbits the target before it leaves, corresponding to a delay or shift in time of the projectile during the interaction. If the width of the resonance is ΔE , then the lifetime is $\tau = \hbar/\Delta E$; E and τ are conjugate variables. The Thomas peak is an overdamped resonance in scattering angle, corresponding to a shift in the impact parameter of the scattering event [13]. However, unlike energy resonances, our Thomas resonance in the scattering angle seems to have no classical analog [14].

61.5 Destructive Interference of Amplitudes

It has already been noted that the location of the Thomas peaks depends on the mass of the collision partners. For the process

there are two separate Thomas peaks [2, 15] corresponding to cases A and B in the Lieber diagram (Fig. 61.2). Experimental evidence exists for both peaks. The standard Thomas peak occurs at small forward angles [11], while the second peak [16] occurs at about 60° . If the mass of the projectile is reduced, the positions of these Thomas peaks move toward one another [17], as illustrated in Fig. 61.6.

When $M_1 = M_2$, then both Thomas peaks occur at 45° . This occurs in positronium formation where $M_1 = M_2 = m_e$, i.e.,

In cases A and B of Fig. 61.2, the two $V_1 G_0 V_2$ second Born terms are of opposite sign because V_2 is of opposite sign in diagrams A and B. This leads to destructive interference for $1s - 1s$ electron capture (which is dominant at high velocities), as was first discussed by *Shakeshaft* and *Wadehra* [17].

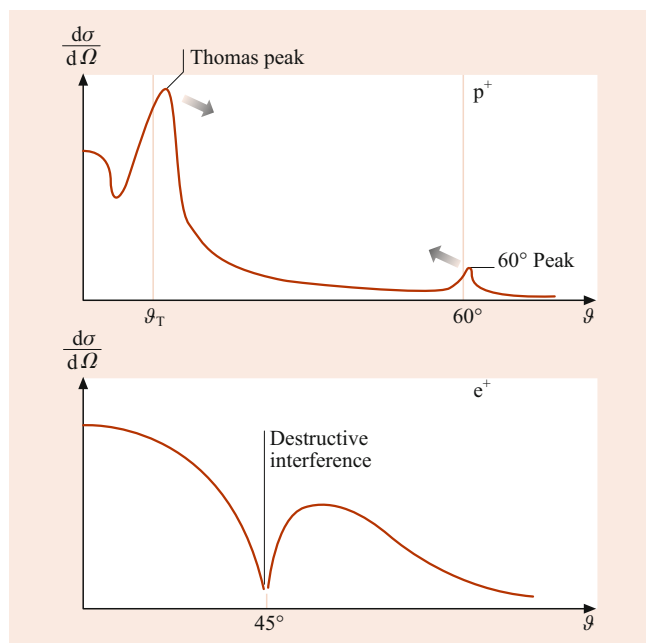

Fig. 61.6 Change of position and nature of the Thomas peaks with decreasing projectile mass

Consequently, the observed Thomas peak structure is expected [18, 19] to be quite different for e^+ impact than for impact of p^+ or other projectiles heavier than an electron. The double ridge structure for transfer ionization of helium by e^+ is expected to differ significantly from the structure shown in Fig. 61.3. Understanding such destructive interference between resonant amplitudes may give deeper insight into the physical nature of the intermediate states in this special few-body collision system.

61.6 Recent Developments

In the late 1990s, observations [20] of the Thomas peak in the case of transfer ionization (where one electron is ionized, and another is transferred) differential in the momentum of the ejected electron provided new specific detail on the kinematics of the two-step process [21]. In 2001, the Thomas peak was discussed [22] in the context of quantum time ordering. In this case, time ordering, surprisingly, is not significant at the center of the peak, in contradiction to the classical picture that there is a definite order in the two-step process for transfer ionization. However, time ordering does contribute to the shape of the Thomas peak. In 2002, the Stockholm group [23] reported that at very high velocities, the ratio of transfer ionization to total transfer approaches the same asymptotic limit as in double to single ionization in (non-Compton) photoionization, namely 1.66%. This was interpreted in terms of a common shake process occurring when the wavefunction collapses after a sudden collision.

Abstract

The classical trajectory Monte Carlo (CTMC) method originated with *Hirschfelder*, who studied the $H + D_2$ exchange reaction using a mechanical calculator [1]. With the availability of computers, the CTMC method was ac-

tively applied to a large number of chemical systems to determine reaction rates and final state vibrational and rotational populations (e.g., *Karplus et al.* [2]). For atomic physics problems, a major step was introduced by *Abrines and Percival* [3], who employed Kepler's equations and the Bohr–Sommerfeld model for atomic hydrogen to investigate electron capture and ionization for intermediate velocity collisions of $H^+ + H$. An excellent description is given by *Percival and Richards* [4]. The CTMC method has a wide range of applicability to strongly coupled systems, such as collisions by multiply charged ions [5]. In such systems, perturbation methods fail, and basis set limitations of coupled-channel molecular-orbital and atomic-orbital techniques have difficulty in representing the multitude of active excitation, electron capture, and ionization channels.

62.1 Theoretical Background

62.1.1 Hydrogenic Targets

Let us consider a simple three-body collision system comprised of a fully-stripped projectile (a), a bare target nucleus (b), and an active electron (c), where each pair of particles of charge Z_i and Z_j , and positions \mathbf{r}_i and \mathbf{r}_j , interact via a Coulomb potential $Z_i Z_j / |\mathbf{r}_i - \mathbf{r}_j|$. The classical Hamiltonian for the system is

$$H = \sum_{i=a,b,c} \frac{|\mathbf{p}_i|^2}{2m_i} + \sum_{i \neq j} \frac{Z_i Z_j}{|\mathbf{r}_i - \mathbf{r}_j|}, \quad (62.1)$$

where \mathbf{p}_i and m_i are the momenta and masses of the particles, respectively.

The initial state of the target is completely determined by five random numbers given by Kepler's equation that constrain the plane and eccentricity of the electron's orbit, and another one is used to determine the impact parameter within the range of interaction [4, 5]. From Eq. (62.1), one obtains a set of 18 coupled (this number can be reduced by energy-momentum conservation considerations) first-order differential equations that determine the time evolution of the Cartesian coordinates and momenta of each particle,

$$d\mathbf{r}_i/dt = \partial H/\partial \mathbf{p}_i \quad (62.2)$$

$$d\mathbf{p}_i/dt = -\partial H/\partial \mathbf{r}_i \quad (62.3)$$

A fourth-order Runge–Kutta integration method is suitable to solve them because of its ease of use and its ability to vary the time step size. This latter requirement is essential since the time step can typically vary by three orders of magnitude during a single trajectory.

In essence, the CTMC method is a computer experiment. Total cross sections for a particular process are determined by

$$\sigma_R = (N_R/N)\pi b_{\max}^2, \quad (62.4)$$

where N is the total number of trajectories run within a given maximum impact parameter b_{\max} , and N_R is the number of positive tests for a reaction, such as electron capture or ionization. Angle and energy differential cross sections are easily generalized from the above. As in an experiment, the cross section given by Eq. (62.4) has a standard deviation of

$$\Delta\sigma_R = \sigma_R[(N - N_R)/NN_R]^{1/2}, \quad (62.5)$$

which for large N is proportional to $1/N_R^{1/2}$. Here lies one of the major difficulties associated with the CTMC method: it takes considerable computation time to determine minor or highly differential cross sections because, to decrease the statistical error of a cross by a factor of 2, four times as many trajectories must be evaluated.

62.1.2 Nonhydrogenic One-Electron Models

For many-electron target atoms, it is sometimes adequate to treat the problem within a one-electron model and employ the independent electron approximation to approximate the atomic shell structure [6]. For an accurate calculation, it is necessary to use an interaction potential that simulates the screening of the target nucleus by the passive electrons, i.e., the electrons that do not participate in the reaction. One can simply apply a Coulomb potential with an effective charge Z_{eff} obtained from, for example, Slater's rules. Then, the computational procedure is the same as for the hydrogenic

case. However, the boundary conditions for the long and short-range interactions are poorly satisfied.

To improve the electronic representation of the target, model potentials derived from quantum mechanical calculations are now routinely used. Here, the simple solution of Kepler's equation cannot be applied. However, *Peach* et al. [7] and *Reinhold* and *Falcón* [8] have provided the appropriate methods that yield a target representation that is correct under the microcanonical distribution. The method of Reinhold and Falcón is popular because of its ease of use and generalizability. For the effective interaction potential, *Garvey* et al. [9] have performed a large set of Hartree–Fock calculations and have parametrized their results by a potential $V(R)$, which depends on the distance to the target R , as

$$V(R) = -[Z - NS(R)]/R, \quad (62.6)$$

where Z and N denote the nuclear charge and number of nonactive electrons in the target core, respectively, and $S(R)$ is the screening of the core given by

$$S(R) = 1 - \{(\eta/\xi)[\exp(\xi R) - 1] + 1\}^{-1/2}, \quad (62.7)$$

where η and ξ are screening parameters. Screening parameters are given in [9] for all ions and atoms with $Z \leq 54$. This potential can also be used for the representation of partially stripped projectile ions. Even though it seems natural to think that the inclusion of more active electrons in the description of the problem would give rise to more accurate cross sections, it is worth noticing that it could also lead to unphysical autoionization, as was pointed out in [10], where a possible remedy to this problem is shown as well.

62.1.3 Multiply Charged Projectiles and Many-Electron Targets

Multiple ionization and electron capture mechanisms in energetic collisions between multiply charged ions and many-electron atoms is poorly understood because major approximations must be made to solve the many-electron problem associated with transitions between two centers. For a representative collision system such as

it is essential to use a theoretical method able to predict simultaneously the various charge states of the projectile and recoil ions, and also the energy and angular spectra of the ejected electrons. Theoretical methods based on the independent electron model fail because the varying ionization energies of the electrons are not well represented by constant values, especially for outer shells. At present, the most

successful implementation is the n CTMC method, which is a direct extension of the hydrogenic CTMC method to an n -electron system and has been able to make reasonable predictions of the cross sections and scattering dynamics of such strongly coupled systems [11]. As such, the number of coupled equations rises to $6n + 12$, where n is the number of electrons included in the calculation.

In the n CTMC technique, all interactions of the projectile and target nuclei with each other and the electrons are implicitly included in the calculations. The inclusion of all the particles then allows a direct determination of their angular scattering, along with an estimate of the energy deposition to electrons and heavy particles. Postcollision interactions are included between projectile and recoil ions with the electrons; however, electron–electron interactions are introduced only in the bound initial state via a screening factor in a central-field approximation. This theoretical model has been very successful in predicting the single and double differential cross sections for the ionized electron spectra. Moreover, since a fixed target nucleus approximation is not used, this method has been the only one available to help understand and predict the results in the field of recoil-ion momentum spectroscopy [12].

62.2 Region of Validity

The CTMC method has a demonstrated region of applicability for ion–atom collisions in the intermediate velocity regime, particularly in the elucidation of both heavy-particle and electron collision dynamics. The method can be termed a semiclassical method in that the initial conditions for the electron orbits are determined by quantum mechanically based interaction potentials with the parent nucleus. Since the method is most suitable for strongly coupled systems, it has been applied successfully to a variety of intermediate energy multiply charged ion collisions. Figure 62.1 describes pictorially and the regions of validity of various theoretical models. Both the atomic orbital (AO) and molecular orbital (MO) basis set expansion methods (Chap. 53) work well until ionization strongly mediates the collision, since the theoretical description of the ionization continuum is not well founded and relies on pseudo states to span all ejected electron energies and angles. We have arbitrarily limited these methods to a projectile charge to target charge ratio of, $Z_P/Z_T, \simeq 8$, since above this value the number of terms in the basis set becomes prohibitively large. The CTMC method does not include molecular effects, and thus it is restricted to low velocities, except in the case of high-charge-state projectiles that capture electrons into high-lying Rydberg states, which are well described classically. Likewise, at high velocities, the method is inapplicable in the perturbation regime, where quantum tunneling is important,

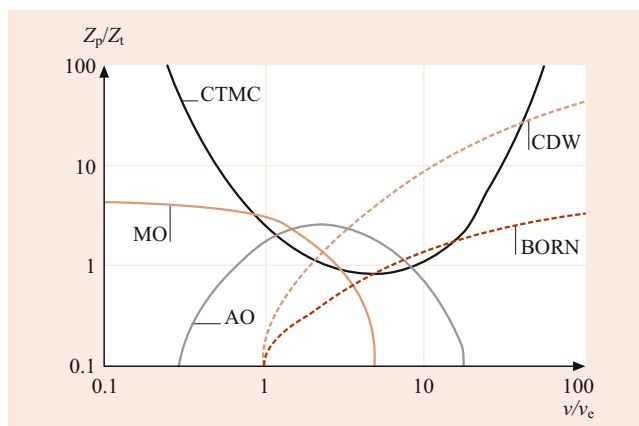

Fig. 62.1 Approximate regions of validity of various theoretical methods; Z_P/Z_T is the ratio of the projectile charge to the target charge, and v/v_e is the ratio of the collision velocity to the velocity of the active target electron. Theoretical methods: molecular orbital (MO), atomic orbital (AO), classical trajectory Monte Carlo (CTMC), continuum distorted wave (CDW), and first-order perturbation theory (BORN)

and is thus restricted to strongly coupled systems. The continuum distorted wave (CDW) method (Chap. 56) greatly extends the region of applicability of first-order perturbation methods and has demonstrated validity in high-charge state ionization collisions.

62.3 Applications

62.3.1 Hydrogenic Atom Targets

The original application of the CTMC method to atomic physics collisions was done on the $H^+ + H$ system [3]. Here, the electron capture and ionization total cross sections were found to be in very good accord with experiment. The Abrines and Percival procedure casts the coupled equations into the center-of-mass (c.m.) coordinate system to reduce the three-body problem to 12 coupled equations. However, this reduction complicates extensions of the code to laser processes and collisions in the presence of electric fields or with many electrons.

An ideal application for the CTMC method is for collisions involving excited targets. Such processes are well described classically, while basis set expansion methods show limited applicability due to computer memory constraints. Considerable early work was done on Rydberg atom collisions, including state-selective electron capture, ionization, and electric fields [13–15]. Presently, there is a resurgence of work on Rydberg atom collisions because new crossed-field experimental techniques allow the production of these atoms with specific spatial orientations and eccentricities [16, 17], and even Rydberg positronium atoms have been achieved experimentally [18].

For hydrogenic ion–ion collision processes, one must be careful to apply the CTMC method only for projectile charges $Z_P \geq Z_T$ because after the initialization of the active electron's orbit and energy, there is no classical constraint on the orbital energy of a captured electron. For a low-charge-state ion colliding with a ground state highly charged ion, one will obtain unphysical results because a captured electron will tend to preserve its original binding energy. Thus, excess probability will be calculated for electron orbits that lead to unrealistic deeply bound states of the projectile.

62.3.2 Pseudo-One-Electron Targets

Collisions involving alkali atoms are of interest because of their relevance to applied programs, such as plasma diagnostics in tokamak nuclear fusion reactors. They are also a testing ground for theoretical methods since experimental benchmarks are difficult to realize with hydrogenic targets but are amenable for such cases as alkali atoms. In such collisions, it is essential to use a theoretical formalism that correctly simulates the screening of the nucleus by the core electrons (Sect. 62.1.2), since a simple $-Z_{\text{eff}}/R$ Coulomb potential is inadequate for both large and small R .

One can also apply the methods of Sect. 62.1.2 to partially or completely filled atomic shells [19]. This works reasonably well for collisions with a low charge state ion such as a proton, but it gets less accurate as the charge of the projectile becomes greater than that of the target nucleus. The reason is that the independent electron approximation [6] must be applied to the calculated transition probabilities in order to simulate the shell structure. This latter method can only maintain its validity if the transition probability is small. Otherwise, it will greatly overestimate the multiple electron removal processes since the first ionization potential is inherently assumed for each subsequent electron that is pulled out from the shell, leading to an underestimation of the energy deposition.

62.3.3 State-Selective Electron Capture

One of the powers of the CTMC method is that it can be applied to electron capture and excitation of high-lying states that are not accessible with basis set expansion techniques [20]. For the C^{4+} colliding on Li, and C^{6+} and N^{7+} colliding on H, where AO calculations and experimental data exist, the CTMC method agrees quite favorably with both [21–23].

The procedure consists in defining first a classical number n_c related to the calculated binding energy E of the active electron to either the projectile (electron capture) or target

nucleus (excitation) as

$$E = -Z^2/(2n_c^2). \quad (62.9)$$

Then, n_c is related to the principal quantum number n of the final state by the condition [24]

$$\left[n \left(n - \frac{1}{2} \right) (n - 1) \right]^{1/3} < n_c \leq \left[n \left(n + \frac{1}{2} \right) (n + 1) \right]^{1/3}. \quad (62.10)$$

The electron's normalized classical angular momentum $l_c = (n/n_c)(\mathbf{r} \times \mathbf{k})$, is related to the orbital quantum number l of the final state by

$$l < l_c \leq l + 1. \quad (62.11)$$

The magnetic quantum number m_l is then obtained from

$$\frac{2m_l - 1}{2l + 1} \leq \frac{l_z}{l_c} < \frac{2m_l + 1}{2l + 1}, \quad (62.12)$$

where l_z is the z -projection of the angular momentum obtained from calculations [25]. In principle, it is also possible to analyze the final-state distributions from the effective quantum number

$$n^* = n - \delta_l, \quad (62.13)$$

where δ_l is the quantum defect. In this latter case, it is necessary to sort the angular momentum quantum numbers first and then sort the principal quantum numbers.

One of the main applications of the method explained in this section can be found in the description of the charge transfer of one electron from a neutral atom or molecule to an excited state of a highly charged ion, from which it deexcites by releasing electromagnetic radiation. It was uncovered in the 1970s that charge exchange (CX) reactions can be used as a diagnostic tool in nuclear fusion reactors, because the CX between impurities – constituted by multiply charged ions – and a H or D neutral beam provides a method for determining the concentration of fully stripped ions and for measuring ion temperature and plasma rotation [26]. This technique, known as charge exchange spectroscopy (XCS), has become widespread as a diagnostic in high-temperature – mostly tokamak – plasmas [27, 28]. Furthermore, the discovery in 1996 [29, 30] that comets undergo a highly efficient generation of X-rays [31–33], originated by the CX between cometary tail neutral gas and the highly charged ions from the solar wind (SWCX), opened up a vast new field of X-ray astrophysics, leading to subsequent studies that revealed many other astrophysical locations where a similar process

occurs, ranging from the heliosphere, planetary atmospheres, the interstellar medium, galaxies, and could even be linked to dark matter radiation [34]. Due to the high relevance of these applications, numerous experimental studies have been performed at the energy intervals of interest. For instance, experiments to study SWCX and CXS in the range from of 1 to 3 keV/amu and of 1 to 40 keV/amu, respectively, have been modeled using the state-selective CTMC method to successfully calculate the nl -resolved CX cross sections [35–37].

62.3.4 Exotic Projectiles

The study of collisions involving antimatter projectiles, such as positrons and antiprotons, is a field that has grown rapidly over the past two decades, spurred on by experimental advances [38, 39]. Such scattering processes are of basic interest, and they also contribute to a better understanding of normal matter–atom collisions. Antimatter–atom studies highlight the underlying differences in the dynamics of the collision, as well as on the partitioning of the overall scattering. In the Born approximation, ionization cross sections depend on the square of the projectile’s charge and are independent of its mass. Thus, the comparison of the cross sections for electron, positron, proton, and antiproton scattering from a specific target gives a direct indication of higher-order corrections to scattering theories [40, 41].

Early work using the CTMC method concentrated on the spectra of ionized electrons for antimatter projectiles [42]. Later work focused on the angular scattering of the projectiles during electron removal collisions, such as positronium formation, on ratios of the electron removal cross sections, and on ejected electron “cusp” and “anticusp” formation. Two complete reviews on antiproton and positron impact collisions, which compare various theoretical results and available experiments, are given in [43, 44].

62.3.5 Heavy-Particle Dynamics

A major attribute of the CTMC method is that it inherently includes the motion of the heavy particles after the collision. A straight-line trajectory for the projectile is not assumed, nor is the target nucleus constrained to be fixed. This allows one to compute easily the differential cross sections for projectile scattering or the recoil momenta of the target nucleus. As a computational note, the angular scattering of the projectile should be computed from the momentum components, not the position coordinates after the collision, since faster convergence of the cross sections using the projectile momenta is obtained. For recoil ion momentum transfer studies, one must initialize the target atom such that the c.m. of the nucleus plus its electrons has zero momentum so that there is

no initial momentum associated with the target. A common error is to initialize only the target nucleus momenta to zero. Then the target atom after a collision has an artificial residual momentum that is associated with the Compton profile of the electrons because target–electron interactions are included in the calculations. Examples of recoil and projectile scattering cross sections are given in [11, 12].

The field of recoil ion momentum spectroscopy rapidly expanded in the early 2000s (e.g., [45, 46]), and the CTMC theoretical method impacted on the interpretation and understanding of experimental results because it inherently provides a kinematically complete description of the collision products. For the studied systems, primarily He targets because of experimental constraints, it is necessary for the theoretical method to follow all ejected electrons and the heavy particles after a collision. As an example, it has been possible to observe the backward recoil of the target nucleus in electron capture reactions, which is due to conservation of momentum when the active electron is transferred from the target’s to the projectile’s frame [47]. Theoretical methods were tested further with magneto-optical traps (MOT) that provide frozen alkali metal atomic targets ($T \ll 1$ mK) from which to perform recoil ion studies [48].

For three and four-body systems, it is now possible to measure the momenta of all collision products. These observations provide a severe test of theory, since all projectile and target interactions must be included in the calculations. The CTMC method addresses all projectile interactions with the target nucleus and electrons. Thus, it is possible to calculate fully differential cross sections (FDCS), the most detailed accessible experimental observable. It is of interest that triply differential cross sections (TDCS) calculated using the CTMC method compare very favorably with sophisticated continuum distorted wave methods [49].

The CTMC technique allows one to incorporate electrons on both the projectile and the target nuclear centers. Furthermore, all interactions between centers are included. The only interaction that needs to be approximated is the electron–electron interaction on a given center. Here, simple screening parameters derived from Hartree–Fock calculations are employed to eliminate nonphysical autoionization. Within this many-electron model, the signatures of the electron–electron and electron–nuclear interactions on the dynamics of the collisions have been observed [50, 51]. Further, projectile ionization studies can be undertaken [52–54].

62.3.6 Ion-Molecule Collisions

Ion-molecule ionization collisions share many aspects with the processes described in 62.1.3, but its study is much more complex because, apart from being multielectronic, the target is composed of several nuclei. Due to its simplicity, the

first of these systems to be analyzed by a CTMC method was the H_2 molecule [55], for which a fixed internuclear axis (Franck–Condon approximation) randomly orientated was assumed, and the electrons initialized in terms of two one-electron microcanonical distributions constructed from the quantum mechanical ground state of the molecule. For more complex molecules, apart from the Franck–Condon approximation, which is a typical assumption, many other approximations must be performed, which give rise to different calculation methods.

Single ionization and electron capture in ion- H_2O collisions (for different projectile charges) have been successfully described by the use of one-center screened Coulomb potentials [56–58], in a similar fashion as was described for many-electron atoms in 62.3.1. In all the cases, a single active electron approximation is also invoked.

We can also mention other methods that introduce approximations on the projectile-target interaction and are based on the classical over-barrier charge transfer process [59, 60], called COB-CTMC. In COB-CTMC, electrons bound to the target molecule are included in the calculation through the course of the collision. At each time step, the internuclear ion-molecule potential is evaluated, and the most weakly bound electrons are released if its maximum is lower than the binding target energy. After this, the electrons change from being *virtual* to being an *active* part of the dynamics of the process, and a further condition is usually established to account for the spatial electron density. This method has been successfully applied to the study of ionization of DNA and RNA uracil by highly charged ion impact [61].

Finally, as was already mentioned in the first paragraph of this section, other methods describe the multicenter nature of the target by fixing the position of the nuclei but rotating the internuclear axis randomly at each trajectory calculation and have been applied to the study of the ionization by ion impact of not only H_2 [55] but also H_2O molecules [62].

62.3.7 Strong Laser Field Ionization

The study of the nonlinear electron dynamics in the ionization of atoms by intense few-cycle laser pulses has gained attention over the last years (e.g., [63]). The limitations of a quantum description for this type of processes come from the fact that perturbation theory is, in most of the cases, not applicable, and nonperturbative calculations are sometimes prohibitively expensive, from a computational viewpoint. The straightforward extension of the CTMC method to photoionization problems is a promising solution to this problem, and it consists simply of adding the external laser field to the particles Hamiltonian, while the rest of the method remains essentially the same as that derived by *Abrines* and *Percival* [3]. As a remarkable example of the power of

this method, we can mention the work of *Ho* et al. [64], who performed a fully classical self contained study of the atomic nonsequential double ionization (NSDI) [65]. Their procedure discards all quantum effects, even tunneling, but describes the dynamics in a complete form, which is a very important feature because electron–electron correlation is supposed to play an instrumental role in this process. The electrons are initialized with an energy corresponding to the two-electron quantum ground state, and then the dynamics are governed by the Coulomb interaction among the particles and their interaction with the laser electric field.

Even though the CTMC method cannot include tunneling by default, features on the cross sections found experimentally for the double ionization of He and Ne [66, 67], and single ionization of He, Ne, and Ar [68] by laser fields at high intensities, on the range of 10^{15} W/cm², have been described by nonrelativistic semiclassical CTMC methods that include an ad hoc tunneling step [69]. These theoretical works are based on a method developed by *Cohen* [70], which treats both the description of the initial state and the dynamics of the particles in the standard way. The improvement of this method on the description of the process is that, using the WKB approximation, tunneling is allowed in the direction of the field starting from classical turning points. At points \mathbf{r}_c for which $dz/dt = 0$ and $-\mathbf{E}(t) \cdot \mathbf{r}_c > 0$, being \hat{z} the polarization direction of the electric field $\mathbf{E}(t)$, the *tunneling probability* is calculated as follows:

$$P_{\text{tun}} = \exp \left\{ -2(2\mu)^{1/2} \int_0^{s_{\text{out}}} [V(\mathbf{r}_c + s\hat{z}) - V(\mathbf{r}_c)] ds \right\}, \quad (62.14)$$

where μ is the reduced mass. If this probability is greater than a random number between 0 and 1, the particle then tunnels out at the point $\mathbf{r}_c + s_{\text{out}}\hat{z}$, at which $V(\mathbf{r}_c + s_{\text{out}}\hat{z}) = V(\mathbf{r}_c)$. On the contrary, the trajectory remains unaltered. For an extension of this model, which includes references to a broad variety of applications of this method, see [71].

Finally, it is also worth giving a brief description of the extension of CTMC method to treat relativistic problems [72]. For laser intensities above 10^{18} W/cm², the motions of electrons become highly relativistic because the mass of the electron starts becoming comparable to its rest mass. Here, we can mention two methods, which are similar in that the equations of motion must be solved relativistically but treat the initial state in a different way depending on the nucleus charge. If the charge of the nucleus is lower than 10, it is possible to treat the electron nonrelativistically in its initial state [73], whereas if it is higher than that value, it needs to be treated relativistically [74]. Additionally, it is possible to study both the ion and electron dynamics driven by an ultrastrong laser field (10^{18} – 10^{26} W/cm²) by applying a fully relativistic extension of the CTMC approach [75].

62.4 Conclusions

In many ways it is surprising that a pure classical model can be successful in a quantum mechanical world, especially since the classical radial distribution for the hydrogen atom is described so poorly. However, hydrogen's classical momentum distribution is exactly equivalent to the quantum one, and since collision processes are primarily determined by velocity matching between projectile and electron, reasonable results can be expected. Moreover, the CTMC method preserves conservation of flux, energy, and momentum, and Coulomb scattering is the same in both quantal and classical frameworks.

Of significant importance is that the CTMC method is not restricted to one-electron systems and can be easily extended to more complicated systems involving electrons on both projectile and target. For these latter cases, multiple electron capture and ionization reactions can be investigated. On the projectiles side, the success of the CTMC process driven by both charged particles and photons is worth mentioning.

Marcelo Ciappina Dr Ciappina received his PhD from the Balseiro Institute at Argentina in 2005 and a Research Professor degree from the Czech Academy of Sciences in 2019. His academic training includes postdoctoral stays at renowned institutions in Germany, Singapore, USA, Spain and Czechia. At present, he is Associate Professor at the Guangdong Technion – Israel Institute of Technology (GTIIT), Shantou, China. His areas of interest include attosecond science and atomic collisions.

Raul O. Barrachina Dr Barrachina received his PhD from the Balseiro Institute at Argentina in 1985. His academic training also includes postgraduate studies in philosophy and the history of science, and postdoctoral stays in USA, France, Italy, and Spain. At present, he is Fellow of the Institute of Physics (IoP) and researcher of the Argentine Atomic Energy Commission (CNEA) and the Council of Scientific and Technical Research (CONICET).

Francisco Navarrete Francisco Navarrete received his PhD from Balseiro Institute, National University of Cuyo at Bariloche, Argentina in 2016. He has worked at the National Atomic Energy Commission in Argentina, at the Department of Physics of Kansas State University in the US, and at the group Quantum Theory and Many-Particle Systems at the Institute of Physics, University of Rostock in Germany, where he currently conducts his research. He has made contributions to the fields of atomic collisions and strong-field physics.

Ronald E. Olson Ronald E. Olson, Curators' Professor of Physics earned his PhD from Purdue University in 1967. He is a Fellow of the American Physics Society and a Fulbright Fellow in France. His research interests concentrate on theory of elastic and inelastic total and differential scattering cross sections and studies of multiply charged ion–atom collisions, Rydberg atom collisions, negative ion detachment mechanisms, and Penning and associative ionization.

Abstract

One-photon processes only are discussed and aspects of line broadening directly related to collisions between the emitting (or absorbing) atom and one perturber are considered. Pointers to other aspects are included and a comprehensive bibliography of work on atomic line shapes, widths, and shifts is regularly updated [1]. The perturber may be an electron, a neutral atom or an atomic ion and can interact weakly or strongly with the emitter. The emitter is either a hydrogenic or a nonhydrogenic atom that is either neutral or ionized. In general, transi-

tions in nonhydrogenic atoms can be treated as isolated, that is the separation between neighboring lines is much greater than the width of an individual line. When the emitter is hydrogen or a hydrogenic ion, the additional degeneracy of the energy levels with respect to orbital angular momentum quantum number means that lines overlap and are coupled.

Pressure broadening is a general term that describes any broadening and shift of a spectral line produced by fields generated by a background gas or plasma. The term Stark broadening implies that the perturbers are atomic ions and/or electrons, and collisional broadening implies that the ‘collision’ model is appropriate; this term is often used to describe an isolated line perturbed by electrons. Neutral atom broadening indicates neutral atomic perturbers; this implies short-range emitter–perturber interactions, which in turn influence the approximations made. The broadening of molecular lines and bands is not considered here, however *Hartmann, Boulet, and Robert* [2] have published a comprehensive review of collisional effects on molecular spectra. This includes a discussion of laboratory experiments and models with their consequences for applications.

General reviews of the theory of pressure broadening have been given [3–5], and in Chap. 2, Chap. 11, Chap. 15, Chap. 20, and Chap. 49 topics relevant to the theory of collisional broadening of spectral lines are discussed. A workshop on the topic of spectral line shapes in plasmas (SLSP) has been established to compare codes and different computational and analytic methods, see [6]. The International Conference on Spectral Line Shapes (ICSLS) and the Serbian Conference on Spectral Line Shapes in Astrophysics (SCSLSA) are devoted exclusively to this subject.

63.1 Impact Approximation

If the perturbers are rapidly moving, the broadening and shift of the line arise from a series of binary collisions between the atom and one of the perturbers. The theory assumes that although weak collisions may occur simultaneously, strong collisions are relatively rare and only occur one at a time. The impact approximation is valid if

$$w\tau \ll 1, \quad \bar{V}\tau/\hbar \ll 1, \quad (63.1)$$

where w is the half-width at half-maximum, τ is the average time of collision and \bar{V} is the average emitter-perturber interaction. It is not only widely applicable to electron and neutral atom broadening, but also, for certain plasma conditions, to broadening by atomic ions. The power radiated per unit time and per unit interval in circular frequency ω , in terms of the line profile $I(\omega)$, is

$$P(\omega) = \frac{4\omega^4}{3c^3} I(\omega). \quad (63.2)$$

For an isolated line produced by a transition from an upper energy level i to a lower level f , the line profile is Lorentzian with a shift d :

$$I(\omega) = \frac{1}{\pi} \langle \langle i f^* | \mathbf{A} | i f^* \rangle \rangle \frac{w}{(\omega - \omega_{if} - d)^2 + w^2}, \quad (63.3)$$

and if the profile is for a transition between an upper set of levels i, i' and a lower set f, f' with quantum numbers $J_i M_i, J_{i'} M_{i'}, J_f M_f$, and $J_{f'} M_{f'}$, then

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \left(\sum_{i' f f'} \langle \langle i f^* | \mathbf{A} | i' f'^* \rangle \rangle \times \langle \langle i' f'^* | [\mathbf{w} + i\mathbf{d} - i(\omega - \omega_{if})\mathbf{I}]^{-1} | i f^* \rangle \rangle \right), \quad (63.4)$$

where \mathbf{I} is the unit operator, and \mathbf{w} and \mathbf{d} are width and shift operators. In Eq. (63.4), \mathbf{A} is an operator corresponding to the dipole line strength defined by

$$\langle \langle i f^* | \mathbf{A} | i' f'^* \rangle \rangle \equiv q^2 \langle i | \mathbf{r} | f \rangle \cdot \langle i' | \mathbf{r} | f' \rangle, \quad (63.5)$$

where \mathbf{r} represents the internal emitter coordinates, $q^2 = e^2/(4\pi\epsilon_0)$ is the square of the electronic charge, and ϵ_0 is the permittivity of vacuum in SI units of F m^{-1} . On taking the average over all degenerate magnetic sublevels,

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \left(\sum_{i' f f'} \langle \langle i f^* | \mathbf{A} | i' f'^* \rangle \rangle \times \langle \langle i' f'^* | [\mathbf{w} + i\mathbf{d} - i(\omega - \omega_{if})\mathbf{I}]^{-1} | i f^* \rangle \rangle \right) \quad (63.6)$$

in terms of reduced matrix elements that are independent of magnetic quantum numbers. They are defined by

$$\langle \langle i f^* | \mathbf{A} | i' f'^* \rangle \rangle = D_{i f i' f'} \langle \langle i f^* | \mathbf{A} | i' f'^* \rangle \rangle, \quad (63.7)$$

where

$$D_{i f i' f'} = \sum_{\mu} (-1)^{J_i + J_{i'} - M_i - M_{i'}} \times \begin{pmatrix} J_i & 1 & J_f \\ -M_i & \mu & M_f \end{pmatrix} \begin{pmatrix} J_{i'} & 1 & J_{f'} \\ -M_{i'} & \mu & M_{f'} \end{pmatrix}, \quad (63.8)$$

$$\begin{aligned} & \langle \langle i' f'^* | [\mathbf{w} + i\mathbf{d} - i(\omega - \omega_{if})\mathbf{I}]^s | i f^* \rangle \rangle \\ &= \sum_{M_i, M_{i'}, M_f, M_{f'}} D_{i f i' f'} \\ & \times \langle \langle i' f'^* | [\mathbf{w} + i\mathbf{d} - i(\omega - \omega_{if})\mathbf{I}]^s | i f^* \rangle \rangle, \quad (63.9) \end{aligned}$$

with $s = -1, 1$. For the line profile Eq. (63.3), the width and shift each have a single element,

$$\gamma = 2w = \langle \langle i f^* | 2\mathbf{w} | i f^* \rangle \rangle, \quad d = \langle \langle i f^* | \mathbf{d} | i f^* \rangle \rangle, \quad (63.10)$$

where γ is the full width at half-maximum.

Throughout the rest of this article, it will be assumed that collisions only connect the set of upper levels i, i' or the set of lower levels f, f' , which is valid when $w \ll \omega$; pressure broadening of spectral lines is also assumed to be independent of Doppler broadening. However, for microwave spectra of molecules, w can be of the order of ω , and collisions connecting the upper to the lower levels become important; for further details, see *Ben-Reuven* [7, 8]. Also for microwave spectra, pressure broadening and Doppler broadening cannot be considered to be independent effects, and a generalized theory has been developed by *Ciurylo* and *Pine* [9].

63.2 Isolated Lines

63.2.1 Semiclassical Theory

The motion of the perturber relative to the emitter is treated classically and is assumed to be independent of the internal states of the emitter and perturber. This common trajectory is specified by an emitter-perturber separation

$$\mathbf{R} \equiv \mathbf{R}(\mathbf{b}, \mathbf{v}, t), \quad \mathbf{b} \cdot \mathbf{v} = 0, \quad (63.11)$$

where \mathbf{v} is the relative velocity, and \mathbf{b} is the impact parameter. The time-dependent wave equation for the emitter-perturber system is

$$i\hbar \frac{d\Psi}{dt} = H\Psi, \quad (63.12)$$

and the eigenfunctions ψ_i for the unperturbed emitter obey

$$H_0\psi_i = E_i\psi_i, \quad i = 0, 1, 2, \dots \quad (63.13)$$

If $\Psi(\mathbf{r}, \mathbf{R})$ is expanded in the form

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_j a_{ji}(t)\psi_j(\mathbf{r}) \exp(-iE_j t/\hbar), \quad (63.14)$$

where initially at time $t = -\infty$

$$a_{ji}(-\infty) = \delta_{ji} \quad (63.15)$$

and Eqs. (63.12)–(63.14) give

$$i\hbar \frac{da_{ji}}{dt} = \sum_k a_{ki} V_{jk} \exp(i\omega_{jk}t), \quad (63.16)$$

$$i, j, k = 0, 1, 2, \dots,$$

where

$$V_{jk}(\mathbf{R}) = \int \psi_j^*(\mathbf{r}) V(\mathbf{r}, \mathbf{R}) \psi_k(\mathbf{r}) d\mathbf{r} \quad (63.17)$$

in which $V(\mathbf{r}, \mathbf{R})$ is the emitter–perturber interaction, and

$$\hbar\omega_{jk} = E_j - E_k. \quad (63.18)$$

Integration of equations Eq. (63.16) for $-\infty \leq t \leq \infty$ gives the unitary scattering matrix \mathbf{S} , with elements

$$S_{ji}(\mathbf{b}, \mathbf{v}) \equiv a_{ji}(\infty), \quad i, j = 0, 1, 2, \dots \quad (63.19)$$

Then

$$w + id = 2\pi N \int_0^\infty v f(v) dv \times \int_0^\infty \left[\delta_{i'i} \delta_{f'f} - S_{i'i}(\mathbf{b}, \mathbf{v}) S_{f'f}^*(\mathbf{b}, \mathbf{v}) \right]_{\text{av}} b db, \quad (63.20)$$

where $J_{i'} = J_i$ and $J_{f'} = J_f$, N is the perturber density and $[\dots]_{\text{av}}$ denotes an average over all orientations of the collision and over the magnetic sublevels [Eq. (63.9)]. In (63.20), $f(v)$ is the Maxwell velocity distribution at temperature T for an emitter–perturber system of reduced mass μ :

$$f(v) = 4\pi v^2 \left(\frac{\mu}{2\pi k_B T} \right)^{3/2} \exp\left(-\frac{\mu v^2}{2k_B T} \right), \quad (63.21)$$

$$\int_0^\infty f(v) dv = 1.$$

63.2.2 Simple Formulae

Simple formulae are useful for making quick estimates but in individual cases may give results in error by a factor of 2 or more. If it is assumed in Eq. (63.17) that

$$V_{ij}(\mathbf{R}) = V_{jj}(\mathbf{R})\delta_{ij}, \quad (63.22)$$

where $V_{jj}(\mathbf{R})$ is a simple central potential

$$V_{jj}(\mathbf{R}) = \hbar C_j R^{-p}, \quad j = i, f, \quad (63.23)$$

and C_j depends only on the state j of the emitter, and if the relative motion is along the straight line

$$\mathbf{R} = \mathbf{b} + \mathbf{v}t, \quad (63.24)$$

then

$$\left[S_{i'i}(\mathbf{b}, \mathbf{v}) S_{f'f}^*(\mathbf{b}, \mathbf{v}) \right]_{\text{av}} = \exp[2i(\eta_i - \eta_f)], \quad (63.25)$$

where the phase shifts are

$$\eta_j(b, v) = -\frac{1}{2\hbar} \int_{-\infty}^{\infty} V_{jj}(R) dt, \quad j = i, f. \quad (63.26)$$

Equations (63.20)–(63.26) give

$$w + id = \pi N \bar{v} \left(\frac{\beta_p |C_p|}{\bar{v}} \right)^{2/(p-1)} \times \Gamma\left(\frac{p-3}{p-1} \right) \exp\left(\pm \frac{i\pi}{p-1} \right) \alpha_p, \quad (63.27)$$

where

$$\alpha_p = \Gamma\left(\frac{2p-3}{p-1} \right) \left(\frac{\pi}{4} \right)^{-1/(p-1)},$$

$$\beta_p = \sqrt{\pi} \frac{\Gamma(\frac{1}{2}(p-1))}{\Gamma(\frac{1}{2}p)},$$

$$C_p = C_i - C_f,$$

$$\bar{v} = \int_0^\infty v f(v) dv = \left(\frac{8k_B T}{\pi\mu} \right)^{1/2}. \quad (63.28)$$

In (63.27), the \pm sign indicates the sign of C_p , $\alpha_p \simeq 1$ for $p \geq 3$, and $\Gamma(\dots)$ is the gamma function.

The cases $p = 3, 4$ and 6 correspond to resonance, quadratic Stark and van der Waals broadening, respectively. This approximation is invalid for the dipole case ($p = 2$) for which Eq. (63.27) is not finite. The dipole–dipole interaction ($p = 3$) occurs when emitter and perturber are identical

atoms (apart from isotopic differences). If the level i is connected to the ground state by a strong allowed transition with absorption oscillator strength f_{gi} , and the perturbation of the level f can be neglected by comparison, then

$$C_3 = c_d \frac{q^2 f_{gi}}{2m_e |\omega_{gi}|},$$

$$c_d = 1 + \frac{1}{2\sqrt{3}} \ln(2 + \sqrt{3}) = 1.380173. \quad (63.29)$$

Also, if g_j is the statistical weight of level j , the constant c_d may be replaced by an empirical value

$$c_d = \frac{4}{\pi} \left(\frac{g_g}{g_i} \right)^{1/2}, \quad (63.30)$$

and this gives a width correct to about 10% [10]. Equation (63.27) does not predict a finite shift. Quadratic Stark broadening occurs when a nonhydrogenic emitter is polarized by electron perturbers. Then

$$C_4 = -\frac{q^2}{2\hbar} (\alpha_i - \alpha_f), \quad (63.31)$$

where α_i and α_f are the dipole polarizabilities of states i and f , respectively. Van der Waals broadening occurs when the emitter and perturber are nonidentical neutral atoms. If energy level separations of importance in the perturbing atom are much greater than those of the emitter (e.g., alkali spectra broadened by noble gases), C_6 is given by

$$C_6 = -\frac{q^2}{\hbar} \alpha_d (\overline{r_i^2} - \overline{r_f^2}), \quad (63.32)$$

where α_d is the dipole polarizability of the perturber. The mean square radii can be calculated from the normalized radial wave functions $\frac{1}{r} P_{n^* l_j}(r)$ or estimated from

$$\overline{r_j^2} = \int_0^\infty P_{n^* l_j}^2(r) r^2 dr$$

$$\simeq \frac{n_j^{*2} a_0^2}{2z^2} [5n_j^{*2} + 1 - 3l_j(l_j + 1)],$$

$$j = i, f, \quad (63.33)$$

in which the effective principal quantum numbers n_j^* are given by

$$E_j \equiv -\frac{z^2}{n_j^{*2}} I_h, \quad z = Z_e + 1, \quad (63.34)$$

where $I_h = hcR_\infty$ is the Rydberg energy, Z_e is the charge on the emitter, and $z = 1$ in this case.

63.2.3 Perturbation Theory

An approximate solution of Eq. (63.16) is given by [3–5, 11, 12]

$$S_{ji}(\mathbf{b}, \mathbf{v}) = \delta_{ji} - \frac{i}{\hbar} \int_{-\infty}^{\infty} V_{ji}(t) \exp(i\omega_{ji}t) dt$$

$$- \frac{1}{\hbar^2} \sum_k \left[\int_{-\infty}^{\infty} V_{jk}(t) \exp(i\omega_{jk}t) dt \right.$$

$$\left. \times \int_{-\infty}^t V_{ki}(t') \exp(i\omega_{ki}t') dt' \right]. \quad (63.35)$$

This gives a cross section for the collisional transition $i \rightarrow j$:

$$\sigma_{ij}(v) = 2\pi \int_0^\infty [P_{ij}(\mathbf{b}, \mathbf{v})]_{\text{av}} b db,$$

$$i, j = 0, 1, 2, \dots, \quad (63.36)$$

where

$$P_{ij}(\mathbf{b}, \mathbf{v}) = |\delta_{ji} - S_{ji}(\mathbf{b}, \mathbf{v})|^2, \quad (63.37)$$

$$2 \operatorname{Re}[1 - S_{ii}(\mathbf{b}, \mathbf{v})] = \sum_j P_{ij}(\mathbf{b}, \mathbf{v}), \quad (63.38)$$

correct to second-order in $V(\mathbf{r}, \mathbf{R})$ on both sides. Using Eqs. (63.10), (63.20), and (63.36)–(63.38), the full width is

$$\gamma = N \int_0^\infty v f(v) dv$$

$$\times \left[\sum_{j \neq i} \sigma_{ij}(v) + \sum_{j \neq f} \sigma_{fj}(v) + \tilde{\sigma}_{if}(v) \right], \quad (63.39)$$

where the sums are taken over all energy-changing transitions, the tilde indicates an interference term, and

$$\tilde{\sigma}_{if}(v) = 2\pi \int_0^\infty [\tilde{P}_{if}(\mathbf{b}, \mathbf{v})]_{\text{av}} b db, \quad (63.40)$$

in which

$$\tilde{P}_{if}(\mathbf{b}, \mathbf{v}) = \left| \frac{1}{\hbar} \int_{-\infty}^{\infty} [V_{ii}(t) - V_{ff}(t)] dt \right|^2. \quad (63.41)$$

63.2.4 Broadening by Charged Particles

The total emitter–perturber interaction is

$$\frac{zZ_p q^2}{R} - \frac{Z_p q^2}{|\mathbf{R} - \mathbf{r}|} \simeq V_0(R) + V(\mathbf{r}, \mathbf{R}), \quad (63.42)$$

where Z_p is the charge on the perturber, and

$$V_0(R) = \frac{Z_e Z_p q^2}{R}, \quad V(\mathbf{r}, \mathbf{R}) = -Z_p q^2 \frac{\mathbf{r} \cdot \mathbf{R}}{R^3}. \quad (63.43)$$

If $Z_e = 0$, the relative motion is described by Eq. (63.24), but if $Z_e \neq 0$, the trajectory is hyperbolic and is given by

$$\mu \frac{d^2 \mathbf{R}}{dt^2} = -\nabla V_0 = \frac{Z_e Z_p q^2}{R^3} \mathbf{R}, \quad (63.44)$$

with the resulting hyperbola characterized by a semimajor axis a and an eccentricity ϵ , where

$$b^2 = a^2(\epsilon^2 - 1), \quad a = \frac{|Z_e Z_p| q^2}{\mu v^2}. \quad (63.45)$$

On using Eqs. (63.17), (63.20), (63.36)–(63.41), and (63.43),

$$V_{ii}(t) = 0, \quad \tilde{P}_{if}(\mathbf{b}, \mathbf{v}) = 0, \quad \tilde{\sigma}_{if}(v) = 0, \quad (63.46)$$

and

$$w + id = 2\pi N \int_0^\infty v f(v) dv \quad (63.47)$$

$$\times \left[\int_0^\infty \sum_{j \neq i} Q_{ij}(b, v) + \sum_{j \neq f} Q_{fj}(b, v) \right] b db,$$

where

$$Q_{ij}(v) = \frac{4Z_p^2 I_h^2 a_0^2}{\hbar m_e |\omega_{ij}|} \frac{f_{ij}}{b^2 v^2} [A(\beta, \xi) + iB(\beta, \xi)],$$

$$2 \operatorname{Re}[Q_{ij}(v)] = [P_{ij}(\mathbf{b}, \mathbf{v})]_{\text{av}}. \quad (63.48)$$

If

$$\xi \equiv \frac{a|\omega_{ij}|}{v}, \quad \beta \equiv \xi \epsilon, \quad \delta \equiv \frac{\epsilon^2 - 1}{\epsilon^2}, \quad (63.49)$$

the functions $A(\beta, \xi)$ and $B(\beta, \xi)$ in Eq. (63.48) are given by

$$A(\beta, \xi) = \delta \exp(\mp \pi \xi) \beta^2 \times \left[|K'_{i\xi}(\beta)|^2 + \delta |K_{i\xi}(\beta)|^2 \right], \quad (63.50)$$

$$B(\beta, \xi) = \frac{2\beta}{\pi} \wp \int_0^\infty \frac{A(\beta', \xi) d\beta'}{(\beta^2 - \beta'^2)}, \quad (63.51)$$

where $K_{i\xi}(\beta)$ is a modified Bessel function. In Eq. (63.50), the \mp sign corresponds to $Z_e Z_p = \pm |Z_e Z_p|$, and in

Eq. (63.51), \wp indicates the Cauchy principal value. If $Z_e = 0$, then

$$\xi = 0, \quad \beta = b \frac{|\omega_{ij}|}{v}, \quad \delta = 1 \quad (63.52)$$

in Eqs. (63.50) and (63.51).

Approximation Eq. (63.48) breaks down at small values of b because of assumption Eq. (63.43) and the lack of unitarity of \mathbf{S} as given by Eq. (63.35). This problem is discussed elsewhere [3, 11, 12], and all methods used involve choosing a cutoff at $b = b_0$, where $b_0^2 \gtrsim \bar{r}_f^2$, and using Eq. (63.48) only for $b > b_0$. For $b \leq b_0$, an effective constant probability is introduced, and the method works well as long as the contribution from $b \leq b_0$ is small. For $b > b_0$ (or $\beta > \beta_0$), the contribution to $\sigma_{ij}(v)$ in Eq. (63.39) is evaluated using Eqs. (63.47)–(63.50) and (63.52), where

$$\int_{b_0}^\infty A(\beta, \xi) \frac{db}{b} = -e^{\mp \pi \xi} \beta_0 K'_{i\xi}(\beta_0) K_{i\xi}(\beta_0). \quad (63.53)$$

A similar treatment exists for the quadrupole contribution to $V(\mathbf{r}, \mathbf{R})$ in Eq. (63.43) [3, 11, 12].

63.2.5 Empirical Formulae

An empirical formula based on the theory of Sect. 63.2.4 for the width of an atomic line Stark broadened by electrons has been developed [13]. *Konjević* [14] has reviewed the data available for nonhydrogenic lines and has provided simple analytical representations of the experimental results for widths and shifts.

The full half-width is given by Eq. (63.39), where $\tilde{\sigma}_{if} = 0$, and

$$\int_0^\infty v f_e(v) \sum_{k \neq j} \sigma_{jk}(v) dv = \frac{8\pi^2}{3\sqrt{3}} \left(\frac{\hbar}{m_e} \right)^2 v^{-1}$$

$$\times \left[T_j g(x_j) + \sum_{l' = l_j \pm 1} \tilde{T}_{jj'} \tilde{g}(x_{jj'}) \right], \quad j = i, f, \quad (63.54)$$

where

$$\overline{v^{-1}} = \int_0^\infty v^{-1} f_e(v) dv = \left(\frac{2m_e}{\pi k_B T} \right)^{1/2}, \quad (63.55)$$

and $f_e(v) = f(v)$ with $\mu = m_e$. In Eq. (63.54),

$$T_j = \left(\frac{3n_j^*}{2z} \right)^2 \frac{1}{9} [n_j^{*2} + 3l_j(l_j + 1) + 11], \quad (63.56)$$

$$\tilde{T}_{jj'} = \frac{l_{>}}{(2l_j + 1)} R_{jj'}^2(n_{l_{>}}^*, n_{l_{<}}^*, l_{>}), \quad (63.57)$$

$$l_{<} = \min(l_j, l_{j'}), \quad l_{>} = \max(l_j, l_{j'}),$$

with

$$R_{jj'}(n_{l_>}^*, n_{l_<}^*, l_>) \equiv a_0^{-1} \int_0^\infty P_{n_{l_>}^* l_>}(r) r P_{n_{l_<}^* l_<}(r) dr. \quad (63.58)$$

The radial matrix element Eq. (63.58) can be written as

$$\begin{aligned} R_{jj'}(n_{l_>}^*, n_{l_<}^*, l_>) &= \widetilde{R}_{jj'}(n_{l_>}^*, l_>) \phi(n_{l_>}^*, n_{l_<}^*, l_>) \\ &\equiv \frac{3n_{l_>}^*}{2z} (n_{l_>}^* - l_>)^{1/2} \phi(n_{l_>}^*, n_{l_<}^*, l_>), \end{aligned} \quad (63.59)$$

and $\phi(n_{l_>}^*, n_{l_<}^*, l_>)$ is tabulated elsewhere [15]. The effective principal quantum numbers $n_{l_>}^*$ and $n_{l_<}^*$ of the states j and j' in Eqs. (63.57)–(63.59) both correspond to principal quantum number n_j and $\phi \simeq 1$ for $(n_{l_>}^* - n_{l_<}^*) \ll 1$. The effective Gaunt factors $g(x)$ and $\widetilde{g}(x)$ are given by

$$\widetilde{g}(x) = 0.7 - 1.1/z + g(x), \quad x = \frac{3k_B T}{2\Delta E}, \quad (63.60)$$

where

x	≤ 2	3	5	10	30	100
$g(x)$	0.20	0.24	0.33	0.56	0.98	1.33

is used for $x < 50$, and for $x > 50$

$$\widetilde{g}(x) = g(x) = \frac{\sqrt{3}}{\pi} \left[\frac{1}{2} + \ln \left(\frac{4}{3z} \frac{|E|}{I_h} x \right) \right], \quad (63.61)$$

with Eqs. (63.60) and (63.61) joined smoothly near $x = 50$. The energy $E = E_j$ is given by Eq. (63.34), and x_j and $x_{j'}$ in Eq. (63.54) are evaluated using

$$\Delta E_j = \frac{2z^2}{n_j^{*3}} I_h, \quad \Delta E_{jj'} = |E_j - E_{j'}|. \quad (63.62)$$

For $Z_e = 2$ and 3, Eq. (63.54) is generally accurate to within $\pm 30\%$ and $\pm 50\%$. For $Z_e \geq 4$, Eq. (63.54) is less accurate, as relativistic effects and resonances become more important. Accuracy increases for transitions to higher Rydberg levels as long as the line remains isolated.

Tables in Appendices IV and V of [3] give widths for atoms with $Z_e = 0, 1$, and other semiempirical formulas based on detailed calculations have been developed by *Seaton* [16, 17] for use in the Opacity Project where simple estimates of many thousands of line widths are required.

63.3 Overlapping Lines

63.3.1 Transitions in Hydrogen and Hydrogenic Ions

The most important case is that of lines of hydrogenic systems emitted by a plasma with overall electrical neutrality, broadened by perturbing electrons and atomic ions. The line profile is given by Eqs. (63.4)–(63.9) in which Eq. (63.20) is generalized to give

$$\begin{aligned} \langle \langle i' f'^* \| \mathbf{w} + i\mathbf{d} \| i f^* \rangle \rangle &= 2\pi N \int_0^\infty v f(v) dv \\ &\times \int_0^\infty \left[\delta_{i'i} \delta_{f'f} - S_{i'i}(\mathbf{b}, \mathbf{v}) S_{f'f}^*(\mathbf{b}, \mathbf{v}) \right]_{\text{av}} b db. \end{aligned} \quad (63.63)$$

The superscripts and suffixes e and i will be used to denote electronic and ionic quantities respectively, and *em* indicates that averaging over magnetic quantum numbers has not been carried out. In the impact approximation, electron and ion contributions evaluated using (63.63) are additive, and the matrix to be inverted is of order $n_i n_f$. However, under typical conditions in a laboratory plasma, e.g., a hydrogen plasma with $N_e = N_i = 10^{22} \text{ m}^{-3}$, perturbing atomic ions cannot be treated using the impact approximation. The ions collectively generate a static field at the emitter that produces first-order Stark splitting of the upper and lower levels. The ions are randomly distributed around the emitter, and the field distribution $W(\mathbf{F})$ used assumes that each ion is Debye screened by electrons; allowance is made for these heavy composite perturbers interacting with each other as well as with the emitter. If the ion field has a slow time variation, ion dynamic effects can produce significant changes in the line shape, see [3, 4, 6, 18].

The shift produced by electron perturbers is very small, and the usual model adopted is to assume that the ions split the line into its Stark components, and that each component is broadened by electron impact. In both cases, only the dipole interactions in Eq. (63.43) are included, and the profile is symmetric. Then (63.4) takes the form

$$\begin{aligned} I(\omega) &= \frac{1}{\pi} \text{Re} \int W(\mathbf{F}) d\mathbf{F} \sum_{ii'ff'} \langle \langle i f^* | \Delta | i' f'^* \rangle \rangle \\ &\times \left\langle \left\langle i' f'^* \left| [\mathbf{w} + i\mathbf{d} - i(\omega - \omega_{if}) \mathbf{I}]^{-1} \right| i f^* \right\rangle \right\rangle, \end{aligned} \quad (63.64)$$

and the destruction of the degeneracy by the ion field means that the matrix to be inverted in Eq. (63.64) is of order $(n_i n_f)^2$. Inclusion of higher multipoles in $V(\mathbf{r}, \mathbf{R})$ in

Eq. (63.43) introduces small asymmetries. The Stark representation for the hydrogenic wave functions is often used because it diagonalizes the shift matrix in Eq. (63.64). The transformation is given by (see Chap. 9.1.2 and Chap. 14.4.2)

$$|n_j K_j m_j\rangle = \sum_{l_j=|m_j|}^{n_j-1} (-1)^K (2l_j + 1)^{1/2} \times \begin{pmatrix} N & N & l_j \\ M_1 & M_2 & -m_j \end{pmatrix} |n_j l_j m_j\rangle, \quad (63.65)$$

$j = i, i', f, f',$

where quantum number K_j replaces l_j , and

$$\begin{aligned} n_j &= K_j + K'_j + |m_j| + 1, \quad N = \frac{1}{2}(n_j - 1), \\ K &= \frac{1}{2}(2K'_j + |m_j| + m_j) + 1, \\ 0 &\leq K_j \leq (n_j - 1), \\ M_1 &= \frac{1}{2}(m_j + K'_j - K_j), \\ M_2 &= \frac{1}{2}(m_j + K_j - K'_j). \end{aligned} \quad (63.66)$$

For the electron impact broadening, it is convenient to separate the energy-changing and the zero energy-change transitions, so that Eq. (63.39) is generalized to give

$$\gamma_{em} = \gamma_{em}^0 + \tilde{\gamma}_{em} \equiv \langle\langle i' f'^* | 2\mathbf{w}_e | i f^* \rangle\rangle, \quad (63.67)$$

where

$$\begin{aligned} \gamma_{em}^0 &\equiv \langle\langle i' f'^* | 2\mathbf{w}_e^0 | i f^* \rangle\rangle = N_e \int_0^\infty v f_e(v) dv \\ &\times \left[\sum_{j \neq i} \sigma_{ij}^{em}(v) + \sum_{j \neq f} \sigma_{fj}^{em}(v) \right] \delta_{i'i'} \delta_{f'f'}, \end{aligned} \quad (63.68)$$

$$\begin{aligned} \tilde{\gamma}_{em} &\equiv \langle\langle i' f'^* | 2\tilde{\mathbf{w}}_e | i f^* \rangle\rangle \\ &= N_e \int_0^\infty v f_e(v) dv \tilde{\sigma}_{i'f'if}^{em}(v). \end{aligned} \quad (63.69)$$

In Eq. (63.68), $|n_i - n_j| \neq 0$ and $|n_f - n_j| \neq 0$ in the first and second terms, respectively, and in Eq. (63.69) $(n_{i'} - n_i) = (n_{f'} - n_f) = 0$. The matrix element Eq. (63.68) can be evaluated using Eqs. (63.36), (63.48), (63.50), and (63.52) as before. In Eq. (63.68),

$$\begin{aligned} \sigma_{ij}^{em}(v) &= 2\pi \int_0^\infty \left[P_{ij}^e(\mathbf{b}, \mathbf{v}) \right]_{\text{av}_0} b db, \\ &i, j = 0, 1, 2, \dots, \end{aligned} \quad (63.70)$$

and in Eq. (63.69)

$$\tilde{\sigma}_{i'f'if}^{em}(v) = 2\pi \int_0^\infty \left[\tilde{P}_{i'f'if}^e(\mathbf{b}, \mathbf{v}) \right]_{\text{av}_0} b db \quad (63.71)$$

by analogy with Eqs. (63.36) and (63.40), where av_0 indicates an average over all orientations of the collision only. On using Eqs. (63.48)–(63.50), (63.59), and (63.8) with $j_i = l_i$, $j_{i'} = l_{i'}$, $j_f = l_f$, and $j_{f'} = l_{f'}$,

$$\begin{aligned} &\left[\tilde{P}_{i'f'if}^e(\mathbf{b}, \mathbf{v}) \right]_{\text{av}_0} \\ &= \frac{8I_h a_0^2}{3m_e b^2 v^2} D_{if i' f'} \tilde{R}_{i' f' i f} A(0, 0), \end{aligned} \quad (63.72)$$

where

$$\begin{aligned} \tilde{R}_{i' f' i f} &\equiv \left[\sum_{l_j=l_i \pm 1} \tilde{R}_{ij}^2(n_i, l_{i>}) + \sum_{l_j=l_f \pm 1} \tilde{R}_{fj}^2(n_f, l_{f>}) \right] \\ &\times \delta_{l_{i'} l_i} \delta_{l_{f'} l_f} \\ &- 2\tilde{R}_{i'i}(n_i, l_{i>}) \tilde{R}_{f'f}(n_f, l_{f>}) \delta_{l_{i'} l_i \pm 1} \delta_{l_{f'} l_f \pm 1}. \end{aligned} \quad (63.73)$$

From Eqs. (63.45) and (63.49)–(63.53)

$$A(0, 0) = \delta,$$

$$\int_{b_0}^{b_1} A(0, 0) \frac{db}{b} = \begin{cases} \ln(\epsilon_1/\epsilon_0), & Z_e \neq 0, \\ \ln(b_1/b_0), & Z_e = 0. \end{cases} \quad (63.74)$$

The impact approximation neglects electron–electron correlations and the finite duration of collisions, so the long-range dipole interaction leads to a logarithmic divergence at large impact parameters in Eq. (63.74). Therefore, a second cutoff parameter is introduced, which is chosen to be the smaller of the Debye length b_D and $v\tau$:

$$b_1 = \min \left[b_D \equiv \left(\frac{k_B T}{4\pi q^2 N_e} \right)^{1/2}, v\tau \right], \quad (63.75)$$

but estimating τ in this case is not straightforward; it depends on the splitting of the Stark components [3].

63.3.2 Infrared and Radio Lines

If the density N_i is low enough, the impact approximation becomes valid for the perturbing atomic ions, and since impact

shifts are unimportant, Eq. (63.6) gives

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \sum_{i'f'f''} \langle \langle i'f'^* \| \Delta \| i'f'^* \rangle \rangle \times \langle \langle i'f'^* \| [\mathbf{w}_e + \mathbf{w}_i - i(\omega - \omega_{if})\mathbf{I}]^{-1} \| if^* \rangle \rangle, \tag{63.76}$$

where in Eq. (63.76)

$$\gamma_{e,i} = \gamma_{e,i}^0 + \tilde{\gamma}_{e,i} \equiv \langle \langle i'f'^* \| 2\mathbf{w}_{e,i} \| if^* \rangle \rangle, \tag{63.77}$$

$$\gamma_{e,i}^0 \equiv \langle \langle i'f'^* \| 2\mathbf{w}_{e,i}^0 \| if^* \rangle \rangle = N_{e,i} \int_0^\infty v f_{e,i}(v) dv \times \left[\sum_{j \neq i} \sigma_{ij}^{e,i}(v) + \sum_{j \neq f} \sigma_{fj}^{e,i}(v) \right] \delta_{i'i} \delta_{f'f}, \tag{63.78}$$

$$\tilde{\gamma}_{e,i} \equiv \langle \langle i'f'^* \| 2\tilde{\mathbf{w}}_{e,i} \| if^* \rangle \rangle = N_{e,i} \int_0^\infty v f_{e,i}(v) dv \tilde{\sigma}_{i'f'if}^{e,i}(v). \tag{63.79}$$

In general, cross sections for electron and heavy-particle impact are roughly comparable for the same velocity and, hence, different impact energies. Therefore, using Eqs. (63.78) and (63.79),

$$\gamma_e^0 \gg \gamma_i^0, \quad \tilde{\gamma}_e \ll \tilde{\gamma}_i, \tag{63.80}$$

and this result is consistent with approximation Eq. (63.64) for high-density plasmas. If $(n_i - n_f) = 1, 2$, say, as n_f increases, the relative contributions from Eqs. (63.78) and (63.79) decrease because there is increasing coherence, and, hence, cancelation in $\tilde{\sigma}_{i'f'if}^e(v)$ and $\tilde{\sigma}_{i'f'if}^i(v)$ between the effects of levels i, i' and f, f' .

Radio lines of hydrogen are observed in galactic HII regions where principal quantum numbers are of the order of $n_f \simeq 100$, temperatures are $T_e = T_i \simeq 10^4$ K, and densities are $N_e = N_i \simeq 10^9 \text{ m}^{-3}$. For a comprehensive review of the theory and observation of radio recombination lines, see *Gordon and Sorochenko* [19].

If γ is the full half-width and $\tilde{\gamma}$ is the full half-width when only contributions Eq. (63.79) are retained, the effect of cancelation is illustrated by

$n_i - n_f = 1$	Electrons	Protons + Electrons
n_f	$\tilde{\gamma}/\gamma$	$\tilde{\gamma}/\gamma$
5	0.82	0.99
10	0.40	0.95
15	0.17	0.86
20	0.08	0.73
25	0.05	0.59
50	0.00	0.17
100	0.00	0.01

Further details are given by *Peach* [20].

63.4 Quantum-Mechanical Theory

63.4.1 Impact Approximation

The scattering amplitude for a collisional transition $i \rightarrow j$ is given in terms of elements of the transition matrix $\mathbf{T} = \mathbf{1} - \mathbf{S}$ by

$$f(\mathbf{k}_j, \mathbf{k}_i) \equiv f(\chi_j M_j \mathbf{k}_j, \chi_i M_i \mathbf{k}_i) = \frac{2\pi i}{(k_i k_j)^{1/2}} \sum_{lm'l'm'} i^{l-l'} Y_{lm}^*(\hat{\mathbf{k}}_i) Y_{l'm'}(\hat{\mathbf{k}}_j) \times T(\chi_j M_j l' m'; \chi_i M_i l m), \tag{63.81}$$

where the quantities $\mathbf{k}_i l m$ and $\mathbf{k}_j l' m'$ refer to the motion of the perturber relative to the emitter before and after the collision, and χ_i and χ_j represent all nonmagnetic quantum numbers associated with the unperturbed states i and j of the emitter. The total energy of the emitter-perturber system is given by

$$E_J = E_j + \varepsilon_j, \quad \varepsilon_j = \frac{\hbar^2}{2\mu} k_j^2, \tag{63.82}$$

$$(J, j) = (I, i), (F, f),$$

and for an isolated line, γ is given by Eq. (63.39), where

$$\sigma_{ij}(v) = \frac{k_j}{k_i} \frac{1}{4\pi g_i} \times \sum_{M_i M_j} \int |f(\chi_j M_j \mathbf{k}_j, \chi_i M_i \mathbf{k}_i)|^2 d\hat{\mathbf{k}}_i d\hat{\mathbf{k}}_j, \tag{63.83}$$

$$k_i = \mu v / \hbar,$$

and the interference term $\tilde{\sigma}_{if}(v) \equiv \tilde{\sigma}_{ifif}(v)$ is given by

$$\tilde{\sigma}_{if}(v) = \frac{1}{4\pi} \sum_{\substack{M_i M_i' \\ M_f M_f'}} D_{if i' f'} \int |f(\chi_i M_i \mathbf{k}', \chi_i M_i \mathbf{k}) - f(\chi_f M_f \mathbf{k}', \chi_f M_f \mathbf{k})|^2 d\hat{\mathbf{k}} d\hat{\mathbf{k}}', \tag{63.84}$$

with $k = k' = \mu v / \hbar$. From Eqs. (63.8) and (63.20),

$$w + id = \pi \left(\frac{\hbar}{\mu} \right)^2 N \int_0^\infty \frac{1}{v} f(v) dv \times \sum_{l=0}^\infty (2l+1) \left[1 - S_{ii}(l, v) S_{ff}^*(l, v) \right], \tag{63.85}$$

where

$$(\mu vb)^2 \implies \hbar^2 l(l+1), \quad (63.86)$$

and the integral over b has been replaced by a summation over l . In Eq. (63.85), $S_{ii}(l, v)S_{ff}^*(l, v)$ is given by

$$\begin{aligned} S_{ii}(l, v)S_{ff}^*(l, v) &= \frac{1}{(2l+1)} \sum_{\substack{M_i M'_i M_f M'_f \\ mm'}} D_{if i' f'} S_I(\chi_{i'} M_{i'} l m'; \chi_i M_i l m) \\ &\times S_F^*(\chi_{f'} M_{f'} l m'; \chi_f M_f l m), \end{aligned} \quad (63.87)$$

and subscripts I and F are introduced to emphasize that the S -matrix elements correspond to different total energies E_I and E_F defined by Eq. (63.82). If scattering by the emitter in a state j is treated using a central potential, the amplitude for elastic scattering is

$$f(k', k) = \frac{i}{2k} \sum_{l=0}^{\infty} (2l+1) T_{jj}(l, v) P_l(\hat{\mathbf{k}}' \cdot \hat{\mathbf{k}}), \quad (63.88)$$

where

$$1 - T_{jj}(l, v) = S_{jj}(l, v) = \exp[2i\eta_j(l, k)], \quad j = i, f, \quad (63.89)$$

[Eqs. (63.23), (63.25), and (63.26)]. For the case of overlapping lines, Eq. (63.63) becomes

$$\begin{aligned} \langle\langle i' f'^* \| \mathbf{w} + i\mathbf{d} \| i f^* \rangle\rangle &= \pi \left(\frac{\hbar}{\mu} \right)^2 N \int_0^{\infty} \frac{1}{v} f(v) dv \\ &\times \sum_{l=0}^{\infty} (2l+1) \left[\delta_{i'i} \delta_{f'f} - S_{ii}(l, v) S_{ff}^*(l, v) \right] \end{aligned} \quad (63.90)$$

on generalizing Eq. (63.85) and using Eq. (63.87). Formulae Eqs. (63.85) and (63.90) have been obtained by assuming that a collision produces no change in the angular momentum of the relative emitter–perturber motion. This corresponds to the assumption of a common trajectory in semiclassical theory and means that the total angular momentum of the emitter–perturber system is not conserved. This assumption is removed in the derivation of the more general expressions given in the following sections.

63.4.2 Broadening by Electrons

Different coupling schemes can be used to describe the emitter–perturber collision. For LS coupling,

$$\chi_j M_j \implies \chi_j^0 L_j M_j S M_S, \quad j = i, i', f, f', \quad (63.91)$$

in Eq. (63.81), where χ_j^0 denotes all other quantum numbers required to describe state j that do not change during the collision. Then

$$\begin{aligned} \left| L_j M_j S M_S l m \frac{1}{2} m_s \right\rangle &= \sum_{L_j^T M_j^T S^T M_S} C_{M_j M_S}^{L_j l L_j^T} C_{M_S m_s M_S}^{S \frac{1}{2} S^T} \\ &\times \left| L_j S l \frac{1}{2} L_j^T M_j^T S^T M_S^T \right\rangle, \end{aligned} \quad (63.92)$$

where $C_{m_1 m_2 m_3}^{j_1 j_2 j_3}$ is a vector coupling coefficient, the superscript T denotes quantum numbers of the emitter–perturber system, and $\frac{1}{2}, m_s$ are the spin quantum numbers of the scattered electron. On using Eq. (63.92), Eq. (63.90) is replaced by

$$\begin{aligned} \langle\langle i' f'^* \| \mathbf{w} + i\mathbf{d} \| i f^* \rangle\rangle &= \pi (\hbar/m_e)^2 N \\ &\times \sum_{L_i^T L_i'^T S^T l l'} (-1)^{L_i + L_i' + l + l'} (2L_i^T + 1) (2L_i'^T + 1) \\ &\times \frac{(2S^T + 1)}{2(2S + 1)} \left\{ \begin{matrix} L_f^T & L_i^T & 1 \\ L_i & L_f & l \end{matrix} \right\} \left\{ \begin{matrix} L_f^T & L_i^T & 1 \\ L_i' & L_f' & l' \end{matrix} \right\} \\ &\times \int_0^{\infty} \frac{1}{v} f_e(v) dv \left[\delta_{l'l'} \delta_{L_i' L_i} \delta_{L_f' L_f} \right. \\ &- S_I \left(L_i' S l' \frac{1}{2} L_i^T S^T; L_i S l \frac{1}{2} L_i^T S^T \right) \\ &\left. \times S_F^* \left(L_f' S l' \frac{1}{2} L_f^T S^T; L_f S l \frac{1}{2} L_f^T S^T \right) \right], \end{aligned} \quad (63.93)$$

where, for an isolated line, the width and shift are given by Eq. (63.93) with $L_{i'} = L_i$ and $L_{f'} = L_f$. For hydrogenic systems, where states i, i' and f, f' with different angular momenta are degenerate, a logarithmic divergence occurs for large values of l and l' [Eq. (63.74)], and must be removed by using Eqs. (63.75) and (63.86).

If a jj coupling scheme is used $\chi_j M_j \implies \chi_j^0 J_j M_j$, $j = i, i', f, f'$ in Eq. (63.81), and

$$\begin{aligned} \left| J_j M_j l m \frac{1}{2} m_s \right\rangle &= \sum_{J_j^T M_j^T j m'} C_{M_j M_j^T}^{J_j j J_j^T} C_{m m_s m'}^{l \frac{1}{2} j} \left| J_j l j J_j^T M_j^T \right\rangle, \end{aligned} \quad (63.94)$$

then Eq. (63.93) becomes

$$\begin{aligned} \langle\langle i' f'^* \| \mathbf{w} + i\mathbf{d} \| i f^* \rangle\rangle &= \pi (\hbar/m_e)^2 N \\ &\times \sum_{J_i^T J_i'^T j j' l l'} (-1)^{J_i + J_i' + 2J_f^T + j + j'} \frac{1}{2} (2J_i^T + 1) (2J_f^T + 1) \end{aligned}$$

$$\begin{aligned}
& \times \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & j \end{array} \right\} \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & j' \end{array} \right\} \\
& \times \int_0^\infty \frac{1}{v} f_e(v) dv \left[\delta_{l'l} \delta_{j'j} \delta_{J_i J_i'} \delta_{J_f J_f'} \right. \\
& \left. - S_I(J_{i'} l' j' J_i^T; J_i l j J_i^T) S_F^*(J_{f'} l' j' J_f^T; J_f l j J_f^T) \right], \quad (63.95)
\end{aligned}$$

where $J_{i'} = J_i$ and $J_{f'} = J_f$ for an isolated line. If the spectrum of the emitter is classified using LS coupling, it is often sufficient to use energies defined by

$$E_{L_j S} = \sum_{J_j} \frac{(2J_j + 1)}{(2L_j + 1)(2S_j + 1)} E_{L_j S J_j} \quad (63.96)$$

and obtain the S -matrix elements in an LS coupling scheme. They are then transformed to jj coupling by using the algebraic transformation

$$\begin{aligned}
& S(J_{i'} l' j' J_i^T; J_j l j J_j^T) \\
& = [(2J_j + 1)(2J_{j'} + 1)(2j + 1)(2j' + 1)]^{1/2} \\
& \times \sum_{L_j^T S^T} (2L_j^T + 1)(2S^T + 1) \\
& \times \left\{ \begin{array}{ccc} L_j & l & L_j^T \\ S & \frac{1}{2} & S^T \\ J_j & j & J_j^T \end{array} \right\} \left\{ \begin{array}{ccc} L_{j'} & l' & L_{j'}^T \\ S & \frac{1}{2} & S^T \\ J_{j'} & j' & J_{j'}^T \end{array} \right\} \\
& \times S\left(L_{j'} S l' \frac{1}{2} L_j^T S^T; L_j S l \frac{1}{2} L_j^T S^T\right), \quad (63.97)
\end{aligned}$$

and introducing the splitting of the fine structure components in Eq. (63.4) or (63.6). If in LS coupling the line is isolated, but nevertheless the broadened fine structure components overlap significantly, then the interference terms in Eq. (63.6) must be included.

63.4.3 Broadening by Atoms

The formal result is very similar to Eq. (63.95), but in this case, the relative motion only gives rise to orbital angular momentum. Thus,

$$\begin{aligned}
& \langle\langle i' f'^* \| \mathbf{w} + i\mathbf{d} \| i f^* \rangle\rangle = \pi (\hbar/\mu)^2 N \\
& \times \sum_{J_i^T J_f^T l l'} (-1)^{J_i + J_{i'} + 2J_f^T + l + l'} (2J_i^T + 1)(2J_f^T + 1) \\
& \times \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & l \end{array} \right\} \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & l' \end{array} \right\}
\end{aligned}$$

$$\begin{aligned}
& \times \int_0^\infty \frac{1}{v} f(v) dv [\delta_{l'l} \delta_{J_i J_i'} \delta_{J_f J_f'} \\
& - S_I(J_{i'} l' J_i^T; J_i l J_i^T) S_F^*(J_{f'} l' J_f^T; J_f l J_f^T)]. \quad (63.98)
\end{aligned}$$

For many cases of practical interest, transitions of type $J_i \rightarrow J_f$ are isolated and so have line profiles given by Eqs. (63.3), (63.10), and (63.98), where $J_i = J_{i'}$ and $J_f = J_{f'}$ [10]. In order to obtain the S -matrix elements in Eq. (63.98), it is usually sufficient to use adiabatic potentials for the emitter–perturber system that have been calculated neglecting fine structure. Since T is typically a few hundred degrees, only coupling between adiabatic states that tend to the appropriate separated-atom limit are retained in the scattering problem. The coupled scattering equations are then solved with fine structure introduced by applying an algebraic transformation to the adiabatic potentials, and using the observed splittings of the energy levels. The Born–Oppenheimer approximation is valid, and details are given in [21].

63.5 One-Perturber Approximation

63.5.1 General Approach and Utility

If only one perturber is effective in producing broadening, $I(\omega)$ can be obtained by considering a dipole transition between initial and final states I and F of the emitter–perturber system. Then $P(\omega)$ is given by Eq. (63.2), where

$$\begin{aligned}
I(\omega) & = [\delta(\omega - \omega_{IF}) \langle\langle IF^* | \mathbf{A} | IF^* \rangle\rangle]_{av}, \\
\hbar\omega_{IF} & = E_I - E_F, \quad (63.99)
\end{aligned}$$

and av denotes an average over states I and a sum over states F [4]. Wave functions Ψ_J are given by

$$\Psi_J(\mathbf{r}, \mathbf{R}) = \mathcal{O} \sum_j \psi_j(\mathbf{r}) \phi(\mathbf{k}_j, \mathbf{k}_{j_0}; \mathbf{R}), \quad (63.100)$$

where $J = I, F$, and \mathcal{O} is an operator that takes account of any symmetry properties of the emitter–perturber system. The energies E_I and E_F are given by Eq. (63.82). The perturber wave functions for initial state j_0 and final state j are expanded in the form

$$\begin{aligned}
\phi(\mathbf{k}_j, \mathbf{k}_{j_0}; \mathbf{R}) & = 2\pi i \sum_{l_{j_0} m_{j_0} l_j m_j} i^{l_{j_0}} k_{j_0}^{-1/2} Y_{l_{j_0} m_{j_0}}^*(\hat{\mathbf{k}}_{j_0}) \\
& \times Y_{l_j m_j}(\hat{\mathbf{R}}) \frac{1}{R} F(\Gamma_j, \Gamma_{j_0}; R), \quad (63.101)
\end{aligned}$$

where Γ_j denotes a channel characterized by

$$\Gamma_j = \chi_j M_j l_j m_j, \quad j = 0, 1, 2, \dots, \quad (63.102)$$

[Eq. (63.81)]. In Eq. (63.101), the radial perturber wave function has the limiting forms

$$F(\Gamma_j, \Gamma_{j_0}; R) \underset{R \rightarrow 0}{\approx} R^{l_j+1} \underset{R \rightarrow \infty}{\approx} k_j^{-1/2} \left[\delta_{\Gamma_j \Gamma_{j_0}} \exp(-i\theta_j) - S_j(\Gamma_j; \Gamma_{j_0}) \exp(i\theta_j) \right], \quad (63.103)$$

with

$$\theta_j = k_j R - \frac{1}{2} l_j \pi - \frac{z}{k_i} \ln(2k_j R) + \arg \Gamma \left(l_j + 1 + i \frac{z}{k_j} \right), \quad z = \frac{\mu q^2}{\hbar^2} Z_c Z_p. \quad (63.104)$$

The coupled equations obtained by using Eqs. (63.12), (63.13), (63.100), and (63.101), where

$$\Psi(\mathbf{r}, \mathbf{R}, t) = \Psi_j(\mathbf{r}, \mathbf{R}) \exp(-iE_j t / \hbar) \quad (63.105)$$

are integrated to give functions $F(\Gamma_j, \Gamma_{j_0}; R)$. Using Eqs. (63.100) and (63.101), Eq. (63.99) becomes

$$I(\omega) = \frac{1}{2} N \sum_{\Gamma_{i_0} \Gamma_i \Gamma_{i'} \Gamma_{j_0} \Gamma_f \Gamma_{f'}} u_{i_0} \langle \langle \Gamma_i \Gamma_{f'}^* | \mathbf{A} | \Gamma_{i'} \Gamma_{f'}^* \rangle \rangle \times \int_0^\infty \frac{1}{v} f(v) dv \mathcal{F}(\Gamma, v), \quad (63.106)$$

where

$$\mathcal{F}(\Gamma, v) = \int_0^\infty F^*(\Gamma_i, \Gamma_{i_0}; R) F(\Gamma_f, \Gamma_{f_0}; R) dR \times \int_0^\infty F(\Gamma_{i'}, \Gamma_{i_0}; R) F^*(\Gamma_{f'}, \Gamma_{f_0}; R) dR, \quad (63.107)$$

$$u_{i_0} = g_{i_0} / \sum_{i'_0} g_{i'_0}, \quad v = \frac{\hbar k_{i_0}}{\mu}. \quad (63.108)$$

The one-perturber approximation is valid when

$$\Delta\omega \equiv |\omega - \omega_{if}| \gg w; \quad V \gg \bar{V}, \quad (63.109)$$

where V is the effective interaction potential required to produce a shift $\Delta\omega$. In the center of the line, many-body effects are always important, and the one-perturber approximation diverges as $\Delta\omega \rightarrow 0$. In many cases, there is a region of overlap where criteria Eqs. (63.1) and (63.109) are all valid, but when $\Delta\omega \tau \gg 1$, Eq. (63.99) is a static approximation, since the average time between collisions is $\Delta\omega^{-1}$.

63.5.2 Broadening by Electrons

If LS coupling is used, definition of channel Γ_j in Eq. (63.104) is replaced by

$$\Gamma_j = L_j S l_j \frac{1}{2} L_j^T S^T, \quad j = i_0, i, i', f_0, f, f', \quad (63.110)$$

[cf. Eqs. (63.91) and (63.92)]. Then assuming that the weights u_{i_0} of all the levels i_0 that effectively contribute to the line are the same, Eq. (63.106) becomes

$$I(\omega) = \frac{1}{2} N_e \sum_{\substack{\Gamma_{i_0} \Gamma_i \Gamma_{i'} \\ \Gamma_{f_0} \Gamma_f \Gamma_{f'}}} \langle \langle L_i S (L_f S)^* | \mathbf{A} | L_{i'} S (L_{f'} S)^* \rangle \rangle \times \delta_{i_l f_l} \delta_{i'_l f'_l} \delta_{L_{i_0}^T L_i^T} \delta_{L_{f_0}^T L_f^T} \delta_{L_{i_0}^T L_{i'}^T} \delta_{L_{f_0}^T L_{f'}^T} \times (-1)^{L_i + L_{i'} + l_i + l_{i'}} \frac{(2S^T + 1)}{2(2S + 1)} \times (2L_i^T + 1)(2L_{f'}^T + 1) \times \begin{Bmatrix} L_f^T & L_i^T & 1 \\ L_i & L_f & l \end{Bmatrix} \begin{Bmatrix} L_f^T & L_{i'}^T & 1 \\ L_{i'} & L_{f'} & l_{i'} \end{Bmatrix} \times \int_0^\infty \frac{1}{v} f_e(v) dv \mathcal{F}(\Gamma, v), \quad (63.111)$$

where $\mathcal{F}(\Gamma, v)$ is defined by Eqs. (63.107) and (63.111). If the functions $F(\Gamma_j, \Gamma_{j_0}; R)$ in Eq. (63.107) are replaced by their asymptotic forms Eq. (63.103), then

$$\mathcal{F}(\Gamma, v) \simeq \Delta\omega^{-2} (\hbar/m_e)^2 \times \left[\delta_{\Gamma_{i_0} \Gamma_i} \delta_{\Gamma_{f_0} \Gamma_f} - S_I(\Gamma_i; \Gamma_{i_0}) S_F^*(\Gamma_f; \Gamma_{f_0}) \right] \times \left[\delta_{\Gamma_{i_0} \Gamma_{i'}} \delta_{\Gamma_{f_0} \Gamma_{f'}} - S_I^*(\Gamma_{i'}; \Gamma_{i_0}) S_F(\Gamma_{f'}; \Gamma_{f_0}) \right]. \quad (63.112)$$

On substituting Eq. (63.112) into Eq. (63.111), summing over Γ_{i_0} and Γ_{f_0} and using the unitary property of the S -matrix,

$$I(\omega) = \frac{1}{\pi \Delta\omega^2} \sum_{L_i^T L_f^T S^T l l'} \langle \langle L_i S (L_f S)^* | \mathbf{A} | L_{i'} S (L_{f'} S)^* \rangle \rangle \times \langle \langle i' f'^* | \mathbf{w} | i f^* \rangle \rangle, \quad (63.113)$$

where $\langle \langle i' f'^* | \mathbf{w} | i f^* \rangle \rangle$ is given by Eq. (63.93). Line shape Eq. (63.113) is identical to that obtained from Eq. (63.6) when $\Delta\omega \gg w$. If the jj coupling scheme specified by Eq. (63.94) is used, and channel Γ_j is defined by

$$\Gamma_j = J_j l_j j_j J_j^T, \quad j = i_0, i, i', f_0, f, f', \quad (63.114)$$

Equation (63.106) becomes [cf. Eq. (63.95)]

$$\begin{aligned}
I(\omega) &= \frac{1}{2} N_e \sum_{\Gamma_{i_0} \Gamma_i \Gamma_{i'} \Gamma_{f_0} \Gamma_f \Gamma_{f'}} \langle \langle J_i(J_f)^* \parallel \Delta \parallel J_{i'}(J_{f'})^* \rangle \rangle \\
&\times \delta_{l_i l_f} \delta_{l_{i'} l_{f'}} \delta_{j_i j_f} \delta_{j_{i'} j_{f'}} \delta_{J_{i_0}^T J_i^T} \delta_{J_{f_0}^T J_f^T} \delta_{J_{i_0}^T J_{i'}^T} \delta_{J_{f_0}^T J_{f'}^T} \\
&\times (-1)^{J_i + J_{i'} + 2J_f^T + j_i + j_{i'}} \\
&\times \frac{1}{2} (2J_i^T + 1) (2J_f^T + 1) \\
&\times \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & j_i \end{array} \right\} \left\{ \begin{array}{ccc} J_f^T & J_{i'}^T & 1 \\ J_{i'} & J_{f'} & j_{i'} \end{array} \right\} \\
&\times \int_0^\infty \frac{1}{v} f_e(v) dv \mathcal{F}(\Gamma, v), \quad (63.115)
\end{aligned}$$

where $\mathcal{F}(\Gamma, v)$ is given by Eqs. (63.107) and (63.114).

63.5.3 Broadening by Atoms and Molecules

In the wings of a line where $\hbar|\Delta\omega| \simeq |E_{J_i} - E_{J_{i'}}|$, $j = i_0, i, i', f_0, f, f'$, coupling between the fine structure levels is important. If channel Γ_j is defined by

$$\Gamma_j = J_j l_j J_j^T, \quad j = i_0, i, i', f_0, f, f', \quad (63.116)$$

Equation (63.106) becomes [cf. Eq. (63.115)]

$$\begin{aligned}
I(\omega) &= \frac{1}{2} N \sum_{\Gamma_{i_0} \Gamma_i \Gamma_{i'} \Gamma_{f_0} \Gamma_f \Gamma_{f'}} \langle \langle J_i(J_f)^* \parallel \Delta \parallel J_{i'}(J_{f'})^* \rangle \rangle \\
&\times \delta_{l_i l_f} \delta_{l_{i'} l_{f'}} \delta_{J_{i_0}^T J_i^T} \delta_{J_{f_0}^T J_f^T} \delta_{J_{i_0}^T J_{i'}^T} \delta_{J_{f_0}^T J_{f'}^T} \\
&\times (-1)^{J_i + J_{i'} + 2J_f^T + l_i + l_{i'}} (2J_i^T + 1) (2J_f^T + 1) \\
&\times \left\{ \begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & l_i \end{array} \right\} \left\{ \begin{array}{ccc} J_f^T & J_{i'}^T & 1 \\ J_{i'} & J_{f'} & l_{i'} \end{array} \right\} \\
&\times \int_0^\infty \frac{1}{v} f(v) dv \mathcal{F}(\Gamma, v), \quad (63.117)
\end{aligned}$$

where $\mathcal{F}(\Gamma, v)$ is given by Eqs. (63.107) and (63.116). In the far wings, where $\hbar|\Delta\omega| \gg |E_{J_i} - E_{J_{i'}}|$, $j = i_0, i, i', f_0, f, f'$, an adiabatic approximation is valid. Adiabatic states of the diatomic molecule formed by the emitter-perturber system are considered in which the total spin is assumed to be decoupled from the total orbital angular momentum of the electrons. The coupling between rotational and electronic angular momentum can also be neglected, because, typically, contributions to the line profile come from

$0 \leq l_j \lesssim 400$, whereas $\Lambda_j \lesssim 2$. Therefore, transitions take place between channels defined by

$$\Gamma_j = \Lambda_j L_j S L_j, \quad j = i, f, \quad (63.118)$$

where the unperturbed emitter in state j has quantum numbers $L_j S$, the quantum number Λ_j represents the projection of the orbital angular momentum on the internuclear axis, and Eq. (63.100) is replaced by

$$\Psi_J(\mathbf{r}, \mathbf{R}) = \mathcal{O} \sum_j \psi_j(\mathbf{r}; \mathbf{R}) \phi(\mathbf{k}_j, \mathbf{k}_{j_0}; \mathbf{R}), \quad (63.119)$$

where $k_j = k_{j_0}$, and $\psi_j(\mathbf{r}; \mathbf{R})$ is the wave function for molecular state Λ_j . In Eq. (63.119), the only molecular states retained are those that correlate with emitter states i and f . The scattering is described by

$$\begin{aligned}
\left[\frac{d^2}{dR^2} - \frac{l_j(l_j + 1)}{R^2} - \frac{2z}{R} - \frac{2\mu}{\hbar^2} V_{\Lambda_j}(R) + k_j^2 \right] \\
\times F_j(R) = 0, \quad (63.120)
\end{aligned}$$

where $k_j = k_{j_0}$ and

$$\begin{aligned}
F_j(R) &= P_{v_j l_j}(R) \text{ or} \\
F_j(R) &\equiv F(\Gamma_j, \Gamma_j; R) = F_{k_i l_i}(R) \quad (63.121)
\end{aligned}$$

for vibrational or free states, respectively, and $V_{\Lambda_j}(R)$ is the potential energy of state Λ_j . Free-free transitions always contribute to the line profile, but bound-free and free-bound transitions only contribute on the red and blue wings, respectively. On using Eqs. (63.82), (63.99), and (63.109), $\hbar\Delta\omega = \varepsilon_i - \varepsilon_f$, and ε_j becomes the energy of bound state j with vibrational quantum number v_j when $\varepsilon_j < 0$. If

$$\mathcal{G}(\Gamma, \varepsilon_i, \varepsilon_f) \equiv \left| \int_0^\infty F_i^*(R) \bar{\Delta}(R) F_f(R) dR \right|^2 \quad (63.122)$$

[cf. Eq. (63.107)], where

$$\bar{\Delta}(R) = -q \int \psi_i^*(\mathbf{r}; \mathbf{R}) \mathbf{r} \psi_f(\mathbf{r}; \mathbf{R}) d\mathbf{r} \quad (63.123)$$

is the dipole moment, then using Eq. (63.119), the free-free contribution is given by

$$\begin{aligned}
I_0(\omega) &= \frac{N}{2} \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1) \\
&\times \int_0^\infty \frac{f(v)}{v} dv \mathcal{G}(\Gamma, \varepsilon_i, \varepsilon_f), \quad (63.124)
\end{aligned}$$

where $\varepsilon_i = \frac{1}{2}\mu v^2$, and u_{Λ_i} is the relative weight of state Λ_i [cf. Eqs. (63.106)–(63.108)]. The bound–free contribution is

$$I_1(\omega) = \frac{N}{2} \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1) \times \sum_i g(\varepsilon_i) \mathcal{G}(\Gamma, \varepsilon_i, \varepsilon_f), \quad (63.125)$$

and the free–bound contribution is

$$I_2(\omega) = \frac{1}{2} N \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1) \exp\left(-\frac{\hbar \Delta \omega}{k_B T}\right) \times \sum_f g(\varepsilon_f) \mathcal{G}(\Gamma, \varepsilon_i, \varepsilon_f), \quad (63.126)$$

where

$$g(\varepsilon) = 2\pi \left(\frac{\hbar}{\mu}\right)^2 \frac{f(v)}{v^2} = 8\pi^2 \left(\frac{\hbar}{\mu}\right)^2 \left(\frac{\mu}{2\pi k_B T}\right)^{3/2} \exp\left(-\frac{\varepsilon}{k_B T}\right), \quad (63.127)$$

on using Eq. (63.21) with $\varepsilon = \frac{1}{2}\mu v^2$. The full line profile is then given by Eqs. (63.124)–(63.126), so that

$$I(\omega) = \sum_{j=0}^2 I_j(\omega). \quad (63.128)$$

The satellite features that are often seen in line wings arise because turning points in the difference potential $[V_{\Lambda_i}(R) - V_{\Lambda_f}(R)]$ produce a phenomenon analogous to the formation of rainbows in scattering theory. The JWKB approximation is often used for the functions $F_{k_j l_j}(R)$ and can be shown to lead to the correct static limit in which transitions take place at fixed values of R called ‘‘Condon points’’, i.e., the Franck–Condon principle is valid. Further details are given in [4, 5, 22–24].

63.6 Unified Theories and Conclusions

The pressure broadening of spectral lines is, in general, a time-dependent many-body problem and as such cannot be solved exactly. After all, even the problem of two free electrons scattered by a proton is still a subject of active research. There is no practical theory that leads to the full static profile in the limit of high density (or low temperature) and to the full impact profile in the limit of low density (or high temperature). As with so many problems in physics, it is the intermediate problem that is intractable because no particular feature can be singled out as providing a weak perturbation on a known physical situation. However, much progress has

been made over the last 30 years in developing theories that take into account many of the key features of the intermediate problem, and they are often successful in predicting line profiles for practical applications [3–5, 22–24]. More recently, time-dependent many-body problems have been tackled using computer-oriented approaches that invoke Monte Carlo and other simulation methods to study line broadening in dense, high-temperature plasmas, see, for example, [25]. In this chapter, the emphasis has been on aspects of the subject that relate directly to electron–atom and low-energy atom–atom scattering. Many experts in the fields of electron–atom and atom–atom collisions are still not exploiting the direct applicability of their work to line broadening. It is hoped that this contribution will encourage more research workers to study these fascinating problems that not only provide links with plasma physics and, in particular, with the physics of fusion plasmas, but also with a quite distinct body of laboratory-based experimental data.

Part E
Scattering Experiment

Part E focuses on the experimental aspects of scattering processes. Recent developments in the field of photodetachment are reviewed, with an emphasis on accelerator-based investigations of the photodetachment of atomic negative ions. The theoretical concepts and experimental methods for the scattering of low-energy photons, proceeding primarily through the photoelectric effect, are given. The main photon–atom interaction processes in the intermediate energy range are outlined. The atomic response to inelastic photon scattering is discussed; essential aspects of radiative and radiationless transitions are described in

the two-step approximation. Advances such as cold-target recoil-ion momentum spectroscopy are also touched upon. Electron–atom and electron–molecule collision processes, which play a prominent role in a variety of systems, are presented. The discussion is limited to electron collisions with gaseous targets, where single collision conditions prevail, and to low-energy impact processes. The involving neutral molecules at chemical energies is presented. Applications of single-collision scattering methods to the study of reactive collision dynamics of ionic species with neutral partners are discussed.

Abstract

Investigations of photon–ion interactions have grown rapidly over the past few decades, primarily due to the increased availability of laser and synchrotron light sources. At photon energies below about 1 keV, the dominant radiative process is the electric dipole induced photoelectric

effect. In the gaseous phase, the photoelectric effect is referred to as either photoionization (atoms and positive ions) or photodetachment (negative ions). This chapter reviews the basics of negative ions, photodetachment, and the experimental methods used when the photodetachment process is applied to the study of negative ions. Negative ions of molecules and cluster exist, but this article covers only atomic negative ions. The monographs of *Massey* [1] and *Smirnov* [2] and a review by *Bates* [3] offer good introductions to the subject of negative ions. The focus will be on accelerator-based measurements. Reviews of experimental methods used to investigate the properties of negative ions have been published by, for example, *Andersen* [4], *Pegg* [5], and *Rienstra-Kiracofe* [6].

64.1 Negative Ions

Interest in negative ions stems from the fact that their structure and dynamics are qualitatively different from those of isoelectronic atoms and positive ions. This can be traced to the nature of the force that binds the outermost electron. In the case of atoms and positive ions, the outermost electron moves asymptotically in the long-range Coulomb field of the positively charged core. The relatively strong $1/r$ potential is able to support an infinite spectrum of bound states that converge on the ionization limit. In contrast, the outermost electron in a negative ion experiences the short-range induced-dipole field of the atomic core. The relatively weak $1/r^4$ polarization potential can typically sup-

port only a single bound state. The weakness of the attractive force is reflected in the binding energies of the outermost electron, i.e., the electron affinities, which are typically an order of magnitude smaller than the ionization energies of atoms. Weakly bound systems such as negative ions are ideally suited for investigations of the effects of electron correlation, which plays an important role in determining the structure and dynamics of many-electron systems [7]. As a result of the more efficient shielding of the nucleus by the atomic core, the electron–electron interactions become relatively more important than the electron–nucleus interaction. A major goal of photodetachment experiments is to measure correlation-sensitive quantities such as electron affinities, the energies and widths of resonant states, and asymmetry parameters describing photoelectron angular distributions. These quantities provide sensitive tests of the ability to incorporate electron correlation into theoretical models. The stimulating interplay between experiment and theory continues to help elucidate the role of many-electron effects in the structure and dynamics of atomic systems.

There exist a number of bound excited states of negative ions, but most of them have the same parity as the ground state [8]. As such, they are long lived and radiate via electric dipole-forbidden transitions. Dipole-allowed transitions have been observed in a few ions. In these cases, excited states connect to the ground state or other excited states of opposite parity [9–12]. Multiple excitations in a negative ion leads to the production of states embedded in continua lying above the detachment limits. Such quasi-discrete states are unbound and decay rapidly via the allowed process of Coulomb autodetachment. Most negative ions exhibit a rich spectrum of these short-lived states [5]. They are manifested as resonance structures at well-defined energies in photodetachment spectra.

Most, but not all, elements form stable negative ions. Exceptions are, for instance, the noble gases, nitrogen and magnesium. Here, the degree of correlation is insufficient to attach an extra electron. Negative ions of other atoms such as Ca have ground states that are very weakly bound and, therefore, easily destroyed [13, 14]. Some negative ions, such as Be^- [15], are formed in states that are embedded in continua but are metastable due to violations of the selection rules for Coulomb autodetachment. A prominent example is the $1s2s2p^4P$ metastable state of He^- [16, 17], which has a binding energy of 77 meV relative to the $1s2s^3S$ metastable state of He. Its decay via autodetachment is strongly suppressed by the selection rule on spin.

64.2 Photodetachment

Pioneering photodetachment experiments using lasers began in the mid 1960s with the work of *Hall* and coworkers [18–20]. The use of a tunable dye laser by *Lineberger* and

coworkers [21, 22] followed soon after. Essentially all information on the structure and dynamics of negative ions comes from controlled experiments in which electrons are detached from the ions when they interact with photons or other particles. Photodetachment is the preferred method since the energy resolution associated with such measurements is typically much higher than that attainable in any particle-induced detachment process. Generally, one or more electrons can be detached from a negative ion following the absorption of one or more photons in the photodetachment process. To date most measurements of the structure of negative ions involve the simplest process of single-electron detachment following single-photon absorption. In this process, the photon transfers energy and angular momentum to the negative ion, which subsequently breaks up into a neutral atom and an electron. The initial energy and angular momentum are conserved and shared in the final state by the residual atom and the free electron.

64.2.1 Photodetachment Cross Sections

The total cross section for photodetachment is proportional to the probability of detaching one electron while leaving the residual atom in its ground state or any of its excited states. The partial cross section describes the detachment probability for leaving the atom in a specific state, which could be either the ground or an excited state. The differential cross section, finally, represents the angular distribution of the detached electrons. Examples of the photon energy dependence of these three types of cross sections are shown in Fig. 64.1.

Fermi's golden rule predicts the photodetachment cross section to be proportional to the product of the square of the dipole matrix element connecting the initial and final states and the density of final states. The general behavior of a photodetachment cross section is that it starts at zero at threshold, rises to a peak that occurs at an energy of a few, to as much as tens of, eV above threshold, and then asymptotically approaches zero at higher energies. In Fig. 64.1a, the total cross section for the photodetachment of Na^- is given as an example. The increase in the probability of detachment just above threshold depends on the density of final states and the ability of the outermost electron to overcome a possible centrifugal barrier. The decrease in the cross section at higher energies is due to the declining overlap between the initial bound state wave function and the rapidly oscillating wave function representing the emitted electron. On top of the otherwise smooth behavior of the photodetachment cross sections different structures occur. One prominent feature that can be observed in certain special cases is called a Wigner cusp (see the sharp peak around 2.7 eV in Fig. 64.1a). This structure arises at the opening of an excited state channel when there

64.2.2 Threshold Behavior

Theoretical aspects of the general subject of threshold laws has been reviewed by Rau [27]. Cross sections for photodetachment are zero at threshold, in contrast to the finite value characteristic of photoionization cross sections. The threshold behavior for systems without Coulomb interaction is determined by the dynamics of the residual atom and the emitted electron. In general terms, Wigner demonstrated that for a two-body final state, the near-threshold cross section depends only on the dominant long-range interaction between the two product particles. The *Wigner law* [28] determines the energy dependence of the near-threshold cross section for the photodetachment of a single electron from an atomic negative ion. It can be written as

$$\sigma = Ak^{2l+1} = B(E - E_{\text{th}})^{l+1/2}, \quad (64.1)$$

where A and B are constants, and k and l represent the wavenumber and angular momentum quantum number of the detached electron, respectively; E is the photon energy, and E_{th} is the threshold energy for the photodetachment process. As a result of the electric dipole selection rules, the detached electron is represented, in general, by two partial waves $l = l_0 + 1$ and $l_0 - 1$, where l_0 is the angular momentum of the bound electron in the negative ion prior to detachment. In the case of photodetachment involving electrons with $l > 0$, the angular momentum dependence arises from the centrifugal force, $l(l + 1)/r^2$. The $1/2$ exponent is associated with the density of continuum states. Shorter-range final state interactions, such as those due to the electric dipole polarizability of the residual atom, will not change the form of the threshold behavior, as long as the potential falls off faster than $1/r$. They will, however, limit the range of validity of the Wigner law. The polarizability of the atom increases rapidly with the degree of excitation, making the range of validity correspondingly smaller. There is no a priori way of determining the range of validity of the Wigner law in any particular experiment. Measured threshold data is usually fit to the Wigner law in order to determine the threshold energy, as is shown in Fig. 64.1b in the case of K^- . It is possible to extend the range of the fit beyond that of the Wigner law.

is a strong configuration interaction between the ground state and excited state final continuum channels [23]. Other, more common, structures called resonances are the result of multiple excitation in the negative ion (see the inset of Fig. 64.1a). Cusps and resonances will be discussed in more detail in Sects. 64.2.2 and 64.2.3, respectively.

O'Malley [29], for example, considered the effects of atomic multipole forces on threshold behavior. *O'Malley's* formalism does not treat polarization explicitly. This is, however, accounted for in the modified effective range theory of *Watanabe* and *Greene* [30]. Anomalous threshold behavior can be observed in cases where there is a coupling of two final state channels as a result of configurational mixing. For example, a sharp feature has been observed in the partial cross section for the photodetachment of Na^- via the p-wave channel as a result of the strong coupling between this channel and the s-wave channel. The sharp peak at threshold in the p-wave channel is called a Wigner cusp, as can be seen in Fig. 64.1a.

64.2.3 Structure in Continuum

Photodetachment cross sections are often modulated by resonance structure at certain photon energies. The structure arises when more than one electron, or a core electron, is excited. These unbound quasi-discrete states are embedded in the continua above the first (or higher) detachment limit and are, therefore, subject to decay via the spontaneous process of autodetachment. The allowed autodetachment process is induced by the relatively strong electrostatic interaction between the outermost electrons. This process causes quasi-discrete continuum states to be very short lived. The decay of a quasi-discrete state in the continuum by autodetachment is manifested as a resonance structure in the detachment cross section, as can be seen in the inset of Fig. 64.1a. The shape of a resonance is determined by the interference between the two pathways for reaching the same final continuum state: direct detachment and detachment via the quasi-discrete state embedded in the continuum. A resonance can be parametrized by fitting it to a Fano profile [31]

$$\sigma(\omega) = \sigma_0 \frac{(q + \varepsilon)^2}{1 + \varepsilon^2}, \quad (64.2)$$

$$\varepsilon = \frac{\hbar\omega - E_r}{\Gamma/2}, \quad (64.3)$$

where σ denotes the cross section, σ_0 the nonresonant cross section, $\hbar\omega$ the photon energy, E_r the resonance energy, Γ the resonance width, and q a shape parameter. The resonance parameters (E_r , Γ) can be extracted from a fit to Eq. (64.2). If the selection rules on the allowed Coulomb-induced process are violated, the state may live much longer. Such metastable states eventually decay via autodetachment induced by weaker higher-order interactions.

64.2.4 Photoelectron Angular Distributions

For an unpolarized target, such as an ion beam, the angular distribution of the photoelectrons, i.e., the differential cross

section can, within the dipole approximation, be written in the form

$$\frac{d\sigma}{d\Omega} = \frac{\sigma}{4\pi} [1 + \beta P_2(\cos\theta)]. \quad (64.4)$$

Here, σ represents the total cross section, θ is the angle between the directions of the linear polarization vector of the photons and the momentum of the outgoing electrons, and $P_2(\cos\theta)$ is the second-order Legendre polynomial. The asymmetry parameter, β , characterizes the angular distribution or anisotropy of the photoelectrons. The angular distribution of the free electrons in the photodetachment process has been treated theoretically by *Cooper* and *Zare* [32]. They showed that the β parameter, in a central-potential model, can be described by

$$\beta = \frac{l(l-1)\sigma_{l-1}^2 + (l+1)(l+2)\sigma_{l+1}^2 - 6l(l+1)\sigma_{l-1}\sigma_{l+1}\cos(\delta_{l+1} - \delta_{l-1})}{(2l+1)l\sigma_{l-1}^2 + (l+1)\sigma_{l+1}^2}, \quad (64.5)$$

where l is the angular momentum of the electron prior to photodetachment, σ and δ are the dipole radial matrix elements and the residual phase shift of the interfering waves, respectively. A bound electron in an s-orbital ($l=0$) yields an outgoing electron represented by a pure p-wave. In this case, $\beta=2$ for all photon energies and the angular distribution has a pure $\cos^2\theta$ distribution. If, however, the bound state electron is in a p-orbital ($l=1$) prior to detachment, the outgoing electron will be represented by both s-waves and d-waves. Close to threshold the d-wave is suppressed due to the centrifugal barrier, and the s-wave dominates. In this case, $\beta=0$, and the angular distribution is isotropic. At higher energies, the value of β will be determined by the relative amplitudes of the s-waves and the d-waves, as well as their relative phases. This behavior can be seen in Fig. 64.1c, in the case of F^- . Most angular distribution measurements have been performed with a crossed laser and ion beams geometry [33, 34]. However, *Hanstorp* et al. [35] investigated the interference between s-waves and d-waves arising from the photodetachment of O^- using a collinear beams geometry. They introduced an approximation in the analysis of a measurement of the energy dependence of the β parameter. They showed that the phase difference between the s-waves and d-waves can be determined from the value of β at the minimum. A β -value of -1 means that the two waves are completely out of phase.

64.2.5 Higher-Order Processes

With the advent of high-power pulsed lasers, it has become possible to observe multiphoton detachment processes. Here, a single electron is ejected following the absorption of two or more photons. *Hall* et al. [18] performed the first such measurement on I^- . Early work in this area has been reviewed by

Blondel [36]. More recently, Bergues et al. [37] used a short-pulse, high-intensity laser to study photodetachment in the strong field regime.

In contrast, multielectron detachment involves the detachment of two or more electrons following the absorption of a single photon. This process, which appears to be initiated by the detachment of an inner shell electron, requires photons with energies higher than can be generated by conventional lasers. Such measurements can, however, be performed at synchrotron radiation [38–40] and free-electron laser sites [41].

64.3 Experimental Procedures

Experimental investigations of negative ions have been performed using ion traps [16], linear accelerators [42], and storage rings [43]. The focus of this article is on the use of photodetachment in accelerated-based measurements, which is by far the most commonly used method.

64.3.1 Production of Negative Ions

Negative ions are created in exoergic attachment processes when an electron is captured by an atom or molecule. These quantum systems are weakly bound with diffuse outer orbitals. As a consequence, they are easily destroyed in collisions with other particles. The production of negative ions with a density sufficiently high for spectroscopic studies poses a challenge to the experimentalist since processes involved in their creation must compete with more probable destruction processes. The most versatile source for the production of negative ions for accelerator-based experiments is the Cs sputter ion source [44]. This source has been used to generate a wide variety of atomic, molecular, and cluster negative ions. Alternatively, negative ions can be produced in a plasma source, either by direct extraction [45] or by extraction of positive ions that are converted to negative ions through a sequential double-charge transfer in an alkali vapor [15].

64.3.2 Interacting Beams

The most common method used for spectroscopic studies of negative ions is to form a unidirectional beam in an accelerator. Here, the ions are extracted from the ion source and focused to form a collimated beam that is accelerated to a desired energy of typically 1–30 keV. A bending magnet is used to select a single mass beam that is essentially monoenergetic. The ions then drift to the interaction region through a beamline that is maintained at low pressure to minimize destructive collisions with the residual gas. Negative ions have also been injected into storage rings, where repeated passes through the interaction region take place.

The well-defined spatial dimensions of an ion beam readily permit an efficient overlap with a beam of photons. Figure 64.2 schematically shows two different geometries that have been used in photodetachment measurements. If the ion and laser beam are merged collinearly, the product particle that is usually detected is the residual atom [46]. In this geometry, the laser beam can be either copropagating or counterpropagating with respect to the ion beam. If, however, the two beams are crossed with respect to each other, either the residual atom or the photoelectrons are detected.

The crossed beam arrangement is best suited for spectroscopic and angular distribution studies of the detached photoelectrons since they are, in this case, collected from a spatially well-defined interaction region. Further, crossed beams are advantageously used for absolute cross section measurements using the so-called animated beams method [47]. Here, the overlap of the ion and photon beam is determined by sweeping the laser beam through the ion beam.

The collinear beam arrangement, on the other hand, yields the best energy resolution. In almost all collinear beam experiments, the residual atoms have constituted the signal. The sensitivity of a measurement is significantly enhanced by the use of the large interaction volume defined by the collinear laser and ion beams. The energy resolution is determined by the convolution of the laser bandwidth and the Doppler broadening. Doppler broadening is the result of the divergence of both the ion and laser beams and the longitudinal velocity spread of the ions that originates from the motion

Fig. 64.2 Schematic showing both the crossed and collinear beam geometries. Negative ions (solid black line) are bent twice using two electrostatic deflectors. The trajectories of positive ions (dotted black line), neutral atoms (dashed black line), photoelectrons (blue lines), and the laser beam (red lines) are also shown. CEM represents “channel electron multiplier” detectors

of the ions in the ion source. The broadening due to the divergences of the two beams is greatly reduced by the use of a collinear interaction geometry. In this case, the derivative of the Doppler angle is zero since the two beams are superimposed at a crossing angle of zero. Furthermore, the longitudinal velocity spread is compressed in the collinear geometry [48]. In collinear beam experiments, the energy resolution will essentially be determined by the bandwidth of the light source. There will remain, however, a Doppler shift of the center-of-mass energy arising from the fast-moving ions. This energy shift can be determined experimentally by performing separate experiments, one with the ion and laser beams parallel and another with them antiparallel. The corrected energy can then be determined, to all orders, by taking the geometric mean of the two results [49].

64.3.3 Light Sources

Most photodetachment experiments to date have been performed using lasers. CW lasers have been used for high-resolution studies but, nowadays, pulsed lasers are most often preferred. The large peak powers characteristic of pulsed lasers are a necessity in, for example, multiphoton experiments. Lasers, in combination with nonlinear techniques such as frequency doubling or optical parametric oscillators, are used in photodetachment experiments to span a wavelength range from the ultraviolet to the infrared. Optical parametric oscillators have also become available commercially. In order to investigate inner shell excitation and detachment processes it is necessary to access the VUV or X-ray region. These regions are still outside the limits of conventional lasers and can only be accessed at synchrotron radiation or free-electron laser facilities.

64.3.4 Detection Schemes

Photodetachment events are usually monitored by detecting the particles (electrons, atoms, or positive ions) produced in the breakup of the negative ion. The heavy residual particles, atoms or positive ions, can be detected in both crossed and collinear beam experiments. The neutral atoms are efficiently detected by allowing them to impact on a solid target [50]. The secondary electrons thus produced can then be detected and used as the signal. The major source of background arises from collisions of the negative ions with the atoms and molecules of the residual gas in the vacuum chamber. By maintaining a high vacuum, typically 10^{-9} mbar or better, the background contribution can be kept at a tolerable level. The signal-to-noise ratio can be further enhanced by using time-gated detection, which becomes possible if a pulsed laser is used. The selectivity and sensitivity of a measurement is im-

proved significantly if the residual atoms are state-selectively detected, i.e., by performing a partial cross section measurement. This can be achieved using the method of resonance ionization spectroscopy [42]. Here, a second laser is used to excite the residual atom to a state near the ionization limit. This resonance step is followed by electric field ionization of the high-lying, Rydberg state. In this case, the resulting positive ions constitute the signal.

An alternative scheme for monitoring photodetachment events involves the detection of photoelectrons. This method is the most efficient if the laser and ion beams are perpendicularly crossed. The total cross section is measured by detecting the yield of photoelectrons, whereas the partial and differential cross sections are obtained by measuring their energy and angular distributions, respectively. Initially, electrostatic analyzers [51] and time-of-flight (TOF) spectrometers [52] were used in such studies. However, more recent measurements have favored a velocity mapping imaging (VMI) technique [53]. In a VMI spectrometer, an electric field is applied to the interaction region to guide all of the emitted electrons onto a position-sensitive detector. Velocity and angular information can be determined from the position on the detector, allowing both energy-resolved and angle-resolved measurements with a detection efficiency approaching 100%.

64.4 Measuring Properties of Negative Ions

64.4.1 Electron Affinities

Initially, most electron affinities (EA) were determined using photoelectron spectroscopy since such experiments could be conducted with a fixed-frequency laser, as long as the photon energy exceeded the EA . More recent EA measurements, however, involve the laser photodetachment threshold (LPT) method. Here, the normalized yield of residual atoms arising from photodetachment is recorded as a function of the photon energy in the near-threshold region of the cross section. The threshold position is obtained by fitting the Wigner law (Eq. (64.1)) to the data. The threshold can be accurately determined if a p-orbital electron is detached into a pure s-wave continuum. Then, according to the Wigner law, a sharp $E^{1/2}$ energy dependence at threshold is predicted. For many elements, however, an s-wave threshold is either not accessible within the energy range of the available laser, or the lowest energy process involves the detachment of an s-orbital electron. In the latter case, the cross section near threshold will exhibit a slowly rising onset, characteristic of a p-wave continuum. Under such circumstances, a high-resolution study of the EA would require access to an excited state threshold in order to detach into an s-wave continuum. The residual atom will then be left in a specific excited state, which can be detected using the RIS method, as was the case of K^- , shown

in Fig. 64.1b. This technique has been applied, for example, to negative ions of the alkalis [25], alkaline earths [42], and helium [17]. Until recently, all LPT measurements involved stable negative ions. However, the method has now been used at the CERN facility to make the first measurements of the electron affinity of a radioactive atom, in this case the radioactive isotope ^{128}I [54] and ^{211}At [55].

The LPT method has been used to accurately determine the electron affinities of many atoms. However, the most accurate affinity measurements to date have been performed using the photodetachment microscope method, pioneered by *Blondel* et al. [56]. Here, the photodetachment takes place in the presence of a weak electric field that provides two paths for the detached electron to travel from the interaction region to a position sensitive detector. In addition to yielding the highest resolution, the method also provides a beautiful demonstration of quantum interference.

The electron affinities of the atoms of the elements was last reviewed in 1999 by *Andersen, Haugen, and Hotop* [8]. *Blondel* is currently maintaining an updated list [57].

64.4.2 Bound States

Long-lived excited states of negative ions with the same parity as the ground state are known to exist. For example, the simplest, associated with the ground state configuration, would be excited fine structure levels and those arising from term splitting. More highly excited metastable states, with different electron configurations but the same parities as the ground state, are also present in a number of negative ions. The energy of such states has been determined using electron spectroscopy [58]. These states are long lived since they can only radiate via forbidden radiative transitions driven by M1, E2, or even higher-order processes. The principal method of measuring the lifetimes of these long-lived states is to use an ion storage ring. The time-varying population of the excited state due to radiative decay can be sampled by laser photodetachment on each trajectory around the ring [59]. The latest measurements have been performed at DESIREE in Stockholm, which is cryogenically cooled to an operating temperature of 13 K, resulting in an extremely low background pressure of 10^{-14} mbar. Such an environment greatly reduces the destruction of the negative ions by particle collisions. The longest lifetime observed so far, obtained in a study of S^- , is 503 ± 54 s [43]. More recently such experiments are now also conducted at the CSR storage ring in Heidelberg [60].

Until relatively recently, it was thought that bound excited states of negative ions that were able to radiate via allowed electric dipole transitions, were nonexistent. Now, however, it has been shown that such states are present in at least three ions, Os^- , [9] Ce^- [10], La^- [11] and Th^- [12]. The first clear observation of a bound-bound transition in a negative

ion was made on Os^- by *Bilodeau and Haugen* [9]. La^- was first studied using photoelectron spectroscopic methods to determine the energies of several of these bound states [61]. In a more recent photodetachment experiment, *Walter* et al. [11] used a crossed beams geometry to identify excited bound states in La^- . A two-step process was employed in which the first photon was used to excite the ion to an intermediate bound state, and a second photon was used to detach an electron from the ion in this state. One of the observed resonances was identified with the intermediate $^3\text{D}_1$ odd parity state that was excited from the $^3\text{F}_2$ even parity ground state. More recently, *Kellerbauer* et al. [62] showed, by performing a high resolution experiment, that this transition is a promising candidate for laser cooling. In 2019 *Tang* et al. [12] showed that also in Th^- there exist an electric dipole transition. Laser cooling of negative ions is of considerable interest to the antimatter physics community since, potentially, it could be used to sympathetically cool antiprotons.

64.4.3 Continuum Processes

Detachment continua contain a wealth of structure, and many Feshbach resonances in negative ions have been studied. The simplest negative ion is the two-electron H^- ion. This three-body Coulomb system is fundamentally important in our understanding of the role played by electron correlation in the atomic structure. The pioneering measurements of the photodetachment of one and two electrons from the H^- ion were performed by *Bryant* and coworkers [63, 64]. In this work, the ion-frame photon energy was scanned by Doppler tuning the angle between a relativistic H^- beam and a laser beam. ASTRID (Aarhus Storage Ring Denmark) was later used in two measurements of resonance structure in H^- with much higher resolution than the previous measurements [65, 66]. Subsequent, collinear beam experiments by *Hanstorp* and coworkers revealed resonance structure in the photodetachment continua of the metastable He^- ion [67] and the alkali-metal negative ions [68, 69].

Synchrotron radiation has been used over the past few years in order to study how negative ions respond to the absorption of high-energy photons. Photons in the VUV and X-ray regions will excite and/or detach inner shell electrons. Multiple electron detachment appears to be initiated by the excitation of a core electron. This process triggers the ejection of one or more valence electrons, either by shake-off or by interactions of the detached core electron with the valence electrons as it leaves the atom. For example, measurements of the absolute cross sections for the detachment of two electrons from the closed shell ions Cl^- [38] and Li^- [39] have been reported. The Advanced Light Source (ALS) has been used to investigate resonance structure and multielectron detachment processes, where, for instance, resonances

associated with the photodetachment of inner-shell electrons have been observed in K^- [70] and He^- [71]. Currently, the most intense light source in the UV regime is the free-electron laser (FEL). *Pedersen* and coworkers used a FEL to study the branching of single-to-double detachment in the photodetachment of O^- [41]. The intense light pulse from the FEL permitted the photoelectron spectrum to be studied using a magnetic bottle spectrometer. More recently, multiphoton detachment of negative ions are also conducted at the PETRA III synchrotron radiation source [40].

64.5 Investigation of Fundamental Processes

A weakly bound quantum system such as a negative ion allows one to study fundamental photon-ion interactions in atomic physics.

64.5.1 Threshold Studies

The photodetachment threshold, as described by Wigner (Eq. (64.1)), is unique in the sense that an atomic process can be described with a very simple analytical expression. Small deviations from this law can be used to observe various physical processes. For example, *Larson* and coworkers applied this approach to negative ions in order to study the fundamental problem of particle breakup in magnetic [72] and electrical [73] fields. Small oscillations in the threshold cross sections were observed superimposed on the normal Wigner behavior.

Atomic dipole polarizabilities are normally positive (as would be expected from a classical model of a dipole in an electric field). However, in certain special cases, an atomic polarizability can be negative, which can only be explained in a quantum context. In recent experiments involving the photodetachment of K^- [74] and Na^- [75], anomalous threshold behavior was observed in which the onset of the photodetachment process occurred at a photon energy well above the predicted threshold energy. This was attributed to the fact that the highest members of a manifold of excited states in alkali atoms have a negative polarizability. In such cases, the Wigner law is no longer valid.

64.5.2 Photodetachment Using Short Laser Pulses

The combination of a weakly bound quantum system such as a negative ion and the strong electric fields associated with intense laser radiation is suitable for fundamental investigations of multiphoton detachment processes. The internal structures of the negative ions of hydrogen and the halogens

Fig. 64.3 Momentum and angular distributions observed in the strong laser field-induced photodetachment of Br^- . Reprinted with permission from [76]. Copyright 2008 by American Physical Society

are particularly suited for such experiments since the initial state is well defined. In addition, long-range $1/r$ potentials are absent in the final state arising from photodetachment.

Kiyan et al. [53] conducted a number of experiments on multiphoton detachment using a velocity-mapping imaging technique. For example, they used intense femtosecond laser pulses to study excess photon detachment (EPD) in the F^- ion, in which many more photons were absorbed than were necessary to reach the detachment threshold [37]. It was also observed that the angular distribution of the ejected photoelectrons became highly directional along the laser polarization vector, as can be seen in the case of EPD of Br^- shown in Fig. 64.3 [76].

Kiyan et al. also used the photodetachment process to create a ground state atom in carbon [77] and silicon [78] that was in a superposition of its fine structure levels. In this superposition state, the atom exhibited spatial oscillations. The oscillations were monitored by applying a second laser, in a pump-probe arrangement, to photoionize the atom.

64.6 Observations and Applications of Negative Ions

Negative ions occur naturally, in both astrophysical environments (plasma state) and terrestrial environments (matter in the liquid and gaseous phases). They also play a role in numerous applications.

64.6.1 Natural Occurrence of Negative Ions

Negative ions are difficult to detect in natural environments due to the rarity of bound excited states and, consequently, the lack of emission/absorption spectra. One of the first iden-

tifications of negative ions in nature was made by *Wildt* in 1939 [79]. He suggested that absorption seen in the black-body radiation spectrum from the sun was the result of photodetachment of H^- in the photosphere. This prediction was confirmed in subsequent calculations and experiments by *Branscomb* and *Smith* [80]. In 2006, the CH_6^- ion was detected in the interstellar medium [81]. This first identification was followed by the observation of other ions in the following years [82]. In addition, negative ions occur in abundance both in liquids, where Cl^- ions in the sea is the most obvious example, and in gases, such as in the Earth's atmosphere.

64.6.2 Applications of Negative Ions

Negative ions have a role in numerous applications. Several applications are based on the fact that the outermost electron in a negative ion is weakly bound and, therefore, easy to remove. For example, in the field of thermonuclear fusion, a commonly used method of heating the plasma in a tokamak reactor is to inject an intense, high-energy beam of neutralized D^- ions. The removal of the outermost electron has so far been achieved by the use of particle collisions; however, the process could be made more efficient if photodetachment were used [83]. The same neutralization principle has also been used to produce fast beams of atoms for particle collision experiments [84]. Currently, one of the most important applications of negative ions is in the field of accelerator mass spectrometry (AMS) [85], which is the most sensitive method for trace element analysis. AMS is based on a tandem accelerator, in which a beam of negative ions produced at the low-energy end of the accelerator is converted into positive ions at the high-voltage terminal. In many cases, however, a major limitation on sensitivity is the presence of interfering atomic isobars in the beam leaving the ion source. The photodetachment process has the potential to overcome such problems by overlapping the negative ions beam with a laser beam prior to injection into the tandem accelerator. The interfering isobar can then be removed from the ion beam by photodetachment provided that the EA of the isobar of interest is larger than the interfering isobar. However, photodetachment cross sections are, unfortunately, typically small due to the nonresonant nature of the bound-free process. As a consequence, only a small fraction of the interfering isobar will normally be detached, even when a powerful laser is employed in a collinear geometry. One viable solution to this problem is to slow down the ion beam in an RF cooler in order to increase the interaction time. It has been shown that using photodetachment in combination with an RF cooler can reduce the presence of an interfering isobar by many orders of magnitude [86]. A successful proof-of-principle of this method has been performed at the VERA facility in Vienna, [87].

David Pegg holds a BSc (Manchester, 1963) and a PhD (New Hampshire, 1970). He has worked at the University of Tennessee, Knoxville (1970–2006) with a research base at Oak Ridge National Laboratory (1971–2000). His research interests lie in the structure and dynamics of positive and negative ions. He has taken part in collaborative research at Lund, Lyon, Brookhaven, and Lawrence Berkeley National Laboratories and is in long-term collaboration with the University of Gothenburg.

Dag Hanstorp received his PhD at the University of Gothenburg in 1992 and now holds a professorship at the same university. He was Chairman of the Scientific Council for Natural and Engineering Sciences at the Swedish Research Council 2019–2021. His research is focused on laser spectroscopy of negative ions and optical levitation.

Abstract

Theoretical and experimental aspects of the atomic photoelectric effect at photon energies up to about 1 keV are presented. Relevant formulae and interpretations are given for the various excitation and decay processes. Techniques and results of photoelectron spectrometry in conjunction with synchrotron radiation are emphasized.

Keywords

photoelectric effect · partial cross section · double ionization · natural width · Auger decay

65.1 Theoretical Concepts

Scattering of low-energy photons proceeds predominantly through the photoelectric effect. In this process a photon γ of

energy $h\nu$, angular momentum $j_\gamma = 1$, and parity $\pi_\gamma = -1$ interacts with a free atom or molecule A , having total energy E_i , angular momentum J_i , and parity π_i to produce an electron of energy ε , spin $s = 1/2$, orbital angular momentum ℓ , total angular momentum j , and parity $\pi_e = (-1)^\ell$ and an ion A^+ with final total energy E_f , angular momentum J_f , and parity π_f . This process can be written as the reaction

$$\gamma(h\nu, j_\gamma = 1, \pi_\gamma = -1) + A(E_i, J_i, \pi_i) \rightarrow A^+(E_f, J_f, \pi_f) + e^-[\varepsilon, \ell s j, \pi_e = (-1)^\ell] . \quad (65.1)$$

Conservation laws require that

$$\begin{aligned} h\nu + E_i &= \varepsilon + E_f , \\ \mathbf{J}_i + \mathbf{j}_\gamma &= \mathbf{J}_f + \mathbf{s} + \boldsymbol{\ell} , \\ \pi_i \cdot \pi_\gamma &= \pi_f \cdot \pi_e = (-1)^\ell \cdot \pi_f . \end{aligned} \quad (65.2)$$

Since $E_f - E_i$ becomes quite large for inner shells or deep core levels, scattering of low-energy photons involves the removal of an electron from a valence or shallow core level. In the low-energy regime, from the first ionization threshold to $h\nu \approx 1$ keV, the photoelectric effect accounts for more than 99.6% of the photon interactions in the elements, with elastic scattering contributing the remainder [1, 2]. Ionization by inelastic scattering, the Compton effect, assumes increasing importance with the higher photon energies and the lower Z elements. Above the first ionization potential, the total photoabsorption cross section and the photoionization cross section are essentially equivalent at the lower photon energies.

The cross section σ_{if} for producing a given final ionic state in the photoionization process is given by

$$\sigma_{if} = \frac{4\pi^2\alpha^2}{k} \sum |\langle \Psi_f | \hat{T} | \Psi_i \rangle|^2 , \quad (65.3)$$

where k is the photon momentum, \hat{T} is the transition operator, Ψ_i and Ψ_f are the wave functions of the initial and final states, and the summation includes an average over all initial

states and a summation over all the unobserved variables in the final state. A detailed derivation of this expression, including the different forms for \hat{T} , is given in the articles by *Fano* and *Cooper* [3] and *Starace* [4] and in Chap. 25. The total cross section is given by the sum of all these different partial cross sections, σ_{if} .

65.1.1 Differential Analysis

Detailed information about the photoionization process can be obtained most directly in emission measurements, especially those involving the photoelectron. The resulting photoelectron spectrum yields the energy and intensity for a given interaction. Further differentiation is obtained by varying the angle of observation and by a spin analysis of the photoelectron. Hence, electron emission analysis can reveal all energetically allowed photoprocesses connecting an initial atomic state i to a final ionic state f and yield their dynamic properties. When averaged over the spin, the differential cross section $d\sigma_{if}/d\Omega$ is given in terms of the partial cross section σ_{if} and an expression involving an expansion in Legendre polynomials of order n with the coefficients B_n

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi}\right) \sum_n B_n P_n(\cos\theta), \quad (65.4)$$

where the angle θ is measured between the direction of the emitted electron and the unpolarized incoming photon beam. In the *dipole* approximation, which describes the dominant process at low energy, only the terms containing P_0 and P_2 contribute. Then Eq. (65.4) reduces, for a photon beam with linear polarization p , to

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi}\right) \left[1 + \frac{\beta_{if}}{4}(1 + 3p \cos 2\theta)\right], \quad (65.5)$$

where the angle θ lies in the plane perpendicular to the direction of propagation and is measured with respect to the major axis of the polarization ellipse [5]. Then, the differential cross section, or photoelectron angular distribution, is characterized by the single angular distribution or anisotropy parameter β_{if} for a particular process $i \rightarrow f$. For observation at the so-called pseudomagic angle θ_m , defined as

$$\theta_m = \frac{1}{2} \cos^{-1}\left(\frac{-1}{3p}\right), \quad (65.6)$$

the differential cross section $d\sigma_{if}/d\Omega$ becomes proportional to the angle-integrated, or partial, cross section σ_{if} .

In the absence of correlation effects, the partial cross section σ_{if} for the production of an individual final state and the corresponding anisotropy parameter β_{if} are given by simple

expressions derived from a single-particle model [1, 4]. For the central field potential,

$$\sigma_{if} = \frac{4\pi^2\alpha}{3} a_0^2 N_{n\ell} h\nu \times \left[\left(\frac{\ell}{2\ell+1}\right) R_-^2 + \left(\frac{\ell+1}{2\ell+1}\right) R_+^2 \right], \quad (65.7)$$

where $N_{n\ell}$ is the occupation number of the subshell, and

$$\beta_{if} = \frac{\ell(\ell-1)R_-^2 + (\ell+1)(\ell+2)R_+^2}{(2\ell+1)[\ell R_-^2 + (\ell+1)R_+^2]} - \frac{6\ell(\ell+1)R_+R_- \cos\Delta}{(2\ell+1)[\ell R_-^2 + (\ell+1)R_+^2]}. \quad (65.8)$$

The subscripts $+$ and $-$ refer to the $(\ell+1)$ and $(\ell-1)$ channels respectively, and $\Delta = \delta_+ - \delta_-$ is the difference in phase shift between these two allowed outgoing waves. The parameter R_{\pm} is the radial dipole matrix element connecting the electron in the bound orbital with orbital angular momentum ℓ with the outgoing wave having orbital angular momentum $\ell \pm 1$.

Effects of the electron correlation on the direct photoionization process can result in values for β which are not reproduced by the Cooper–Zare expression in Eq. (65.8) [4]. The contribution of the different partial waves to the outgoing wave function can, however, be ascertained through the angular momentum transfer formalism developed by *Fano* and *Dill* [6]. In this approach, one defines the angular momentum transferred from the photon to the unobserved variables j_t as

$$\mathbf{j}_t = \mathbf{j}_\gamma - \ell = \mathbf{J}_f + \mathbf{s} - \mathbf{J}_i, \quad (65.9)$$

where the second portion of the equality results from the conservation of angular momentum. For each allowed value of j_t the associated transfer can be defined as either parity favored or parity unfavored according to whether the product $\pi_i \pi_f$ is equal to $+(-1)^{j_t}$ or $-(-1)^{j_t}$ respectively. (All symbols have the same definition as in Eq. (65.1).) Calculation of the partial cross section for the production of a given final state characterized by the values \mathbf{J}_f and \mathbf{s} is then determined from the cross section corresponding to each angular momentum transfer according to

$$\sigma_{if} = \sum_{j_t} \sigma(j_t). \quad (65.10)$$

The associated anisotropy parameter β_{if} is derived from a similar sum

$$\sigma_{if} \beta_{if} = \sum_{j_t=\text{fav}} \sigma(j_t)_{\text{fav}} \beta(j_t)_{\text{fav}} - \sum_{j_t=\text{unfav}} \sigma(j_t)_{\text{unfav}}. \quad (65.11)$$

The second equation derives from the fact that $\beta(j_i)$ for each parity-favored value must be calculated separately, whereas for the parity-unfavored case $\beta(j_i) = -1$ always.

The physical effect described by the angular momentum transfer approach is the interaction between an electron and the anisotropic distribution of the other electrons in the atom. Thus, it becomes most useful in the case of ionization from an open-shell atom having an extra electron or a hole in a shell with $\ell \neq 0$. An illustrative example is the 3s ionization of chlorine. Here $\beta_{if} = 2$ identically in Eq. (65.8) because only the single value $\ell = 1$ is allowed in the single-particle model. However, the three possible values, $j_t = 0, 1, 2$ are allowed, of which only the first corresponds to the Cooper–Zare or single-particle, central field result [4]. That $\beta \neq 2$ for 3s ionization of atomic chlorine has been demonstrated experimentally [7].

It is generally the case for ionization of elements which are found naturally in the atomic state that there is an equal population in all the fine-structure components of the initial state. This is because of the relatively small energies associated with the fine-structure splitting. (This does not necessarily apply to atomic species generated through a process of molecular dissociation or high-temperature metal vaporization.) Thus, the determination of all cross sections and angular distributions involves an average over these fine-structure components. However, it is possible to generate atoms in which one of the fine-structure components is preferentially populated. In this case there can also be a preferential ionization to a particular J -component of the final ionic state even in the limit in which the electron correlation is neglected, i.e., the geometrical limit. The partial intensities for the production of a given ionic state characterized by the angular momenta $L_f S_f J_f$ by removal of an electron from an orbital ℓ of a state characterized by $L_i S_i J_i$ are given by

$$R_\ell^{L_f S_f J_f} = \frac{[J_f][L_f][S_f]}{[1/2][\ell]} g(\ell, L_i, S_i, L_f, S_f) \times \sum_{j=\ell-1/2}^{j=\ell+1/2} [j] \left\{ \begin{array}{ccc} \ell & 1/2 & j \\ L_i & S_i & J_i \\ L_f & S_f & J_f \end{array} \right\}^2. \quad (65.12)$$

Here the term in curly brackets is a 9- j symbol, and the notation $[J] = 2J + 1$ is used. The quantities $g(\ell, L_i, S_i, L_f, S_f)$ are weighting factors determined solely by the initial-state wave function. For the case in which ℓ represents a closed shell, these factors are equal to unity [8].

In situations in which the target atoms possess an initial orientation, i.e., have an average value $\langle J_z \rangle \neq 0$, or if the ionization is performed with circularly polarized radiation, the electrons which are produced have a net spin [9, 10]. It is also possible that unpolarized atoms which are ionized by unpolarized photons can have a net spin, provided that the

detection is carried out at a specific angle, and the ionization is from a given fine-structure component of the initial state to a given fine-structure component of the final state. In the latter case, the transverse spin polarization is given by

$$P = \frac{-2\xi \sin \theta \cos \theta}{1 + \beta P_2(\cos \theta)}, \quad (65.13)$$

for linearly polarized radiation, and by

$$P = \frac{2\xi \sin \theta \cos \theta}{2 - \beta P_2(\cos \theta)}, \quad (65.14)$$

for unpolarized radiation [11, 12]. The angle θ is the same as in the angular distribution measurement; the parameter ξ is the spin parameter analogous to β ; and $P_2(\cos \theta)$ is the Legendre polynomial of order 2.

Yet another parameter which describes the differentiation inherent in the photoionization process is the alignment A , which reflects an anisotropy in the quadrupole distribution of the angular momentum J_f of the ion [12]. For the cylindrically symmetric coordinate system appropriate to dipole photon excitation, only one moment A_0 of the distribution is nonzero. This is defined by

$$A_0 = \frac{\sum_{m_j} [3m_j^2 - J_f(J_f + 1)] \sigma(m_j)}{J_f(J_f + 1) \sum_{m_j} \sigma(m_j)}, \quad (65.15)$$

where $\sigma(m_j)$ is the partial cross section for production of a given m_j component of J_f . A very useful approach to the interpretation of the alignment can be obtained through the angular-momentum-transfer formalism [13]. In this approach the angular momentum transfer j_t is defined as

$$\mathbf{j}_t = \mathbf{j}_\gamma - \mathbf{J}_f. \quad (65.16)$$

In contrast to the case of the electron angular distribution, it is possible to derive an alignment for each value of j_t as a function of the angular momentum J_f of the ion. The net alignment is then the incoherent sum of the contributions corresponding to each

$$A_0 = \sum_{j_t} A_0(j_t) \sigma(j_t) / \sum_{j_t} \sigma(j_t). \quad (65.17)$$

If the photoionization produces an ion in an excited state which decays by photoemission, the parameter A_0 is reflected either in the angular distribution of the fluorescence photons $I(\theta)$ or the linear polarization P measured at one angle, typically 90° , according to

$$I(\theta) = I_0 \left[1 - \frac{1}{2} h^{(2)} A_0 P_2(\cos \theta) + \frac{3}{4} h^{(2)} A_0 \sin^2 \theta \cos(2\chi) \cos(2\eta) \right] \quad (65.18)$$

or, for $\theta = \pi/2$ and $\chi = 0$,

$$P = \frac{I(\eta = 0) - I(\eta = \pi/2)}{I(\eta = 0) + I(\eta = \pi/2)} = \frac{3h^{(2)}A_0}{4 + h^{(2)}A_0}, \quad (65.19)$$

respectively. The angle θ is the angle at which the fluorescence is determined, and the angle χ is measured between the axis of the polarization selected by the detector and the quantization axis. The polarization of the fluorescence is given by $\zeta = (\cos \eta, i \sin \eta, 0)$. The quantity $h^{(2)}$ is a ratio of $6-j$ symbols depending on the angular momenta J_f of the intermediate ion and the final state J'_f

$$h^{(2)} = (-1)^{J_f - J'_f} \times \left\{ \begin{matrix} J_f & J_f & 2 \\ 1 & 1 & J'_f \end{matrix} \right\} / \left\{ \begin{matrix} J_f & J_f & 2 \\ 1 & 1 & J_f \end{matrix} \right\}. \quad (65.20)$$

When it is energetically allowed, a hole in a shallow inner-shell will preferentially undergo Auger decay, emitting an electron with an energy ε_A determined by the energy difference between the energy E_f of the ion and E'_f of the state of the doubly-charged ion to which the decay occurs. Angular analysis of the Auger electrons reflects the alignment of the intermediate ionic state, which is different from, and does not bear a one-to-one relationship to, the angular distribution parameter β of the photoelectrons. Normally, Auger decay is regarded as a two-step process in which the first step is the production of the hole and the release of the primary photoelectron, followed by the decay and the release of the second electron. Within this approximation [14], the angular distribution of the Auger electrons takes on the simple form

$$I(\theta) = \left(\frac{I_0}{4\pi} \right) [1 + \alpha_2 A_0 P_2(\cos \theta)]. \quad (65.21)$$

Here $P_2(\cos \theta)$ is the second-order Legendre polynomial, and α_2 is the matrix element corresponding to the Auger decay. For the specific case in which the Auger decay is to a final ionic state of 1S_0 symmetry, α_2 is purely geometric, and a measurement of the angular distribution leads directly to a determination of the alignment. Correspondingly, if the alignment of a specific state can be determined through such a decay, then analysis of the angular distribution of the decay to other states provides a value for α_2 .

65.1.2 Electron Correlation Effects

The primary focus of advanced studies in photoionization is to determine the role played by electron correlation in the structure and dynamics of electron motion above the lowest ionization threshold. Because the form of the interaction potential for the Coulomb interaction is very well

known, theory can focus on the many-body aspects of the process (Chap. 24). Electron correlation manifests itself in many ways. Most prominent are the appearance of autoionization structure due to the excitation of one or two electrons, the production of correlation satellites due primarily to the ionization of one electron accompanied by the excitation of another, and the creation of two continuum electrons in a double ionization process.

Autoionization resonances are perhaps the oldest known features associated with electron correlation (Chap. 26). These features arise when the absorption of a photon creates a localized state which lies in energy above at least one ionization limit. This state is then degenerate in energy with a state of an electron in the continuum, and the interaction between these states results in the decay of the quasi-localized state into the continuum. Such resonance states appear in an absorption spectrum in the form of strong, localized variations over an energy range characteristic of the width Γ of the feature, which is in turn related to the lifetime τ of the state by

$$\Gamma = \hbar/\tau. \quad (65.22)$$

In contrast to absorption features between bound states, autoionization resonances are characterized by having an asymmetric line shape. When only one localized state and one continuum are involved, these line shapes can be derived analytically, as first shown by *Fano* [15] and later by *Shore* [16], resulting in simple parametrized forms which are suitable for numerical calculation of overlap integrals for determining widths. For the Fano profile

$$\sigma(\epsilon) = \sigma_a \frac{(\epsilon + q)^2}{\epsilon^2 + 1} + \sigma_b, \quad (65.23)$$

with

$$\epsilon = \frac{E - E_r}{(\Gamma/2)}, \quad (65.24)$$

the parameter q describes the asymmetry of the line, E_r is the resonance position, and Γ is the width of the line. The parameters σ_a and σ_b reflect the relative contributions to states in the continuum which do and do not interact with the autoionizing state respectively. The energy E_r does not correspond to the peak energy E_m of the resonance feature but is related to the maximum through

$$E_m = E_r + \frac{\Gamma}{2q}. \quad (65.25)$$

The Shore profile,

$$\sigma(\epsilon) = C(\epsilon) + \frac{A\epsilon + B}{\epsilon^2 + 1}, \quad (65.26)$$

describes the same phenomenon except that the interpretation of the parameters A and B is different. In this case, they represent products of dipole and Coulomb matrix elements. $C(\epsilon)$ is the continuum contribution.

From an experimental point of view, the parametrized forms for the Fano and Shore profiles are very useful as a basis for fitting autoionization spectra. However, they both have the limitation that they only describe the interaction of an isolated state with the continuum. While they can be extended to include several continua [4], they do not allow for an interaction among two or more localized states [17, 18]. Nevertheless, it is possible to use these functions to achieve often good fits of states which do interact with each other, as these functions are mathematical representations of localized resonances in a continuous spectral distribution. If this is done, the parameters no longer have the physical meaning which they have for the noninteracting case.

Mixing of discrete ionization channels with competing continuum channels adds complexity to the photoionization process, not just in the classical autoionization regime but also in the vicinity of inner shells [19–21]. In a rigorous application of the Mies formalism [17], feasible with modern computer power, even complex experimental spectra can now be satisfactorily interpreted and reproduced. A case in point is the excitation spectrum from the 2p level of the open-shell chlorine atom [19].

The process of autoionization is discussed in more detail in Chap. 26. In Fig. 65.1 an example is shown of the set of $2s^2 2p^3(^4S) \rightarrow 2s 2p^3 np$, $n \geq 3$ autoionization resonances which decay into the 3P ground state of the N^+ ion [22]. The energies E_n of these resonances are related to the ionization limit E_∞ of the series by the Rydberg formula

$$E_n = E_\infty - R_\infty / (n - \mu_s)^2, \quad (65.27)$$

where n is the principal quantum number and μ_s is the quantum defect characteristic of a given series and reflecting the short-range electrostatic interactions of the electron with the ion core. Values of μ_s for s, p, d, and f electrons have been calculated for atoms and ions up to $Z = 50$ [23]. For high precision work, the reduced Rydberg constant

$$R_M = \frac{R_\infty}{1 + 5.485\,799 \times 10^{-4} / (M_A - m_e)} \quad (65.28)$$

should be used instead of the value R_∞ for infinite nuclear mass (Chap. 1). The atomic mass M_A and the electron mass m_e are in a.u.

A process closely related to the autoionization phenomenon is resonant Auger decay. This process differs from the ordinary Auger process [24] in that an electron from an inner shell is not ionized but excited to either a partially filled or an empty subshell. It may be viewed either as an Auger process or as autoionization. Such an inner-shell excited state

Fig. 65.1 Autoionization resonances $2s^2 2p^3(^4S) \rightarrow 2s 2p^3 np$ in atomic nitrogen

of a neutral atom (molecule) lies above one or more of the ionization limits of the singly ionized species and consequently must decay by electron emission unless the decay is forbidden by selection rules. As a result, resonance structure will appear superimposed on the continua of direct photoionization from the various subshells. From a most general point of view, the resonant Auger process can be considered as resonances in the continua of single photoionization, while the ordinary Auger process can be regarded as resonances in the continua of double photoionization. If excitation proceeds to a partially filled subshell *within* a principal shell, as, for example, Mn 3p \rightarrow 3d [20], interference between the direct photoionization channels and the indirect resonance channel may be strong, and the lineshapes are given by Eq. (65.23) with arbitrary q values and σ_a/σ_b ratios. If, however, the excitation proceeds to an empty shell, as, for example, Mg 2p \rightarrow ns or nd, $n \geq 4$, interference with the direct channels is likely to be negligible, and the resulting resonances are distinguished by essentially Lorentzian line shapes (as for normal Auger lines) with $q \gg 1$ and $\sigma_a/\sigma_b \gg 1$ in Eq. (65.23). For a given excitation state a number of resonance peaks may arise because more than one ionization channel is usually available and, in addition, the excited electron can change its orbital from n to $n' = n \pm 1, 2, \dots$ in a shakeup or shakedown process [25].

As a consequence of the electron–electron interactions which occur simultaneously with the electron–photon interaction, ions are produced in states which do not correspond to those which would be expected based on an interpretation using an independent particle model, which allows for only a single-electron transition (Chap. 25). Evidence for these states appears as correlation satellites in the photoelectron spectrum, the Auger electron spectrum or the X-ray spectrum [26]. Figure 65.2 [27] presents as an example the photoelectron spectrum of argon produced by photons with $h\nu = 60.6$ eV. In addition to the 3s main line of single electron

Fig. 65.2 Photoelectron spectrum (PES) of 3s, 3p satellites in argon at a photon energy of 60.6 eV. Note the reduced intensity of the satellites compared to the 3s main line

photoionization (and the 3p main lines not shown) numerous satellite lines are seen as the manifestation of two-electron transitions involving ionization-with-excitation correlations. It is convenient to categorize the satellites in a photoelectron spectrum according to various electron correlations, as, for example, initial state interactions which mix different configurations into the initial state, and final state interactions, which include core relaxation and electron–electron interactions in the final ionic state, electron–continuum, and continuum–continuum interactions. While initial-state correlations are essentially independent of the photon energy, final-state correlations depend on the energy of the photon through the interactions with the continuum channels. However, the heuristic value of placing correlation effects into a strict classification scheme is limited by the fact that their relative strengths depend on the basis set used in a particular theoretical model and its expansion into a *fully correlated* system within a given gauge [3, 4, 28, 29] (see also Chap. 25).

Another manifestation of double-electron processes is the simultaneous excitation of two electrons to bound states. These states may decay by electron or photon emission and are seen as resonance structures above the thresholds of inner-shell ionization or near autoionizing members of Rydberg series. As single or double ionization continua are usually strong in the spectral range of the double excitations, interference occurs, and the lineshapes can display dispersion forms. Typically, the cross section for the sum of all correlation processes is between 10 and 30% of that for single photoionization, but may exceed this range considerably in special cases.

Photon scattering near thresholds is complex because of the possibility of strong interactions between the various particles created and the different modes of deexcitation (Chap. 66). In the case of ionization-with-excitation pro-

cesses, the threshold cross section is finite, as it is for single electron photoionization, in accord with Wigner’s theorem [30] (Sect. 64.2.2). In the case of double photoionization, the cross section is zero at threshold and then rises according to Wannier’s law [31] (Chap. 56). For the motion of two electrons with essentially zero kinetic energies in the field of the ionic core,

$$\sigma \propto E^{(2\mu-1)/4}, \quad (65.29)$$

where μ depends on the value of the nuclear charge Z through

$$\mu = \frac{1}{2} \left(\frac{(100Z - 9)}{(4Z - 1)} \right)^{\frac{1}{2}}. \quad (65.30)$$

For $Z = 1$ the Wannier exponent has the value 1.127.

In the case of Auger decay following ionization at threshold, interaction between the two electrons results in a shift in the energy of the Auger electron and a corresponding shift in that of the photoelectron (to conserve energy), as well as an asymmetry in the shape of the Auger electron peak and a corresponding asymmetry in the photoelectron peak shape. In this so-called post-collision interaction (Chap. 66), the lineshape, averaged over angles, has the form [32]

$$K(\varepsilon) = \frac{(\Gamma/2\pi)}{(\varepsilon - \varepsilon_A)^2 + (\Gamma/2)^2} f(\varepsilon) \quad (65.31)$$

with

$$f(\varepsilon) = \frac{\pi \psi}{\sinh(\pi \psi)} \exp \left[2\psi \tan^{-1} \left(\frac{\varepsilon - \varepsilon_A}{(\Gamma/2)} \right) \right]. \quad (65.32)$$

In the above equations, ε is the energy of the Auger line, ε_A is the nominal Auger energy, Γ is the initial hole-state width, and the parameter $\psi = 1/\sqrt{2\varepsilon_e} - 1/\sqrt{2\varepsilon_A}$, with ε_e being the energy of the photoelectron, and $\varepsilon_A \geq \varepsilon_e$.

65.2 Experimental Methods

An overview of the experimental approaches to the study of photon interactions at low energies is given in Fig. 65.3. The sketch emphasizes the interaction of a polarized photon beam with a small static or particle-beam target of atoms, ions, molecules, or clusters, and the detection of the reaction products at various angles in a plane perpendicular to the direction of propagation of the photon beam, where the general equation in Eq. (65.5) is valid. Emission products, such as electrons, ions, or photons, may be studied by way of the total yields, which can be related to the total photoionization cross section, or by differential analysis in a spectrometer according to energy, intensity, emission angle, and polarization.

Fig. 65.3 Generic arrangement for detection of particles in an emission measurement. The incoming radiation is assumed to be linearly polarized along the z -axis

The various particles may be measured independently, simultaneously, or in coincidence. The photon monitor provides the information for normalization of the data with regard to flux and polarization. The photon monitor can also be used for a measurement of the total photoionization cross section, equivalent to the photoabsorption or photoattenuation coefficient at low photon energies. For this purpose, the size of the target source is advantageously increased in the direction of the photon beam. While experimental apparatus differs, sometimes drastically, for the photon sources as well as for the spectrometry of electrons, ions, and fluorescence photons, many features are common, and the relationships of the measured quantities to basic properties of the atoms and the photon–atom interaction are similar. Thus, the following will place emphasis only on the roles of the synchrotron radiation source and photoelectron spectrometry, whereas specific references to other methods can be found elsewhere [5, 33–38].

65.2.1 Synchrotron Radiation Source

The primary source of photons over a broad energy range for experiments in the VUV and soft X-ray region of the spectrum is the synchrotron radiation source [39, 40]. In a synchrotron or electron storage ring, radiation is produced as the electrons are bent to maintain the closed orbit. Such bending magnet radiation is emitted in a broad continuous spectrum which begins in the infra-red and ends sharply

at a critical photon energy given by $h\nu_c = \kappa E_e^2$, where E_e is the energy of the electrons in the ring and κ is a constant characteristic of the ring. Synchrotron radiation can also be generated by introducing additional magnetic field structures [41] into the ring, such as undulators or wigglers, which produce a deviation of the electron motion from a straight path in a well-defined manner. Wiggler radiation has the same spectrum as a bending magnet, except that the critical energy is generally much higher because the effective magnetic fields can be larger than those of the bending magnet. Undulator radiation is very different in that it consists of a sharp spiked profile of about a 1% bandwidth at energies determined by the magnetic field within the undulator and by the electron beam energy in the storage ring.

Synchrotron radiation, no matter what the magnetic field structure of the source, requires monochromatization before it can be used for experiments. For the wavelengths of interest in low-energy photon scattering, this can be achieved by using grating instruments with a metallic coating on the grating surface. The highest resolution possible is obtained through the use of a normal incidence monochromator (NIM) with a plane grating set at normal incidence. However, because the reflectivity of the metallic coating at normal beam incidence decreases drastically as the photon energy increases, use of a NIM has an upper limit of about 40 eV. At energies above this, up to about 1 keV, gratings can still be used but must be mounted at grazing incidence. There is a number of functional designs for these grazing-incidence instruments which vary in the shape of the grating – spherical, toroidal, or plane surfaces (SGM, TGM, PGM) – and the associated optics. Above 1 keV, gratings are no longer suitable, and crystal diffraction must be used. While the radiation emerging from a beamline which couples the monochromator to a bending magnet, wiggler, or undulator has a high degree of linear polarization, varying from 80 to 99% in the plane of the electron orbit, a useful flux of circularly polarized radiation can be derived from out-of-plane radiation [33], by the use of multiple reflection optics, or from a helical undulator.

65.2.2 Photoelectron Spectrometry

The primary particle emitted in photoionization is the photoelectron. Hence, a photoelectron spectrum provides a detailed view of the photon interaction by (a) specifying the individual processes from an initial state i to a final state f by way of the electron energy, (b) determining their differential and partial cross sections by recording the number of electrons as a function of emission angle, and (c) measuring the polarization of the electrons by a spin analysis (spin polarimetry). The experimental approach is governed largely by the relations in Eqs. (65.3), (65.5), and (65.6). The num-

ber of electrons N_{if} (e) detected per unit time at an angle θ within an energy interval $d\varepsilon$ and within a solid angle $d\Omega$ is given by

$$N_{if}(e) = GN(h\nu)N(A)f(h\nu)f(\varepsilon)\frac{d\sigma_{if}}{d\Omega}d\varepsilon \quad (65.33)$$

where G is a geometry factor, which includes the source dimensions, $N(h\nu)$ the number of photons, $N(A)$ the number of atoms in the source, $f(h\nu)$ and $f(\varepsilon)$ efficiency factors depending, respectively, on photon and electron kinetic energies, and $d\sigma_{if}/d\Omega$ is the differential cross section for a particular transition $i \rightarrow f$. Equation (65.33) assumes that $d\Omega$ and $d\varepsilon$ are sufficiently small that integration over the pertinent parameters is not needed. Since $N_{if} \propto d\sigma_{if}/d\Omega$, a measurement at two angles, e.g., $\theta = 0^\circ$ and 90° , yields the electron angular distribution parameter β_{if} according to Eq. (65.5), and a measurement at θ_m in Eq. (65.6) yields the partial cross section σ_{if} . In the case of closed-shell atoms, $n\ell j$ notation is sufficient to designate single ionization to an $\varepsilon\ell$ continuum, e.g., $3p_{1/2,3/2} \rightarrow \varepsilon s$ or εd in argon, but for open-shell atoms LSJ notation is required, e.g., $3P^5(2P^0_{3/2}) \rightarrow 3P^4(3P^e_{2,1,0}, 1D^e_2, 1S^e_0)\varepsilon\ell(2D^e, 2P^e, 2S^e)$ in chlorine. Similarly, for ionization-with-excitation transitions, the final state requires an open-shell designation.

The sum of the partial cross sections is equal to the total photoionization or absorption cross section

$$\sigma_{\text{tot}} = \sum_{i,f} \sigma_{if} \quad (65.34)$$

where the σ_{if} encompass (a) single ionization events in all energetically accessible subshells $n\ell j$, or the LSJ multiplet components, (b) ionization-with-excitation events (shakeup or shakedown), and (c) double ionization events (shakeoff). All σ_{if} can be determined from a photoelectron spectrum from its discrete peaks (cf. Fig. 65.2) and from the continuum distribution of multiple ionization. However, the latter process is measured more readily by observing the multiply charged ions in a mass spectrometer.

The differentiation afforded by measuring the various partial cross sections, and the associated β parameters, can be augmented by differentiating the continuum channels according to the spin using a spin polarimeter [33]. In closed-shell atoms, this allows for an experimental determination of the relevant matrix elements and phase shifts, and hence for a direct comparison with theory at the most basic level [34, 35]. In a more global measurement, the cross section σ_{tot} is obtained by ion or mass spectrometry from

$$\sigma_{\text{tot}} = \sigma(A^+) + \sigma(A^{2+}) + \sigma(A^{3+}) + \dots \quad (65.35)$$

Generally, the charge states can be correlated with the various initial photoionization processes if allowance is made for

Auger transitions and the fluorescence yield upon exceeding the binding energies of core levels.

If the charge states are not distinguished, as in a total ion yield measurement, σ_{tot} is obtained directly. Similarly, a direct measurement of the global quantity σ_{tot} is obtained by the total electron yield, although care must be exercised to avoid discrimination by angular distribution effects. At photon energies below about 1 keV, ionization, absorption, and attenuation are virtually equivalent, and σ_{tot} can also be determined in an ion chamber setup [36] or in a photoabsorption measurement in which the number of photons ΔN absorbed in a source of length d and having an atom density n is given by

$$\Delta N = N(\text{ph})[1 - \exp(-\sigma_{\text{tot}}nd)] \quad (65.36)$$

with $N(\text{ph})$ being the flux of incident photons. As a rule, in all experiments employing the relation in Eq. (65.5), the total, partial, or differential cross sections are determined on a relative rather than an absolute scale because it is very difficult to know accurately such factors as the geometry of the source volume and the number density. However, once a single absolute value of σ_{tot} or any σ_{if} is available, all relative values of the other quantities can be converted to absolute values.

An electron spectrometric experiment can be carried out in three different operational modes, as defined in Fig. 65.4. In the most conventional mode, PES, the photon energy is fixed, and a scan of the electron kinetic energy reveals all the electron-emission processes possible and yields their properties. The CIS (constant ionic state) mode is especially suited to follow continuously a selected process as a function of photon energy by locking onto a given state $E_f - E_i$ (denoted by E_B) which requires a strict synchronization of the photon energy ($h\nu$) and electron kinetic energy (ε) during a scan. This mode is particularly advantageous to elucidate resonance features, such as autoionization resonances. Finally, a CKE (constant kinetic energy) scan allows one to access various processes sequentially or, most importantly, follow a process of fixed energy, such as an Auger transition, as a function of photon energy. This description also includes the technique of zero-kinetic-energy measurements. Most frequently, the PES and CIS modes are employed, and Fig. 65.5 gives a self-explanatory example of an actual experiment directed at the characterization of the argon $3s \rightarrow np$ autoionizing resonances. It should be stressed that the cross section σ_{tot} can be partitioned into its components by CIS scans that differentiate between the $3p_{1/2}$ and $3p_{3/2}$ doublet states.

Energy analysis can be performed either by electrostatic energy analyzers or by time-of-flight techniques. The latter is well-suited to those electrons which have very low ki-

Fig. 65.4 Energy relationship among the three different operational modes of the technique of photoelectron spectrometry. E_B is the binding energy of the level

Fig. 65.5 Connection between the PES and CIS techniques as illustrated by the $3s \rightarrow np$ autoionization resonances in argon

netic energy, including threshold electrons with $\varepsilon \approx 0$ eV. Of the electrostatic energy analyzers now in use, two designs are prevalent, the cylindrical mirror analyzer (CMA) and the hemispherical analyzer, where the latter readily lends itself to the application of multichannel detectors.

65.2.3 Resolution and Natural Width

The details that can be gleaned from an experiment using photons depend on the resolution achievable with the particular photon source and spectrometry used, the particular excitation or analysis modes and the target conditions chosen, and, ultimately, on the natural width of either the levels or transitions examined as well as any fine structure present. Generally, the instrumental and operational resolution should approach, but need not exceed by much, the natural width inherent in the photoprocess under scrutiny. The demands are most severe for processes involving outer levels because of their typically very narrow widths, and are relatively mild for processes involving inner levels [5, 35]. It is desirable that in the former case the resolving power (the inverse of the resolution) of the instrument exceed 10^5 , while in the latter case 10^4 may suffice. If the target atoms move randomly, a resolution limit is set by the thermal motion, namely

$$\Delta\varepsilon = 0.723 (\varepsilon T/M)^{1/2} \text{ (meV)}, \quad (65.37)$$

where, in an experiment involving photoelectron spectrometry, ε is the kinetic energy of the photoelectron in eV, T the temperature in K, and M the mass in a.u. of the target atom. This contribution can be limited in first order by employing a suitably directed atomic beam.

The experimental peak-width and shape generally contain the natural width; the extent to which instrumental factors enter depends on the specific experiment. In a measurement of the total or partial photoionization cross section in which either the fluorescence photons, the electrons, or the ions are monitored, the resolution of the photon source (often called the bandpass) is the only instrumental contributor. This applies specifically to the CIS mode of electron spectrometry, in which features are scanned in photon energy and the electron serves solely as a monitor. However, in such a CIS study, or a corresponding fluorescence study, the resolution of the electron or fluorescence spectrometer must be adequate to be able to distinguish adjacent processes. For the example of Fig. 65.5, the $3p_{3/2}$ and $3p_{1/2}$ levels of Ar need to be separated if the partial photoionization cross sections are to be determined across the resonances. In such a case of more than one open ionization channel, the natural widths of the features will be identical in all channels [4], but the shapes may be different. In emission processes subsequent to initial photoionization, namely electron (Auger) decay or photon (X-ray) emission, the resolution of only the spectrometer performing the detection counts on the instrumental side. In the PES mode (Fig. 65.4) the observed lines contain contributions from all sources, the photon source or photon monochromator, the electron analyzer, thermal broadening, and the natural level width. In the special case of photo-

processes near inner thresholds, the post-collision interaction influences the position and shape of photoelectron and Auger lines (Chap. 66).

Excluding threshold regions and the resonant Raman effect, the line profile observed in the various experiments is given by the Voigt function

$$V(\omega, \omega_0) = \int L(\omega' - \omega)G(\omega' - \omega_0)d\omega'. \quad (65.38)$$

In this the Lorentzian function L represents the natural level or transition profile, and the Gaussian function G is representative of the window functions of the dispersive apparatus. Although the integral representing the Voigt profile has no analytic form, it can be represented for practical purposes by the analytic Pearson-7 function [42]

$$P_7(\varepsilon) = A \left(1 + \frac{(\varepsilon - \varepsilon_0)^2}{B^2 C} \right)^{-C}, \quad (65.39)$$

where A is the peak height, ε_0 the peak position, B the nominal half-width-half-maximum of the peak, and C the shape of the peak. In the limit in which $C = 1$, this function is identically a Lorentzian; in the limit $C \rightarrow \infty$, the function is essentially Gaussian. Use of this function allows one to fit the resulting photoelectron spectrum using standard numerical techniques. If the width of the feature is the only quantity of interest, the simple approximate expression

$$\frac{\Gamma_L}{\Gamma_V} = 1 - \left(\frac{\Gamma_G}{\Gamma_V} \right)^2 \quad (65.40)$$

which relates the Voigt width Γ_V with the Lorentzian width Γ_L and the Gaussian width Γ_G can be used to determine either Γ_L or Γ_G from the measured Γ_V [5]. Often the observed feature exhibits a dispersive shape given by the Fano or Shore profile. In this instance the instrumental function must be convoluted with the resonance profiles given by Eq. (65.23) or (65.26) in order to fit the data and to extract the parameters [43].

For the special case of resonant Auger decay in which the bandpass of the exciting radiation is very narrow compared with the natural width of the excited state, the experimental linewidth is governed by the width of the exciting radiation, and will be more narrow than the natural width of the line. The resulting lineshape in this resonant Raman effect is then the simple product [24]

$$L'(\omega, \omega_0) = L(\omega)G(\omega - \omega_0), \quad (65.41)$$

where $L(\omega)$ is the line profile as determined by the natural width, typically Lorentzian for resonant Auger decay, and $G(\omega - \omega_0)$ is the, usually, Gaussian function representing the bandpass of the exciting radiation.

65.3 Additional Considerations

Although low-energy photon interactions are well described nonrelativistically in the dipole approximation, relativistic and higher multipole effects which become increasingly important at higher energies cannot be ignored even below 1 keV. Spin-orbit effects [44] and relativistic effects [45] are of special significance even at low energies in Cooper minima, where one of the transition matrix elements becomes zero. Moreover, the use of intermediate coupling, which includes both the spin-orbit and electrostatic interactions [46], is required in open-shell systems, as exemplified for the halogen atoms and atomic oxygen [47]. Level energies of heavy elements also require a relativistic treatment [48] (Chap. 23), and it is natural to employ relativistic formulations for calculating the spin parameters appearing in photoionization [49].

Although low energy photon scattering is dominated by the dipole contribution, experiments and theory have shown higher multipole effects to be present at $h\nu < 1$ keV [50–57]. As a result, measurements that take the dipole formulations as a basis in Eqs. (65.5) and (65.6) can incur a discernible error in both the differential cross sections $d\sigma_{if}/d\Omega$ and the partial cross sections σ_{if} . A more accurate determination of $d\sigma_{if}/d\Omega$ can be made [51, 55, 56] on the basis of the equation

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi} \right) \left[1 + \beta P_2(\cos \theta) + (\delta + \gamma \cos^2 \theta) \sin \theta \cos \phi \right], \quad (65.42)$$

using linearly polarized radiation, where $P_2(\cos \theta)$ is the second-order Legendre polynomial, θ is the angle between the electron emission direction and the electric vector, ϕ is the angle between the electron and photon directions, β is the angular distribution parameter related to B_2 , and the parameters δ and γ are related to B_1 and B_3 in Eq. (65.4). Figure 65.6 shows the geometry for the relationship between the photoelectron momentum vector, the polarization vector, and the photon momentum vector,

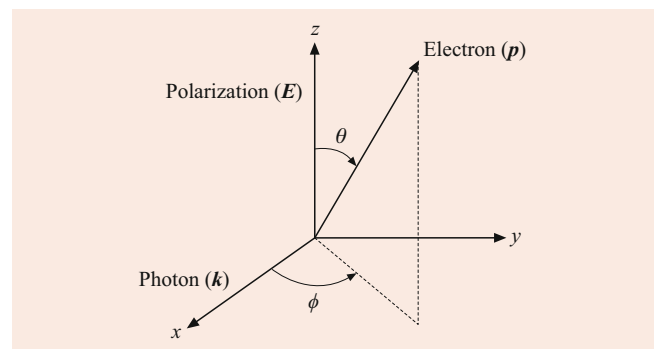

Fig. 65.6 Geometry of the relationship between the photoelectron momentum p , the polarization vector E , and the photon momentum k . (Courtesy of O. Hemmers)

and the photon propagation vector as used in Eq. (65.42). It serves as the template for the arrangement and motion of the electron detector, or, for added efficiency and accuracy, several detectors [51–53, 56]. The parameters β , δ , and γ have been calculated for most subshells of the noble gases for photoelectron energies between 100 eV and 5 keV [55] and 20 eV to 5 keV [57]. Generally, the electric quadrupole (E2) and magnetic dipole (M1) photoionization channels are the most important beyond the dipole (E1) photoionization channel. Similar to the dipole angular distribution parameter β , the parameter γ may also be subject to interchannel coupling and relativistic effects, as demonstrated for xenon 5s photoionization [51].

Abstract

This chapter provides an overview of our understanding of photon–atom interactions involving soft x-rays, hard x-rays, and gamma-rays with “intermediate” photon energies roughly between 1 keV to 1 MeV (37 a.u. to 37×10^3 a.u.). These energies correspond to wavelengths of 1.2 nm to 1.2 pm, where the electronic shell structure of a multielectron atom can be probed, and resonant excitations and deexcitations can be important. Here, we will emphasize the cross sections of various processes, which are independent of the intensity of the incoming electromagnetic field. We explore elastic Rayleigh scattering and inelastic scattering, including photoionization, Auger, Raman, and Compton processes. We describe various experimental methods, Monte Carlo approaches and other applications of the sets of atomic data, all spanning the intermediate energy range.

66.1 Overview

The photon–atom interactions through the intermediate 1 keV to 1 MeV regime are broadly classified into elastic and inelastic processes, depending on whether the outgoing photon energy changes [1, 2]. The interactions are also classified into coherent or incoherent processes [3]. In this chapter, we will explore the physics of each process through the intermediate energy regime.

The atom–photon interaction Hamiltonian in this regime involves the quantized radiation field corresponding to a photon of frequency ω , wave vector \mathbf{k} , and polarization vector $\boldsymbol{\epsilon}^{(\alpha)}$, which couples to the electron position \mathbf{r} , via [4]

$$\mathbf{A}_{k\alpha}(\mathbf{r}, t) \propto c \sqrt{\frac{\hbar}{2\omega}} \boldsymbol{\epsilon}^{(\alpha)} e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)}, \quad (66.1)$$

with speed of light c . The quantized radiation field operator is then built through creation and annihilation operators over field modes

$$\hat{\mathbf{A}}(\mathbf{r}, t) = \sum_{\mathbf{k}, \alpha} [\hat{a}_{k\alpha} \mathbf{A}_{k\alpha}(\mathbf{r}, t) + \hat{a}_{k\alpha}^\dagger \mathbf{A}_{k\alpha}^*(\mathbf{r}, t)], \quad (66.2)$$

which gives the interaction Hamiltonian, H_{int} , by summing over $j = 1, N$ electrons with momentum \mathbf{p}_j

$$H_{\text{int}} = \sum_j \left[\frac{e^2}{2m_e c^2} \hat{\mathbf{A}}(\mathbf{r}_j, t)^2 - \frac{e}{m_e c} \mathbf{p}_j \cdot \hat{\mathbf{A}}(\mathbf{r}_j, t) \right], \quad (66.3)$$

where e and m_e are the charge and mass of the electron. This form assumes that $\mathbf{p}_j \cdot \hat{\mathbf{A}}(\mathbf{r}_j, t) = \hat{\mathbf{A}}(\mathbf{r}_j, t) \cdot \mathbf{p}_j$ as per the Coulomb gauge [4].

Fig. 66.1 Feynman diagram vertices for the photon interaction in the Hamiltonian H_{int} (Eq. (66.3)). The *solid lines* represent the electronic states of the atom, the *squiggly lines* are the interacting photons [5]

The two terms in the interaction Hamiltonian in Eq. (66.3) are best visualized through the two Feynman vertices shown in Fig. 66.1. The A^2 term shown in Fig. 66.1a only couples to the position of the electron. This permits instantaneous two-photon absorption, emission, and scattering processes, which begin to dominate at intermediate photon energies [5]. The $\mathbf{p} \cdot \mathbf{A}$ term shown in Fig. 66.1b couples to both the position and momentum of the electron and allows for single-photon absorption and emission processes (including via an intermediate state). The solution to the $\mathbf{p} \cdot \mathbf{A}$ term in the Hamiltonian in Eq. (66.3) is normally undertaken with perturbation theory, where the number of interacting photons determines the order of the process, e.g., first order are single-photon absorption and emission processes, and second order are scattering processes.

66.2 Scattering Cross Sections

For time-dependent scattering processes such as absorption, emission, and scattering, the photon contributes to both real and virtual transitions between atomic states, including the atomic continuum, and must also be systematically included [4]. Using time-dependant perturbation theory, the scattering of a photon by an atom can be considered through transition amplitudes, \mathcal{T}_{fi} between atomic states either discrete or through a continuum [6]. The photon scattering transition rate $\Gamma_{i \rightarrow f}$ and the cross section $\sigma_{i \rightarrow f}$ are [7]

$$\Gamma_{i \rightarrow f} \propto \int \frac{|\mathcal{T}_{fi}|^2}{T} d^3k, \quad \sigma_{i \rightarrow f} \propto \int \frac{|\mathcal{T}_{fi}|^2}{|\Phi_i|T} d^3k, \quad (66.4)$$

where d^3k is a differential of the outgoing photon frequency, Φ_i is the incoming photon flux, and T is the duration of the interaction. The differential cross sections, $d\sigma/d\Omega$, are usually computed through the Kramers–Heisenberg–Waller formula, which includes both A^2 and $\mathbf{p} \cdot \mathbf{A}$ terms [4]. From a time-independent viewpoint, off-resonant interactions pro-

duce successive Stark corrections of the eigenstates and eigenenergies of the unperturbed atomic system described through the (frequency dependent) polarizability [8].

An example of the cross sections of various processes for atomic hydrogen is shown in Fig. 66.2. Such cross section data are often tabulated as photon mass attenuation coefficients, (μ/ρ) , which describe the decay of the photon beam of intensity I (given incoming intensity I_0) as [9–11]

$$\frac{I}{I_0} = \exp(-\mu d) = \exp\left[-\left(\frac{\mu}{\rho}\right)x\right] = \exp\left[-\left(\frac{\sigma}{m}\right)x\right], \quad (66.5)$$

where μ is the attenuation coefficient, d is the thickness of the material, ρ is the nominal density of the material, $x \equiv (\rho d)$ is the mass thickness, which are all related to σ , the relevant atomic scattering cross section, through the atomic mass $m \equiv uA$ where u is the atomic mass unit, and A the relative atomic mass. An illustrative way to gauge the scale of the various cross sections is to compare them, as can be seen in Fig. 66.2, relative to the Thomson (free-electron) scattering cross section,

$$\sigma_{\text{Th}} = \frac{8\pi}{3} \alpha^4 a_0^2 = 6.652\,458\,7321(60) \times 10^{-29} \text{ m}^2, \quad (66.6)$$

where a_0 is the Bohr radius, and the classical electron radius $r_e = a_0 \alpha^2 \approx 2.8$ fm. The error brackets indicate the standard uncertainty in the last two digits of the 2018 CODATA value [12]; $\sigma_{\text{Th}} \approx 6.65 \times 10^{-25} \text{ cm}^2 = 0.665 \text{ barn} = 66.5 \text{ fm}^2$, which is much smaller than the scale of an atomic cross section of πa_0^2 , due to the factor of $\alpha^4 \approx 3 \times 10^{-9}$. This dictates that away from thresholds and resonances the photon–atom coupling strength is weaker than typical electron–atom interactions, e.g., the electron–hydrogen threshold elastic scattering cross section is around $30\pi a_0^2$ [13]. Instead, as the size of r_e suggests, σ_{Th} is on the order of typical nucleon–nucleon interactions, e.g., the low-energy proton–aluminium total cross section is about 0.65 barn, whilst the fundamental proton–proton cross section is smaller at about 0.04 barn [14].

We now discuss several aspects that Fig. 66.2 highlight:

1. *Elastic photon–atom scattering* (solid line in Fig. 66.2), also known as Rayleigh scattering [3], shows the classic ω^4 dependence for sub-10 eV energies before hitting the atomic $1s \rightarrow np \rightarrow 1s$ excitation resonances between 10.2–13.6 eV. If the wavelength of the incoming photon is large compared to the dimensions of the atom, the dipole approximation $e^{i\mathbf{k} \cdot \mathbf{r}} \approx 1$ holds. In this regime, the vector potential $\mathbf{A}_{k\alpha}(\mathbf{r}, t)$ (Eq. (66.1)) does not significantly depend on the position of the electron \mathbf{r} ; this means that the A^2 term does not directly couple with the atom. Therefore, the $\mathbf{p} \cdot \mathbf{A}$ term dominates for transitions at lower incoming photon energies [5]. An analytic solution

Fig. 66.2 Theoretical (total) cross sections for photon–atomic hydrogen scattering given incoming photon energy in eV, and dimensionless cross sections, $\sigma/\sigma_{\text{Th}}$, are scaled by the Thomson cross section σ_{Th} . The nonrelativistic elastic (Rayleigh) scattering result is the *solid line* (shown up to 100 a.u. = 2.7 keV) and includes resonances. The FFAST [11] database results are included as the + symbols (photoionization) and × symbols (coherent + incoherent). The XCOM [9] results above 1 keV are the *solid squares* (coherent), *solid circles* (incoherent), and *open triangles* (pair-production processes). The Bergstrom et al. [15] results are shown as the *dot-dash line* (coherent), *dashed line* (incoherent), *dash-dot-dot line* ($\mathbf{p} \cdot \mathbf{A}$ Compton). The Drukarev et al. $\mathbf{p} \cdot \mathbf{A}$ Compton calculations [16] are shown as the *three-dash line*. The *filled triangles* are the $\sigma_{\text{K-N}}$ Klein–Nishina cross section (scaled by 10 since it otherwise lies over the other data above 10^5 eV perfectly, indicated by the *vertical arrows*)

to the Kramers–Heisenberg equation exists for hydrogen [17, 18], which approaches the Thomson scattering cross section (the cross section of a photon interacting with an electron in vacuum) at around 100 eV energy. Elastic scattering is classified as “coherent”, shown in Fig. 66.2 for FFAST [11] and XCOM [9] theoretical data, where relativistic effects are important by around 1 keV, which will be discussed further shortly.

There is also, for high- Z atoms, the nuclear (Thomson) scattering of the photon from the nuclear charge that also contributes to the elastic cross section [19–21]. At intermediate photon energies, the nucleus interacts like a point charge, and so the nuclear contribution to the total cross section is [19]

$$\sigma_N = Z^4 \left(\frac{m_e}{M} \right)^2 \sigma_{\text{Th}}, \quad (66.7)$$

where M is the mass of the nucleus. For light atoms, this is very small, e.g., for hydrogen $\sigma_N \approx 3 \times 10^{-7} \sigma_{\text{Th}}$, which is well below the range shown in Fig. 66.2.

2. *Inelastic single-photon photoionization* (the + symbols in Fig. 66.2) dominates above the ionization threshold. As it

is a first-order process, in this energy regime, it is orders of magnitude above the scale of the other processes shown but then reduces with increasing photon energy. The photoionization process is both inelastic and incoherent [22]. For hydrogenic systems, there are analytic results [23], and there are systematic calculations and databases of photoionization cross sections [24], which will be discussed later. Not shown are small radiative corrections to the photoionization cross sections [25], which, above the ionization threshold, are on the same order as the Rayleigh contributions [15].

3. *Inelastic Compton scattering* (shown in Fig. 66.2) is considered to be “incoherent” and is also an inelastic contribution to the cross section [22]. This process requires that the photon have enough energy to photoionize the atom and eject an electron, however, with an associated emission of a photon with a lower frequency than the incident [7, 26]. Compton scattering involves both $\mathbf{p} \cdot \mathbf{A}$ and \mathbf{A}^2 Hamiltonian terms [16]. Figure 66.2 shows the calculations for hydrogen by Drukarev et al. [16] (the line with three dashes) and Bergstrom et al. [15] (the dot-dot-dash line), where only the $\mathbf{p} \cdot \mathbf{A}$ terms were included and shows

a relatively small contribution between onset at 13.6 eV up to about 500 eV. The differences between these two calculations can be explained by the different numerical cut-offs applied that truncate the infrared divergence [27]. The A^2 term represents the dominant method of transferring momentum during Compton scattering [28]. It dominates at keV and above incoming photon energies [5], where atomic recoil is more important, and the dipole approximation is increasingly not valid. This is seen in the incoherent scattering results in Fig. 66.2 from Bergstrom et al. [15] (line with small dashes), which rises up from 100 eV and crosses over the $\mathbf{p} \cdot \mathbf{A}$ Compton cross section and at 1 keV connects with the incoherent XCOM database results [9] (the large dots in Fig. 66.2). Including the A^2 term only is known as the impulse approximation [5].

Not shown in Fig. 66.2 is (inelastic) Raman scattering [29], which has $1s-np-ns$ resonances [30]; for hydrogen these behave similarly to those seen for Rayleigh scattering in Fig. 66.2. However, the Raman cross sections are generally smaller than the Rayleigh and Compton cross sections above the ionization threshold.

4. *Relativistic scattering* of a photon from a free-electron has an analytic result given by the Klein–Nishina formula [27, 31, 32], which, in dimensionless form, is

$$\frac{\sigma_{K-N}}{\sigma_{Th}} = \frac{3}{4} \left[\frac{(1+\epsilon)}{\epsilon^3} \left(\frac{2\epsilon(1+\epsilon)}{(1+2\epsilon)} - \ln(1+2\epsilon) \right) + \frac{\ln(1+2\epsilon)}{2\epsilon} - \frac{(1+3\epsilon)}{(1+2\epsilon)^2} \right], \quad (66.8)$$

where $\epsilon = E/m_e c^2 \approx \hbar\omega/511$ keV. This is also shown in Fig. 66.2, where at energies about 10^4 eV, there begins a significant departure from the Thomson value, σ_{Th} . The curve tracks the hydrogen calculations almost perfectly through the keV to MeV energies, compared to the database and numerical cross sections. Note that the relativistic treatment of photon-particle scattering includes virtual particle creation [4].

The inclusion of relativistic effects on the photon–atom scattering cross sections is mostly clearly seen in the decrease of the coherent XCOM database results [9] starting at energies from 1 keV and above (large squares in Fig. 66.2). They rely on relativistic atomic form factors such that Rayleigh scattering cross sections are approximated as [33],

$$\sigma_{coh} = \frac{3}{8} \sigma_{Th} \int_{-1}^1 (1 + \cos^2 \theta) [F(x, Z)]^2 d(\cos \theta), \quad (66.9)$$

where Z is the atomic number and $x = \sin(\frac{1}{2}\theta)/\lambda$ of wavelength, λ . Numerical methods to compute $F(x, Z)$

rely on the density distribution of the electron/s, whilst $F(x, Z) \rightarrow 0$ and, thus, $\sigma_{coh} \rightarrow 0$ at keV energies (large x). Attempts to improve the form-factor approximation hit some limitations [3], however, calculations using the relativistic impulse approximation show that the Compton scattering cross sections are in general agreement with the Klein–Nishina formula at keV–MeV energies [34]. It is possible to systematically include relativistic, retardation, and higher multipole effects [15, 35].

For all atoms through the intermediate keV to MeV energy regime, photoionization tends to dominate all scattering cross sections, but there is a cross-over point where incoherent inelastic scattering processes begin to dominate. The cross-over point generally increases with the atomic number, e.g., for copper atoms, it crosses over at around 100 keV [2].

5. *Nuclear scattering* processes contribute towards both the elastic and inelastic scattering amplitudes [3]. As mentioned above, there is elastic (nuclear) Thomson scattering, but there are other high-energy processes that can exceed that of (bound electron/s) Rayleigh scattering cross sections around the GeV and above energy range. XCOM data (glimpsed at GeV energies in the bottom-right corner of Fig. 66.2), shows the scattering cross section for electron–positron pair production in the field of the atomic nucleus (starting at $2m_e c^2 \approx 2 \times 511$ keV) [9]. This is one of the phenomena classified as Delbrück nuclear scattering [36], which is considered as an inelastic contribution where the pairs are produced. There is also a smaller contribution due to elastic scattering off the vacuum polarization, with annihilation of the virtual pair created [3], which is not included in XCOM [9]. There is also a contribution due to pair production in the field of the atomic electrons, which is also presented in XCOM tabulations [9]. For light atoms, the pair-production contribution from the electron/s can be larger than the nuclear contribution at energies above hundreds of GeV. For heavy atoms, the nuclear contribution is significantly larger [36]. For all atoms, XCOM shows that these processes at well above GeV photon energies are the largest cross sections and approach an asymptotic limit. XCOM does not include photonuclear resonance scattering, two-photon Delbrück scattering, or other higher-energy inelastic processes [37, Fig. 1].

66.2.1 Applications of Atomic Cross Sections

Photon–atom cross sections are used throughout the physical sciences [38]. Intermediate energy photon scattering has a wide range of applications in both medical and biological contexts, i.e., radiological physics and radiation dosimetry [39], including medical diagnosis [40]. Another

important area is nondestructive testing and 3-D imaging, such as for detecting explosives [41] and food contaminants [42], as well as archaeology [43].

Some of the example photon energy regimes are:

- 10 keV – materials science using x-ray elastic diffraction (XRD) to probe crystal and other material structures
- 10–150 keV – high-resolution medical imaging using x-ray and computed tomography (CT) [44]
- 28–60 keV – x-ray back-scattering-based airport security [45]
- 1–15 MeV – megavoltage x-rays are used in external beam radiation therapy (EBRT), i.e., photon therapy.

With so many diverse applications, it is infeasible to collect experimental data for each one. These applications are designed through the simulation of photon transport through techniques such as Monte-Carlo codes and radiation hydrodynamics, which are discussed later. In such radiation transport simulations, the frequency of the photon ω tends to decrease with successive collisions, depositing energy into the material. Individual photons are tracked as they interact with a material and tend to lose energy to the atoms/molecules they interact with for each collision. For example, cross sections are used to the combined attenuation and buildup factors, for energies into the GeV regime and distances (10 cm) relevant in photon-based treatments [46].

Photon–atom scattering cross sections are the main ingredient in characterizing the opacity of a material through different temperatures and phases and with photons of varying energy [47]. The input cross section data is computed by various approximations, requiring major data compilations and software developed by large collaborations, including the Opacity Project [48], as well as at Los Alamos [49]. The focus of the input cross sections is in single-photon physics, including photoionization and core excitations [48], but does include low-energy Rayleigh scattering [49]. There is a vast number of applications of opacity data [47], ranging from sub-keV photon energies (greenhouse gas and stellar structure) through to GeV energies (nuclear and high-temperature plasma modeling).

Atomic cross sections in the intermediate energy regime are found throughout astrophysics [50]. There have been many space-based x-ray detecting missions, since the Earth’s atmosphere absorbs x-rays, and the satellites need to orbit outside the Earth’s radiation belts. Some examples of active satellites, their launch dates, and x-ray observation ranges are [51]

- 1999 – XMM-Newton observatory, low-mid energy x-rays 0.1–15 keV
- 1999 – Chandra x-ray observatory, high-resolution spectroscopy < 0.5 keV or > 2 keV

- 2007 – AGILE, x-rays 18–60 keV, gamma-rays 350 keV–100 MeV, 30 MeV–50 GeV
- 2017 – Insight, hard x-ray modulation telescope (HXMT), 20–250 keV, 5–30 keV, 1–15 keV
- 2019 – Spektr-RG, medium-band 0.3–10 keV and 4–30 keV.

Theoretical knowledge of spectroscopic lines and cross sections is critical to their design and, subsequently, to understanding their astrophysical observations.

66.3 Experimental Progress

X-rays can be produced on demand through several means; primarily, through synchrotrons. Secondly, electroluminescence using an x-ray tube where the collision of high-energy electrons in a material with core electrons can produce a photon flux with well-defined energies. Thirdly, radioactive sources that emit with well-defined energies both through the x-ray and gamma ray regimes. Fourthly, like electroluminescence but using proton beams colliding with a material at core-electron excitation and subsequent emission. For x-ray manipulation, generally diffraction gratings are used for the soft x-ray range, whereas perfect Bragg crystal optics are utilized in the hard x-ray range [52]. The *X-Ray Booklet* is a regularly updated collection of both data and articles that summarizes various technological advances used for x-ray production and also x-ray measurement (updated v3 in 2009) [53]. Another regularly updated x-ray resource is the massive *International Tables for Crystallography, Volume C* (3rd edition 2004) [54], with a new x-ray-related Volume I in preparation <https://it.iucr.org/>.

Experimental total absorption cross sections have been in broad agreement with theory over a wide range of energies for many years. For example, see the total cross section comparisons in 1980 shown in Figs. 1/2/3 (for C/Cu/Pb) in [36]. The experimental data in those figures consist of 90, 116, and 121 independent measurements, tracking the theoretical core-electron structure due to photoionization, then the incoherent dominated region around 1 MeV, and then the pair-production cross section above MeV energies. Measurements of high-energy Rayleigh scattering tend to be above the energy ranges considered, i.e., in above 1 MeV, where the nuclear effects begin to dominate [20].

The 1 keV to 1 GeV x-ray regime presents challenges and opportunities for using photon–atom studies that probe the core electron/s in various ways. The primary experimental data needed are the transition energies, defined as the energies at which the possibility of a core electron being excited to the continuum by a photon exists. Experimental data has been combined with theoretical data in an extensive data review by *Deslattes et al.* [55].

There are several well-developed techniques now routinely employed (with acronyms deployed) such as:

- XRD – x-ray elastic diffraction – experimental information of the long-range order in the material that an atom is surrounded by can be obtained, with wavelengths $1 \text{ keV} \equiv 8.07 \times 10^6 \text{ cm}^{-1} \equiv 1.24 \text{ nm}$ being on the order of the spacing in materials (note $1 \text{ MeV} \equiv 8.07 \times 10^9 \text{ cm}^{-1} \equiv 0.00124 \text{ nm}$). Whilst (Rayleigh) elastic scattering of photons from an isolated atom is coherent, the presence of nearby atoms generates Bragg–Laue coherent scattering, which gives peaks and profiles and enables both x-ray diffraction and, thus, crystallography. However, thermal effects can result in thermal diffuse scattering (TDS), where a more complicated interference structure arises due to the incoherence between scattering events [54].
- XAS – x-ray absorption spectroscopy – is a broad set of methods where the x-ray photon is absorbed by an electron with enough energy to transition into an excited state or photoionize and place it above the Fermi-level of the material, which does not need to have long-range material order [56]. When an atom interacts with a photon of frequency ω_i , the first-order absorption processes are

Thus, the photon is removed from the beam, which is then seen as a signal loss as a function of incident frequency. This is initially seen as a series of edges where the absorption rapidly rises when there is more incoming photon energy than the core electron binding energy, and it photoionizes to the continuum (with nomenclature K for removal of a $1s$ core electron, L for $2s$ or $2p$ core electron, etc. [2]). XAS also is used to encompass the absorption both through the “pre-edge” energy region and below it. XAS includes XANES, EXAFS, XAFS, and XERT, which are discussed individually below. The XAS field and range of applications have exploded in the last decade [52, 57].

- XANES – x-ray absorption near-edge structure – are the lowest energy XAS absorption signatures, resulting from the transition of the core electron to (unoccupied) bound states. For example, chromium has valence states of $3d^5 4s^1$, so the lowest energy absorption peak series seen at the K -edge is from $1s \rightarrow 3d$, then $1s \rightarrow 4s$, then $1s \rightarrow 4p$, etc. [56]. As the energy levels are modified by the chemical environment that the atom is in, there are changes in the measured spectra that can be interpreted [58].
- EXAFS – extended x-ray absorption fine structure – is also XAS but is performed in the region of energy above XAFS. XAS absorption signature where the absorption,

for example, for the K -shell, is above the $1s \rightarrow n\ell$ (Rydberg) bound state series and into the $1s \rightarrow \varepsilon p$ continuum. This EXAFS regime is where the photoionization process involves the relatively slow emission of a photoelectron, which can have a de Broglie wavelength on the order of the surrounding material, and, thus, a particular interference pattern due to the local chemistry is observed as a function of incoming photon frequency.

- XAFS – x-ray fine structure absorption spectroscopy – represents both XANES and EXAFS, i.e., the overall XAS structures spanning the valence and low-lying continuum at a core-excitation edge [59].
- DAFS – diffraction anomalous fine structure – is a combined XRD and XAS technique that relies on the long-range order in the material with a high brightness of the source [57].
- XERT – x-ray extended-range technique – is XAFS used with multiple measurements taken with varying material thicknesses, which is used to reduce errors [60, 61]. Given improved synchrotron and detector resolution below the linewidth of atomic transitions, XAFS is able to resolve the (atomic fine-structure) level splitting (e.g., between $p_{\frac{1}{2}}$ and $p_{\frac{3}{2}}$ core states in the L edge) and is sensitive to quantum electrodynamics (QED)-level correction physics [62].

66.3.1 Inelastic Processes

The initial suggestion of inelastic photon scattering with quantized emission was made by *Smekal* [63] and was experimentally observed in the optical regime by *Raman* [64], with the suggestion that a similar mechanism should be seen in x-rays. Inelastic (Smekal–Raman) x-ray scattering was spectroscopically observed in 1958 along with Rayleigh scattering from the core electrons, as well as Compton scattering [65].

There are now many methods relying on inelastic x-ray scattering (IXS). IXS covers a broad set of methods where the photon is absorbed with resulting excitation or photoionization, resulting in a secondary process, which is experimentally involved with the spectroscopic detection of outgoing photon/s with a different energy to the incident (or correlated electron/s) [66]. This, along with the momentum transfer, provides information about the materials surrounding the atom [67].

When an atom (or ion) is placed in an excited state A^* with a hole in a core shell, this can decay through either radiative or radiationless (Auger) processes

Each of these processes is restricted to the usual quantum selection rules, which, in LS -coupling, are all conserved for Auger processes [2]

$$\Delta J = \Delta M_J = \Delta L = \Delta M_L = \Delta S = \Delta M_S = 0, \quad (66.10)$$

where the total angular momentum of the A^* wave function is $J = L + S$, and the initial wave function parity is the same as the final ($\pi_i = \pi_f$). For radiative processes via electric dipole allowed transitions,

$$\begin{aligned} \Delta J &= 0, \pm 1 \quad (\text{but not } J_i = 0 \rightarrow J_f = 0), \\ \Delta M_J &= 0, \pm 1, \quad \pi_i = -\pi_f. \end{aligned} \quad (66.11)$$

Within LS -coupling, if it is a single-electron transition then $\Delta L = \pm 1$, and if $\Delta S = 0$, then $\Delta L = 0, \pm 1$ (but not $L_i = 0 \rightarrow L_f = 0$). In most atoms, when a core electron has been removed, these selection rules mean that many more Auger transitions are allowed than radiative transitions [2].

The probability of each (allowed) decay pathway occurring depends on their transition matrix elements, which, to compute them accurately, requires complicated wave functions with many-body correlations. However, simpler approximations such as Wentzel’s independent particle approximation are often an illustrative, if not always accurate, starting point. For an Auger process, the probability is related to the Coulomb matrix element [68–70]

$$P \propto \left\langle \left\langle n_c \ell_c j_c, \varepsilon \ell_\varepsilon j_\varepsilon \left| \frac{1}{r_1 - r_2} \right| n_a \ell_a j_a, n_b \ell_b j_b \right\rangle \right\rangle^2, \quad (66.12)$$

with a and b denoting the two initial electrons, c the final state core orbital, and ε the continuum orbital, which is the (Auger) ejected electron. Such two-body matrix elements must include both direct and exchange contributions [2] and obey the above total angular momentum selection rules. The (ionized) continuum electron carries off the energy that the remaining electron/s require to be released to drop down into the core shell. The (x-ray fluorescence emission) radiative dipole transition matrix elements in their reduced form look like $\langle n_c \ell_c j_c || r \cos \theta || n_a \ell_a j_a \rangle$, which can provide a good description of these decay pathways [70].

Atoms tend to decay predominantly via Auger processes [2, 69], which can involve cascades of multiple states [71, 72]. An initial state (i) has partial widths for radiative decay, $\Gamma_R(i)$, and for Auger $\Gamma_A(i)$. The fluorescence yield for this state is then given by $\Gamma_R(i)/(\Gamma_R(i) + \Gamma_A(i))$ since decay rates are additive [68].

Raman and Compton scattering are heuristically

The notation “...” indicates that, as per Fig. 66.1, either the first-order A^2 interaction will skip straight to the final state or the second-order consecutive $p \cdot A$ operations proceed through a complete set of intermediate states. In Raman processes, each emitted photon is from the set of frequencies $\{\omega_n\}$, which are based on an available quantized relaxation transition to a lower bound state. In contrast, the photoionization-based Compton process emits a photon from the continuous distribution of energetically available photon frequencies ω_c . These are often grouped together as inelastic “Raman–Compton” scattering [66].

Capturing x-ray emission yields information about the atoms and their local environment [57]. Some techniques (and their acronyms) are:

- XES – x-ray emission spectroscopy – a broad set of techniques that measures the outgoing photon frequencies using x-ray spectrometry [57]. XES is an intrinsic part of both XAS and XAFS, i.e., the emission/fluorescence spectroscopy forms the toolkit.
- XRS – x-ray Raman spectroscopy/scattering – is a specific type of XES that involves inelastic Raman scattering, detecting photons at characteristic energies that have been emitted at a different frequency to the incident [59]. Note that the final state (A^* as above) can be a continuum state above the Fermi level [67].
- RIXS – resonant inelastic x-ray scattering – is the second-order $p \cdot A$ -dominated Raman scattering process, which is enhanced during absorption of the photon to a continuum state near threshold, which is observed through emission at discrete frequencies $\{\omega_n\}$ [67]. This is also known as resonant Auger scattering [73], RRS (resonant Raman scattering) [74], or RXES (resonant XES) [75].

Some key experiments using different photon generation schemes that measured inelastic scattering are the following.

- 1989 – Synchrotron-generated tunable x-ray beams of energy between a few keV up to 19 keV, detector tunable, e.g., at 6 keV with 0.155 eV resolution [76, 77]. Scattering off Zr (whose K-shell binding energy is close to 18 keV) measured “Raman–Compton” and Rayleigh scattering and the infrared divergence.
- 1989 – Radioactive ^{137}Cs source that emits 662 keV photons, an x-ray detector, e.g., operating at 80 keV with resolution of 0.7 keV for fluorescent photon in coincidence with a gamma-ray detector for the scattered photon for Compton scattering studies of Pb [78].
- 1996 – X-ray tube with W-anode (the $K\alpha_1$ line is 59.32 keV), with a detector at 60 keV with resolution 0.4 keV for Compton scattering off Cu in coincidence with fluorescence photons [79].

- 2006 – Resonant Raman study with incident synchrotron beam scanned across the energy range near the Si K-absorption edge (1.840 keV) with a beam width of 6 eV and a high-resolution (0.9 eV) spectrometer measuring the emitted photons at the fluorescence line (1.740 keV) [74].
- 2010 – 1 MeV proton beam, which irradiates Mg, Al, and Si targets to form soft-x-ray beams of 1.235, 1.486, and 1.740 keV, which then target the same materials, measuring resonant Raman scattering [80, 81].
- 2010 – Benchmark IXS experiments have been performed with Compton scattering on He with synchrotron radiation using a detector fixed at 9.88968 keV with energy resolution down to 70 meV [82].

66.4 Theory, Computation, and Data

Excellent introductory tutorials covering both soft and hard x-ray interactions with atoms have been given by *Pratt* [83] and *Santra* [70]. The *Hopersky* and *Yavna* monograph presents the general many-body theory of x-ray photon-atom interactions, with an emphasis on computation of both atoms and molecules [84]. Detailed theoretical approaches to resonant x-ray Auger/Raman scattering emphasizing Kramers-Heisenberg and Weisskopf-Wigner descriptions can be found in [73, 75, 85].

Overviews of the fundamental theories used in inelastic scattering calculations can be found in [86, 87]. The most successful computational approach remains the relativistic S-matrix with independent particle approximation, which goes beyond the impulse approximation [88]. Accurate calculations require solving challenging many-body problems, which presents problems even when computing the underlying atomic structure [55].

Beyond single-atom physics, computing the effects of the local material requires a combination of approaches since x-ray absorption involves a description of the chemical interactions between the valence orbitals, the conduction band, and phonon-like excitations.

This is challenging for the theoretical and computational modeling of experimental XAS/EXAFS/XANES data where multiple-particle scattering effects need to be included [89, 90], and chemistry-based methods such as density functional theory (DFT) are now routinely applied [58]. High-performance computing software is now readily available to solve a broad range of such physics and systems. For example, several programs have been developed in recent decades that have a lot of versatility, e.g., the GNXAS suite, which handles XAS data analysis including the molecular/crystal structure [91], the FDMNES suite models XANES and RXS [92], whilst the FEFF suite can handle XAS, Compton, NRIXS (nonresonant IXS) [93].

66.4.1 Databases

The history of photon cross section calculations, as used in databases, is discussed by *Hubbell* [38]. Three photon-atom scattering cross section databases at NIST are part of their Atomic and Molecular Physics component of the Standard Reference Data (SRD) program:

- **SRD 8** XCOM/XGAM: Photon Cross Sections Database [9, 94],
- **SRD 66** FFAST: x-ray Form Factor, Attenuation and Scattering Tabulation [95],
- **SRD 126** XAAMDI: x-ray Attenuation and Absorption for Materials of Dosimetric Interest [10].

Lawrence Livermore National Laboratories (LLNL) have had a long history of photon-atom database development. As was mentioned earlier, the XDB x-ray Data Booklet contains a massive regularly updated set of data [53]. It appears that their standalone RTAB database for Rayleigh scattering cross sections [21] is no longer publicly available via URL. They produced the Evaluated Photon Data Library (EPDL), which is part of the Evaluated Nuclear Data File ENDF/B-VI photon interaction library, which covers photons in the energy range 10 eV–100 MeV interacting with elements $Z = 1-100$ [96]. This was revised in 2018 as ENDF/B-VIII.0 [97, 98].

These databases, which focus on x-ray through γ -ray photon energies, find application through fundamental physics, materials sciences, and medical physics [39, 99].

66.4.2 Bulk Modeling

The tracking of how intermediate energy photons propagate through bulk material is extremely challenging due to the aforementioned inelastic channels that are open. Radiation transport is handled through *Monte-Carlo* simulations that can consider first and second-order photon scattering processes [100, 101]. Some examples of programs are GEANT4 Geometry and Tracking [102, 103], PENELOPE [104, 105], EGS5 [106], EGSnrc [107], FLUKA [108, 109], ROSI Roentgen Simulation [110], MRED Radiative Energy Deposition [111], and ARCHER [112].

A popular alternative to the above tracking-based Monte-Carlo schemes is to use *radiation hydrodynamics*, which treats the flow of radiation as a fluid [113]. This uses as input the first-order atom-photon interactions, such as the opacity, where emission and absorption processes are considered as distinct. Codes such as FLYCHK [114] and PURGATORIO [115] have been used to model extreme material environments involving intense pulses of several keV x-rays [116]. Such experiments are able to extract information

about extreme temperatures of stellar interiors and high-energy density plasmas using x-rays in the laboratory [117].

66.5 Future Directions

Finally, we mention a few areas of recent activity with a view towards the future.

Continuing improvements in synchrotron brightness and spectrometer resolution [52, 53, 57] will enable the next generation of x-ray reaction microscopes, e.g., for coincidence measurements of photons from cascades and photoelectrons from gas phase targets.

For even a relatively simple atom like Si [118], XAFS experimental measurements have, as yet, unresolved errors on the order of 5% between theory and experiment [62]. There has been a call for experimental XAFS benchmarking between facilities to identify the error sources [119]. RIXS experiments have become increasingly sophisticated, with precision spectroscopy (sub-1eV detector resolution) involving multiple channels with gas phase targets presenting challenges for theory to keep up with [120], especially where more than one electron is involved in the absorption/emission process [121].

Pratt previously summarized some outstanding theoretical issues [22], which remain relevant and should be pursued. Very recently, a promising new computational approach to x-ray processes was developed and released [122]; it uses MCDHF (multiconfiguration Dirac–Hartree–Fock) calculations to model the atomic structure and is designed to compute atomic cascades and the time evolution of density matrices. The availability of new high-performance computing codes using configuration interaction such as GRASP [123], and with particle-hole excitations and with over five valence particles, e.g., AMBIT [124, 125], opens up the ability to compute the atomic levels, x-ray transition probabilities, and Auger physics to even higher-accuracy than MCDHF systematically across the periodic table. These codes are also systematically able to compute and quantify isotope and QED effects that are able to be resolved in x-ray experiments with highly-charged ions in electron beam ion traps (EBITs) [62], and a major effort should be undertaken for the ab-initio computation of atomic processes involving keV to MeV photons.

The nonlinear response of atoms and ions interacting with intense electromagnetic fields is useful in a wide-range of applications throughout the physical sciences [126]. Nonlinear x-ray optics presents a new frontier to probe atoms and materials, with the latest generation of synchrotron sources capable of reaching such brightness, especially if applied in intense ultrashort pulses. New theoretical work has begun to appear to describe Rayleigh scattering of two x-ray photons by an atom [127] and to develop a time-dependent QED ap-

proach to x-ray nonlinear Compton scattering (XNCS) [128], where the independent photon model breaks down. Applications to multielectron systems present a theoretical, computational, and experimental challenge.

All of the NIST database calculations are not ab-initio and are generally thought to work best above the keV photon regime [95]. The development of improved intermediate-energy approximations towards improved modeling of photon transport as the photons drop from the GeV and down into the sub-keV would be welcome. For example, a side-by-side comparison of Monte-Carlo ROSI and GEANT4 calculations with x-rays at 100 keV, 400 keV, 1 GeV, and higher, showed that the use of the different input data sets makes observable differences in the outputs [129].

There are other extreme facilities available for x-ray studies, such as ZAPP, The Z Astrophysical Plasma Properties collaboration [130]. This has enabled benchmarking photoionized plasma models and validating extreme radiation transport models in laboratory astrophysics [131].

For the future of x-ray astrophysics, there are a couple of main missions in planning: for 2022 launch of the x-ray Imaging and Spectroscopy Mission (XRISM) to measure 0.3–12 keV x-rays with 5–7 eV energy resolution, and in 2031 the launch of the next generation ATHENA telescope with spectroscopic imaging in the energy range of 0.2–12 keV [132].

Acknowledgments The author would like to thank Dr Swaantje Grunefeld, Dr Emily Kahl, Gian Carlo Ruzzi Villacres, and Corey Hanrahan for many discussions and for providing Fig. 66.1 and the Rayleigh data in Fig. 66.2. He further thanks Dr Ivan Mikhaylov for providing the [16] data in Fig. 66.2 and Professor Christopher Chantler for helpful suggestions. This work was partially supported through an Australian Research Council Future Fellowship FT100100905 at The University of Queensland.

as electrical discharges, electron-beam lasers, plasma processing, and fusion devices. They are also significant in various environments, such as planetary atmospheres and astrophysical and solar plasmas. Early studies of these interactions contributed significantly to the understanding of the quantum nature of matter. Experimental activities in this field, initiated by *Franck* and *Hertz* [1], flourished in the 1930s and, after a dormant period of about a quarter of a century, had a renaissance in the latter half of the century. More recently, sophisticated developments in experimental and theoretical techniques have led to increased physical insight and data production.

When electrons collide with atomic or molecular targets, a large variety of reactions can take place (Sect. 67.1.1). We limit our discussion to electron collisions with neutral atoms and molecules, where single collision conditions prevail. Furthermore, we discuss only low-energy (threshold to few hundred eV) impact processes where the interaction between the valence-shell electrons of the target and the free electron dominates.

Comprehensive discussions on electron–atom (molecule) collision physics can be found in the books of *Massey* et al. [2], *McDaniel* [3], and the volumes of *Advances in Atomic and Molecular* (since 1990 *Atomic, Molecular and Optical*) *Physics*. The latest developments are usually published in *Physical Review Letters*, *Physical Review A*, *Journal of Physics B*, *Journal of Chemical Physics*, *European Physics Journal D* and *Journal of Physical and Chemical Reference Data*, and are presented at the biannual International Conference on Photonic, Electronic and Atomic Collisions (ICPEAC).

Keywords

ionization cross section · scatter cross section · electron collision · excitation cross section · integral cross section

67.1 Basic Concepts

67.1.1 Electron Impact Processes

Low-energy electrons can very effectively interact with the valence-shell electrons of atoms and molecules, in part because they have similar speeds. In elastic scattering, the continuum electron changes direction and transfers momentum to the target. Inelastic collisions also include a transfer of kinetic energy to the target, such as excitation of valence electrons to discrete energy levels, to the ionization continuum, and, in the case of molecules, excitation of nuclear motion (rotational, vibrational), and excitation to states that dissociate into neutral or ionic fragments. Various combinations of these processes are also possible, e.g., dissociative attachment, excitation, or ionization. Excitation of more than one valence electron at the same time, or excitation of electrons from intermediate and inner shells, may also occur, but these processes are more likely at impact energies of a few keV. These excitations lie above the first ionization limit and, therefore, with high probability lead to autoionization, except for heavy elements where X-ray emission is an important competing process.

67.1.2 Definition of Cross Sections

The parameters that characterize collision processes are the cross sections. Electron collision cross sections depend on impact energy E_0 and scattering polar angles θ and ϕ . The differential cross section (DCS), for a specific well-defined excitation process indicated by the index n , is defined as

$$\frac{d\sigma_n(E_0, \Omega)}{d\Omega} = \frac{k_f}{k_i} |f_n(E_0, \Omega)|^2, \quad (67.1)$$

where Ω is the polar angle of detection, k_i and k_f are the initial and final electron momenta, and f_n is the complex scattering amplitude ($n = 0$ refers to elastic scattering). Integration over the energy-loss profile is assumed. If the energy-loss spectrum is broad, differentiation with respect to energy loss also has to be included. For certain processes it may be necessary to define DCSs with respect to angle and energy for both primary and secondary particles.

Integration over all scattering angles yields the integral cross sections

$$\sigma_n(E_0) = \int_0^{2\pi} \int_0^\pi \frac{d\sigma_n(E_0, \Omega)}{d\Omega} \sin \theta \, d\theta \, d\phi. \quad (67.2)$$

In the case of elastic scattering, the momentum transfer cross section is defined as

$$\sigma_0^M(E_0) = \int_0^{2\pi} \int_0^\pi \frac{d\sigma_0(E_0, \Omega)}{d\Omega} (1 - \cos \theta) \sin \theta \, d\theta \, d\phi. \quad (67.3)$$

The total electron scattering cross section is obtained by summing all integral cross sections

$$\sigma_{\text{tot}}(E_0) = \sum_n \sigma_n(E_0) + \sum_m \sigma_m(E_0), \quad (67.4)$$

where σ_m are the cross sections for other possible channels. Experimental cross sections typically represent averages over indistinguishable processes (e.g., magnetic sublevels, hyperfine states, rotational states, etc.). The cross section obtained this way corresponds to an average over initial and sum over final indistinguishable states with equal weight given to the initial states. (This may not always be true, as discussed later.) If the target molecules are randomly oriented, the cross section averaged over these orientations is independent of ϕ . In addition, there is an averaging over the finite energy and angular resolution of the apparatus. It is important, therefore, to specify clearly the nature of the measured cross section, otherwise their utilization and comparison with other experimental and theoretical cross sections become meaningless. We denote the conventionally measured differential and integral cross sections by $D_n(E_0, \theta)$ and $Q_n(E_0)$, with the various averagings implied. Similarly, $Q^M(E_0)$ and $Q_{\text{tot}}(E_0)$ are the corresponding momentum transfer and total scattering cross sections.

The collision strength for a process $i \rightarrow j$, which is the particle equivalent of the oscillator strength, is defined by

$$\Omega_{ij}(E_0) = q_i E_0 \sigma_{ij}(E_0), \quad (67.5)$$

where q_i is the statistical weight of the initial state [$q_i = (2L_i + 1)(2J_i + 1)$], E_0 is in Rydbergs, and σ_{ij} is in units of πa_0^2 .

The rate for a specific collision process (e.g., excitation) for electrons of energy E_0 is given as

$$R_{ij}(E_0) = NI(E_0)\sigma_{ij}(E_0), \quad (67.6)$$

where N is the density of the target particles (m^{-3}), and $I(E_0)$ is the electron flux ($\text{m}^{-2} \text{s}^{-1}$); σ_{ij} is in m^2 , yielding R_{ij} in units of $\text{m}^{-3} \text{s}^{-1}$. For nonmonoenergetic electron beams, Eq. (67.6) must be integrated over E_0 to get the average rate.

67.1.3 Scattering Measurements

Most scattering experiments are carried out in a beam–beam arrangement (Fig. 67.1). A beam of nearly monoenergetic electrons is formed by extracting electrons from a hot filament and selecting a narrow segment of the thermal energy distribution. For the formation and control of the electron beam, electrostatic lenses are used, and the energy selection is achieved with electrostatic energy selectors. A magnetic field may also be applied to obtain a magnetically collimated

Fig. 67.1 A schematic diagram for electron scattering measurements

electron beam. The target beam is formed by letting the sample gas effuse from an orifice, tube or capillary array with various degrees of collimation. Target species that are in the condensed phase at room temperature need to be placed in a crucible and evaporated by heating. An extensive discussion of this technique was given by *Scoles* [4]. The electron beam intersects the target beam at a 90° angle, and electrons scattered into a specific direction, over a small solid angle ($\approx 10^{-3}$ sr), are detected. However, the scattered electron is not necessarily the same as the incoming electron. Exchange with the target electrons may occur and is required for spin-forbidden transitions in light elements. The detector system consists of electron lenses and energy analyzers similar to those used in the electron gun. The actual detector is an electron multiplier that generates a pulse for each electron. In the scattering process, secondary species (electrons, photons, ions, neutral fragments) may also be generated and can be detected individually or in various coincidence schemes. The experiments are carried out in a vacuum chamber, and it is important to minimize stray electric and magnetic fields. More details about the apparatus and procedures can be found in a review by *Trajmar* and *Register* [5]. The primary information gained in these experiments is the energy and angular distribution of the scattered electrons.

There are several methods used to carry out scattering measurements. In the most commonly used energy-loss mode, the impact energy and scattering angle are fixed, and the scattering signal as a function of energy lost by the electron is measured by applying pulse counting and multi-channel scaling techniques. The result of such an experiment is an energy-loss spectrum. The elastic scattering feature appears at zero energy loss; the other features correspond to various excitation processes and to ionization. Energy-loss spectra can also be generated in the constant residual energy mode. In this case, the detector is set to detect only electrons with a specific residual energy $E_R = E_0 - \Delta E$ at a fixed scattering angle, and E_0 and ΔE are simultaneously varied. Each feature in the energy-loss spectrum is then obtained at

Fig. 67.2 Energy-loss spectrum of He at a constant residual energy of 1.2 eV and scattering angle of 90° . The inelastic features with the corresponding principal quantum numbers are shown. IE is the ionization potential of He (24.58 eV). No background is subtracted, and true signal zero is indicated by a dotted line under the expand portion of the spectrum m. (Taken from *Allen* [6])

the same energy above its own threshold. An example, taken from the work of *Allen* [6], is shown in Fig. 67.2.

The energy loss spectrum becomes equivalent to the photoabsorption spectrum in the limit of small momentum transfer \mathbf{K} , where $\mathbf{K} = \mathbf{k}_f - \mathbf{k}_i$ (i.e., high impact energy, small scattering angle). The equivalence of electrons and photons in this limit follows from the Born approximation, and it can be used to obtain optical absorption and ionization cross sections. The correspondence is defined through the limit theorem

$$\lim_{\mathbf{K} \rightarrow 0} f_n^G(\mathbf{K}) = f_n^{\text{opt}}, \quad (67.7)$$

$$f_n^G(\mathbf{K}) = \frac{\Delta E}{2} \frac{k_i}{k_f} \mathbf{K}^2 \frac{d\sigma_n}{d\Omega}(\mathbf{k}), \quad (67.8)$$

where f_n^G is the generalized oscillator strength for excitation process n , and f_n^{opt} is the corresponding optical f -value. Equation (67.7) was originally derived by *Bethe* [7] from the Born cross section. It was later extended by *Lassette* et al. [8] to cases where the Born approximation does not hold. In this case, $f_n^G(\mathbf{K})$ is replaced by $f_n^{\text{app}}(\mathbf{K})$, the apparent generalized oscillator strength. The limit theorem implies that, in the limit of small \mathbf{K} , optical selection rules apply to electron impact excitation. The practical problem is that the limit is nonphysical and the extrapolation to zero \mathbf{K} involves some arbitrariness. When \mathbf{K} is significantly different from zero, optical-type selection rules do not apply to electron-impact excitation. Spin and/or symmetry forbidden transitions then readily occur and can be an efficient way of producing metastable species.

Selection rules for electron impact excitations can be derived from group theoretical arguments [9, 10]. For atoms, the selection rule $S_g \leftrightarrow S_u$ applies in general, and scattering to 0° and 180° is forbidden if $(L_i + \Pi_i + L_f + \Pi_f)$ is odd.

Here, L_i and L_f are the angular momenta and Π_i , and Π_f are the parities. For molecules, selection rules can be derived under two special conditions: (a) rules concerning 0° and 180° scattering for arbitrary orientation of the molecule and (b) rules concerning scattering to any angle but for specific orientation of the molecule. An important example of the first case is the $\Sigma^- \leftrightarrow \Sigma^+$ selection rule for linear molecules at 0° and 180° scattering angles.

The energy dependence of cross sections is obtained by fixing the energy-loss value (scattering channel) and studying the variation of scattering signals with impact energy at a given angle or integrated over all scattering angles. In general, cross sections associated with spin forbidden and optically allowed transitions peak near and at several times the threshold impact energy respectively, and they usually vary smoothly with impact energy. However, resonances may appear at certain specific impact energies. These sudden changes are associated with temporary electron capture and are the result of quantum mechanical interference between two indistinguishable paths.

Integral cross sections can be obtained from extrapolation of the measured $D_n(E_0, \theta)$ to 0° and 180° scattering angles and integration over all angles. Recently, incorporation of an *angle-changing* device has enabled measurements to be extended over the whole range of scattering angles [11, 12]. In certain cases, it is possible to measure integral cross sections directly by detecting secondary products such as photons and ions. These procedures and the resulting cross sections will be discussed in some detail in Sect. 67.2.

67.2 Collision Processes

In addition to the basic elastic and inelastic processes defined in Sect. 67.1.2, we now also explicitly include dissociation (to neutral and charged fragments) cross sections $Q_D(E_0)$; and ionization cross sections $Q_I(E_0)$. Each of these is now considered separately.

67.2.1 Total Scattering Cross Sections

Total electron scattering cross sections represent the sum of all integral cross sections

$$Q_{\text{tot}}(E_0) = \sum_n Q_n(E_0) + Q_I(E_0) + Q_D(E_0), \quad (67.9)$$

$Q_{\text{tot}}(E_0)$ are useful for checking the validity of scattering theories, and the consistency of available data, for normalization of integral and differential cross sections, and as input to the Boltzmann equation. At low impact energies, elastic scattering dominates, while at intermediate and high impact

Fig. 67.3 Cross sections for various processes in the electron–helium collision (see text for data sources)

energies, electronic excitations and ionization become major contributors to Q_{tot} . Figure 67.3 shows the various cross sections for electron–helium collisions. The data are from the recommended values of *Trajmar* and *Kanik* [13].

Two methods are commonly used for measuring $Q_{\text{tot}}(E_0)$: the transmission method and the target recoil method (for details, [5, 14]). Total scattering cross sections measured by these techniques are, in general, accurate to within a few percent. The extensive reviews by *Zecca* and coworkers [15–17] should be noted.

67.2.2 Elastic Scattering Cross Sections

Elastic scattering cross sections $Q_0(E_0)$ are not as readily available as $Q_{\text{tot}}(E_0)$. They are obtained from differential scattering experiments over limited angular ranges by extrapolation and integration of the measured values. Typical error limits are 5 to 20%. For molecular species, rotational excitation is usually not resolved but is included in the $D_0(E_0, \theta)$ and $Q_0(E_0)$ values. In order to obtain the absolute $D_0(E_0, \theta)$ directly from the scattering signal, one has to know the electron flux, the number of scattering species, the scattering geometry, and the overall response function of the apparatus. A direct measurement of these parameters can be made at high energies (> 100 eV). However, at low electron energies, this approach is not feasible. A number of methods have been devised to derive relative $D_0(E_0, \theta)$ from the measured scattering intensities and then to normalize the $D_0(E_0, \theta)$ to the absolute scale. Here, we briefly outline only the most commonly used procedure.

The most practical and reliable method of obtaining the absolute $D_0(E_0, \theta)$ is the relative flow technique in which scattering signals for a known standard gas and an unknown test gas are compared at each energy and angle [5, 18–20].

The He elastic cross section is the natural choice of standard since it is known accurately over a wide energy and angular range, and He is experimentally easy to handle. Only the relative electron beam flux and molecular beam densities (and their distributions) need be known in the two measurements. The flow rate of the test gas is adjusted so that the flux and density distribution patterns of the two gases are identical, and all geometrical factors cancel in the scattering intensity ratios. The absolute $D_0(E_0, \theta)$ for the sample gas is obtained from the measured scattering intensity, target density, and electron beam intensity ratios, and the standard $D_0(E_0, \theta)$ value. See [5, 20, 21] for a detailed discussion of this technique.

67.2.3 Momentum Transfer Cross Sections

The $Q^M(E_0)$ can be obtained both from the elastic DCSs (differential cross sections) and from swarm measurements. At low electron-impact energies (from 0.05 to a few eV), where only a few collision channels are open, the electron swarm technique is the most accurate ($\approx 3\%$) way to determine the momentum transfer cross sections. Beam–beam experiments are mandatory at higher energies. A detailed discussion of these techniques is given by *Trajmar* and *Reg-ister* [5].

67.2.4 Excitation Cross Sections

The $D_n(E_0, \theta)$ and $Q_n(E_0)$ can be derived from energy-loss spectra obtained in beam–beam scattering experiments. The relative $D_n(E_0, \theta)$ is usually normalized to $D_0(E_0, \theta)$, which in turn is normalized to the helium $D_0(E_0, \theta)$ by the relative flow technique described in Sect. 67.2.2. There are, however, complications and uncertainties associated with this technique because of the sensitivity of the instrument response function to the residual energy of the scattered electrons. For more details, see *Trajmar* and *McConkey* [21]. Data obtained by this procedure are rather limited, partly due to experimental difficulties and partly due to the time required to carry out such measurements.

For cases where an excited state j is formed, which can radiatively decay by means of a short-lived (dipole-allowed) transition to a lower lying state i , the intensity of the resultant radiation is directly related to the cross section for production of the excited state in the original collision process. An optical emission cross section, $Q_{ji}(E_0)$, is defined by

$$Q_{ji}(E_0) = \frac{N_j \Gamma_{ji}}{I n_0 \tau_j}, \quad (67.10)$$

where N_j and n_0 are the densities in the excited and ground states, respectively, Γ_{ji} is the branching ratio for radiative

decay from state j to state i , I is the electron beam flux, and τ_j is the natural radiative lifetime of state j . Since the excited state may be produced either by direct electron impact or by cascade from higher-lying states k , also formed in the collision process, we may define the direct excitation cross section $Q_j^d(E_0)$ by

$$Q_j^d(E_0) = \sum_i Q_{ji}(E_0) - \sum_k Q_{kj}(E_0). \quad (67.11)$$

The last term subtracts the cascade contribution from higher-lying states. The quantity $Q_j^a(E_0) = \sum_i Q_{ji}(E_0)$ is known as the apparent excitation cross section for level j . Clearly, to obtain $Q_j^d(E_0)$ from $Q_j^a(E_0)$, the cascade contribution must be known.

In Eq. (67.10), $N_j \Gamma_{ji} / \tau_j$ gives the steady-state number of $j \rightarrow i$ photons per unit time per unit volume emitted from the interaction region. Since observation is made in a particular direction care must be taken to correct for any anisotropy in the radiation pattern. Alternatively, if observation is made at the so-called *magic* angle ($54^\circ 44'$) to the electron beam direction, the emission intensity per unit solid angle is equal to the average intensity per unit solid angle irrespective of the polarization of the emitted radiation. However, even at this magic angle, care must be taken to avoid problems with polarization sensitivity of the detection equipment [22, 23].

The phenomenon of radiation trapping is often a problem if the radiative decay channels of the excited state include a dipole allowed channel to the ground state. Repeated absorption and re-emission of the radiation can occur and can lead to a diffuse emitting region much larger than the original interaction region, and the polarization of the emitted light can also be altered. Often, a study of the variation of the emitted intensity or polarization with the target gas pressure is sufficient to reveal the presence of radiation trapping or other secondary effects.

The emission cross sections of certain lines have been measured with great care and now serve as benchmarks for other work. Examples of these are the measurements of *van Zyl* et al. [24] on the n^1S levels of He in the visible spectral region or the measurements of the cross section for production of Lyman α from H_2 in the VUV region ([25, 26] for a full discussion of this including many references). Use of secondary standards is particularly important when crossed-beam measurements are being carried out because of the cancellation of geometrical and other effects that occur.

The Bethe–Born theory [27] provides a convenient calibration of the detection system for optically allowed transitions of known oscillator strength. At sufficiently high energies, the excitation cross section, Q_n , of level n is given by

$$Q_n = \frac{4\pi a_0^2}{E_0/R_\infty} \frac{f_n^{\text{opt}}}{\Delta E_n/R_\infty} \ln\left(\frac{4c_n E_0}{R_\infty}\right). \quad (67.12)$$

Here, ΔE_n is the excitation energy, and c_n is a constant dependent on the transition. A plot of $Q_n E_0$ versus $\ln E_0$ is a straight line with a slope proportional to f_n^{opt} and the intercept with the $\ln E_0$ axis yields an experimental value for c_n independent of the normalization. For example, the He n^1P – 1^1S optical oscillator strengths are very accurately known, as are cascade contributions. Thus, accurate normalization of the slope of the Bethe plot can be made, yielding accurate excitation cross sections.

As was mentioned above, the excitation cross sections display characteristic shapes as a function of energy. For optically allowed transitions, the cross section rises relatively slowly from threshold to a broad maximum approximately five times the threshold energy. At higher energies, the $(\ln E_0)/E_0$ dependence of the cross section predicted by Eq. (67.12) is observed. For exchange processes, e.g., a triplet excited state from a singlet ground state, the cross section peaks sharply close to threshold and falls off at high energy as E^{-3} . If the excitation is spin allowed but optically forbidden, e.g., He n^1D from 1^1S , then the Bethe theory predicts an E^{-1} dependence of the cross section at high energies.

When excitation occurs to a long-lived (metastable or Rydberg) state following electron impact, it is often possible to detect the excited particle directly. Time-of-flight (TOF) techniques are used to distinguish the long-lived species from other products, e.g., photons, produced in the collisions.

67.2.5 Dissociation Cross Sections

Dissociation of a molecular target can result in fragments that may be excited or ionized. Such processes may be studied using the techniques discussed in the previous section or in the following section, where charged particle detection is considered. Because a repulsive state of the molecule is accessed, the fragments can leave the interaction region with considerable kinetic energy (several eV). If the fragment is in a long-lived metastable or Rydberg state, TOF techniques may be used to distinguish the long-lived species from other products such as photons, and also to measure the energies of the excited fragments, and thus provide information on the repulsive states responsible for the dissociation. For a further discussion, see the reviews by *Compton and Bardsley* [28], *Freund* [29], and *Zipf* [30]. If the detector can be made sensitive to a particular excited species, its excitation can be isolated and studied. Examples are the work of *McConkey* and coworkers [31, 32] on O($1S$) and S($1S_0$) production from various molecules. The detection of unexcited neutral fragments is more challenging. One early method was to trap selectively the dissociation products using a getter and measure the resulting pressure decrease. In a more sophisticated approach, *Cosby* [33] produced a fast (≈ 1 keV) target molecular beam by resonant charge exchange and sub-

jected it to electron-impact dissociation. The fast dissociation products were detected by conventional particle detectors in a time-correlated measurement. Laser techniques, such as laser-induced fluorescence or multiphoton ionization, were also used recently to detect the dissociation products.

The Franck–Condon principle largely governs molecular dissociation. The principle states that if the excitation takes place on a time scale that is short compared with vibrational motion of the atomic nuclei, the transition occurs vertically between potential energy curves. Since dissociation rapidly follows a vertical transition to the repulsive part of a potential energy curve, compared with the period of molecular rotation, the dissociation products tend to move in the direction of vibrational motion. Since the excitation probability depends on the relative orientation of the electron beam and the molecule, dissociation products often demonstrate pronounced anisotropic angular distributions. The angular distributions have been analyzed by *Dunn* [34] using symmetry considerations.

67.2.6 Ionization Cross Sections

Some 90 years ago, *Tate and Smith* [35] developed the basic techniques for measuring total ionization cross sections. These were later improved by *Rapp and Englander-Golden* [36]. Full details of the experimental methods are given in the reviews and books already cited. *Märk and Dunn* [37] reviewed the situation as it existed in the mid 1980s. In the basic *parallel plate* method, the electron beam is directed through a beam or a static target gas between collector plates that detect the resultant ions. Unstable species can be studied by the *fast neutral beam* technique [38], in which the neutral target species is formed by charge neutralization from a fast ion beam, and is subsequently ionized by a crossed electron beam. For the determination of partial ionization cross sections specific to a given ion species in a given ionization stage, mass spectroscopic (quadrupole mass spectrometer, electrostatic, or magnetic charged particle analyzer or time-of-flight) methods are used. Fourier transform mass spectrometry (FTMS) has also been used effectively to study fragmentation with formation of both positive and negative ions. A recent example of this can be found in [39]. Absolute total ionization cross sections have been measured for a large number of species with an accuracy of better than 10%. *Christophorou* and colleagues have presented helpful compilations of ionization and other data of particular relevance to the plasma processing industry, [40, and earlier references in this journal].

A large number of mechanisms can contribute to the ionization of atoms and molecules by electron impact. For targets with only a few atomic electrons, the dominant process is single ionization of the outer shell, with the resultant ion being left in its ground state. The process is direct and

is characterized by large impact parameters b and small momentum transfers. The cross section varies with incident electron energy in a way very similar to the optically allowed excitation processes discussed in Sect. 67.2.4. Processes involving ionization of more than one outer-shell electron become more important as the size of the target increases. These events are associated with small b , and electron–electron correlations are usually strong. Autoionization increases in significance for heavier targets. Here, also, collisions with small b dominate and electron–electron correlations are strong. For heavier targets, inner-shell effects, such as Auger electron or X-ray emission, become progressively more important. For molecular targets, dissociative ionization (either directly or through a highly excited intermediate state) and ion-pair formation also play a significant role.

In addition to the measurement of gross ion production, it is also possible to study the ionization process by monitoring the electron(s) ejected or scattered inelastically. Conventional electron spectroscopic techniques are used for this purpose. The addition of coincidence techniques (e–2e measurements) in which the momenta of all the electrons involved are completely specified has allowed many of the fine details of the ionization process to be extracted [41].

A major advance in the study of dissociative ionization has come with the development of so-called “reaction microscopes” [42–45] and “velocity slice imaging” spectrometers [46–48]. These allow 4π detection of fragment ions but also bring the possibility of complete momentum and angular distribution analysis of the fragment ions even from quite complicated polyatomic targets. *Slaughter et al.* [49] provide a recent review of how these and advanced theoretical techniques have been applied successfully in the case of dissociative attachment.

Dissociative attachment studies have featured prominently in the field of electron collisions ever since the early work [50] by Sanche’s group demonstrated that this process could lead to strand-breaking in DNA molecules. Since production of electrons in biological material following high-energy radiation input is governed by ionization processes, there has been much work on these as well [51]. A recent paper [52] provides an update on recent work on DNA bases together with references to relevant earlier studies. A recent discussion of absolute cross section evaluations following low-energy electron impact on DNA and the formation of transient anions is given in [53].

67.3 Coincidence and Superelastic Measurements

The cross section measurements described so far do not yield complete information on electron scattering processes. As was mentioned in Sect. 67.1.2, these cross sections do not

Fig. 67.4 Collisionally induced charge cloud in a p -state atom. The scattering plane is fixed by the direction of incoming \mathbf{k}_{in} and outgoing \mathbf{k}_{out} momentum vectors of the electrons. The atom is characterized by the relative length (l), width (w), and height (h) of the charge cloud, by its alignment angle γ , and by its inherent angular momentum L_{\perp} . The coordinate frame is the natural frame with the z -axis perpendicular to the scattering plane and with the x and y -axes defined as shown in the figure relative to \mathbf{k}_{in} and \mathbf{k}_{out}

distinguish magnetic sublevels, electron spin, etc., and represent summation of cross sections over these experimentally indistinguishable processes (summation of the square moduli of the corresponding scattering amplitudes). The quantum mechanical description of a scattering process is given in terms of scattering amplitudes and under certain conditions requires summing up amplitudes and squaring the sum. This leads to interference terms that arise from the coherent nature of the scattering process. A complete characterization of a scattering process, therefore, requires knowledge of the complex scattering amplitudes.

Sophisticated experimental techniques have been developed in recent years, which go beyond the conventional scattering cross section measurements and yield information on magnetic sublevel specific scattering amplitudes and the polarization (alignment and orientation) of the excited atomic ensemble. The experimental techniques fall into two main categories: a) electron–photon coincidence measurements and b) superelastic scattering measurements involving coherently excited species. (We still consider unpolarized electron beams in the description of these two techniques here and will address the question of spin polarization in the following section.)

In electron–photon coincidence measurements, the radiation pattern emitted by the excited atom is determined for a given direction of the scattered electron. A scattering plane is defined by \mathbf{k}_i and \mathbf{k}_f , and hence the symmetry is lowered from cylindrical (around the incident beam direction) to planar, see Fig. 67.4.

It is now possible to determine, at least in principle, both the atomic alignment (i.e., the shape of the excited state

charge cloud and its alignment in space) and its orientation (i.e., the angular momentum transferred to the atom during the course of the collision). Complete sets of excitation amplitudes for the coherently excited atomic states and their relative phases have been measured in some cases. A comparison with theory can then be made at the most fundamental level. See [54] for a full discussion and analysis.

The electron–photon coincidence measurements can be carried out in two ways: (1) measuring polarization correlations and (2) measuring angular correlations. In (1), polarization analysis of the emitted photon in a given direction occurs, while in (2), the angular distribution of the emitted photons is determined without polarization analysis. We will describe here only method (1) in some detail.

Method (1) has the advantage that it directly measures the angular momentum (perpendicular to the scattering plane) transferred in the collision. For P -state excitation from a 1S_0 ground state, four parameters plus a cross section are needed to describe the collisionally excited P -state fully. The natural parameters introduced by Andersen et al. [54] are defined as follows (Fig. 67.4): γ is the alignment angle of the excited state charge cloud relative to the electron beam axis, P_ℓ^+ is the linear polarization in the scattering plane, L_\perp^+ is the orbital angular momentum perpendicular to the scattering plane that is transferred to the atom in the collision, and ρ_{00} is the relative height of the charge cloud perpendicular to the scattering plane at the point of origin. The $+$ superscript indicates positive reflection symmetry with respect to the scattering plane.

In polarization correlation experiments, one typically measures two linear (P_1, P_2) and one circular (P_3) polarization correlation parameters perpendicular to the scattering plane. One additional linear polarization correlation parameter P_4 is measured in the scattering plane. Each parameter is the result of two intensity measurements for different orientations of the polarization analyzer

$$\begin{aligned} P_1 &= \frac{I(0^\circ) - I(90^\circ)}{I(0^\circ) + I(90^\circ)} \beta^{-1}, \\ P_2 &= \frac{I(45^\circ) - I(135^\circ)}{I(45^\circ) + I(135^\circ)} \beta^{-1}, \\ P_3 &= \frac{I^R - I^L}{I^R + I^L} \beta^{-1}, \\ P_4 &= \frac{I(0^\circ) - I(90^\circ)}{I(0^\circ) + I(90^\circ)} \beta^{-1}. \end{aligned} \quad (67.13)$$

Here, $I(\alpha)$ denotes the photon intensity measured for a polarizer orientation α with respect to the electron beam axis, I^R and I^L refer to right and left-handed circularly polarized light, and β denotes the polarization sensitivity of the polarization analyzer. The relationships between the experimentally determined polarization correlation parameters and

the natural parameters are given by

$$\begin{aligned} \gamma &= \frac{1}{2} \tan^{-1}(P_2/P_1), \\ P_1^+ &= (P_1^2 + P_2^2)^{1/2}, \\ L_\perp^+ &= -P_3, \\ \rho_{00} &= \frac{(1 + P_1)(1 - P_4)}{4 - (1 - P_1)(1 - P_4)}. \end{aligned} \quad (67.14)$$

The total polarization P_{tot}^+ , which is defined as

$$\begin{aligned} P_{\text{tot}}^+ &= \left[(P_1^+)^2 + (L_\perp^+)^2 \right]^{1/2} \\ &= (P_1^2 + P_2^2 + P_3^2)^{1/2}, \end{aligned} \quad (67.15)$$

is a measure for the degree of coherence in the excitation process. In the absence of atomic depolarizing effects due to, for example, fine and/or hyperfine interactions, a value of $P_{\text{tot}}^+ = +1$ for the emitted radiation indicates total coherence of the excitation process.

Much of the earlier work involved excitation of helium n^1P states. Here, the situation is simplified as L – S coupling applies strictly: $P_4 = 1$, and ρ_{00} is zero. Excitation of the 2^1P state, for example, is fully coherent, and hence the excitation is completely specified by just two parameters, γ and L_\perp (or P_1 since $P_1 = (1 - L_\perp^2)^{1/2}$). More recently, the techniques have been applied to heavier targets and more complicated excitation processes [55–59].

The superelastic scattering experiments could be looked at as time-inverse electron–photon coincidence experiments (although this is not exactly the case). In these experiments, a laser beam is utilized to prepare a coherently excited, polarized ensemble of target atoms for the electron scattering measurement. The superelastic scattering intensity is then measured as a function of laser-beam polarization and/or angle with respect to a reference direction. Linearly polarized laser light produces an aligned target (uneven population in magnetic sublevels for quantum numbers of different $|M_J|$ values). Circularly polarized laser light produces oriented targets (uneven population in $M_J = +m$ and $M_J = -m$ magnetic sublevels). From these measurements, the same electron impact coherence parameters can be deduced as from the coincidence experiments. The big advantage of these experiments over the coincidence ones is that the data production rates are much higher, often by many orders of magnitude. When the technique is combined with the use of the magnetic angle changing device (MAC) [60], the coherence parameters can be obtained for the complete range of electron scattering angles. The MAC device is basically a coil system generating variable magnetic fields without disturbing a free flow of atomic and electron beams. The B-field steers the incident electron beam into the interaction region, and the electrons change angle as they pass into the MAC

device, which is a direct consequence of the B-field changing from negative to positive. This superelastic scattering approach has been applied to atomic species (mainly metal atoms) that are conveniently excited with available lasers. Detailed descriptions of the experimental techniques, the underlying theoretical background, and the interpretation of the experimental data are given in [61–70].

It should be noted that electron scattering by coherently excited atoms can be utilized not only to obtain electron impact coherence parameters for inelastic processes originating from ground state but for elastic, inelastic, and superelastic transitions involving excited states. These measurements yield information on the creation, destruction, and transfer of alignment and orientation in electron collision processes, which is needed, e.g., in the application of plasma polarization spectroscopy [71].

67.4 Experiments with Polarized Electrons

So far, we have considered the utilization of unpolarized electron beams that yield spin-averaged cross sections. Little information on spin-dependent interactions is gained from these experiments. However, these interactions can be studied using polarized electron beam techniques. Developments on both the production and detection of spin-polarized electron beams have resulted in a wide range of elegant experiments probing these effects. The theory is also highly developed. For a detailed discussion, see the work of Kessler [72, 73], Blum and Kleinpoppen [74], Hanne [75–77], and Andersen et al. [57, 58] and the references therein. Some basic concepts are presented here.

The degree of polarization P of an electron beam is given by

$$P = \frac{N(\uparrow) - N(\downarrow)}{N(\uparrow) + N(\downarrow)}, \quad (67.16)$$

where $N(\uparrow)$ and $N(\downarrow)$ are the numbers of electrons with spins parallel and antiparallel, respectively, to a particular quantization direction. Measurements of P both before and after the collision enable one to probe directly for specific spin-dependent processes. For example, in elastic scattering from heavy spinless atoms, any changes in the polarization of the electrons must be caused by spin–orbit interactions alone since, in this instance, it is not possible to alter the polarization of the electron beam by electron exchange. Measurements have been carried out for Hg and Xe for both direct (f) and spin-flip (g) scattering amplitudes, as well as their phase differences [73].

The spin–orbit interaction for the continuum electron caused by the target nucleus leads to different scattering potentials and, consequently, to different cross sections for

spin-up and spin-down electrons (called Mott scattering). Consequently, an initially unpolarized electron beam can become spin polarized after scattering by a specific angle according to

$$\mathbf{P}' = S_p(\theta)\hat{\mathbf{n}}, \quad (67.17)$$

where $\hat{\mathbf{n}}$ is the unit vector normal to the scattering plane, $S_p(\theta)$ is the polarization function, and \mathbf{P}' is the polarization of the scattered beam. For the same reasons, when a spin-polarized electron beam is scattered by an angle θ to the left and to the right, an asymmetry is found in the scattering cross sections. Furthermore, an existing polarization \mathbf{P}' can be detected through the left–right asymmetry A in the differential cross section, which is given by

$$A \equiv \frac{\sigma_l(\theta) - \sigma_r(\theta)}{\sigma_l(\theta) + \sigma_r(\theta)} = S_A(\theta)\mathbf{P}' \cdot \hat{\mathbf{n}}, \quad (67.18)$$

where $\sigma_l(\theta)$ and $\sigma_r(\theta)$ are the differential cross sections for scattering at an angle θ relative to the incident beam axis to the left and to the right, respectively. For elastic scattering, the polarization function S_p , and the asymmetry function S_A are identical and are called the Sherman function.

When electron exchange is studied under conditions where other explicitly spin-dependent forces can be neglected, the cross sections for the scattering of polarized electrons from polarized atoms depend on the relative orientation of the polarization vectors. According to [73]

$$\sigma(\theta) = \sigma_u(\theta)[1 - A_{\text{ex}}(\theta)\mathbf{P}_e \cdot \mathbf{P}_A], \quad (67.19)$$

where \mathbf{P}_e and \mathbf{P}_A are the electron and atom polarization vectors, and $\sigma_u(\theta)$ is the cross section for unpolarized electrons. Hence, an *exchange asymmetry* $A_{\text{ex}}(\theta)$ can be defined by

$$A_{\text{ex}}(\theta)\mathbf{P}_e \cdot \mathbf{P}_A = \frac{\sigma_{\uparrow\downarrow}(\theta) - \sigma_{\downarrow\uparrow}(\theta)}{\sigma_{\uparrow\downarrow}(\theta) + \sigma_{\downarrow\uparrow}(\theta)}, \quad (67.20)$$

where $\sigma_{\uparrow\uparrow}(\theta)$ and $\sigma_{\uparrow\downarrow}(\theta)$ denote the cross sections for parallel and antiparallel polarization vectors, respectively. As Bartschat [78] points out, an asymmetry can occur even if the scattering angle is not defined. In this case, the function $A_{\text{ex}}(\theta)$ is averaged over all angles. Differential and integral measurements of this kind have been performed for elastic scattering, excitation, and ionization.

For heavy target systems it is necessary to consider a combination of effects together with a description of the target states in the intermediate or fully coupled scheme. Consequently, the number of independent parameters can become very large, and the *complete* experiments, which disentangle the various contributions to any observed asymmetry in the scattering, are rarely possible.

Even for very light target atoms, where conventional Mott scattering is negligible, *Hanne* [75] has shown that the *fine structure* effect, in which electron scattering from individual fine structure levels of a multiplet occurs, can lead to polarization effects. In fact, it can be a dominating effect for inelastic collision processes.

For full details of these various mechanisms and how density matrix theory and other theoretical techniques have been applied to scattering involving polarization effects, the reader is referred to the review articles cited, particularly *Andersen* et al. [57].

In certain cases, experiments involving spin-polarized electron beams coupled with coincidence (or superelastic) measurements allow one to extract the maximum possible information for a given process and are termed complete or perfect in the sense defined by *Bederson* [79–81].

It has also been possible to use spin-polarized electron beams to extract the fine details of electron–atom and electron–molecule interactions, where the detection of photons or ions rather than electrons occurs (e.g., [82, 83]).

67.5 Electron Collisions with Excited Species

There are many plasma systems where electron collisions with excited atoms and molecules play a prominent role, e.g., electron beam and discharge pumped lasers, and planetary and astrophysical plasmas. Especially important are electron collisions with metastable species because of the long lifetime, large cross section, and large amount of excitation energy associated with them. Electron collision studies and cross section data in this area are scarce, mainly due to experimental difficulties associated with the production of target beams with sufficiently high densities of excited species. With the application of lasers for the preparation of the excited species, this problem can be overcome. However, this approach has not yet been extensively exploited. Reviews of this field are given by *Lin* and *Anderson* [84], *Trajmar* and *Nickel* [85], and *Christophorou* and *Olthoff* [86].

Since electron collisions with excited species necessarily involve a method of preparation, they are two-step processes. Excitation and ionization in these cases are frequently referred to as stepwise excitation and ionization. The target preparation leads to mixed beams containing both ground and excited atoms or molecules. Preparation of excited atoms is achieved by electron impact or photoabsorption. Fast metastable beams can be produced by near-resonance charge exchange. For more details, see [85, 87, 88]. Electron impact excitation is simple and effective but highly nonspecific, and characterization of the composition of the mixture is difficult. Laser excitation is more involved but very well defined. Specific fine and hyperfine levels of individual isotopes can be excited. When laser excitation is used in conjunction with su-

perelastic electron scattering, an energy resolution of 10^{-8} eV is easily achieved, compared with the 10^{-2} eV resolution possible in conventional electron scattering.

Depending on the method of preparation, the population distribution in the magnetic sublevels of the target atoms may be uneven and some degree of polarization (alignment or orientation) may be present. The scattering will then be ϕ -dependent. For polarized target atoms the measured electron collision cross sections do not correspond to the conventional cross sections (which are summed over final and averaged over initial experimentally indistinguishable states, with equal populations in the initial states). One, therefore, has to characterize precisely the state of the target beam in order to be able to deduce a well-defined, meaningful cross section. Polarization of atoms can be conveniently controlled, in the case of excitation with laser light, through the control of the laser light polarization (as discussed in Sect. 67.3). Since the atomic ensemble is coherently excited in this case, the scattering cross sections will depend on the azimuthal scattering angle ϕ . These considerations also come into play when one tries to relate measured inelastic and corresponding inverse superelastic cross sections by the principle of detailed balancing.

67.6 Electron Collisions in Traps

A technique that has recently begun to be exploited involves collisions with trapped atoms. Pioneered by *Lin* and colleagues [89, 90], using Rb targets, the technique has many advantages over more conventional techniques, not the least of which is the fact that the absolute number density of the target need not be known. Cross section data are obtained from measurements of trap loss and electron beam current density. Because up to half of the atoms in the trap can be in the excited state, it is possible to make measurements of cross sections involving excited states as well [91, 92]. Measurements involving Cs targets have also been reported [93].

67.7 Current Applications

Electron-impact driven processes have been identified as being of fundamental importance in many diverse areas, including waste remediation and environmental cleanup [94], and medical [95], technological [96], and space applications. For example, one of the most important environmental applications is terrestrial “space weather”. This can affect the accurate functioning of spaceborne and ground-based communication systems, have a negative impact on infrastructure and technology, as well as endanger human health. Space weather is created by N_2 , the most abundant constituent of the Earth’s atmosphere. Nitrogen molecules collide with

low-energy secondary electrons generated by collision processes involving high-energy particles from the “solar wind”. Line (band) intensities (cross sections) from atmospheric species (such as N_2 in the case of the Earth) are widely used as indirect probes of atomic and molecular concentrations and are, thus, used as a diagnostic tool in atmospheric chemistry [97].

In the medical field, investigations on low-energy electrons and their role in DNA damage have been carried out; see Sect. 63.2.6 for more details. A comprehensive understanding of data of this nature has a vital importance in the modeling of radiation damage to biological tissues and in cancer treatment. [95].

In the technology area, for example, atomic and molecular collision processes play an important role in the edge region of fusion plasmas for understanding the plasma–wall interactions that govern fueling and recycling processes. This leads to optimization in designing a new generation of fusion reactors [98]. Recent advancements in the availability of reliable data for electron impact collisions with atoms and molecules have also enabled development of high-efficiency lasers [99].

In space environments, the modeling of planetary plasmas (energy budget and general behavior), interpretation of optical observations, electron flux and energy distributions require accurate dissociative and direct electron impact excitation cross sections for processes involving the atmospheric and ionospheric constituents of planetary bodies. A large fraction of these electrons are energetic enough to cause further ionization and, thus, produce a large number of secondary electrons. In addition, charged particles accelerated in the magnetic field of planets can contribute significantly to the planetary plasma by ionizing collisions. These secondary electrons are very effective in various collision processes because both the cross sections and the electron energy distributions peak at low energies (from a few tenths of an eV to about 100 eV). The auroral phenomenon in the atmospheres of Earth [97, 100], Venus [101], and Mars [102], the electroglow in the ionosphere of giant planets [103], the oxygen emission features prominent in the far ultraviolet (FUV) airglow spectrum of Europa [104] and Ganymede [105], the UV emission from the Io plasma torus [106], and the UV emission from Titan [107, 108] all clearly demonstrate the importance of the electron impact excitation and emission processes from atomic and molecular species (and their ions) such as O, S, O_2 , CO, N_2 , H_2 , CO_2 , and SO_2 .

67.8 Emerging Applications

Electron collisions with atoms, molecules, ions, and surfaces have formed the basis of many areas of science and technology and will continue to empower new, emerging applications [109]. Next-generation laser development and

micro and nanotechnology-based microprocessor fabrication are exciting emerging applications of electron collisions.

Recently, the international community has been investing heavily in high-powered (kW-class) diode-pumped alkali laser (DPAL) development research, with particular interest in scaling for defense, power beaming, and industrial applications. Key alkali laser processes require accurate ionization and recombination data [110]. Electron collisions in intense laser field situations is also an exciting field that is rapidly expanding [111, 112].

Plasma-using technologies such as the remote plasma etching (RPE) technique in fabricating next generation microprocessors require accurate and comprehensive sets of electron collision data. Further development and optimization of the RPE technique is critically dependent on the quality of fundamental electron and ion scattering data [113]. Developments in large-scale supercomputing capabilities have opened the door to calculations involving large molecules, which could not even have been contemplated a few years ago. Electron-initiated dissociation of large molecules can act as a catalyst for reactive chemistry in environmentally sensitive situations.

Abstract

This chapter outlines the physical principles and experimental methods used to investigate low energy ion–atom collisions. A low-energy collision is here defined as one in which the initial ion–atom relative velocity v is less than the mean orbital velocity $\langle v_e \rangle$ of the active electrons during the collision. For outer or valence electrons, $\langle v_e \rangle \simeq v_B$, where $v_B = 2.1877 \times 10^8$ cm/s is the Bohr velocity. In terms of the energy of a projectile ion, v_B corresponds to 24.8 keV/u.

The theory and results of ion–atom scattering studies are further discussed in other chapters of the book. The focus here is on the experimental techniques. Since several of these depend on the characteristics of a specific process, the following section presents a summary of the physics of low-energy ion–atom collisions.

Keywords

electron capture · single-electron capture · relative collision energy · total cross section · measurement · model charge transfer

68.1 Low-Energy Ion–Atom Collision Processes

For the low-energy region, electron capture between charged ions and atoms is the most important and widely studied inelastic collision process. Electron capture, also referred to as charge exchange or charge transfer, is a process where one or several target electrons are captured by the projectile ion and is described by

where Q is the potential energy difference between the initial and final states.

For an exoergic process, $Q > 0$, and this energy appears as excess kinetic energy of the products after the collision. For an endoergic process, $Q < 0$ and must be provided by the initial kinetic energy of the reactants, so that the corresponding cross section is usually small at low collision energies. If Q is zero or very small, it is a resonant or near-resonant electron capture process, and the resulting cross section is appreciable even at very low energies.

Electron capture by multiply charged ions from atoms is predominantly an exoergic process, for which cross sections

Fig. 68.1 Typical cross section variation with collision energy for electron capture by a multiply charged ion from hydrogen. The low-energy behavior depends on the structure of the quasi molecule formed during the collision

may also be large at low energies. In this case, electrons are preferentially captured into excited levels of $A^{(q-k)+}$. As shown in Fig. 68.1, the typical cross section behavior for single-electron capture ($k = 1$) by a multiply charged ion from atomic hydrogen is described by the $q \times 10^{-15} \text{ cm}^2$ scaling law. At intermediate and high collision energies, the initial ionic charge is no longer the major determinant of the cross section, whereas at low energies, the cross section strongly depends on the structure of the transient quasi molecule formed during the collision. For the thermal energy region (not shown in Fig. 68.1), the cross section shows a $1/v$ dependence (v is the collision velocity) due to the attractive ion-induced dipole [1]. Several techniques like gas target, crossed ion beam, merged beam methods, etc., have been developed for total cross section measurements.

For a multiply charged ion collision with a neutral atom, as shown in Fig. 68.2, electron capture reaction channels that are moderately exoergic produce curve crossings at internuclear separations where there is sufficient overlap of the electron clouds for electron capture to be a likely process. The Landau–Zener curve-crossing model [2], the classical over-barrier model for single capture [3], and the extended classical over-barrier model for multiple capture [4] are useful in predicting the important final product states, and in providing a semiquantitative interpretation. In the case of single-electron capture by a bare multiply charged ion (of charge $q = Z$) from a hydrogen atom, the principal quantum number n_p of the most probable final ionic state is given in

Fig. 68.2 Potential energy curves for the collision of a multiply charged ion A^{q+} with a multielectron atom B

this model [3] by

$$n_p = \sqrt{\frac{2Z^{1/2} + 1}{Z + 2Z^{1/2}}} \quad (68.2)$$

The internuclear separation R_p at which the potential curves cross in this case is given by

$$R_p = \frac{2(Z - 1)}{Z^2/n_p^2 - 1} \quad (68.3)$$

Multiple electron capture ($k > 1$) from multielectron atoms occurs predominantly into multiply excited levels, which stabilize either radiatively, leading to stabilized or *true* double capture, or via autoionization. The latter process is usually referred to as transfer ionization,

At low energies, transfer ionization is particularly important in collisions of highly charged ions with multielectron atoms. There has been much discussion of the role of electron correlation in the multiple-electron capture process. An issue is the relative importance of the mechanism whereby several electrons are transferred (in a correlated manner) at a single curve crossing compared with electrons transferred sequentially at different curve crossings.

Measurements of the distribution of final product electronic states as well as its angular scattering can provide insight into electron capture collision mechanisms [5]. This motivated the development of experimental detection techniques beyond the total cross section measurement for measuring the nl -resolved differential cross sections (n and l

are the principal quantum number and angular momentum quantum number, respectively) and angular differential cross sections. To this end, traditional electron spectroscopy, energy gain spectroscopy, photon emission spectroscopy, as well as recoil ion momentum spectroscopy, etc., have been developed [6]. A lot of progress has been achieved by measuring nl -resolved differential cross sections. There have been some measurements of the electron dipole and current density following electron transfer [7, 8]. The next generation of electron capture experiment would be expected to measure nlm -resolved differential cross sections (m is the magnetic substate quantum number), i.e., the captured electron is initially prepared in a specific nlm state.

Other inelastic ion-atom collision processes, such as direct electronic excitation and ionization, are endothermic, with relatively small cross sections that fall off with decreasing energy below a few tens of keV/u. Exceptions are collisions involving Rydberg atoms and collisional excitation of fine structure transitions, for which the required energy transfer is relatively small. There is only a small amount of experimental data available for direct excitation and ionization processes at low collision energies.

68.2 Experimental Methods for Total Cross Section Measurements

In the present context, a total cross section measurement refers to an integration or summation over scattering angles, product kinetic energies and (frequently) electronic states. The total cross section is usually measured as a function of relative collision energy or velocity.

68.2.1 Gas-Target Beam Attenuation Method

The attenuation of a collimated ion beam of incident intensity I_0 in a differentially pumped gas target cell or gas jet is related to the collision cross section σ by

$$I = I_0 e^{-\sigma NL}, \quad (68.5)$$

where I is the intensity after traversing an effective length L of the target gas, and N is the number density of target atoms. For a gas target cell with entrance and exit apertures of diameter d_1 and d_2 , which are much less than the physical length z of the gas cell, L is given to a good approximation by $z + (d_1 + d_2)/2$. This is valid under molecular flow conditions, for which the mean free path between collisions of target atoms is much larger than the dimensions of the gas cell.

In designing the gas cell for measurements of total cross sections, d_2 and the beam detector must be large enough that elastic scattering may be eliminated as a contributor to the measured attenuation. Usually d_2 is made larger than d_1 . Measurement of the gas pressure in a target cell is usually made using a capacitance manometer connected to the cell via a tube whose conductance is much larger than that of the gas cell apertures so that, to a good approximation, the pressure will be the same in both the manometer and the gas cell. For gas jet targets, the effective target thickness NL is usually determined by in-situ normalization to some well-known cross section.

The quantity σ in Eq. (68.5) refers to an effective cross section for removing projectile ions from the incident beam, which is the sum of cross sections for all such processes. In many cases, a single process (e.g., electron capture) is dominant, and σ primarily describes that process. Whether or not a collision process removes a projectile ion from the reactant beam depends on the configuration of the experiment. For example, the projectile particle may remain physically in the beam after passing through the target, but with a changed charge due to a collision. This would be registered as an attenuation of the primary ion beam if the beam is charge analyzed after the reaction.

68.2.2 Gas-Target Product Growth Method

The product growth method is similar to the beam attenuation method; the major difference is that the growth of reaction products is measured rather than the loss of reactant projectiles. The products may be derived from either the projectile beam or the gas target, or both. The main advantage of this method is its higher degree of selectivity of a specific collision process. In addition, the reactants and products can usually be registered simultaneously, or in some cases in coincidence, eliminating the sensitivity of the measurement to temporal variation of ion beam intensity.

An important criterion is that the density of the target gas be low enough that single collision conditions prevail (i.e., that the likelihood of an ion passing through the gas target and interacting with more than one target atom is negligibly small). This must, in general, be satisfied in order for Eq. (68.5) to correctly relate the measured attenuation to the collision cross section of interest and is critical to the product growth method [9]. In this case, under single-collision conditions, one may set the number of products $I_p = I_0 - I$, and Eq. (68.5) may then be written as

$$\frac{I_p}{I_0} = 1 - e^{-\sigma NL} \approx \sigma NL. \quad (68.6)$$

The approximate expression is useful for $\sigma NL \ll 1$, which is a requirement for single-collision conditions. It is also important that the products not be lost in a subsequent collision in the gas cell, so the magnitudes of cross sections for the loss of products in the target gas must also be considered. The products in such an experiment may be derived from either the projectile beam or the target gas (e.g., collection of slow product ions in a gas cell), or from both in coincidence to enhance the specificity of the method. The method may, in principle, be used to determine either total or differential cross sections, depending on the degree of selectivity of collision products.

68.2.3 Crossed Ion and Thermal Beams Method

Replacement of the gas target cell by an effusive thermal beam is advantageous for studying collisions of ions with reactive species such as atomic hydrogen, as well as for collecting slow ion products. The use of accelerating electrodes or grids for slow charged products allows coincident detection of fast and slow products, permitting measurement of ionization as well as electron-capture cross sections. The use of an effusive source or gas jet precludes accurate measurement of the effective target thickness, and in-situ normalization to the cross section for some well-known process is usually employed. A comprehensive discussion of such methods as applied to collisions of multiply charged ions with atomic hydrogen is given by *Gilbody* [9].

68.2.4 Fast Merged Beams Method

Cross sections for ion–atom collision processes at very low energies have been measured by merging fast beams of ions and neutral atoms [10], as in Fig. 68.3. In this case, σ is determined from experimental parameters by

$$\sigma = \frac{R}{\epsilon} \frac{qe}{I_+ I_0} \frac{v_+ v_0}{|v_+ - v_0|} \frac{1}{L \Omega}, \quad (68.7)$$

where R is the number of products detected per second, ϵ is the product detection efficiency, q is the charge state of projectile ion, e is the electronic charge, I_+ is the ion current, I_0 is the neutral “current” (number/second) of atoms, v_+ and v_0 the laboratory velocities of the ion and atom beams, v_{rel} their relative velocity, and Ω is the overlap integral and is a measure of the spatial overlap of the two beams along the merged path L . Rigorously, the overlap of the beams should be determined by integrating the product of the current density j_+ and j_0 of the two beams at every point along the merged path

Fig. 68.3 The merged beams arrangement used at the multicharged ion research facility at Oak Ridge National Laboratory to study low-energy electron capture collisions of multicharged ions with H [10]

and is given by

$$\Omega = \frac{\iiint j_+(x, y, z) j_0(x, y, z) dx dy dz}{\iiint j_+(x, y, z) dx dy dz \iiint j_0(x, y, z) dx dy dz}. \quad (68.8)$$

A variety of three-dimensional and approximate schemes have been developed to measure the overlap of the two beams (Chap. 4 in [6] and references therein).

The relative collision energy E_{rel} in eV/u is given by

$$\frac{E_{\text{rel}}}{\mu} = \frac{E_+}{m_+} + \frac{E_0}{m_0} - 2 \sqrt{\frac{E_+}{m_+} \frac{E_0}{m_0}} \cos \theta, \quad (68.9)$$

where E_+ , m_+ , and E_0 , m_0 are the energies and masses of the ion and atom, respectively, and μ is their reduced mass. For collinear merged beams, $\theta = 0$ and E_{rel} can be reduced to zero by making the two beam velocities the same. In practice, the finite divergences of the beams place a lower limit on the energy and the energy resolution. The fast neutral atom beam can be created by neutralizing an accelerated positive ion in a gas via electron capture, or by electron detachment of a negative ion beam either in a gas, or by using a laser. In gas collisions, a small fraction of the neutral beam is produced in excited n -levels (with an n^{-3} distribution), which may influence the measurements.

With fast colliding beams, the maximum effective beam densities are invariably much smaller than the background gas density, even under ultrahigh vacuum conditions. For example, a typical 10 keV proton beam with a circular cross section of diameter 3 mm and a current $I = 10 \mu\text{A}$ has an average effective density $n = I/(eav) = 1.6 \times 10^6 \text{ cm}^{-3}$ (a is the beam cross sectional area, and v is its velocity). It is, therefore, necessary either to modulate the beams or to use coincidence techniques to separate signal events due to beam–beam collisions from background events produced by collisions of either beam with residual gas. A typical two-beam modulation scheme is described in [10]. To eliminate

the production of spurious signals, the signal detector is gated “on” a short time after the beams are switched, and the beam modulation period is made much shorter than the pressure time constant of the vacuum system.

Absolute electron-capture cross sections have been measured for $\text{Si}^{4+} + \text{D}$ collisions to energies below 1 eV/u, where the attractive ion-induced-dipole (polarization) interaction is expected to play a role [1]. The inverse velocity dependence of the cross section in this region is suggestive of the classical Langevin orbiting model for ion–neutral collisions [11].

68.2.5 Trapped Ion Method

The trapped ion method is used to determine rate coefficients and effective cross sections for ion–atom collisions at near thermal energies. The technique involves storing ions in an electrostatic or electromagnetic trap and measuring the rate of loss of ions from the trap after a small quantity of neutral gas is admitted [12]. Like the beam attenuation method, the trap technique cannot distinguish different processes that cause ions to be lost from the trap. The mean collision energy is estimated from an analysis of the ion dynamics in the trap. Collisions at temperatures of a few K and below have been achieved in, e.g, a magneto-optical (MOT) trap.

68.2.6 Swarm Method

The swarm method, using the flowing afterglow, drift tube, or selected-ion flow tube, has been used successfully to study ion–atom collisions at very low energies [13]. Ions are injected into a homogeneous electric field and drift through a suitable low-density buffer gas such as helium. The ions move as a swarm whose mean energy depends on the applied electric field and on collisions with the buffer gas and can be varied from the near-thermal region to tens of eV. The method involves measuring the additional attenuation of the directed ion swarm by a known quantity of added reactant gas and is the major technique that has been used for the study of ion–atom collisions at near-thermal energies [14]. As with ion beam attenuation and ion trap methods, the drift tube is not selective of the process that leads to attenuation of the ion swarm.

68.3 Methods for State-Selective Measurements

Four principal methods have been developed and applied to the measurement of partial cross sections for the population of specific product electronic states in ion–atom collisions involving electron capture [15]. These are photon emission, translational energy gain, electron emission, and cold target

recoil ion momentum spectroscopy (COLTRIMS) in collisions of ion beams with gas targets.

68.3.1 Photon Emission Spectroscopy

At low energies, electron capture from an atom by a charged ion usually populates excited levels. Since the timescale of photon emission deexcitation is several orders of magnitude larger than the collision time, and photon emissions usually show discrete spectroscopic structure, the measured photon spectra contain state-selective information. For example, photon emission spectra can be used to measure emission cross sections and electron capture state-selectivity involving angular momentum quantum states [16, 17]. A calibrated grating or crystal spectrometer can be used to record spectra. By summing the signal under a peak area in the spectra, the emission cross sections can be calculated via the relation

$$\sigma_{\text{em}}\lambda = \frac{4\pi}{\omega} \frac{q}{K(\lambda)Q_c} \frac{S(\lambda)}{NL}, \quad (68.10)$$

where σ_{em} is the emission cross section, ω is the solid angle of observation, q is the charge of the projectile ions, Q_c is the accumulated ion charge, $K(\lambda)$ is the wavelength dispersive quantum yield of the detection system, $S(\lambda)$ is the measured signal, N is the effective target density, and L is the observation length.

Similar measurements have also been performed with an x-ray quantum microcalorimeter (XQC) detector based on cryogenic techniques [18], with which the photon spectral range is extended beyond the visible and vacuum ultraviolet to the X-ray region. The measurements are able to cover all direct and many possible cascade emissions. Complementary, with an electron beam ion trap, those X-ray emissions due to charge exchange arising from forbidden transitions can be observed [19–21]. These long-lived transitions are not accessible with the traditional ion extraction mode.

68.3.2 Translational Energy Spectroscopy

Translational energy loss or energy gain spectroscopy provides a convenient method to determine the distribution of final states in low-energy ion–atom collisions that are either endoergic or exoergic ($Q \neq 0$). For example, this method has been used extensively by the Belfast group [22] to study the predominantly exoergic process of electron capture by multiply charged ions from hydrogen atoms. An ion beam with a well-defined energy is directed through a gas target, and the energy of the product ion beam is energy analyzed after the collision. Since the energy gain or loss to be measured is only a very small fraction of the initial kinetic energy, it is

usually necessary to reduce the initial energy spread to a few tenths of an eV by decelerating the reactant ion beam prior to energy selection by an electrostatic analyzer. If the scattering angle of the ion is very small, its energy change is approximately equal to Q . Since the ion beam is attenuated by deceleration and energy analysis, cross sections for collisionally populating specific states are determined by normalizing the measured product-state distributions to total cross section data. The attainable state resolution is not as good as for photon emission spectroscopy.

68.3.3 Electron Emission Spectroscopy

As noted in Sect. 68.1, multiple-electron capture by multiply charged ions from atoms at low energies occurs primarily into multiply excited states, which decay either radiatively or via autoionization [5]. The latter decay pathway (transfer ionization) provides an experimental method to determine the product ionic states by ejected-electron spectroscopy. Analysis of electrons emitted into the forward (ion beam) direction (zero degree spectroscopy) offers significant advantages for analysis of low-energy electrons with high resolution [23]. Since a gas jet is often employed, and absolute electron collection and spectrometer efficiencies are difficult to determine, some normalization procedure is usually employed to determine state-selective cross sections by this method. Electrons and product projectile or recoil ions have also been detected in coincidence to increase the specificity of the method.

68.3.4 Recoil-Ion Momentum Spectroscopy

Over the past 20 years, a significant experimental technique development in ion–atom collisions is cold-target recoil ion momentum spectroscopy [24, 25], also called a *reaction microscope*. Its powerful multifold differential measurements have advanced ion–atom electron capture to the point where the details of state-selectivity become available. It has also been used to identify molecular or cluster geometry configurations and dissociation dynamics.

As shown in Fig. 68.4, the core components of a COLTRIMS apparatus are a time-of-flight (TOF) spectrometer, an ultracold supersonic gas jet, and two-dimensional position sensitive detectors (PSD). For an ion–atom electron capture collision, an energetic ion beam interacts with a precooled and localized supersonic gas jet at a right angle in the center of the TOF spectrometer, which consists of a homogenous electric field acceleration-region and field-free drift region. The slow recoil ions produced are accelerated by the electric field away from the collision zone towards a recoil-ion PSD. The charge changed projectile ions are separated from

Fig. 68.4 Schematic of the COLTRIMS apparatus used for ion–atom electron capture

the primary beam by the electrostatic deflector downstream of the collision zone and directed to a projectile PSD, while the primary beam is collected by a Faraday cup. The PSD detectors can record time and position information of the recoil ions and projectile ions. By making a time coincidence between the recoil ions and scattered projectile ions, the desired electron capture process can be identified, and background events are suppressed. Three-dimensional momentum vectors of the recoil ions can be constructed using kinematical expressions. The binding energy difference of the active electrons in the state-selective electron capture is reflected in the measured longitudinal momentum distributions of recoil ions. Angular differential information is obtained by the measured transversal momentum of the recoil ions, which is equivalent to that of the scattered projectile ions according to momentum conservation.

More recently, COLTRIMS was updated by replacing the supersonic gas jet with a MOT trap where more targets are available by laser cooling. This updated COLTRIMS is the so-called MOTRIMS [26], with which electron capture measurements have achieved an unprecedented resolution in low-energy ion–atom collisions. In addition, it is promising to combine x-ray detecting techniques with COLTRIMS, with which the spectroscopy of charged ions as well as collision dynamics can be studied in electron capture processes [27].

Charles Havener Charles Havener received his PhD in Physics from North Carolina State University in 1983. This was followed by a postdoc and research staff position at Oak Ridge National Laboratory. The merged-beam apparatus he developed measures charge exchange cross sections from meV to keV collision energies for ions on atomic H and is currently used to measure high-resolution x-ray spectra.

Ruitian Zhang Ruitian Zhang received his PhD from the Lanzhou University in 2013. He worked at Helmholtz Centre for Heavy Ion Research in Germany, at Oak Ridge National Laboratory and Columbia University in the City of New York, and at the Institute of Modern Physics, Chinese Academy of Sciences in China. He is currently working on experimental atomic collision physics, focusing on heavy ion-atom collision dynamics.

Ronald Phaneuf Phaneuf earned a PhD in Physics from the University of Windsor (1973) and has since been engaged in experimental research on interactions of ions with electrons, photons, atoms, and molecules using merged-beams and crossed-beams techniques. He was a postdoctoral fellow at JILA and researcher and program manager for atomic physics and plasma diagnostics for fusion at Oak Ridge National Laboratory. He is Professor Emeritus (University of Nevada).

Abstract

This chapter deals with inelastic processes that occur in collisions between fast, often highly charged, ions and atoms. Fast collisions are here defined to be those for which $V/v_e \geq 1$, where V is the projectile velocity and v_e the orbital velocity of this electron. For processes involving outer-shell target electrons, this implies $V \gtrsim 1$ a.u., or the projectile energy $\gtrsim 25$ keV/a.m.u. For inner-shell electrons, typically, $V \gtrsim Z_2/n$ a.u., where Z_2 is the target nuclear charge and n the principal quantum number of the active electron. A useful relationship is $V = 6.35\sqrt{E/M}$, where V is in a.u., E is in MeV, and M is in a.m.u. Fast

collisions involving outer-shell processes can be studied using relatively small accelerators, while those involving inner-shell processes require larger van de Graaffs, LINACs (linear accelerators), etc. Because the motion of the inner-shell electrons is dominated by the nuclear Coulomb field of the target, and because transitions involving these electrons take place rather independently of what transpires with the outer-shell electrons, it has proven to be somewhat easier to understand one-electron processes involving inner-shell electrons. Thus, for a long time, a great deal of the work on fast ion–atom collisions concentrated on inner-shell processes involving heavy-target atoms. However, more recently, new experimental techniques have led to a shift of this focus to inelastic processes involving light-target atoms. Furthermore, present investigations go beyond the one-electron picture to include the influence of the electron–electron interaction. The present chapter outlines some of the developments in this area over a very active past few decades. The literature is vast, and only a small sampling of references is given. Emphasis is on experimental results (for the theory, see Part D of this book).

69.1 Basic One-Electron Processes

69.1.1 Perturbative Processes

Inner-Shell Ionization of Heavy Targets

For ion–atom collisions involving projectile and target nuclear charges Z_1 and Z_2 , respectively, the parameters $\eta_1 = [\hbar V/(Z_1 e^2)]^2$ and $\eta_2 = [\hbar v_e/(Z_2 e^2)]^2$ are useful in characterizing the strength of the interaction between Z_1 , Z_2 , and

the target electron. If $\eta_2 \ll \eta_1$, (i.e., $Z_1/Z_2 \ll V/v_e$), the effect of the projectile on the target wave function can be treated perturbatively. Perturbation treatments of inner-shell ionization by lighter projectiles have been extensively studied and reviewed [1–8]. Two well-known formulations have been used: the plane wave Born approximation (PWBA) [1–4] and the semiclassical approximation (SCA) [9, 10]. The former represents the nuclear motion with plane waves, while the latter is formulated in terms of the impact parameter b with the nuclear motion treated classically. For straight line motion of the nuclei, the results are equivalent [11]. The total cross section for ionizing the K-shell of a target of charge Z_2 by a projectile of charge Z_1 is given within the PWBA by

$$\sigma_i = (8\pi Z_1^2/Z_2^4 \eta_2) f(\theta_2, \eta_2) a_0^2, \quad (69.1)$$

where $\theta_2 = 2u_k n^2/Z_2^2$, and u_k is the target binding energy. The function f rises rapidly for $V < v_e$, reaching a value near unity near $V = v_e$ and falling very slowly thereafter. Tables of f for K and L-shell ionization are given in [3, 4]. Figure 69.1 shows a comparison of experimental data for K vacancy production by protons with PWBA calculations, and with a classical binary encounter approximation [12] for a large range of proton data [6]. For larger Z_1 , corrections to the PWBA and SCA must be made for the effective increase of u_k due to the presence of the projectile during the ionization, for nuclear projectile deflection, for relativistic corrections, and for the polarization of the electron cloud, as reviewed in [13–17]. Total cross section measurements for inner-shell vacancy production in the perturbative region are reviewed in [15, 16].

In the SCA treatment, the heavy-particle motion is taken to be classical, and the evolution of the electronic wave function under the influence of the projectile field is calculated by time-dependent perturbation theory. The assumption of classical motion is valid if the Bohr parameter $K = 2Z_1 Z_2 e^2 / (\hbar V)$ is much larger than unity [18]. If this condition is satisfied, the projectile scattering angle can be associated with a particular b through a classical deflection function. For K-shell ionization, the action occurs typically at sufficiently small b that a screened Coulomb potential is sufficient for calculating the deflection. In the absence of screening, $\theta = r_0/b$, where $r_0 = Z_1 Z_2 e^2 / E$ with θ and E expressed in either the laboratory or center of mass system. Calculations for K and L-shell ionization have been carried out [10]. The typical ionization probability $P(b)$ for $V \approx v_e$ and $b = 0$ is $P(0) \approx (Z_1/Z_2)^2$. For $V < v_e$, $P(b)$ decreases with increasing b with a characteristic scale length of $r_{\text{ad}} = V/\omega$, the *adiabatic radius*, where ω is the transition energy. For $V > v_e$, $P(b)$ cuts off near the K-shell radius of the target. A more sophisticated relativistic SCA program has been written [19] and is widely used for calculating $P(b)$,

Fig. 69.1 Comparison of experimental cross sections for K-shell vacancy production with PWBA (*dashed line*) and binary encounter (*solid line*) theories; U_k is the target binding energy in keV and λ the projectile/electron mass ratio [6]

cross sections, and probabilities differential in the final electron energy and angle. Experimentally, the probability $P(b)$ for inner-shell ionization can be determined from

$$P(b) = \frac{1}{\epsilon \omega \Delta \Omega} \left(\frac{Y}{N[\theta(b)]} \right), \quad (69.2)$$

where Y is the coincidence yield for the scattering of $N(\theta)$ ions into a well-defined angle $\theta(b)$ accompanied by X-ray (or Auger electron) emission with fluorescence yield ω into a detector of efficiency ϵ and solid angle $\Delta \Omega$ [20]. The necessary ω can be obtained from calculations for neutral targets [21] (Chap. 66). However, they must be corrected for changes due to extensive outer-shell ionization during the collision. Such corrections are particularly important for targets with low fluorescence yields, for Z_2 below 30, and for collisions in which the L-shell is nearly depleted in the collision [15, 16]. Values of $P(b)$ have been measured for many systems and generally show good agreement (better than 10%) with the SCA for fast light projectiles such as protons, with increasing deviation as higher Z_1 or slower V are used [22]. Examples of $P(b)$ for K vacancy production for several systems are shown in Fig. 69.2, showing the evolution away from the SCA as the collision becomes less perturbative.

Fig. 69.2 $P(b)$ for K-shell vacancy production versus b/r_{ad} for several systems (see text). The ratio V/v_e is designated as V here. For protons p , agreement with the SCA theory is found [10], while for higher Z_1/Z_2 , $P(b)$ moves to larger impact parameters as one leaves the perturbative region [22]

Ionization of light-target Atoms

Ionization of light-target atoms by bare ion impact is a particularly suitable process to study the atomic few-body problem. In the case of an atomic hydrogen target the collision represents a three-body system, i.e., the simplest system for which the Schrödinger equation is not analytically solvable. However, because of the experimental difficulties associated with atomic hydrogen, measurements with this target species are rare [23, 24] and experimental studies have focused on helium targets. Here, the collision still constitutes a relatively simple four-body system. With regard to the few-body problem, studies of ionization processes have the important advantage that, in contrast to pure excitation and capture processes, the final state involves at least three independently moving particles.

Detailed information about the few-body dynamics in a collision can be extracted from multiply differential measurements. This can be accomplished by measuring the kinematic properties (e.g., energy, momentum, ejection angle) of one or more of the collision fragments. The first experimental multiply differential single-ionization cross sections were obtained by studying the ionized electron spectra as a function of energy and ejection angle. Such studies were reviewed by *Rudd et al.* [25] and are discussed in more detail in

Sect. 69.3. More recently, complementary multiply differential data were obtained by measuring projectile energy-loss spectra as a function of the scattering angle in $p + \text{He}$ and $p + \text{H}$ collisions [24, 26, 27].

A comprehensive picture of ionizing collisions can be obtained from kinematically complete experiments. In such a study, the momentum vectors of all collision fragments need to be determined. However, in the case of single ionization, it is sufficient to directly measure the momentum vectors of any two particles in the final state; the third one is then readily determined by momentum conservation. For ionization by electron impact, this has been accomplished by momentum-analyzing the scattered and the ejected electrons ([28] for a review). For ion impact, this approach is difficult because of the very small scattering angles and energy losses (relative to the initial collision energy) resulting from the large projectile mass. Consequently, the only kinematically complete experiments involving a direct projectile-momentum analysis were reported for light ions at relatively low projectile energies [29]. For heavy-ion impact at high projectile energies, in contrast, the complete determination of the final space state is only possible through a direct measurement of the ejected electron and recoil-ion momenta [30].

The technology to measure recoil-ion momenta with sufficient resolution, and therefore to perform kinematically complete experiments for heavy-ion impact, has only become available over the last 2 decades ([31–33] for reviews). Figure 69.3 shows measured (top) and calculated (bottom) three-dimensional angular distributions of electrons ionized in 100 MeV/a.m.u. $\text{C}^{6+} + \text{He}$ collisions for fully determined kinematic conditions [34]. The arrows labeled p_o and q indicate the direction of the initial projectile momentum and the momentum transfer defined as the difference between p_o and the final projectile momentum p_f . This plot is rich in information about the dynamics of the ionization process. The main feature is a pronounced peak in the direction of q . It can be explained in terms of a binary interaction between the projectile and the electron, i.e., a first-order process, and is thus dubbed the *binary peak*. A second, significantly smaller, structure is a contribution centered on the direction of $-q$ (called the *recoil peak*). This has been interpreted as a two-step mechanism where the electron is initially kicked by the projectile in the direction of q and then backscattered by the residual target ion by 180° . Although this process involves two interactions of the electron, it is nevertheless a first-order process in the projectile–target atom interaction. Therefore, as expected for this very large value of $\eta_1 = 100$ (in a.u.), the ionization cross sections are dominated by first-order contributions.

The basic features of the data in Fig. 69.3 are well reproduced even by the relatively simple first Born approximation (FBA). Furthermore, the calculation shown at the bottom

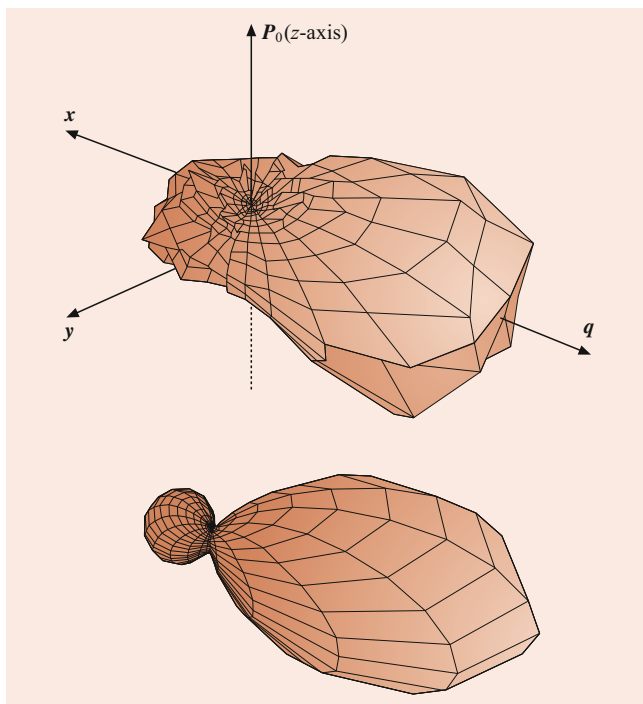

Fig. 69.3 Three-dimensional angular distribution for fully determined kinematic conditions of electrons ionized in 100 MeV/a.m.u. $C^{6+} + He$ collisions. *Top*, experimental data; *bottom*, CDW calculation (see text)

of Fig. 69.3, which is based on the more sophisticated continuum distorted wave approach (CDW) ([35–37], also Chap. 56), yields practically identical results to the FBA. In the CDW method, higher-order contributions are accounted for in the final-state scattering wavefunction. Apart from this good overall agreement, a closer inspection of the comparison between experiment and theory also reveals some significant discrepancies. While in the calculation the binary and recoil peaks are sharply separated by a minimum near the origin, in the data, this minimum is almost completely filled up, giving rise to a *ring-like* shape of the recoil peak. This was explained by a higher-order ionization mechanism involving an interaction between the projectile and the residual target ion [34, 37, 38]. Although the contribution of this process to the total cross section is negligible, it is a very surprising result that for selected kinematic conditions higher-order processes can be important even at large projectile energies. A sobering conclusion of recent research on ionization of light-target atoms is that even well inside the perturbative regime the atomic few-body problem is not nearly as well understood as was previously assumed based on studies for restricted collision geometries. At large perturbation, the lack of understanding is dramatic [39].

Part of these discrepancies may be related to a realization that was recently made in studies of ionization of H_2 by proton impact at a much smaller projectile energy. There it was found that interference structures are present in the scattering angle-dependent cross sections when the incoming

projectiles are coherent relative to the dimension of the target molecule but absent if the projectiles are incoherent [40]. The coherence properties of the projectiles, in turn, are basically determined by the width of the projectile wave packet in momentum space. If the momentum spread is too large, the phase relation between the overlapping amplitudes is not well defined, and no interference structure is observable. In contrast, in scattering theory, it is usually assumed that the incoming projectiles can be described in terms of a plane wave or a distorted wave, which corresponds to a sharp momentum, i.e., to fully coherent projectiles. Therefore, theory may predict interference structures that are not observable in experiments if the projectiles are incoherent.

In the ionization of atomic targets interference can arise from the superposition of different (nonobservable) impact parameters leading to the same (observable) scattering angle. Formally, this type of interference is reflected in the Fourier transform, which converts an impact parameter transition amplitude to a scattering angle-dependent amplitude. If the projectile is represented by a broad wave packet in momentum space, rather than, e.g., a plane wave, the Fourier transform can be altered considerably. Even in the coherent case, the interference resulting from the Fourier transform is not necessarily reflected by an oscillating pattern in the cross sections. Nevertheless, the effect of the momentum wave packet on the Fourier transform could explain differences between cross sections for coherent and incoherent projectiles and, thereby, the aforementioned discrepancies between theory and experiment on ionization of atomic targets.

This interpretation seemed to be confirmed by a study of ionization for a similar collision system as 100 MeV/a.m.u. $C^{6+} + He$, but for projectiles with a much higher degree of transverse coherence [41]. There, the discrepancies to theory were drastically reduced. Furthermore, this interpretation is supported by theoretical analyses [42, 43]. Another experimental study, also performed for a collision system with a perturbation parameter similar to 100 MeV/a.m.u. $C^{6+} + He$, was consistent with calculations assuming coherent projectiles [44]. However, there the smallest coherence length realized in the experiment was several orders of magnitude larger than for 100 MeV/a.m.u. C^{6+} and larger than the size of the target atom. A theoretical study showed that under these circumstances, much smaller decoherence effects are to be expected than for 100 MeV/a.m.u. C^{6+} collisions [43]. Nevertheless, further studies on the role of the projectile coherence properties are needed for collisions with small perturbation parameters. While for much slower collisions coherence effects have been reported for several cases ([45] for a recent review), the question of the extent to which the discrepancies between experiment and theory for the 100 MeV/a.m.u. $C^{6+} + He$ collision system can be explained by such effects has not yet been settled.

Initially, recoil-ion and electron-momentum spectrometers were operated in conjunction with supersonic gas jets

Fig. 69.4 Fully differential, three-dimensional angular distribution of electrons ejected in $7\text{ MeV Li}^{2+} + \text{Li}$ collisions

delivering target beams with a temperature around 1 K. While these setups made kinematically complete experiments possible, which, in turn, led to major advances in our understanding of the few-body dynamics, they also entail some drawbacks compared to conventional approaches. These include: a) the recoil-ion momentum resolution is limited by the achievable temperature that can be reached in supersonic gas jets. b) The energies of electrons detected simultaneously with the recoil ions is limited by the extraction voltage on the spectrometer. For the large voltages required to detect large-energy electrons with sufficiently large solid angle, the recoil-ion momentum resolution is compromised. c) The method is restricted to molecular and noble gas targets. However, the recoil-ion momentum resolution gets worse with increasing target mass. As a result, many applications are actually restricted to H_2 and He targets.

While the second problem is inherent to the spectrometer design, the first and third problems can be addressed by a different target design. A successful approach was to replace the supersonic jet with a gas target cooled in a magneto-optical trap (MOT). Initially, this method was only used in conjunction with momentum spectroscopy of the recoil ions, but no ejected electrons were momentum analyzed [46, 47]. Target temperatures reduced by about two orders of magnitude compared to gas jets were achieved, resulting in drastically improved recoil-ion momentum resolution. Furthermore, in principle, recoil ions can be momentum analyzed with much improved resolution for any target that can be optically pumped, independent of the target mass.

One enormous challenge posed by a MOT target is the momentum analysis of ejected electrons. Conventional setups operating with supersonic gas jets use a magnetic field in order to detect electrons for a sufficiently large momen-

tum space. In order to achieve good momentum resolution this field needs to be as uniform as possible, which seems to be in conflict with the requirement of a field gradient in order to trap the target atoms magnetically. This problem was overcome with a sophisticated switching device so that the trapping magnetic field can be turned off during a brief electron detection period [48]. With this apparatus, the only fully differential cross sections for ion impact ionization of targets other than He or H_2 were measured, and the resolution was improved by about a factor of 3. In Fig. 69.4, a measured fully differential three-dimensional angular distribution of electrons ejected in $7\text{ MeV Li}^{2+} + \text{Li}$ collisions is shown [49]. In the region of the binary peak, the data reveal a considerably richer structure than for $100\text{ MeV/a.m.u C}^{6+} + \text{He}$. This was explained in terms of a combination of the nodal structure of the initial state wave function and the interaction between the nuclei of the collision partners.

Excitation

Inner-shell excitation can be treated within the same perturbative framework, which leads to a cross section given in terms of the generalized oscillator strength for the transition [50–52]. For inner-shell vacancy production by light projectiles, excitation is generally much smaller than ionization, since the oscillator strengths are strongest for transitions to low-lying occupied orbitals, as reviewed by *Inokuti* [51]. Excitation cross sections can be deduced from photon production cross sections and from inelastic energy-loss experiments. An example of the cross section for excitation of the $n = 2$ level of H by protons, measured by the latter technique, is shown in Fig. 69.5 [53].

Fig. 69.5 Energy loss spectrum for 50 keV protons in atomic hydrogen, showing excitation to discrete states in H proceeding smoothly into ionization at the continuum limit [53]

Capture

As Z_1/Z_2 is raised, the probability for direct transfer of inner-shell electrons from the projectile to the target becomes competitive with, and can even exceed, that for ionization of the target electron into the continuum. The first-order perturbation treatment for electron capture, given by *Oppenheimer* [54] and by *Brinkman* and *Kramers* [55] (OBK) [11, p. 379] results in a cross section per atom

$$\sigma_{\text{OBK}} = 2^9 \pi (Z_1 Z_2)^5 / 5 V^2 v^5 n^3 \beta^5 a_0^2, \quad (69.3)$$

from a filled shell ν to all final states n , where

$$\beta = \frac{1}{4} V^2 \left[V^4 + 2V^2 (Z_2^2 / \nu^2 + Z_1^2 / n^2) + (Z_2^2 / \nu^2 - Z_1^2 / n^2)^2 \right]. \quad (69.4)$$

Both the PWBA/SCA and the OBK cross sections maximize near the matching velocity, but the OBK falls off much more strongly with increasing V beyond this, eventually falling as V^{-12} , while the ionization cross section only falls as $V^{-2} \ln V$. The OBK amplitude for capture is simply the momentum space overlap of the initial wave function with the final state wave function, where the latter is simply a bound state on the projectile but moving at a velocity V relative to the initial bound state. The integral is done only over the transverse momentum, since the longitudinal momentum transfer is fixed by energy conservation [11]. This capture amplitude thus depends heavily on there being enough momentum present in the initial and/or final wave function to enable the transfer, and the loss of this match is what leads to the steep decrease in the OBK cross section above velocity matching. Cross sections for K-shell capture have been measured by detection of K Auger electrons and K X-rays in coincidence with charge capture by the projectiles [22, 56, 57]. On the basis of these and much other data on electron capture, the OBK is a factor of approximately 3 too large [56–59]. This factor comes from a fundamental failure of first-order perturbation theory for electron capture. As was pointed out already in 1927 by *Thomas* [60], who proposed a classical two-collision mechanism for capture, it is essential that the electron interacts with both nuclei during the collision in order to be captured (Chap. 61). In quantum theories, this corresponds to the fundamental need to include second-order terms (and higher) in the capture amplitude. In the limit of large V , the second-order cross section decreases more slowly than the OBK term, as V^{-10} , and is, thus, asymptotically larger than the first-order term [61]. At large V , the coefficient of the V^{-12} term, the dominant one at most experimentally reachable V , is 0.29 times the OBK cross section, when the theory is carried out to second order in the projectile potential [61, 62]. Roughly speaking, this provides an explanation for the factor of 3. Much more sophisticated treatments of high-velocity capture are now available [63–

71]. The underlying role of the second-order scattering process was confirmed experimentally by the detection of the Thomas peak in the angular distribution of protons capturing electrons from He and H [72, 73] (Chap. 61).

In spite of the basic importance of second-order amplitudes in perturbative capture, the OBK gives an excellent account of the relative contributions from and to different final shells over a large range of V above v_e , and is thus, when appropriately reduced, still useful as an estimate for perturbative capture cross sections between well-defined ν and n for large V .

For electron capture, as in the case of ionization (see Sect. 69.1.1, *Inner-Shell Ionization of Heavy Targets*), the development of recoil-ion momentum spectroscopy (RIMS) has enabled much more detailed studies of the collision dynamics. The transverse (perpendicular to the beam direction) recoil-ion momentum component p_{\perp} reflects the closeness of the collision both relative to the target nucleus and the electrons. The longitudinal (parallel to the beam direction) component p_z , on the other hand, is related to the internal energy transfer Q in the collision by (in a.u.)

$$p_z = -Q/V - nV/2, \quad (69.5)$$

where n is the number of captured electrons. A measurement of p_z is, therefore, equivalent to a measurement of Q . The advantage over measuring Q from the projectile energy loss is that at large collision energies, a much better energy resolution is achievable. A sample Q measurement with RIMS is shown in Fig. 69.6 [74]. Very recently, RIMS was applied to study capture processes in collisions with an atomic hydrogen target [75]. This could be an important breakthrough in advancing our understanding of the atomic

Fig. 69.6 Longitudinal momentum spectrum of recoil ions from 0.25 MeV He^{2+} capturing a single electron from a cold He target, showing clear resolution of capture to $n = 1$ from that which leaves target or projectile excited [74]

few-body problem as it opens the possibility to perform kinematically complete experiments on the true three-body system $X^{Z+} + H$, where X can be any bare projectile.

69.1.2 Nonperturbative Processes

Fano–Lichten Model

When the collision becomes increasingly perturbative, either due to a decreased V or increased Z_1/Z_2 , higher-order effects become generally more important. One approach to account for such contributions is the continuum distorted wave–eikonal initial state (CDW-EIS) model ([35, 36, 76], see also Chap. 56 and Sect. 69.1.1). The range of validity of CDW-EIS is roughly given by $Z_1/V^2 \ll 1$ [35]. Therefore, if the perturbation is large due to the projectile charge, the collision may still be treated perturbatively provided that the collision energy is sufficiently large. Otherwise, the perturbation treatment is replaced by a molecular orbital treatment.

Fano and Lichten [77] pointed out that the ratio V/v_e can be small for inner orbitals even for V of several a.u., and thus an adiabatic picture of the collision holds. K vacancy production cross sections become much larger than the perturbation treatments above predict and extend to much larger b . In the molecular orbital picture, the collision system is described in terms of time-dependent molecular orbitals (MO) formed when the inner shells of the systems overlap. Vacancy production occurs due to rotational, radial, and potential coupling terms between these orbitals during the collision. The independent electron model is used, but the results in any specific collision are quite sensitive to the occupation numbers (or vacancies) in the initial orbitals. These are very difficult to control in ion–atom collisions in solids and even problematic in gases, since outer-shell couplings can produce vacancies at large internuclear distances, which then enable transfers at smaller distances. Numerous reviews of the subject are available, including [78–82]. The most famous MO ionization mechanism involves the promotion of the $4f\sigma$ orbital in a symmetric collision (Fig. 69.7), which promotes both target and projectile L electrons to higher energies where they are easily lost to the continuum during the collision. There are now many treatments of inner-shell vacancy production mechanisms based on MO expansions (Chaps. 53, 55). For the case of K vacancy production in quasi-symmetric collisions, an important MO mechanism is the transfer of L vacancies in the projectile to the K-shell of the target through the rotational coupling between $2p\pi$ and $2p\sigma$ orbitals, which correlate to the L and K-shells, respectively, of the separated systems (Fig. 69.7) [83, 84]. The process can be dynamically altered by the sharing at large b between L vacancies of target and projectile through a radial coupling mechanism [85, 86]. This sharing mechanism can also give rise to the direct transfer of K vacancies from

Fig. 69.7 Schematic correlation diagram for the Cl–Ar system, indicating the rotational coupling and radial couplings important for K vacancy production and the $4f\sigma$ orbital whose promotion leads to L vacancy production [89]

projectile to target (KK sharing). In symmetric systems, the KK sharing results in an oscillation of the K vacancy back and forth between target and projectile during the collision and leads to an oscillatory behavior of the transfer probability with V and b [87, 88]. Both of the above vacancy production mechanisms are electron transfer processes rather than direct ionization processes in that no inner-shell electron need be liberated into the continuum. Between the perturbation region and the full MO region the importance of transfer increases relative to ionization. While the MO correlation diagrams and mechanisms are qualitatively useful, actual close-coupling calculations for both inner and outer-shell processes are often carried out using atomic orbitals instead of molecular orbitals, as well as other basis sets (Chaps. 53, 55).

69.2 Multielectron Processes

In a single collision between multielectron partners, two or more electrons may be simultaneously excited or ionized. The electric fields created during a violent ion–atom collision are so large that at small impact parameters the probability of such multielectron processes can be of order unity. While there are many similarities between ion–atom collisions and the interaction of atoms with photons (X-rays or short laser pulses) or electrons, the dominance of multielectron processes is very much less common in the photon and

Fig. 69.8 K X-ray spectrum of Ti for various projectiles showing dominance of multielectron transitions when K vacancies are collisionally produced by heavily ionizing projectiles (^{16}O beam) [90]

electron cases. As an example, when a K-shell electron is removed from a target atom (which is selective on small impact parameters) by the passage of a fast highly charged ion through its heart, the probability that L-shell electrons will be removed at the same time can be large. This gives rise to target X-ray and Auger-electron spectra that are dominated by satellite structure [20]. For example, the spectrum of X-rays from Ti bombarded by 30 MeV oxygen shows that the production of the K vacancy is accompanied by multiple L vacancy production and that the dominant K X-rays are those of systems that are missing several L electrons [90] (Fig. 69.8).

When a gas target is used, the recoil target ion is heavily ionized and/or excited electronically without receiving much translational kinetic energy. In the impulse approximation the transverse momentum Δp_{\perp} received by the target from a projectile passing at impact parameter b is given in a.u. by $\Delta p_{\perp} = 2Z_1Z_2/bV$. This expression ignores the exchange of electronic translational momentum but gives a good estimate. The resulting recoil energies are typically quite small, ranging from thermal to a few eV. This subject was reviewed in [74, 91]. These slow moving recoils have been used to provide information about the primary collision dynamics, and as secondary highly charged ions from a fast-beam-pumped ion source. Such an ion source has, for moderately charged ions, a high brightness and has been used extensively for energy-gain measurements. The primary recoil production process is difficult to treat without the independent electron model, and even in this model, the nonperturbative nature of the collision makes the theory difficult. The most successful treatments have been the CTMC (Chap. 62) and a solution of the Vlasov equation [75].

Studies of many-electron transitions in collisions of bare projectiles with a He target are particularly suitable to investigate the role of electron–electron correlation effects because such collisions represent the simplest systems where the electron–electron interaction is present. Such studies have been performed extensively for a variety of processes, such as double ionization, transfer-ionization, double excitation, transfer-excitation, or double capture ([92–94] for reviews). It is common to distinguish (somewhat artificially) between such correlations in the initial state, the final state, and during the transition (dynamic correlation). From a theoretical point of view, the biggest challenge is to describe electron–electron correlation effects and the dynamics of the two-center potential generated by the projectile and the target nucleus simultaneously with sufficient accuracy.

In the case of double ionization, an experimental method, based on the so-called correlation function [95], was developed to analyze electron–electron correlations independently of the collision dynamics. Here, a measured two-electron spectrum (for example, the momentum difference spectrum of both ejected electrons) is normalized to the corresponding spectrum one would obtain for two independent electrons. An example of such a correlation function R is shown in Fig. 69.9 for three very different collision systems (η_1 ranging from 0.05 to 100 and η_2 from 0.01 to 0.5 in a.u.). The similarity in these three data sets illustrates that R is remarkably insensitive to the collision dynamics. Rather, the shape of R is determined predominantly by correlations in the final state [95, 97]. However, for selected kinematic conditions, R can also be sensitive to initial-state correlations [98]. Clear signatures of initial-state correlations

Fig. 69.9 Correlation function R for double ionization in the collisions indicated in the legend as a function of the momentum difference between the two electrons [95]; R is defined as $R = I_{\text{exp}}/I_{\text{IEM}} - 1$, where I_{exp} is the directly measured momentum spectrum and I_{IEM} the one obtained for independent electrons

were found in the recoil-ion momentum spectra for transfer-ionization [99].

Early attempts to identify dynamic correlations were based on measurements of the ratio of double to single-ionization cross sections [100, 101]. From such studies, it was found that at small V , double ionization is dominated by an uncorrelated mechanism involving two independent interactions of the projectile with both electrons. In contrast, at large V , the double to single ionization ratio asymptotically approaches a common value for all collision systems [102]. This is indicative of the dominance of first-order double-ionization mechanisms, where the projectile interacts with only one electron, and the second electron is ionized through an electron–electron correlation effect. This may either be a rearrangement process of the target atom adjusting to a new Hamiltonian (shake-off, an initial-state correlation) or a direct interaction with the first electron (i.e., dynamic correlation). However, a recent, nearly kinematically complete experiment on double ionization in $p + \text{He}$ collisions revealed that even at large V , higher-order contributions are not negligible [96]. In Fig. 69.10, the ejection angles of both electrons are plotted against each other for almost completely determined kinematics. For comparison, the bottom part of Fig. 69.10 shows the corresponding spectra for elec-

Fig. 69.10 Differential double-ionization cross sections in 6 MeV $p + \text{He}$ (a–c) and 2 keV $e^- + \text{He}$ (d–f) collisions as a function of the polar emission angle of both electrons, which are emitted into the scattering plane. The electrons have equal energy, and data are shown for small (a,d), medium (b,e), and large momentum transfers (c,f) [96]

tron impact at the same V [103]. For both projectiles, the basic features of these spectra are determined by the electric dipole selection rules, which again is indicative of dominating first-order contributions. However, a closer inspection of the comparison between the proton and electron impact data shows some nonnegligible differences. Since in a first-order treatment, the cross sections should be identical for both projectile species, this demonstrates that higher-order contributions cannot be ignored.

Another efficient method to distinguish different double-ionization mechanisms, like e.g., first from higher-order processes, is to analyze four-particle Dalitz (4-D) plots [104]. Here, the data are presented in a tetrahedral coordinate system, where each tetrahedron plane represents one final-state particle (i.e., the scattered projectile, the two ejected electrons, and the residual target ion). The quantities that are plotted are the relative squared momenta $\epsilon_i = p_i^2 / \Sigma p_j^2$ so that $\Sigma \epsilon_i = 1$. For a given data point, each ϵ_i for the four particles is given by the distance of that data point from the corresponding tetrahedron plane.

An example of such a 4-D plot for double ionization in 6 MeV $p + \text{He}$ collisions is shown in Fig. 69.11 [105]. The spectrum is dominated by a strong peak structure at the intersection line between the planes representing the two ejected electrons. This intersection line corresponds to events for which both ejected electrons have a small momentum compared to the heavy particles, i.e., momentum exchange occurs mostly between the nuclei. This shows that a higher-order mechanism involving the nucleus–nucleus interaction plays an important role even at this relatively large projectile energy. Further information about the underlying double-ionization mechanism was obtained from a comparison with various theoretical models [105]. In fact, a new mechanism,

Fig. 69.11 Four-particle Dalitz plot for double ionization of helium by 6 MeV proton impact

which can be viewed as a hybrid between a correlated and an uncorrelated process, could be identified. Here, the projectile only ejects one electron directly; the second electron is ejected by an interaction with the first electron (like in the correlated mechanism). Nevertheless, the projectile does interact with the second electron as well (like in the uncorrelated mechanism), but only after the latter has already been promoted to the continuum.

69.3 Electron Spectra in Ion–Atom Collisions

69.3.1 General Characteristics

An ionizing collision between a single ion and a neutral atom ejects electrons into the continuum via two major processes. Electrons ejected during the collision form broad features or continua and are traditionally referred to as delta rays; electrons ejected after the collisions from the Auger decay of vacancies created during the collision form sharp lines in the spectra. The distributions of energy and the angle of all electrons determine the electronic stopping power and characteristics of track formation of ions in matter, and the study of these distributions in the binary encounter of one ion with one atom forms the basis of any detailed understanding of these averaged quantities. Figure 69.12 shows a typical electron spectrum from the collision of a fast O ion with O_2 [106, 107]. Electrons from the projectile can be identified in the cusp peak (electron loss, P) or ELC, and the O-K-Auger (P) peak. Electrons from the target include the soft (large b) collision electrons (T), which are ejected directly by Coulomb ionization by the projectile, the binary collision (or encounter) electrons coming from hard collisions between projectile and quasi-free target electrons, and the target O-K-Auger (T) electrons. The electron loss peak is widely called the *cusp* peak because the doubly differential cross section in the laboratory $d^2\sigma/dEd\Omega$ becomes infinite, in principle, if it is finite in the projectile frame. In general, this peak may also contain capture to the continuum. All of these features have been heavily studied; some reviews can be found in [108, 109]. Capture to the continuum [109] is an extension of normal capture into the continuum of the projectile and is not a weak process. Both it and ELC produce a heavy density of events in the electron-momentum space centered on the projectile velocity vector and, thus, appear strongly only at or near zero degrees in the laboratory and at $v_e \simeq V$.

The binary encounter electrons at forward angles occur at $v_e \simeq 2V$. For relatively slow collisions, it was found that the ELC and binary peaks are just part of a more general and complex structure of the electron spectra [110]. Additional peaks in the forward direction were found for $v_e \simeq nV$, where

Fig. 69.12 Electron spectrum from 30 MeV O on molecular oxygen. See text for an explanation of features [106, 107]

n can, in principle, be any integer number. These structures reflect a *bouncing back and forth* (known as the Fermi shuttle) between the projectile and the target core before the electron eventually gets ejected from the collision system.

In electron spectra for molecular targets, additional structures were found that were not observed for atomic targets [111]. These were initially interpreted as an interference effect. The electronic wavefunction has maxima at the atomic centers of the molecule. Since in the experiment, it cannot be distinguished from which center the electron is ionized, both possibilities have to be treated coherently. However, more recent studies showed that at small electron energies the structures in the electron spectra reflect vibrational excitation of the molecule [112].

69.3.2 High-Resolution Measurements

The Auger electron spectra provide detailed information about inner-shell vacancy production mechanisms. When coupled with fluorescence yields, Auger electron production probabilities, and cross sections can be converted into the corresponding quantities for vacancy production [15, 108]. This is best done when sufficient resolution can be obtained to isolate individual Auger lines. The Auger spectra in ion-atom collisions are often completely different from those obtained from electron or photon bombardment because of

Fig. 69.13 High-resolution Auger electron spectrum from H-like B on H_2 , showing resolved lines from doubly excited projectile states lying on top of a continuum due to electron elastic scattering [115]. The *bottom part* shows an R-matrix calculation, which does not account for the experimental resolution. The *smooth line* in the *upper figure* is the R-matrix calculation convoluted with the experimental spectrometer resolution

the multiple outer-shell ionization that attends the inner-shell vacancy producing event, in close analogy to X-ray spectra (see Sect. 69.2). Projectile Auger electron spectra suffer from kinematic broadening due to the finite solid angle of the spectrometer and velocity of the emitter, but at 0° to the beam this problem vanishes, and the resolution in the emitter frame is actually enhanced by the projectile motion, such that for electrons with eV energies in the projectile frame, resolutions in the meV region are possible [113, 114]. The highest resolution Auger lines from ion-atom collisions have been recorded for electrons ejected from projectiles. A sample spectrum is shown in Fig. 69.13. From such high resolution spectra, one-electron processes in which one electron is excited, captured, or ionized can be distinguished from the configuration of the emitting state.

69.4 Quasi-Free Electron Processes in Ion-Atom Collisions

At sufficiently low V , those electrons not actively involved in a transition play only a passive role in screening the Coulomb potential between the nuclei and, thereby, create

a coherent effective potential for their motion. However, at high V , the colliding electrons begin behaving as incoherent quasi-free particles capable of inducing transitions directly via the electron–electron interaction. Such processes signal their presence through their free-particle kinematics, as if the parent nucleus were not present. For example, a projectile ionization process requiring energy U has a threshold at $(1/2)m_e V^2 \simeq U$, in collisions with light targets where the quasi-free picture is meaningful. The threshold is not sharp, due to the momentum distribution or Compton profile of the target electrons. Within the impulse approximation, the cross section for any free electron process can be related to the corresponding cross section for the ion–atom process by folding the free electron cross section into the Compton profile [115–117].

69.4.1 Radiative Electron Capture

The first quasi-free electron process to be observed was radiative electron capture (REC), the radiative capture of a free electron by an ion. Conservation of energy and momentum is achieved by the emission of a photon that carries away the binding energy. The cross section exceeds that for bound-state capture at high V . Radiative electron capture was observed through the X-ray spectra from fast heavy projectiles for which the electrons of light targets appear to be *quasi free*. The corresponding free electron process was seen [118] and has recently been heavily studied in EBIT [119], cooler [120], and storage rings [121]. Total cross sections for REC have also been deduced from measured total capture cross sections at large V , where REC dominates the bound-state capture [122]. At high velocities, the cross section for radiative capture to the K-shell of a bare projectile is given approximately by

$$\sigma_n = [n / (\kappa^{-2} + \kappa^{-4})] \times 2.1 \times 10^{-22} \text{ cm}^2, \quad (69.6)$$

where [123] $\kappa = \sqrt{E_B/E_0}$, E_B is the binding energy of the captured electron, E_0 the energy of the initial electron in the ion frame, and n the principal quantum number of the captured electron. The theory seems to be in good agreement with experiment for capture to all shells of fast bare projectiles, although a small unexplained discrepancy between theory and experiment exists for capture to the K-shell [121].

69.4.2 Resonant Transfer and Excitation

Dielectronic recombination in electron–ion collisions is the process whereby an incident electron excites one target electron and, having suffered a corresponding energy loss, drops

into a bound state on the projectile (Chap. 59). If the doubly excited state so populated decays radiatively, resonant radiative recombination is achieved (DR); if it Auger decays, resonant elastic scattering has occurred. The process has long been known to be important as a recombination process in hot plasmas [124] but was not observed in the laboratory until 1983 [125–127]. The corresponding ion–atom process, known as resonant transfer and excitation (RTE), was seen a bit earlier by *Tanis* et al. [128]; see [129, 130] for reviews of both DR and RTE.

69.4.3 Excitation and Ionization

Excitation and ionization of inner shells of fast projectile ions by the quasi-free electrons of light targets (usually He or H₂) have been identified and studied. This process competes with excitation and ionization by the target nucleus [131–133], and special signatures must be sought to distinguish the processes. In the case of excitation, the e–e excitation populates states through the exchange part of the interaction, which is excluded for the nuclear excitation, and this has been used to separate this mechanism [134]. For ionization, enhancements of the ionization cross section above the Born result for nuclear ionization [135], coincident charge exchange measurements [136], and projectile [137] and recoil-ion momentum spectroscopy [138, 139] have been used to distinguish the two processes. Rapid development in the production of good sources of beams of highly charged ions (EBIS/T, ECR; [140]) have made these studies possible. Continued study of this field in heavy-ion storage rings is now achieving resolutions of meV and is opening broad new opportunities for data of unprecedented high quality for electron–ion collisions [141].

Recently, the first kinematically complete experiment on projectile ionization by quasi-free electrons was reported [142]. The observed features are qualitatively similar to those found for ionization of neutral target atoms by free electron impact.

69.5 Some Exotic Processes

69.5.1 Molecular Orbital X-Rays

A typical time duration for an ion–atom encounter is $\approx 10^{-17}$ s, which is much shorter than Auger and X-ray lifetimes, so that hard characteristic radiation is emitted by the products long after the collision. There remains, however, a small but finite probability that X-rays or Auger electrons can be emitted during the collision, in which case the radiation proceeds between the time-dependent molecular orbitals formed in the collision and reflects the time evolution of the

energies and transition strengths between the orbitals. Such molecular orbital X-radiation (MOX) has now been observed in many collision systems [143] and is reviewed in [144–146]. MOX spectra have been studied in total cross sections as well as a function of impact parameter. In the latter case, oscillating structures in the MOX spectra are seen [145, 147], due to the interference between amplitudes for the emission of X-rays with the same energy on the incoming and outgoing parts of the trajectory.

The formation of transient molecular orbitals in close collisions between highly charged ions provides opportunities for studying the electrodynamics of very highly charged systems [148]. For example, two uranium nuclei passing within one K-shell radius of each other form a transient molecule whose energy levels resemble those of an atom of charge 184.

69.5.2 Positron Production from Atomic Processes

Investigating the MOX interference patterns in such exotic systems offers the interesting prospect of performing spectroscopy on superheavy ions.

Reinhart et al. [149] predicted that, for such highly charged species, the binding energy of the united atom K-shell exceeds twice the rest mass energy of the electron, and that if a K vacancy is either brought into the collision or created during it, spontaneous electron–positron pair production occurs (the decay of the charged vacuum) with the electron filling the K-hole. However, further analysis showed that the dominant mechanism for positron production (other than those resulting from the decay of nuclear excitations) likely results from the dynamic time dependence of the fields during the collision [150]. Experiments showed evidence for such positron production in collisions at 6 MeV/u [151], but reported sharp lines in the positron spectra were later attributed to an error in the data analysis.

Present theories for the production of lepton pairs in the close collision of two highly charged systems predict that the cross section grows rapidly with the collision energy. Electrons produced in such a process may end up in bound states on either collision partner, and thus represent a new charge-changing mechanism. At highly relativistic velocities, the cross section for this process exceeds that for any other charge-changing process. In a heavy-ion collider, such as RHIC, this process could limit the ultimate storage time for the counterpropagating beams, since charge-exchanged ions are lost. The cross section has been measured recently by Vane et al. [152], for 6.4 TeV S on several targets (the highest energy ion–atom collision experiment performed to date) and are in good agreement with theory [153]. The bound-

state capture was measured at lower energy by Belkacem et al. [154], with similarly good agreement. The extension of ion–atom collisions to such extreme velocities has opened the field for the study of processes that not even imagined a short time ago.

Abstract

This chapter presents the experimental aspects of reactive scattering from neutral–neutral chemical reactions under single-collision conditions. It begins with a discussion of the principle of molecular beam sources, developments of reagent preparation, various detection methods of neutral products, and a typical signal calculation. Two main crossed-beam configurations are also summarized here: one with a rotatable ionizer mass spectrometer detector and the other one with velocity-map ion-imaging detection. The differential cross section is introduced and discussed in application to elastic, inelastic, and reactive scattering. Various mechanisms are illustrated in reactive scattering, such as harpoon, stripping, rebound, and long-lived complexes mechanisms. In the last part, recent developments and advances are summarized to show the power of crossed-beam techniques to study the chemical reaction dynamics.

70.1 Introduction

This chapter presents a résumé of the methods commonly employed in scattering experiments involving neutral molecules at chemical energies, i.e., less than about 10 eV. These experiments include the study of intermolecular potentials, the transfer of energy in molecular collisions, and elementary chemical reaction dynamics. Closely related material is presented in Chaps. 37, 39, and 40, as well as in other chapters on quantum optics.

70.2 Experimental Methods

70.2.1 Molecular Beam Sources

The development of molecular beam methods has transformed the study of chemical physics [1]. Supersonic molecular beam sources allow one to prepare reagents possessing a very narrow velocity distribution with very low internal energies, ideal for use in detailed studies of intermolecular interactions. Early experiments generally employed continuous beam sources, but since the 1980s more intense pulsed beam sources have come into common usage [2]. The advantages of pulsed beams primarily arise from the lower gas loads associated with their use, hence reduced demands on the pumping system. If any component of the experiment is pulsed (pulsed laser detection, for example), then considerable advantages may be obtained by also pulsing the beam. Although the theoretical descriptions of pulsed and continuous expansions are essentially equivalent, in practice, some care is required in employing pulsed beams because the temperature and velocity distributions may change dramatically through the course of the pulse. Free jet expansions are supersonic because the dramatic drop in the local temperature in the beam is associated with a drop in the local speed of sound. A detailed description of the supersonic expansion may be found in [3–5]. In practice, many of the detailed features associated with a supersonic expansion may be ignored, and one may assume an isentropic expansion into the vacuum. For an isentropic nozzle expansion of an ideal gas, the maximum terminal velocity is given by

$$v_{\max} = \sqrt{2\hat{C}_p T_0}, \quad (70.1)$$

where, for an ideal gas, the heat capacity is

$$\hat{C}_p = \left(\frac{\gamma}{\gamma - 1}\right) \frac{R}{m}, \quad (70.2)$$

R is the gas constant, m is the molar molecular mass, T_0 is the temperature in the stagnation region, and γ is the heat capacity ratio. For ideal gas mixtures, and assuming C_p independent of temperature for the range encountered in the expansion, one may use

$$\bar{C}_p = \sum_i X_i C_{p_i} = \sum_i X_i \left(\frac{\gamma_i}{\gamma_i - 1}\right) R, \quad (70.3)$$

and the average molar mass

$$\bar{m} = \sum_i X_i m_i, \quad (70.4)$$

where X_i is the mole fraction of component i , to obtain an estimate of the maximum velocity for a mixture:

$$v_{\max} = \sqrt{\frac{2\bar{C}_p T_0}{\bar{m}}}. \quad (70.5)$$

Table 70.1 Collision numbers for coupling between different modes. V, R, and T refer to vibrational, rotational, and translational energy, respectively. Each entry is the typical range of Z_{A-B}

	V	R	T
V	10^{5-3}	10^{3-4}	10^{5-6}
R		10^{0-1}	10^{2-3}

By seeding heavy species in light gases one may accelerate them to superthermal energies. Supersonic beams are characterized by the speed ratio, i.e., the mean velocity divided by the velocity spread:

$$S \equiv \frac{v}{\sqrt{2kT/m}}, \quad (70.6)$$

where T is the local translational temperature, or by the Mach number

$$M \equiv \frac{v}{\sqrt{\gamma kT/m}}. \quad (70.7)$$

For the purpose of order-of-magnitude calculations, the number density on axis far from the nozzle may be estimated as

$$n \approx n_0 \left(\frac{d}{x}\right)^2, \quad (70.8)$$

where n_0 is the number density in the stagnation region, d is the nozzle diameter, and x is the distance from the nozzle. The number density versus speed distribution of a nozzle beam is well described as a Gaussian characterized by the speed ratio S and a parameter $\alpha = v_0/S$, where v_0 is the most probable velocity:

$$n(v) = v^2 \exp\left[-\left(\frac{v}{\alpha} - S\right)^2\right]. \quad (70.9)$$

Cooling efficiencies for the various internal degrees of freedom correlate with the efficiency of coupling of these modes with translation, hence they vary widely. Coupling of modes A and B are expressed by the collision number Z_{A-B} :

$$Z_{A-B} \equiv Z \tau_{A-B}, \quad (70.10)$$

where τ_{A-B} is the bulk relaxation time and Z the collision frequency. This represents the number of collisions between effective inelastic events. Typical values are summarized in Table 70.1. R-T coupling is relatively efficient, while V-T coupling is quite inefficient, so that vibrational excitation may not be effectively cooled in the expansion.

70.2.2 Reagent Preparation

Molecular beam methods may be used in conjunction with a variety of other techniques to prepare atoms or molecules in excited or polarized initial states (Chap. 48), to generate unstable molecules or radicals [6, 7], or to produce

beams of refractory materials such as transition metals or carbon [8, 9]. Some of the common techniques are outlined below. Optical pumping of atoms to excited electronic states is a useful means of reagent preparation, and this topic is presented in detail in Chap. 11. This technique further allows one, using polarized lasers, to explore the influence of angular momentum polarization in the reagents on the collision dynamics [10]. Most of these studies have been performed using alkali and alkaline earth metals since there exist strong electronic transitions and convenient narrowband visible lasers suitable for use with these systems. Laser excitation may also be used to generate vibrationally excited molecules in their ground electronic states. The techniques employed include direct IR excitation using an HF chemical laser [11], population depletion methods [12], and various Raman techniques [13]. Adiabatic passage techniques, such as stimulated Raman adiabatic passage (STIRAP), Stark-induced Raman adiabatic passage (SARP), and rapid adiabatic passage (RAP), opened new opportunities for coherent laser control of atomic and molecular processes and were applied to prepare molecules in a single excited rovibrational level in their ground electronic states with near 100% efficiency. They are applied to use for different molecules with differing advantages. STIRAP allows efficient population transfer through a third upper electronic intermediate state [14]. SARP can be used for molecules that have no vibrational transition moment and no conveniently accessible excited states, like H_2 [15]. RAP only requires a single laser but is only applicable for molecules that possess a strongly allowed vibrational transition [16]. Stimulated emission pumping (SEP) [17] is an alternative technique for preparing very highly excited vibrational states, which does not require a coherent laser but needs convenient electronically excited states, as is the case for NO.

Metastable atoms may also be prepared by laser photolysis of a suitable precursor. $\text{O}(^1D)$ is readily prepared by photolysis of ozone or N_2O , for example [18]. Alternatively, RF or microwave discharges may be used to produce metastable species or reactive atoms or radicals [19]. These techniques may also be used to prepare ground-state atoms; for example, hot H atom beams are frequently produced by photolysis of HI or H_2S [20]. Such atomic or molecular radical beams may also be generated by pyrolysis in the nozzle. In this case, care must be taken to minimize recombination through careful choice of the temperature, nozzle geometry, and transit time through the heated region. Beams of refractory materials are now commonly generated using laser ablation sources [8, 9]. Typically, these employ a rod or disk of the substrate of interest, which is simultaneously rotated and translated to provide a fresh surface for ablation at each laser pulse. A laser beam is focused on the substrate and timed to fire just as a carrier gas pulse passes over. Laser power and wavelength must be optimized for a given sub-

strate. Lasers operating in the IR, visible, and UV have all been employed. Aligned or oriented molecules have been prepared using multipole focusing [21, 22], and more recently using strong electric fields (“brute force”) [23]. In the former case, specific quantum states are focused by the field. In the latter case, so-called pendular states are prepared from the low rotational levels of molecules possessing large dipole moments and small rotational constants. The ability to orient these molecules can be estimated on the basis of the Stark parameter $\omega = \mu E/B$, where μ is the dipole moment, E the electric field strength, and B the rotational constant. Orientation is feasible for low rotational levels of molecules when the Stark parameter is on the order of 10 or higher [23]. Manipulating the motion or control over the velocity of molecules in a molecular beam is achieved by concepts from charged-particle accelerator physics. Stark [24, 25] and Zeeman [26, 27] decelerators have been developed to control the motion of molecules that possess an electric or magnetic dipole moment using time-varying electric and magnetic fields, respectively. These decelerator techniques can not only slow the molecular beam to a narrow distribution of velocities but also select molecules into a single rotational quantum state.

70.2.3 Detection of Neutral Products

Broadly speaking, detection of neutral molecules is accomplished either by optical (spectroscopic) or nonoptical techniques. Nonoptical methods usually involve nonspecific ionization of neutral particles, most commonly by electron impact, followed by mass selection and ion counting. Thermal detectors such as cryogenic bolometers are also finding widespread application in molecular beam experiments owing to their remarkable sensitivity [28]. In general, optical methods may rely on resonant or nonresonant processes, hence they may or may not enjoy quantum-state selectivity. Both photoionization and laser-induced fluorescence methods are now in common usage, usually in applications where quantum-state resolved information is desired. The advantage of nonoptical methods is primarily one of generality: all neutral molecules may be detected and branching into different channels readily measured. Quantum-state resolution is more difficult to achieve using nonoptical detection methods, but both vibrationally and rotationally resolved measurements have been obtained by these means [29, 30].

The primary advantage of spectroscopic detection is the aforementioned possibility of quantum-state specificity. Another unique opportunity afforded by spectroscopic probes is the measurement of product alignment and orientation. In addition, in some cases, background interference may be reduced or eliminated using state-specific probes, thereby affording enhanced signal-to-noise ratios.

Nonoptical Techniques

Detectors based on nonspecific ionization remain the most commonly used in molecular beam experiments, owing to the ease of subsequent mass selection, and the convenience and sensitivity of ion detection. Surface ionization is a sensitive means of detecting alkali atoms and other species exhibiting low ionization potentials [31]. Surface ionization occurs when a neutral atom or molecule with a low ionization potential sticks on a surface with a high work function and is subsequently desorbed. Typically, these detectors employ a hot platinum or oxidized tungsten wire or ribbon for formation and subsequent desorption of the ions, which is surrounded by an ion collector. They are very efficient for the detection of alkali atoms and molecules whose ionization potentials are $\lesssim 6$ eV.

All neutral gas molecules may be ionized by collision with energetic electrons, and electron beam ionizers may be produced that couple conveniently to quadrupole mass spectrometers [32]. Collision of a molecule with a 100–200 eV electron leads predominantly to formation of the positive ion and a secondary electron. Other processes also occur and can be very significant: doubly or triply charged ions may be formed and, importantly, molecules can fragment yielding many daughter ions in addition to the parent ion. These fragmentation patterns vary with different molecules and may further show a strong dependence on molecular internal energy, so particular care must be taken to determine the role of these phenomena in each particular application. It is often necessary to record data for the parent ion and daughter ions for a given product channel and compare them to eliminate contributions arising from cracking of the parent molecule or other species [33]. Electron impact ionization probabilities for most species exhibit a similar dependence on electron energy, rising rapidly from the ionization potential to a peak at 80–100 eV, then falling more slowly with increasing collision energy. The ionization cross section for different species scales with molecular polarizability according to a well-established empirical relation [34]:

$$\sigma_{\text{ion}} = 36\sqrt{\alpha} - 18, \quad (70.11)$$

where σ_{ion} is in \AA^2 and α , the molecular polarizability, is in \AA^3 . This relation can be used to estimate branching ratios in the absence of any other means of calibrating the relative contributions of two different channels. The ionization rate is given by

$$\frac{d[M^+]}{dt} = I_e \sigma [M], \quad (70.12)$$

where I_e is the electron beam intensity, typically 10 mA/cm^2 or 6×10^{16} electrons/($\text{cm}^2 \text{ s}$), and $[M]$ is the number density of molecules M in the ionizer. If one assumes an ionization

cross section σ_{ion} of 10^{-16} cm^2 for collision with 150 eV electrons (a typical value for a small molecule), the ionization probability for molecules residing in the ionizer is then

$$\frac{d[M^+]}{dt} \frac{1}{[M]} = I_e \sigma = 6 \times 10^{16} \times 10^{-16} = 6 \text{ s}^{-1}. \quad (70.13)$$

However, product molecules arriving in the detector are not stationary. Typically, product velocities are on the order of 500 m/s. If the ionization region has a length of 1 cm, the residence time τ of a product molecule is on the order of 2×10^{-5} s. Consequently, the ionization probability of product molecules passing through the ionizer is

$$\frac{d[M^+]}{dt} \frac{\tau}{[M]} = 2 \times 10^{-5} \times 6 = 1.2 \times 10^{-4}. \quad (70.14)$$

Although this does not appear very efficient (indeed, it is four orders of magnitude less so than surface ionization), nevertheless, if the background count rate is sufficiently low, then good statistics may be obtained with signal levels as low as 1 Hz. Thus, for detection based on electron impact ionization, a key factor determining the sensitivity of the experiment is the background count rate at the masses of interest.

Spectroscopic Detection

Spectroscopic detection methods usually involve either laser-induced fluorescence (LIF) or resonant photoionization (REMPI) (Chap. 46). Alternative techniques such as laser-induced grating methods and nonresonant vacuum ultraviolet (VUV) photoionization are also being applied to scattering experiments. VUV photoionization can detect molecules and radicals with ionization energy lower than the photon energy that provides universal detection ability but does not resolve any vibrational or rotational information. Essential to the use of spectroscopic methods for reactive scattering studies is an understanding of the spectrum of the species of interest. This may be challenging for many reactive systems because the products may be produced in highly excited vibrational or electronic states that may not be well characterized. Additional spectroscopic data may be required. Franck–Condon factors are necessary to compare the intensities of different product vibrational states, while a calibration of the relative intensities of different electronic bands requires a measure of the electronic transition moments. In some cases, one must include the specific dependence of the electronic transition moment on the internuclear distance by integrating over the vibrational wave function. Populations corresponding to different rotational lines may be compared after the appropriate correction, which is represented by the Hönl–London factors, only for isotropic irradiation and detection. This is certainly not the case for most laser-based experiments. Generally, the detailed dependence of the excitation and detection on the relevant magnetic sublevels must be

considered [35–37]. Caution is required in using any spectroscopic method involving a level that is predissociated. This may lead to a dramatic decrease in the associated fluorescence or photoionization yield if the predissociation rate approaches or exceeds the rate of fluorescence or subsequent photoionization. An important question in any experiment based on spectroscopic detection is whether product flux or number density is probed. This question is considered in detail in several articles [13, 38]. It depends on the lifetime of the state that is probed, the relative time that the molecule is exposed to the probe laser field, and its residence time in the interaction region. Saturation phenomena are also important, yet not necessarily easily anticipated. Complete saturation does not readily occur because excitation in the wings of the laser beam profile becomes more significant as the region in the center of the beam becomes saturated [39].

LIF was a widely used spectroscopic technique in inelastic and reactive scattering experiments [35, 40, 41] in the 1980s to 1990s. It has been used to measure state-resolved total cross sections [42] and differential cross sections in electronic [43], vibrational, and rotationally inelastic scattering [12], as well as reactive scattering [44]. With the development of high-power tunable lasers and the broad use of imaging methods, REMPI is becoming a more general technique [45, 46]. REMPI has the advantages associated with ion detection, namely considerable convenience in mass selection and efficient detection, in addition to the capability of quantum-state selectivity. Disadvantages associated with REMPI arise primarily from higher laser power employed compared with LIF. Caution is required in attempting to extract quantitative information from REMPI spectra if one or several of the steps involved in the ionization process are saturated. This is of particular concern at the high laser powers necessary for multiple photon transitions. Another disadvantage, similar to LIF measurement, is the lack of available spectroscopic information for larger molecules, which limits its versatility in terms of universal detection. An alternative to direct photoionization involves excitation of products to metastable Rydberg states, followed by field ionization some distance from the interaction region. This technique has the advantage of very low background and is capable of extraordinary time-of-flight resolution. One example is the H atom Rydberg time-of-flight (HRTOF) method [47, 48] pioneered by the late *Karl Welge* and coworkers [49] for the hydrogen exchange reaction, $D + H_2$. This approach employs a conventional scattering geometry and is suitable only for experiments yielding product H or D atoms. Despite this narrow focus, owing to the general importance of hydrogen elimination reactions and the remarkable resolution of the technique, this has been an important development. The H or D atom products are excited to long-lived high- n Rydberg states in a $1 + 1'$ excitation scheme at the interaction region. They fly through a field-free region and impinge upon a rotat-

able field-ionization detector. The result is very high velocity resolution, largely because the spreads in the beam velocities make a negligible contribution to the product velocity spread since the H atoms are moving so fast. In addition, the dimensions of the scattering volume and ionization region may easily be made small relative to the flight length. Using this technique, Welge and coworkers achieved fully rotationally resolved differential cross sections for the hydrogen exchange reaction. Now, this technique has also been widely applied by the Yang group in studying the benchmark systems such as $F + H_2$ and $Cl + H_2$ [50–52]. They were able to observe quantum effects from the reactive resonances trapped in the transition-state region of those reactions.

70.2.4 A Typical Signal Calculation

For a crossed-beam system in which a beam of atoms A collides with a beam of molecules B yielding products C and D, the rate of formation of C is given by

$$\frac{dN_C}{dt} = n_A n_B \sigma_r g \Delta V, \quad (70.15)$$

where n_A and n_B are the number densities of the respective reagents at the interaction region, σ_r is the reaction cross section, g the magnitude of the relative velocity between the reactants, and ΔV the volume of intersection of the beams. For a typical experiment employing continuous supersonic beams, the number densities of the atomic and molecular reactants are $\approx 10^{11}$ – 10^{12} cm^{-3} and the scattering volume 10^{-2} cm^3 . For $g = 10^5$ cm/s and $\sigma_r = 10^{-15}$ cm^2 , the rate of product formation $dN_C/dt = 10^{11}$ molecules/s. The kinematics and energetics of the reaction then determines the range of laboratory angles into which the products scatter and the magnitude of the scattered signal.

If the products scatter into 1 sr of solid angle, and the detector aperture is 3×10^{-3} sr (roughly 1° in both directions perpendicular to the detector axis), then the detector receives 3×10^7 product molecules/s. Given the detection probability obtained above, 3600 product ions/s are detected. This is adequate to obtain very good statistics in a short time, as long as the background count rate is not considerably higher.

For a nonspecific detection technique, such as electron bombardment ionization coupled with mass filtering, it is necessary to use ultrahigh vacuum ($\approx 10^{-10}$ Torr) in the detector region to minimize interference from background gases. The residual gases are then primarily H_2 and CO, with number densities on the order of 10^6 cm^{-3} . Differential pumping stages, each of which may reduce the background by two orders of magnitude, are generally used to lower the background from gases whose partial pressures are lower than the ultrahigh vacuum limit of the detector chamber. However, this differential pumping helps only for those molecules that

do not follow a straight trajectory through the detector. The contribution from the latter is given by

$$n' = \frac{nA}{4\pi x^2}, \quad (70.16)$$

where n is the number density of molecules effusing from an orifice of area A , and n' is their number density at a distance x on the axis downstream. For a distance of 30 cm and a main chamber pressure of 3×10^{-7} Torr, this corresponds to a steady-state density of 10^5 molecules/cm³ at the ionizer, a reduction of six orders of magnitude. Three stages of differential pumping are, thus, the most useful under these conditions, since the primary source of background is then molecules following a straight trajectory from the main chamber. A liquid helium-cooled surface opposite the detector entrance may then be useful to minimize scattering of background molecules into the ionizer.

70.3 Experimental Configurations

70.3.1 Crossed-Beam Rotatable Detector

The configuration illustrated in Fig. 70.1 represents a standard, now widely used [32], usually with two continuous beams fixed at 90°. The molecular beam sources are differentially pumped and collimated to yield an angular divergence of about 2°. The beams cross as closely as possible to the nozzles, with a typical interaction volume of 3 mm³. Scattered products pass through an aperture on the front of the detector, thence through several stages of differential

pumping before reaching the ionizer. Ions formed by electron impact on the neutral products are then extracted into a quadrupole mass spectrometer with associated ion counter. A chopper wheel is generally used at the entrance to the detector to provide a time origin for recording time-of-flight spectra.

Pseudo-random sequence chopper disks provide optimal counting statistics while maintaining a high-duty cycle (50%) [53]. The detector may be rotated about the interaction region, typically through a range of 120° or so, allowing one to examine products scattered at a range of laboratory angles. In addition to time-of-flight detection, one of the beams may be gated on and off for background subtraction, and the detector moved to record the integrated signal at each laboratory angle.

Two kinds of measurements are typically made in these experiments: time-of-flight spectra and angular distributions. Usually, one is interested in obtaining the complete product-flux versus velocity contour map, since this contains full details of the scattering process. This is obtained by measuring a full angular distribution as well as time-of-flight data at many laboratory angles. The results are then simulated using a forward convolution fitting procedure to obtain the underlying contour map [54–56]. Because scattering of isotropic reagents exhibits cylindrical symmetry about the relative velocity vector, it is sufficient to measure products scattered in any plane containing this vector to determine the product distribution. This is not true for structured particles (e.g., involving atoms in P states); however, this azimuthal anisotropy has been used to explore the impact parameter dependence of the reaction dynamics [57].

Fig. 70.1 Experimental arrangement for $F + D_2 \rightarrow DF + F$ reactive scattering. Pressure (in Torr) indicated in each region

In a typical reactive scattering experiment, $A + BC \rightarrow AB + C$, either of the two products may be detected. Conservation of linear momentum requires that the center-of-momentum (CM) frame momenta of the two products must sum to zero. It is, thus, only necessary to obtain the contour map for one of the products. The choice of detected product is usually dictated by kinematic considerations, although one may choose to detect a product that is kinematically disfavored if its partner happens to have a mass with a large natural background in the detector. Kinematic considerations can be critical in assessing the suitability of a given system for study. It is very important that one of the products be scattered entirely within the viewing range of the detector in order to obtain a complete picture of the reaction dynamics.

The advantages of crossed beams employed in conjunction with an electron impact ionizer-mass spectrometer detector derive primarily from the universality of the detector. No spectroscopic information is required, and there are no invisible channels, such as may occur with spectroscopic detection methods. In addition, the resolution of these machines may be increased almost arbitrarily; indeed, even rotationally inelastic scattering has been studied [58]. The disadvantages are complementary to the advantages: the universal detector implies that quantum-state resolution is not achieved directly, although in favorable cases, the product vibrational states may be resolved in the translational energy distributions [29, 59]. In addition, if the product of interest represents a mass that receives interference from one of the beam masses, background interference may be problematic. The kinematic considerations mentioned above may also preclude study of certain systems. However, the kinematic requirements for the imaging approach discussed below are complementary to those of the rotatable-detector configuration.

70.3.2 Laboratory to Center-of-Mass Transformation

Angular and velocity distributions measured in the laboratory frame must be transformed to the CM frame for theoretical interpretation. Accounts of this transformation and details concerning the material presented below may be found in [60–63], among others. The Newton diagram is useful to aid in visualizing the transformation and in understanding the kinematics of a given collision system. For the scattering of $F + D_2$, for example, shown in Fig. 70.2, a beam of fluorine atoms with a velocity \mathbf{v}_F is crossed by a beam of D_2 , velocity \mathbf{v}_{D_2} , at 90° . The relative velocity between the two reactants is $\mathbf{g} = \mathbf{v}_F - \mathbf{v}_{D_2}$, and the velocity of the CM of the entire system is

$$\mathbf{V}_{\text{CM}} = \frac{M_F \mathbf{v}_F + M_{D_2} \mathbf{v}_{D_2}}{M_F + M_{D_2}}; \quad (70.17)$$

Fig. 70.2 Newton diagram for collision of F with H_2 with superimposed CM flux versus velocity contour map

\mathbf{V}_{CM} divides the \mathbf{g} into two segments corresponding to the CM velocities of the two reagents. The magnitude of these vectors, u_F and u_{D_2} , are inversely proportional to the respective masses. If scattered DF products are formed with a laboratory scattering angle Θ and a laboratory velocity \mathbf{v}_{DF} , as shown in Fig. 70.2, this corresponds to DF *backscattered* with respect to the incident F atom, in the CM system. It is common to refer the scattering frame direction to the atomic reagent in an $A + BC \rightarrow AB + C$ reaction, for example, to make clear the dynamics of the process. In this case, the backscattered DF arises as a result of a direct rebound collision. Some useful kinematic quantities are summarized here. For beams A and BC intersecting at 90° , the angle of the CM velocity vector with respect to A is given by

$$\Theta_{\text{CM}} = \arctan \frac{M_{\text{BC}} v_{\text{BC}}}{M_A v_A}. \quad (70.18)$$

For an arbitrary Newton diagram with angle α between the two beams, the magnitude of the relative velocity is

$$g^2 = v_A^2 + v_{\text{BC}}^2 - 2v_A v_{\text{BC}} \cos \alpha, \quad (70.19)$$

the relative velocity vector is

$$\mathbf{g} = \mathbf{v}_A - \mathbf{v}_{\text{BC}}, \quad (70.20)$$

and the collision energy is

$$E_{\text{coll}} = \frac{1}{2} \mu_i g^2, \quad (70.21)$$

where μ_i is the reduced mass of the initial collision system. The magnitude of the CM frame velocity of particle A before collision is

$$\mathbf{u}_A = \frac{m_{\text{BC}}}{m_A + m_{\text{BC}}} \mathbf{g}. \quad (70.22)$$

The final relative velocity is

$$\mathbf{g}' = \mathbf{v}_{\text{AB}} - \mathbf{v}_C, \quad (70.23)$$

with magnitude

$$g' = \sqrt{\frac{2E_{\text{avail}}}{\mu_{\text{F}}}}, \quad (70.24)$$

where the available energy E_{avail} is

$$E_{\text{avail}} = E_{\text{coll}} + E_{\text{int, reac}} + E_{\text{exo}} - E_{\text{int, prod}}, \quad (70.25)$$

in which $E_{\text{int, reac}}$ is the internal energy of the reactants, E_{exo} is the exoergicity of the reaction, and $E_{\text{int, prod}}$ is the internal energy of the products.

One must transform the laboratory intensity $I(\Omega) \equiv d^2\sigma/d^2\Omega$ into $I(\omega) (\equiv d^2\sigma/d^2\omega)$, the corresponding CM quantity. For the crossed-beam configuration described in Sect. 70.3.1, the laboratory distributions are distorted by a transformation Jacobian that arises because the laboratory detector views different CM frame solid angles, depending on the scattering angle and recoil velocity. For the spectroscopic experiments described in Sect. 70.3.3, the Jacobian is unity (the CM velocity represents a simple frequency offset of the Doppler profiles, for example); however, the transformation of the scattering distributions from the recorded quantities (two-dimensional projections or intensity versus wavelength) to recoil velocity distributions may be complex. Two cases must be considered for the configuration discussed in Sect. 70.3.1: one in which discrete velocities result (such as elastic or state-resolved scattering experiments), and one in which continuous final velocities are measured. For the first case, the laboratory and CM differential cross sections are independent of the respective product velocities v and u , and these quantities are related by

$$\frac{d^2\sigma}{d^2\Omega} = J \frac{d^2\sigma}{d^2\omega}, \quad (70.26)$$

so that the transformation Jacobian is given by

$$J = \frac{d^2\omega}{d^2\Omega}. \quad (70.27)$$

For discrete recoil velocities, the CM solid angle is

$$d^2\omega = \frac{dA}{u^2}, \quad (70.28)$$

where dA is a surface element of the product Newton sphere. The laboratory solid angle corresponding to this quantity is

$$d^2\Omega = \frac{\cos(\mathbf{u}, \mathbf{v})}{v^2} dA, \quad (70.29)$$

so that the Jacobian for the first case is given by

$$J = \frac{v^2}{u^2 \cos(\mathbf{u}, \mathbf{v})}. \quad (70.30)$$

For the case of continuous final velocities, the σ are velocity dependent and are related by

$$\frac{d^3\sigma}{d^2\Omega dv} = J \frac{d^3\sigma}{d^2\omega du}, \quad (70.31)$$

so that here the Jacobian is given by

$$J = \frac{d^2\omega du}{d^2\Omega dv}. \quad (70.32)$$

In this case, we consider a recoil volume element $d\tau$ (in velocity space), which must be the same in both coordinate frames:

$$d\tau_{\text{CM}} = u^2 du d^2\omega = d\tau_{\text{lab}} = v^2 dv d^2\Omega, \quad (70.33)$$

so that the Jacobian is

$$J = \frac{v^2}{u^2}. \quad (70.34)$$

The laboratory intensity is then related to that in the CM frame by

$$I_{\text{lab}}(v, \Theta) = \left(\frac{v^2}{u^2}\right) I_{\text{CM}}(u, \theta). \quad (70.35)$$

For a mass spectrometer detector with electron bombardment ionizer, one measures the number density of particles rather than the flux, so that the recorded signal is given by

$$N_{\text{lab}}(v, \Theta) = \frac{I_{\text{lab}}(v, \Theta)}{v} = \frac{v}{u^2} I_{\text{CM}}(u, \theta). \quad (70.36)$$

The usual flux versus velocity contour map is a polar plot of the quantity $I_{\text{CM}}(u, \theta)$. The product velocity distributions are then

$$I(u) = \iint I(\theta, u) \sin \theta d\theta d\phi = 2\pi \int_0^\pi I(u, \theta) \sin \theta d\theta, \quad (70.37)$$

and the translational energy distributions are

$$I(E_{\text{T}}) = I(u) \left| \frac{du}{dE_{\text{T}}} \right|. \quad (70.38)$$

70.3.3 Product Imaging

An important approach now is based on direct imaging of the scattered product distribution. The technique was first used to record state-resolved angular distributions of methyl radicals from the photodissociation of methyl iodide [64] and

has since been widely employed to study unimolecular photodissociation dynamics [65]. In 1993, *Houston* and coworkers first applied imaging detection in a crossed-beam experiment to record state-resolved inelastic scattering of NO with argon [66]. Since then, velocity map imaging combined with crossed-beam apparatus has been widely used to measure inelastic and reactive scattering of bimolecular reactions [67]. The crossed-beam configuration coupled with velocity map imaging detection, which was first used by *Houston* and coworkers and now widely adopted to use by many research groups, is shown schematically in Fig. 70.3. The two skimmed supersonic beams cross at right angles, and scattered products are state-selectively ionized on the axis of a time-of-flight mass spectrometer using resonant photoionization (or ionized by a VUV nonresonant photoionization without state selectivity). The ion cloud thus formed continues to expand with its nascent recoil velocity as it drifts through the flight tube. The ions then strike a microchannel plate coupled to a phosphor screen. The latter is viewed by a video camera gated to record the signal at the mass of interest. The images are, thus, two-dimensional projections of the nascent three-dimensional product distributions. From this projection, it is necessary to generate the three-dimensional distribution. This is a tomographic reconstruction, achieved using an inverse Abel transform or related method, as widely used in photodissociation studies [68–70]. It is a direct inversion procedure feasible for cases in which the image is the projection of a cylindrically symmetric object, with its axis of symmetry parallel to the image plane. This analysis yields a unique product contour map directly from the image, but it is difficult to incorporate apparatus functions, and it is sensitive to noise in the data. The problem of the noise or uncertainty induced from the reconstruction process was overcome by an important innovation in ion imaging, time slicing, in the early twenty-first century. Time slicing was first reported by *Kit-sopoulos* and coworkers [71] using delayed pulsed extraction in 2001, followed by two closely related velocity mapping versions in 2003: “DC slicing” [72] and “time-sliced imaging” [73]. Ideally, DC slice-imaging techniques do not require any reconstruction procedure in the analysis; however, in practice, most slice-imaging experiments achieve a velocity slice width of 10–25% or more around the center of the distribution due to the limited experimental conditions. This will carry significant out-of-plane elements that can blur the spectrum, lose fine resolution, and underestimate the contribution from slow recoiling products. To overcome these limitations, a finite-slice analysis (FINA) slice reconstruction method was recently developed [74, 75] to remove these out-of-plane elements from a sliced image. This method allows reconstruction procedure at any velocity slice width and can even be applied to nonsliced or conventional images.

The advantages of the imaging method again derive from its reliance on a spectroscopic probe, so that quantum-state

Fig. 70.3 Crossed molecular beam apparatus with product imaging detection

resolution is possible, and background interference may be avoided. In addition, it possesses a multiplexing advantage since the velocity distribution is recorded for all angles simultaneously. Imaging relies exclusively on photoionization, unlike the Doppler methods, which may use either photoionization or LIF. This is somewhat disadvantageous since the available photoionization schemes are limited, and often high laser power is necessary to achieve adequate signal intensity. As a result, background ions can be a problem. In general, resonantly enhanced two-photon ionization, i.e., $[1 + 1]$, detection schemes are thus preferable. As we mentioned earlier in the spectroscopic detection in Sect. 70.2.3, nonresonant VUV photoionization is an alternative ionization method for the velocity map imaging technique when a REMPI scheme is not available for probed products. VUV photoionization does not have quantum-state resolution but provides universal detection that can ionize all molecules and radicals with their ionization energy lower than the VUV photon energy. VUV photoionization from an excimer laser serves as a convenient and powerful probe with crossed beams for a variety of systems [76]. This combination of crossed molecular beam experiment with a high-resolution velocity map imaging technique directly measures the product velocity-flux contour map that reflects the underlying dynamics of the bimolecular reaction. High-resolution product images provide coupling information between scattering angles, i.e., the differential cross section and the energy partitioning into translational and internal degrees of freedom

of the products [77–79]. The velocity map imaging technique has been a powerful probe tool and been used in many crossed-beam studies, as discussed in Sect. 70.6.

70.4 Elastic and Inelastic Scattering

When particles collide, they may exchange energy or recouple it into different modes, they may change their direction of motion, and they may even change their identity. The study of these processes reveals a great deal of information about the forces acting between the particles and their internal structure. It is useful to begin with a summary of the dominant features of elastic and inelastic scattering.

70.4.1 The Differential Cross Section

Figure 70.4 illustrates the relation between the deflection function χ and the impact parameter b for a realistic potential containing an attractive well and a repulsive core. For large b there is no interaction, hence no deflection. At smaller values of b , the attractive part of the potential is experienced, and some positive deflection results. At a smaller value of b , b_r , the influence of the attractive component of the potential reaches a maximum, giving the greatest positive deflection: this is the *rainbow angle* by analogy with the optical phenomenon. There is another value of the b for which point the attractive and repulsive parts of the potential balance, yielding no net deflection. This is the *glory* impact parameter b_g . For yet smaller values of b , the interaction is dominated by the repulsive core, and rebound scattering gives a negative deflection function.

The important expressions related to the differential cross section are summarized here [80]. For scattering involving an isotropic potential, the deflection angle is $\Theta = |\chi|$. The

Fig. 70.4 Schematic diagram showing the relation between impact parameter b and deflection function χ

differential cross section $d\sigma$ gives the rate of all collisions leading to deflection angles in the solid angle element $d\omega$:

$$\frac{dN(\theta)}{dt} \propto I(\theta) d\omega = I(\theta) 2\pi \sin(\theta) d\theta. \quad (70.39)$$

The incremental cross section is $d\sigma = I(\theta) d\omega = 2\pi b db$, so

$$I(\theta) = \frac{b}{\sin \theta (d\theta/db)}. \quad (70.40)$$

For classical particles, the relation between the deflection function and the potential is

$$\chi = \pi - 2b \int_{R_0}^{\infty} \frac{dR}{R^2} \left[1 - \frac{V(R)}{E_T} - \frac{b^2}{R^2} \right]^{-1/2}, \quad (70.41)$$

where $V(R)$ is the potential as a function of interparticle distance R , R_0 is the turning point of the collision, and E_T the collision energy.

In the high energy limit, for large $b \approx R_0$,

$$\chi(b, E_T) \propto \frac{V(b)}{E_T}. \quad (70.42)$$

For a long-range potential $V(R)$ proportional to R^{-s} ,

$$E_T^{2/s} \theta^{2(1+1/s)} I(\theta) = \text{const.} \quad (70.43)$$

For a potential exhibiting a minimum, the rainbow angle θ_r is proportional to the collision energy and clearly resolved when the collision energy is three to five times the well depth. In addition, supernumary rainbows and quantum-mechanical “fast oscillations” occur in the $d\sigma$, and these provide a sensitive probe of the interaction. Accurate interatomic potentials are routinely obtained from elastic scattering experiments [62, 81].

70.4.2 Rotationally Inelastic Scattering

Classical scattering involving an anisotropic potential results in another rainbow phenomenon, distinct from that seen in pure elastic scattering and notable in that it does not require an attractive component in the potential. These rotational rainbows are equivalently seen in a plot of integral cross section against change in rotational angular momentum Δj or in the differential cross section for a particular value of Δj . The rotational rainbow peaks arise from the range of possible orientation angles γ in a collision involving an anisotropic potential. When there is a minimum in $d\gamma/d\theta$ for a given Δj , the differential cross section reaches

a maximum [82]. The rotational rainbow peak occurs at the most forward classically allowed value of the scattering angle, and $d\sigma$ drops rapidly at smaller angles. The rainbow moves to more backward angles with increasing Δj because the larger j -changing collisions require greater momentum transfer and, hence, must arise from lower impact parameter collisions. For heteronuclear molecules, two rainbow peaks may be observed, corresponding to scattering off either side of the molecule. One can relate the location of the rainbow peak to the shape of the potential using a classical hard ellipsoid model [83]:

$$A - B = \frac{j}{p_0} \left[2 \sin \left(\frac{\theta_{r,cl}}{2} \right) \right]^{-1}, \quad (70.44)$$

where j is the rotational angular momentum, p_0 is the initial linear momentum, $\theta_{r,cl}$ is the classical rainbow position, and A and B are the semimajor and semiminor axes of a hard ellipse potential. The classical rainbow positions occur somewhat behind the quantum-mechanical and experimental rainbow positions, so the classical rainbow may be estimated as the point at which the peak has fallen to 44% of the experimental value. Real molecular potentials may be far from ellipsoids, however, such detailed quantitative insight into the potential requires a comparison of scattering data with quantum-mechanical calculations. The open-shell, close-coupled quantum-mechanical (CC QM) scattering calculations have been proved successfully in the rotationally inelastic scattering of NO with rare gases. Interesting phenomena, like scattering resonances [84], diffraction oscillations [85], and stereodynamic effects [86], have been observed in the joint work of high-resolution imaging detection with crossed-beam experiments and CC QM calculations.

70.4.3 Vibrationally Inelastic Scattering

There has been no direct observation of the differential cross section of T-V or V-T energy transfer involving neutral molecules owing to the small cross sections for these processes. Integral cross section data are available, however. Above threshold, the latter has shown a linear dependence of σ on collision energy for $\Delta v = 1$, quadratic for $\Delta v = 2$ and cubic for $\Delta v = 3$ [87]. In addition, a great deal of information on vibrational relaxation processes has been obtained in cell experiments [88].

70.4.4 Electronically Inelastic Scattering

A wealth of information is available on electronically inelastic scattering systems, since these in general exhibit much

larger cross sections than V-T processes [89, 90]. In addition, spectroscopic methods may be used to overcome some of the background problems that hamper the study of the latter. Often, quenching of electronically excited states involves curve crossing mechanisms, so that very effective coupling of electronic to vibrational energy may occur. Spin-orbit changing collisions of Ba(1P) with O₂ or NO, for example, occur by a near-resonant process and result in almost complete conversion of electronic energy to vibrational excitation of the product [91]. The analogous collisions with N₂ and H₂, however, reveal very repulsive energy release with little concomitant vibrational excitation. Both processes likely occur via curve crossings of the relevant electronic states, but the near-resonant mechanism occurs by way of an ionic intermediate.

70.5 Reactive Scattering

Reactive differential cross sections reveal several distinct aspects of the chemical encounter. The angular distributions themselves may be used to infer the lifetime of the collision intermediate: long-lived complexes exhibit forward-backward symmetry along the relative velocity vector. In this case, “long-lived” means on the order of several rotational periods. The rotational period of the complex may thus be used as a clock to study the energy dependence of the intermediate’s lifetime. The angular distributions further reveal the relation of initial and final orbital angular momentum. Sharply peaked angular distributions generally indicate strongly correlated initial and final orbital angular momentum vectors. Finally, the product translational energy release contains the details of the energy disposal and reveals a wealth of information about the thermodynamics of the process, the existence of barriers, and sometimes even the geometry of the transition state. Together, the angular and translational energy distributions reveal many of the details of the potential energy surface.

The dynamics of reactive collisions fall broadly into three main categories characterized by distinct angular and energy distributions. The three categories are harpoon/stripping reactions, rebound reactions, and long-lived complex formation. Some reactions may exhibit more than one of these mechanisms at once, or the dynamics may change from one to another as the collision energy is varied.

70.5.1 Harpoon and Stripping Reactions

It was known in the 1930s that collisions of alkali atoms with halogen molecules exhibit very large cross sections and yield highly excited alkali halide products. These observations were accounted for by the *harpoon* mechanism proposed by

M. Polanyi. Because alkali atoms have low ionization potentials and halogen molecules large electron affinities, as the alkali atom approaches the molecule, electron transfer may occur at long range. These processes are considered in detail in Chap. 52 [92, 93]. The harpooning distance R_c at which this curve crossing takes place may be estimated simply as the distance at which the Coulomb attraction of the ion pair is sufficient to compensate for the endoergicity of the electron transfer:

$$R_c = \frac{e^2}{I_P - A_e}, \quad (70.45)$$

where I_P and A_e represent the ionization potential and electron affinity of the electron donor and recipient, respectively. For R in Å and E in eV, this relation is

$$R_c = \frac{14.4}{I_P - A_e}. \quad (70.46)$$

Due to the large Coulombic attraction between the ion pair, reaction proceeds immediately following electron transfer. The crossing distance may then be used to estimate the effective reaction cross section. The vertical A_e is not necessarily the appropriate value to use in estimating these crossing distances; stretching of the halogen bond may occur during approach, so the effective A_e is generally somewhere between the vertical and adiabatic values. Often, there exists some repulsion between the atoms in the resulting halogen molecular ion, so that electron transfer is accompanied by dissociation of the molecule in the strong field of the ion pair. The alkali ion, having sent out the electron as the “harpoon”, then reels in the negative ion, leaving the neutral halogen atom nearly undisturbed as a spectator. Because these events occur at long range, there is no momentum transfer to the spectator atom, and it is a simple matter to estimate the anticipated angular and translational energy distributions in this *spectator-stripping* limit. The product molecule is scattered forward (relative to the direction of the incident atom), and for the reaction $A + BC \rightarrow AB + C$, the final CM velocity for the product AB is given by

$$\mathbf{u}'_{AB} = \frac{-M_C \mathbf{u}_{BC}}{M_{AB}}, \quad (70.47)$$

where \mathbf{u}_{BC} is the initial CM velocity of the BC molecule. This spectator-stripping mechanism may occur in systems other than harpoon reactions, and it is useful to remember it as a limiting case.

The likelihood of electron transfer at these crossings may be estimated using a simple Landau–Zener model [93] (Chap. 52). For relative velocity g , impact parameter b , and crossing distance R_c , the probability for undergoing a transition from one adiabatic curve to another (that is, the

probability for remaining on the diabatic curve) is given by

$$p = 1 - e^{-\delta}, \quad (70.48)$$

where

$$\delta = \frac{2\pi H_{12}^2 R_c^2}{g} \left[1 - \frac{b^2}{R_c^2} \right]^{-\frac{1}{2}}, \quad (70.49)$$

and H_{12} is the coupling matrix element between the two curves; H_{12} may be estimated from an empirical relation that is accurate within a factor of three over a range of ten orders of magnitude [94]. In atomic units,

$$H_{12} = \sqrt{I_1 I_2} R_c^* e^{-0.86 R_c^*}, \quad (70.50)$$

where

$$R_c^* = (\sqrt{I_1} + \sqrt{I_2}) \quad (70.51)$$

is the reduced crossing distance, and I_1 and I_2 are the initial and final ionization potentials of the transferred electron. One finds electron transfer probabilities near unity for curve crossing distances below about 5 Å, dropping to zero for crossing at distances greater than about 8 Å. These estimates are based on electron transfer in atom–atom collisions, and it is important to remember that atom–molecule collisions occur on surfaces rather than curves, so the crossing seam may cover a broad range of internuclear distances.

70.5.2 Rebound Reactions

Another common direct reaction mechanism is the *rebound* reaction exemplified by $F + D_2 \rightarrow DF + D$ [29]. The CM product flux versus velocity contour map obtained for this reaction is shown in Fig. 70.2. Due to the favorable kinematics and energetics in this case, the FD product vibrational distribution is clearly resolved and peaks at $v = 2$. The dominant $v = 2$ product peaks at a CM angle of 180° (referred to the direction of the incident F atom). This rebound scattering is characteristic of reactions exhibiting a barrier in the entrance channel. Rebound scattering implies small b collisions, and this serves to couple the translational energy efficiently into overcoming the barrier. Small b collisions necessarily have smaller cross sections however, since the cross section scales quadratically with b .

70.5.3 Long-Lived Complexes

A third, important reaction mechanism involves the formation of an intermediate that persists for some time before dissociating to give products. If the collision complex survives

for many rotational periods ($\approx 10^{-11}$ s), then the CM angular distribution exhibits a characteristic forward–backward symmetry, usually with peaking along the poles. The latter occurs because the initial and final orbital angular momenta tend to be parallel (and perpendicular to the initial relative velocity vector). When there exist dynamical constraints enforcing some other relation, as in the case $F + C_2H_4$, then sideways scattering may be observed, despite a lifetime of several rotational periods [95–97]. For some systems exhibiting this long-lived behavior, the rotational period may be used as a *molecular clock* to monitor the lifetime of the complex. By increasing the collision energy until the distribution begins to lose its forward–backward symmetry, one can investigate the internal energy of the system just when its lifetime is on the order of a rotational period.

Systems that have an inherent symmetry may exhibit this forward–backward symmetry in the scattering distributions despite lifetimes that are considerably shorter than a rotational period. This is the case for $O(^1D)$ reacting with H_2 , for example [98]. This reaction involves insertion of the O atom into the H_2 bond, resulting in an intermediate that accesses the deep H_2O well and contains considerable vibrational excitation. Trajectory calculations show that the complex dissociates after a few vibrational periods, but the distribution exhibits forward–backward symmetry because the O atom is equally likely to depart with either H atom.

70.6 Recent Developments

Astonishing progress in reactive scattering methods have continued in the past decade, and a few highlights are summarized here. These advances have taken the form of improvements in detection methods, or in some cases, entirely new experimental approaches and new achievements that people have made from crossed-beam experiments.

One of the most important of these is the high-resolution H/D-atom Rydberg tagging time-of-flight (HRTOF) technique in the crossed molecular beam experiment, which is suitable for the study of bimolecular reaction yielding product H or D atoms. Yang and coworkers applied this method to systematically study the benchmark reaction of $F + H_2$ and look for reactive resonances in this elementary bimolecular reaction. The lowest barrier height for the $F + H_2$ reaction is $1.63 \text{ kcal mol}^{-1}$, [99]; however, H products were probed when collision energies were lower than the barrier height that indicates some tunneling effects here [100]. Based on the conservation of the linear momentum, such high-resolution H-atom TOF spectra of the H atom products resolve the rovibrational states of the HF ($v' = 1, 2, 3, j'$) coproducts. Pronounced forward-scattered HF products in the $v' = 2$ vibrational state were clearly observed at the collision energy of $0.52 \text{ kcal mol}^{-1}$. Full quantum scattering calculations

based on an accurately constructed potential energy surface indicate that this is attributed to the Feshbach resonances trapped in the peculiar HF($v' = 3$) – H' vibrationally adiabatic potential (VAP) and decay to the HF($v' = 2$) product channel via strong coupling between HF($v' = 3$) – H' and HF($v' = 2$) – H' adiabatic curves [100–102].

The advantage of HRTOF is its very high resolution, but it can only detect H/D products at one angle each time and requires rotating the detector in order to get full differential cross section (DCS) information. This could be improved by combining it with velocity map imaging (VMI) detection, since VMI can measure the product angular distribution (proportional to DCS distribution) at all angles together and can measure the translational energy distribution simultaneously. The problem for imaging the H/D-atom is that the H/D-atom is light, and electron recoil will blur the image and result in spectrum resolution that is not good. Very recently, Wang and coworkers applied the $1 + 1'$ REMPI threshold ionization technique to eliminate the electron recoil for H(D)-atom detection that gives rise to a high-resolution time-sliced velocity map ion imaging apparatus [103]. Such a high-resolution experiment allowed them to observe the geometric phase effect in the $H + HD \rightarrow H_2 + D$ reaction for the first time.

Compelling applications of time-sliced VMI with crossed beams can be found in the work of Liu and coworkers on state-resolved detection on methyl radicals following reactions of methane with X (X: F, Cl, $O(^3P)$, and OH) [104–106]. Unlike an atom detected in HRTOF, polyatomic molecules/radicals have vibrational and rotational excitation when they are first produced. In general, their REMPI schemes are not available for all vibrational and rotational states, i.e., the methyl radical only has the origin bands and the umbrella-mode excited bands known in its first REMPI spectrum [107]. Nevertheless, the methyl ion images provide quantum-state correlated differential cross sections for this type of reactions directly, allowing comparison to theory at an unprecedented level of detail [108–111].

Another significant new direction in detection strategies is the use of near-threshold VUV product ionization, especially for larger molecules whose REMPI probe schemes are not available. This is a universal approach, in that little advance spectroscopic information is required, but it is selective in that dissociative ionization is minimized, and sometimes isomer-selective detection may be achieved. This approach has been used in synchrotron-based studies of Cl atom reactions [112], radical–radical reactions [113] and in transition metal reactions [114, 115], and in product imaging studies of oxygen and chlorine atom reactions using the F_2 excimer at 157 nm [77, 79, 116]. Inspired by the threshold VUV detection methods, Casavecchia and coworkers recently advanced the use of near-threshold electron impact ionization in a conventional universal crossed-beam config-

uration [117]. Their recent results show the great promise of this technique to deliver higher signal-to-noise ratio and to minimize fragmentation processes in the detection step that may obscure the underlying dynamics [118].

A final note concerns developments in the study of chemical dynamics in the cold and ultracold regime with crossed beams. Quantum phenomena such as resonances dominate at low temperatures where few partial waves contribute to the collision. One can reduce the collision energy by slowing the beams with a Stark decelerator [119], merged beams [120, 121], or by making the small intersection angles of the two beams as shown in Eq. (70.19) [122–124]. These approaches are ushering in a new era in scattering studies, and reactive applications of these methods hold promise for interesting new effects.

Abstract

Ionized matter is ubiquitous in Nature, occurring over a large range of length scales and energy densities, in environments ranging from plasmas to condensed phases. In the gas phase, collisions that occur between ions and neutral atoms and molecules provide important microscopic routes for the formation of species that influence the macroscopic behavior of chemical and physical systems such as flames and planetary atmospheres. The term “ion–molecule” reactions generally applies to an entire class of gas phase collision phenomena in which electrons and atoms can be transferred among the approaching reactants to form products with new chemical bonds and distributions of charge. Such reactions are generally regarded as low energy phenomena, occurring over a collision energy range from thermal up to several eV.

71.1 Introduction

Mass spectrometry has played a crucial role in the discovery and the study of ion–molecule reactions. At the beginning of the twentieth century, *J.J. Thomson* discovered that operating his positive ray parabola apparatus in a hydrogen atmosphere produced signals at a mass to charge ratio of 3, which he correctly attributed to the species H_3 [1]. Later experiments by *Hogness* and *Lunn* [2] employing mass spectrometry with a high-pressure ion source demonstrated unequivocally that this species was produced by a very fast reaction between the primary ionization product H_2^+ and molecular hydrogen.

The pioneering work of *Tal'rose* in Moscow on ion formation in methane gas irradiated by electrons [3, 4] initiated the study of ion–molecule reactions as a distinct discipline within the field of chemical kinetics and established the central role of such reactions in radiation chemistry. The same reactions were also observed by *Stevenson* and coworkers [5–7] in the ion source of a laboratory mass spectrometer. Their analysis [8] via an orbiting collision model [9] predicted that ion–molecule reactions proceed with encounter-controlled rates in excess of $10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, corresponding to thermal energy cross sections of magnitude $10^{-16}–10^{-15} \text{ cm}^2$. This recognition and its confirmation by experiment has made ion–molecule reactions critical contributors to the modeling of planetary atmospheres, interstellar chemistry, and reactive plasmas. Studies of chemical dynamics that focus on how reactant energy is consumed and how available energy appears in products have highlighted the

importance of scattering processes and the critical role that features of multidimensional potential surfaces play to control reaction dynamics.

This chapter builds on the relationship between ion–molecule reactions and advances in mass spectrometry. Under single-collision conditions, which may be achieved when a collimated ion beam interacts with neutral reactants also formed into a beam, the experimental data for product formation take the form of one of a number of quantities called “cross sections”. In its simplest, phenomenological form, the total cross section σ parameterizes the attenuation of an ion beam with a collision gas of number density n and interaction length L according to Eq. (71.1)

$$\sigma = (nL)^{-1} \ln \frac{I_0}{I} . \quad (71.1)$$

In this expression, I_0 denotes the initial ion beam intensity, and I is the intensity measured after attenuation. Although Eq. (71.1) defines a cross section including all processes that scatter reactant ions from the beam, it is useful to think of the more specific cross section for chemical reaction as a major contributor to σ , providing a means to estimate the total rate of product formation

$$\frac{dN_{\pm}}{dt} = \sigma V_{\text{rel}} n_1 n_2 \Delta V . \quad (71.2)$$

In this expression, σ is the total reaction cross section, V_{rel} is the relative speed of the collision partners, n_1 is the number density of the primary (ion) beam, n_2 is the number density of the collision gas, and ΔV is the collision volume defined by the overlap of the ion beam with the target gas. This expression can be converted to a particularly useful form for computing signal levels from experimental parameters such as ion beam current I_{\pm} , cross section σ , neutral number density n_2 , and attenuation length L as follows

$$\frac{dN_{\pm}}{dt} = 6.25 \times 10^{-7} \sigma I_{\pm} n_2 L , \quad (71.3)$$

where σ is expressed in \AA^2 , I_{\pm} in units of 10^{-9} A, n_2 in cm^{-3} , and L , the attenuation length, in cm. An ion beam of current 1×10^{-9} A, intersecting a target of length 1 cm at a pressure of 10^{-3} Torr, corresponding to a number density of $3.5 \times 10^{13} \text{ cm}^{-3}$, and reacting with a cross section of 1 \AA^2 yields a total rate of product formation of $2 \times 10^7 \text{ s}^{-1}$. The cross section σ used to estimate total product formation rates is phenomenological, and in order to understand measurements, we need to define a hierarchy of cross sections based on the incident velocities and quantum states of reactants, as well as the quantum states, relative velocities, and scattering angles of products. Experimental conditions

may also require us to consider quantities that are averages over initial states, sums over final states, or are averaged over initial and final velocity distributions. The next section provides assistance in interpreting cross sections for these less well-specified processes.

71.2 Specification of Cross Sections

An “ideal” experiment is one in which reactants with well-specified quantum numbers, collectively denoted \mathbf{n} , collide at a precisely defined relative velocity V , resolving products in quantum states \mathbf{n}' scattered through center of mass scattering angle θ . Technological advances, particularly in laser preparation of quantum state-selected reactants and in state-specific product detection, have made this goal a near-reality in favorable circumstances, particularly in neutral–neutral interactions, e.g., in experiments on $\text{H} + \text{H}_2$ and its isotopic variants. Most experiments, however, require the experimenter to settle for a less precisely defined system in which one carries out partial averages over initial conditions or partial summations over final states. Figure 71.1 shows that the detailed differential cross section described above and denoted $\sigma(\mathbf{n}', \theta | \mathbf{n}, V_{\text{rel}})$ can be averaged over scattering angle to yield a state-to-state cross section at a fixed collision velocity V_{rel} denoted as $\sigma(\mathbf{n}' | \mathbf{n}, V_{\text{rel}})$. Averaging this cross section over a Maxwell–Boltzmann distribution of molecular speeds at a specified temperature T yields the detailed state-to-state rate constant $k(\mathbf{n}' | \mathbf{n}, T)$, while summation over the final states \mathbf{n}' and averaging over the initial states \mathbf{n} yields the thermal rate constant $k(T)$. The rate constant is a thermally averaged, multiple-collision property and not the subject of this chapter, although $k(T)$ plays an important role in modeling applications. Less detailed differential cross sections $\sigma(\mathbf{n}', \theta | \mathbf{n}, V_{\text{rel}})$ arise from averaging over initial states \mathbf{n} and summing over final states \mathbf{n}' to yield cross sections dependent on product velocity V'_{rel} and scattering angle at fixed collision velocity, denoted by $\sigma(V'_{\text{rel}}, \theta | V_{\text{rel}})$. An average over scattering angles and product velocities yields the velocity dependent total cross section $\sigma(V_{\text{rel}})$, and its average over the Maxwell–Boltzmann reactant speed distribution produces the thermal rate constant $k(T)$ once again. As one moves from more highly averaged quantities to the detailed cross sections, more sophisticated reactant preparation and product detection schemes are required to extract the desired information content. More highly specified cross sections lead to lower signal levels as defined in Eq. (71.3). The subject of this chapter will be a discussion of the various cross sections σ shown in Fig. 71.1, emphasizing new experimental methods and results that focus on the determination of cross sections for state-selected reactants and for state-to-state processes.

71.3 Instrumentation

Instrumentation to study ion–molecule reactions is quite diverse, and numerous literature sources are available for further discussion [10, 11]. A typical instrument has an ionization source that may allow for some degree of reactant state specification, a primary mass selector, a collision region, and a detector, consisting of a mass spectrometer or employing a spectroscopic technique allowing product quantum state and molecular identification. The “traditional” method for determining high-resolution/high-information content cross sections employs continuous ion and neutral beams in a crossed beam configuration. Product detection with an energy/mass analyzer that rotates about the collision center allows pointwise construction of the velocity space distribution of reaction products. In principle, with adequate resolution, product vibrational state-resolved angular distributions may be measured. Experiments conducted at Rochester on the $\text{O}^- + \text{D}_2$ reactive system [12, 13] and at Freiburg on the $\text{H}^- + \text{D}_2$ system [14, 15] have approached this limit. However, except for optical detection of reaction products, rotational state resolution has yet to be achieved. These limitations reflect the low signal levels associated with increasing resolution.

Significant progress in extending the scope of high-resolution experiments has come from the application of pulsed methods of reactant preparation and pulsed techniques for product detection. Matching the time structures for reactant formation and product detection has yielded promising results for measuring cross sections with enhanced information content and for extending the range of chemical complexity of reactants and products. Elegant methods employing ions trapped by electrodynamic poten-

tials and probed optically have also led to major advances in the quest to measure state-to-state cross sections.

71.3.1 Reactant Ion Preparation

Ion–molecule reactions were the first chemical reactions for which initial quantum state selection was achieved. Photoionization has been the method of choice for vibrational and vibrational–rotational state selection of molecular ions. Historically, single-photon VUV ionization methods played a special role in illustrating fundamental concepts of reactivity. The selective role of reactant vibrational excitation in overcoming potential energy barriers to endothermic chemical reactions was first demonstrated in the pioneering work of *Chupka* and coworkers on the $\text{H}_2^+ + \text{He}$ system [16]. Many more studies on systems of comparable complexity have followed; the recent development of pulsed-field ionization – photoelectron secondary ion coincidence (PFI-PESICO) on this same system and others [17, 18] provides a picture of the high resolution that is now accessible to simple ion–molecule systems. In systems of greater complexity, *Anderson* and colleagues [19–21] applied guided beam methods to reactions of polyatomic ions prepared by photoionization to demonstrate “mode-selective” chemistry. *Ng* and coworkers demonstrated recently [22] that single rotational states in H_2O^+ can be prepared and that significant dynamical effects can be observed in the reactions with D_2 .

Laser-based multiphoton ionization methods have also been applied to the production of state-selected ions. Measurements of photoelectron spectra of emitted electrons are often necessary to assess the vibrational state purity of the photoions, as demonstrated by *Zare* and coworkers [23] on NH_3^+ prepared in the ν_2 umbrella bending mode. Although such methods are, in principle, capable of producing usable populations of state-selected ions, examples are relatively few in number [20, 24]. State selection of N_2^+ , for example, to produce rovibronic ground-state ions has been accomplished by $(2 + 1)$ multiphoton ionization of N_2 via the $a''^1 \sum_g^+ v' = 0, J' = 2$ intermediate state [25].

Less selective ionization methods forming a range of internally excited states have been teamed with ion trapping methods that contain excited ions in a small volume with a cold collision gas to cool them to the lowest vibrational state. Examples will be discussed below.

71.3.2 Reactant Mass Selection

“Traditional” mass selection methods using deflecting fields are continuous in nature. To complement the quantum-state selection methods described above, which are intrinsically pulsed, time-of-flight methods are ideally suited to add mass

Fig. 71.2 Schematic view of the Innsbruck ion–molecule crossed-beam imaging spectrometer. (Reprinted from [27] with permission from the PCCP Owner Societies)

selection to reactant ion preparation schemes. The standard Wiley–McLaren time-of-flight (TOF) method [26] produces a train of spatially compressed, time-separated ions with the proper time structure to mate with pulsed methods for neutral reactant preparation and time-dependent methods for product detection. *Wester* and coworkers have combined these methods in instrumentation in the last few years [27]. Figure 71.2 shows a schematic of this instrument, illustrating the formation of a pulsed beam of mass selected ions by a Wiley–McLaren TOF mass spectrometer, cooling of the ions in a multipole trap, and injection of those ions into the collision region along with pulsed neutral reactants. The collision region, the dimensions of which are controlled by the spatial extent of the overlap of the pulsed reactant beams, is monitored by a velocity map imaging (VMI) detector, which is also intrinsically pulsed. The operation of such a detection scheme will be discussed in a later section.

71.3.3 The Collision Region

The potential difference between the volume where ions are created and where they undergo reaction generally determines the incident collision energy of an ion–molecule system. In a “traditional” experiment with continuous beams, the collision volume is typically held at a constant potential, most often ground potential. With pulsed beams, the collision volume can be held at ground potential when the pulsed reactant beams intersect but can be pulsed to a nonzero potential to extract product ions into an imaging detector, for example. Constraints on such extraction pulses will be discussed in a later section.

Fig. 71.3 Collision- and state-controlled ion–molecule reactions. Schematic of the experimental setup of the Basel instrument. N_2^+ ions were prepared in their rotational–vibrational ground state using a threshold-photoionization scheme and were sympathetically cooled into a Coulomb crystal of laser-cooled Ca^+ ions (*inset*). The state-selected N_2^+ ions were exposed to rotationally cold neutral N_2 molecules introduced into the ion trap via a doubly skimmed supersonic molecular beam. (Reproduced from [11] by permission of John Wiley & Sons Ltd)

Significant progress in the study of ion–molecule collisions has also been achieved by allowing reaction to occur within the volume of a multipole ion trap such that all product ions are collected and analyzed. *Willitsch* and collaborators [11, 25, 28] have made noteworthy use of the idea of “sympathetic cooling”, as shown in Fig. 71.3, to produce state-selected ions whose reactions can be initiated by pulsing a reactant gas into the trap. Further details are discussed below.

71.3.4 Product Detection

Mass spectrometry and angle-resolved product energy and mass analysis have opened the door to cross section measurements of product-state resolved ion–molecule reactions. The ability to determine product state-resolved cross sections via product kinetic energy analysis is determined by the kinetic energy resolution of the detection system. The majority of extant crossed-beam experimental studies construct three-dimensional velocity space distributions with a series of one-dimensional sections through the full distribution such that, in any interval of time, only a single detection element in velocity space can be measured. Typically, kinetic energy distributions at N energy points are collected at M different scattering angles, yielding a dataset of dimension $N \times M$. Acquisition of the product signal occurs in a pointwise manner, in which any given measurement interval only collects signals in a single element of the velocity space. The total signal level calculated by Eq. (71.2) must be distributed among all $N \times M$ elements of velocity space,

providing a practical limit on this method's abilities. As described below, imaging methods allow all $N \times M$ velocity space elements to be measured in a single time window.

71.3.5 Imaging Methods in Velocity Space

Originally proposed in the late 1980s by *Paul Houston* and *David Chandler* [29] to study the velocity distributions of the products of pulsed laser photolysis of molecules such as CH_3I , methods for reconstructing velocity space flux distributions have undergone significant development since that time. The velocity focusing method of *Parker* and *Ep-pink* [30] is a particularly important improvement: the use of an additional electrostatic lens after the extraction region allows all points in the plane of the intersecting beams with the same V_x and V_y components to be imaged to a single point. Such a geometry is particularly useful in crossed beam applications. In this geometry, two pulsed beams of reactants intersect in a small volume, and the reactive products separate with their characteristic velocities. The locus of points in the center of the mass coordinates for each product quantum state is distributed, perhaps nonuniformly, on the surface of a sphere. After the beams intersect, a repeller plate pushes the ions up a drift tube. During this drift time, a given product-state sphere grows in coordinate space, until the sphere is flattened on the MCP detector. Spheres associated with individual quantum states of a single product of unique mass are “nested”, having a common origin, and produce concentric rings of intensity on the MCP detector. Figure 71.4 shows a schematic of an instrument that illustrates the imaging prin-

Fig. 71.4 Schematic of crossed beam imaging instrument. Product flux extracted from the collision volume with a single center-of-mass speed describes a sphere in velocity space. This flux is projected onto a multichannel plate/phosphor screen detector and recorded with a CCD camera

ciple. Products with different masses describe spheres with different delay times, providing mass-selective detection of products via temporal gating of the MCP detector. Electrons from the MCP are accelerated into a phosphor screen, the light from which is detected by a CCD camera. The signal detected on the phosphor screen is a two-dimensional representation of the three-dimensional distribution. One method for recovering the true three-dimensional distribution employs inverse Abel transformation of the data [31]. Time-sliced methods have also been developed that gate the imaging detector such that slices of the product spheres can be analyzed [32]. The azimuthal symmetry of the flux distribution about the relative velocity vector is sufficient to ensure that equatorial slices represent the full distribution.

One limitation of the simplest version of VMI is its inherent two-dimensional focusing capability. The thickness of the collision volume along the focusing direction can degrade resolution. Three-dimensional imaging methods that correlate arrival position and time have been applied successfully to reduce this “chromatic aberration” contribution to this degradation of resolution [27, 33].

71.4 Kinematics

The sliced or inverse Abel-transformed images represent product ion flux in laboratory Cartesian velocity coordinates [34, 35] (v_x, v_y), and a simple velocity shift to the center of mass

$$\mathbf{u} = \mathbf{v} - \mathbf{C} \quad (71.4)$$

yields barycentric distributions in Cartesian coordinates, symbolized by $P(u_x, u_y)$. Barycentric recoil speed and scattering angle are given by the following expressions

$$u = (u_x^2 + u_y^2)^{1/2}, \quad (71.5)$$

$$\theta = \tan^{-1} \frac{u_y}{u_x}. \quad (71.6)$$

The relationship between Cartesian and polar flux intensity is given by the following expression

$$I_{\text{c.m.}}(u, \theta) = u^2 P(u_x, u_y). \quad (71.7)$$

Product angular and kinetic energy distributions, computed by averaging the flux distribution over recoil speed and scattering angle, respectively, and denoted by the bracket notation below, require integration over the Cartesian flux. The angle-averaged relative translational energy distribution of products, $P(E'_T)$, is given by the following expression

$$\langle P(E'_T) \rangle_\theta = \int_0^\pi d\theta \sin \theta u P(u_x, u_y). \quad (71.8)$$

Integration over specific angular regions provides a means to assess how energy disposal may depend on scattering angle. For example, the angular distribution for a particular product may arise from a superposition of long-lived complex decay with flux distributed symmetrically about the relative velocity vector, and direct reaction, with an asymmetric flux distribution.

The speed-averaged angular distribution is computed as follows

$$\langle g(\theta) \rangle_u = \int_0^\infty du u^2 P(u_x, u_y). \quad (71.9)$$

The kinetic energy and angular distributions described in Eqs. (71.8) and (71.9) are the primary quantities that are subject to comparison with theory. Depending on the resolution of a given experiment, the limits of integration in Eq. (71.8), for example, can be controlled to allow relative vibrational state populations to be extracted from experimental data. Most often, dynamical calculations in the form of quasi-classical trajectories or an appropriate approximation in quantum theory can be undertaken with a parametrized potential energy surface, in order to probe a particular region of the surface or to test a particular dynamical approximation.

71.5 Recent Examples of State-Resolved Measurements

The study of ion–molecule reactions in the context of scattering or collision phenomena is a technologically dependent activity. As single-collision methods have advanced from crossed-beam geometries to configurations in which reactant states may be controlled and/or selected, and products can be detected state-selectively, either kinematically or optically, information content has increased, and tests of theory have become more stringent. In the final section of this chapter, examples of a few of the more recent and advanced experiments will be presented. They should be viewed as a representative sampling rather than an exhaustive compilation of recent advances in the field of ion–molecule reactions.

71.5.1 Velocity-Angle Differential Cross Sections $\sigma(V'_{\text{rel}}, \theta | V_{\text{rel}})$

Implementing VMI detection in a crossed beam experiment with a continuous ion beam and a pulsed neutral beam has led to a number of new results. The $\text{C}^+ + \text{NH}_3$ reaction, important in circumstellar shells, has been studied in the author's lab, [36] providing one of the first examples of a system in

which more than a single reaction product has been detected by VMI. Figure 71.5 shows images for the NH_3^+ product and the HCNH^+ product at a collision energy of 1.5 eV. The NH_3^+ charge transfer product appears in velocity space in the vicinity of the neutral NH_3 beam, consistent with long-range electron transfer that results in negligible momentum transfer to the ionic product. The formation of HCNH^+ around the centroid indicates that this product arises from a long-lived collision complex. Product images are readily separated in time since the extraction process acts like a TOF mass spectrometer, with the lower mass NH_3^+ products arriving at the detection plane before the heavier HCNH^+ products. The detector is gated to allow only a single product to be imaged at a time. This instrument has also been used with free-radical reactants, yielding the first crossed beam VMI studies of ion-radical reactions [37, 38].

Wester and coworkers [27] have used the instrument shown in Fig. 71.2 to study ion–molecule interactions with an emphasis on increased reactant complexity. A long-standing interest of the group is the second-order nucleophilic $\text{S}_{\text{N}}2$ reaction of the form

Among the recent examples from the group is a series of studies in which $\text{X} = \text{OH}$ and $\text{Y} = \text{I}$, with the incoming nucleophile OH^- solvated by a variable number of H_2O molecules [39]. Such studies are critical in making the connection between the gas phase and the solution phase in which nucleophilic substitution is a benchmark reaction in organic chemistry. Figure 71.6 shows product images for the $\text{I}^- (\text{H}_2\text{O})_{1,2}$ products of the reactions

at collision energies of 0.5 and 1.5 eV [27]. The images show significant dynamical signatures that depend both on collision energy and degree of solvation. Most important, the data provide evidence of the degree of chemical complexity that may be probed in contemporary experiments.

71.5.2 State-Resolved Cross Sections $\sigma(n'|n, V_{\text{rel}})$ and Rate Constants $k(n'|n, T)$

Measurements of state-to-state total cross sections as a function of initial relative velocity have advanced significantly in the past decade. Improved resolution in photoionization, advances in methods for confinement of ions in multipole traps, and the use of sympathetic cooling techniques have been responsible for these advances.

Until recently, photoionization methods were limited to elucidation of the role of reactant vibrational excitation in

Fig. 71.5 Product images for charge transfer and C–N bond formation from the $C^+ + NH_3$ reaction, superimposed on the most probable Newton diagrams at a collision energy of 1.5 eV. The *left-hand image* corresponds to the formation of NH_3^+ by charge transfer, and the *right-hand image* corresponds to the formation of $HCNH^+$ products by C–N

bond formation. The *circles* denote the loci of center of mass speeds that correspond to the maximum product values allowed by energy conservation. (Reprinted with permission from [36]. Copyright 2012, American Institute of Physics)

promoting reactivity. A recent example from the laboratory of N_g at UC Davis [22] has provided convincing evidence for the role of reactant rotational excitation in promoting atom transfer in the system

The reactant H_2O^+ species was prepared in the 2_{11} , 1_{11} , and 0_{00} asymmetric rotor states by vacuum ultraviolet (VUV) photoionization, and was transported to the interaction re-

Fig. 71.7 Comparison of the σ values for the reaction $H_2O^+(X^2B_1; v_1^+v_2^+v_3^+ = 000; N_{Ka+Kc}^+ + D_2 \rightarrow H_2DO^+ + D$ in the E_{cm} range of 0.05–10.00 eV. (Reprinted with permission from [22]. Copyright 2012, American Institute of Physics)

gion with a quadrupole mass filter. The collision region consists of a gas cell where ions are confined by an octupole trap, and products are mass-analyzed by another quadrupole mass filter. The geometry allows absolute total cross sections to be measured. Figure 71.7 shows plots of energy-dependent total cross sections from 0.05 to 10 eV, indicating a strong rotational state dependence at the lowest collision energies. Relative to ground-state ions, rotational excitation enhances the cross section by as much as 30%. Quasi-classical trajectory studies [40] have shown that rotational excitation reorients the H_2O^+ ion to allow the oxygen atom to achieve the necessary orientation with respect to H_2 , thereby accessing the transition state that leads to the $H_3O^+ \cdots H$ complex and subsequent product formation.

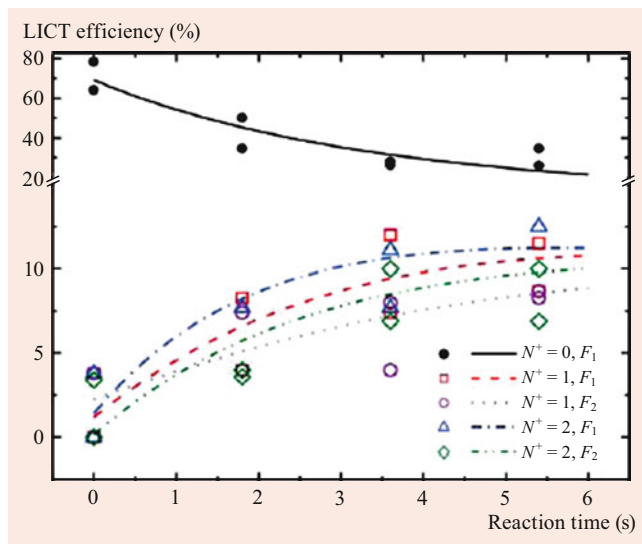

Fig. 71.8 Dynamics of the populations in different spin-rotational states N^+ , $F_{1,2}$ of sympathetically cooled N_2^+ ions as a function of the time of exposure to the molecular beam of neutral N_2 molecules. The populations in the different states have been probed by laser-induced charge transfer (LICT) with Ar atoms. (Reproduced from [11] by permission of John Wiley & Sons Ltd)

The high degree of control that can be achieved in ion-molecule reactions studied in ion trapping configurations is illustrated beautifully in recent work by Willitsch and coworkers. By preloading the multipole trap with Ca^+ , cooling those ions, and establishing a “Coulomb crystal” [28] in which the individual trapped ions are arranged in a regular spatial pattern, reactions of Ca^+ ions with CH_3F , CH_2F_2 , and CH_3Cl have been studied [41, 42]. Ground-state N_2^+ ions produced by multiphoton ionization may also be injected into the trap and cooled by the process of sympathetic cooling to form a bicomponent Coulomb crystal, as shown in Fig. 71.3. The individual trapped N_2^+ ions may then be reacted with rotationally cooled N_2 molecules to produce rotationally excited product N_2^+ ions. Rotational excitation cross sections may be detected by employing a laser-induced charge transfer (LICT) method. Photoexcitation of the reaction products with a 787 nm laser pumps rotationally excited N_2^+ , via the first electronically excited state, into vibrationally excited N_2^+ , which selectively undergoes LICT with Ar. This detection scheme results in time-dependent depletion of the ground rotational state of N_2^+ , and growth of excited rotational state populations, as shown in Fig. 71.8. The data yield cross sections $\sigma(n'|n, T)$ and rate constants $k(n'|n, T)$ for rotational excitation in $N_2^+-N_2$ collisions. Equally impressive is the fact that these cross sections may be determined for the reactions of single ions.

71.6 The Future of the Field

Compared to the examples covered in the last edition of the Handbook, many experimental methods such as ion imaging have reached maturity, and the potential of new methods, particularly ion trapping and cooling, is just beginning to be realized. New methods have allowed collision studies to be carried out with single ions and at very low collision energies, approaching 1 K. In a field as technologically dependent as collision physics and chemistry, there is every expectation that new phenomena in the quantum regime will be discovered and that new chemistry with ultracold reagents will be elucidated. In the same way that single-molecule methods have revolutionized the study of condensed matter, we also expect that the ability to “pick apart the ensemble” in gas phase collisions will yield new insights into reactivity and provide exciting theoretical challenges for many years to come.

James Farrar James Farrar received his PhD degree from The University of Chicago in 1974. He is currently Professor Emeritus at the University of Rochester, where he served as Professor of Chemistry from 1976 to 2018. His research has been concerned with the application of mass spectrometry, molecular beams, and computational chemistry to the study of ion–molecule interactions.

Part F
Quantum Optics

Part F presents a coherent collection of the main topics and issues found in quantum optics. Optical physics, which is concerned with the dynamical interactions of atoms and molecules with electromagnetic fields, is first discussed within the context of semiclassical theories, and then extended to a fully quantized version. The theoretical techniques used to describe absorption and emission spectra using density matrix methods are developed. Applications of the dark state in laser physics is briefly mentioned. The basic concepts common to all lasers, such as gain, threshold, and electromagnetic modes of oscillation are described. Recent developments in laser physics, including single-atom lasers, two-photon lasers, and the generation of attosecond pulses are also introduced. The current status of the development of different types of lasers – including nanocavity, quantum-cascade, and free-electron lasers – are summarized. The important operational characteristics, such as frequency range and output power, are given for each of the types of lasers described. Nonlinear processes arising from the modifications of the optical properties of a medium due to the passage of intense light beams are discussed. Additional processes that are enabled by the use of ultrashort or ultra-intense laser pulses are presented. The concept of coherent optical transients in atomic and molecular systems is reviewed; homogeneous and inhomogeneous relaxation in the theory are properly distinguished. Multiphoton and strong-field pro-

cesses are given a theoretical description. A discussion of the generation of sub-femtosecond pulses is also included. General and specific theories for the control of atomic motion by light are presented. Various traps used for the cooling and trapping of charged and neutral particles and their applications are discussed. The fundamental physics of dilute quantum degenerate gases is outlined, especially in connection with Bose–Einstein condensation. de Broglie optics, which concerns the propagation of matter waves, is presented with a concentration on the underlying principles and the illustration of these principles. The fundamentals of the quantized electromagnetic field and applications to the broad area of quantum optics are discussed. A detailed description of the changes in the atom–field interaction that take place when the radiation field is modified by the presence of a cavity is given. The basic concepts needed to understand current research, such as the EPR experiment, Bell’s inequalities, squeezed states of light, the properties of electromagnetic waves in cavities, and other topics depending on the nonlocality of light are reviewed. Applications to cryptography, tunneling times, and gravity wave detectors are included, along with recent work on “fast light” and “slow light”. Correlations and quantum superpositions, which can be exploited in quantum information processing and secure communication, are delineated. Their link to quantum computing and quantum cryptography is given explicitly.

cal physics, while quantum optics treats the interaction of atoms or molecules with quantized electromagnetic fields. A significant part of optical physics and quantum optics is the study of near-resonant atom–field interactions and concentrates on nonperturbative dynamics, where the effects of the optical fields have to be kept to all orders. The atomic properties themselves are assumed to be known.

The vast majority of problems in light–matter interactions can be treated quite accurately within semiclassical theories. However, an important class of problems where this is not the case is presented in Chaps. 82–84. While much of optical physics and quantum optics ignores the effects of the electromagnetic fields on the center-of-mass motion of the atoms, important topics such as atomic trapping and cooling (Chap. 79) and de Broglie optics (Chap. 81) rely in an essential way on such mechanical effects of light. The present chapter deals with more *traditional* aspects of optical physics, where these effects are ignored.

Abstract

Optical physics is concerned with the dynamical interactions of atoms and molecules with electromagnetic fields. Semiclassical theories, which study the interaction of atoms with classical fields, are often said to comprise opti-

72.1 Multipole Expansion

Consider a test charge q of mass m localized within an atom and acted upon by an external electromagnetic field with electric field $\mathbf{E}(\mathbf{r}, t)$ and magnetic field $\mathbf{B}(\mathbf{r}, t)$. In the multipole expansion formalism [1, 2], the electric and magnetic interaction energies between the charge and the electromagnetic field are

$$V_e = V_{E0}(t) - q \int_0^r ds \cdot \mathbf{E}(\mathbf{R} + \mathbf{s}, t), \quad (72.1)$$

P. Meystre (✉)

Tucson, AZ, USA
e-mail: pierre.meystre@optics.arizona.edu

$$V_m = -q \int_0^r ds \cdot \mathbf{v} \times \mathbf{B}(\mathbf{R} + \mathbf{s}, t), \quad (72.2)$$

respectively. (The material of this chapter is discussed in detail in a number of texts and review articles. We cite such references rather than the original sources whenever possible.) These energies correspond to the work done by the electric and magnetic components of the Lorentz force in first moving the charge to a stationary origin of coordinates at a point \mathbf{R} and then to a location \mathbf{r} relative to \mathbf{R} . Here, $V_{E0}(t)$ represents the energy of the charge when located at the reference point \mathbf{R} . It may be expressed in terms of the electrostatic potential $\phi(\mathbf{R}, t)$ as $V_{E0}(t) = +q\phi(\mathbf{R}, t)$.

A Taylor series expansion of $V_e(t)$ and $V_m(t)$ about $\mathbf{r} = 0$ yields

$$V_e(t) = V_{E0}(t) - q \sum_{n=1}^{\infty} \frac{1}{n!} \left(\mathbf{r} \cdot \frac{\partial}{\partial \mathbf{R}} \right)^{n-1} \mathbf{r} \cdot \mathbf{E}(\mathbf{R}, t), \quad (72.3)$$

$$V_m(t) = -\frac{q\hbar}{m} \sum_{n=1}^{\infty} \frac{n}{(n+1)!} \left(\mathbf{r} \cdot \frac{\partial}{\partial \mathbf{R}} \right)^{n-1} \boldsymbol{\ell} \cdot \mathbf{B}(\mathbf{R}, t), \quad (72.4)$$

where $\hbar\boldsymbol{\ell} = \mathbf{r} \times \mathbf{p}$ is the angular momentum of the test charge relative to the coordinate origin \mathbf{R} . Here, use of the mechanical momentum $\mathbf{p} = m\dot{\mathbf{r}}$, instead of the canonical momentum, neglects the electromagnetic component of the momentum responsible for diamagnetic effects.

In addition to the electromagnetic interaction, electrons and nuclei are characterized by a spin magnetic moment $\mathbf{m}_s = (q\hbar/2m)g_s\mathbf{s}$, where \mathbf{s} is the spin of the test charge and g_s its gyromagnetic factor, equal to 2.002... for electrons. The factor $q\hbar/2m$ is the particle's magneton. The spin magnetic moment yields an additional term to the magnetic energy V_m , which becomes

$$V_m(t) = -\frac{e\hbar}{2m} \sum_{n=1}^{\infty} \frac{1}{n!} \left(\mathbf{r} \cdot \frac{\partial}{\partial \mathbf{R}} \right)^{n-1} \times \left(\frac{2}{n+1} g_\ell \boldsymbol{\ell} + g_s \mathbf{s} \right) \cdot \mathbf{B}(\mathbf{R}, t), \quad (72.5)$$

where the orbital g -factor is $g_\ell = q/e$ ($g_\ell = -1$ for an electron). For an ensemble $\{\alpha\}$ of charged particles q_α in an atom, these expressions are to be summed over all particles. Thus, the electric energy becomes

$$\begin{aligned} V_e(t) &= \sum_{\alpha} q_{\alpha} \phi(\mathbf{R}, t) - \sum_{i=1}^3 \sum_{\alpha} q_{\alpha} r_i(\alpha) E_i(\mathbf{R}, t) \\ &\quad - \frac{1}{2} \sum_{i,j=1}^3 \left[\sum_{\alpha} q_{\alpha} r_i(\alpha) r_j(\alpha) \right] \\ &\quad \times \frac{\partial}{\partial R_j} E_i(\mathbf{R}, t) + \dots \\ &\equiv V_{E0}(t) + V_{E1}(t) + V_{E2}(t) + \dots, \end{aligned} \quad (72.6)$$

and the magnetic energy becomes

$$\begin{aligned} V_m(t) &= \sum_{i=1}^3 B_i(\mathbf{R}, t) \\ &\quad \times \sum_{\alpha} \frac{e\hbar}{2m_{\alpha}} [g_{\ell}(\alpha) \ell_i(\alpha) + g_s(\alpha) s_i(\alpha)] \\ &\quad - \sum_{i,j=1}^3 \frac{\partial B_i(\mathbf{R}, t)}{\partial R_j} \sum_{\alpha} \frac{e\hbar}{2m_{\alpha}} \left[\frac{2}{3} g_{\ell}(\alpha) \ell_i(\alpha) r_j(\alpha) \right. \\ &\quad \left. + g_s(\alpha) s_i(\alpha) \right] + \dots \\ &\equiv V_{M1}(t) + V_{M2}(t) + \dots. \end{aligned} \quad (72.7)$$

72.1.1 Electric Dipole (E1) Interaction

For optical fields whose wavelength is large compared with the interacting atom, only the first few terms in the Taylor expansions of $V_e(t)$ and $V_m(t)$ need to be retained. The first term, $V_{E0}(t)$, of $V_e(t)$ is the net charge of the atom, which vanishes for neutral atoms. The second term, $V_{E1}(t)$, is the electric dipole interaction energy. Introducing the electric dipole (E1) moment,

$$\mathbf{d} = \sum_{\alpha} q_{\alpha} \mathbf{r}(\alpha), \quad (72.8)$$

or

$$\mathbf{d} = \int d^3r \rho(\mathbf{r}) \mathbf{r}, \quad (72.9)$$

for a charge distribution, this contribution to the interaction energy may be re-expressed as

$$V_{E1}(t) = -\mathbf{d} \cdot \mathbf{E}(\mathbf{R}, t). \quad (72.10)$$

The E1 term dominates most optical phenomena.

72.1.2 Electric Quadrupole (E2) Interaction

The $V_{E2}(t)$ contribution to $v_e(t)$ describes electric quadrupole (E2) interactions. In terms of the quadrupole tensor

$$Q = 3 \int d^3r \rho(\mathbf{r}) r_i r_j, \quad (72.11)$$

$V_{E2}(t)$ becomes

$$V_{E2}(t) = -\frac{1}{6} \sum_{i,j=1}^3 Q_{ij} \frac{\partial}{\partial R_i} E_j(\mathbf{R}, t). \quad (72.12)$$

Alternatively, E2 interactions can be expressed in terms of the traceless quadrupole tensor $Q_{ij}^{(2)} = \int d^3r \rho(\mathbf{r}) \times (3r_i r_j -$

$\delta_{ij} r^2$). E2 interactions are typically weaker than E1 interactions by a factor a_0/λ , where a_0 is the Bohr radius, and λ is the wavelength of the transition. Since a_0/λ is very small for optical transitions, E2 interactions are typically neglected in quantum optics.

72.1.3 Magnetic Dipole (M1) Interaction

The first term in the multipole expansion of the magnetic interaction (Sect. 72.6) is the magnetic dipole M1 interaction,

$$V_{M1} = -\mathbf{m} \cdot \mathbf{B}(\mathbf{R}, t), \quad (72.13)$$

of a magnetic moment \mathbf{m} in a magnetic field, where

$$\begin{aligned} \mathbf{m} &= \sum_{\alpha} \left(\frac{q_{\alpha} \hbar}{2m_{\alpha}} \right) [g_{\ell}(\alpha) \boldsymbol{\ell}(\alpha) + g_s(\alpha) \mathbf{s}(\alpha)] \\ &= -\mu_B (\mathbf{L} + 2\mathbf{S}), \end{aligned} \quad (72.14)$$

and we have used the fact that for electrons $g_{\ell} = -1$ and $g_s \simeq -2$. The Bohr magneton μ_B is

$$\mu_B = \frac{e\hbar}{2mc} = \frac{\alpha e a_0}{2}, \quad (72.15)$$

where α is the fine structure constant. Thus, M1 interactions tend to be smaller than E1 interactions by a factor of order $\alpha/2$. The connection between \mathbf{m} and angular momentum \mathbf{J} is $\mathbf{m} = \gamma \mathbf{J}$, where γ is the gyromagnetic ratio.

72.2 Lorentz Atom

The Lorentz atom consists of a classical electron harmonically bound to a proton. It provides a framework for understanding a number of elementary aspects of the electric dipole interaction between a single atom and light [3–7]. Assuming that the center of mass (CM) motion of the atom is unaffected by the field, and neglecting magnetic effects, the equation of motion of the electron is

$$\left(\frac{d^2}{dt^2} + \frac{\Gamma_0}{2} \frac{d}{dt} + \omega_0^2 \right) \mathbf{r} = -\frac{e}{m} \mathbf{E}(\mathbf{R}, t), \quad (72.16)$$

where ω_0 is the electron's natural oscillation frequency, and Γ_0 represents a frictional decay rate that accounts for the effects of radiative damping. For the classical Lorentz atom

$$\Gamma_0 = 2\omega_0^2 r_0 / 3c, \quad (72.17)$$

where $r_0 = e^2 / 4\pi\epsilon_0 m c^2$ is the classical electron radius. This damping arises physically from the radiation reaction of the field radiated by the atom on itself. In the E1 approximation, the electric field is evaluated at the location \mathbf{R} of the atomic c.m.

72.2.1 Complex Notation

The study of light–matter interactions is simplified by the introduction of complex variables [8–11]. For example, an electric field

$$\mathbf{E}(\mathbf{R}, t) = \sum_{n,\mu} \boldsymbol{\epsilon}_{\mu} \mathcal{E}_n \cos(\omega_n t), \quad (72.18)$$

where $\boldsymbol{\epsilon}_{\mu}$ is the polarization vector of the field Fourier component at frequency ω_n , is expressed as

$$\mathbf{E}(\mathbf{R}, t) = \mathbf{E}^+(\mathbf{R}, t) + \mathbf{E}^-(\mathbf{R}, t), \quad (72.19)$$

where the *positive frequency part* of the field is

$$\mathbf{E}^+(\mathbf{R}, t) = \frac{1}{2} \sum_{n,\mu} \boldsymbol{\epsilon}_{\mu} \mathcal{E}_n \exp[i(\mathbf{k}_n \cdot \mathbf{R} - \omega_n t)]. \quad (72.20)$$

Due to the linearity of Eq. (72.16), it is sufficient to study the response of the Lorentz atom to a plane monochromatic electric field of frequency ω , complex amplitude \mathcal{E} and polarization $\boldsymbol{\epsilon}$. Introducing the *complex dipole moment*

$$\mathbf{d} = -e\mathbf{r} = \boldsymbol{\epsilon} \mathcal{P} \exp[i(\mathbf{k} \cdot \mathbf{R} - \omega t)] + \text{c.c.}, \quad (72.21)$$

where \mathcal{P} is in general complex for \mathcal{E} real, and the complex polarizability $\alpha(\omega)$ via $\mathcal{P} = \alpha(\omega)\mathcal{E}$, then

$$\alpha(\omega) = \frac{e^2/m}{\omega_0^2 - \omega^2 - i\Gamma_0\omega}. \quad (72.22)$$

72.2.2 Index of Refraction

From the Maxwell wave equation

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \mathbf{E}(\mathbf{R}, t) = \frac{1}{\epsilon_0 c^2} \frac{\partial^2 \mathbf{P}(\mathbf{R}, t)}{\partial t^2}, \quad (72.23)$$

where $\mathbf{P}(\mathbf{R}, t)$ is the electric polarization, given by the electric dipole density of the medium $\mathbf{P} = N\mathbf{d}$, N being the atomic density, the plane wave dispersion relation is

$$k^2 = \frac{\omega^2}{c^2} n^2(\omega), \quad (72.24)$$

where the index of refraction $n(\omega)$ is

$$n(\omega) = \sqrt{1 + \frac{N\alpha(\omega)}{\epsilon_0}}. \quad (72.25)$$

72.2.3 Beer's Law

Since the polarizability $\alpha(\omega)$ is normally complex, so is the index of refraction. Its real part leads to dispersive effects, while its imaginary part leads to absorption. Specifically, $\text{Re}[n(\omega)] - 1$ has the form of a standard dispersion curve, positive for $\omega - \omega_0 < 0$ and negative for $\omega - \omega_0 > 0$, while $\text{Im}[n(\omega)]$ is a Lorentzian curve peaked at $\omega = \omega_0$. The intensity absorption coefficient $a(\omega)$ is

$$\begin{aligned} a(\omega) &= 2 \text{Im}[n(\omega)]\omega/c \\ &= \frac{2\omega}{c} \text{Im} \left[1 + \left(\frac{Ne^2}{m\epsilon_0} \right) \frac{i\gamma\omega + (\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2} \right]^{1/2}. \end{aligned} \quad (72.26)$$

For atomic vapors, the corrections to the vacuum index of refraction are normally small, so that the square root in Eq. (72.26) can be expanded to first order, giving

$$a(\omega) = \left(\frac{Ne^2}{\epsilon_0 mc} \right) \frac{\gamma\omega^2}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2}. \quad (72.27)$$

The intensity of a monochromatic field propagating along the z -direction through a gas of Lorentz atoms is, therefore, attenuated according to *Beer's law* given by

$$I(\omega, z) = I(\omega, 0) e^{-a(\omega)z}. \quad (72.28)$$

If the index of refraction at a given frequency becomes purely imaginary, no electromagnetic wave can propagate inside the medium. In a plasma this is the case for field frequencies smaller than the plasma frequency

$$\omega_p = \sqrt{\frac{Ne^2}{m\epsilon_0}}. \quad (72.29)$$

While the Lorentz atom model gives an adequate description of absorption and dispersion in a weakly excited absorbing medium, it fails to predict the occurrence of important phenomena such as saturation and light amplification. This is because, in this model, the phase of the induced atomic dipoles with respect to the incident field is always such that the polarization field adds destructively to the incident field. The description of light amplification requires a quantum treatment of the medium, which gives a greater flexibility to the possible relative phases between the incident and polarization fields.

72.2.4 Slowly Varying Envelope Approximation

Light-matter interactions often involve quasi-monochromatic fields for which the electric field (taken to propagate along

the z -axis) can be expressed in the form

$$\mathbf{E}(\mathbf{R}, t) = \frac{1}{2} \boldsymbol{\epsilon} \mathcal{E}^+(\mathbf{R}, t) e^{i(kz - \omega t)} + \text{c.c.}, \quad (72.30)$$

such that

$$\left| \frac{\partial \mathcal{E}^+}{\partial t} \right| \ll \omega |\mathcal{E}^+|, \quad \left| \frac{\partial \mathcal{E}^+}{\partial z} \right| \ll k |\mathcal{E}^+|. \quad (72.31)$$

It is further consistent within this approximation to assume that the polarization takes the form

$$\mathbf{P}(\mathbf{R}, t) = \frac{1}{2} \boldsymbol{\epsilon} \mathcal{P}^+(\mathbf{R}, t) e^{i(kz - \omega t)} + \text{c.c.}, \quad (72.32)$$

with

$$\left| \frac{\partial \mathcal{P}^+}{\partial t} \right| \ll \omega |\mathcal{P}^+|. \quad (72.33)$$

Under these conditions, known as the *slowly varying envelope approximation* [5], Maxwell's wave equation reduces to

$$\left(\frac{\partial}{\partial z} + \frac{1}{c} \frac{\partial}{\partial t} \right) \mathcal{E}^+(z, t) = -\frac{k}{2i\epsilon_0} \mathcal{P}^+(z, t). \quad (72.34)$$

Hence, in the slowly varying envelope approximation, we ignore the backward propagation of the field [12]. The slowly varying amplitude and phase approximation is essentially the same, except that it expresses the electric field envelope in terms of a real amplitude and phase.

72.3 Two-Level Atoms

A large number of optical phenomena can be understood by considering the interaction between a quasi-monochromatic field of central frequency ω and a two-level atom, which simulates a (dipole-allowed) atomic transition [5, 7, 10, 11, 13–17]. This approximation is well justified for near-resonant interactions; i.e., $\omega \simeq \omega_0$. The next three sections discuss the model Hamiltonian for this system in the *semiclassical* approximation where the electromagnetic field can be described classically. The formal results are then extended to the case of a quantized field, where the electric field is treated as an operator.

72.3.1 Hamiltonian

In the absence of dissipation mechanisms, the dipole interaction between a quasi-monochromatic classical field and a two-level atom is

$$H = \hbar\omega_e |e\rangle\langle e| + \hbar\omega_g |g\rangle\langle g| - \mathbf{d} \cdot \mathbf{E}(\mathbf{R}, t), \quad (72.35)$$

where $|e\rangle$ and $|g\rangle$ label the upper and lower atomic levels, of frequencies ω_e and ω_g , respectively, with $\omega_e - \omega_g = \omega_0$, and \mathbf{R} is the location of the center of mass of the atom. The electric dipole operator Eq. (72.8) couples the excited and ground levels and may be expressed as

$$\mathbf{d} = \epsilon_d d (|e\rangle\langle g| + |g\rangle\langle e|), \quad (72.36)$$

where ϵ_d is a unit vector in the direction of the dipole and d the matrix element of the electric dipole operator between the ground and excited state, which we take to be real for simplicity. We also neglect the vector character of \mathbf{d} and $\mathbf{E}(\mathbf{R}, t)$ in the following, assuming, for example, that both ϵ_d and ϵ are parallel to the x -axis. The Hamiltonian Eq. (72.35) may then be expressed as

$$H = \hbar\omega_e |e\rangle\langle e| + \hbar\omega_g |g\rangle\langle g| - d(|e\rangle\langle g| + |g\rangle\langle e|) \times [E^+(\mathbf{R}, t) + E^-(\mathbf{R}, t)], \quad (72.37)$$

where we have generalized the notation of Eq. (72.20) in an obvious way. One can introduce the *pseudo-spin operators*

$$\begin{aligned} s_z &= (|e\rangle\langle e| - |g\rangle\langle g|)/2, \\ s_+ &= s_-^\dagger = |e\rangle\langle g|, \end{aligned} \quad (72.38)$$

and redefine the zero of atomic energy to introduce the commonly used form

$$H = \hbar\omega_0 s_z - d(s_+ + s_-)[E^+(\mathbf{R}, t) + E^-(\mathbf{R}, t)]. \quad (72.39)$$

72.3.2 Rotating Wave Approximation

Under the influence of a monochromatic electromagnetic field of frequency ω , atoms undergo transitions between their lower and upper states by interacting with either the positive or the negative frequency part of the field. The corresponding contributions to the atomic dynamics oscillate at frequencies $\omega_0 - \omega$ and $\omega_0 + \omega$, respectively, and their contributions to the probability amplitudes involve denominators containing this same frequency dependence. For near-resonant atom-field interactions, the rapidly oscillating contributions lead to small corrections, the first-order one being the Bloch–Siegert shift, whose value near resonance is, for $\omega \simeq \omega_0$, [17].

$$\delta\omega_{eg} = -\frac{(d|E^+|/\hbar)^2}{4\omega} \quad (72.40)$$

to lowest order in $dE/\hbar\omega$. The neglect of these terms is the rotating wave approximation (RWA). Note that it is normally inconsistent to regard an atom as a two-level system and not

to perform the RWA. In the RWA, the atomic system is described by the Hamiltonian

$$H = \hbar\omega_0 s_z - d[s_+ E^+(\mathbf{R}, t) + s_- E^-(\mathbf{R}, t)], \quad (72.41)$$

or, in a frame rotating at the frequency ω of the field,

$$H = \hbar\Delta s_z - \frac{1}{2}d(s_+ \mathcal{E} e^{ik\cdot\mathbf{R}} + \text{h.c.}), \quad (72.42)$$

where $\Delta = \omega_0 - \omega$ is the atom–light detuning. (Note that the alternate definition $\delta = \omega - \omega_0$ is frequently used in the literature.) In the rest of this chapter, we consider atoms placed at $\mathbf{R} = 0$.

72.3.3 Rabi Frequency

The dynamics of the two-level atom is conveniently expressed in terms of its density operator ρ , whose evolution is given by the Schrödinger equation

$$\frac{d\rho}{dt} = -\frac{i}{\hbar}[H, \rho], \quad (72.43)$$

where $\rho_{ee} = \langle e|\rho|e\rangle$ and $\rho_{gg} = \langle g|\rho|g\rangle$ are the upper and lower state populations P_e and P_g , respectively, while the off-diagonal matrix elements $\rho_{eg} = \langle e|\rho|g\rangle = \rho_{ge}^*$ are called the atomic coherences, or simply coherences, between levels $|e\rangle$ and $|g\rangle$. These coherences play an essential role in optical physics and quantum optics, since they are proportional to the expectation value of the electric dipole operator.

The evolution of $P_g(t)$ and $P_e(t) = 1 - P_g(t)$, is characterized by oscillations at the generalized Rabi frequency

$$\Omega = (\Omega_1^2 + \Delta^2)^{1/2}, \quad (72.44)$$

where the *Rabi frequency* Ω_1 is $\Omega_1 = dE/\hbar$, (or $\Omega_1 = dE(\epsilon_d \cdot \epsilon)/\hbar$ when the vector character of the electric field and dipole moment are included). Specifically, assuming that the atom is initially in its ground state $|g\rangle$, the probability that it is in the excited state $|e\rangle$ at a subsequent time t is given by Rabi's formula

$$P_e(t) = (\Omega_1/\Omega)^2 \sin^2(\Omega t/2). \quad (72.45)$$

At resonance ($\Delta = 0$), the generalized Rabi frequency Ω reduces to the Rabi frequency Ω_1 . (In addition to the texts on quantum optics already cited, see also [18].)

72.3.4 Dressed States

Semiclassical Case

The atomic dynamics can alternatively be described in terms of a *dressed states* basis instead of the *bare states* $|e\rangle$ and

Fig. 72.1 Dressed levels of a two-level atom driven by a classical monochromatic field as a function of the detuning $\Delta = \omega_0 - \omega$

$|g\rangle$ [17]. The dressed states $|1\rangle$ and $|2\rangle$ are eigenstates of the Hamiltonian Eq. (72.42), and, by convention, the state $|1\rangle$ is the one with the greatest energy. They are conveniently expressed in terms of the bare states via the Stückelberg angle $\theta/2$ as

$$\begin{aligned} |1\rangle &= \sin \theta |g\rangle + \cos \theta |e\rangle, \\ |2\rangle &= \cos \theta |g\rangle - \sin \theta |e\rangle, \end{aligned} \quad (72.46)$$

where $\sin(2\theta) = -\Omega_1/\Omega$, $\cos(2\theta) = \Delta/\Omega$. The corresponding eigenenergies are

$$\begin{aligned} E_1 &= +\frac{1}{2}\hbar\Omega, \\ E_2 &= -\frac{1}{2}\hbar\Omega. \end{aligned} \quad (72.47)$$

These energies are illustrated in Fig. 72.1 as a function of the field frequency ω . The dressed levels repel each other and form an anticrossing at resonance $\omega = \omega_0$. As the detuning Δ varies from positive to negative values, state $|1\rangle$ passes continuously from the excited state $|e\rangle$ to the bare ground state $|g\rangle$, with both bare states having equal weights at resonance. The distances between the perturbed levels and their asymptotes for $|\Delta| \gg \Omega_1$ represent the AC Stark shifts, or light shifts, of the atomic states when coupled to the laser. From Fig. 72.1, the AC Stark shift of $|g\rangle$ is positive for $\Delta < 0$ and negative for $\Delta > 0$, while the $|e\rangle$ state shift is negative for $\Delta < 0$ and positive for $\Delta > 0$.

Quantized Field

The concept of dressed states can readily be generalized to a two-level atom interacting with a single-mode quantized field in the dipole and rotating wave approximations. The atom and its dipole interaction with the field are still described by the Hamiltonian Eq. (72.41), except that the positive and negative frequency components of the field are now operators, and the free field Hamiltonian must be

included. The Hamiltonian of the total atom–field system becomes

$$H = \hbar\omega_0 s_z + \hbar\omega \left(a^\dagger a + \frac{1}{2} \right) + \hbar g (s_+ a + a^\dagger s_-), \quad (72.48)$$

where the creation and annihilation operators a^\dagger and a obey the boson commutation relation $[a, a^\dagger] = 1$ (Chap. 6), and the coupling constant

$$g = d \sqrt{\frac{\omega}{2\epsilon_0 \hbar V}} \quad (72.49)$$

is the vacuum Rabi frequency, with V being a photon normalization volume. This Hamiltonian defines the Jaynes–Cummings model, [7, 19] which is discussed in more detail in Chap. 83.

The dressed states of the atom–field system are the eigenstates of the Jaynes–Cummings model. Since, in the RWA, the dipole interaction only couples states of same *excitation number*, e.g., $|e, n\rangle$ and $|g, n+1\rangle$, where $|n\rangle$ is an eigenstate of the photon number operator, $a^\dagger a |n\rangle = n |n\rangle$, with n an integer, the diagonalization of the Jaynes–Cummings model reduces to that of the semiclassical driven two-level atom in each of these manifolds. Hence, the dressed states are

$$\begin{aligned} |1, n\rangle &= \sin \theta_n |g, n+1\rangle + \cos \theta_n |e, n\rangle, \\ |2, n\rangle &= \cos \theta_n |g, n+1\rangle - \sin \theta_n |e, n\rangle, \end{aligned} \quad (72.50)$$

with

$$\tan(2\theta_n) = -2g\sqrt{n+1}/\Delta. \quad (72.51)$$

(The factor of 2 difference between this and the semiclassical case is due to the use of a running waves quantization scheme, while the semiclassical discussion was for standing waves.) The corresponding eigenenergies are

$$\begin{aligned} E_{1n} &= \hbar(n+1)\omega - \hbar R_n, \\ E_{2n} &= \hbar(n+1)\omega + \hbar R_n, \end{aligned} \quad (72.52)$$

where

$$R_n = \frac{1}{2} \sqrt{\Delta^2 + 4g^2(n+1)}. \quad (72.53)$$

Chapter 83 shows that by including the effects of spontaneous emission, this picture yields a straightforward interpretation of a number of effects, including the Burshtein–Mollow resonance fluorescence spectrum. Dressed states also help to elucidate the interaction between two-level atoms and quantized single-mode fields, as occur, for example, in cavity QED ([19] and Chap. 83). Their generalization to the case of moving atoms offers simple physical interpretations of several aspects of laser cooling, see Chap. 79 and [20].

72.3.5 Optical Bloch Equations

Introducing the density operator matrix elements $\rho_{ab} = \langle a|\rho|b\rangle$, where a, b can be either e or g , as well as the real quantities

$$\begin{aligned} U &= \rho_{eg} e^{i\omega t} + \text{c.c.} , \\ V &= i\rho_{eg} e^{i\omega t} + \text{c.c.} , \\ W &= \rho_{ee} - \rho_{gg} , \end{aligned} \quad (72.54)$$

the equations of motion for the density matrix elements $\rho_{ij} = \langle i|\rho|j\rangle$ may be expressed, with Eq. (72.43), as

$$\begin{aligned} \frac{dU}{dt} &= -\Delta V , \\ \frac{dV}{dt} &= \Delta U + \Omega_1 W , \\ \frac{dW}{dt} &= -\Omega_1 V . \end{aligned} \quad (72.55)$$

These are the optical Bloch equations, as discussed extensively in [5, 17]. Physically, U describes the component of the atomic coherence in phase with the driving field, V the component in quadrature with the field, and W the atomic inversion. The optical Bloch equations have a simple geometrical interpretation offered by thinking of U , V , and W as the three components of a vector called the Bloch vector \mathbf{U} , whose equation of motion is

$$\frac{d\mathbf{U}}{dt} = \boldsymbol{\Omega} \times \mathbf{U} , \quad (72.56)$$

where $\boldsymbol{\Omega} = (-\Omega_1, 0, \Delta)$. Thus, \mathbf{U} precesses about $\boldsymbol{\Omega}$, of length Ω , while conserving its length. The evolution of a two-level atom driven by a monochromatic field is, thus, mathematically equivalent to that of a spin- $\frac{1}{2}$ system in two magnetic fields \mathbf{B}_0 and $2\mathbf{B}_1 \cos \omega t$, which are parallel to the z - and x -axis, respectively, and whose amplitudes are such that the Larmor spin precession frequencies around them are ω and $2\Omega_1 \cos \omega t$, respectively. In optics, this vectorial picture is often referred to as the Feynman–Vernon–Hellwarth picture [21]. It is very useful in discussing the coherent transient phenomena discussed in Chap. 77.

72.4 Relaxation Mechanisms

In addition to their coherent interaction with light fields, atoms suffer incoherent relaxation mechanisms, whose origin can be as diverse as elastic and inelastic collisions and spontaneous emission. Collisional broadening is discussed in Chap. 63, while a QED microscopic discussion of spontaneous emission is described in Chap. 83 in terms of reservoir

theory. One advantage of describing the atomic state in terms of a density operator ρ is that the physical interpretation of its elements allows us phenomenologically to add various relaxation terms directly to its elements.

72.4.1 Relaxation Toward Unobserved Levels

If the relaxation mechanisms transfer populations or atomic coherences toward uninteresting or unobserved levels, their description can normally be given in terms of a Schrödinger equation, but with a complex Hamiltonian. In contrast, if all levels involved in the relaxation mechanism are observed, a more careful description, e.g., in terms of a master equation, is required. Specifically, in the case of relaxation to unobserved levels, the evolution of the atomic density operator, restricted to the levels of interest, is of the general form [16]

$$\frac{d\rho}{dt} = -\frac{i}{\hbar} (H_{\text{eff}}\rho - \rho H_{\text{eff}}^\dagger) , \quad (72.57)$$

where

$$H_{\text{eff}} = H + \hat{\Gamma} , \quad (72.58)$$

H being the atom–field Hamiltonian and $\hat{\Gamma}$ the non-Hermitian relaxation operator, defined by its matrix elements

$$\langle n|\hat{\Gamma}|m\rangle = \frac{\hbar}{2i} \gamma_n \delta_{nm} . \quad (72.59)$$

Both inelastic collisions and spontaneous emission to unobserved levels can be described by this form of evolution. In the framework of this chapter, inelastic, or strong, collisions are defined as collisions that can induce atomic transitions into other energy levels.

72.4.2 Relaxation Toward Levels of Interest

A master equation description is necessary when all levels involved are observed [7, 17]. This master equation can rapidly take a complicated form if more than two levels are involved. We give results only for the case of a two-level atom and upper to lower-level spontaneous decay and elastic or soft collisions; i.e., collisions that change the separation of energy levels during the collision but leave the level populations unchanged. In that case, the atomic master equation takes the form

$$\begin{aligned} \frac{d\rho}{dt} &= -\frac{i}{\hbar} [H, \rho] - \frac{\Gamma}{2} (s_+ s_- \rho + \rho s_+ s_- - 2s_- \rho s_+) \\ &\quad - \frac{1}{2} \gamma_{\text{ph}} \rho + 2\gamma_{\text{ph}} s_z \rho s_z , \end{aligned} \quad (72.60)$$

where the free-space spontaneous decay rate Γ is found from QED to be

$$\Gamma = \frac{1}{4\pi\epsilon_0} \frac{4d^2\omega_0^3}{3\hbar c^3}, \quad (72.61)$$

and γ_{ph} is the decay rate due to elastic collisions.

It is possible to express the classical decay rate Eq. (72.17) in terms of the quantum spontaneous emission rate Eq. (72.61) as

$$\Gamma = \Gamma_{\text{cl}} f_{ge}, \quad (72.62)$$

where f_{ge} is the oscillator strength of the transition. The various oscillator strengths characterizing the dipole-allowed transitions from a ground state $|e\rangle$ to excited levels $|g\rangle$ obey the Thomas–Reiche–Kuhn sum rule

$$\sum_e f_{ge} = 1, \quad (72.63)$$

where the sum is on all levels dipole-coupled to $|g\rangle$. Assuming that \mathbf{d} and the polarization of the field are both parallel to the x -axis, this gives

$$f_{ge} = \frac{2m\omega_0}{\hbar} |\langle g|x|e\rangle|^2. \quad (72.64)$$

72.4.3 Optical Bloch Equations with Decay

In general, the optical Bloch equations cannot be generalized to cases where relaxation mechanisms are present. There are, however, two notable exceptions corresponding to the following situations.

1. The upper level spontaneously decays to the lower level only, while the atom undergoes only elastic collisions.
2. Spontaneous emission between the upper and lower levels can be ignored in comparison with decay to unobserved levels, which occur at equal rates $\gamma_e = \gamma_g = 1/T_1$.

Under these conditions, Eq. (72.55) generalizes to

$$\begin{aligned} \frac{dU}{dt} &= -U/T_2 - \Delta V, \\ \frac{dV}{dt} &= -V/T_2 + \Delta U + \Omega_1 W, \\ \frac{dW}{dt} &= -(W - W_{\text{eq}})/T_1 - \Omega_1 V, \end{aligned} \quad (72.65)$$

where we have introduced the longitudinal and transverse relaxation times T_1 and T_2 , with $T_1 = 1/\Gamma$ and $T_2 = (1/2T_1 + \gamma_{\text{ph}})^{-1}$ in the first case, and $T_2 = (1/T_1 + \gamma_{\text{ph}})^{-1}$ in the second case. The equilibrium inversion W_{eq} is equal to zero in the second case since the decay is to unobserved levels.

72.4.4 Density Matrix Equations

In the general case, it is necessary to consider the density operator equation (72.43) instead of the optical Bloch equations. The equations of motion for the components of ρ become, for the general case of complex Ω_1 ,

$$\begin{aligned} \frac{d\rho_{ee}}{dt} &= -\gamma_e \rho_{ee} - \frac{1}{2}(i\Omega_1^* \tilde{\rho}_{eg} + \text{c.c.}), \\ \frac{d\rho_{gg}}{dt} &= -\gamma_g \rho_{gg} + \frac{1}{2}(i\Omega_1^* \tilde{\rho}_{eg} + \text{c.c.}), \\ \frac{d\tilde{\rho}_{eg}}{dt} &= -(\gamma + i\Delta)\tilde{\rho}_{eg} - i\frac{\Omega_1}{2}(\rho_{ee} - \rho_{gg}), \end{aligned} \quad (72.66)$$

where $\gamma = (\gamma_e + \gamma_g)/2 + \gamma_{\text{ph}}$, and $\tilde{\rho}_{eg} = \rho_{eg} e^{i\omega t}$. In the case of spontaneous decay from the upper to the lower level, these equations become

$$\begin{aligned} \frac{d\rho_{ee}}{dt} &= -\Gamma \rho_{ee} - \frac{1}{2}(i\Omega_1^* \tilde{\rho}_{eg} + \text{c.c.}), \\ \frac{d\rho_{gg}}{dt} &= +\Gamma \rho_{ee} + \frac{1}{2}(i\Omega_1^* \tilde{\rho}_{eg} + \text{c.c.}), \\ \frac{d\tilde{\rho}_{eg}}{dt} &= -(\gamma + i\Delta)\tilde{\rho}_{eg} - i\frac{\Omega_1}{2}(\rho_{ee} - \rho_{gg}), \end{aligned} \quad (72.67)$$

where $\gamma = \Gamma/2 + \gamma_{\text{ph}}$. Equations (72.67) are completely equivalent to the optical Bloch equations (72.65).

72.5 Rate Equation Approximation

If the coherence decay rate γ is dominated by elastic collisions, and hence is much larger than the population decay rates γ_e and γ_g , $\tilde{\rho}_{eg}$ can be adiabatically eliminated from the equations of motion Eqs. (72.66) and (72.67) to obtain the rate equations (Sect. 72.2)

$$\begin{aligned} \frac{d\rho_{ee}}{dt} &= -\gamma_e \rho_{ee} - R(\rho_{ee} - \rho_{gg}), \\ \frac{d\rho_{gg}}{dt} &= -\gamma_g \rho_{gg} + R(\rho_{ee} - \rho_{gg}), \end{aligned} \quad (72.68)$$

and

$$\begin{aligned} \frac{d\rho_{ee}}{dt} &= -\Gamma \rho_{ee} - R(\rho_{ee} - \rho_{gg}), \\ \frac{d\rho_{gg}}{dt} &= +\Gamma \rho_{gg} + R(\rho_{ee} - \rho_{gg}), \end{aligned} \quad (72.69)$$

respectively, where the transition rate is

$$R = |\Omega_1|^2 \mathcal{L}(\Delta)/(2\gamma), \quad (72.70)$$

and we have introduced the dimensionless Lorentzian

$$\mathcal{L}(\Delta) = \gamma^2/(\gamma^2 + \Delta^2). \quad (72.71)$$

The transitions between the upper and lower state are, thus, described in terms of simple rate equations.

Adding phenomenological pumping rates Λ_e and Λ_g on the right-hand side of Eq. (72.68) provides a description of the excitation of the upper and lower levels from some distant levels, as would be the case in a laser. The equations then form the basis of conventional, single-mode laser theory. In the absence of such mechanisms, the atomic populations eventually decay away.

72.5.1 Steady State

In the case of upper to lower-level decay, the state populations reach a steady state with inversion [5, 17]

$$W_{\text{st}} = -\frac{\Gamma}{\Gamma + 2R} = -\frac{1}{1 + s}, \quad (72.72)$$

where s is the saturation parameter. In the case of pure radiative decay, $\gamma_{\text{ph}} = 0$, s is given by

$$s = \frac{\Omega_1^2/2}{\Gamma^2/4 + \Delta^2}. \quad (72.73)$$

In steady state, the other two components of the Bloch vector U are given by

$$U_{\text{st}} = -\frac{2\Delta}{\Omega_1} \left(\frac{s}{1 + s} \right) \quad (72.74)$$

and

$$V_{\text{st}} = \frac{\Gamma}{\Omega_1} \left(\frac{s}{1 + s} \right); \quad (72.75)$$

U_{st} varies as a dispersion curve as a function of the detuning Δ , while V_{st} is a Lorentzian of power-broadened half-width at half-maximum $(\Gamma^2/4 + \Omega_1^2)^{1/2}$.

72.5.2 Saturation

As the intensity of the driving field, or Ω_1^2 , increases, U_{st} and V_{st} first increase linearly with Ω_1 , reach a maximum, and finally tend to zero as $\Omega_1 \rightarrow \infty$. The inversion W_{st} , which equals -1 for $\Omega_1 = 0$, first increases quadratically and asymptotically approaches $W_{\text{st}} = 0$ as $\Omega_1 \rightarrow \infty$. At this point, where the upper and lower state populations are equal, the transition is said to be saturated, and the medium becomes effectively transparent, or bleached. (This should not be confused with self-induced transparency, which is discussed in Chap. 77.) The inversion is always negative, which, in particular, means that no steady-state light amplification can be achieved in this system. This is one reason why external pump mechanisms are required in lasers.

72.5.3 Einstein A and B Coefficients

When atoms interact with broadband radiation instead of the monochromatic fields considered so far, Eq. (72.69) still apply, but the rate R becomes

$$R \rightarrow B_{eg}\varrho(\omega), \quad (72.76)$$

where $\varrho(\omega)$ is the spectral energy density of the inducing radiation. Einstein's A and B coefficients apply to an atom in thermal equilibrium with the field, which is described by Planck's blackbody radiation law

$$\varrho(\omega) = \frac{\hbar\omega^3}{\pi^2 c^3} \frac{1}{e^{\hbar\omega/k_B T} - 1}, \quad (72.77)$$

where T is the temperature of the source, and k_B is Boltzmann's constant. Invoking the principle of detailed balance, which states that at thermal equilibrium, the average number of transitions between arbitrary states $|i\rangle$ and $|k\rangle$ must be equal to the number of transitions between $|k\rangle$ and $|i\rangle$, one finds

$$\frac{A_{ki}}{B_{ki}} = \frac{\hbar\omega^3}{\pi^2 c^3}, \quad (72.78)$$

where A_{ki} is the rate of spontaneous emission from $|k\rangle$ to $|i\rangle$, and $\Gamma_k = \sum_i A_{ki}$ is the level width.

72.6 Light Scattering

Far from resonance, the approximation of a two-level or few-level atom is no longer adequate. Two limiting cases, which are always far from resonance, are Rayleigh scattering for low frequencies and Thomson scattering for high frequencies.

72.6.1 Rayleigh Scattering

Rayleigh scattering is the elastic scattering of a monochromatic electromagnetic field of frequency ω , wave vector \mathbf{k} , and polarization $\boldsymbol{\epsilon}$ by an atomic system in the limit where ω is very small compared with its excitation energies [4, 17]. To second order in perturbation theory, the Rayleigh scattering differential cross section into the solid angle Ω' about the wave vector \mathbf{k}' with $k' = k$, and polarization $\boldsymbol{\epsilon}'$ is

$$\frac{d\sigma}{d\Omega'} = r_0^2 \omega^4 (\boldsymbol{\epsilon} \cdot \boldsymbol{\epsilon}')^2 \left(\sum_e \frac{f_{ge}}{\omega_{eg}^2} \right)^2, \quad (72.79)$$

where r_0 is the classical electron radius, the sum is over all states $|e\rangle$, f_{ge} is the E1 oscillator strength Eq. (72.64), and

ω_{ge} is the transition frequency. The corresponding total cross section is

$$\sigma = \frac{8\pi r_0^2 \omega^4}{3} \left(\sum_e \frac{f_{ge}}{\omega_{eg}^2} \right)^2. \quad (72.80)$$

72.6.2 Thomson Scattering

Thomson scattering is the corresponding elastic photon scattering by an atom in the limit where ω is very large compared with the atomic ionization energy, yet small enough compared to $\alpha mc^2/\hbar$, that the dipole approximation can be applied. The differential cross section for this process is [4, 17]

$$\frac{d\sigma}{d\Omega'} = r_0^2 (\boldsymbol{\epsilon} \cdot \boldsymbol{\epsilon}')^2, \quad (72.81)$$

and the total cross section is

$$\sigma = \frac{8}{3} \pi r_0^2. \quad (72.82)$$

This is a completely classical result, which exhibits no frequency dependence.

72.6.3 Resonant Scattering

We finally consider elastic scattering in the limit where ω is close to the transition frequency ω_0 between $|g\rangle$ and $|e\rangle$. Provided that no other level is near resonant with the ground state, the resonant scattering differential cross section is [6, 17]

$$\frac{d\sigma}{d\Omega'} = \frac{9}{16\pi^2} \lambda_0^2 (\boldsymbol{\epsilon} \cdot \boldsymbol{\epsilon}')^2 \frac{(\Gamma/2)^2}{\Delta^2 + (\Gamma/2)^2}, \quad (72.83)$$

where $\lambda_0 = 2\pi c/\omega_0$ is the wavelength of the transition, and Γ is the spontaneous decay rate Eq. (72.61). The total elastic scattering cross section is

$$\sigma = \frac{3}{2\pi} \lambda_0^2. \quad (72.84)$$

In contrast to the nonresonant Rayleigh and Thomson scattering cross sections, which scale as the square of the classical electron radius, the resonant scattering cross section scales as the square of the wavelength. For optical frequencies, $\lambda_0/r_0 \simeq 10^4$, giving a *resonant enhancement* of about eight orders of magnitude. This illustrates why near-resonant phenomena, which form the bulk of the following chapters, are so important in optical physics and quantum optics.

Abstract

This chapter develops theoretical techniques to describe absorption and emission spectra, using concepts introduced in Chap. 72, and density matrix methods from Chap. 7. The simplest cases are treated, compatible with the physics involved, and more realistic applications are referred to in other chapters. Vector notation is not used, but it can be inserted as required. Only steady-state spectroscopy is covered; for time-resolved transient techniques see Chap. 77.

Laser technology has greatly expanded the potential of atomic and molecular spectroscopy, but the same techniques for describing the interaction of light with matter also apply to the traditional arc lamps and flash discharges, and the more recent synchrotron radiation sources.

Keywords

density matrix · rotate wave approximation · hole burning · density matrix element · radiation trapping

73.1 Introduction

In many cases, departures from the thin sample limit, such as beam attenuation, light scattering and radiation trapping (Sect. 73.3) may be important. However, the properties of laser devices themselves depend in an essential way on these effects, making a self-consistent treatment of their properties necessary.

At the other extreme, the spectroscopy of dilute gases is well characterized by ensemble averages over the properties of the individual particles, interrupted by occasional brief collisions. Ensemble averages, however, may no longer apply to recent experiments probing a single atomic particle in a trap, as discussed in Chap. 79.

73.2 Index of Refraction

As discussed in Sect. 72.2.2, the complex index of refraction for a medium containing harmonically bound charges (electrons) [1] with natural frequency ω_0 is

$$\begin{aligned}
 n(\omega) &= \sqrt{1 + \frac{N\alpha(\omega)}{\epsilon_0}} \approx 1 + \frac{N\alpha(\omega)}{2\epsilon_0} \\
 &= 1 + \frac{Ne^2}{2m\epsilon_0} \left(\frac{i\gamma\omega + (\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2} \right) \\
 &= n' + i n'' .
 \end{aligned} \tag{73.1}$$

The expansion is valid when the density of atoms N is low. A plane wave can be written in the form

$$\mathcal{E} \propto e^{ikz} = e^{i\omega n z/c} = e^{i\omega n' z/c} e^{-\omega n'' z/c} . \tag{73.2}$$

The absorption of light through the medium then shows a resonant behavior near $\omega \approx \omega_0$ determined by

$$\begin{aligned} n'' &= \frac{Ne^2}{2m\epsilon_0} \left(\frac{\gamma\omega}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2} \right) \\ &\approx \frac{\pi Ne^2}{4m\epsilon_0\omega_0} \left(\frac{\gamma/2\pi}{(\omega - \omega_0)^2 + \gamma^2/4} \right). \end{aligned} \quad (73.3)$$

This is called an absorptive lineshape. When the single electron is harmonically bound, its interaction with radiation is found in this response. For a real atom, the response of the electron is divided among the various transitions to other states. The fraction assigned to one single transition is characterized by the oscillator strength f_n as discussed in Sect. 72.4.2.

In ordinary linear spectroscopy, the laser is tuned through the resonance $\omega \approx \omega_0$, and the value of ω_0 is determined from the lineshape Eq. (73.3). Several closely spaced resonances can be *resolved* if their spacing is larger than their widths

$$\left| \omega_0^{(1)} - \omega_0^{(2)} \right| > \gamma. \quad (73.4)$$

This defines the *spectral resolution* (Chap. 11).

The velocity of light in the medium is seen to be given by the expression

$$c_{\text{eff}} = \frac{c}{n'} \approx c \left[1 - \frac{Ne^2}{2m\epsilon_0} \left(\frac{\omega_0^2 - \omega^2}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2} \right) \right]. \quad (73.5)$$

This expression shows a *dispersive behavior* around the position $\omega = \omega_0$, where the modification of the velocity disappears. Below resonance $\omega < \omega_0$, the velocity of light is lower than in vacuum. This derives from the fact that the polarization is in phase with the driving field. Thus, by storing the incoming energy, the driving field retards the propagation of the radiation.

For a harmonically bound charge, the refractive index Eq. (73.1) always stays absorptive and it is independent of the intensity of the laser radiation. This no longer holds for discrete level atomic systems. In order to see this, we consider the *two-level atom* in Sect. 73.3.

73.3 Density Matrix Treatment of the Two-Level Atom

The response of atoms to light is conveniently expressed in terms of the density matrix ρ . In addition to the direct physical meaning of the density matrix elements discussed in Sect. 72.3.3, the density matrix formalism is advantageous because the various relaxation mechanisms effecting the atomic resonances can be introduced phenomenologically

into its equations of motion, and theoretical derivations often provide *master equations* for the density matrix (Chap. 7).

The two-level Hamiltonian Eq. (72.35) can be written as

$$\mathbf{H} = \begin{bmatrix} \hbar\omega_0/2 & -d\mathcal{E}(R, t) \\ -d\mathcal{E}(R, t) & -\hbar\omega_0/2 \end{bmatrix}. \quad (73.6)$$

The equation of motion for the density matrix Eq. (72.67) is then

$$\begin{aligned} \frac{d}{dt}\rho_{ee} &= -\Gamma\rho_{ee} + \frac{id\mathcal{E}}{\hbar} \cos\omega t (\rho_{ge} - \rho_{eg}), \\ \frac{d}{dt}\rho_{gg} &= \Gamma\rho_{ee} - \frac{id\mathcal{E}}{\hbar} \cos\omega t (\rho_{ge} - \rho_{eg}), \\ \frac{d}{dt}\rho_{eg} &= -(\gamma + i\omega_0)\rho_{eg} + \frac{id\mathcal{E}}{\hbar} \cos\omega t (\rho_{gg} - \rho_{ee}). \end{aligned} \quad (73.7)$$

Here Γ is the spontaneous decay rate given by Eq. (72.61) and

$$\gamma = \Gamma/2 + \gamma_{\text{ph}}, \quad (73.8)$$

where γ_{ph} derives from all processes that tend to randomize the phase between the quantum states $|e\rangle$ and $|g\rangle$, such as collisions (Chaps. 7 and 20), noise in the laser fields and thermal excitation of the environment in solid state spectroscopy. The Greek letters Γ and γ correspond to the longitudinal relaxation rate (T_1 -process) and the transverse relaxation rate (T_2 -process), respectively.

In the rotating wave approximation (RWA) the density matrix equations Eq. (73.7) become identical to Eq. (72.67) with

$$\rho_{eg} = \tilde{\rho}_{eg} e^{-i\omega t}. \quad (73.9)$$

Using the condition of conservation of probability

$$\rho_{ee} + \rho_{gg} = 1, \quad (73.10)$$

the steady state solutions to Eq. (72.67) are [2]

$$\rho_{ee} = \frac{\Omega_1^2 \gamma}{2\Gamma} \left(\frac{1}{\Delta^2 + \gamma^2 + \Omega_1^2 \gamma / \Gamma} \right), \quad (73.11)$$

$$\begin{aligned} \tilde{\rho}_{eg} &= \frac{i\Omega_1}{2} \frac{(\rho_{gg} - \rho_{ee})}{\gamma + i\Delta} \\ &= \frac{i\Omega_1}{2} \left(\frac{\gamma - i\Delta}{\Delta^2 + \gamma^2 + \Omega_1^2 \gamma / \Gamma} \right), \end{aligned} \quad (73.12)$$

where Ω_1 is the Rabi frequency from Eq. (72.44), and $\Delta = \omega_0 - \omega$ is the detuning. The induced polarization is then

$$\begin{aligned} \mathcal{P} &= N \text{Tr}(\hat{d}\rho) = N \text{Tr} \left[\begin{pmatrix} 0 & d \\ d & 0 \end{pmatrix} \begin{pmatrix} \rho_{ee} & \rho_{eg} \\ \rho_{ge} & \rho_{gg} \end{pmatrix} \right] \\ &= Nd (e^{-i\omega t} \tilde{\rho}_{eg} + e^{i\omega t} \tilde{\rho}_{ge}) \\ &= N (\alpha \mathcal{E}^{(+)} + \alpha^* \mathcal{E}^{(-)}), \end{aligned} \quad (73.13)$$

where N is the density of active two-level atoms. Setting

$$\mathcal{E}^{(+)} = \frac{1}{2} \mathcal{E} e^{-i\omega t}, \quad (73.14)$$

the complex polarization is

$$\alpha(\omega) = \frac{d^2}{\hbar} \left(\frac{i\gamma + \Delta}{\Delta^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma} \right), \quad (73.15)$$

and from Eq. (73.1), the complex index of refraction is

$$\begin{aligned} n(\omega) &= 1 + \frac{N\alpha(\omega)}{2\varepsilon_0} \\ &= 1 + \frac{\pi N e^2}{4\varepsilon_0 m \omega_0} \left(\frac{f_0}{\pi} \right) \frac{i\gamma + \Delta}{\Delta^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma}, \end{aligned} \quad (73.16)$$

where $f_0 = 2d^2 m \omega_0 / \hbar e^2$ is the oscillator strength. Summing over all possible transitions yields the f-sum rule Eq. (72.63), (Chap. 22).

The imaginary part of Eq. (73.16) shows exactly the same absorptive behavior as in the harmonic oscillator model of Sect. 73.2 [see Eq. (73.3)]. However, the additional factor of $(\Omega_1^2\gamma/\Gamma)$ in the denominator makes the line appear broader than in the harmonic case; the line is power broadened. Physically, this derives from a saturation of the two-level system in which the population of the upper level becomes an appreciable fraction of that of the lower level. In the limit $\Omega_1 \rightarrow \infty$, Eq. (73.16) shows that $n(\omega) \rightarrow 1$ and the atom-field interaction effectively vanishes. In this limit, $\rho_{ee} \rightarrow \frac{1}{2}$ Eq. (73.11), and the field induces as many upward transitions as downward transitions.

When radiation at the frequency ω propagates in a medium of two-level atoms, the energy density is

$$I(z) \propto \mathcal{E}^* \mathcal{E} \propto \exp \left[- \left(\frac{N d^2 \omega}{\hbar \varepsilon_0 c} \right) \frac{\gamma z}{(\omega - \omega_0)^2 + \gamma^2} \right]. \quad (73.17)$$

Far from resonance ($|\omega - \omega_0| \gg \gamma$), the medium is transparent; but near resonance, damping is observed. The impinging radiation energy is deposited in the medium and propagation is impeded. This is called radiation trapping. In spectroscopy, the phenomenon is seen as a prolongation of the radiative decay time; the spontaneously emitted energy is seen to emerge from the sample more slowly than the single atom lifetime implies.

73.4 Line Broadening

The effective width of a spectral line from Eq. (73.16) is

$$\gamma_{\text{eff}} = \sqrt{\gamma^2 + \Omega_1^2 \frac{\gamma}{\Gamma}} \simeq \frac{1}{2} \Gamma + \gamma_{\text{ph}} + \frac{\Omega_1^2}{2\Gamma} + O(\Omega_1^4). \quad (73.18)$$

The various contributions are as follows [3]. The term γ contains all the transverse relaxation mechanisms. If decay to

additional levels occurs, these must be included (Sect. 73.5). The term γ_{ph} contains all perturbing effects effecting each single atom. For low enough pressures, collisional perturbations are proportional to the density of perturbing atoms so that

$$\gamma_{\text{ph}} = \eta_{\text{coll}} p, \quad (73.19)$$

where p is the pressure of the perturbing gas and η_{coll} is a constant of proportionality. This is called *collision* or *pressure broadening* (Chap. 63), whose order of magnitude can be estimated to be the inverse of the average free time between collisions. For high pressure (usually of the order of torrs), the linearity in Eq. (73.19) breaks down. When identical atoms collide, *resonant exchange* of energy may also take place. The third term in Eq. (73.18) is the *power broadening* term. It derives from the effect of the laser field on each individual atom. All such relaxation processes that are active on each and every individual atom separately are called *homogeneous broadening* processes. For a detailed discussion of *line broadening*, consult Chap. 20.

In contrast to homogeneous broadening, Doppler broadening is characterized by an atomic velocity parameter v which varies over the observed assembly. In a thermal assembly at temperature T (e.g., a gas cell), the velocity distribution is

$$P(v) = \frac{1}{\sqrt{2\pi}u^2} \exp\left(-\frac{v^2}{2u^2}\right), \quad (73.20)$$

where $u^2 = k_B T / M$. A particular atom with velocity v in the direction of the optical beam with wave vector k then experiences the Doppler-shifted frequency $\omega - kv$ relative to a stationary atom, and the effective detuning becomes

$$\Delta' = \Delta + kv, \quad (73.21)$$

replacing Δ . The population in the lower level from Eq. (73.11) is then

$$\rho_{gg} = 1 - \frac{\Omega_1^2 \gamma}{2\Gamma} \left(\frac{1}{(\Delta + kv)^2 + \gamma^2 + \Omega_1^2 \gamma / \Gamma} \right). \quad (73.22)$$

The atoms in the lower level, originally distributed according to Eq. (73.20), are now depleted from the velocity group around

$$v = (\omega - \omega_0) / k. \quad (73.23)$$

The width of the depleted region is given by γ_{eff} of Eq. (73.18). This region is called a *Bennett hole*. When the laser frequency ω is tuned, the hole sweeps over the velocity distribution of the atoms. The atomic response is saturated at the velocity group of the hole, indicating that *spectral hole burning* has occurred.

The observed spectrum is obtained by averaging the single atom response Eq. (73.15) over the velocity distribution. From the imaginary part, the absorption response is

$$\alpha''(\omega) = \frac{d^2}{\hbar\sqrt{2\pi}u^2} \int_{-\infty}^{+\infty} \frac{\gamma e^{-v^2/2u^2}}{(\Delta + kv)^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma} dv. \quad (73.24)$$

In the limits $\Omega_1 \rightarrow 0$ (no saturation), and $\gamma \ll ku$ (the Doppler limit), the Lorentzian line shape sweeps over the entire velocity profile, finding a resonant velocity group according to Eq. (73.23) as long as $v \leq u$. Thus, the linear spectroscopy sees a *Doppler broadened line* of width ku . This is called *inhomogeneous broadening*.

In the unsaturated regime, the atomic response function Eq. (73.24) is proportional to the imaginary part of the function

$$V(z) = \frac{1}{\sqrt{2\pi}\sigma^2} \int_{-\infty}^{+\infty} \frac{\exp(-x^2/2\sigma^2)}{z - x} dx, \quad (73.25)$$

at $z = -\Delta - i\gamma$ and $\sigma = ku$. This is the Hilbert transform of the Gaussian, and its shape is called a *Voigt profile* [4]. For $\gamma \ll ku$, it traces over the Gaussian, but for large detunings it always goes to zero as slowly as the Lorentzian, i.e., as Δ^{-1} . The profile has been widely used to interpret the data of *linear spectroscopy*. The function is tabulated [5] and its expansion is

$$V(z) = \sqrt{-\frac{\pi}{2\sigma^2}} \sum_{n=0}^{\infty} \frac{(iz/\sqrt{2}\sigma)^n}{\Gamma(1 + n/2)}, \quad (73.26)$$

and it has the continued fraction representation,

$$V(z) = \frac{1}{z - \frac{\sigma^2}{z - \frac{2\sigma^2}{z - \frac{3\sigma^2}{z - \frac{4\sigma^2}{z - \dots}}}}} \quad (73.27)$$

In addition to velocity, any other parameter shifting the individual atomic resonance frequencies ω_0 by different amounts for the different individuals leads to *inhomogeneous broadening*. The detuning Δ is then different for different members of the observed assembly, and a line shape similar to Eq. (73.24) applies. The distribution function must be replaced by the one relevant for the problem. In practice a Gaussian is almost always assumed.

An example of inhomogeneous broadening is the influence of the lattice environment on impurity spectroscopy

in solids. The resonant light selectively excites atoms at those particular positions which make the atoms resonant. Thus only these spatial locations are saturated, and the phenomenon of *spatial hole burning* occurs. This has been investigated as a method for storing information, signal processing, and volume holography.

It is, however, possible that the effects of collisions can counteract the inhomogeneous broadening. In order to see this we observe that the induced atomic dipole is proportional to the induced density matrix element, from Eq. (73.9),

$$\rho_{eg} = \tilde{\rho}_{eg} e^{i(kz(t) - \omega t)} \propto e^{ikvt}. \quad (73.28)$$

If the atoms now experience collisions characterized by an average free time of flight τ , the phase $kv t$ cannot build up coherently for times longer than this duration, the atomic velocity is quenched on the average, and the full Doppler profile cannot be observed. To see how this comes about, consider a time $t \gg \tau$. During this period the atom experiences on the average $\bar{n} = t/\tau$ collisions. Assuming a Poisson distribution, the probability of n collisions in time t is

$$p_n = \frac{e^{-\bar{n}} \bar{n}^n}{n!}. \quad (73.29)$$

Taking the average of Eq. (73.28) over the time $t = n\tau$ with the distribution p_n yields

$$\begin{aligned} \bar{\rho}_{eg} &\propto \sum_{n=0}^{\infty} e^{ikv n\tau} \left(\frac{e^{-\bar{n}} \bar{n}^n}{n!} \right) \\ &= e^{-\bar{n}} \exp(\bar{n} e^{ikv\tau}) \\ &\approx e^{ikvt} \exp\left(-\frac{1}{2} t k^2 v^2 \tau\right). \end{aligned} \quad (73.30)$$

This heuristic derivation suggests that for long enough interaction times ($t \gg \tau$), the large velocity components are suppressed. This tends to prevent the tails of the velocity distribution from contributing to the observed spectral profile. The effect is called *collisional narrowing* or *Dicke narrowing*. It is an observable effect, but the narrowing cannot be very large. To overcome the Doppler broadening one has to turn to nonlinear laser methods (Sect. 73.6).

73.5 The Rate Equation Limit

Consider now a generalized theory for the case of several incoming electromagnetic fields of the form

$$\mathcal{E}(R, t) = \sum_i \frac{1}{2} \mathcal{E}_i(R) e^{-i\omega_i t + i\varphi_i} + \text{c.c.} \quad (73.31)$$

The index i may range over several laser sources, the output of a multimode laser or the multitude of components of

a flashlight or a thermal source. Each component carries its own amplitude \mathcal{E}_i .

In steady state, the generalization of Eq. (73.12) becomes

$$\rho_{eg} = \frac{i}{2} \sum_i \frac{d\mathcal{E}_i}{\hbar} \frac{(\rho_{gg} - \rho_{ee})}{\gamma + i\Delta_i} e^{-i\omega_i t + i\varphi_i}, \quad (73.32)$$

where the detuning is

$$\Delta_i = \omega_0 - \omega_i. \quad (73.33)$$

The response of the atom now separates into individual contributions oscillating at the various frequencies ω_i according to

$$\rho_{eg} = \sum_i \rho_{eg}^{(i)} e^{-i\omega_i t + i\varphi_i}. \quad (73.34)$$

This resolution is of key importance to the theory.

With the multimode field, Eq. (72.67) for the level occupation probabilities become

$$\begin{aligned} \frac{d}{dt} \rho_{ee} &= -\frac{d}{dt} \rho_{gg} \\ &= -\Gamma \rho_{ee} + \frac{i}{2} \sum_i \\ &\quad \times \left(\frac{d\mathcal{E}_i}{\hbar} e^{-i\omega_i t + i\varphi_i} \rho_{ge} - \text{c.c.} \right). \end{aligned} \quad (73.35)$$

Insertion of the steady state result Eq. (73.32) into this equation yields a closed set of equations for the level occupation probabilities. These are called *rate equations*.

To justify the above steps, consider the single frequency case again. The off-diagonal time derivatives can be neglected when

$$\left| \frac{d}{dt} \rho_{eg} \right| \ll |\gamma + i\Delta| |\rho_{eg}|. \quad (73.36)$$

This can be surmised to hold when the phase relaxation contributions to γ are large Eq. (73.8) or the detuning $|\Delta|$ is large. Insertion of Eq. (73.32) into Eq. (73.35) for the single mode case gives

$$\frac{d}{dt} \rho_{ee} = -\Gamma \rho_{ee} - W (\rho_{ee} - \rho_{gg}), \quad (73.37)$$

where the rate coefficient is given by

$$W = 2\pi \left(\frac{d\mathcal{E}}{2\hbar} \right)^2 \frac{\gamma/\pi}{\Delta^2 + \gamma^2}. \quad (73.38)$$

Multiplying Eq. (73.37) by the density of active atoms N then produces the conventional rate equations for the populations $N_{ee} = N\rho_{ee}$ and $N_{gg} = N\rho_{gg}$.

Two physical effects can be discerned in Eq. (73.37): *induced* and *spontaneous emission*. The term with Γ gives

the spontaneous emission which forces the entire population to the lower level. The terms proportional to W describe induced emission, with upward transitions proportional to $W\rho_{gg}$ and downward transitions proportional to $W\rho_{ee}$. In the absence of spontaneous emission, they strive to equalize the population of the two levels. Using Eq. (73.10), the steady-state solution is

$$\begin{aligned} \rho_{ee} &= \frac{W}{\Gamma + 2W} \\ &= \frac{1}{2} \left(\frac{d\mathcal{E}}{\hbar} \right)^2 \frac{\gamma}{\Gamma \Delta^2 + \gamma^2 + (d\mathcal{E}/\hbar)^2 \gamma/\Gamma}. \end{aligned} \quad (73.39)$$

This is clearly seen to agree with the solution Eq. (73.11) as is expected in steady state.

Although the rate equations were derived in the limit Eq. (73.36), the rate coefficient Eq. (73.38) has a special significance in the limit $\gamma \rightarrow 0$. In this limit, the factor

$$\begin{aligned} \frac{1}{\hbar} \lim_{\gamma \rightarrow 0} \left(\frac{\gamma/\pi}{\Delta^2 + \gamma^2} \right) &= \frac{1}{\hbar} \delta(\Delta) \\ &= \delta(\hbar\omega - \hbar\omega_0), \end{aligned} \quad (73.40)$$

enforces energy conservation in the transition. Using the field in Eq. (73.14), and the interaction from Eq. (73.6), the off-diagonal matrix element is

$$|\langle e|H|g\rangle| = \frac{1}{2} d\mathcal{E}. \quad (73.41)$$

With these results, Eq. (73.38) can be written in the form of *Fermi's Golden Rule*

$$W = \frac{2\pi}{\hbar} |\langle e|H|g\rangle|^2 \delta(\hbar\omega - \hbar\omega_0), \quad (73.42)$$

usually derived from time dependent perturbation theory.

Returning to the multimode rate equations, an incoherent *broad band light source* has many components that contribute to the sum over field frequencies. In the case of flash pulses, thermal light sources, or free-running multimode lasers the spectral components are uncorrelated. Inserting Eq. (73.32) into Eq. (73.35) yields

$$\begin{aligned} \frac{d}{dt} \rho_{ee} &= -\frac{d}{dt} \rho_{gg} \\ &= -\Gamma \rho_{ee} + \frac{d^2}{2\hbar^2} (\rho_{gg} - \rho_{ee}) \\ &\quad \times \sum_{i,j} \mathcal{E}_i \mathcal{E}_j e^{i(\omega_j - \omega_i)t} e^{i(\varphi_i - \varphi_j)} \frac{\gamma}{\Delta_{j,j}^2 + \gamma^2}. \end{aligned} \quad (73.43)$$

The contributions from the different terms $i \neq j$ average to zero either by beating at the frequencies $|\omega_i - \omega_j|$ or by incoherent effects from the random phases φ_j . Thus, only the coherent sum survives to give

$$\begin{aligned} \frac{d}{dt} \rho_{ee} &= -\frac{d}{dt} \rho_{gg} \\ &= -\Gamma \rho_{ee} \times \sum_i W^{(i)} (\rho_{gg} - \rho_{ee}), \end{aligned} \quad (73.44)$$

where the rate coefficients $W^{(i)}$ are given by Eq. (73.38) with the appropriate detunings $\Delta_j = \omega_0 - \omega_j$. This is a *rate equation* in the limit of many uncorrelated components of light, i.e., for a *broad band light source*. In this case the incoherence between the different components justifies the use of a rate approach, and no assumption like Eq. (73.36) is needed. Thus, the limit $\gamma \rightarrow 0$ Eq. (73.40) is legitimate, and the $W^{(i)}$ can be calculated in time dependent perturbation theory from Fermi's Golden Rule.

In the limit of an incoherent broad band light source, the sum in Eq. (73.44) can be replaced by an integral. In particular, this is allowed for incandescent light sources as used in *optical pumping* experiments [6]. Pumping of lasers by strong lamps or flashes are also describable by the same rate equations.

In amplifiers and lasers, the atoms must be brought into states far from equilibrium by incoherent optical excitation or resonant transfer of excitation energy in collisions (Chap. 74). In the two-level description, the atomic levels are constantly replenished. The normalization condition Eq. (73.10) is then no longer appropriate; often the density matrix is normalized so that $\text{Tr}(\rho)$ directly gives the density of active atoms.

With pumping into the levels, one must allow for decay out of the two-level system in order to prevent the atomic density from growing in an unlimited way. This decay takes the atom to unobserved levels. In the rate equation approximation, the pumping and decay processes can be described by terms added to the equations of the form Eq. (72.68)

$$\begin{aligned} \frac{d}{dt}\rho_{ee} &= \lambda_e - \gamma_e\rho_{ee}, \\ \frac{d}{dt}\rho_{gg} &= \lambda_g - \gamma_g\rho_{gg}. \end{aligned} \quad (73.45)$$

In a laser, the level $|g\rangle$ is usually not the ground state of the system.

From Eq. (73.45), the steady state population is

$$\rho_{gg}^{(0)} - \rho_{ee}^{(0)} = \lambda_g/\gamma_g - \lambda_e/\gamma_e. \quad (73.46)$$

A *population inversion* exists when this is negative. The population difference Eq. (73.46) is modified when the effects of spontaneous and induced processes are added, as in Eq. (73.37). Then the transitions saturate because of the *induced processes*.

Using Eq. (73.46) in Eq. (73.12), the calculated polarizability without saturation is

$$\alpha(\omega) = \left(\frac{d^2}{\hbar}\right) \left(\frac{i\gamma + \Delta}{\gamma^2 + \Delta^2}\right) (\rho_{gg}^{(0)} - \rho_{ee}^{(0)}). \quad (73.47)$$

According to Eq. (73.1), the index of refraction is

$$\begin{aligned} n'(\omega) &= 1 + \frac{N\alpha'(\omega)}{2\varepsilon_0} \\ &= 1 - \left(\frac{Nd^2}{2\varepsilon_0\hbar}\right) \frac{(\omega - \omega_0)}{(\omega - \omega_0)^2 + \gamma^2} (\rho_{gg}^{(0)} - \rho_{ee}^{(0)}). \end{aligned} \quad (73.48)$$

For weakly excited atoms, $\rho_{gg} \approx 1$, and Eq. (73.47) agrees with the unsaturated limit of Eq. (73.16). The dispersion of a light signal behaving according to Eq. (73.48) is called *normal*, i.e., according to the harmonic model in Sect. 73.2. Below resonance ($\omega < \omega_0$), n' is larger than unity, implying a reduction of the velocity of light. As a function of ω , the curve Eq. (73.48) starts above unity, and passes below unity for $\omega > \omega_0$. This is *normal dispersion*.

However, for an *inverted medium* ($\rho_{gg}^{(0)} < \rho_{ee}^{(0)}$), n' is less than unity for low frequencies and goes through unity with a positive slope. This is called *anomalous dispersion* and signifies the presence of a *gain profile*. In such a medium, $\alpha'' = \text{Im}[\alpha(\omega)]$ is of opposite sign, as seen from Eq. (73.47); in the inverted medium, α'' becomes negative near $\Delta = 0$. From Eq. (73.2), this indicates a growing electromagnetic field, i.e., an *amplifying medium*. The amplitude grows, and the assumption of a small signal becomes invalid. Then saturation has to be included, either at the rate equation level or by performing a full density matrix calculation. This regime describes a laser with *saturated gain*. In steady state, the two levels become nearly equally populated ($\rho_{ee} \approx \rho_{gg}$), and the operation is stable. The theory of the laser is discussed in detail in Chap. 74.

73.6 Two-Level Doppler-Free Spectroscopy

The *linear absorption* of a scanned laser signal defines *linear spectroscopy* and gives information characterizing the sample. However, Sect. 73.4 shows that inhomogeneous broadening masks the desired information by dominating the line shape. The availability of laser sources has made it possible to overcome this limitation, and to use the *saturation* properties of the medium to perform *nonlinear spectroscopy*. This section discusses how Doppler broadening can be eliminated to achieve *Doppler-free spectroscopy*. Similar techniques may be used to overcome other types of *inhomogeneous line broadening*; a general name is then *hole-burning spectroscopy* (see the discussion in Sect. 73.4). Other aspects of nonlinear matter-light interaction are found in Chap. 76.

Equation (73.24) shows that a single laser cannot resolve beyond the Doppler width. However, if a strong laser is used to pump the transition, a weak *probe signal* can see the hole burned into the spectral profile by the pump. This technique is called *pump-probe spectroscopy*. Because the probe

is taken to be weak, perturbation theory may be used to calculate the induced polarization to lowest order in the probe amplitude only.

In the field expansion Eq. (73.31), define the strong pump amplitude to be \mathcal{E}_1 and the weak probe \mathcal{E}_2 at frequency ω_2 . From the resolution Eq. (73.34), the component $\rho_{eg}^{(2)}$ carries the information about the linear response at frequency ω_2 . If the field \mathcal{E}_2 propagates in a direction opposite to that of \mathcal{E}_1 , its detuning is

$$\Delta'_2 = \Delta_2 - kv \quad (73.49)$$

(as compared with $\Delta'_1 = \Delta_1 + kv$ for \mathcal{E}_1). Since $\omega_1 \simeq \omega_2$, the two k -vectors are nearly equal in magnitude.

The linear response now becomes

$$\rho_{eg}^{(2)} = \left(\frac{id\mathcal{E}_2}{2\hbar} \right) \frac{1}{\gamma + i(\Delta_2 - kv)} (\rho_{gg} - \rho_{ee}). \quad (73.50)$$

With only the signal \mathcal{E}_1 present, the population difference follows directly from Eq. (73.22). The linear response at frequency ω_2 is then

$$\begin{aligned} \rho_{eg}^{(2)} &= \left(\frac{d\mathcal{E}_2}{2\hbar} \right) \frac{i\gamma + (\Delta_2 - kv)}{\gamma^2 + (\Delta_2 - kv)^2} \\ &\times \left[1 - \frac{\Omega_1^2 \gamma}{\Gamma} \left(\frac{1}{(\Delta_1 + kv)^2 + \gamma^2 + \Omega_1^2 \gamma / \Gamma} \right) \right]. \end{aligned} \quad (73.51)$$

This is the linear response of atoms moving with velocity v . To obtain the polarization of the whole sample, we must average over the velocity distribution using the Gaussian weight Eq. (73.20). The first term in Eq. (73.51) gives the linear response in the form of a *Voigt profile*, as discussed in Sect. 73.4. This part of the response carries no Doppler-free information. The second terms contain the nonlinear response. This shows the details of the homogeneous features under the Doppler line shape. For simplicity we assume the Doppler limit, $\gamma \ll kv$, and neglect the variation of the Gaussian over the atomic line shape. We also neglect the power broadening due to the field \mathcal{E}_1 and obtain, using Eqs. (73.13), (73.20), and (73.51),

$$\begin{aligned} \alpha''(\omega) &= - \left(\frac{d^2}{\hbar} \right) \frac{\Omega_1^2 \gamma^2}{\sqrt{2\pi} \Gamma u} \\ &\times \int_{-\infty}^{+\infty} \frac{dv}{\left[(\Delta_2 - kv)^2 + \gamma^2 \right] \left[(\Delta_1 + kv)^2 + \gamma^2 \right]} \\ &= - \left(\frac{d^2}{\hbar} \right) \frac{\sqrt{2\pi} \Omega_1^2}{4\Gamma ku} \frac{\gamma}{(\omega - \omega_0)^2 + \gamma^2}. \end{aligned} \quad (73.52)$$

This denotes the energy absorbed from the field \mathcal{E}_1 , as induced nonlinearly by the intensity \mathcal{E}_1^2 . The resonance is still at $\omega = \omega_0$, but with a homogeneous atomic line shape. In the Doppler limit, the Doppler broadening is only seen in the prefactor

$$\frac{\Omega_1^2}{\Gamma ku} = \left(\frac{\Omega_1^2}{\Gamma \gamma} \right) \frac{\gamma}{ku}, \quad (73.53)$$

which shows that only the fraction (γ/ku) of all atoms can contribute to the resonant response. The first factor on the right-hand side of Eq. (73.53) is the dimensionless saturation factor.

The Doppler-free character of this spectroscopy derives from the fact that the two fields burn their two separate Bennett holes at the velocities

$$kv_1 = -\Delta_1, \quad \text{and} \quad kv_2 = \Delta_2. \quad (73.54)$$

When these two groups coincide, i.e., when $v_1 = v_2$, the probe \mathcal{E}_2 sees the absorption saturated by the pump field \mathcal{E}_1 and a decreased absorption is observed. For $\omega_1 = \omega_2$, the two holes meet in the middle at zero velocity. With two different frequencies, one can make the holes meet at a nonzero velocity to one side of the Doppler profile. The decreased absorption seen in these experiments is called an *inverted Lamb dip* Chap. 74.

The results derived here are based on a simplified view of the pump-probe response which in turn is based on the rate equation approach. Certain coherent effects are neglected, which would considerably complicate the treatment [2]. Section 73.7 discusses these effects in the three-level system where they are more important.

In addition to measuring the probe absorption induced by the pump field, it is also possible to observe the dispersion of the probe signal caused by the saturation induced by the pump. Assuming that the pump introduces the velocity dependent population difference

$$\rho_{ee} - \rho_{gg} = \Delta\rho(v), \quad (73.55)$$

then from Eq. (73.50), $\text{Re}(n)$ is

$$n' = 1 + \frac{Nd^2}{2\hbar\epsilon_0} \int \frac{\Delta_2 - kv}{(\Delta_2 - kv)^2 + \gamma^2} \Delta\rho(v) dv. \quad (73.56)$$

From Eq. (73.2), the phase of the electromagnetic signal feels the value of n' through the factor

$$\mathcal{E} \propto \exp(i\omega n' z/c). \quad (73.57)$$

Thus, by modifying $\Delta\rho(v)$, a pump laser can control the phase acquired by light traversing the sample, and thereby control the optical length of the sample.

A real atom has magnetic sublevels, which are coupled to light in accordance with *dipole selection rules* (see the

discussion in Chap. 35). If a pump laser is used to affect populations in the various sub-levels differently, the optical paths experienced by the differently circularly polarized components of a linearly polarized probe signal are different. Thus, its plane of polarization will turn, corresponding to the *Faraday effect*. By tuning the pump and the probe over the spectral lines of the sample, the turning of the probe polarization provides a signal to investigate the atomic level structure. This method of *polarization spectroscopy* can be used both with two-level and three-level systems [7].

73.7 Three-Level Spectroscopy

New nonlinear phenomena appear when one of the levels in the two-state configuration, $|e\rangle$ say, is coupled to a final level $|f\rangle$ by a weak probe. This may be above the level $|e\rangle$ (the cascade configuration denoted by \mathcal{E}) or below $|e\rangle$ (the lambda configuration Λ) (if the third level were coupled to $|g\rangle$ we would talk about the inverted lambda or V configuration) [8]. For simplicity, only the \mathcal{E} configuration is discussed here.

Assume that the level pair $|g\rangle \leftrightarrow |e\rangle$ is pumped by the field \mathcal{E}_1 and its effect probed by the field \mathcal{E}_2 coupling $|e\rangle \leftrightarrow |f\rangle$. The dipole matrix element is $d_2 = \langle f|H|e\rangle$. The RWA is now achieved by introducing slowly varying quantities through the definitions

$$\begin{aligned}\rho_{fe} &= e^{i(k_2z - \omega_2t)} \tilde{\rho}_{fe}, \\ \rho_{fg} &= e^{i[(k_1+k_2)z - (\omega_1+\omega_2)t]} \tilde{\rho}_{fg},\end{aligned}\quad (73.58)$$

and omitting all components oscillating at multiples of the optical frequencies. From the equation of motion for the density matrix, the steady state equations are [2]

$$\begin{aligned}(\Delta_2 + k_2v - i\gamma_{fe})\tilde{\rho}_{fe} &= \frac{d_2\mathcal{E}_2}{2\hbar}\rho_{ee} - \frac{d_1\mathcal{E}_1}{2\hbar}\tilde{\rho}_{fg}, \\ [(\Delta_1 + \Delta_2) + (k_1 + k_2)v - i\gamma_{fg}]\tilde{\rho}_{fg} &= \frac{d_2\mathcal{E}_1}{2\hbar}\tilde{\rho}_{eg} - \frac{d_1\mathcal{E}_1}{2\hbar}\tilde{\rho}_{fe},\end{aligned}\quad (73.59)$$

where the second step detuning is now

$$\Delta_2 = \omega_{fe} - \omega_2. \quad (73.60)$$

These equations contain the lowest order response proportional to \mathcal{E}_2 , including some coherence effects. The coherence effects remain to lowest order, even when the last term

in Eq. (73.59) is neglected; in that case, the solution is

$$\begin{aligned}\tilde{\rho}_{fe} &= \left(\frac{d_2\mathcal{E}_2}{2\hbar}\right)\frac{\rho_{ee}}{\Delta_2 + k_2v - i\gamma_{fe}} \\ &\quad - \left(\frac{d_1\mathcal{E}_1}{2\hbar}\right)\left(\frac{d_2\mathcal{E}_2}{2\hbar}\right) \\ &\quad \times \frac{\tilde{\rho}_{eg}}{(\Delta_2 + k_2v - i\gamma_{fe})} \\ &\quad \times \frac{1}{[(\Delta_1 + \Delta_2) + (k_1 + k_2)v - i\gamma_{fg}]}. \quad (73.61)\end{aligned}$$

The result to lowest order in \mathcal{E}_2 follows by replacing the density matrix elements for the two-level system $|e\rangle \leftrightarrow |g\rangle$ by their results calculated without this field. This shows that the polarization induced at the frequency ω_2 consists of two parts: one induced by the population excited to level $|e\rangle$ by the field \mathcal{E}_1 proportional to ρ_{ee} , and the other one is induced by the coherence $\tilde{\rho}_{eg}$ created by the pump. Retaining only the former produces a rate equation approximation, called a *two-step process*. This misses important physical features which are included in the second term called a *two-photon or coherent process*.

In order to see the effects of the two terms most clearly, consider the two-level matrix elements from Eqs. (73.11) and (73.12) in lowest perturbative order with respect to the pump field \mathcal{E}_1 , i.e.,

$$\begin{aligned}\rho_{ee} &= \left(\frac{d_1\mathcal{E}_1}{\hbar}\right)^2 \frac{\gamma_{eg}}{2\gamma_{ee}} \frac{1}{(\Delta_1 + k_1v)^2 + \gamma_{eg}^2}, \\ \tilde{\rho}_{eg} &= \frac{d_1\mathcal{E}_1}{2\hbar} \frac{1}{\Delta_1 + k_1v - i\gamma_{eg}}\end{aligned}\quad (73.62)$$

From Eq. (73.61), these matrix elements give

$$\begin{aligned}\tilde{\rho}_{fe} &= -\left(\frac{A}{\Delta_1 + k_1v - i\gamma_{eg}}\right) \\ &\quad \times \left[\left(\frac{2\gamma_{eg}}{\gamma_{ee}}\right)\frac{1}{(\Delta_1 + k_1v + i\gamma_{eg})(\Delta_2 + k_2v - i\gamma_{fe})}\right. \\ &\quad \left. - \frac{1}{(\Delta_2 + k_2v - i\gamma_{fe})}\right] \\ &\quad \times \frac{1}{[(\Delta_1 + \Delta_2) + (k_1 + k_2)v - i\gamma_{fg}]}, \quad (73.63)\end{aligned}$$

where

$$A = -\left(\frac{d_2\mathcal{E}_2}{2\hbar}\right)\left(\frac{d_1\mathcal{E}_1}{2\hbar}\right)^2. \quad (73.64)$$

The imaginary part of this yields the absorptive part of the polarization at the frequency ω_2 . The first term becomes the product of two Lorentzians, and is an incoherent rate contribution. It dominates when the induced population ρ_{ee} decays

much more slowly than the induced coherence $\tilde{\rho}_{eg}$, i.e., when $\gamma_{ee} \ll \gamma_{eg}$.

The significance of the second term in Eq. (73.63) is evident in the limit when no phase perturbing processes intervene, so that

$$\begin{aligned} \gamma_{ee} &= \Gamma, & \gamma_{eg} &= \frac{1}{2}\Gamma, \\ \gamma_{fg} &= \frac{1}{2}\gamma_{ff}, & \gamma_{fe} &= \frac{1}{2}(\gamma_{ff} + \Gamma). \end{aligned} \quad (73.65)$$

For $v = 0$, $\tilde{\rho}_{fe}$ becomes

$$\tilde{\rho}_{fe} = -\frac{A}{\Delta_1^2 + (\Gamma/2)^2} \left(\frac{1}{\Delta_1 + \Delta_2 - i\frac{1}{2}\gamma_{ff}} \right). \quad (73.66)$$

Neglecting the decay of the final level $|f\rangle$, $\gamma_{ff} \rightarrow 0$, the absorption becomes proportional to

$$\text{Im}(\tilde{\rho}_{fe}) = \frac{\pi|A|}{\Delta_1^2 + (\Gamma/2)^2} \delta(\Delta_1 + \Delta_2). \quad (73.67)$$

In this limit, strict energy conservation between the ground state and the final state must prevail; the final state must be reached by the absorption of exactly two quanta. The delta function in Eq. (73.67) indicates precisely this:

$$\begin{aligned} \Delta_1 + \Delta_2 &= \omega_{fe} + \omega_{eg} - (\omega_1 + \omega_2) \\ &= \omega_{fg} - \omega_1 - \omega_2 \\ &= 0. \end{aligned} \quad (73.68)$$

The detuning and the width of the intermediate state affect the total transition rate, but not the condition of energy conservation. The presence of the second term in Eq. (73.63) makes the resonance contributions at

$$\Delta_2 = \omega_{fg} - \omega_2 = 0 \quad (73.69)$$

cancel approximately. Only a *two-photon transition* remains; in the Λ configuration this would be a *Raman process* (Chaps. 66 and 76).

If the velocity dependence in Eq. (73.63) is retained, the nonlinear response of an atomic sample must be averaged over the velocity distribution given by the Gaussian Eq. (73.20). The computations become involved, but the results show more or less well resolved resonances around the two positions Eqs. (73.68) and (73.69), i.e., the *coherent two-photon process* and the single step rate process $|e\rangle \rightarrow |f\rangle$ appearing due to a previous single step process $|g\rangle \rightarrow |e\rangle$; this is the *two-step process*.

A special situation arises when the intermediate step is detuned so much that no velocity group is in resonance, i.e., $|\Delta_1| \approx |\Delta_2| \gg kv$ for all velocities contributing significantly to the spectrum. Then the second coherent term of

Eq. (73.63) can be written in the form

$$\tilde{\rho}_{fe} = -\frac{A}{\Delta_1^2} \left(\frac{1}{(\Delta_1 + \Delta_2) + (k_1 + k_2)v - i\gamma_{fg}} \right). \quad (73.70)$$

If the two fields \mathcal{E}_1 and \mathcal{E}_2 have the same frequency but are counterpropagating, then $k_1 + k_2 = 0$, and no velocity dependence occurs in Eq. (73.70) for the two-photon resonance. All atoms in the sample contribute to the strength of the resonance, and then polarization is obtained directly by multiplication with the total atomic density. Equation (73.13) then gives

$$\alpha_2'' = \frac{d_2^2}{\hbar} \left(\frac{d_1 \mathcal{E}_1}{2\hbar \Delta_1} \right)^2 \frac{\gamma_{fg}}{(2\omega - \omega_{fg})^2 + \gamma_{fg}^2}. \quad (73.71)$$

This is a sharp *Doppler-free resonance* on the two-photon transition ω_{fg} . The advantage is that all atoms contribute with the sharp line width γ_{fg} , which is not easily affected by phase perturbations because of the two-photon nature of the transition. The disadvantage is the weakness of the transition, which is caused by the large detuning, making $d_1 \mathcal{E}_1 / |\Delta_1| \ll 1$ in most cases. With tunable lasers, however, this Doppler-free spectroscopy method has been used successfully in many cases.

73.8 Special Effects in Three-Level Systems

We continue our considerations of a three-level system but this time in the V -configuration. Thus, we have a ground state $|g\rangle$ coupled to a doublet of excited states $\{|e\rangle, |f\rangle\}$ through the interaction

$$V = \Omega_1 |g\rangle \langle e| + \Omega_2 |g\rangle \langle f| + \text{h.c.}, \quad (73.72)$$

where the couplings are due to radiation fields and given by

$$\Omega_i = \frac{d_i \mathcal{E}_i}{2\hbar}. \quad (73.73)$$

We use the rotating wave approximation and set the detunings to

$$\Delta\omega_e = \omega_e - \omega_1 \quad \text{and} \quad \Delta\omega_f = \omega_f - \omega_2, \quad (73.74)$$

where the frequency ω_i derives from the coupling field \mathcal{E}_i . The energy $E_g = 0$.

The time-dependent Schrödinger equation for this system is then written as

$$i\dot{c}_g = \Omega_1 c_e + \Omega_2 c_f, \quad (73.75)$$

$$i\dot{c}_e = \Delta\omega_e c_e + \Omega_1 c_g, \quad (73.76)$$

$$i\dot{c}_f = \Delta\omega_f c_f + \Omega_2 c_g. \quad (73.77)$$

We now introduce the two new variables

$$c_C = \bar{\Omega}^{-1}(\Omega_1 c_e + \Omega_2 c_f) \quad (73.78)$$

$$c_{NC} = \bar{\Omega}^{-1}(\Omega_2 c_e - \Omega_1 c_f), \quad (73.79)$$

where

$$\bar{\Omega}^2 = \Omega_2^2 + \Omega_1^2. \quad (73.80)$$

The equations of motion follow:

$$\begin{aligned} i\dot{c}_{NC} &= \left(\frac{\Omega_2}{\bar{\Omega}} \Delta\omega_e c_e - \frac{\Omega_1}{\bar{\Omega}} \Delta\omega_f c_f \right) \\ &= \frac{1}{\bar{\Omega}^2} \left[\Omega_1 \Omega_2 (\Delta\omega_e - \Delta\omega_f) c_C \right. \\ &\quad \left. + (\Delta\omega_e \Omega_2^2 + \Delta\omega_f \Omega_1^2) c_{NC} \right], \end{aligned} \quad (73.81)$$

$$\begin{aligned} i\dot{c}_C &= \left(\frac{\Omega_1}{\bar{\Omega}} \Delta\omega_e c_e + \frac{\Omega_2}{\bar{\Omega}} \Delta\omega_f c_f \right) + \bar{\Omega} c_g \\ &= \frac{1}{\bar{\Omega}^2} \left[(\Delta\omega_e \Omega_1^2 + \Delta\omega_f \Omega_2^2) c_C \right. \\ &\quad \left. + \Omega_1 \Omega_2 (\Delta\omega_e - \Delta\omega_f) c_{NC} \right] + \bar{\Omega} c_g. \end{aligned} \quad (73.82)$$

We notice that c_{NC} is not coupled to the ground state, but, in general, its coupling to the state c_C provides an indirect coupling. This indirect coupling, however, can be made to disappear, if we set $\Delta\omega_e = \Delta\omega_f \equiv \Delta\omega$. Then we find the equations

$$\begin{aligned} i\dot{c}_{NC} &= \Delta\omega c_{NC}, \\ i\dot{c}_C &= \Delta\omega c_C + \bar{\Omega} c_g, \\ i\dot{c}_g &= \bar{\Omega} c_C. \end{aligned} \quad (73.83)$$

This describes a pair of coupled quantum levels and a single uncoupled level. Thus, if we start in the ground state, this latter level can never be populated. It remains unpopulated and is called a dark state. This state corresponds to the superposition

$$|NC\rangle = \frac{1}{\bar{\Omega}}(\Omega_2|e\rangle - \Omega_1|f\rangle). \quad (73.84)$$

Using the coupling operator Eq. (73.72), we find the matrix element

$$\langle g|V|NC\rangle = 0. \quad (73.85)$$

We also notice that the dark state can be found if the states $|e\rangle$ and $|f\rangle$ are the lower ones, i.e., we have the Λ -configuration.

Alternatively, if we start the system off in the dark state, it will never be able to get out of this state. This is also taken to hold true if we let the couplings depend slowly on time.

In this case, we may let Ω_1 come on later than Ω_2 . Then we may have

$$\begin{aligned} \lim_{t \rightarrow -\infty} \left(\frac{\Omega_1}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) &= 0, \\ \lim_{t \rightarrow -\infty} \left(\frac{\Omega_2}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) &= 1 \end{aligned} \quad (73.86)$$

and

$$\begin{aligned} \lim_{t \rightarrow \infty} \left(\frac{\Omega_1}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) &= 1, \\ \lim_{t \rightarrow \infty} \left(\frac{\Omega_2}{\sqrt{\Omega_2^2 + \Omega_1^2}} \right) &= 0. \end{aligned} \quad (73.87)$$

Both couplings are thus pulses, but they occur with a slight time delay. If we now start the system in the state $|e\rangle$, we find from Eq. (73.84) that

$$\lim_{t \rightarrow -\infty} |NC\rangle = |e\rangle, \quad (73.88)$$

and

$$\lim_{t \rightarrow +\infty} |NC\rangle = -|f\rangle. \quad (73.89)$$

Thus, by keeping the system in this uncoupled state we can adiabatically transfer its population between the states without involving any population of the intermediate state $|g\rangle$. Especially if this is an upper state, which may decay and dephase rapidly, the proposed population transfer may be greatly advantageous. Because it is usually applied in the Λ -configuration, it is termed Stimulated Raman Adiabatic Passage (STIRAP).

The dark state has found a wide range of applications in laser physics. As we may use the method to pass radiation through a medium without any absorption, it has led to the phenomenon of light-induced transparency. It can also be used to affect the index of refraction without having the accompanying absorption. The absorptive part of a resonance normally manifests itself as a quantum noise; utilizing the dark state idea one may reduce the noise in quantum devices. The dressing of the levels due to the special features of the interaction has also made it possible to achieve lasing without an inversion of the bare levels. These topics, however, will not be treated here.

A special application of the method to affect the refractive index deserves a more detailed consideration. We look at the relationship between the electric field vectors in the medium:

$$D(\omega) = \varepsilon_0 E + N\alpha(\omega)E(\omega) = \chi(\omega)\varepsilon_0 E(\omega), \quad (73.90)$$

where $\chi(\omega)$ is the susceptibility of the medium. From Maxwell's equations we find the relation Eq. (72.24)

$$k^2 = n^2(\omega) \frac{\omega^2}{c^2} = \frac{\omega^2}{c^2} [1 + \chi(\omega)]. \quad (73.91)$$

If we take the real parts of the quantities, this describes the propagation of waves in the medium.

Now we may use the relations Eq. (73.16) to estimate the function $\alpha(\omega)$ in the case when we have two weak fields exciting the three-level system in the V -configuration. We assume that both couplings have the same frequency, $\omega_1 = \omega_2 = \omega$. We write

$$\chi(\omega) \approx \Lambda \left(\frac{(\omega - \omega_e)}{(\omega - \omega_e)^2 + \gamma^2} + \frac{(\omega - \omega_f)}{(\omega - \omega_f)^2 + \gamma^2} \right); \quad (73.92)$$

in the weak field limit we may assume the two processes to add independently. The parameter

$$\Lambda = \frac{Nd^2}{2\hbar\epsilon_0} \quad (73.93)$$

has the dimension of a frequency and indicates the strength of the interaction. It is clear that tuning the frequency between the levels may give rise to a value of zero for the susceptibility. For a large enough γ , we write, in the neighbourhood of the zero,

$$\chi(\omega) \approx \frac{2\Lambda}{\gamma^2} (\omega - \bar{\omega}), \quad (73.94)$$

where $\bar{\omega} = \frac{1}{2}(\omega_e + \omega_f)$.

We now have the relation Eq. (73.91) to determine the dispersion relation, and assuming the effect of the medium to be substantial, we may derive an expression for the group velocity in the medium

$$v_g^{-1} = \frac{\partial k}{\partial \omega}. \quad (73.95)$$

We find

$$\frac{2k}{v_g} = \frac{2\omega}{c^2} (1 + \chi) + \frac{\omega^2}{c^2} \left(\frac{2\Lambda}{\gamma^2} \right). \quad (73.96)$$

Even though $\chi = 0$ near the point $\bar{\omega}$, we still have $\omega \approx ck$, so that

$$v_g = \frac{c}{1 + \frac{\Lambda\omega}{\gamma^2}} \approx c \left(\frac{\gamma^2}{\Lambda\omega} \right) \ll c. \quad (73.97)$$

The last inequality follows from the fact that in all cases $\gamma \ll \omega$.

We have thus found that utilizing the interference of two near quantum levels, the refractive index may acquire a very strong dependence on frequency. This may manifest itself in

an exceedingly slow propagation of light pulses. Such slow light has been shown to travel at only a few kilometers per hour, which is a most remarkable result. The drawback is, however, that this can only occur over a very narrow frequency range, as follows from the assumption of a strong dependence on frequency.

73.9 Summary of the Literature

Much of the material needed to formulate the basic theory of interaction between light and matter can be found in the text book [2]. A comparison between the harmonic model and the two-level model is given by *Feld* [1]. The density matrix formulation is presented in detail in [2]. The influence of various line broadening mechanisms on laser spectroscopy is discussed in the book [3]. The Voigt profile is related to the error function, which is treated in the compilation [5]. The numerical evaluation of the Voigt profile is discussed in [4]. Rate equations are commonly used in laser theory and they are derived for optical pumping and laser-induced processes in the lectures [6]. The Doppler-free spectroscopy was developed in the 1960s and 1970s by many authors following the initial discovery of the Benett hole by Bill R. Bennett Jr. and the Lamb dip by Willis E. Lamb Jr. Much of the pioneering work can be found in the book [3]. The three-level work has been reviewed by *Chebotayev* [8]. Various applications of lasers in spectroscopy are treated by *Levenson* and *Kano* [7]. For references to other topics, we refer to the specialized chapters of the present book.

Many features of the quantum dynamics of a few-level system are found in [9, 10]. The theoretical methods to treat such systems are presented in detail in [11]. The ensuing physical processes are presented in [12] with much additional material on quantum optics phenomena. The basic theory of the dark state and many of its applications in spectroscopy and laser physics are found in [13]. A rather complete review of adiabatic processes induced by delayed pulses is the article [14]. The slowing down and stopping of light is reviewed in [15]. A very recent article with earlier references is [16].

Abstract

Despite their great variety and range of size, power, wavelength, and temporal, spatial, and polarization characteristics, all lasers involve certain basic concepts, such as gain, threshold, and electromagnetic modes of oscillation [1–6]. In addition to these universal characteristics are features, such as Gaussian beam modes, that are important to such a wide class of devices and must be included in any reasonable compendium of important laser concepts and formulas. We have, therefore, included here both generally applicable results as well as some more specific but widely applicable ones.

Keywords

gain coefficient · laser resonators · Gaussian beams · laser linewidth · frequency stabilization · ultrashort laser pulses

74.1 Gain, Threshold, and Matter–Field Coupling

All lasers involve some medium that amplifies an electromagnetic field within some band of frequencies. At the simplest level of description, the amplifying medium changes the intensity I of a field according to the equation

$$\frac{dI}{dz} = gI, \quad (74.1)$$

where z is the coordinate along the direction of propagation, and g is the gain coefficient, typically expressed in cm^{-1} . Amplification occurs as a consequence of stimulated emission of radiation from the upper state (or band of states) of a transition for which a population inversion exists, i.e., for which an upper state has greater likelihood of occupation than a lower state. Different types of lasers may be classified by the pump mechanisms used to achieve population inversion (Chap. 75). In the case that the amplifying transition involves two discrete energy levels, E_1 and $E_2 > E_1$, the gain coefficient at the frequency ν is given by

$$g(\nu) = \frac{\lambda^2 A}{8\pi n^2} \left(N_2 - \frac{g_2}{g_1} N_1 \right) S(\nu). \quad (74.2)$$

Here, $\lambda = c/\nu$ is the transition wavelength, A (s^{-1}) is the Einstein A coefficient for spontaneous emission for the transition, and g_2, g_1 are the degeneracies of the upper and lower energy levels. In nearly every case, these quantities are fixed characteristics of the medium, independent of the laser intensity or the pump mechanism; N_2 and N_1 are the population densities (cm^{-3}) of the upper and lower levels, respectively, and $S(\nu)$ is the normalized transition lineshape function (Chap. 20); n is the refractive index at frequency ν and has contributions from all nonlasing transitions and from the host medium. Equations (74.1) and (74.2) describe either amplification or absorption, depending on whether the population inversion $N_2 - (g_2/g_1)N_1$ is positive or negative.

Equation (74.2) is a standard expression for the gain coefficient [2], which can also be written in terms of the stimulated emission cross section [4] or the oscillator strength of the laser transition [5].

By far the most common configuration is that in which the gain medium is contained in a cavity bounded on two sides by reflecting surfaces. The mirrors, defining what is called the laser resonator or cavity, allow feedback, i.e., the redirection of the field back into the gain medium for multipass amplification and sustained laser action. The two mirrors allow the field to build up along the directions parallel to the *optical axis* and to form a pencil-like beam of light. The design of the resonator determines the spectral, spatial, temporal, and polarization properties of the laser radiation within the limitations set by the properties of the chosen laser medium. In order to sustain laser action, the gain in intensity due to stimulated emission must equal or exceed the loss due to transmission through the mirrors, scattering, absorption in the host medium, and diffraction.

Transmission through at least one of the mirrors is, of course, required to obtain a usable laser beam, and it is typically the dominant field loss mechanism. If the mirror reflectivities are r_1 and r_2 , then the intensity I is reduced by the factor $r_1 r_2$ in a round-trip pass through the cavity, while according to Eq. (74.1) the gain medium causes the intensity to increase by a factor $\exp(2g\ell)$ in the two passes through the gain medium of length ℓ . Equating of the gain and loss factors leads to the threshold condition for laser oscillation: $g \geq g_t$, where the threshold gain is

$$g_t = -\frac{1}{2\ell} \ln(r_1 r_2) + a, \quad (74.3)$$

a being an attenuation coefficient associated with any loss mechanisms that may exist in addition to reflection losses at the mirrors.

Suppose, for example, that a laser has a 50 cm gain cell and mirrors with reflectivities 0.99 and 0.97, and that absorption within the host medium of the gain cell is negligible. Then the threshold gain is $g_t = 4 \times 10^{-4} \text{ cm}^{-1}$. If the lasing transition is the 6328 Å Ne transition of the He-Ne laser, $A \cong 1.4 \times 10^6 \text{ s}^{-1}$, $n \cong 1.0$ and, assuming a pure Doppler lineshape,

$$S(\nu) = \left(\frac{4 \ln 2}{\pi} \right)^{1/2} \frac{1}{\delta\nu_D} \quad (74.4)$$

at line center, where $\delta\nu_D$ is the width (FWHM) of the Doppler lineshape (Sect. 73.4). For $T = 400 \text{ K}$ and the Ne atomic weight, $\delta\nu_D \cong 1500 \text{ MHz}$ and $S(\nu) \cong 6.3 \times 10^{-10} \text{ s}$. Then the threshold population difference required for laser oscillation is

$$\left(N_2 - \frac{g_2}{g_1} N_1 \right)_t = \frac{8\pi n^2 g_t}{\lambda^2 A S(\nu)} \cong 2.8 \times 10^9 \text{ cm}^{-3}. \quad (74.5)$$

This is a typical result: the population *inversion* required for laser oscillation tends to be relatively small compared with the total population.

Calculations of population inversions and other properties of the gain medium are based on rate equations, or more generally, the density matrix ρ . This density matrix and, thus, the gain coefficient g can be functions of time, space, frequency, and polarization of the laser light. However, in many instances, the laser process in the medium is fairly well described in terms of two energy eigenstates, other states appearing only indirectly through pumping and decay channels. In this case, ρ is a 2×2 matrix whose elements satisfy (Chap. 72)

$$\begin{aligned} \dot{\rho}_{22} &= -(\Gamma_2 + \Gamma)\rho_{22} - \frac{1}{2}i(\Omega^* \rho_{21} - \Omega \rho_{12}), \\ \dot{\rho}_{11} &= -\Gamma_1 \rho_{11} + \Gamma \rho_{22} + \frac{1}{2}i(\Omega^* \rho_{21} - \Omega \rho_{12}), \\ \dot{\rho}_{21} &= -(\gamma + i\Delta)\rho_{21} - \frac{1}{2}i\Omega(\rho_{22} - \rho_{11}), \end{aligned} \quad (74.6)$$

with $\rho_{12} = \rho_{21}^*$. Here, Γ_2 and Γ_1 are, respectively, the rates of decay of the upper and lower states due to all processes other than the spontaneous decay from state 2 to state 1 described by the rate $\Gamma = A$. γ , which is 2π times the homogeneous linewidth (HWHM) of the transition, is the rate of decay of off-diagonal coherence due to both elastic and inelastic processes; in general, $\gamma \geq (\Gamma_1 + \Gamma_2 + \Gamma)/2$. $\Omega = \mathbf{d}_{21} \cdot \mathcal{E}/\hbar$ is the Rabi frequency (Chaps. 72 and 77). (The Rabi frequency is often defined as $2\mathbf{d}_{21} \cdot \mathcal{E}/\hbar$.) \mathcal{E} is the complex amplitude of the electric field; i.e., the electric field is

$$\mathbf{E}(\mathbf{r}, t) = \text{Re} [\mathcal{E}(\mathbf{r}, t) e^{i(\mathbf{k} \cdot \mathbf{r} - \omega t)}] \cong \text{Re} [\epsilon \mathcal{E}(\mathbf{r}, t) e^{i\mathbf{k} \cdot \mathbf{z}} e^{-i\omega t}]. \quad (74.7)$$

It is assumed that \mathcal{E} is slowly varying in time compared with the oscillations at frequency ω ($= 2\pi\nu$), and that the wave vector \mathbf{k} is approximately $k\hat{\mathbf{z}} = (n\omega/c)\hat{\mathbf{z}}$, where $\hat{\mathbf{z}}$ is a unit vector pointing in the direction of propagation. Finally, $\Delta = \omega_0 - \omega$ in Eq. (74.6) is the detuning of ω from the central transition frequency $\omega_0 = (E_2 - E_1)/\hbar$ of the lasing transition. Rapidly oscillating terms involving $\omega_0 + \omega$ are ignored in the rotating-wave approximation that pervades nearly all of laser theory (Chap. 72).

In most lasers, γ is so large compared with the diagonal decay rates that the off-diagonal elements of ρ may be assumed to relax quickly to the quasi-steady values obtained by setting $\dot{\rho}_{12} = 0$ in Eq. (74.6). Then the diagonal density matrix elements satisfy the rate equations

$$\begin{aligned} \dot{\rho}_{22} &= -(\Gamma_2 + \Gamma)\rho_{22} - \frac{|\Omega|^2 \gamma / 2}{\Delta^2 + \gamma^2} (\rho_{22} - \rho_{11}), \\ \dot{\rho}_{11} &= -\Gamma_1 \rho_{11} + \Gamma \rho_{22} + \frac{|\Omega|^2 \gamma / 2}{\Delta^2 + \gamma^2} (\rho_{22} - \rho_{11}). \end{aligned} \quad (74.8)$$

Such rate equations, usually expressed equivalently in terms of population densities N_2, N_1 rather than occupation probabilities ρ_{22}, ρ_{11} , are the basis of most practical models of laser oscillation. These equations, or, more generally, the density matrix equations, must also include terms accounting for the pump mechanism. In the simplest model of pumping, one adds a constant pump rate Λ_2 to the right-hand side of the equation for ρ_{22} to obtain

$$\dot{\rho}_{22} = \Lambda_2 - (\Gamma_2 + A)\rho_{22} - \frac{|\Omega|^2\gamma/2}{\Delta^2 + \gamma^2}(\rho_{22} - \rho_{11}). \quad (74.9)$$

In the case of an inhomogeneously broadened laser transition, equations of the type Eqs. (74.6) and (74.8) apply separately to each detuning Δ arising from the distribution of atomic or molecular transition frequencies. In writing these equations, we have assumed a nondegenerate electric dipole transition. The generalization to magnetic or multiphoton transitions, or to a case where the amplification is due, for instance, to a Raman process, is straightforward but of less general interest.

A more realistic treatment of the electromagnetic field than that based on Eq. (74.1) proceeds from the Maxwell equations, which, for a homogeneous and nonmagnetic medium, lead to the equation

$$\frac{1}{2ik} \nabla_T^2 \mathcal{E} + \left(\frac{\partial}{\partial z} + \frac{1}{c} \frac{\partial}{\partial t} \right) \mathcal{E} = \frac{4\pi i \omega}{nc} N \mu^* \rho_{21}. \quad (74.10)$$

Here, N is the density of active atoms, $\mu^* \equiv (\mathbf{d}_{12} \cdot \boldsymbol{\epsilon})$, and $\nabla_T^2 \equiv \partial^2/\partial x^2 + \partial^2/\partial y^2$. This result assumes the validity of the rotating-wave approximation as well as the assumption that \mathcal{E} is slowly varying compared with $\exp(ikz)$ and $\exp(-i\omega t)$. In the plane-wave approximation, Eq. (74.10) becomes

$$\left(\frac{\partial}{\partial z} + \frac{1}{c} \frac{\partial}{\partial t} \right) \mathcal{E} = \frac{4\pi i \omega}{nc} N \mu^* \rho_{21}. \quad (74.11)$$

(More generally, the velocity c on the left-hand sides of Eqs. (74.10) and (74.11) should be replaced by the group velocity v_g associated with nonresonant transitions. If there is substantial group velocity dispersion, it is sometimes necessary to include a term involving the second derivative of \mathcal{E} with respect to t .) Equations (74.6) or (74.8) and (74.10) or (74.11) are coupled matter–field equations whose self-consistent solutions determine the operating characteristics of the laser. The density matrix or rate equations must be modified to include pumping, as in Eq. (74.9), and the field equations must be supplemented by boundary conditions and loss terms. Laser media based on more complicated energy-level schemes (e.g., “three-level” and “four-level” lasers [2–6]) are described similarly with more general rate or density-matrix equations. With these modifications, the

equations are the basis of semiclassical laser theory, wherein the particles constituting the gain medium are treated quantum mechanically whereas the field is treated according to classical electromagnetic theory. Aside from fundamental linewidth considerations and photon statistics (Sects. 74.2 and 74.4), very few aspects of lasers require the quantum theory of radiation.

74.2 Continuous Wave, Single-Mode Operation

In the case of steady-state, continuous-wave (CW) operation, the appropriate matter–field equations are those obtained by setting all time derivatives equal to zero. Equation (74.11), for instance, becomes

$$\frac{d\mathcal{E}}{dz} = \frac{2\pi\omega N |d|^2}{3n\hbar c} \frac{1}{\gamma + i\Delta} (\rho_{22} - \rho_{11}) \mathcal{E}, \quad (74.12)$$

or, in terms of the intensity I ,

$$\begin{aligned} \frac{dI}{dz} &= \frac{4\pi\omega N |d|^2}{3n\hbar c} \frac{\gamma}{\Delta^2 + \gamma^2} (\rho_{22} - \rho_{11}) I \\ &= \frac{\lambda^2 A}{8\pi n^2} (N_2 - N_1) S(\nu) I = g(\nu) I, \end{aligned} \quad (74.13)$$

for the nondegenerate case under consideration. Here, $|d|^2 = 3|\mathbf{d}_{12} \cdot \boldsymbol{\epsilon}|^2$, $N_j = N\rho_{jj}$, $S(\nu) = 2\pi \times (\gamma/\pi)/(\Delta^2 + \gamma^2)$ is the Lorentzian lineshape function for homogeneous broadening, and $A = 4\omega^3 |d|^2 n / 3\hbar c^3$ is the spontaneous emission rate in the host medium of (real) refractive index n . Local (Lorentz–Lorenz) field corrections will, in general, modify these results, but such corrections are ignored here [7].

The steady-state solution of the density matrix or rate equations gives, similarly,

$$g(\nu) = \frac{g_0(\nu)}{1 + I/I_{\text{sat}}}, \quad (74.14)$$

where the saturation intensity I_{sat} , like the small-signal gain coefficient $g_0(\nu)$, depends on decay rates and other characteristics of the lasing species. Thus, in the plane-wave approximation, the growth of intensity in a homogeneously broadened laser medium is typically described by the equation

$$\frac{dI}{dz} = \frac{g_0(\nu) I}{1 + I/I_{\text{sat}}}. \quad (74.15)$$

This equation, supplemented by boundary conditions at the mirrors and possibly other terms on the right-hand side to account for any distributed losses within the medium, determines the intensity in CW, single-mode operation.

The simplest model for calculating output intensity assumes that the intensity is uniform throughout the laser cavity. In steady state, the gain exactly compensates for the loss; i.e., $g(\nu) = g_t$, the ‘‘gain clamping’’ condition for CW lasing. Equation (74.14) then implies that the steady-state intracavity intensity is

$$I = I_{\text{sat}}[g_0(\nu)/g_t - 1]. \quad (74.16)$$

If I is assumed to be the sum of the intensities of waves propagating in the $+z$ and $-z$ -directions, i.e., $I = I_+ + I_-$, then the output intensity from the laser is

$$I_{\text{out}} = t_2 I_+ + t_1 I_-, \quad (74.17)$$

where t_2, t_1 are the mirror transmissivities at the right and left mirrors, respectively. The uniform intensity approximation implies that $I_+ = I_- = I/2$, and

$$I_{\text{out}} = \frac{1}{2}(t_2 + t_1)I_{\text{sat}}[g_0(\nu)/g_t - 1]. \quad (74.18)$$

Suppose one of the mirrors is perfectly reflecting, so that $t_1 = 0$ and $t_2 = t$. If the reflectivity r of the transmitting mirror is close to unity, then $g_t \cong (1/2\ell)(1-r) = (1/2\ell)(t+s)$, where s is the fraction of the incident beam power that is scattered or absorbed at the output mirror. Then

$$I_{\text{out}} \cong \frac{1}{2}I_{\text{sat}}t \left(\frac{2g_0(\nu)\ell}{t+s} - 1 \right), \quad (74.19)$$

and it follows that the optimal output coupling, i.e., the transmissivity that maximizes the output intensity, is

$$t_{\text{opt}} = \sqrt{2g_0(\nu)\ell s} - s. \quad (74.20)$$

This output coupling gives the output intensity

$$I_{\text{out}}^{\text{max}} = I_{\text{sat}} \left[\sqrt{g_0(\nu)\ell} - \sqrt{s/2} \right]^2; \quad (74.21)$$

$g_0(\nu)I_{\text{sat}}$ is the largest possible power per unit volume extractable as output laser radiation at the frequency ν .

More generally, when mirror reflectivities are not necessarily close to unity, $I_+ \neq I_-$ and both I_+ and I_- vary with the axial coordinate z . In this more general case, Eqs. (74.14) and (74.15) are replaced by

$$g(\nu, z) = \frac{g_0(\nu)}{1 + [I_+(z) + I_-(z)]/I_{\text{sat}}} \quad (74.22)$$

and

$$\frac{dI_+}{dz} = g(\nu, z)I_+, \quad \frac{dI_-}{dz} = -g(\nu, z)I_-, \quad (74.23)$$

where it is assumed that $g_0(\nu)$ is independent of z , and that all cavity loss processes occur at the mirrors. The solution of these equations with the boundary conditions $I_-(L) =$

$r_2 I_+(L)$, $I_+(0) = r_1 I_-(0)$ for mirrors at $z = 0$ and $z = L$ gives, for $I_{\text{out}} = t_1 I_-(0) + t_2 I_+(L)$, the formula [5, 8]

$$I_{\text{out}} = I_{\text{sat}} \left(t_2 + \sqrt{\frac{r_2}{r_1}} t_1 \right) \frac{\sqrt{r_1}}{(\sqrt{r_1} + \sqrt{r_2})(1 - \sqrt{r_1 r_2})} \times [g_0(\nu)\ell + \ln \sqrt{r_1 r_2}]. \quad (74.24)$$

Analysis of this result gives an optimal output coupling that reduces to Eq. (74.19) in the limit $t + s \ll 1$. Curves for optimal output coupling and I_{out} as a function of g_0 and s are given by *Rigrod* [8]. These results are based on several assumptions and approximations: the gain medium is assumed to be homogeneously broadened and to saturate according to the formula Eq. (74.14); g_0 and I_{sat} are taken to be constant throughout the medium; the field is approximated as a plane wave; field loss processes occur only at the mirrors; and interference between the left and right-going waves is ignored.

Interference of the counterpropagating waves in a standing-wave, single-mode laser modifies the gain saturation formula Eq. (74.14) as follows:

$$g(\nu, z) = \frac{g_0(\nu)}{1 + (2I_+/I_{\text{sat}}) \sin^2 kz} \quad (74.25)$$

in the case of small output coupling, where $I_+ \cong I_-$ as assumed in Eq. (74.18). (The general case of arbitrary output coupling with spatial interference of counterpropagating waves is somewhat complicated and is not considered here.) The $\sin^2 kz$ term is responsible for spatial hole burning: *holes* are *burned* in the curve of $g(\nu, z)$ versus z at points where $\sin^2 kz$ is largest. This spatially dependent saturation of the gain acts to reduce the output intensity, typically by as much as about 30%, compared with the case where interference of counterpropagating waves is absent or ignored. Spatial hole burning tends to be washed out by atomic motion in gas lasers and is absent entirely in pure traveling-wave ring lasers. If complete spatial hole burning based on Eq. (74.25) is assumed, the output intensity is

$$I_{\text{out}} = \frac{t}{2} I_{\text{sat}} \left(\frac{g_0(\nu)}{g_t} - \frac{1}{4} - \sqrt{\frac{g_0(\nu)}{2g_t} + \frac{1}{16}} \right) \quad (74.26)$$

in the case where one mirror is perfectly reflecting.

In inhomogeneously broadened media, the gain coefficient is obtained by integrating the contributions from all possible values of ν_0 . The different contributions saturate differently, depending on the detuning of ν_0 from the cavity mode frequency ν . If spatial hole burning and power broadening are ignored, then, to a good approximation, the gain saturates as

$$g(\nu) = \frac{g_0(\nu)}{\sqrt{1 + I/I_{\text{sat}}}} \quad (74.27)$$

in typical inhomogeneously broadened media.

Oscillation on a single longitudinal mode (Sect. 74.3) may be realized simply by making the cavity length L small enough that the mode spacing $c/2nL$ (Eq. (74.28)) exceeds the spectral width of the gain curve. This is possible in many gas lasers where the spectral width is small, and in semiconductor lasers, where L is very small. More generally, the gain clamping condition $g(\nu) = g_t$ implies that the cavity mode frequency having the largest small-signal gain $g_0(\nu)$ saturates the gain $g(\nu)$ down to the threshold value g_t , while the gain at all other mode frequencies then lies below g_t . In other words, the gain clamping condition implies single-mode oscillation. However, this conclusion assumes homogeneous broadening and also that spatial hole burning is negligible, so that the gain saturates uniformly throughout the cavity. High-pressure gas lasers, where the line broadening is due primarily to collisions and is, therefore, homogeneous, tend to oscillate on a single mode because spatial hole burning is largely washed out by atomic motion. On the other hand, homogeneously broadened solid-state lasers can be multimode as a consequence of spatial hole burning.

Single-mode oscillation in inhomogeneously broadened media is generally more difficult to achieve because of spectral hole burning, which makes the simple gain clamping argument inapplicable. However, single-mode oscillation can be enforced in any case by introducing, in effect, an additional loss mechanism for all mode frequencies except one. This is commonly done with a Fabry–Pérot etalon inside the cavity having a free spectral range that is large compared with the spectral width of the gain curve. By choosing the tilt angle appropriately, a particular resonant frequency of the etalon can be brought close to the center of the gain curve, while all other resonance frequencies lie outside the gain bandwidth.

Laser oscillation at a fixed polarization can likewise be achieved by discriminating against the orthogonal polarization, as is done when Brewster angles are employed.

Laser oscillation, in general, does not occur precisely at one of the allowed cavity mode frequencies. Associated with the $\sin kz$ dependence of the intracavity field is the condition $kL = N\pi$, or

$$\nu = N \frac{c}{2nL} \quad (N \text{ an integer}), \quad (74.28)$$

for the cavity mode frequencies in the plane-wave approximation. If the gain medium of refractive index n does not fill the entire length L between the mirrors, then Eq. (74.28) is replaced by

$$\nu = \frac{Nc/2}{L_{\text{opt}}}, \quad (74.29)$$

or

$$\frac{\ell}{L}[n(\nu) - 1]\nu = \nu_N - \nu, \quad (74.30)$$

where L is the geometrical distance between the resonator mirrors, ℓ ($\leq L$) is the length of the gain medium, $L_{\text{opt}} = n\ell + (L - \ell)$ is the optical length of the cavity, and $\nu_N = Nc/2L$ is an empty-cavity mode frequency. The laser oscillation frequency will, therefore, be different, in general, from any of the allowed empty-cavity mode frequencies. If the refractive index $n(\nu)$ here is attributable primarily to the lasing transition, as opposed to the host material, or other nonlasing transitions, then the following relation between $n(\nu)$ and $g(\nu)$ may be used in the case of homogeneous broadening (for instance [5]):

$$n(\nu) - 1 = -\frac{\lambda_0}{4\pi} \frac{\nu_0 - \nu}{\delta\nu_0} g(\nu), \quad (74.31)$$

where λ_0 , ν_0 , and $\delta\nu_0$ are the wavelength, frequency, and homogeneous linewidth (HWHM), respectively, of the lasing transition. This implies that

$$\nu = \frac{\nu_0 \delta\nu_c + \nu_N \delta\nu_0}{\delta\nu_c + \delta\nu_0}, \quad (74.32)$$

for the laser oscillation frequency ν , where

$$\delta\nu_c \equiv \frac{cg(\nu)\ell}{4\pi L} \quad (74.33)$$

is the cavity bandwidth. Thus, the actual lasing frequency is not simply one of the allowed empty-cavity frequencies ν_N , but is rather *pulled* away from ν_N toward the center of the gain profile. This is called frequency pulling.

If spatial hole burning is absent, then $g(\nu) = g_t$ in steady-state oscillation, and the cavity bandwidth $\delta\nu_c = cg_t\ell/4\pi L$ is the largest for lossy cavities. Most lasers fall into the *good cavity* category, that is, $\delta\nu_c \ll \delta\nu_0$, so that Eq. (74.32) may be approximated by

$$\nu \cong \nu_N + (\nu_0 - \nu_N)\delta\nu_c/\delta\nu_0. \quad (74.34)$$

Similar results apply to inhomogeneously broadened lasers. For a Doppler broadened medium, for instance, the frequency pulling formula is

$$\nu \cong \nu_N + (\nu_0 - \nu_N)(\delta\nu_c/\delta\nu_D)\sqrt{4 \ln \frac{2}{\pi}}, \quad (74.35)$$

for good cavities. These results show that frequency pulling is most pronounced in lasers with large peak gain coefficients and narrow gain profiles, such as the 3.51 μm He-Xe laser, as observed experimentally [9].

Spectral hole burning leads to especially interesting consequences in Doppler-broadened gas lasers. Since two traveling waves propagating in opposite ($\pm z$) directions will strongly saturate spectral packets of atoms with oppositely Doppler-shifted frequencies, a standing-wave field will burn

two holes on opposite sides of the peak of the Doppler profile. When the mode frequency is exactly at the center of the Doppler profile, however, the two holes merge, the field now being able to saturate strongly only those atoms with zero velocity along the z -direction. In this case, since the field feeds off a single spectral packet of more strongly saturated atoms, there is a dip in the output power compared with the case when the mode frequency is detuned from the line center. This dip in the output power at the line center is called the Lamb dip. It can be used to determine whether a gas laser is Doppler broadened, and more importantly, to stabilize the laser frequency to the center of the dip. High-precision measurements often require that a laser operate at a very stable frequency, in spite of mirror vibrations and other noise processes. Lamb-dip frequency stabilization is based on an “error signal” that is the difference between the measured output intensity and the intensity at the center of the Doppler gain profile. A feedback circuit controls the bias voltage across a piezoelectric element used to vary the cavity length so as to minimize the error signal and thereby to stabilize the laser frequency. Fractional frequency stabilities of about 1 part in 10^{10} can be obtained by Lamb-dip stabilization.

The widely used *Pound–Drever–Hall* frequency stabilization technique employs a Fabry–Pérot cavity to provide an error signal proportional to the intensity reflected when the field frequency differs from a cavity resonance frequency. This method has the advantage that it is not restricted to stabilization of laser frequencies near that of a laser material resonance [10–13]. With high-finesse etalons it has been possible to obtain short-time fractional frequency stabilities $\approx 10^{-16}$ and laser linewidths < 40 mHz [13].

Semiclassical laser theory suggests that CW laser radiation could ideally be perfectly monochromatic, since the amplitude and phase of the field given by Eq. (74.7) are time-independent. However, when quantum electrodynamic considerations are built into laser theory, it is found that spontaneous emission, which adds to the number of photons put in the lasing mode by stimulated emission, causes a phase diffusion that results in a Lorentzian linewidth (FWHM)

$$\Delta\nu = \frac{N_2}{N_2 - N_1} \frac{8\pi h\nu}{P_{\text{out}}} \left[\frac{\delta\nu_c}{n_g + 1 + \delta\nu_c/\delta\nu_0} \right]^2, \quad (74.36)$$

where P_{out} is the output laser power and $n_g = d(n\omega)/d\omega$ is the group index associated with nonlasing transitions in the laser medium. In the *bad cavity* limit in which $\delta\nu_c \gg \delta\nu_0$, this reduces to the expression originally derived by *Schawlow* and *Townes* [14] when it is assumed that the contribution (n_g) from nonlasing transitions is negligible:

$$\Delta\nu = \frac{N_2}{N_2 - N_1} \frac{8\pi h\nu}{P_{\text{out}}} (\delta\nu_0)^2. \quad (74.37)$$

In the more common case of a *good cavity*,

$$\Delta\nu = \frac{N_2}{N_2 - N_1} \frac{8\pi h\nu}{P_{\text{out}}} (\delta\nu_c)^2. \quad (74.38)$$

The “Schawlow–Townes linewidth” $\Delta\nu$ is a fundamentally quantum-mechanical, finite linewidth that persists no matter how small various sources of “technical noise”, such as mirror jitter, are made. Although it has been observed in highly stabilized gas lasers, it is negligible compared with technical noise in conventional lasers. However, in free-running semiconductor lasers, L is very small and, consequently, $\delta\nu_c$ is large, and the fundamental lower limit $\Delta\nu$ to the laser linewidth can be the dominant contribution to the laser linewidth.

However, linewidths 10–100 MHz observed in semiconductor lasers are too large to be explained by these expressions for $\Delta\nu$, and two modifications are necessary, each of them involving a multiplication of the Schawlow–Townes linewidth $\Delta\nu$ by a certain factor:

$$\Delta\nu \rightarrow \Delta\nu' = (1 + \alpha^2)K\Delta\nu; \quad (74.39)$$

α is called the *Henry α parameter* and is associated with a coupling between phase and intensity fluctuations above the laser threshold [15, 16]. Values of α between about 4 and 6 are typical in semiconductor injection lasers, and consequently, the correction to the Schawlow–Townes linewidth due to the Henry α parameter is substantial. The K factor [17–19] arises as a consequence of the deviation from the spatially uniform intracavity intensity assumed in the derivation of the Schawlow–Townes formula [20, 21]. (Intracavity intensities along the optical axis are approximately uniform only in the case of low output couplings.) The fundamental quantum-mechanical linewidth under consideration can be associated with vacuum field fluctuations, which, according to general fluctuation–dissipation theory, will increase as the cavity loss increases. This explains why the *Petermann K factor* deviates increasingly from unity as the output coupling (cavity loss) increases. Values of K between 1 and 2 appear to be typical for lossy, stable resonators [22, 23], but much larger values are possible for unstable resonators [24].

74.3 Laser Resonators and Transverse Modes

The assumption that the complex field amplitude $\mathcal{E}(\mathbf{r}, t)$ is slowly varying in z compared with $\exp(ikz)$ leads to the paraxial wave equation Eq. (74.10),

$$\nabla_T^2 \mathcal{E} + 2ik \frac{\partial \mathcal{E}}{\partial z} = 0, \quad (74.40)$$

for a monochromatic field in vacuum. If $\mathcal{E}(x, y, z)$ is specified in the plane $(x, y, z = 0)$, it follows that

$$\mathcal{E}(x, y, z) = -\frac{i}{\lambda z} \iint dx' dy' \times \mathcal{E}(x', y', 0) e^{ik[(x-x')^2 + (y-y')^2]/2z}. \quad (74.41)$$

Thus, in the case of a laser resonator, the field $\mathcal{E}(x, y, L)$ at the mirror at $z = L$ is related to the field $\mathcal{E}(x, y, 0)$ at the mirror at $z = 0$ by

$$\begin{aligned} \mathcal{E}(x, y, L) &= -\frac{i}{\lambda L} \iint dx' dy' \\ &\times \mathcal{E}(x', y', 0) e^{ik[(x-x')^2 + (y-y')^2]/2L} \\ &\equiv \iint dx' dy' K(x, y; x', y') \mathcal{E}(x', y', 0). \end{aligned} \quad (74.42)$$

Similarly, the field at $z = 0$ after one round-trip pass through the resonator is

$$\begin{aligned} \mathcal{E}(x, y, 0) &= \iint dx' dy' K(x, y; x', y') \mathcal{E}(x', y', L) \\ &= \iint dx' dy' K(x, y; x', y') \\ &\times \iint dx'' dy'' K(x', y'; x'', y'') \mathcal{E}(x'', y'', 0) \\ &\equiv \iint dx'' dy'' \tilde{K}(x, y; x'', y'') \mathcal{E}(x'', y'', 0). \end{aligned} \quad (74.43)$$

By definition, a mode of the resonator is a field distribution that does not change on successive round-trip passes through the resonator. More precisely, since an empty cavity is assumed, a mode will be such that the field spatial pattern remains the same except for a change in amplitude per pass. A longitudinal mode is defined by the value of k in $\exp(ikz)$, whereas a transverse mode is defined by the corresponding (x, y) dependence and satisfies the integral equation

$$\gamma \mathcal{E}(x, y, z) = \iint dx' dy' \tilde{K}(x, y; x', y') \mathcal{E}(x', y', z), \quad (74.44)$$

where z defines any plane between the mirrors, and γ accounts for the change per pass of the complex field amplitude. Iterative numerical solutions of this equation for laser resonator modes were first presented by Fox and Li [25].

Laser resonators may be classified as stable or unstable according to whether a paraxial ray traced back and forth through the resonator remains confined in the resonator or escapes. This leads to the condition

$$0 \leq g_1 g_2 \leq 1, \quad (74.45)$$

Fig. 74.1 Variation of the beam radius $w(z)$ of a Gaussian beam with the propagation distance z from the beam waist

for stable resonators, where the g parameters are defined in terms of the (spherical) mirror curvatures R_i and the mirror separation L by $g_i \equiv 1 - L/R_i$; R_i is defined as positive or negative depending on whether the mirror i is concave or convex, respectively, with respect to the interior of the resonator. Plane-parallel mirrors ($R_i \rightarrow \infty$) can be used, but they are difficult to keep aligned and have large diffractive losses.

Among stable configurations, the symmetric confocal resonator with $R_1 = R_2 = L$ has the smallest beam radii at the mirrors, while the concentric resonator with $R_1 = R_2$ slightly greater than $L/2$, has the smallest beam waist (Fig. 74.1). The hemispherical resonator ($R_1 = \infty$, R_2 slightly greater than L) is relatively easy to keep aligned and allows the beam radius w at mirror 2 to be adjusted by slight changes in L .

The fundamental Gaussian beam modes of stable resonators may be constructed from the free-space solutions of the paraxial wave equation. The most important (lowest-order) solution for this purpose is

$$\mathcal{E}(x, y, z) = \frac{A e^{-i\phi(z)} e^{ik(x^2 + y^2)/2R(z)} e^{-(x^2 + y^2)/w^2(z)}}{\sqrt{1 + z^2/z_0^2}}, \quad (74.46)$$

where A is a constant, $\phi(z) = \tan^{-1}(z/z_0)$, and $R(z)$, $w(z)$, and z_0 are the radius of curvature of surfaces of constant phase, the beam radius, and the Rayleigh range, respectively. The confocal parameter, $2z_0$, is also used to characterize Gaussian beams. Here, $z_0 \equiv \pi w_0^2/\lambda$, where w_0 is the beam radius at the waist at $z = 0$ (Fig. 74.1), and $R(z)$ and $w(z)$ vary with the distance z as follows:

$$R(z) = z + z_0^2/z, \quad w(z) = w_0 \sqrt{1 + z^2/z_0^2}. \quad (74.47)$$

The divergence angle of a Gaussian beam (Fig. 74.1) is $\theta = \lambda/\pi w_0$.

The ABCD law for Gaussian beams [2–6] allows the effects of various optical elements on Gaussian beam propagation to be calculated in a relatively simple fashion. For instance, a Gaussian beam incident on a lens of focal length f at its waist is focused to a new waist at a distance $d =$

$f/(1 + f^2/z_0^2)$ behind the lens, and the beam radius at the new waist is

$$w'_0 = \frac{f\lambda}{\pi w_0} \frac{1}{\sqrt{1 + f^2/z_0^2}}, \quad (74.48)$$

which is approximately $f\lambda/\pi w_0 = f\theta$ for tight focusing. This shows that a Gaussian beam can be focused to a very small spot, on the order of a wavelength. On the other hand, beam expanders consisting of two appropriately spaced lenses may be used to increase the beam radius by the ratio of the focal lengths in order to realize very small divergence angles.

Gaussian beam modes of laser resonators have radii of curvature $R(z)$ that match in magnitude those at the positions of mirrors. The beam radii at the mirrors and the location of the beam waist with respect to the mirrors may be expressed in terms of λ , L , and g_1g_2 . The empty-cavity mode frequencies are given by

$$\nu_N = \frac{c}{2L} \left(N + \frac{1}{\pi} \cos^{-1} \sqrt{g_1g_2} \right), \quad (74.49)$$

where N is an integer. For a host medium of refractive index n , $c/2L$ is replaced by $c/2nL$, and Eq. (74.49) then generalizes the plane wave result Eq. (74.28) to account for both longitudinal and transverse effects in the determination of the cavity mode frequencies.

The assumption of Gaussian modes presupposes that the resonator mirrors are large enough to intercept the entire beam without any spillover; i.e., that $a \gg w_1, w_2$, where w_1, w_2 are the beam radii at the mirrors, and a is an effective mirror cross sectional radius; this is very easy to realize. This implies that the Fresnel number $N_F \equiv a^2/\lambda L \gg 1$. Diffraction losses generally increase with decreasing Fresnel numbers.

Higher-order Gaussian modes, where the Gaussian functions of x and y in Eq. (74.46) are replaced by higher-order Hermite (or Laguerre) polynomials, or combinations of them (hybrid modes) [4], can be produced via suitable resonator designs and may be used in special applications.

In general, it is not possible to write closed-form expressions for laser modes. There are at least two reasons for this, the first being that the gain medium cannot, in general, be regarded as a simple amplifying element that preserves the basic empty-cavity mode structure. In general, the gain coefficient and the refractive index of the laser material, especially in the high-power regime, are functions of space, time, frequency, and light intensity. In low-power gas lasers, the spatial variations of the gain and refractive index are sufficiently mild that the lasing modes can be accurately described as Gaussians. However, there can be strong gain and index variations that themselves play an important role in determining the modes of the laser, as in *index-guided* and *gain-guided* semiconductor lasers or in fiber lasers.

Secondly, the resonator structure itself may introduce complications that preclude closed-form solutions even for the empty cavity. This is generally true, for instance, of unstable resonators, where iterative numerical solutions of the integral equation (Eq. (74.44)) are necessary for accurate predictions of modes. In such computer simulations, the mode structure must be determined self-consistently with the numerical solutions of the density matrix or, more commonly, rate equations for the gain medium.

The diffraction-limited divergence angle of the ideal lowest-order (TEM₀₀) Gaussian mode, $\theta = \lambda/\pi w_0$, may be difficult to realize in practice. The deviation from the ideal diffraction-limited field is characterized by a beam quality M^2 defined by writing the actual divergence angle of the output field as

$$\theta_M = M^2 \lambda / \pi w_0. \quad (74.50)$$

For the lowest-order Hermite–Gaussian mode $M^2 = 1$ by definition, whereas for the first-order mode $M^2 = 3$ and increases to 13 for the sixth-order mode, for example. Comparable values are obtained for the circularly symmetric Gauss–Laguerre modes [4]. For a low-power gas laser, M^2 might be around 1.1, whereas for a high-power laser, it might be ≈ 10 or more. The *brightness* L of a laser beam, defined as the power per unit area per unit solid angle, is, therefore, inversely proportional to M^2 and may be defined as [4]

$$L = \frac{P}{\lambda^2 (M^2)^2}, \quad (74.51)$$

where P is the beam power.

Unstable resonators, although inherently lossy, offer some important advantages for high-gain and high-power lasers. Thus, whereas the Gaussian modes of stable resonators typically involve small beam radii, the distinctly non-Gaussian modes of unstable resonators often have large mode volumes and make more efficient use of the available gain volume. Phase conjugation mirrors can be used to improve the beam quality of high-power lasers [4].

74.4 Photon Statistics

Optical fields may be characterized and distinguished by their photon statistical properties (Chap. 82 and [26–30]). In a photon counting experiment, the number of photons registered at a photodetector during a time interval T is measured and used to infer the probability $P_n(T)$ that n photons are counted in a time interval T . If the probability of counting a photon at the time t in the interval dt is denoted $\eta I(t)dt$, where $I(t)$ is the intensity of the field, and η is a factor depending on the microscopic details of the photon absorption

process and on the photodetector geometry, then it may be shown from largely classical considerations that [5, 28, 29]

$$P_n(T) = \left\langle \frac{1}{n!} \left[\eta \int_0^T dt' I(t') \right]^n e^{-\eta \int_0^T dt' I(t')} \right\rangle, \quad (74.52)$$

where the average $\langle \dots \rangle$ is over the intensity variations during the counting interval. (The fully quantum-mechanical treatment involves normally ordered products of electric field operators [28, 29].) In the simplest case of constant intensity, P_n follows the Poisson distribution:

$$P_n = \bar{n}^n e^{-\bar{n}} / n!, \quad (74.53)$$

where $\bar{n} = \eta IT$. Since a single-mode laser field can be thought of approximately as a classical stable wave [29], it is not surprising that its photocount distribution is found both theoretically and experimentally to satisfy Eq. (74.53), which is characteristic of a coherent state of the field (Chap. 82). Because of spontaneous emission a laser cannot produce exactly a coherent state of the field but, if the phase diffusion due to spontaneous emission is sufficiently slow, laser radiation on sufficiently short time scales can be treated in effect as a coherent-state field to a very good approximation.

A thermal light source, by contrast, follows the Bose–Einstein distribution,

$$P_n = \bar{n}^n / (1 + \bar{n})^{n+1}, \quad (74.54)$$

if the time interval T is short compared with the coherence time of the light; i.e., if $T\Delta\nu \ll 1$, where $\Delta\nu$ is the bandwidth. If $T\Delta\nu \gg 1$, P_n is again Poissonian. Thus, if a quasi-monochromatic beam of light is made from a natural source by spatial and spectral filtering, it has measurably different photon counting statistics from a single-mode laser beam of exactly the same bandwidth and average intensity. These differences are exhibited, for example, in measurements of intensity correlations of the Brown–Twiss type [28–30]. In such experiments, thermal photons (or more generally photons from a “chaotic” source [29]) have a statistical tendency to arrive in pairs (“photon bunching”), whereas the photons from a laser arrive independently.

74.5 Multimode and Pulsed Operation

Multimode laser theory is generally much more complicated than single-mode theory, particularly in the case of inhomogeneous broadening with both spectral and spatial hole burning. In certain situations, however, considerable simplification is possible. For instance, when the cavity mode frequency spacing is small compared with the homogeneous

linewidth $\delta\nu_0$, the gain tends to saturate homogeneously, and the total output power on all modes is well described by the analysis outlined in Sect. 74.2.

Pulsed laser operation adds the further complication of temporal variations to the CW theory outlined in the preceding sections. It is possible, nevertheless, to understand some of the most important types of multimode and pulsed operation using relatively simple models.

One method of obtaining short, high-power laser pulses is Q switching [31]. In a very lossy cavity, the gain can be pumped to large values before the threshold condition is met and gain saturation occurs. If the cavity loss is suddenly decreased via an optical switch, there will be a rapid buildup of intensity because the gain is far above the (now reduced) threshold value. The switching of the cavity loss is called Q switching, the quality factor Q being defined as $\nu/2\delta\nu_c$. The buildup time for a Q -switched pulse is typically on the order of the cavity round-trip time [4], resulting in pulses of duration on the order of 10 ns for solid-state lasers, for example. Q switching requires that the gain medium be capable of retaining a population inversion over a time much larger than the Q -switched pulse duration, and, in particular, that the spontaneous emission lifetime be relatively long. The pulse duration can be reduced to approximately a single cavity round-trip time by Q switching from low reflectivity mirrors to 100% reflectivities, and then switching the reflectivity of the outcoupling mirror from 100% to 0% at the peak of the amplified pulse. In addition to this pulsed transmission mode is cavity dumping, where both mirrors have nominally 100% reflectivity and the intracavity power is “dumped” by an acousto-optic or electro-optic intracavity element that deflects the light out of the cavity. The pulse duration achieved in this way is again roughly a round-trip time. Cavity dumping can be employed with CW lasers and does not require the long energy storage times necessary for ordinary Q switching.

Shorter pulses can be realized by mode locking, where the phases of N longitudinal cavity modes are locked together. (The evolution of the mode-locking technique is reviewed in [32].) In the simplest model, assuming equal amplitudes and phases of the individual modes, the net field amplitude is proportional to

$$\begin{aligned} X(t) &= \sum_{n=-(N-1)/2}^{(N-1)/2} X_0 \sin[(\omega_0 + n\Delta)t + \phi_0] \\ &= X_0 \sin(\omega_0 t + \phi_0) \frac{\sin(N\Delta t/2)}{\sin(\Delta t/2)}. \end{aligned} \quad (74.55)$$

The temporal variation described by this function for large N is a train of spikes of amplitude NX_0 at times $t_m = 2\pi m/\Delta$, $m = 0, \pm 1, \pm 2, \dots$, the width of each spike being $2\pi/(N\Delta)$. In the case of a mode-locked laser, $\Delta = 2\pi(c/2L)$, and the

output field consists of a train of pulses separated in time by $T = 2\pi/\Delta = 2L/c$. The peak amplitude of the spikes is proportional to N , and the duration of each spike is approximately $2L/cN$. The spectrum of such a field may be described as a “comb” of frequencies with “teeth” separated by the angular frequency Δ . The regular, controllable comb of frequencies in the output of a mode-locked laser serves as a “ruler” for measurements of absolute optical frequencies (optical frequency metrology) [33–35].

The maximum number N_{\max} of modes that can actually be phase-locked is limited by the spectral width $\Delta\nu_g$ of the gain curve:

$$N_{\max} = \frac{\Delta\nu_g}{c/2L} = \frac{2L}{c} \Delta\nu_g. \quad (74.56)$$

Similarly, the shortest pulse duration is

$$\tau_{\min} = \frac{2L}{cN_{\max}} = \frac{1}{\Delta\nu_g}. \quad (74.57)$$

Mode locking thus requires a gain bandwidth large compared with the cavity mode spacing, and the shortest and most intense mode-locked pulse trains are obtained in gain media having the largest gain bandwidths. Trains of picosecond pulses are routinely obtained with liquid dye and solid gain media having gain bandwidths $\Delta\nu_g \approx 10^{12} \text{ s}^{-1}$ or more.

Various techniques, employing acoustic or electro-optic modulation or saturable absorbers, are used to achieve mode locking. The different methods all basically rely on the fact that a modulation of the gain or loss at the mode separation frequency $c/2L$ tends to cause the different modes to oscillate in phase. Such a modulation is achieved *passively* when a saturable absorber is placed in the laser cavity; because of the intensity-dependent loss caused by the saturable absorber, the multimode intensity oscillates with a beat frequency that is impressed on the saturated loss coefficient.

Kerr lens mode locking (KLM) [36–38] is based on the self-focusing of a field in a medium with a nonlinear refractive index (Chap. 76)

$$n = n_0 + n_2 I. \quad (74.58)$$

With such a nonlinear index the field can be strongly self-focused (assuming $n_2 > 0$) where the intensity I is largest. The basic idea in KLM is that there is an intensity-dependent loss, as in a saturable absorber. However, this intensity-dependent loss now occurs within the laser medium; the extent to which the field is susceptible to diffractive losses depends on the degree of self-focusing and, therefore, the intracavity intensity. Megawatt mode-locked pulses with durations and repetition rates on the order of femtoseconds and 100 MHz, respectively, are routinely produced with KLM Ti:sapphire lasers (Chap. 75).

Ultrashort pulse generation is possible with other nonlinear techniques. The colliding-pulse laser [39] is a three-mirror ring laser in which two mode-locked pulse trains

Fig. 74.2 Nonlinear pulse compression by frequency chirping. In (a), the nonlinear refractive index of a glass fiber results in a time-dependent frequency of the transmitted pulse, and in (b), a pair of diffraction gratings is used to produce frequency-dependent path delays such as to temporally compress the pulse

propagate in opposite senses and overlap in a very thin ($\approx 10 \mu\text{m}$) saturable absorber placed in the ring in addition to the gain cell. The cavity loss is least when the two pulses synchronize to produce the highest intensity, and, therefore, the lowest loss coefficient in the saturable absorber. The short length of the absorbing cell forces the pulses to overlap within a very small distance and, therefore, to produce very short pulses ($10 \mu\text{m}/c \approx 30 \text{ fs}$ pulse duration with a $c/L \approx 100 \text{ MHz}$ repetition rate).

Another method of ultrashort pulse generation relies on, i.e., a time dependent shift of the frequency of an optical pulse [40–43]. In a medium (e.g., a glass fiber) with a nonlinear refractive index (Eq. (74.58)), a field experiences an instantaneous phase shift $\phi(t)$ that depends on the instantaneous intensity. Therefore, as $I(t)$ increases toward the peak intensity of the pulse, $\phi(t)$ increases (assuming $n_2 > 0$), whereas $\phi(t)$ decreases as $I(t)$ decreases from its peak value. The frequency shift $\dot{\phi}(t)$ is such that the instantaneous frequency of the pulse is smaller at the leading edge and larger at the trailing edge of the pulse (Fig. 74.2), resulting in a stretching of the pulse bandwidth. Following this spectral broadening by the nonlinear medium, the pulse can be compressed in time by means of a frequency-dependent delay line such that the smaller frequencies, say, are delayed more than the higher frequencies. The trailing edge of the pulse can, therefore, catch up to the leading edge, resulting in a shorter pulse whose duration is given by the inverse of the chirp bandwidth. The delay line can be realized with a pair of diffraction gratings (Fig. 74.2). More than two decades ago this pulse compression technique was used to compress 40 fs amplified pulses from a colliding pulse laser to 8 fs, corresponding to about four optical cycles [44].

One of the most important techniques in ultrashort, high-power laser pulse generation is chirped pulse amplification (CPA) [45, 46] in which a laser pulse is chirped, temporally

stretched, and then passed through one or more amplifiers. The lengthening in time of the pulse by factors typically $\approx 10^3$ – 10^4 prior to amplification allows greater energy extraction from the amplifier and avoids optical damage and nonlinear effects causing spatiotemporal pulse distortion. After amplification, pulse compression is performed with a grating pair. The Ti:sapphire (Ti:Al₂O₃) amplifier is particularly attractive for femtosecond CPA because of its very large spectral width and high saturation fluence.

The wavelength dependence of the linear refractive index n_0 in Eq. (74.58) results in a group velocity

$$v_g = c \left[n_0 - \lambda \frac{dn_0}{d\lambda} \right]^{-1} \quad (74.59)$$

that, if $dn_0/d\lambda < 0$, is such that higher frequencies propagate more rapidly than lower frequencies. Assuming $n_2 > 0$, on the other hand, the nonlinear part of the index causes a delay of higher frequencies with respect to lower ones, as discussed above. This leads to soliton solutions of the wave equation, such that the opposing effects of the linear and nonlinear dispersion are balanced, and the pulse propagates without distortion. Soliton lasers, with pulse durations ranging from picoseconds down to ≈ 100 fs, depending on the fiber length, have been made with solid-state lasers and intracavity optical fibers [47].

The generation of coherent, extreme ultraviolet and x-ray radiation by creating a population inversion and gain (Eq. (74.2)) on atomic transitions is impractical due to the very short lifetimes and large energies required to populate excited levels of such transitions; there is the additional problem that conventional optical components like mirrors and lenses are unavailable at x-ray wavelengths. Such radiation is generated in free electron “lasers” (FELs) by undulator radiation from relativistic electron beams in a “wiggler” magnetic field [48, 49]. (For reviews of FEL developments and x-ray FELs: [50, 51].)

The high intensities produced with mode locking and chirped pulse amplification allow highly nonlinear atom–field interactions, such as the generation of high harmonics of the central frequency of an incident pulse. This has made possible the generation of *attosecond* pulses [52, 53]. High-harmonic generation (HHG) has been achieved by focusing high-intensity, femtosecond infrared pulses onto atoms with high ionization potentials (inert gases), resulting in the generation of coherent extreme ultraviolet pulses and *tabletop* x-ray “lasers” [54]. HHG has been explained by a classical “three-step” model [55, 56] involving (i) ionization of the atom by the field, (ii) the field drives the freed electron back to the ion, and (iii) the emission of high-harmonic radiation by the accelerated electron. General features of the classical model are recovered in fully quantum-mechanical theory [57].

74.6 Instabilities and Chaos

Mode-locked pulses and solitons exemplify an ordered dynamics, as opposed to the erratic and seemingly random intensity fluctuations that are sometimes observed in the output of a laser. In fact, it is possible, under certain circumstances, for laser oscillation to exhibit deterministic chaos; i.e., an effectively random behavior that can nevertheless be described by purely deterministic equations of motion. Extensive experimental and theoretical work on unstable and chaotic behavior in a wide variety of laser systems has been reported [58–61]. Instabilities of single transverse mode dynamics have also been studied, especially in connection with spontaneous spatial pattern formation [61]. The high gain and strong nonlinearities of diode lasers can result in chaotic behavior, which is of interest for possible applications including secure communications and random number generation [62].

Ralf Menzel Ralf Menzel studied physics, received his PhD from the Humboldt University, Berlin, in 1978, and finished his Habilitation in Physical Chemistry at the Technical University, Berlin, in 1989. In 1994 he became a full Professor for Experimental Physics in Photonics at the University of Potsdam. His research interests are in the fields of lasers, nonlinear optics, measurement techniques for biological and medical applications, and quantum optics.

Peter Milonni Peter Milonni received his PhD from the University of Rochester in 1974. He is currently a Laboratory Fellow and Guest Scientist at Los Alamos National Laboratory and a Research Professor at the University of Rochester. He previously had positions with the US Air Force, the Perkin-Elmer Corporation, and the University of Arkansas. His research interests include quantum optics and electrodynamics.

Abstract

The availability of coherent light sources has revolutionized atomic, molecular, and optical science. Since its invention in 1960, the laser has become the basic tool for atomic and molecular spectroscopy and for elucidating fundamental properties of optics and optical interactions with matter. The unique properties of laser light have found many practical applications as well, and the laser

has become an essential component of industries such as telecommunications, manufacturing, medicine, and photonics. The various types of lasers can be categorized in a number of different ways; for example, in terms of spectral range, temporal characteristics, pumping mechanism, or by the phase (solid, liquid, gas, plasma) of the laser gain medium. In keeping with a handbook on atomic, molecular and optical physics, the types of lasers will be organized here more fundamentally, according to the type of quantum states involved in the lasing transition. Lasing can arise, for example, from transitions between quantum states that are primarily associated with either a single atom, a single molecule, or an extended solid. But it can also arise from stimulated scattering and nonlinear parametric processes that do not require population inversion between the energy levels of a medium.

fiber laser · solid state laser · color center · laser emission · pulsed lasers

75.1 Introduction

Various types of lasers are listed in Table 75.1. The list is not comprehensive but illustrates the variety and properties of the most important lasers that are currently of interest for applications. Included in the table are examples of specific lasers of a given type, the type of lasing medium, and the typical spectral range. Also indicated is the nature of the transition: between electronic states, between vibrational states, a combination of electronic and vibrations, or not involving transitions between discrete energy levels of the medium (nonlinear processes). In this chapter, the emphasis will be on understanding the basic operational principles of and differences between the laser types, with details of a few representative lasers as space allows. For a more comprehensive discussion of different laser types, the reader is

Table 75.1 Overview of laser types, organized by the nature of the lasing transition

Laser type	Typical lasers	Host	Transition type	Spectral range
Single-atom transitions				
Neutral atom gas lasers	He-Ne	Low-pressure gas	Elec	Vis/IR
Ion gas lasers	Ar ⁺	Low-pressure gas	Elec	Vis/IR
Metal vapor lasers	Cu vapor	High-temp metal	Elec	UV/vis
Rare-earth ion lasers	Er:YAG Yb:silica glass fiber Yb thin disk lasers	Dielectric crystal glass fiber thin disk crystal	Elec	UV/vis/IR
Transition metal ion lasers	Ti:sapphire Cr:ZnSe/S	Dielectric crystal semiconductor	Elec-vib	IR tunable
Molecular transitions				
Molecular vibrational lasers (IR)	CO ₂	Gas mixture	Vib	IR
Dye lasers (visible)	Rhodamine 6G	Liquid (ethanol)	Elec-vib	Vis
Excimer lasers (UV)	ArF	Gas discharge	Elec-vib	UV
Solid-state transitions				
Semiconductor lasers	Double heterostructure quantum well VCSEL	III/V semiconductor II/VI semiconductor	E-h interband transition	Near IR-vis
Quantum cascade lasers	QCL	III/V semiconductor II/VI semiconductor	Intraband transition	IR
Free electron lasers	Synchrotron facility linac facility	High-energy electron beam in vacuum	Radiation from electron oscillations	IR-vis-UV-Xray
Nonlinear optical processes				
Raman lasers	Phosphosilicate fiber Yb fiber laser pump	Glass optical fiber	Stimulated scattering	Near IR-vis
Optical parametric oscillators	OPA & OPO	Transparent dielec- tric crystal	Parametric process	Near-mid IR
Frequency conversion	Frequency doubling frequency difference generation	Transparent dielec- tric crystal	Parametric process	Mid IR THz
High harmonic generation	Table-top XUV soft X-ray source	Noble gas	High field ↔ atom interaction	Extreme UV soft X-ray

75.2 Single-Atom Transitions

The simplest type of laser transition, and the one usually considered when explaining or learning about laser theory, is a transition between energy levels associated with a single atom. As discussed in the previous chapter, it is generally necessary to have population inversion (more atoms in the upper level than in the lower level) in order to have amplification of light in the medium, and thus lasing. There are exceptions to this general rule, however. For example, atomic transitions can occur between two energy level manifolds, with a quasi-thermal distribution of population within each manifold. This can lead to unequal absorption and emission cross sections at the lasing wavelength, relaxing the requirement of population inversion. Another exception occurs when two closely spaced lower levels are put into a coherent superposition state, such that absorption to a higher level is

suppressed relative to emission. This makes “lasing without inversion” [19] possible (see also Sect. 78.2.7).

For our purpose, transitions will be considered single-atom type even if the atoms are not completely isolated or in the gaseous or plasma phase. Certain atoms, such as the rare-earth or transition metals, can occur as ionic impurities in an insulating dielectric solid, and they have optical transitions that are between energy levels of one atom. The host solid does interact with the impurity atom, perturbing its energy levels to various degrees, but nonetheless the transition can be described as between these perturbed levels of a single atom.

75.2.1 Neutral Atom Gas Lasers

The signature laser of this type is the He-Ne laser, one of the first lasers to be developed in the early 1960s, and still in use today. Although the lasing medium is a mixture of two gases, only Ne is involved in the lasing transition, He serving only to populate the 3s levels of Ne by collisional energy transfer. Lasing occurs on Ne transitions from the excited 3s levels to the lower 3p levels in the infrared (3.39 μm),

and also to the lower 2p levels in the visible (543.3, 594.1, and 632.8 nm) and infrared (1.15, 1.529 μm). For operation at the visible wavelengths, it is necessary to suppress lasing on the much stronger 3.39 μm transition, for example by using end mirrors with less than 0.5% reflectivity at that wavelength. The gas mixture ($\approx 10\%$ Ne) is excited in a low pressure (4–7 mbar) discharge tube of small diameter (0.5–2 mm), with 1–5 kV and 4–11 mA. The tube diameter is limited because of the need for wall collisions to return the Ne to the ground state, and this limits the practical output power to tens of mW. Although not scalable to high power, He-Ne lasers are still relevant for applications such as interferometry, where long coherence lengths are needed. For typical tube lengths of 20–50 cm, there is simultaneous lasing of two to three longitudinal modes, and this limits the coherence length to ≈ 20 cm. However, operation on a single longitudinal mode and frequency stabilization can result in coherence lengths greater than 1 km. Although diode lasers have replaced He-Ne lasers for many applications, these long coherence lengths along with the nearly diffraction-limited output of the He-Ne laser remain distinct advantages, and it continues to be relevant for interferometry and educational instruction.

75.2.2 Ion Lasers

Ion lasers operate on transitions between energy levels of ionized noble gas atoms such as Ar or Kr. The noble gas (argon, for example) is excited in a high voltage (100–400 V) and high current (5–30 A) electrical discharge. The upper laser level is excited by a two-step process: first, the neutral argon atom is ionized by electron collisions (≈ 16 eV), and then the Ar^+ ions are raised to an excited electronic state (≈ 20 eV) by further electron collisions. Lasing occurs on the Ar^+ $4p \rightarrow 4s$ transition (≈ 2 eV). The gas pressure is carefully adjusted to give the greatest possible density of argon atoms, while at the same time allowing the electron mean free path to be great enough to give the electrons sufficient kinetic energy when they collide with Ar atoms. Even with optimum tube pressure, the gain coefficients are small, and this requires long cavity lengths, very high mirror reflectivities, and low cavity losses. To minimize reflection losses at the plasma tube windows, they are tilted at Brewster's angle (Brewster windows) and must be kept very clean. The spectral output of argon lasers is a series of green and blue lines, most prominently at 514.5 and 488 nm, which can be selected by an intracavity prism. Krypton lasers ($5p \rightarrow 5s$ transition) emit in the green and red, most prominently at 521, 568, and 647 nm. The wall-plug efficiency is quite low ($\approx 0.1\%$), and for output powers greater than 1 W, water cooling is needed to extract the waste heat. Ion lasers were at one time the most important source of high-power laser light in the visible but have decreased in

popularity due to competition from frequency-doubled solid-state lasers such as Nd:YAG.

75.2.3 Metal Vapor Lasers

These lasers are similar in operation to the neutral atom gas or ion lasers discussed above, except that the excitation process begins with vaporizing a solid or liquid to produce the gas for lasing, then followed by normal electrical discharge pumping. A typical ion laser of this class is the helium–cadmium laser. For the excitation processes, metallic Cd is evaporated and mixed with He. Then a DC electric discharge excites the He atoms and ionizes the Cd. The excited He atoms transfer their energy to the Cd ions, and lasing occurs between electronic levels of the Cd ion. The main emission lines are 441.6 and 325 nm, with CW output powers in the range 10–150 mW. The wall-plug efficiency is low, between 0.002% and 0.02%.

A typical neutral atom laser of this type is the copper vapor laser, with emission lines at 510.5 and 578.2 nm. These lasers operate only in the pulsed mode since the lower levels of the laser transitions are metastable and the transition is self-terminating. These lasers have high gain (10–30%/cm), and high wall-plug efficiency ($\approx 1.0\%$), but require high temperatures to create the vapor.

75.2.4 Rare-Earth Ion Lasers

This section and the next (Sect. 75.2.5) discuss lasers in which the gain medium is a dielectric solid (crystal or glass), doped with metal impurity ions to form an optically active center. The solid host itself is not usually optically active, and this type of laser has come to be referred to as a “solid-state laser”. This is in contrast to the case of semiconductor lasers (Sect. 75.4), in which the solid itself is the optically active material. Although semiconductor lasers might be considered a kind of “solid-state laser” (they are, after all, a laser that is in the solid state), conventional terminology is to reserve the term “solid-state laser” for those based on impurity-doped dielectric solids.

When elements of the lanthanide series (Ce, Pr, Nd, Pm, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb) are doped as impurities into an dielectric crystal or glass, they typically become triply ionized, e.g., Er^{3+} . These rare-earth ions have atomic-like transitions between levels of the same $(4f)^n$ configuration, where n ranges from 1 for Ce to 13 for Yb [20]. The host matrix perturbs these levels only weakly, due to the shielding of the optically active inner 4f shell by the filled outer 5s and 5p shells. The intermediate coupling scheme applies here, where spin–orbit interactions are small but not negligible compared to electrostatic interactions [21]. In this

case, the LS Russell–Saunders states with the same J are mixed, forming states that are linear combinations of different LS with a common value of J . The notation used to identify a given level is that of the principal LSJ component (i.e., $^{2S+1}L_J$). The local electric field from surrounding atoms in the host splits the $(2J + 1) M_J$ levels of each LSJ state through the Stark effect, resulting in a manifold of closely spaced sublevels [22]. For even values of n , there are $2J + 1$ Stark levels, but for odd n , there are $(2J + 1)/2$ levels, due to Kramer's degeneracy. The three types of splittings of the $4f$ states differ from each other by roughly an order of magnitude: electrostatic ($\approx 10^4 \text{ cm}^{-1}$), spin–orbit ($\approx 10^3 \text{ cm}^{-1}$), and Stark effect ($\approx 10^2 \text{ cm}^{-1}$).

Radiative $(4f)^n \rightarrow (4f)^n$ transitions are not electric dipole allowed by parity, and although magnetic dipole and quadrupole transitions are allowed, they are very weak. However, the local electric field mixes some of the higher $5d$ levels into the nominal $4f$ states, allowing so-called “forced electric dipole” transitions with an oscillator strength of $\approx 10^{-6}$ [23]. Typical absorption and emission cross sections are on the order of $\approx 10^{-20} \text{ cm}^2$, and with rare-earth ion concentrations of $\approx 10^{20} \text{ cm}^{-3}$ ($\approx 1\%$ doping), the gain coefficient can be as high as $\approx 1 \text{ cm}^{-1}$. This is intermediate between the very low gain typical of gas lasers and the very high gain of semiconductor lasers.

There are many varieties of rare-earth-doped lasers, and they have become one of the most important lasers for a variety of applications. The main characteristics that distinguish the different types are the nature of the optical pump, the type of solid host, the geometry of the host, and, of course, the selection of a particular rare-earth ion. In what follows, each of these aspects will be examined to illustrate the large and still growing variety of rare-earth-doped lasers.

Rare-earth doped lasers are excited optically and were originally pumped by lamps. However, the brightness of lamps is limited, and their spectral output does not couple efficiently with the narrow absorption lines of the rare earth. These issues were overcome with the advent of efficient and powerful diode lasers for pumping (Sect. 75.4.1), and today diode laser pumping of solid-state lasers has largely replaced lamp pumping [24].

The first host materials used in solid-state lasers were oxide crystals such as Al_2O_3 (sapphire) and $\text{Y}_3\text{Al}_5\text{O}_{12}$ (YAG). Fluoride crystals such as LiYF_3 (YLF) were found to have desirable properties, such as lower nonradiative relaxation between levels, which allows transitions further into the infrared. Glass hosts were tried early on [25], but the low thermal conductivity presented thermal management problems. It was not until the advent of fiber lasers, with a very small diameter that allows efficient cooling, that glass hosts began to compete seriously with crystal hosts. Just as with crystals, it was found that fluoride-based glasses such as ZBLAN [26] exhibit lower nonradiative relaxation, and hence the potential

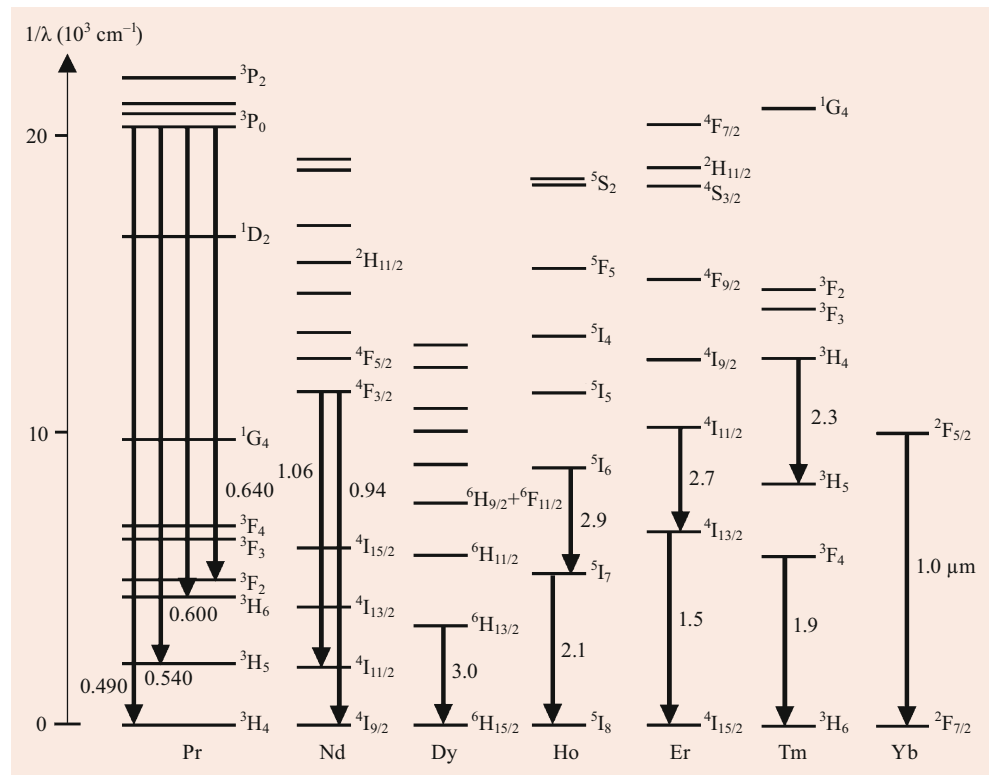

for lasing further into the infrared. A major difference between crystal and glass hosts is the smoothness of the optical spectra. Crystals provide similar crystal field sites for every dopant ion, while the disorder associated with glass structure gives many different types of local crystal field sites for the dopant ions, leading to inhomogeneous broadening of the spectral lines. As a result, absorption and emission spectra for rare earths in crystals show a great deal of structure [22], while in glasses, the spectra are significantly smoothed out, which is an advantage for tunable lasers. More recently, there has been a developing interest in glass ceramics [27], where active ions embedded in nanocrystals see essentially a crystalline environment, while on a macroscopic scale, the material is amorphous and can be molded and drawn into shapes like a glass. This topic is under active development.

The classic geometry of the gain medium is a cylindrical rod, typically 5–15 cm long and a few mm in diameter. This is still a common geometry, although for higher powers, rectangular slabs with Brewster's angle ends are sometimes used [14]. At high powers where thermal lensing limits the output power of traditional rod or slab geometries, there is increasing interest in thin-disk lasers [14], which have the active medium in the form of a thin disk mounted directly on a reflecting element and heat sink. Both pumping and lasing occur perpendicularly to the plane of the disk, which is efficiently cooled with the temperature gradient in the direction of lasing, avoiding thermal lensing issues.

Fiber lasers take the opposite geometric approach – instead of being short with large diameter like a disk, they are long and have a small diameter [28, 29]. In both cases, the surface-to-volume ratio is large, leading to efficient cooling. Comparing the two approaches, fiber lasers are better suited for high CW power, whereas thin-disk lasers are better for pulses with high peak power. In a fiber laser, the fiber core is doped with the active ion, while the cladding is undoped. It is usually end-pumped with another laser, most often with a diode laser but sometimes with another fiber laser. For very high power operation, the diode laser sources that are available do not provide a Gaussian beam that can be coupled into the core of a single-mode fiber. In this case, a double-clad fiber is used, which has a second inner cladding into which the pump light is launched and guided. The fraction of pump light absorbed per unit length is smaller than in core pumping, but for a sufficiently long fiber, most of the pump light can be absorbed. This amounts to a brightness converter, in which low brightness pump light is converted into high brightness lasing light.

The output power in a fiber laser is ultimately limited by nonlinear optical effects, due to the confinement of significant power in the very small mode area of the core. This led to the development of large-mode-area (LMA) fibers [30], which reduce the light intensity in the core. Another approach is hollow core fibers, a special class of photonic

Fig. 75.1 Low-lying energy levels of selected rare-earth 3+ ions, showing the wavelength of important lasing transitions in μm

crystal fibers in which the light propagates mostly in air, avoiding nonlinear effects in the glass [30]. The guiding of light in such fibers is due to the photonic bandgap effect, rather than the index guiding characteristic of traditional optical fibers. Although optical fibers are typically made of glass, there is increasing interest in single-crystal fibers (SCF), especially for very high power ultrashort pulse amplification [31]. These can have diameters from $\approx 100 \mu\text{m}$ to as large as $\approx 1 \text{ mm}$, approaching the dimensions of a traditional rod but with guiding of the pump light much as in a traditional fiber amplifier.

There are many possible laser transitions for the 12 optically active rare-earth ions, but only a few important examples can be mentioned here. A more comprehensive listing can be found elsewhere [11, 20, 23]. Figure 75.1 shows the more important lasing transitions in the visible (Pr), near-IR (Nd, Yb, Er), and mid-IR (Dy, Ho, Er, Tm). The development of efficient GaN diode lasers [32–34] at 440 nm has made practical the direct pumping of the Pr 3P levels to give visible lasers in the blue (490 nm), green (540 nm), and red (600, 640 nm). Typical hosts for these lasers are fluorozirconate glass (ZBLAN) and the crystal LiYF_4 (LYF). In the near-IR, the Nd:YAG laser has been and continues to be one of the most widely used solid-state lasers for scientific, industrial, and medical applications, operating most efficiently at 1064 nm, but also at 946, 1123, and 1319 nm. Originally pumped with lamps, it is now mostly pumped with high power diode lasers. When the 1064 beam is frequency

doubled (Sect. 75.6.3), the 532 nm output has replaced the 514.5 nm line of the more bulky and less efficient argon ion laser for many applications. The Nd:YAG laser is now, in turn, gradually being replaced by the more compact and efficient Yb fiber laser, which operates in the same $\approx 1 \mu\text{m}$ wavelength region. These Yb lasers have been scaled to the kW range and higher in recent years, pumped by increasingly efficient and powerful diode laser stacks [35].

Also important in the near-IR is the $\text{Er}^{3+} \ ^4I_{13/2} \rightarrow \ ^4I_{15/2}$ transition at 1.5–1.6 μm , which falls right at the wavelength of minimum attenuation in silica glass fibers. With Er doped in silica fiber, this transition forms the basis for the erbium-doped fiber amplifier (EDFA), which is largely responsible for the explosive growth in telecommunications bandwidths in the past two decades [28, 36]. The EDFA can be pumped with diode lasers at 980 or 1480 nm, the latter having a higher potential efficiency due to a smaller quantum defect (difference between pump and lasing photon energy). In the case of 980 nm pumping, the fiber is sometimes codoped with Yb, which absorbs the pump more strongly and transfers the energy to Er nonradiatively. Output powers can be several to $\approx 100 \text{ W CW}$ [11]. Er-doped crystals also operate with high power on this transition, for example, Er:YAG at $\approx 1645 \text{ nm}$.

For operation in the $\approx 2 \mu\text{m}$ region, both Tm (1.9 μm) and Ho (2.1 μm) have transitions that terminate on the ground-state manifold (three-level systems). Tm has an especially large tuning range of up to $\approx 250 \text{ nm}$ in a fiber and $\approx 300 \text{ nm}$ in a crystal. Another unique advantage of Tm is the cross-

relaxation that occurs at high ($> 2\%$) Tm concentrations when the $^3\text{H}_4$ level is pumped at 790 nm [37]. In this process, the excited Tm^{3+} exchanges energy nonradiatively with a neighboring Tm^{3+} in the ground state, leaving both ions in the $^3\text{F}_4$. The result is two ions in the upper laser level for a single pump photon absorbed – a quantum efficiency of 200%. Another mid-IR transition in Tm is the $^3\text{H}_4 \rightarrow ^3\text{H}_5$ transition at 2.3 μm , which can also be pumped at 790 nm. In this case, however, the Tm concentration is kept below 2% because cross-relaxation would have the undesirable effect of depleting the upper laser level.

The first excited state of Ho^{3+} is a bit lower in energy than that of Tm^{3+} , and its ground state transition is somewhat longer in wavelength, $\approx 2.1 \mu\text{m}$. Unfortunately, Ho^{3+} does not have a convenient wavelength for high power diode laser pumping, so Tm is often codoped to efficiently absorb the pump light at 790 nm. The excited Tm^{3+} cross relaxes as described above, and then the Tm^3F_4 level transfers its energy to a nearby Ho^{3+} in the ground state, exciting it to the $^5\text{I}_7$. This process can be efficient with proper adjustment of the Tm and Ho concentrations [38].

In the $\approx 3 \mu\text{m}$ spectral region, there are transitions in Dy, Ho, and Er that have proven successful in fiber and crystalline solid-state lasers. For these lasers, fluoride hosts are preferred due to decreased multiphonon quenching of the laser transition and increased host transparency. The Dy ($^6\text{H}_{13/2} \rightarrow ^6\text{H}_{15/2}$) transition is three-level, whereas the Ho ($^5\text{I}_6 \rightarrow ^5\text{I}_7$) and Er ($^4\text{I}_{11/2} \rightarrow ^4\text{I}_{13/2}$) transitions are four-level. The four-level transitions have the disadvantage of a lower laser level that is metastable with a long (ms) lifetime, and this limits the output power due to accumulation of population in the excited states. Three techniques that have been used to reduce this problem are codoping with a quencher ion, energy transfer upconversion (ETU), and cascade lasing. An example of the first method is codoping Pr into a Ho-doped host, which results in energy transfer from the lower laser level of Ho ($^5\text{I}_7$) to a nearby Pr ion, recycling the Ho ion to the ground state [39]. Similarly, codoping of Pr into an Er-doped host depopulates the lower laser level of Er ($^4\text{I}_{13/2}$). An important example of the second method (ETU) occurs in highly doped Er materials [40], whereby two neighboring Er ions both in the lower laser level ($^4\text{I}_{13/2}$) exchange energy, leaving one in the ground state ($^4\text{I}_{15/2}$) and the other in the excited state ($^4\text{I}_{9/2}$). The ($^4\text{I}_{9/2}$) then relaxes nonradiatively to the ($^4\text{I}_{11/2}$). This has a double benefit: the lower laser level is quenched while the upper level population is simultaneously increased. A similar ETU process can occur in highly doped Ho systems [41]. In the third method, simultaneous lasing (cascade lasing) is established on, for example, both the Ho ($^5\text{I}_6 \rightarrow ^5\text{I}_7$) transition at 2.9 μm , and the ($^5\text{I}_7 \rightarrow ^5\text{I}_8$) transition at 2.1 μm [42]. For Er, cascade lasing can be established on the ($^4\text{I}_{11/2} \rightarrow ^4\text{I}_{13/2}$) and ($^4\text{I}_{13/2} \rightarrow ^4\text{I}_{15/2}$) transitions [43]. This method is especially advantageous for high-power op-

eration, because it not only solves the population bottleneck problem, but also reduces the heat load and cooling requirements. In contrast to Ho and Er, a Dy 3 μm laser does not suffer from population bottlenecks. As a three-level system, however, it requires high pump intensity to reach lasing threshold, and, therefore, the fiber geometry with fluoride glass is most efficient.

75.2.5 Transition Metal Ion Lasers

When transition metal elements of the fourth row of the periodic table (Ti, V, Cr, Mn, Fe, Co, Ni, Cu, and Zn) are doped as impurities into an dielectric crystal or glass, they can take on various oxidation states, such as 2+, 3+, or 4+. In the oxidation process, they first lose the two outer 4s electrons and then the 3d electrons according to the oxidation state. Example electron configurations for the optically active electrons are $(3d)^1$ for Ti^{3+} , and $(3d)^3$ for Cr^{3+} . Unlike the case of the rare-earth ions, there is little shielding of these optically active 3d states from external electric fields, and the energy level positions are strongly influenced by the host. The quantum states become characterized by the symmetry of the ion's crystallographic site, rather than by the atomic states of an isolated ion [44, 45].

This strong ion–host interaction leads to broadly tunable optical transitions, best understood in terms of a “configurational coordinate diagram” [21]. In this picture, the collective motion of all nearby host atoms is represented by a single coordinate Q , and the Born–Oppenheimer approximation is used to separate the degrees of freedom into electronic (fast) and nuclear (slow) parts. The energies of the ion's different electronic levels are calculated assuming a stationary Q and then plotted as a function of Q as shown in Fig. 75.2. For each electronic state, there is a minimum energy at some value of Q , about which the system oscillates with a frequency given by the curvature of $E(Q)$. This gives rise to vibrational sublevels superimposed on the electronic states, with the total quantum state now characterized by the electronic state and an integer number of vibrational quanta. Optical transitions are nearly vertical in this diagram, because the electron motion is much faster than the nuclear motion during the transition. During the optical transition, the atoms of the host can be thought of as “frozen in position” (the Franck–Condon principle). When the minima for the two electronic states occur at different values of Q , there is a shift to lower energy (longer wavelength) between absorption and emission, known as the “Stokes shift”. Both the absorption and emission spectra are then broadened and shifted as shown in Fig. 75.3. When the two minima occur at nearly the same Q , however, as is the case for rare-earth 4f transitions and certain pairs of transition metal states, the op-

Fig. 75.2 Configuration coordinate diagram for strong electron-lattice interaction

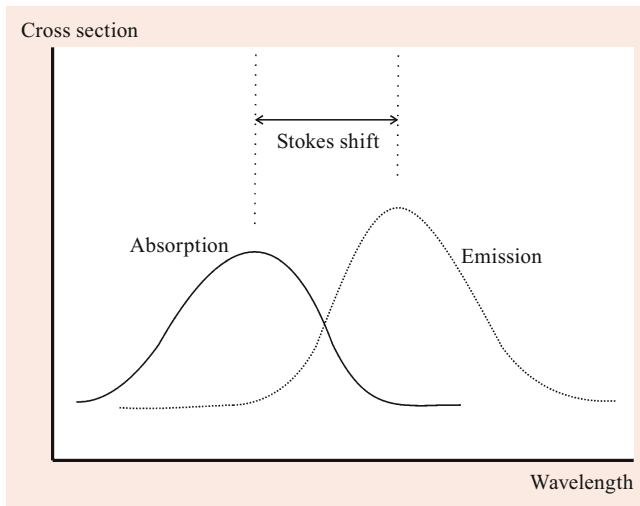

Fig. 75.3 Stokes shift between absorption and emission

tical transition is mostly purely electronic (“zero-phonon”), with a very weak phonon sideband.

Taking Cr^{3+} as an example, Fig. 75.4 shows how the energy E/B of different atomic orbitals in a site having octahedral symmetry vary with the crystal field strength Dq/B , relative to the ground state. This is known as a Tanabe–Sugano diagram [21]. For certain states (2E , 2T), the energy difference with the ground state changes little as the field strength changes, indicating weak ion–lattice coupling. At sufficiently high field strength, these are the lowest-lying excited states, leading to sharp spectral absorption and emission for transitions to and from the ground state. This explains why the ruby laser ($\text{Cr}^{3+}:\text{Al}_2\text{O}_3$), the first laser to be demonstrated in 1960, operates at a single wavelength of 694 nm, with no tunability. Other crystalline hosts for Cr^{3+} provide a “low field” envi-

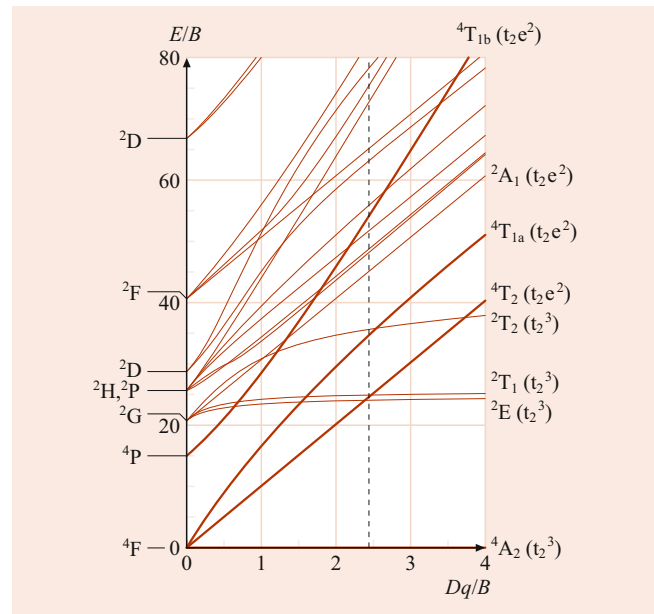

Fig. 75.4 Energy E/B of transition metal ion states versus crystal field strength Dq/B [11]

ronment, such that the 4T_2 level lies lower in energy than the 2E . The first tunable laser based on Cr^{3+} was $\text{Cr}^{3+}:\text{BeAl}_2\text{O}_4$ (alexandrite), which is tunable from 700–820 nm with good efficiency and thermal properties [46]. Other hosts for Cr^{3+} that are similarly tunable have been demonstrated, such as LiCaAlF_6 and LiSrAlF_6 , but these have poorer crystal properties and lower power output than alexandrite [47].

The really significant advance in tunable lasers after alexandrite was the introduction of the Ti-sapphire laser ($\text{Ti}^{3+}:\text{Al}_2\text{O}_3$) in 1982 [10, 48]. The $(3d)^1$ configuration for Ti^{3+} leads to a very simple energy level diagram, with a single absorption band from 450–550 nm and tuning range from 670–1100 nm. This wide tunability, along with the lack of excited-state absorption, high slope efficiency ($\approx 60\%$), high crystal thermal conductivity, scalability to high power, and good mechanical and chemical hardness, have made the Ti-sapphire laser one of the most important and commercially successful of all solid-state lasers. The same broad emission bandwidth that gives wide tunability also allows ultrashort mode-locked pulses, and pulse widths of ≈ 5 fs have been achieved. Pumping was originally with an Ar ion laser in the blue/green, and then with frequency-doubled Nd:YAG lasers at 532 nm. Recent progress in high-power blue diode lasers based on GaN (Sect. 75.4.1) now allows direct diode laser pumping [34], which permits a much more compact and efficient Ti-sapphire laser.

Other valence states of Cr are possible for tunable solid-state lasers, in particular Cr^{4+} and Cr^{2+} . Cr^{4+} has the $(3d)^2$ configuration, and the best hosts are found to be YAG ($\text{Y}_3\text{Al}_5\text{O}_{12}$) with $1350 < \lambda < 1550$ nm, and Mg_2SiO_4 , with $1200 < \lambda < 1350$ nm. The main drawbacks of Cr^{4+} systems

are excited-state absorption (ESA) at the lasing wavelength and nonradiative relaxation that reduces the quantum efficiency. Furthermore, careful material preparation is needed to make sure that only the Cr^{4+} oxidation state is present and not Cr^{3+} [49]. More promising is the divalent state Cr^{2+} , most notably $\text{Cr}^{2+}:\text{ZnSe}$, which has a lasing transition tunable from 2.0–3.1 μm [50]. The many advantages of this system include high absorption and emission cross sections ($\approx 10^{-18} \text{ cm}^2$) due to the tetrahedral site symmetry, near unity quantum efficiency due to the low phonon energy of the chalcogenide host, and no significant ESA because all relevant ESA transitions are spin-forbidden. For all these reasons, the $\text{Cr}^{2+}:\text{ZnSe}$ laser has come to be called the “Ti-sapphire laser of the mid-IR”, and has been commercialized [35].

A rather new type of impurity-doped solid-state laser is the bismuth-doped fiber laser. Although bismuth is not actually a transition metal ion, it is discussed here because its optical properties in the near-IR, like those of transition metal ions, depend strongly on the host. The actual nature of the Bi-related near-IR emitting centers is not yet understood, despite extensive research. The emitting center may be not a single ion, but rather clusters of ions of some valence (Bi^{5+} , Bi^{3+} , Bi^{2+} , and Bi^{+}), perhaps in association with an oxygen vacancy. Despite this current lack of understanding, such fiber lasers were first demonstrated in the range 1140–1215 nm using Bi-doped aluminosilicate fibers, and subsequent work has extended the range to include 1270–1800 nm using newly developed phosphogermanosilicate, germanosilicate, and silica fibers [51, 52]. Although these are not currently as efficient as rare-earth-doped fiber lasers, a better understanding of the nature of the optical centers may allow improved efficiency.

75.3 Molecular Transitions

This section considers lasers involving transitions between the quantum states associated with a molecule. Vibrational transitions in a gas (e.g., the carbon dioxide laser) are discussed in Sect. 75.3.1, electronic-vibrational transitions in a liquid (e.g., dye lasers) in Sect. 75.3.2, and electronic-vibrational transitions in a gas (e.g., excimer lasers) in Sect. 75.3.3.

75.3.1 Molecular Vibrational Lasers

The flagship laser of this type is the carbon dioxide (CO_2) laser, operating on transitions between different vibrational states of the CO_2 molecule [14]. It was developed at Bell Laboratories by Patel in 1964, and while the basic operational principles have changed little over the years, the applications have evolved as newer types of lasers have been developed. Once the go-to laser for cutting, welding,

Fig. 7.5 Vibrational modes (a) and laser transitions (b) in a CO_2 laser [4]

marking, surface treatments, as well as spectroscopy in the 9.2–11 μm region, it now faces competition with high-power Yb fiber lasers in the 1 μm region, and quantum cascade lasers (Sect. 75.4.1) in the 2–12 μm region. However, the CO_2 laser still remains relevant for certain applications [53] because of its unique combination of longer wavelengths ($\approx 10 \mu\text{m}$), high power (kW CW), good beam quality (often diffraction limited), and spectral purity (linewidth $< 1 \text{ kHz}$).

CO_2 is a linear molecule and has three vibrational modes, as indicated in Fig. 7.5. Transitions from the asymmetric stretch mode to the symmetric stretch or bending modes give rise to the two principle laser transitions around 10.6 and 9.6 μm , each having a number of closely spaced ($\approx 10 \text{ GHz}$) rotational sidebands. Rotational states with quantum number J have energies $\propto J(J+1)$, and vibrational-rotational transitions obey the selection rule $J_{\text{final}} = J_{\text{initial}} \pm 1$, with the result that the rotational sideband energies are evenly spaced in frequency. The so-called P branch has $J_{\text{final}} = J_{\text{initial}} + 1$, and the R branch has $J_{\text{final}} = J_{\text{initial}} - 1$ [1, 54]. Tuning the laser to discrete lines in the range 9.2–11 μm region is possible using a diffraction grating in place of the end mirror. With no wavelength selection, lasing occurs on the 10P branch with $J \approx 20$. Since the thermal population of the different rotational states depends on gas temperature, cooling of the gas is needed for stable high-power operation.

Excitation of the CO_2 vibrational levels occurs in a high-voltage ($\approx 15 \text{ kV/m}$) gas discharge tube, either sealed or with flowing gases. The gas mixture contains CO_2 , N_2 , and He, with approximate ratios 1, 2, and 8, respectively. The N_2 serves to selectively enhance excitation of the CO_2 upper laser level by collisional energy transfer, while the He helps depopulate the lower CO_2 laser level and also cool the gas due to its high thermal conductivity. Other gases that are

sometimes added include Xe (few %), which absorbs fast electrons in the discharge that would otherwise disassociate the CO₂ molecules. The wall-plug efficiency is rather high ($\approx 10\text{--}15\%$) for a gas laser, and output power scales with increasing tube length ($\approx 80\text{ W/m}$). Tube diameters are limited to $\approx 5\text{--}10\text{ mm}$ due to limits on heat extraction.

Other vibrational transition lasers include the carbon monoxide (CO) laser operating at $5\text{--}6.5\ \mu\text{m}$, and the nitrous oxide (NO₂) laser operating at $10\text{--}11\ \mu\text{m}$, although these are much less commonly used. Some vibrational lasers utilize a chemical reaction to achieve an excited vibrational state, and are termed chemical lasers. Examples are the hydrogen fluoride (HF) laser operating at $2.6\text{--}3.3\ \mu\text{m}$, and the deuterium fluoride (DF) laser operating at $3.5\text{--}4.2\ \mu\text{m}$.

75.3.2 Dye Lasers

Dye molecules consist of a hydrocarbon backbone chain terminated by a more complicated structure on each end. The electrons in the conjugate double bonds give broad and efficient absorption and emission spectra in the visible, making them useful for lasers as well as decorative coloration. Developed by Sorokin and Lankard in 1966, dye lasers became very popular during the next three decades as one of the few sources of widely tunable visible and near-IR laser light [55]. The optically active electrons in the conjugate double bonds are strongly coupled to vibrational modes of the molecule, and the configurational coordinate diagram of Fig. 75.2 can be used to understand the large Stokes shift between absorption and emission, as previously discussed for transition metal ions (Sect. 75.2.5). A typical tuning range for one particular dye is $50\text{--}60\text{ nm}$, and by sequentially choosing different dyes it is possible to cover the range $300\text{--}1200\text{ nm}$ [56]. The wide emission bandwidth makes dye lasers attractive for mode-locking, and they have played an important role in developing ultrashort pulse technology, first in the ps and then the fs region [57].

Dye lasers have desirable properties in the frequency as well as time domain. With CW pumping (Ar ion laser or frequency-doubled Nd:YAG, for example), spectral linewidths in the tens of kHz can be obtained on a single longitudinal cavity mode [58]. To avoid spatial hole burning, which would otherwise cause multimode output, an etalon or a ring laser configuration can be used. In pulsed operation (e.g. flashlamp, N₂ laser, excimer laser) the linewidth is longer, typically hundreds of MHz.

Despite the dye laser's desirable properties, it does have some drawbacks that have decreased its popularity in the past two decades. One issue is the need to avoid triplet quenching, in which an excited-state population accumulates in the lowest triplet spin level, followed by excited-state absorption, which quenches laser action [55]. In pulsed operation, this is

not a problem, because the triplet states can relax back to the ground state between pulses. For CW operation, however, it is necessary to circulate the dye and move it rapidly through a small nozzle in a thin jet of flowing liquid across the optically pumped area. This limits the ability to make the laser compact and robust. Eventually, the dye degrades and needs to be replaced for both continuous wave (CW) and pulsed operation. Most significantly, perhaps, are the safety and convenience issues dealing with messy and, in many cases, carcinogenic dyes. Because of these drawbacks, newer options such as frequency-doubled solid-state lasers or fiber lasers are now often seen as more desirable for applications once served by the dye laser. Dye lasers do, however, continue to serve in niche applications such as laser isotope separation [59] and laser guide stars at large terrestrial telescopes [60].

75.3.3 Excimer Lasers

The excimer laser was developed in the 1970s and operates in the UV region in a pulsed mode [61]. The lasing transition is between electronic energy states of an “excited dimer” molecule, or excimer, which has the interesting property that bound states only exist when the molecule is in the excited state. When the molecule returns to the ground state, it dissociates, breaking up into two separate atoms.

Taking KrF as a typical example, the lasing process is illustrated in Fig. 75.6, which shows the electronic energy of a KrF “molecule” as a function of the separation of the two nuclei. This is similar in concept to the configurational coordinate diagram of Fig. 75.2, where Q is now simply the internuclear separation R . When an atom of Kr and F are brought together, each in their ground state, the energy of the system increases monotonically due to Coulomb repulsion, and the “molecule” is unbound. This is characteristic of the noble gases (He, Ne, Ar, Kr, and Xe), which are gener-

Fig. 75.6 An excimer laser operates on a bound \rightarrow unbound transition [4]

ally unreactive and not inclined to form stable molecules. If the KrF molecule is promoted to the next-highest electronic state, however (by electron bombardment in an electrical discharge, for example), then the energy curve has a minimum at $R = 0.23$ nm. This gives rise to a bound state at this value of R , which remains stable as long as the molecule remains in the excited state (≈ 10 ns for KrF). During this excited-state lifetime, lasing can occur on the transition from the bound excited state to the unbound ground state. Since there is no stable population in the lower laser level, this is an example of a perfect four-level system.

In KrF, lasing occurs at a wavelength of 248 nm. Other noble-gas-halide pairs operate in the same fashion, for example XeCl at 309 nm, XeF at 351 nm, and ArF at 193 nm. Excimer lasers have moderately high efficiencies (≈ 1 –4%), short pulse duration (≈ 10 ns), high pulse energies (0.1–1 J), and can be scaled up to high average power (100 W). They have numerous applications, including photolithography [62], materials processing, and ophthalmology (LASIK – laser-assisted in situ keratomileusis). The short wavelengths are strongly absorbed by most materials, a distinct advantage for precision cutting. The principal disadvantage of these lasers is the need to work with highly reactive gases such as fluorine, which requires proper ventilation and safety precautions. Typically, the gases are circulated through the electrical discharge chamber to maintain the purity of the reactants. A high concentration of helium (about 2 atm pressure) is added as a buffer gas to facilitate the reactions between noble and halide gases.

75.4 Solid-State Transitions

This section considers lasers based on transitions between extended, band-like states in a solid. These can be divided into two categories: semiconductor lasers, in which the transitions occur between conduction and valence band, and quantum cascade lasers (QCL), in which transitions occur between electronic sublevels of the conduction band. Semiconductor lasers are typically pumped by an electric current, in which case, they are also referred to as diode lasers. When the semiconductor is pumped optically (the optically pumped semiconductor laser, OPSL), it is often configured in the thin-disk geometry for high-power operation, similar to that of the thin-disk solid-state laser [63]. Semiconductor lasers have high gain coefficients ($\approx 10^3$ cm⁻¹), which allows for compact photonic devices.

75.4.1 Semiconductor Lasers

The fundamental light emission process in semiconductor lasers arises from radiative recombination of electrons

and holes. In the simplest case, this occurs at the junction of an n -type material having excess electrons (e.g., n -Al_{*x*}Ga_{1-*x*}As) and a p -type material having excess holes (e.g., p -Al_{*x*}Ga_{1-*x*}As). At this p - n junction, there is an electric field that keeps the charges separated until they are “injected” by an applied voltage into the depletion region, where light emission occurs. A double-heterostructure (DH) laser [64, 65] improves the performance by introducing a middle layer of a different composition (e.g., GaAs) sandwiched between the original p and n -type materials. This provides several advantages over the single homojunction laser: (1) a well-defined recombination region (given by the thickness of the middle layer) that confines the carriers, reducing lasing threshold and improving temperature stability, (2) index guiding of the emitted light due to the index difference between middle and outer layers, and (3) reduced reabsorption of emitted light in the outer layers, due to the higher bandgap there. In choosing materials for these heterostructures, lattice matching at the junctions is important to minimize strain. Common III-V compound families that exhibit good lattice matching and have wavelengths of interest for photonic applications include Al_{*x*}Ga_{1-*x*}In_{*y*}P_{1-*y*} (635–670 nm), Al_{*x*}Ga_{1-*x*}As (720–850 nm), In_{*x*}Ga_{1-*x*}As (900–1100 nm), and In_{*x*}Ga_{1-*x*}As_{*y*}P_{1-*y*} (1000–1650 nm). Most recently there has been significant progress in developing high-power blue diode lasers, based on the In_{*x*}Ga_{1-*x*}N family [32], with operation at 380, 405, 450, and 470 nm. This permits efficient diode laser pumping of certain solid-state lasers, as discussed in Sects. 75.2.4 and 75.2.5.

Quantum well (QW) structures are often used to improve the diode laser performance [66]. These are thin (≈ 10 nm) regions within the active gain region that have a smaller bandgap than the surrounding material, forming a potential well for charge carriers. The quantum states become localized in the well, resulting in a ladder of discrete energy levels that is similar to the familiar “particle in a box” of elementary quantum mechanics. The laser wavelength then depends not only on the host material but also on the width of the wells. This flexibility, along with improved device performance, has made QW structures common in commercially available laser diodes.

There are a number of configurations and geometries for the semiconductor laser cavity [14, 65]. In an edge emitter, laser light propagates along the plane of the thin semiconductor layers and is emitted from the edge of the semiconductor chip. The simplest of these is the Fabry–Perot (FP) laser, in which Fresnel reflections from the cleaved semiconductor end facets suffice for reaching the lasing threshold, due to the very high gain coefficient. Another option is a feedback mirror external to the semiconductor, which allows insertion of an intracavity element for modulation or control of polarization. Single-frequency operation can be obtained in a distributed feedback (DFB) laser, which has an undulat-

ing element of period Λ incorporated throughout the gain region of the waveguide. The laser frequency is then given by the Bragg condition $\nu = c/(2n\Lambda)$, where n is the effective waveguide index of refraction. A variation of this is the distributed Bragg reflector (DBR) laser, where the Bragg reflection occurs only at the cavity ends, separate from the gain region.

The gain region in an edge emitter is usually confined in the lateral dimension to a width $\approx 10\ \mu\text{m}$, known as the stripe geometry. This improves stability at high powers by confining both light and charge carriers to a smaller, well-defined area. For high-power applications, multiple stripes are incorporated in a single layer of a diode laser, and for even higher powers, a number of multistripe lasers are packaged in a linear array, in a diode laser bar. These bars can be stacked to provide a planar array with very high ($\approx \text{kW}$) power suitable for pumping high-power solid-state lasers [14].

In contrast to the edge emitters, there is an entirely different class of semiconductor laser in which the emission is perpendicular to the plane of the semiconductor chip [67]. These “vertical cavity surface emitting lasers” (VCSELs) consist of a small circular active region of thickness $\leq 1\ \mu\text{m}$ and diameter $\approx 10\ \mu\text{m}$, with Bragg reflecting mirrors above and below formed by a series of dielectric layers with alternating refractive index. Since the fractional gain in one pass through the active region is only $\approx 1\%$, the Bragg reflectors must have a reflectivity $R > 99.5\%$. The small cavity length L has the advantage of naturally promoting single-frequency operation, since the mode spacing $c/(2nL)$ is greater than the width of the gain spectrum. VCSELs have a number of other advantages, including a symmetrical emission pattern with diffraction-limited divergence, suitable for efficient coupling to single-mode optical fibers. They can be modulated up to $\approx 25\ \text{GHz}$ due to the small surface area (and small capacitance) and formed into arrays that are individually modulable. CW lasers can have linewidths of $\approx 200\ \text{MHz}$. A practical advantage of VCSELs is that thousands of individual devices can be processed on a single wafer and tested at various stages of the manufacturing process, increasing reliability and yield.

Closely related to the VCSEL is the vertical external-cavity surface-emitting laser (VECSEL), in which one of the Bragg reflecting elements is replaced by an external mirror in an extended cavity. This allows intracavity elements such as saturable absorbers for mode-locking or nonlinear crystals for second harmonic generation (SHG). VECSELs have potential as a compact high-power fs laser source [68].

75.4.2 Quantum Cascade Lasers

In the quantum cascade Laser (QCL), light generation arises not from electron–hole recombination but rather from electron transitions from one quantum-well (QW) state to another, all within the conduction band [69]. The bandgap and valence band states play no role, in contrast to a conventional semiconductor laser. The gain medium consists of alternate layers of higher and lower bandgap material, forming a series of closely spaced QWs. A voltage is applied across the device, which causes the electron’s potential energy to vary linearly with position, as shown in Fig. 75.7. There is no p–n junction, so in a circuit, the device behaves much like a resistor. It is termed a unipolar circuit element, because its operation depends on only one type of charge carrier (i.e., the electron). Conventional laser diodes, in contrast, are bipolar circuit elements.

As electrons flow through the QCL opposite to the electric field direction, they lose potential energy, not continuously, but in steps, as they jump from one QW to the next. Electrons in the lowest energy level of each QW see a potential barrier on both sides but can tunnel through with a probability that depends on the barrier height and width. In the lasing process, an electron first tunnels through a number of QWs in the “electron injection” region, as shown in Fig. 75.7, and then tunnels into a higher state of the laser active QW. Light is emitted as the electron relaxes to the lower level, followed by tunneling into the next injection region. This process is repeated many times (typically 20–25) during the transit of a single electron across the device, so that a single electron gives rise to many individual photons.

Fig. 75.7 Electron energy levels in a quantum cascade laser [11]

The most important application of the QCL is as a light source in the mid-IR wavelength range (4–12 μm) [69]. For a conventional diode laser, this would require working with materials with a very small bandgap energy, which is problematic due to the high levels of thermally generated electrons and holes. Since the photon energy in the QCL is independent of the band gap, wide bandgap materials can be used in the layers for better performance. The lasing wavelength can be selected simply by choosing the proper QW width and spacing. In fact, it is possible to operate the QCL laser at multiple wavelengths simultaneously, by varying the QW energy levels across the device. QCLs have also been operated in the THz region [70].

A variation of the QCL concept is the interband cascade laser (ICL), which differs from the QCL in that the lasing transition is from QW states in the conduction band to QW states in the valence band. However, unlike a traditional interband transition, the transition in the ICL is between QW states in adjacent layers of the material. There must be sufficient overlap between the wavefunctions of the QW states in the two adjacent layers for this method to work. These lasers operate in the 3–6 μm range and can have advantages in terms of power dissipation [71].

75.5 Free Electron Lasers

The free electron laser (FEL) is very different from the other lasers discussed so far; the electrons emitting the radiation are not bound to any atom. A beam of high-energy (relativistic) electrons in a vacuum is sent through an undulator (or “wiggler”), where they are deflected by a transverse magnetic field that periodically reverses direction. The resulting oscillatory motion of the electrons creates a dipole radiation pattern in the electron rest frame, which becomes a beam of light colinear with the electron beam in the laboratory frame. The light beam has wavelength $\lambda \cong \Lambda/(2\gamma^2)$, where Λ is the undulation period, and γ is the relativistic factor. Varying the electron beam kinetic energy $(\gamma - 1)m_e c^2$ changes the emission wavelength, and this leads to a very wide tunability, a hallmark of the FEL. By using different combinations of beam energy and undulation period, FELs have been demonstrated with wavelengths from the microwave region ($\approx \text{mm}$) to hard X-rays ($\approx 0.1 \text{ nm}$) [72, 73].

Free electron lasers can be operated as either an amplifier or an oscillator, depending on the availability of reflecting optics at the laser wavelength. In the oscillator configuration, reflecting elements are placed at each end of the undulation region, and laser action proceeds much in the same way as in a traditional laser. Spontaneous emission provides the seed light for subsequent amplification, and very high gain is not required since the light makes multiple passes through the cavity. In the absence of mirrors, the device acts as a single-

pass amplifier, which amplifies either a seed pulse that is injected from one end or spontaneous emission. High gain is desirable in this case. With seed pulse injection, the system is referred to as a master oscillator power amplifier, or MOPA, which has the advantage of preserving the spectral and noise properties of the seed, while increasing its power in the undulator region. With no seed pulse, the output is actually superradiance rather than lasing, termed amplified spontaneous emission (ASE) in general laser theory or self-amplified spontaneous emission (SASE) in connection with FELs. This has less temporal coherence than laser oscillation but still has high spatial (transverse) coherence, and therefore high brightness (brilliance). The main drawback of the FEL is the need for a high-energy electron accelerator, found only at a few large facilities around the world [73]. Both linear accelerator (linac-based) and storage ring facilities are available with FEL sources, and users must schedule time at the facility that meets their requirements for wavelength, power, temporal structure of output, etc.

There is increasing interest in an X-ray FEL (XFEL), a spectral region where few other laser sources are available [74]. Due to a lack of suitable mirrors, the XFEL operates in the single-pass amplifier mode. An important figure-of-merit is the single-pass gain, which can be as high as 10^7 for $\lambda < 1 \text{ nm}$. Preliminary success has led to governmental support of a number of linac facilities, including the Linac Coherent Light Source (LCLS) in the US, the SPring-8 Compact SASE Source (SACLA) in Japan, the European X-FEL in Germany, and the SwissFEL XFEL in Switzerland. All of these use a room-temperature LINAC except for the Swiss facility, which uses superconducting accelerator technology that enables orders of magnitude higher brilliance. The LCLS operates in the hard X-ray wavelength range 0.12–1 nm, with pulse energies of 1–3 mJ and pulse duration from 40–500 fs. The SACLA produces 0.06 nm hard X-ray pulses with pulse energies $\approx 0.5 \text{ mJ}$ and pulse duration 2–10 fs.

75.6 Nonlinear Optical Processes

The final section of this chapter is concerned with various types of nonlinear optical processes that can be used to extend the wavelength range of available lasers. These processes arise from the optical behavior of materials at high light intensity and are discussed from a theoretical viewpoint in the next chapter. In these processes, the medium plays a different role than in a conventional laser, where the medium stores energy in electronic or vibrational energy states, with lasing occurring due to transitions between those states. Instead, nonlinear processes such as stimulated Raman scattering, optical parametric amplification and oscillation, second harmonic generation (SHG), and difference

frequency generation (DFG) use the medium as an intermediary, by which two or more optical waves can interact with each other. High-harmonic generation is a special case of extreme nonlinearity, in which electrons are forced to emit radiation by an incident pump beam but in a manner quite different from that of a conventional laser.

75.6.1 Raman Lasers

In Raman scattering, a pump photon of frequency ν_p is incident on a molecule or solid with vibrational modes of frequency f_v . After scattering, the photon has frequency $\nu_s = \nu_p - f_v$, which is lower than that of the incident photon because some of the photon's energy was converted into vibrational energy. This process occurs spontaneously with low efficiency, but at sufficiently high incident intensity, stimulated emission of the scattered light can occur, making the process more efficient. The gain (fractional increase per unit length) of the scattered "signal" light is proportional to the intensity of the incident "pump" light and is described by a third-order nonlinear process (Sect. 76.5.1). To make a Raman laser, the gain medium is placed between mirrors with high reflectivity at the signal frequency ν_s and high transmission at the pump frequency ν_p . The pump beam comes in along the cavity axis from a separate laser. Optical fiber is an ideal medium for a CW Raman laser because of its good light confinement (high intensity) over a long path length [75]. Typical frequency shifts for fluoride glass fiber are 550–650 cm^{-1} (16.5–19.5 THz), while for phosphosilicate glass, the shift is as high as 1330 cm^{-1} (≈ 40 THz). The conversion efficiency in a fiber can be so high that cascaded Raman shifts are possible, where the first-order Raman shift becomes the pump for the second-order Raman shift, and so on, up to six to seven orders [76].

Raman conversion can also be accomplished in bulk crystals, especially diamond, which has a high Raman gain and excellent thermal properties. CW Raman lasing in diamond has been achieved with a pump threshold of 11 W at 1064 nm [77].

75.6.2 Optical Parametric Oscillators

In an optical parametric oscillator (OPO), a high-intensity pump beam of frequency ν_p incident on a crystal inside an optical resonator creates two additional optical beams, a signal beam of frequency ν_s and an idler beam of frequency ν_i [78, 79]. There is no physical distinction between signal and idler, but by convention the signal is the higher of the two frequencies. This three-wave mixing process is mediated by the second-order nonlinear susceptibility $\chi^{(2)}$ of the crystal, which is nonzero only for crystals that lack inversion sym-

metry (Sect. 76.3). The signal light originates from quantum fluctuations (optical parametric fluorescence), with no need to seed the oscillator with an external signal. The optical cavity can be resonant with only ν_s (singly resonant oscillator – SRO) or with both ν_s and ν_i (doubly resonant oscillator – DRO), the latter having a lower pump threshold for lasing.

An important requirement for efficient parametric amplification is that both energy and crystal momentum be conserved, a condition known as phase matching (Sect. 76.2.2). In a single crystal, this can be accomplished by varying the angle of a birefringent crystal (critical phase matching) or varying the temperature of the crystal at fixed angle (noncritical phase matching). An alternative to these perfect phase matching schemes is quasi-phase-matching (QPM), in which the nonlinear crystal is periodically modified in the direction of light propagation. In this scheme, the accumulated phase mismatch in one section is reversed in the next section, giving an average conversion efficiency somewhat smaller than for perfect phase matching, but still good. This approach has the advantage of allowing more flexibility in the choice of crystal axis and polarization, so a higher value of $\chi^{(2)}$ may be used. A commonly used QPM material with high $\chi^{(2)}$ is periodically poled lithium niobate (LiNbO_3) or PPLN [80].

75.6.3 Frequency Conversion

Two other parametric processes that depend on $\chi^{(2)}$ are second harmonic generation (SHG), outlined in Sect. 76.3.2, and difference frequency generation (DFG), outlined in Sect. 76.3.4. Phase matching is required for both of these. In SHG (also known as frequency doubling), high-intensity light at frequency ν_p is incident on a crystal, resulting in a newly generated lightwave at frequency $2\nu_p$. Efficient SHG requires high incident intensity, which tends to be naturally available in pulsed operation. For CW operation, the nonlinear crystal can be located inside a laser cavity, to take advantage of the high intracavity intensity there [81], or inside a separate resonator tuned to the harmonic wavelength [82]. An important example is frequency doubling of the Nd:YAG laser ($\lambda = 1064$ nm) to green light at 532 nm [83], which has played a large role in advancing the technology of Ti:sapphire lasers (Sect. 75.2.5).

The difference-frequency generation process is similar to that of the OPO, except that two strong beams at frequencies ν_p and ν_s are incident on the crystal, rather than just one at ν_p . A third beam at $\nu_i = \nu_p - \nu_s$ is generated, which, in spite of being labeled the "idler", is actually the desired output. DFG is often used to generate mid-IR light from near-IR lasers. For example, tunable coherent light in the range 6.4–7.5 μm has been generated by mixing a Tm fiber laser at 2010 nm with a Yb-fiber-pumped OPO in orientation-patterned GaAs [84]. DFG can also be used to generate THz

radiation, using two lasers with closely spaced frequencies, incident on a semiconductor.

75.6.4 High Harmonic Generation

High harmonic generation (HHG) is of interest as a coherent source of extreme ultraviolet (XUV, 30–100 nm) and soft X-ray (0.2–30 nm) radiation and is generated by focusing intense ($\approx 10^{14}$ W/cm²) femtosecond laser pulses on a gaseous target. This process involves an extreme (nonperturbative) atom–laser interaction, in which the electric field of the pump light is comparable to the Coulomb field of the atom. The light generation process can be understood as occurring in three steps. First, an electron in the atom's bound state tunnels through the potential barrier that has been lowered by the strong laser field, freeing the electron from the atom. Second, the electron is accelerated by the laser field, first away from the parent ion and then back to it when the laser field reverses its direction in the second half-cycle. Third, the electron recombines with the ion, releasing the kinetic energy it has acquired and the binding energy as an optical pulse. Since this process repeats every half-cycle of the fundamental field, it gives rise to a series of attosecond pulses that create a harmonic spectrum going up to very high order [85]. The photon energy of the maximum harmonic component scales with pump intensity I and wavelength λ as $h\nu_{\max} \propto I\lambda^2$. This allows table-top generation of X-ray pulses in the few nm region and is a more accessible technology for many researchers than the use of large free electron facilities. Although HHG naturally results in a pulse train, single attosecond pulses can be obtained in a number of ways by careful control of the spectral phase [86]. Thus, HHG not only allows table-top access to these short wavelengths but also opens the door to the optical investigation of phenomena on an attosecond timescale.

Abstract

Nonlinear optics is concerned with the propagation of intense beams of light through a material system. The optical properties of the medium can be modified by the intense light beam, leading to new processes not present in a material that responded linearly to an applied optical field. These processes can lead to the modification of the spectral, spatial, or polarization properties of the light beam or the creation of new frequency components. More complete accounts of nonlinear optics including the origin of optical nonlinearities can be found in [1–4].

Both the Gaussian and MKS system of units are commonly used in nonlinear optics. Thus, we have chosen to express the equations in this chapter in both the Gaussian and MKS systems. Each equation can be interpreted in the MKS system as written or in the Gaussian system by omitting the prefactors (e.g., $1/4\pi\epsilon_0$) that appear in square brackets at the beginning of the expression on the right-hand-side of the equation.

Keywords

nonlinear refractive index · stimulate Brillouin scattering · nonlinear susceptibility · difference-frequency generation · nonlinear polarization

76.1 Nonlinear Susceptibility

In linear optics it is customary to describe the response of a material in terms of a macroscopic polarization $\tilde{\mathbf{P}}$ (i.e., dipole moment per unit volume) that is linearly related to the applied electric field $\tilde{\mathbf{E}}$ through the linear susceptibility $\chi^{(1)}$. In order to extend the relationship between $\tilde{\mathbf{P}}$ and $\tilde{\mathbf{E}}$ into the nonlinear regime, the polarization is expanded in a power series of the electric field strength. We express this relationship mathematically by first decomposing the field and the polarization into their frequency components such that

$$\tilde{\mathbf{E}}(\mathbf{r}, t) = \sum_l \mathbf{E}(\mathbf{r}, \omega_l) e^{-i\omega_l t}, \quad (76.1)$$

$$\tilde{\mathbf{P}}(\mathbf{r}, t) = \sum_l \mathbf{P}(\mathbf{r}, \omega_l) e^{-i\omega_l t}, \quad (76.2)$$

where the summations are performed over both positive and negative frequencies. The reality of $\tilde{\mathbf{E}}$ and $\tilde{\mathbf{P}}$ is then assured by requiring that $\mathbf{E}(\mathbf{r}, \omega_l) = \mathbf{E}^*(\mathbf{r}, -\omega_l)$ and $\mathbf{P}(\mathbf{r}, \omega_l) = \mathbf{P}^*(\mathbf{r}, -\omega_l)$. In this case, the general expression for the Cartesian component i of the polarization at frequency ω_σ is given by

$$\begin{aligned} P_i(\omega_\sigma) = [\epsilon_0] & \left[\sum_j \chi_{ij}^{(1)}(\omega_\sigma) E_j(\omega_\sigma) \right. \\ & + \sum_{jk} \sum_{(mn)} \chi_{ijk}^{(2)}(\omega_\sigma; \omega_m, \omega_n) \\ & \times E_j(\omega_m) E_k(\omega_n) \\ & + \sum_{jkl} \sum_{(mno)} \chi_{ijkl}^{(3)}(\omega_\sigma; \omega_m, \omega_n, \omega_o) \\ & \left. \times E_j(\omega_m) E_k(\omega_n) E_l(\omega_o) + \dots \right], \quad (76.3) \end{aligned}$$

where $ijkl$ refer to field components, and the notation (mn) , for example, indicates that the summation over n and m should be performed such that $\omega_\sigma = \omega_m + \omega_n$ is held constant. Inspection of Eq. (76.3) shows that the $\chi^{(n)}$ can be required to satisfy intrinsic permutation symmetry, i.e., the Cartesian components and the corresponding frequency components [e.g., (j, ω_j) but not (i, ω_σ)] associated with the applied fields may be permuted without changing the value of the susceptibility. For example, for the second-order susceptibility,

$$\chi_{ijk}^{(2)}(\omega_\sigma; \omega_m, \omega_n) = \chi_{ikj}^{(2)}(\omega_\sigma; \omega_n, \omega_m). \quad (76.4)$$

If the medium is lossless at all the field frequencies taking part in the nonlinear interaction, then the condition of full permutation symmetry is necessarily valid. This condition states that the pair of indices associated with the Cartesian component and the frequency of the nonlinear polarization

[i.e., (i, ω_σ)] may be permuted along with the pairs associated with the applied field components. For example, for the second-order susceptibility, this condition implies that

$$\chi_{ijk}^{(2)}(\omega_\sigma; \omega_m, \omega_n) = \chi_{kji}^{(2)}(-\omega_n; \omega_m, -\omega_\sigma). \quad (76.5)$$

If full permutation symmetry holds, and in addition all the frequencies of interest are well below any of the transition frequencies of the medium, the $\chi^{(n)}$ are invariant upon free permutation of all the Cartesian indices. This condition is known as the Kleinman symmetry condition.

76.1.1 Tensor Properties

The spatial symmetry properties of a material can be used to predict the tensor nature of the nonlinear susceptibility. For example, for a material that possesses inversion symmetry, all the elements of the even-ordered susceptibilities must vanish (i.e., $\chi^{(n)} = 0$ for n even). The number of independent elements of the nonlinear susceptibility for many materials can be substantially fewer than the total number of elements. For example, in general, $\chi^{(3)}$ consists of 81 elements, but for the case of isotropic media such as gases, liquids, and glasses, only 21 elements are nonvanishing, and only three of these are independent. The nonvanishing elements consist of the following types: $\chi_{iijj}^{(3)}$, $\chi_{ijij}^{(3)}$, and $\chi_{ijji}^{(3)}$, where $i \neq j$. In addition, it can be shown that

$$\chi_{iiii}^{(3)} = \chi_{iijj}^{(3)} + \chi_{ijij}^{(3)} + \chi_{ijji}^{(3)}. \quad (76.6)$$

76.1.2 Nonlinear Refractive Index

For many materials, the refractive index n is intensity-dependent such that

$$n = n_0 + n_2 I, \quad (76.7)$$

where n_0 is the linear refractive index, n_2 is the nonlinear refractive index coefficient, and $I = [4\pi\epsilon_0]n_0c|E|^2/2\pi$ is the intensity of the optical field. For the case of a single, linearly polarized light beam traveling in an isotropic medium or along a crystal axis of a cubic material, n_2 is related to $\chi^{(3)}$ by

$$n_2 = \left[\frac{1}{16\pi^2\epsilon_0} \right] \frac{12\pi^2}{n_0^2 c} \chi_{iiii}^{(3)}(\omega; \omega, \omega, \omega, -\omega). \quad (76.8)$$

For the common situation in which n_2 is measured in units of cm^2/W , and $\chi^{(3)}$ is measured in Gaussian units, the relation becomes

$$n_2 \left(\frac{\text{cm}^2}{\text{W}} \right) = \frac{12\pi^2 \times 10^7}{n_0^2 c} \chi_{iiii}^{(3)}(\omega; \omega, \omega, \omega, -\omega). \quad (76.9)$$

There are various physical mechanisms that can give rise to a nonlinear refractive index. For the case of induced molecular orientation in CS₂, $n_2 = 3 \times 10^{-14} \text{ cm}^2/\text{W}$. If the contribution to the nonlinear refractive index is electronic in nature (e.g., glass), then $n_2 \approx 2 \times 10^{-16} \text{ cm}^2/\text{W}$.

76.1.3 Quantum Mechanical Expression for $\chi^{(n)}$

The general quantum mechanical perturbation expression for the $\chi^{(n)}$ in the nonresonant limit is

$$\begin{aligned} \chi_{i_0 \dots i_n}^{(n)}(\omega_\sigma; \omega_1, \dots, \omega_n) &= \left[\frac{1}{\varepsilon_0} \right] \frac{N}{\hbar^n} \mathcal{P}_F \sum_{g a_1 \dots a_n} \rho_0(g) \\ &\times \frac{1}{(\omega_{a_1 g} - \omega_1 - \dots - \omega_n)} \\ &\times \frac{\mu_{g a_1}^{i_0} \mu_{a_1 a_2}^{i_1} \dots \mu_{a_{n-1} a_n}^{i_{n-1}} \mu_{a_n g}^{i_n}}{(\omega_{a_2 g} - \omega_2 - \dots - \omega_n) \dots (\omega_{a_n g} - \omega_n)}, \end{aligned} \quad (76.10)$$

where $\omega_\sigma = \omega_1 + \dots + \omega_n$, N is the density of atoms or molecules that compose the material, $\rho_0(g)$ is the probability that the atomic or molecular population is initially in the state g in thermal equilibrium, $\mu_{a_1 a_2}^{i_1}$ is the i_1 -th Cartesian component of the $(a_1 a_2)$ dipole matrix element, $\omega_{a_1 g}$ is the transition frequency between the states a_1 and g , and \mathcal{P}_F is the full permutation operator that is defined such that the expression that follows it is to be summed over all permutations of the pairs (i_0, ω_σ) , $(i_1, \omega_1) \dots (i_n, \omega_n)$ and divided by the number of permutations of the input frequencies. Thus, the full expression for $\chi^{(2)}$ consists of six terms and that for $\chi^{(3)}$ consists of 24 terms. (Under conditions of resonant excitation, relaxation phenomena must be included in the treatment, and the density matrix formalism must be used [4]. The resulting equation for the nonlinear susceptibility is then more complicated.)

In the limit in which the frequencies of all the fields are much smaller than any resonance frequency of the medium, the value of $\chi^{(n)}$ can be estimated to be

$$\chi^{(n)} \approx \left[\frac{1}{\varepsilon_0} \right] \left(\frac{2\mu}{\hbar\omega_0} \right)^n N\mu, \quad (76.11)$$

where μ is a typical value for the dipole transition moment, and ω_0 is a typical value of the transition frequency between the ground state and the lowest-lying excited state. For the case of $\chi^{(3)}$ in Gaussian units, the predicted value is $\chi^{(3)} = 3 \times 10^{-14}$, which is consistent with the measured values of many materials (e.g., glass) in which the nonresonant electronic nonlinearity is the dominant contribution.

76.1.4 Hyperpolarizability

The nonlinear susceptibility relates the macroscopic polarization \mathbf{P} to the electric field strength \mathbf{E} . A related microscopic quantity is the hyperpolarizability, which relates the dipole moment \mathbf{p} induced in a given atom or molecule to the electric field \mathbf{E}^{loc} (the Lorentz local field) that acts on that atom or molecule. The relationship between \mathbf{p} and \mathbf{E}^{loc} is

$$\begin{aligned} p_i(\omega_\sigma) &= [\varepsilon_0] \left[\sum_j \alpha_{ij}(\omega_\sigma) E_j^{\text{loc}}(\omega_\sigma) \right. \\ &+ \sum_{jk} \sum_{(mn)} \beta_{ijk}(\omega_\sigma; \omega_m, \omega_n) E_j^{\text{loc}}(\omega_m) E_k^{\text{loc}}(\omega_n) \\ &+ \sum_{jkl} \sum_{(mno)} \gamma_{ijkl}(\omega_\sigma; \omega_m, \omega_n, \omega_o) \\ &\left. \times E_j^{\text{loc}}(\omega_m) E_k^{\text{loc}}(\omega_n) E_l^{\text{loc}}(\omega_o) + \dots \right], \end{aligned} \quad (76.12)$$

where α_{ij} is the linear polarizability, β_{ijk} is the first hyperpolarizability, and γ_{ijkl} is the second hyperpolarizability. The nonlinear susceptibilities and hyperpolarizabilities are related by the number density of molecules N and by local-field factors, which account for the fact that the field \mathbf{E}^{loc} that acts on a typical molecule is not, in general, equal to the macroscopic field \mathbf{E} . Under many circumstances, it is adequate to relate \mathbf{E}^{loc} to \mathbf{E} through use of the Lorentz approximation

$$\mathbf{E}^{\text{loc}}(\omega) = \mathbf{E}(\omega) + \left[\frac{1}{4\pi\varepsilon_0} \right] \frac{4\pi}{3} \mathbf{P}(\omega). \quad (76.13)$$

To a good approximation, one often needs to include only the linear contribution to $\mathbf{P}(\omega)$, and thus the local electric field becomes

$$\mathbf{E}^{\text{loc}}(\omega) = \mathcal{L}(\omega) \mathbf{E}(\omega), \quad (76.14)$$

where $\mathcal{L}(\omega) = \{[\varepsilon_0^{-1}]\varepsilon(\omega) + 2\}/3$ is the local field correction factor, and $\varepsilon(\omega)$ is the linear dielectric constant. Since $\mathbf{P}(\omega) = N \mathbf{p}(\omega)$, Eqs. (76.3) and (76.12) through Eq. (76.14) relate the $\chi^{(n)}$ to the hyperpolarizabilities through

$$\chi_{ij}^{(1)}(\omega_\sigma) = \mathcal{L}(\omega_\sigma) N \alpha_{ij}(\omega_\sigma), \quad (76.15)$$

$$\begin{aligned} \chi_{ijk}^{(2)}(\omega_\sigma; \omega_m, \omega_n) &= \mathcal{L}(\omega_\sigma) \mathcal{L}(\omega_m) \mathcal{L}(\omega_n) \\ &\times N \beta_{ijk}(\omega_\sigma; \omega_m, \omega_n), \end{aligned} \quad (76.16)$$

$$\begin{aligned} \chi_{ijkl}^{(3)}(\omega_\sigma; \omega_m, \omega_n, \omega_o) &= \mathcal{L}(\omega_\sigma) \mathcal{L}(\omega_m) \mathcal{L}(\omega_n) \mathcal{L}(\omega_o) \\ &\times N \gamma_{ijkl}(\omega_\sigma; \omega_m, \omega_n, \omega_o). \end{aligned} \quad (76.17)$$

For simplicity, the analysis above ignores the vector character of the interacting fields in calculating $\mathcal{L}(\omega)$. A generalization that does include these effects is given in [5].

76.2 Wave Equation in Nonlinear Optics

76.2.1 Coupled-Amplitude Equations

The propagation of light waves through a nonlinear medium is described by the wave equation

$$\nabla^2 \tilde{\mathbf{E}} - \frac{1}{c^2} \frac{\partial^2 \tilde{\mathbf{E}}}{\partial t^2} = \left[\frac{1}{4\pi\epsilon_0} \right] \frac{4\pi}{c^2} \frac{\partial^2 \tilde{\mathbf{P}}}{\partial t^2}. \quad (76.18)$$

For the case in which $\tilde{\mathbf{E}}$ and $\tilde{\mathbf{P}}$ are given by Eq. (76.1), the field amplitudes associated with each frequency component can be decomposed into their plane wave components such that

$$\begin{aligned} \mathbf{E}(\mathbf{r}, \omega_l) &= \sum_n \mathbf{A}_n(\mathbf{r}, \omega_l) e^{i\mathbf{k}_n \cdot \mathbf{r}}, \\ \mathbf{P}(\mathbf{r}, \omega_l) &= \sum_n \mathbf{P}_n(\mathbf{r}, \omega_l) e^{i\mathbf{k}_n \cdot \mathbf{r}}, \end{aligned} \quad (76.19)$$

where $k_n = n(\omega_l)\omega_l/c$ is the magnitude of the wave-vector \mathbf{k}_n . The amplitudes \mathbf{A}_n and \mathbf{P}_n are next decomposed into vector components whose linear optical properties are such that the polarization associated with them does not change as the field propagates through the material. For example, for a uniaxial crystal these eigenpolarizations could correspond to the ordinary and extraordinary components. In order to describe the propagation and the nonlinear coupling of these eigenpolarizations, the vector field amplitudes are expressed as

$$\begin{aligned} \mathbf{A}_n(\mathbf{r}, \omega_l) &= \hat{\mathbf{u}}_{ln} A_n(\mathbf{r}, \omega_l), \\ \mathbf{P}_n(\mathbf{r}, \omega_l) &= \hat{\mathbf{u}}_{ln} P_n(\mathbf{r}, \omega_l), \end{aligned} \quad (76.20)$$

where $\hat{\mathbf{u}}_{ln}$ is the unit vector associated with the eigenpolarization of the spatial mode n at frequency ω_l . If the fields are assumed to travel along the z -direction, and the slowly-varying amplitude approximation $\partial^2 A_n / \partial z^2 \ll 2k_n \partial A_n / \partial z$ is made, the change in the amplitude of the field as it propagates through the nonlinear medium with no linear absorption is described by the differential equation

$$\frac{dA_n(\omega_l)}{dz} = \pm \left[\frac{1}{4\pi\epsilon_0} \right] \frac{i2\pi\omega_l}{n(\omega_l)c} P_n^{\text{NL}}(\omega_l), \quad (76.21)$$

where P_n^{NL} is the nonlinear contribution to the polarization amplitude P_n , $n(\omega_l)$ is the linear refractive index at frequency ω_l , and the plus (minus) sign indicates propagation in the positive (negative) z -direction. Sections 76.3 and 76.4 give expressions for the P_n^{NL} for various second- and third-order nonlinear optical processes. Equation (76.21) is used to determine the set of coupled-amplitude equations describing a particular nonlinear process. For example, for the case of sum-frequency generation, the two fields of frequency

ω_1 and ω_2 are combined through second-order nonlinear interaction to create a third wave at frequency $\omega_3 = \omega_1 + \omega_2$. Assuming full permutation symmetry, the amplitudes of the nonlinear polarization for each of the waves are

$$P^{\text{NL}}(z, \omega_1) = [\epsilon_0] 2\chi_{\text{eff}}^{(2)} A(z, \omega_3) A^*(z, \omega_2) e^{-i\Delta k z}, \quad (76.22)$$

$$P^{\text{NL}}(z, \omega_2) = [\epsilon_0] 2\chi_{\text{eff}}^{(2)} A(z, \omega_3) A^*(z, \omega_1) e^{-i\Delta k z}, \quad (76.23)$$

$$P^{\text{NL}}(z, \omega_3) = [\epsilon_0] 2\chi_{\text{eff}}^{(2)} A(z, \omega_1) A(z, \omega_2) e^{i\Delta k z}, \quad (76.24)$$

where $\Delta k = k_1 + k_2 - k_3$ is the wave-vector mismatch (Sect. 76.2.2), and $\chi_{\text{eff}}^{(2)}$ is given by

$$\chi_{\text{eff}}^{(2)} = \sum_{ijk} \chi_{ijk}^{(2)} (\hat{\mathbf{u}}_1^*)_i (\hat{\mathbf{u}}_2)_j (\hat{\mathbf{u}}_3)_k, \quad (76.25)$$

where $(\hat{\mathbf{u}}_i)_i$ is the i -th Cartesian component of $\hat{\mathbf{u}}_i$. For simplicity, the subscripts on each of the field amplitudes have been dropped, since only one spatial mode at each frequency contributed. The resulting coupled-amplitude equations are

$$\frac{dA(\omega_1)}{dz} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_1 \chi_{\text{eff}}^{(2)}}{n(\omega_1)c} A(\omega_3) A^*(\omega_2) e^{-i\Delta k z}, \quad (76.26)$$

$$\frac{dA(\omega_2)}{dz} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_2 \chi_{\text{eff}}^{(2)}}{n(\omega_2)c} A(\omega_3) A^*(\omega_1) e^{-i\Delta k z}, \quad (76.27)$$

$$\frac{dA(\omega_3)}{dz} = \left[\frac{1}{4\pi} \right] \frac{i4\pi\omega_3 \chi_{\text{eff}}^{(2)}}{n(\omega_3)c} A(\omega_1) A(\omega_2) e^{i\Delta k z}. \quad (76.28)$$

76.2.2 Phase Matching

For many nonlinear optical processes (e.g., harmonic generation) it is important to minimize the wave-vector mismatch in order to maximize the efficiency. For example, if the field amplitudes $A(\omega_1)$ and $A(\omega_2)$ are constant and $\chi_{\text{eff}}^{(2)}$ does not depend upon z , the solution to Eq. (76.28) yields for the output intensity

$$\begin{aligned} I(L, \omega_3) &= \left[\frac{1}{64\pi^3 \epsilon_0} \right] \\ &\times \frac{32\pi^3 \left[\chi_{\text{eff}}^{(2)} \right]^2 \omega_3^2 I(\omega_1) I(\omega_2) L^2}{n(\omega_1) n(\omega_2) n(\omega_3) c^3} \\ &\times \text{sinc}^2(\Delta k L / 2), \end{aligned} \quad (76.29)$$

in terms of $\text{sinc } x = (\sin x)/x$, where $I(L, \omega_3) = (4\pi\epsilon_0)n(\omega_3)c|A(L, \omega_3)|^2/2\pi$, and $I(\omega_1)$ and $I(\omega_2)$ are the corresponding input intensities. Clearly, the effect of the wave-vector mismatch is to reduce the efficiency of the generation of the sum-frequency wave. The maximum propagation distance over which efficient nonlinear coupling can

occur is given by the coherence length

$$L_c = \frac{2}{\Delta k}. \quad (76.30)$$

As a result of the dispersion in the linear refractive index that occurs in all materials, achieving phase matching over typical interaction lengths (e.g., 5 mm) is nontrivial. For the case in which the nonlinear material is birefringent, it is sometimes possible to achieve phase matching by insuring that the interacting waves possess some suitable combination of ordinary and extraordinary polarization. Other techniques for achieving phase matching include quasi-phase matching [5], which relies on a $\chi_{\text{eff}}^{(2)}$ that varies in the propagation direction z , and the use of the mode dispersion in waveguides [6].

However, the phase-matching condition is automatically satisfied for certain nonlinear optical processes, such as two-photon absorption (Sect. 76.4.6) and Stokes amplification in stimulated Raman scattering (Sect. 76.5.1). One can tell when the phase-matching condition is automatically satisfied by examining the frequencies that appear in the expression for the nonlinear susceptibility. For a nonlinear susceptibility of the sort $\chi^{(3)}(\omega_1; \omega_2, \omega_3, \omega_4)$, the wave-vector mismatch in the corresponding set of coupled differential equations is given, in general, by $\Delta \mathbf{k} = \mathbf{k}_2 + \mathbf{k}_3 + \mathbf{k}_4 - \mathbf{k}_1$. Thus, for the example of Stokes amplification in stimulated Raman scattering, the nonlinear susceptibility is given by $\chi^{(3)}(\omega_1; \omega_1, \omega_0, -\omega_0)$, where ω_0 (ω_1) is the frequency of the pump (Stokes) wave, and, consequently, the wave-vector mismatch vanishes identically.

76.2.3 Manley–Rowe Relations

Under conditions of full permutation symmetry, there is no flow of power from the electromagnetic fields to the medium, and thus the total power flow of the fields is conserved. The flow of energy among the fields can be described by the Manley–Rowe relations. For example, for the case of sum-frequency generation, one can deduce from Eqs. (76.26)–(76.28) that

$$\frac{d}{dz} \left[\frac{I(\omega_1)}{\omega_1} \right] = \frac{d}{dz} \left[\frac{I(\omega_2)}{\omega_2} \right] = -\frac{d}{dz} \left[\frac{I(\omega_3)}{\omega_3} \right]. \quad (76.31)$$

The expressions in square brackets are proportional to the flux of photons per unit area per unit time and imply that the creation of a photon at ω_3 must be accompanied by the annihilation of photons at both ω_1 and ω_2 . Similar relations can be formulated for other nonlinear optical processes that are governed by a nonlinear susceptibility that satisfies full permutation symmetry. Since this behavior occurs at the photon level, nonlinear optical processes can lead to the generation

of light fields that have esoteric quantum statistical properties (Chaps. 82 and 84).

A nonlinear optical process that satisfies the Manley–Rowe relations is called a parametric process. Conversely, a process for which field energy is not conserved, and thus Manley–Rowe relations cannot be formulated, is said to be nonparametric. Thus, parametric processes are described by purely real $\chi^{(n)}$, whereas nonparametric processes are described by complex $\chi^{(n)}$.

76.2.4 Pulse Propagation

If the optical field consists of ultrashort (< 100 ps) pulses, it is more convenient to work with the temporally varying amplitude, rather than with the individual frequency components. Thus, for a linearly polarized plane wave pulse propagating along the z -axis, the field is decomposed into the product of a slowly varying amplitude $A(z, t)$ and a rapidly varying oscillatory term such that

$$\tilde{E}(\mathbf{r}, t) = A(z, t) e^{i(k_0 z - \omega_0 t)} + \text{c.c.}, \quad (76.32)$$

where $k_0 = n_0 \omega_0 / c$. For a pulse propagating in a material with an intensity-dependent refractive index, the propagation can be described by the nonlinear Schrödinger equation

$$\frac{\partial A}{\partial z} + \frac{i\beta_2}{2} \frac{\partial^2 A}{\partial \tau^2} = i\gamma |A|^2 A, \quad (76.33)$$

where $\beta_2 = (d^2 k / d\omega^2)|_{\omega=\omega_0}$ is the group velocity dispersion parameter, $\tau = t - z/v_g$ is the local time for the pulse, $v_g = [(dk/d\omega)|_{\omega=\omega_0}]^{-1}$ is the group velocity, and $\gamma = [4\pi\epsilon_0]n_2 n_0 \omega_0 / 2\pi$ is the nonlinear refractive index parameter.

76.3 Second-Order Processes

Second-order nonlinear optical processes occur as a consequence of the second term in expression Eq. (76.3), i.e., processes whose strength is described by $\chi^{(2)}(\omega_\sigma; \omega_m, \omega_n)$. These processes entail the generation of a field at frequency $\omega_\sigma = \omega_m + \omega_n$ in response to applied fields at (positive and/or negative) frequencies ω_m and ω_n . Several examples of such processes are described in this section.

76.3.1 Sum-Frequency Generation

Sum-frequency generation produces an output field at frequency $\omega_3 = \omega_1 + \omega_2$ for ω_1 and ω_2 both positive. It is useful, for example, for the generation of tunable radiation in the UV

if ω_1 and/or ω_2 are obtained from tunable lasers in the visible range. Sum-frequency generation is described in detail in Sects. 76.2.1–76.2.3.

76.3.2 Second Harmonic Generation

Second harmonic generation is routinely used to convert the output of a laser to a higher frequency. It is described by $\chi^{(2)}(2\omega; \omega, \omega)$. Let η be the power conversion efficiency from frequency ω to 2ω . Assuming that phase matching is perfect, and the pump wave has the fundamental frequency ω , a derivation analogous to that for Eq. (76.29) yields

$$\eta = \tanh^2(z/l), \quad (76.34)$$

where the characteristic conversion length l is given by

$$l = [4\pi] \frac{c \sqrt{n(\omega)n(2\omega)}}{4\pi\omega\chi^{(2)}|A_1(0)|}. \quad (76.35)$$

Note that the conversion efficiency asymptotically approaches unity. In practice, conversion efficiencies exceeding 80% can be achieved.

76.3.3 Parametric Amplification and Oscillation

Under the assumption that the pump at ω_3 in a second-order process is undepleted and strong, the system of coupled differential Eqs. (76.26) and (76.27) can be solved analytically. The solution for $A(\omega_j) = A_j$ and up to a global phase factor is [4]

$$A_{1,2}(z) = A_{1,2}(0) \left(\cosh gz + i \frac{\Delta k}{2g} \sinh gz \right) - i \sqrt{\frac{n_{2,1}\omega_{1,2}}{n_{1,2}\omega_{2,1}}} \frac{\kappa}{g} \frac{A_3}{|A_3|} A_{2,1}^*(0) \sinh gz, \quad (76.36)$$

where the gain κ for conditions of perfect phase matching is given by

$$\kappa^2 = \left[\frac{1}{16\pi^2} \right] \frac{16\pi^2 [\chi^{(2)}]^2 \omega_1^2 \omega_2^2}{k_1 k_2 c^4} |A_3|^2, \quad (76.37)$$

and the generalized gain for arbitrary phase matching is

$$g^2 = \kappa^2 - (\Delta k/2)^2. \quad (76.38)$$

Equation (76.36) shows simultaneous (and exponential) amplification of the two fields A_1 and A_2 , often called signal and idler. The process is referred to as parametric amplification. It is a direct consequence of the Manley–Rowe

relations, as described above in Sect. 76.2.3. Because of the relation $\omega_3 = \omega_1 + \omega_2$, the annihilation of an ω_3 photon must be accompanied by the simultaneous creation of photons ω_1 and ω_2 . From Eq. (76.36) it is apparent that the intensity of the generated fields depends on the phase relations among the three incoming fields, and the amplification is, therefore, a phase sensitive process.

An optical parametric oscillator can be constructed by placing the nonlinear optical material inside an optical resonator that provides feedback at ω_1 and/or ω_2 . When such a device is excited by a wave at ω_3 , it can produce output frequencies ω_1 and ω_2 that satisfy $\omega_1 + \omega_2 = \omega_3$. Optical parametric oscillators are of considerable interest as sources of broadly tunable radiation [7].

76.3.4 Difference-Frequency Generation

Difference-frequency generation can be used to create light in the infrared and far infrared by generating the difference frequency $\omega_2 = \omega_3 - \omega_1$ (where ω_3 and ω_1 are positive, and $\omega_3 > \omega_1$) of two incident lasers. Consider the case in which a strong (undepleted) pump wave at frequency ω_3 and a weak (signal) wave at ω_1 are incident on a nonlinear medium described by $\chi^{(2)}(\omega_2; \omega_3, -\omega_1) = \chi^{(2)}(\omega_1; \omega_3, -\omega_2)$. The amplitude A_3 of the strong wave can be taken as a constant, and Eq. (76.36) describes the solution to a system of coupled differential equations. Since there is no incident idler field, we have $A_2(0) = 0$, and the solution reduces to

$$A_1(z) = A_1(0) \left(\cosh gz + \frac{i\Delta k}{2g} \sinh gz \right), \quad (76.39)$$

$$A_2(z) = -i \sqrt{\frac{n_1\omega_2}{n_2\omega_1}} \frac{A_3}{|A_3|} A^*(0, \omega_1) \frac{\kappa}{g} \sinh gz. \quad (76.40)$$

Equation (76.40) describes the spatial growth of the difference-frequency signal.

76.3.5 Two-Mode Squeezing

To describe the quantum mechanical properties of light–matter interactions, one has to quantize the electromagnetic fields participating in the nonlinear interaction. However, the Heisenberg equations of motion of the respective field operators are very similar to their classical counterparts from Eqs. (76.26)–(76.28), and one can just replace $A_j \rightarrow \text{const.} \times \sqrt{\omega_j/n_j} \hat{a}_j$ and A_j^* by the Hermitian conjugate of this operator. Note that the photon annihilation operators \hat{a}_j are defined per field mode, and the proportionality factor depends on the quantization volume. Note further that the commutation relation $[\hat{a}_j, \hat{a}_j^\dagger] = \delta_{j,l}$ is preserved upon propagation of the quantum field. For an undepleted and strong pump, the so-

lution to the Heisenberg equations of motion is in analogy to Eq. (76.36) the Bogoliubov transformation [8]

$$\hat{a}_{1,2}(z) = u\hat{a}_{1,2}(0) + v\hat{a}_{2,1}^\dagger(0), \quad (76.41)$$

with the coefficients

$$u = \cosh gz + i\frac{\Delta k}{2g} \sinh gz \quad (76.42)$$

$$v = -ie^{i\phi_3} \frac{\kappa}{g} \sinh gz, \quad (76.43)$$

where ϕ_3 is the phase of the pump wave, and g as well as κ are defined as in Eqs. (76.38) and (76.37), respectively. Note that $|u|^2 - |v|^2 = 1$, which ensures unitarity of the amplification process. This transformation leads to a squeezing of the quadratures, as demonstrated in the following.

The two-mode quadratures of the electromagnetic field are defined by $\hat{x}_\pm = [\hat{a}_1 \pm \hat{a}_1^\dagger + \hat{a}_2 \pm \hat{a}_2^\dagger]/\sqrt{\pm 8}$. They correspond to the quantum analog of the real and imaginary parts of the electric fields. From Eq. (76.41) with $\phi_3 = \pi/2$ and $\Delta k = 0$ (for phase matching), we find that the two-mode quadratures are amplified or deamplified according to [9]

$$\hat{x}_\pm(z) = e^{\pm\kappa z} \hat{x}_\pm(0). \quad (76.44)$$

Hence, the variances $\Delta^2 x_\pm = \langle (\hat{x}_\pm - \langle \hat{x}_\pm \rangle)^2 \rangle$ of these quadrature operators can be written as $\Delta^2 x_\pm(z) = e^{\pm 2\kappa z} \Delta^2 x_\pm(0)$ and are amplified and suppressed, respectively. Since the variances correspond to the intrinsic noise of the electric fields, the squeezing process can lead to its suppression. Therefore, squeezed light is used to increase the sensitivity of interferometers and gives a sensitivity below the shot-noise level. Single-mode squeezing and the associated squeezing operator are discussed in Chaps. 82 and 84.

76.3.6 Spontaneous Parametric Down-Conversion

With the results from the preceding section, it is possible to look at the squeezing of vacuum input states and the limit of a small coupling κz , which leads to spontaneous parametric down-conversion (SPDC). In this process, a pump photon is spontaneously converted into one signal and one idler photon, without the process being seeded by input fields. The two generated photons always appear pairwise and are, therefore, often used as a source of single photons. The detection of an idler photon implies that there is a single photon in the signal field.

For any uncorrelated input state, it is easy to show with Eq. (76.41) and the commutation relations that the expectation value $n_j = \langle \hat{a}_j^\dagger \hat{a}_j \rangle$ of the photon number is

$$n_{1,2}(z) = |u|^2 n_{1,2}(0) + |v|^2 [n_{2,1}(0) + 1]. \quad (76.45)$$

Unlike for the case of its classical counterpart, the output photon number $n_{1,2}(z) = |v|^2$ is nonvanishing even for a vacuum input $n_{1,2}(0) = 0$ because of the noncommutativity of the photon creation and annihilation operators. This means that one can not only squeeze input light, but also the vacuum itself. Moreover, a weak nonlinear interaction or a weak pump field leads to spontaneous emission. In this case, $\kappa \ll \Delta k/2$ and Eq. (76.45) reduces to

$$n_{1,2}^{\text{SPDC}}(L) = \kappa^2 L^2 \text{sinc}^2(\Delta k L/2), \quad (76.46)$$

for a bulk crystal of length L . A more sophisticated treatment shows that there are not only photons spontaneously emitted, but they are strongly correlated. The photons are always generated in pairs and share common properties, a feature that is called entanglement. There have been numerous experimental verifications of polarization entanglement, but also entanglement of continuous variables such as energy and time or transverse position and momentum, discussed in Chap. 84. Position-momentum entanglement is a direct consequence of the shape of the crystal and the pump beam in SPDC. The two-photon wave function $\psi(\mathbf{q}_1, \mathbf{q}_2)$ of signal and idler photons with a transverse momentum \mathbf{q}_1 and \mathbf{q}_2 , respectively, is proportional to [10]

$$\psi(\mathbf{q}_1, \mathbf{q}_2) \propto A_3(\mathbf{q}_1 + \mathbf{q}_2) e^{i\Delta k L/2} \text{sinc}(\Delta k L/2), \quad (76.47)$$

with $\Delta k = k_3(\mathbf{q}_1 + \mathbf{q}_2) - k_1(\mathbf{q}_1) - k_2(\mathbf{q}_2)$. Here, k_j corresponds to the longitudinal component of the respective wave vector. $A_3(\mathbf{q}_3)$ is the angular distribution of the pump field. For degenerate down-conversion ($\omega_1 = \omega_2$), we find in the paraxial regime that $\Delta k = \lambda_3(\mathbf{q}_1 - \mathbf{q}_2)^2/(4\pi)$. For a plane wave pump, $A_3(\mathbf{q}_3)$ becomes very narrow and the transverse wave vectors become anticorrelated, which is implied by momentum conservation. The squared modulus of Eq. (76.47) is proportional to the coincidence count rate of signal and idler photons with the respective momenta.

With a Fourier transform, the two-photon wave function from Eq. (76.47) is transformed into position space, and it may reveal that the transverse positions are correlated. The combination of position correlation and momentum anticorrelation can lead to the apparent violation of a Heisenberg uncertainty relation for a linear combination of the two positions and momenta, which is a clear witness of continuous-variable entanglement. In fact, a photon pair that is not entangled cannot have correlated positions of the signal and idler photons and simultaneously anticorrelated momenta, as these are two conjugate variables. However, for an entangled photon pair, quantum correlations allow for simultaneous position correlation and momentum anticorrelation [11, 12].

76.3.7 Focused Beams

For conceptual clarity, much of the discussion so far has assumed that the interacting beams are plane waves. In practice, the incident laser beams are often focused into the nonlinear material to increase the field strength within the interaction region and, consequently, to increase the nonlinear response. However, it is undesirable to focus too tightly, because doing so leads to a decrease in the effective length of the interaction region. In particular, if w_0 is the radius of the laser beam at the beam waist, the beam remains focused only over a distance of the order $b = 2\pi w_0^2/\lambda$, where λ is the laser wavelength measured in the nonlinear material. For many types of nonlinear optical processes, the optimal nonlinear response occurs if the degree of focusing is adjusted so that b is several times smaller than the length L of the nonlinear optical material.

76.4 Third-Order Processes

A wide variety of nonlinear optical processes are possible as a result of the nonlinear contributions to the polarization that are third-order in the applied field. These processes are described by $\chi^{(3)}(\omega_\sigma; \omega_m, \omega_n, \omega_o)$ as defined in Eq. (76.3) and can lead not only to the generation of new field components (e.g., third-harmonic generation) but can also result in a field affecting itself as it propagates (e.g., self-phase modulation). Several examples are described in this section.

76.4.1 Third-Harmonic Generation

Assuming full-permutation symmetry, the nonlinear polarization amplitudes for the fundamental and third-harmonic beams are

$$\begin{aligned} \mathcal{P}^{\text{NL}}(z, \omega) &= [\varepsilon_0] 3\chi_{\text{eff}}^{(3)} A(z, 3\omega) [A^*(z, \omega)]^2 e^{-i\Delta k z}, \\ \mathcal{P}^{\text{NL}}(z, 3\omega) &= [\varepsilon_0] \chi_{\text{eff}}^{(3)} [A(z, \omega)]^3 e^{i\Delta k z}, \end{aligned} \quad (76.48)$$

where $\Delta k = 3k(\omega) - k(3\omega)$ and $\chi_{\text{eff}}^{(3)}$ is the effective third-order susceptibility for third-harmonic generation and is defined in a manner analogous to the $\chi_{\text{eff}}^{(2)}$ in Eq. (76.25). If the intensity of the fundamental wave is not depleted by the nonlinear interaction, the solution for the output intensity $I(L, 3\omega)$ of the third-harmonic field for a crystal of length L is

$$\begin{aligned} I(L, 3\omega) &= \left[\frac{1}{256\pi^4 \varepsilon_0^2} \right] \frac{48\pi^2 \omega^2 [\chi_{\text{eff}}^{(3)}]^2}{n(3\omega)n(\omega)^3 c^4} \\ &\times I(\omega)^3 L^2 \text{sinc}^2 \left[\frac{\Delta k L}{2} \right], \end{aligned} \quad (76.49)$$

where $I(\omega)$ is the input intensity of the fundamental field. As a result of the typically small value of $\chi_{\text{eff}}^{(3)}$ in crystals, it is generally more efficient to generate the third harmonic by using two $\chi^{(2)}$ crystals in which the first crystal produces second harmonic light, and the second crystal combines the second harmonic and the fundamental beams via sum-frequency generation. It is also possible to use resonant enhancement of $|\chi^{(3)}|$ in gases to increase the efficiency of third-harmonic generation [13].

76.4.2 Self-Phase and Cross-Phase Modulation

The nonlinear refractive index leads to an intensity-dependent change in the phase of the beam as it propagates through the material. If the medium is lossless, the amplitude of a single beam at frequency ω propagating in the positive z -direction can be expressed as

$$A(z, \omega) = A(0, \omega) e^{i\phi^{\text{NL}}(z)}, \quad (76.50)$$

where the nonlinear phase shift $\phi^{\text{NL}}(z)$ is given by

$$\phi^{\text{NL}}(z) = \frac{\omega}{c} n_2 I z, \quad (76.51)$$

and $I = [4\pi\varepsilon_0] n_0 c |A(0, \omega)|^2 / 2\pi$ is the intensity of the laser beam. If two fields at different frequencies ω_1 and ω_2 are traveling along the z -axis, the two fields can affect each other's phase; this effect is known as cross-phase modulation. The nonlinear phase shift $\phi_{1,2}^{\text{NL}}(z)$ for each of the waves is given by

$$\phi_{1,2}^{\text{NL}}(z) = \frac{\omega_{1,2}}{c} n_2 (I_{1,2} + 2I_{2,1}) z. \quad (76.52)$$

For the case of a light pulse, the change in the phase of the pulse inside the medium becomes a function of time. In this case, the solution to Eq. (76.33) shows that in the absence of group-velocity dispersion (GVD) (i.e., $\beta_2 = 0$), the time-varying amplitude $A(z, \tau)$ is of the form of Eq. (76.50), except that the temporal intensity profile $I(\tau)$ replaces the steady-state intensity I in Eq. (76.51). As the pulse propagates through the medium, its frequency becomes time dependent, and the instantaneous frequency shift from the central frequency ω_0 is given by

$$\delta\omega(\tau) = -\frac{\partial\phi^{\text{NL}}(\tau)}{\partial\tau} = -\frac{\omega_0 n_2 z}{c} \frac{\partial I}{\partial t}. \quad (76.53)$$

This time-dependent self-phase modulation leads to a broadening of the pulse spectrum and to a frequency chirp across the pulse.

If the group velocity dispersion parameter β_2 and the nonlinear refractive index coefficient n_2 are of opposite sign, the

nonlinear frequency chirp can be compensated by the chirp due to group velocity dispersion, and Eq. (76.33) admits soliton solutions. For example, the fundamental soliton solution is

$$A(z, t) = \sqrt{\frac{1}{|\gamma L_D|}} \operatorname{sech}\left(\frac{\tau}{\tau_p}\right) e^{-iz/2L_D}, \quad (76.54)$$

where τ_p is the pulse duration, and $L_D = \tau_p^2/\beta_2$ is the dispersion length. As a result of their ability to propagate in dispersive media without changing shape, optical solitons show a great deal of promise in applications such as optical communications and optical switching. For further discussion of optical solitons, see [14].

76.4.3 Four-Wave Mixing

Various types of four-wave mixing processes can occur among different beams. One of the most common geometries is backward four-wave mixing used in nonlinear spectroscopy and optical phase conjugation. In this interaction, two strong counterpropagating pump waves with amplitudes A_1 and A_2 and with equal frequencies $\omega_{1,2} = \omega$ are injected into a nonlinear medium. A weak wave, termed the probe wave, (with frequency ω_3 and amplitude A_3) is also incident on the medium. As a result of the nonlinear interaction among the three waves, a fourth wave with an amplitude A_4 is generated, which is counterpropagating with respect to the probe wave and with frequency $\omega_4 = 2\omega - \omega_3$. For this case, the third-order nonlinear susceptibilities for the probe and conjugate waves are given by $\chi^{(3)}(\omega_{3,4}; \omega, \omega, -\omega_{4,3})$. For constant pump wave intensities and full permutation symmetry, the amplitudes of the nonlinear polarization for the probe and conjugate waves are given by

$$\begin{aligned} P^{\text{NL}}(z, \omega_{3,4}) \\ = \pm[\varepsilon_0]6\chi^{(3)}[(|A_1|^2 + |A_2|^2)A_{3,4} + A_1A_2A_{4,3}^* e^{i\Delta kz}], \end{aligned} \quad (76.55)$$

where $\Delta k = k_1 + k_2 - k_3 - k_4$ is the phase mismatch, which is nonvanishing when $\omega_3 \neq \omega_4$. For the case of optical phase conjugation by degenerate four-wave mixing (i.e., $\omega_3 = \omega_4 = \omega$, and $A_4(L) = 0$), the phase conjugate reflectivity R_{PC} is

$$R_{\text{PC}} = \frac{|A_4(0)|^2}{|A_3(0)|^2} = \tan^2(\kappa L), \quad (76.56)$$

where $\kappa = [1/16\pi^2\varepsilon_0][24\pi^2\omega\chi^{(3)}/(n_0c)^2]\sqrt{I_1I_2}$ and $I_{1,2}$ are the intensities of the pump waves. Phase-conjugate reflectivities greater than unity can be routinely achieved by performing four-wave mixing in atomic vapors or photorefractive media.

76.4.4 Self-Focusing and Self-Trapping

Typically, a laser beam has a transverse intensity profile that is approximately Gaussian. In a medium with an intensity-dependent refractive index, the index change at the center of the beam is different from the index change at the edges of the beam. The gradient in the refractive index created by the beam can allow it to self-focus for $n_2 > 0$. For this condition to be met, the total input power of the beam must exceed the critical power P_{cr} for self-focusing, which is given by

$$P_{\text{cr}} = \frac{\pi(0.61\lambda)^2}{8n_0n_2}, \quad (76.57)$$

where λ is the vacuum wavelength of the beam. For powers much greater than the critical power, the beam can break up into various filaments, each with a power approximately equal to the critical power. For a more extensive discussion of self-focusing and self-trapping, see [15, 16].

76.4.5 Saturable Absorption

When the frequency ω of an applied laser field is sufficiently close to a resonance frequency ω_0 of the medium, an appreciable fraction of the atomic population can be placed in the excited state. This loss of population from the ground state leads to an intensity-dependent saturation of the absorption and the refractive index of the medium (for a more detailed discussion: Chap. 73.3) [4]. The third-order susceptibility as a result of this saturation is given by

$$\chi^{(3)} = \left[\frac{1}{\varepsilon_0}\right] \frac{|\mu|^2 T_1 T_2 \alpha_0 c}{3\pi\omega_0 \hbar^2} \frac{\delta T_2 - i}{[1 + (\delta T_2)^2]^2}, \quad (76.58)$$

where μ is the transition dipole moment, T_1 and T_2 are the longitudinal and transverse relaxation times, respectively (Chap. 72.4.3), α_0 is the line-center weak-field intensity absorption coefficient, and $\delta = \omega - \omega_0$ is the detuning. For the $3s \leftrightarrow 3p$ transition in atomic sodium vapor at 300°C, the nonlinear refractive index $n_2 \approx 10^{-7} \text{ cm}^2/\text{W}$ for a detuning $\delta T_2 = 300$.

76.4.6 Two-Photon Absorption

When the frequency ω of a laser field is such that 2ω is close to a transition frequency of the material, it is possible for two-photon absorption (TPA) to occur. This process leads to a contribution to the imaginary part of $\chi^{(3)}(\omega; \omega, \omega, -\omega)$. In the presence of TPA, the intensity $I(z)$ of a single, linearly polarized beam as a function of propagation distance is

$$I(z) = \frac{I(0)}{1 + \beta I(0)z}, \quad (76.59)$$

where $\beta = [1/16\pi^2\varepsilon_0]24\pi^2\omega \text{Im}[\chi^{(3)}]/(n_0c)^2$ is the TPA coefficient. For wide-gap semiconductors such as ZnSe at 800 nm, $\beta \approx 10^{-8}$ cm/W.

76.4.7 Nonlinear Ellipse Rotation

The polarization ellipse of an elliptically polarized laser beam rotates but retains its ellipticity as the beam propagates through an isotropic nonlinear medium. Ellipse rotation occurs as a result of the difference in the nonlinear index changes experienced by the left-circular and right-circular components of the beam, and the angle θ of rotation is

$$\begin{aligned} \theta &= \frac{1}{2}\Delta n\omega z/c \\ &= \left[\frac{1}{16\pi^2\varepsilon_0} \right] \frac{12\pi^2}{n_0^2c} \chi_{xyyx}^{(3)}(\omega; \omega, \omega, -\omega)(I_+ - I_-)z, \end{aligned} \quad (76.60)$$

where I_{\pm} are the intensities of the circularly polarized components of the beam with unit vectors $\hat{\sigma}_{\pm} = (\hat{x} \pm i\hat{y})/\sqrt{2}$. Nonlinear ellipse rotation is a sensitive technique for determining the nonlinear susceptibility element $\chi_{xyyx}^{(3)}$ for isotropic media and can be used in applications such as optical switching.

76.5 Stimulated Light Scattering

Stimulated light scattering occurs as a result of changes in the optical properties of the material that are induced by the optical field. The resulting nonlinear coupling between different field components is mediated by some excitation (e.g., acoustic phonon) of the material that results in changes in its optical properties. The nonlinearity can be described by a complex susceptibility and a nonlinear polarization that is of third order in the interacting fields. Various types of stimulated scattering can occur. Discussed below are the two processes that are most commonly observed.

76.5.1 Stimulated Raman Scattering

In stimulated Raman scattering (SRS), the light field interacts with a vibrational mode of a molecule. The coupling between the two optical waves can become strong if the frequency difference between them is close to the frequency ω_v of the molecular vibrational mode. If the pump field at ω_0 and another field component at ω_1 are propagating in the same direction along the z -axis, the steady-state nonlinear polarization amplitudes for the two field components are given by

$$P^{\text{NL}}(z, \omega_{0,1}) = [\varepsilon_0]6\chi_{\text{R}}(\omega_{0,1})|A(z, \omega_{1,0})|^2A(z, \omega_{0,1}), \quad (76.61)$$

where $\chi_{\text{R}}(\omega_{0,1}) \equiv \chi^{(3)}(\omega_{0,1}; \omega_{0,1}, \omega_{1,0}, -\omega_{1,0})$, the Raman susceptibility, actually depends only on the frequency difference $\Omega = \omega_0 - \omega_1$ and is given by

$$\chi_{\text{R}}(\omega_{0,1}) = \left[\frac{1}{\varepsilon_0} \right] \frac{N(\partial\alpha/\partial q)_0^2}{6\mu_M} \frac{1}{\omega_v^2 - \Omega^2 \mp 2i\gamma\Omega}, \quad (76.62)$$

where the minus (plus) sign is taken for the ω_0 (ω_1) susceptibility, μ_M is the reduced nuclear mass, and $(\partial\alpha/\partial q)_0$ is a measure of the change of the polarizability of the molecule with respect to a change in the intermolecular distance q at equilibrium. If the intensity of the pump field is undepleted by the interaction with the ω_1 field and is assumed to be constant, the solution for the intensity of the ω_1 field at $z = L$ is given by

$$I(L, \omega_1) = I(0, \omega_1) e^{G_{\text{R}}}, \quad (76.63)$$

where the SRS gain parameter G_{R} is

$$\begin{aligned} G_{\text{R}} &= \left[\frac{1}{16\pi^2\varepsilon_0} \right] 48\pi^2 \frac{\omega_1}{(n_1c)^2} \text{Im}[\chi_{\text{R}}(\omega_1)]I_0L \\ &= g_{\text{R}}I_0L, \end{aligned} \quad (76.64)$$

g_{R} is the SRS gain factor, and I_0 is the input intensity of the pump field. For $\omega_1 < \omega_0$ ($\omega_1 > \omega_0$), the ω_1 field is termed the Stokes (anti-Stokes) field, and it experiences exponential amplification (attenuation). For sufficiently large gains (typically $G_{\text{R}} \gtrsim 25$), the Stokes wave can be seeded by spontaneous Raman scattering and can grow to an appreciable fraction of the pump field. For a complete discussion of the spontaneous initiation of SRS, see [17]. For the case of CS₂, $g_{\text{R}} = 0.024$ cm/MW.

Four-wave mixing processes that couple a Stokes wave having $\omega_1 < \omega_0$ and an anti-Stokes wave having $\omega_2 > \omega_0$, where $\omega_1 + \omega_2 = 2\omega_0$, can also occur [4]. In this case, additional contributions to the nonlinear polarization are present and are characterized by a Raman susceptibility of the form $\chi^{(3)}(\omega_{1,2}; \omega_0, \omega_0, -\omega_{2,1})$. The technique of coherent anti-Stokes Raman spectroscopy is based on this four-wave mixing process [18].

76.5.2 Stimulated Brillouin Scattering

In stimulated Brillouin scattering (SBS), the light field induces and interacts with an acoustic wave inside the medium. The resulting interaction can lead to extremely high amplification for certain field components (i.e., Stokes wave). For many optical media, SBS is the dominant nonlinear optical process for laser pulses of duration > 1 ns. The primary applications for SBS are self-pumped phase conjugation and pulse compression of high-energy laser pulses.

If an incident light wave with wave vector \mathbf{k}_0 and frequency ω_0 is scattered from an acoustic wave with wave vector \mathbf{q} and frequency Ω , the wave vector and frequency of the scattered wave are determined by conservation of momentum and energy to be $\mathbf{k}_1 = \mathbf{k}_0 \pm \mathbf{q}$ and $\omega_1 = \omega_0 \pm \Omega$, where the (+) sign applies if $\mathbf{k}_0 \cdot \mathbf{q} > 0$ and the (-) applies if $\mathbf{k}_0 \cdot \mathbf{q} < 0$. Here, Ω and \mathbf{q} are related by the dispersion relation $\Omega = v|\mathbf{q}|$ where v is the velocity of sound in the material. These Bragg scattering conditions lead to the result that the Brillouin frequency shift $\Omega_B = \omega_1 - \omega_0$ is zero for scattering in the forward direction (i.e., in the \mathbf{k}_0 direction) and reaches its maximum for scattering in the backward direction given by

$$\Omega_B = 2\omega_0 v n_0 / c, \quad (76.65)$$

where n_0 is the refractive index of the material.

The interaction between the incident wave and the scattered wave in the Brillouin-active medium can become nonlinear if the interference between the two optical fields can coherently drive an acoustic wave, either through electrostriction or through local density fluctuations resulting from the absorption of light and consequent temperature changes. The following discussion treats the more common electrostriction mechanism.

Typically, SBS occurs in the backward direction (i.e., $\mathbf{k}_0 = k_0 \hat{z}$ and $\mathbf{k}_1 = -k_1 \hat{z}$), since the spatial overlap between the Stokes beam and the laser beam is maximized under these conditions and, as mentioned above, no SBS occurs in the forward direction. The steady-state nonlinear polarization amplitudes for backward SBS are

$$\mathcal{P}^{\text{NL}}(z, \omega_{0,1}) = [\varepsilon_0] 6\chi_B(\omega_{0,1}) |A(z, \omega_{1,0})|^2 A(z, \omega_{0,1}), \quad (76.66)$$

where $\chi_B(\omega_{0,1}) \equiv \chi^{(3)}(\omega_{0,1}; \omega_{0,1}, \omega_{1,0}, -\omega_{1,0})$, the Brillouin susceptibility, depends only on $\Omega = \omega_0 - \omega_1$ and is given by

$$\chi_B(\omega_{0,1}) = \left[\frac{1}{\varepsilon_0} \right] \frac{\omega_0^2 \gamma_e^2}{24\pi^2 c^2 \rho_0} \frac{1}{\Omega_B^2 - \Omega^2 \mp i\Gamma_B \Omega}, \quad (76.67)$$

where the minus (plus) sign is taken for the ω_0 (ω_1) susceptibility, γ_e is the electrostrictive constant, ρ_0 is the mean density of the material, and Γ_B is the Brillouin linewidth given by the inverse of the phonon lifetime. If the pump field is undepleted by the interaction with the ω_1 field and is assumed to be constant, the solution for the output intensity of the ω_1 field at $z = 0$ is given by

$$I(0, \omega_1) = I(L, \omega_1) e^{G_B}, \quad (76.68)$$

where the Brillouin gain coefficient G_B is given by

$$G_B = \left[\frac{1}{16\pi^2 \varepsilon_0} \right] 48\pi^2 \frac{\omega_1}{(n_0 c)^2} \text{Im}[\chi_B(\omega_1)] I_0 L$$

$$\begin{aligned} &= g_0 \frac{\Omega \Omega_B \Gamma_B^2}{[\Omega_B^2 - \Omega^2]^2 + (\Omega \Gamma_B)^2} I_0 L \\ &= g_B I_0 L, \end{aligned} \quad (76.69)$$

g_B is the SBS gain factor, I_0 is the input intensity of the pump field, and

$$g_0 = \left[\frac{1}{\varepsilon_0^2} \right] \frac{\omega_0^2 \gamma_e^2}{n_0 c^3 \rho_0 v \Gamma_B} \quad (76.70)$$

is the line-center (i.e., $\Omega = \pm \Omega_B$) SBS gain factor. For $\Omega > 0$ ($\Omega < 0$), the ω_1 field is termed the Stokes (anti-Stokes) field, and it experiences exponential amplification (attenuation). For sufficiently large gains (typically $G_B \gtrsim 25$), the Stokes wave can be seeded by spontaneous Brillouin scattering and can grow to an appreciable fraction of the pump field. For a complete discussion of the spontaneous initiation of SBS, see [19]. For CS_2 , $g_0 = 0.15 \text{ cm/MW}$.

76.6 Other Nonlinear Optical Processes

76.6.1 High-Order Harmonic Generation

If full permutation symmetry applies, and the fundamental field ω is not depleted by nonlinear interactions, then the intensity of the q -th harmonic is given by

$$\begin{aligned} I(z, q\omega) &= \left[\frac{1}{4\pi(4\pi\varepsilon_0)^{(q-1)/2}} \right] \\ &\times \frac{2\pi q^2 \omega^2}{n^2(q\omega)c} \left[\frac{2\pi I(\omega)}{n(\omega)c} \right]^q \\ &\times |\chi^{(q)}(q\omega; \omega, \dots, \omega) J_q(\Delta k, z_0, z)|^2, \end{aligned} \quad (76.71)$$

where $\Delta k = [n(\omega) - n(q\omega)]\omega/c$,

$$J_q(\Delta k, z_0, z) = \int_{z_0}^z \frac{e^{i\Delta k z' dz'}}{(1 + 2iz'/b)^{q-1}}, \quad (76.72)$$

$z = z_0$ at the input face of the nonlinear medium, and b is the confocal parameter (Sect. 76.3.7) of the fundamental beam. Defining $L = z - z_0$, the integral J_q can be easily evaluated in the limits $L \ll b$ and $L \gg b$. The limit $L \ll b$ corresponds to the plane-wave limit in which case

$$|J_q(\Delta k, z_0, z)|^2 = L^2 \text{sinc}^2\left(\frac{\Delta k L}{2}\right). \quad (76.73)$$

The limit $L \gg b$ corresponds to the tight-focusing configuration in which case

$$J_q(\Delta k, z_0, z) = \begin{cases} 0, & \Delta k \leq 0, \\ \frac{\pi b}{(q-2)!} \left(\frac{b\Delta k}{2}\right)^{q-2} e^{-b\Delta k/2}, & \Delta k > 0. \end{cases} \quad (76.74)$$

Note that in this limit, the q -th harmonic light is only generated for positive phase mismatch. *Reintjes* et al. [20, 21] observed both the fifth and seventh harmonics in helium gas, which exhibited a dependence on $I(\omega)$, which is consistent with the $I^q(\omega)$ dependence predicted by Eq. (76.71). However, more recent experiments in gas jets have demonstrated the generation of extremely high-order harmonics, which do not depend on the intensity in this simple manner (Chap. 78 for further discussion of this nonperturbative behavior).

76.6.2 Electro-Optic Effect

The electro-optic effect corresponds to the limit in which the frequency of one of the applied fields approaches zero. The linear electro-optic effect (or Pockels effect) can be described by a second-order susceptibility of the form $\chi^{(2)}(\omega; \omega, 0)$. This effect produces a change in the refractive index for light of certain polarizations, which depends linearly on the strength of the applied low-frequency field. More generally, the linear electro-optic effect induces a change in the amount of birefringence present in an optical material. This electrically controllable change in birefringence can be used to construct amplitude modulators, frequency shifters, optical shutters, and other optoelectronic devices. Materials commonly used in such devices include KDP and lithium niobate [22]. If the laser beam is propagating along the optic axis (i.e., z -axis) of the material of length L , and the low-frequency field E_z is also applied along the optic axis, the nonlinear index change $\Delta n = n_y - n_x$ between the components of the electric field polarized along the principal axes of the crystal is given by

$$\Delta n = \left[\frac{1}{4\pi} \right] n_0^3 r_{63} E_z, \quad (76.75)$$

where r_{63} is one of the electro-optic coefficients.

The quadratic electro-optic effect produces a change in the refractive index that scales quadratically with the applied DC electric field. This effect can be described by a third-order susceptibility of the form $\chi^{(3)}(\omega; \omega, 0, 0)$.

76.6.3 Photorefractive Effect

The photorefractive effect leads to an optically induced change in the refractive index of a material. In certain ways,

this effect mimics that of the nonlinear refractive index described in Sect. 76.1.2, but it differs from the nonlinear refractive index in that the change in refractive index is independent of the overall intensity of the incident light field and depends only on the degree of spatial modulation of the light field within the nonlinear material. In addition, the photorefractive effect can occur only in materials that exhibit a linear electro-optic effect and contain an appreciable density of trapped electrons and/or holes that can be liberated by the application of a light field. Typical photorefractive materials include lithium niobate, barium titanate, and strontium barium niobate.

A typical photorefractive configuration might be as follows: two beams interfere within a photorefractive crystal to produce a spatially modulated intensity distribution. Bound charges are ionized with greater probability at the maxima than at the minima of the distribution and, as a result of the diffusion process, carriers tend to migrate away from regions of large light intensity. The resulting modulation of the charge distribution leads to the creation of a spatially modulated electric field that produces a spatially modulated change in refractive index as a consequence of the linear electro-optic effect. For a more extensive discussion, see [23].

76.7 New Regimes of Nonlinear Optics

76.7.1 Ultrafast and Intense-Field Nonlinear Optics

Additional nonlinear optical processes are enabled by the use of ultrashort (< 1 ps) or ultraintense laser pulses. For reasons of basic laser physics, ultraintense pulses are necessarily of short duration, and, thus, these effects normally occur together. Ultrashort laser pulses possess a broad frequency spectrum, and, therefore, the dispersive properties of the optical medium play a key role in the propagation of such pulses. The three-dimensional nonlinear Schrödinger equation must be modified when treating the propagation of these ultrashort pulses by including contributions that can be ignored under other circumstances [24, 25]. These additional terms lead to processes such as space–time coupling, self-steepening, and shock-wave formation [26, 27]. The process of self-focusing is significantly modified under short-pulse (pulse duration shorter than approximately 1 ps) excitation. For example, temporal splitting of a pulse into two components can occur; this pulse splitting lowers the peak intensity and can lead to the arrest of the usual collapse of a pulse undergoing self-focusing [28]. Moreover, optical shock formation, the creation of a discontinuity in the intensity evolution of a propagating pulse, leads to supercontinuum generation, the creation of a light pulse with

an extremely broad frequency spectrum [29]. Shock effects and the generation of supercontinuum light can also occur in one-dimensional systems, such as a microstructure optical fiber. The relatively high peak power of the ultrashort pulses from a mode-locked laser oscillator and the tight confinement of the optical field in the small ($\approx 2 \mu\text{m}$) core of the fiber yield high intensities and strong self-phase modulation, which results in a spectral bandwidth that spans more than an octave of the central frequency of the pulse [30]. Such a coherent octave-spanning spectrum allows for the stabilization of the underlying frequency comb of the mode-locked oscillator and has led to a revolution in the field of frequency metrology [31]. Multiphoton absorption [32] constitutes an important loss process that becomes important for intensities in excess of $\approx 10^{13} \text{ W/cm}^2$. In addition to introducing loss, the electrons released by this process can produce additional nonlinear effects associated with their relativistic motion in the resulting plasma [33, 34]. For very large laser intensities (greater than approximately 10^{16} W/cm^2), the electric field strength of the laser pulse can exceed the strength of the Coulomb field that binds the electron to the atomic core, and nonperturbative effects can occur. A dramatic example is that of high-harmonic generation [35–37]. Harmonic orders as large as the 341-st have been observed, and simple conceptual models have been developed to explain this effect [38]. Under suitable conditions, the harmonic orders can be suitably phased so that attosecond pulses are generated [39].

76.7.2 Nonlinear Plasmonics and Epsilon-Near-Zero Effects

Despite their intrinsic loss, plasmonic materials (i.e., metals) have shown stronger nonlinear effects than insulators or dielectrics [40]. The optical properties of such materials are determined by the dynamics of quasi-free electrons in the conduction band and can be understood in terms of the Drude model for sufficiently low frequencies. In this model, the permittivity

$$\epsilon(\omega) = \epsilon_\infty - \omega_p^2 / (\omega^2 + i\gamma\omega) \quad (76.76)$$

shows a strong dependence on the frequency ω and is determined by the high-frequency permittivity ϵ_∞ , a damping constant γ , and the plasma frequency

$$\omega_p^2 = [1/(4\pi\epsilon_0)] 4\pi N e^2 / m^* . \quad (76.77)$$

Here, N is the electron density, and m^* the effective mass of the electrons in the conduction band, $-e$ denotes the el-

ementary charge. Note that for most plasmonic materials the optical response deviates significantly from the Drude model due to interband transitions at optical frequencies. However, the model can be improved by including additional contributions to the permittivity that arise in a Lorentz-oscillator description of bound electrons. Even though such models give a better quantitative description of the response, Eq. (76.76) describes the qualitative behavior of plasmonic materials very well [41].

The permittivity from Eq. (76.76) has some remarkable features. For example, the real part of ϵ can take negative values. Moreover, it may even vanish for $\omega^2 = \omega_p^2 / \epsilon_\infty$ (neglecting terms of the order of γ^2). This resonance gives rise to a new class of epsilon-near-zero (ENZ) materials, which possess unique nonlinear optical properties. For a vanishing real part of ϵ , the real part of the refractive index becomes small and, following Eq. (76.8), the nonlinear refractive index n_2 is enhanced [42, 43]. This heuristic explanation captures some features of the outstanding optical response of some plasmonic materials. Other nonlinear mechanisms that dominate in such materials [44–47] are (i) saturable absorption due to the filling of the conduction band, (ii) quantum-size effects for small particles where the electrons in the conduction band are confined to a small volume and, thus, not completely free, (iii) ponderomotive effects in Fermi–Dirac metals where the electron density is depleted by high intensities, and (vi) hot-electron effects where the distribution of electrons in the conduction band is modified by the absorption of heat from high intensities. The latter effect leads to a shift of the frequency where the real part of the permittivity vanishes, which can be easily understood in terms of Eq. (76.77), since a modified distribution changes the effective mass m^* and by that ω_p . Note that such thermal effects are not instantaneous and depend relatively strongly on the laser pulse parameters.

A field of magnitude $|E_0|$ incident on such an ENZ medium is also significantly enhanced inside the material. Since the perpendicular component of the electric displacement is continuous at the interface, the electric field inside a material depends on the inverse of the permittivity. For an angle of incidence ϕ , the magnitude of the field $|E_{\text{mat}}|$ within the material is

$$|E_{\text{mat}}| = |E_0| (\cos^2 \phi + \epsilon^{-1} \sin^2 \phi)^{1/2} \quad (76.78)$$

and, therefore, enhanced for an oblique angle of incidence and small values of ϵ . In fact, the field enhancement leads to an angle-dependence for the nonlinear optical response of ENZ materials [42].

Robert Boyd Robert Boyd received the BS degree in Physics from MIT and the PhD degree from UC Berkeley under the supervision of Charles Townes. Dr Boyd holds faculty appointments at the University of Rochester and University of Ottawa. His research interests include optical physics and quantum effects in nonlinear optics. He has written two textbooks.

Alexander L. Gaeta Alexander Gaeta received his BS, MS, and PhD in Optics from the University of Rochester in Rochester, NY in 1983, 1985, and 1991, respectively. He remained there as a postdoctoral associate from 1991 to 1992. Gaeta joined Columbia Engineering as the David M. Rickey Professor of Applied Physics and Materials Science in 2015. Prior to that, Gaeta was the Samuel B. Eckert Professor of Engineering at Cornell University and was Chair of the School of Applied and Engineering Physics from 2011 to 2014. He is a Fellow of the American Physical Society, the Institute of Electrical and Electronics Engineers, and of Optica (formerly the Optical Society of America) and is also the founding Editor-in-Chief of the journal *Optica*.

Enno Giese Enno Giese received his Dr rer nat from Ulm University in 2015 and subsequently worked on quantum nonlinear optics, quantum imaging, and nonlinear interferometry in the Department of Physics, University of Ottawa. His current position is at the Technical University of Darmstadt, where he focuses on matter wave optics and interferometry in microgravity and in curved space–time for tests of relativity.

Abstract

Coherent transients are excited in atomic and molecular systems when a phase relation is able to persist at least

semistably between an exciting light field and the system’s response. A steady state can occur whenever the multiplicity of “reservoir” effects in the background has reached a stable average. The theory of coherent transients typically makes an important distinction between two types of average, labeled either *homogeneous* or *inhomogeneous*. The terms refer to the type of randomness existing over the experimental “system” and originating in the system’s environment.

An example of inhomogeneous randomness and relaxation to a steady state is found in the distribution of transition frequencies of otherwise identical atoms or molecules trapped as impurities in a host crystal and arising from the host crystal’s random strain fields, which induce a permanent energy-level shift in each of the impurities under study. These unchanging level shifts allow, in principle, the experimenter to assign permanent energy-level information in a one-by-one way to system members.

Examples of homogeneous randomness are also common. For example, because of continuing collisions, energy-level shifts throughout a vapor cell are random and are constantly changing. Their effect is individually transient, and any consequent relaxation effects are observable only homogeneously over the entire sample, allowing no information to be retained about individual atoms and molecules.

We remark at the end of this chapter that the existence of vector-space non factorization, called “quantum entanglement” by Schrödinger in 1935, leads to nonintuitive effects in transients that are currently still under some discussion as not being completely explained. One example is the predicted, and multiply observed, phenomenon labelled ESD, which stands for entanglement sudden death.

77.1 Introduction

When an electromagnetic field is incident on matter it polarizes the matter by causing a displacement between the electrons and the nuclei. As the electromagnetic field oscillates the induced polarization also oscillates. The nature of this induced oscillation is determined by both the incident field and the internal dynamics of the matter. This same physics occurs whether the matter is made of isolated atoms or molecules, dopant atoms, quantum dots, or color centers in a host medium, or bulk matter: an insulator, semiconductor or metal. The bulk matter might even be an electronic circuit in the form of a radio receiver or a superconducting quantum interference device (SQUID).

For all of these systems, the energy is exchanged between the field and the matter according to

$$\frac{dW_m}{dt} = \int d^3r \mathbf{J} \cdot \mathbf{E}, \quad (77.1)$$

where W_m is the energy of the matter, \mathbf{J} is the induced current, and \mathbf{E} is the electric field. This relation holds both for classical variables and the corresponding quantum operators. For most cases of interest, the dipole approximation is appropriate. The atoms, molecules, and quantum dots are small compared with the wavelength of optical fields, and the circuits are small compared with the wavelength of the microwave fields with which they interact. The electric field is then constant over the integration region and can be taken outside the integral. The integral over the current density can then be carried out reducing the energy absorption integral to

$$\frac{dW_m}{dt} = \frac{d\mathbf{p}}{dt} \cdot \mathbf{E}, \quad (77.2)$$

where \mathbf{p} is the dipole moment associated with the absorber.

If both the field and the induced dipole are oscillatory, then whether the matter is absorbing or emitting energy depends on the phase relation between the two. Coherent optical transients are excited in a quantum system when a stable phase relation persists between (typically) an exciting electric field and the system's electronic response. The extreme sensitivity of phase-dependent effects is responsible for the many applications of optical transient techniques in atomic, molecular and optical (AMO) physics [1–7]. While all of our discussion thus far applies equally to many classical or quantum systems, we must specialize somewhat to discuss the dynamic response of the induced polarization. We will assume that our dipole is associated with a single resonance in a quantum system. A quantum resonance is associated with two energy levels. We can usually ignore all of the other levels of quantum system and reduce our consideration to a “two-level atom”, equivalently in modern context in an atomic “qubit”. Even in the case of a superconducting cir-

cuit, the bias voltage can be adjusted to form such a two-level quantum system [8].

The coherent oscillations of the induced dipole are subject to the influence of the environment. One way that the dipole interacts with the environment is through the field that the dipole itself generates. This field interacts back on the dipole, causing damping and a frequency shift. In classical circuits, we refer to this as the *impedance of free space* and the frequency shift as *self-inductance* [9]. The impedance of free space is given exactly by

$$Z = \sqrt{\mu_0/\epsilon_0} = 120\pi \text{ (Ohms)}, \quad (77.3)$$

and the self-inductance depends on the exact shape of the dipole radiator. In the case of a circuit, this resistance and inductance will be a part of the impedance in the circuit. In the case of an atomic or molecular dipole, the impedance of free space will lead directly to the Einstein A-coefficient damping and the Lamb shift of the quantum transition. If the radiator is placed in a cavity, the self-field of the dipole radiator will be modified leading to the Purcell-effect-enhanced damping rate [10] and modification of the Lamb shift.

77.2 Origin of Relaxation

We will examine the transient effects that are present as a result of interactions that lead to relaxation. The first step is to mention the two types of relaxation, homogeneous and inhomogeneous, and to distinguish between coherent and incoherent evolution. Relaxation occurs whenever the environment of a physical system fluctuates randomly, that is, it is too irregular and too complex to be treated fundamentally. Typically, such fluctuation leads to degradation of some degree of regularity in the evolution of a particular subsystem of interest. The inability to track short-term irregularities requires signal-smoothing of some kind, and this means a loss of microscopic coherence. The time scales of environmental fluctuations determine the division between homogeneous and inhomogeneous decoherences, as follows.

When environmental fluctuations are sufficiently rapid that all dynamical systems in a macroscopic sample experience the whole range of fluctuations in a time that is short compared with the time scale of interest, the resultant relaxation is called homogeneous. If environmental differences exist randomly over a macroscopic sample, but change relatively slowly in time, then the relaxation is called inhomogeneous. As examples, weak distant collisions are experienced constantly by all atoms at thermal equilibrium in a vapor cell and give rise to homogeneous relaxation. If the vapor is sufficiently dilute, the same atoms may nevertheless retain their own individual velocities and, thus, transition frequencies for long times. These transition frequencies are

relatively fixed in time, as are the frequency shifts experienced by impurity atoms in crystal lattices. However, they are random over a distribution of shifts and give rise to inhomogeneous relaxation. Fundamentally, the distinction between homogeneous and inhomogeneous relaxation is artificial, depending on a separation of timescales that may not always exist. Nevertheless, when it exists, the distinction provides an extremely useful way to classify coherent transients. It is one of the foundations of the subject.

77.3 State Evolution

A very weakly excited dipole transition in a ground-state quantum system responds linearly to an applied time-dependent electric field. This is the case when transitions to upper quantum levels are negligibly excited, and this is the basis for classical and linear Lorentzian dielectric theory in Chap. 72. However, the generally unequal spacing of dipole-allowed levels introduces the possibility of partial or even complete transfer of occupation probability from the ground level to just one of the upper levels. If the transition frequency ω_0 between upper and lower levels is nearly resonant with ω , the frequency of the exciting electric field, one can, to first approximation ignore other levels and deal with a much-simplified “two-level” quantum system. Its wave function is then simply written in terms of lower and upper (ground and excited) states $|g\rangle$ and $|e\rangle$ and two complex time-dependent coefficients:

$$|\Psi(t)\rangle = c_g(t)|g\rangle + c_e(t)|e\rangle. \quad (77.4)$$

We will adopt the Hamiltonian described for such a two-state system in Eqs. (72.38)–(72.41):

$$H = \frac{\hbar\omega_0}{2}(|e\rangle\langle e| - |g\rangle\langle g|) - d\left[|e\rangle\langle g|E^+(t) + |g\rangle\langle e|E^-(t)\right], \quad (77.5)$$

and apply the Schrödinger equation $i\hbar\frac{\partial}{\partial t}|\Psi(t)\rangle = H|\Psi(t)\rangle$ to obtain equations of motion for the quantum state amplitudes. Some minor algebra leads to

$$i\hbar\dot{c}_g = -\frac{\hbar\omega_0}{2}c_g - dE^-(t)c_e, \quad (77.6)$$

$$i\hbar\dot{c}_e = -\frac{\hbar\omega_0}{2}c_e - dE^+(t)c_g, \quad (77.7)$$

where the positive and negative frequency radiation fields are defined in Eq. (72.30):

$$E^\pm(t) = \frac{1}{2}\mathcal{E}^\pm(t)e^{\mp i\omega t}, \quad (77.8)$$

with the understanding that $\mathcal{E}^\pm(t)$ is a field amplitude that is very slowly varying in comparison to the applied field’s carrier frequency oscillations $e^{\pm i\omega t}$.

Equations (77.6) and (77.7) for the level amplitudes can be used to obtain the equations of motion for the level probabilities $|c_g(t)|^2$ and $|c_e(t)|^2$, with an important conservation equation as a consequence:

$$\frac{d}{dt}\left(|c_g(t)|^2 + |c_e(t)|^2\right) = 0, \quad (77.9)$$

indicating that all of the initial probability remains confined to those two levels. Under these approximations, pure state evolution is fully conservative.

However, as indicated in Chap. 72, it is usually impossible to describe fully an interacting two-level system by a state vector such as Eq. (77.4) simply because of environmental fluctuations. There is no way, consistent with the two-level model, to add damping terms such as $-i\hbar\gamma c_e$ to a state amplitude equation such as Eq. (77.6) and (77.7) to account for the relaxation due to those fluctuations. The density matrix approach is required. The pure state Eq. (77.4) is equivalent to the fully coherent density matrix ρ_{coh} :

$$\begin{aligned} \rho_{\text{coh}} &\equiv |\Psi(t)\rangle\langle\Psi(t)| \\ &= \left(c_g(t)|g\rangle + c_e(t)|e\rangle\right)\left(\langle g|c_g^*(t) + \langle e|c_e^*(t)\right), \end{aligned} \quad (77.10)$$

with matrix elements $(\rho_{\text{coh}})_{ge} = c_g^*c_e$, etc. The actual density matrix is the same as the one in Eq. (77.10), after it has been averaged over environmental randomness:

$$\rho(t) = \begin{pmatrix} \rho(t)_{gg} & \rho(t)_{ge} \\ \rho(t)_{eg} & \rho(t)_{ee} \end{pmatrix}, \quad (77.11)$$

where $\rho(t)_{ge} = [c_g(t)c_e^*(t)]_{\text{avg.}}$, etc.

We note that restriction to two levels implies full conservation of level probability: $\rho_{gg} + \rho_{ee} = 1$, and the Hermitian character of ρ means that $\rho_{ge} = \rho_{eg}^*$, so that three real variables are sufficient to exhibit the entire temporal evolution of the two-level system’s density matrix. As in Chap. 72, we will denote by U and V the amplitudes of the components of the time-dependent dipole expectation value that are, respectively, in-phase and in-quadrature with the field. That is, U and V are given by

$$-\langle ex(t) \rangle = -\langle\Psi(t)|ex|\Psi(t)\rangle = \text{Re}\{d(U - iV)e^{-i\omega t}\}, \quad (77.12)$$

where d is the matrix element of the transition dipole. Still following Chap. 72, for simplicity both dipole moment matrix element and field amplitude have been taken to be real scalars. The complications of vector notation add little to a discussion of the principles of coherent transients.

Chapter 72.3.5 shows that U and V are dynamically coupled to each other and to the inversion W through three equations introduced by Felix Bloch initially for spin resonance theory and now called “optical Bloch equations” and commonly abbreviated as OBE:

$$\begin{aligned}\frac{dU}{dt} &= -\Delta V, \\ \frac{dV}{dt} &= \Delta U + \Omega_1 W, \\ \frac{dW}{dt} &= -\Omega_1 V.\end{aligned}\quad (77.13)$$

Furthermore, Bloch showed that weak Markovian interactions with environmental oscillators had the effect of decohering the evolution of U , V , and W in specific ways. These decohering influences can be accounted for by adding damping terms into the U , V , and W (i.e., density matrix) equations, rather than into the state vector equations. Chap. 72 shows that when Bloch’s damping terms are included, the OBEs are given by Eq. (72.55):

$$\begin{aligned}\frac{dU}{dt} &= -\Delta V - U/T_2, \\ \frac{dV}{dt} &= \Delta U + \Omega_1 W - V/T_2, \\ \frac{dW}{dt} &= -\Omega_1 V - (W - W_{\text{eq}})/T_1,\end{aligned}\quad (77.14)$$

where $\Delta = \omega_0 - \omega$ is the detuning, and the so-called Rabi frequency Ω_1 is given by $\hbar\Omega_1 = d\mathcal{E}$. These are the key equations of the theory of optical transients [1, 2].

Clearly, Ω_1 is, in frequency units, the dipole interaction energy between the electric field and the quantum system, but it has a significance beyond this, as is discussed in Sect. 77.5.2.

77.4 Numerical Estimates of Parameters

The nature of the coherent interaction between a quantum system and a time-dependent electric field is controlled by the relative size of a number of frequencies or rates. In the case of single-photon transitions, they include Δ and Ω_1 , the detuning and Rabi frequency defined above, $1/T_2$ the transverse, and $1/T_1$ the longitudinal damping rates, given in Eq. (77.14) and $1/T^*$ the inhomogeneous linewidth, and $2\pi/\tau_p$ the transform bandwidth of the exciting field or pulse. All of these frequencies are defined in Chap. 2, with the exception of the last, so we should mention its effect.

A wide excitation bandwidth can overcome the two-level assumption by leading to excitation of several or many levels beyond the single one we have been calling “upper”. This can occur with any exciting pulse, from radio and microwave to X-ray frequencies, if the pulse is short enough to provide

a bandwidth that engages some or many other “resonances”. For perspective, in the atomic case, one can note that with $\tau_p \geq 1$ ns and with an intensity less than about 1 GW/cm², a laser pulse can be tuned to an isolated atomic resonance, and the interaction can be described in terms of a simple two-level theory. However, laser pulses as short as a few fs in duration, or with intensities greater than 10²⁰ W/cm², are available, and such pulses can quasi-resonantly excite many more than just one upper level. For example, if a 1 ps pulse (bandwidth approximately 20 cm⁻¹) were tuned so that it resonantly excited the $n = 95$ Rydberg state of an atom, it would also simultaneously and coherently excite all the levels from $n = 67$ to the continuum limit, while a 10 fs pulse would excite all the levels from $n = 4$ to the continuum. In other extended cases, in which multiphoton transitions are possible, or simultaneous excitation by a number of near-resonant fields occurs, the appropriately generalized versions of these same parameters apply.

77.5 Homogeneous Relaxation

Homogeneous relaxation is ubiquitous and can be dominant when the wave function phase is rapidly and irregularly interrupted, as from quantum acoustic or other collisional interactions. In the absence of an exciting field (i.e., $\Omega_1 = 0$), the solutions of the OBEs are

$$\begin{aligned}(U - iV) &= (U_0 - iV_0) e^{-(1/T_2 + i\Delta)t}, \\ W &= -1 + (W_0 + 1) e^{-t/T_1},\end{aligned}\quad (77.15)$$

where the subscripts denote values at $t = 0$. Then the roles of T_1 and T_2 as relaxation times are clear. They are homogeneous because they apply to each atom individually.

77.5.1 Rabi Oscillations

The OBEs predict damped, although well-defined (coherent, many-period) oscillations of the inversion W with the angular frequency Ω_1 even in the presence of T_1 and T_2 if Ω_1 is large enough: $\Omega_1 T_1 \gg 1$ and $\Omega_1 T_2 \gg 1$. These are usually called *Rabi oscillations* and were originally called *optical nutations* following the terminology of nuclear magnetic resonance. Figure 77.1 shows the behavior of the Bloch variables undergoing Rabi oscillations in a representative case.

77.5.2 Bloch Vector and Bloch Sphere

Coherent dynamical behavior is simplest for times much shorter than the relaxation times T_1 and T_2 . In this case, the

Fig. 77.1 Damped Rabi oscillations of the atomic variables after sudden turn-on of the field. In this example, $T_1 = T_2$, $\Delta T_2 = 1$, and $\Omega_1 T_2 = 15$

damping terms can be dropped from the OBEs and the resulting equations can be written in the form (Chap. 72.3.5)

$$\frac{d\mathbf{U}}{dt} = \boldsymbol{\Omega} \times \mathbf{U} \quad \text{with} \quad \boldsymbol{\Omega} = (-\Omega_1, 0, \Delta), \quad (77.16)$$

where $\mathbf{U} = (U, V, W)$ is the Bloch vector, and $\boldsymbol{\Omega}$ acts as a torque vector defining the axis and rate of precession. Conservation of probability is reflected in the unit length of the undamped Bloch vector: $\mathbf{U} \cdot \mathbf{U} = 1$.

All possible states of an undamped two-level quantum system can be mapped onto a unit sphere in U - V - W space. Conventionally, W defines the polar axis with the ground state at the south pole, and the excited state at the north pole. Points on the sphere surface between the poles represent coherent superpositions of the two states. The azimuthal angle ϕ represents the phase between the expectation value of the quantum dipole moment and the incident field. In Fig. 77.2, the solutions to Eq. (77.16) are shown for the case of a square pulse applied to the system in its ground state at $t = 0$. The solutions in this case are

$$\begin{aligned} U(t, \Delta) &= \frac{\Omega_1}{\Omega} \sin \Omega t, \\ V(t, \Delta) &= -\frac{\Delta \Omega_1}{\Omega^2} (1 - \cos \Omega t), \\ W(t, \Delta) &= -1 + \frac{\Omega_1^2}{\Omega^2} (1 - \cos \Omega t). \end{aligned} \quad (77.17)$$

For any Δ , the solution orbit is a circle on the surface of the sphere with the orbit passing through the south pole. The rate at which the system precesses about the circle is given by the *generalized Rabi frequency* $\Omega \equiv \sqrt{\Delta^2 + \Omega_1^2}$.

Fig. 77.2 Orbits of the Bloch vector on the unit sphere for various ratios of the detuning Δ to the Rabi frequency Ω_1

77.5.3 Pi Pulses and Pulse Area

The exactly resonant ($\Delta = 0$) undamped OBEs can be solved analytically even for arbitrarily time-dependent exciting pulse envelopes. The solutions are

$$\begin{aligned} U(t, 0) &= 0, \\ V(t, 0) &= -\sin \theta(t), \\ W(t, 0) &= -\cos \theta(t), \end{aligned} \quad (77.18)$$

a rotation of the Bloch vector in the V - W plane. The rotation angle θ is called the *pulse area*, defined by the integrale

$$\theta(t) \equiv \int_{-\infty}^t dt' \Omega_1(t') = \frac{d}{\hbar} \int_{-\infty}^t dt' \mathcal{E}(t'). \quad (77.19)$$

The area under the envelope of the Rabi frequency is the same as the angle through which an exactly-resonant Bloch vector turns due to the pulse. If $\theta = \pi$, the system is driven from the ground state exactly to the excited state. This is “ π -pulse” inversion. A “ 2π -pulse” takes the system from the lower state through the excited state and back to the lower state. The Bloch vector rotation angle does not depend upon the shape of the field pulse, only on the area of the pulse.

77.5.4 Adiabatic Following

The Bloch vector picture for fixed Δ and Ω_1 can be used for semiquantitative predictions even if Δ and Ω_1 are time dependent, if they change slowly. For example, if $\boldsymbol{\Omega}$ is moved slowly, the Bloch vector follows closely. It is possible to achieve complete inversion smoothly in this way. If the field is initially tuned far below resonance so Δ is large and negative, then $\boldsymbol{\Omega}$ points approximately toward the south pole of the Bloch sphere. As shown in Fig. 77.3, the Bloch vector

Fig. 77.3 In adiabatic inversion, the Bloch vector precesses in a small cone about the torque vector as the torque vector goes from straight down to straight up

then precesses about the torque vector in a very small circle near the south pole. If the field frequency is now slowly changed (chirped) so that Δ goes from a large negative value to a large positive value, then every atomic Bloch vector will continue to precess rapidly around the torque vector and follow it as it proceeds from pointing nearly straight down to pointing nearly straight up. In this way, the population can be transferred from lower to upper levels.

77.6 Inhomogeneous Relaxation

The fact that individual otherwise identical quantum systems in a sample may have slightly different resonance frequencies produces a number of notable phenomena. Given a distribution $g(\Delta)$ of detunings in a dilute sample of density N , the macroscopic collective polarization can be written as

$$P(t) = -N \langle ex(t) \rangle = Nd \int g(\Delta) \text{Re} [(U - iV) e^{-i\omega t}] d\Delta . \quad (77.20)$$

77.6.1 Free Induction Decay

Free induction refers to evolution of the polarization in the absence of an exciting field. For $\Omega_1 = 0$, the Bloch vector of a system with $\Delta < 0$ precesses counterclockwise in the “transverse” $U-V$ plane. In a macroscopic sample, there are many values of Δ , and about as many are positive as negative. Thus, a collection of Bloch vectors, all pointing in the V direction at $t = 0$, will rapidly fan out in the $U-V$ plane due to differing positive and negative Δ precession rates, and after a short time, the net U and V values will be zero. This is free induction decay (FID) of polarization and is indicated in the top row of Fig. 77.4.

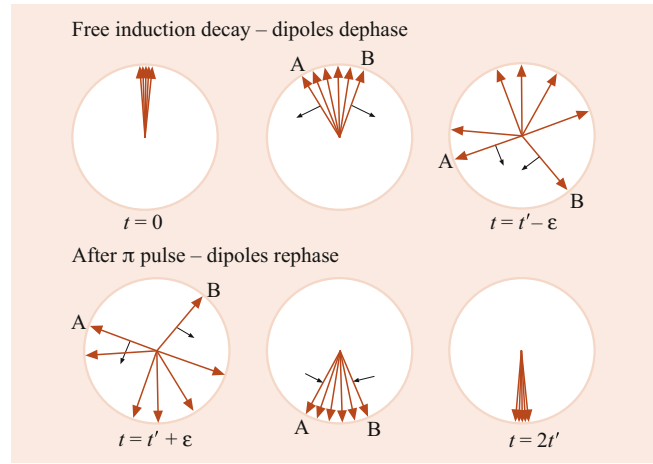

Fig. 77.4 The ensemble of dipole moments spreads due to the distribution of resonance frequencies. The distribution of Bloch vectors in the $U-V$ plane is shown at various times after the initial short-pulse excitation. By the time t' , the dipoles have spread uniformly around the unit circle. A π -pulse then flips the relative orientation of the dipoles, so that they subsequently rephase

More specifically, if all systems are first exposed to a θ_0 pulse, so that at $t = 0$

$$\begin{aligned} U(0, \Delta) &= 0 , \\ V(0, \Delta) &= -\sin \theta_0 , \\ W(0, \Delta) &= -\cos \theta_0 , \end{aligned} \quad (77.21)$$

then if $\mathcal{E} = 0$ for $t > 0$, an individual system with detuning Δ evolves according to Eq. (77.15):

$$U - iV = i \sin \theta_0 e^{-(1/T_2 - i\Delta)t} . \quad (77.22)$$

The macroscopic polarization is found by summing the individual $(U - iV)$ values over the detuning distribution $g(\Delta)$.

If we temporarily ignore competition from homogeneous decay (take $1/T_2 \approx 0$) and assume the most common inhomogeneous lineshape (i.e., Doppler–Maxwellian):

$$g(\Delta) = \frac{T^*}{\sqrt{2\pi}} e^{-(\Delta - \Delta_0)^2 T^{*2}/2} , \quad (77.23)$$

where $1/T^*$ is defined as the width (standard deviation) of the Doppler distribution, and Δ_0 is the detuning of the zero-velocity atoms, then the collective result is

$$P(t) = Nd \sin \theta_0 \sin \omega t e^{i\Delta_0 t} \exp(-t^2/2T^{*2}) . \quad (77.24)$$

The detuning “inhomogeneity” in the sample leads to dephasing of the collective dipole moment at the rate $1/T^*$, so the inhomogeneous relaxation time is obviously T^* . This is illustrated by the decrease of collective alignment of Bloch vectors in the top row of Fig. 77.4. The Doppler effect for

atoms makes a common example, and in a typical room temperature gas, a visible transition has a Doppler width given by $1/(2\pi T^*) \approx 1.5$ GHz so that $T^* \approx 10^{-10}$ s.

77.6.2 Photon Echoes

A photon echo is generated by pulse-induced *recovery* of a nonzero $P(t)$ after free induction decay (FID) and $P(t) \rightarrow 0$. This analog of the spin echo effect is possible when each near-resonant quantum system retains its own detuning for a relatively long time, i.e., up to an average collision time T_2 .

During FID, the U - V projection of every atom's Bloch vector precesses steadily clockwise or counterclockwise, depending on the sign of its Δ . Thus, the Bloch vectors could be rephased, if they could all be forced at the same moment to reverse their relative sense of precession. The prototypical echo scenario begins with FID at $t = 0$, as an established $P(t)$ approaches zero for $t \gg T^*$. This is followed by injection of a π -pulse at the time t' , where $t' \gg T^*$. The effect of the π -pulse is to reverse the sign of V and W (recall Eq. (77.21)), in effect flipping the equatorial plane of the Bloch sphere upside-down. Thus, for $t \gg t'$, we have Bloch vectors fanning back together. The macroscopic polarization obeys

$$P(t) = Nd \sin \theta_0 \sin \omega t \exp[-(t - 2t')^2/2T^{*2}] e^{-t/T_2}, \quad (77.25)$$

where the last factor reinserts the effect of homogeneous dipole damping. We require $T_2 \gg t' \gg T^*$ for a strong echo signal in the neighborhood of $t = 2t'$.

The result is illustrated in Fig. 77.4. An "echo" of the initial excitation at $t = 0$ appears at the time $t = 2t'$. After this, FID occurs again. This second decay can also be reversed by applying another π -pulse, and so on, until $t \approx T_2$, at which time the inevitable and irreversible homogeneous relaxation cannot be avoided. The scenario employing π -pulse reversal is only the most ideal, leading to the most complete echo, and other pulse areas will also lead to echoes. A more important factor is that the reversing pulse must be short enough that negligible dephasing takes place during its application.

77.7 Resonant Pulse Propagation

77.7.1 Maxwell–Bloch Equations

Time-dependent atomic dipole moments created by applied fields are themselves a source of fields, another form of coherent transient. We limit discussion to plane-wave propagation in the z -direction. Note that we use z rather than Z for convenience, although in the dipole approximation, the coordinate entering our equations is the coordinate of the center

of mass of the atom rather than the internal electron coordinate. The field is generalized from Eq. (77.2) to

$$E(t, z) = \frac{1}{2} [\mathcal{E}(t, z) e^{i(Kz - \omega t)} + \text{c.c.}], \quad (77.26)$$

and the macroscopic polarization is the correspondingly generalized form of Eq. (77.20):

$$P(t, z) = Nd \int g(\Delta) \text{Re}\{(U - iV) e^{i(Kz - \omega t)}\} d\Delta. \quad (77.27)$$

The difference between K and $k = \omega/c$ indicates that the refractive index is nonzero. The traveling-pulse rotating frame is also obtained by replacing ωt by $\omega t - Kz$.

If the field envelope \mathcal{E} is slowly varying, its second derivatives can be dropped when $E(t, z)$ is substituted into Maxwell's wave equation. The resulting dispersive and absorptive *reduced wave equations* are

$$\begin{aligned} [K^2 - k^2] \mathcal{E} &= 4\pi k^2 Nd \int g(\Delta) U(t, z, \Delta) d\Delta, \\ \left[K \frac{\partial}{\partial z} + k \frac{\partial}{\partial(ct)} \right] \mathcal{E} &= 2\pi k^2 Nd \int g(\Delta) V(t, z, \Delta) d\Delta. \end{aligned} \quad (77.28)$$

The Bloch equations along with these reduced wave equations form the *self-consistent Maxwell–Bloch equations* that are used to treat resonant propagation problems in quantum optics and laser theory [1, 2, 5, 11].

77.7.2 Index of Refraction and Beer's Law

If a weak field propagates in a ground-state medium ($W \approx -1$), the Bloch equations have simple quasi-steady-state solutions

$$U = \frac{\Omega_1 \Delta}{\Delta^2 + 1/T_2^2}, \quad (77.29)$$

$$V = \frac{-\Omega_1/T_2}{\Delta^2 + 1/T_2^2}. \quad (77.30)$$

When U and V are substituted back into the reduced wave equations Eq. (77.28), the dispersive equation gives the index of refraction $n = K/k$:

$$n^2 - 1 = \frac{4\pi Nd^2}{\hbar} \int \frac{\Delta g(\Delta)}{\Delta^2 + 1/T_2^2} d\Delta, \quad (77.31)$$

and the absorptive equation predicts steady-state field attenuation during propagation:

$$\frac{\partial}{\partial z} \mathcal{E} = -\frac{1}{2} \alpha_B \mathcal{E}. \quad (77.32)$$

The constant α_B given by

$$\alpha_B = \frac{4\pi N d^2 \omega}{\hbar c T_2} \int \frac{g(\Delta)}{\Delta^2 + 1/T_2^2} d\Delta \quad (77.33)$$

is called the *extinction coefficient* or the *reciprocal Beer's length*.

Since field intensity $I(z)$ is proportional to \mathcal{E}^2 , the solution to the absorptive equation is

$$I(z) = I(0) e^{-\alpha_B z} . \quad (77.34)$$

This relation is called Beers law. Both the dispersive and absorptive results are familiar from classical physics [12], with the important distinction that here the quantum \hbar -dependence is apparent in the oscillator strength, which is only an empirical parameter in Lorentzian dielectric theory [11, 12].

77.7.3 The Area Theorem and Self-Induced Transparency

A form of pulse propagation with no classical analog arises in the short-pulse limit. By integration over the entire pulse, the absorptive Maxwell equation becomes an equation for $\partial\theta/\partial z$, where θ is the pulse area defined in Eq. (77.19). In the short-pulse limit, the relaxation terms in the OBEs can be ignored and when substituting from the OBEs we obtain the *McCall–Hahn area theorem* [1]:

$$\frac{\partial}{\partial z} \theta(z) = -\frac{1}{2} \alpha_B \sin \theta(z) . \quad (77.35)$$

When $\sin \theta \approx \theta$, this predicts the same exponential attenuation as Eq. (77.32) for the case of a small area pulse, $\theta(z) \ll \pi$, but in the case of larger area pulses, the behavior dictated by Eq. (77.35) is quite different. The area decreases during propagation for areas in the range $0 < \theta(z) < \pi$, but it *increases* for areas $\pi < \theta(z) < 2\pi$. As seen from Fig. 77.5, this change of area with propagation causes the pulse area to evolve to one of the stable values $0, 2\pi, 4\pi, \dots$

There is one special pulse, a *soliton* solution with area exactly 2π , which propagates without shape change in the short-pulse limit, given by

$$\mathcal{E}(t, z) = \frac{2\hbar}{\tau d} \operatorname{sech}\left(\frac{t - z/v}{\tau}\right) , \quad (77.36)$$

where τ is the pulse duration, which is arbitrary but must satisfy the short-pulse inequality $\tau \ll T_1, T_2$. The soliton's group velocity is determined by the dispersive wave equation to be

$$v = \frac{c}{1 + \frac{1}{2} \alpha_B c \tau} . \quad (77.37)$$

The group velocity can be slower than the speed of light by orders of magnitude if $\alpha_B c \tau \gg 1$.

Fig. 77.5 McCall–Hahn area theorem for an absorbing medium. On propagation the area of the pulse will follow the arrows toward one of the stable values, $0, 2\pi, 4\pi, \dots$

77.8 Multilevel Generalizations

77.8.1 Rydberg Packets and Intrinsic Relaxation

A short laser pulse can populate a band of excited states, and their probability amplitudes will exhibit mutual coherence [13]. This single-atom coherence is transient, even without collisions or other external perturbations to disrupt it, and its decay can be called *intrinsic relaxation*. The decay is basically a dephasing. The dipole moments associated with the excited band interfere due to the wide variety of resonance frequencies of the states in the superposition. Because of the discreteness of the energy levels of any bound quantum system, this relaxation has its own unique characteristics, including similarities with both homogeneous and inhomogeneous decay.

The wave function for a coherently excited system can be expressed in the interaction picture in the form [13]

$$\Psi(r, t) = a(t) \psi_g(r) + \sum_n b_n(t) e^{-i\omega_n t} \psi_n(r) , \quad (77.38)$$

where $\psi_g(r)$ is the ground-state wave function, and n labels the states in an upper band with excitation frequencies $\omega_n \approx \omega$. If $|\omega_n - \omega| \ll \omega_n$, the transition frequency ω_n can be expanded about the principal quantum number \bar{n} of the resonant excited state $E_{\bar{n}} = \hbar\omega$ to obtain

$$\begin{aligned} \omega_n &= \omega_{\bar{n}} + (n - \bar{n}) \frac{\partial \omega_n}{\partial n} + \frac{1}{2!} (n - \bar{n})^2 \frac{\partial^2 \omega_n}{\partial n^2} + \dots \\ &= \omega_{\bar{n}} + (n - \bar{n}) \frac{2\pi}{T_K} + (n - \bar{n})^2 \frac{2\pi}{T_R} + \dots \end{aligned} \quad (77.39)$$

Thus, $2\pi/T_K$ is the mean frequency separating neighboring levels, i.e., $T_K/2\pi = \hbar\rho(E)$, where $\rho(E)$ is the density of excited states, and $2\pi/T_R$ is the mean change in this frequency separation; T_K is the same as the *Kepler period* of a classical orbit, and T_R is the *revival time*. Substituting the Bohr frequencies into the definitions for T_K and T_R yields $T_R = \bar{n}T_K/3$.

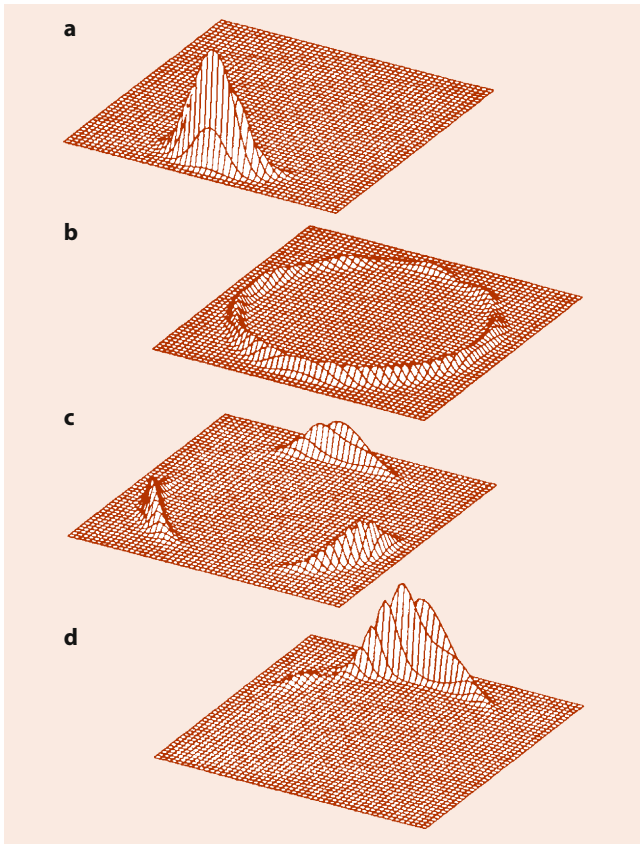

Fig. 77.6 The free evolution of a Rydberg wave packet made up of a superposition of circular-orbit states centered about $n = 360$. (a) Initially, the wave packet is to good approximation a minimum uncertainty wave packet in all three dimensions, but after 12 orbits, (b) the packet has spread all the way around the orbit so that the head and tail of the wave packet overlap, producing interference fringes. (c) After 40 orbits, $t = T_R/3$, the fringes have produced the one-third fractional revival in which three miniature replicas of the original wave packet are equally spaced around the orbit. (d) After 120 orbits, $t = T_R$, the complete wave packet revival occurs

For times $t \leq T_R$, the expansion can be truncated after the third term. Then the wave function is given approximately by

$$\Psi(r, t) \approx a(t)\psi_g(r) + e^{-i\omega\pi t} \sum_m b_{\bar{n}+m}(t) e^{-i2\pi m t/T_K} \times e^{-i2\pi m^2 t/T_R} \psi_{\bar{n}+m}(r), \quad (77.40)$$

where $m = n - \bar{n}$. For high Rydberg states, $\bar{n} \gg 1$, the timescales associated with the two exponentials inside the sum are quite different. For times $t \ll T_K$, the individual levels are not resolved, thus the laser excites what is effectively a continuum with a density of states $\rho(E)$. In that case, the ground-state population simply decays exponentially at the rate given by first-order perturbation theory, $\Gamma = (2\pi/\hbar)d^2\mathcal{E}^2\rho(E)$. At longer times $t \approx T_K$, the first exponential contributes, but the second does not, giving a simple Fourier series time dependence. In this regime, the evolution of the wave function is just periodic motion of a wave packet around a Kepler orbit, as is illustrated in Fig. 77.6a.

Fig. 77.7 Model two-photon resonances. Two photons couple the ground state $|g\rangle$ with an excited state $|e\rangle$. Many intermediate nonresonant levels $|j\rangle$ are present. In (a) we have the cascade system and in (b) the Λ pump-probe system

The coherent quantum wave packet behaves like a classical particle for many Kepler periods, gradually spreading out as the second exponential in the sum Eq. (77.40) begins to contribute. This spreading of the wave packet produces the intrinsic relaxation of the collective dipole moments from the various transitions. However, because the levels are discrete, this decay is not permanent but is reversed and leads to a spontaneous “revival” of the original wave packet [6], without the need for a π -pulse to produce an “echo”.

In its evolution toward the revival, the wave packet passes through a number of *fractional revivals* in which miniature replicas of the original wave packet are equally spaced around the orbit, each traveling at the velocity of a particle traveling in a corresponding classical Kepler orbit. This complex time evolution arises from the spreading of the wave packet all the way around the orbit, so that the head and tail of the packet interfere with each other, producing interference fringes. The further evolution of this fringe pattern produces the various revival phenomena shown in Fig. 77.6.

77.8.2 Multiphoton Resonance and Two-Photon Bloch Equations

Multiphoton transitions (Fig. 77.7a) introduce new coherent transient phenomena. If levels $|g\rangle$ and $|e\rangle$ have the same parity, two photons from the same laser field are sufficient to excite level $|e\rangle$. For simplicity, we regard $|e\rangle$ as a single state, but any number of intermediate levels $|j\rangle$ of opposite parity may be present.

Substituting the state vector

$$|\Psi(t)\rangle = a_g(t)|g\rangle + \sum_j b_j(t) e^{-i\omega t} |j\rangle + a_e(t) e^{-i2\omega t} |e\rangle \quad (77.41)$$

into the Schrödinger equation yields

$$i \frac{da_g}{dt} = -\frac{1}{2} \sum_j \Omega_{gj} b_j, \quad (77.42)$$

$$i \frac{db_j}{dt} = \Delta_{jg} b_j - \frac{1}{2} [\Omega_{jg} a_g + \Omega_{je} a_e], \quad (77.43)$$

$$i \frac{da_e}{dt} = \Delta_{eg} a_e - \frac{1}{2} \sum_j \Omega_{ej} b_j, \quad (77.44)$$

where the Δ s are the detunings, and the Ω s are the Rabi frequencies for the dipole-allowed transitions. For example, $\Omega_{gj} = d_{gj} \mathcal{E} / \hbar$, and $\Delta_{jg} = (E_j - E_g) / \hbar - \omega$ and $\Delta_{eg} = (E_e - E_g) / \hbar - 2\omega$.

If the states $|j\rangle$ are not too close to resonance, the b_j oscillate rapidly and to a first approximation average to zero. A better approximation is to retain the small nonzero solution for b_j obtained by setting $db_j/dt = 0$ in Eq. (77.43) to obtain

$$b_j = -\frac{[\Omega_{jg} a_g + \Omega_{je} a_e]}{2\Delta_{jg}}, \quad (77.45)$$

which can be used to eliminate b_j from the equations for a_g and a_e . This is called *adiabatic elimination* of dipole coherence. In this approximation, levels $|g\rangle$ and $|e\rangle$ are directly coupled to each other, and *two-photon coherence* arises. The coupling of levels $|g\rangle$ and $|e\rangle$ is similar to the two-level coupling described in Sects. 77.3–77.6, and *two-photon Bloch equations* analogous to Eq. (77.16) are the result:

$$\begin{aligned} \frac{dU^{(2)}}{dt} &= -\Delta^{(2)} V^{(2)}, \\ \frac{dV^{(2)}}{dt} &= \Delta^{(2)} U^{(2)} + \Omega^{(2)} W^{(2)}, \\ \frac{dW^{(2)}}{dt} &= -\Omega^{(2)} V^{(2)}. \end{aligned} \quad (77.46)$$

Here the superscript (2) indicates that the variables are identified with the two-photon $|g\rangle \rightarrow |e\rangle$ transition.

The various coefficients are similarly generalized [14]. For example, the two-photon Rabi frequency is given by

$$\Omega^{(2)} \equiv \frac{1}{2} \sum_j \frac{d_{gj} d_{je}}{\hbar^2 \Delta_{jg}} \mathcal{E}^2, \quad (77.47)$$

and the *two-photon detuning* $\Delta^{(2)}$ incorporates the laser-induced level shifts

$$\begin{aligned} \Delta^{(2)} &\equiv \Delta_{ej} + \Delta_{jg} \\ &+ \frac{1}{4} \sum_j \frac{|d_{ej}|^2 \mathcal{E}^2(t)}{\hbar^2 \Delta_{ej}} + \frac{1}{4} \sum_j \frac{|d_{jg}|^2 \mathcal{E}^2(t)}{\hbar^2 \Delta_{jg}}. \end{aligned} \quad (77.48)$$

The last two terms give the difference in the *AC Stark shifts* of the upper and lower levels produced by the laser field.

As before, $W^{(2)}$ is the inversion, but $U^{(2)}$ and $V^{(2)}$ are somewhat different. They cannot be directly tied to the expectation value of a dipole moment because here levels $|g\rangle$ and

$|e\rangle$ have the same parity. Thus, the quantity $U^{(2)} - iV^{(2)}$ is the two-photon analog of $U - iV$ in the original OBEs; however, it cannot serve as a source term in the Maxwell equation.

In the case of continuous wave (CW) applied fields, the solutions to the two-photon OBEs are formally identical to those for a two-level atom. In the case of pulsed fields, however, the detuning $\Delta^2(t)$ is automatically “chirped” in frequency by the Stark shifts. This chirping may significantly modify the dynamics. Multiphoton generalizations of the Bloch equations can be made for other arrangements and numbers of levels. The two-photon version applies to three-level **A** and **V** configurations as well as to the *cascade* system shown in Fig. 77.7a, for which they were derived.

77.8.3 Pump-Probe Resonance and Dark States

Dark states or *trapping states* occur whenever a field-dependent linear combination of active levels is dynamically disconnected from the other levels. This occurs, e.g., in a pump-probe interaction, which fits the scenario of Fig. 77.7b, if two lasers instead of one are used to excite level $|e\rangle$ from the ground level via two-photon resonance. A strong steady laser a is applied for the $|g\rangle \rightarrow |j\rangle$ transitions and a weak tunable “probe” laser b for the $|j\rangle \rightarrow |e\rangle$ transitions. In the simplest format, $\Delta_{eg} = 0$, and all the $|j\rangle$ levels can be combined into a single level labeled $|2\rangle$.

The three-level state vector can be written in terms of field-free states

$$|\Psi(t)\rangle = a_g |g\rangle + b_2 |2\rangle + a_e |e\rangle, \quad (77.49)$$

or, in terms of field-dependent dressed states,

$$|\Psi(t)\rangle = A_T |T\rangle + b_2 |2\rangle + A_S |S\rangle, \quad (77.50)$$

where $\Omega|T\rangle \equiv \Omega_a |e\rangle - \Omega_b |g\rangle$, $\Omega|S\rangle \equiv \Omega_a |g\rangle + \Omega_b |e\rangle$ and

$$A_S(t) \equiv \Omega^{-1} [\Omega_a a_g + \Omega_b a_e], \quad (77.51)$$

$$A_T(t) \equiv \Omega^{-1} [\Omega_a a_e - \Omega_b a_g]. \quad (77.52)$$

The normalizing factor is $\Omega \equiv \sqrt{\Omega_a^2 + \Omega_b^2}$.

The state $|T\rangle$ is an eigenvector of the three-level rotating wave approximation (RWA) Hamiltonian, with eigenvalue zero, and the amplitude $A_T(t)$ is a constant of motion. Thus, $|T\rangle$ is termed a *trapping state*, and the population in $|T\rangle$ is inaccessible to the (possibly very strong) laser fields. At two-photon resonance, this conclusion is robust, not depending strongly on the idealized conditions assumed here. In fact, A_T , the trapping state amplitude, is an adiabatic invariant, remaining constant to first order even under slow changes in Ω_a and Ω_b . In a pump-probe experiment, this trapping state is observed as an abrupt drop in probe absorption, as

the probe frequency is tuned through two-photon resonance. Since only two-photon resonance is required (both transitions can be equally detuned) this coherent transient effect has no analog in two-level physics.

The ideal method for exciting the trapping state from the ground state uses another coherent transient process called *counterintuitive pulse sequencing* in which pulse b is turned on first. The trapping state $|T\rangle$ is essentially the ground state $|g\rangle$ if $\Omega_a = 0$. Thus, if Ω_b is turned on first, and then Ω_a is turned on later, the ground state adiabatically becomes the trapping state, and all initial probability flows smoothly with it.

An essential point is the ease with which pump-probe adiabaticity is maintained, particularly for strong fields on resonance, in contrast to one-photon adiabaticity, which is never achieved at strong-field resonance. In the pump-probe case, one must only satisfy the inequality

$$\left| \frac{d\Omega_a}{dt} \Omega_b - \frac{d\Omega_b}{dt} \Omega_a \right| \ll (\Omega_a^2 + \Omega_b^2)^{3/2}, \quad (77.53)$$

which is automatically accomplished by counterintuitive pulse sequencing. The inequality allows one to tolerate a rapid change of Ω_b while $\Omega_a = 0$. Then after Ω_b has reached a high value, Ω_a can also be turned on very rapidly because the right-hand side of Eq. (77.53) is already very large. This is “counterintuitive” excitation because if the population is in level $|g\rangle$, it is “natural” to turn on pulse Ω_a first, not Ω_b . It can be dramatically beneficial to use counterintuitive excitation when it is important to avoid relaxation associated with level $|2\rangle$.

77.8.4 Induced Transparency

The foregoing results for three-level excitation can be extended to resonant pulse propagation in three-level media. The equations governing simultaneous two-pulse evolution in the local-time coordinates $cT \equiv ct - z$ and $\zeta \equiv z$ are

$$\frac{\partial \Omega_a}{\partial \zeta} = i\mu_a a_g^* a_2, \quad (77.54)$$

$$\frac{\partial \Omega_b}{\partial \zeta} = i\mu_b a_e^* a_2, \quad (77.55)$$

where, as before,

$$\mu_a = \frac{4\pi d_a^2 N \omega_a}{\hbar c}, \quad \text{etc.} \quad (77.56)$$

Note that the bilinear combination $2a_g^* a_2$ corresponds to $U - iV$ in Eq. (77.27).

Soliton-like pulses can propagate in three-level media. Both pulses must compete for interaction with level $|2\rangle$. They

depend only on a single variable $Z \equiv \zeta - uT$, where u is the pulse’s constant velocity in the moving frame. Soliton solutions are given (for $\mu_a = \mu_b$) by

$$\Omega_a = A \operatorname{sech} KZ, \quad \Omega_b = B \tanh KZ, \quad (77.57)$$

and

$$\begin{aligned} a_g &= -\tanh KZ, \\ a_2 &= \frac{-2iKu}{A} \operatorname{sech} KZ, \\ a_e &= \frac{B}{A} \operatorname{sech} KZ, \end{aligned} \quad (77.58)$$

where the parameters A, B, Ku are nonlinearly related to the pulse length τ :

$$Ku \equiv 1/\tau \quad \text{and} \quad (2/\tau)^2 = A^2 - B^2. \quad (77.59)$$

The moving frame velocity is given by $1/u = 2\mu/A^2$, and the expression for the lab frame velocity V is $1/V = 1/c + 2\mu/A^2$.

If $B \rightarrow 0$, then $A \rightarrow 2/\tau$, which is the exact McCall–Hahn formula for the two-level one-pulse soliton amplitude [1]. No adiabatic condition was invoked in obtaining the soliton solutions. The physical measure of adiabaticity comes from the pulse duration τ . If τ is short, an appreciable population appears transiently in level $|2\rangle$, but if τ is long (an adiabatic pulse), the population skips level $|2\rangle$ and goes directly from $|g\rangle$ to $|e\rangle$ and back again during the pulse.

Note that the sech and tanh functions are ideally counterintuitive, with pulse b starting infinitely far ahead of pulse a . In practice, the infinite leading edge of the tanh function plays no role and can be truncated to several times τ without appreciable change in the character of the pulse pair.

77.9 Disentanglement and “Sudden Death” of Coherent Transients

The existence of entanglement (nonseparability) of states is the most prominent evidence that quantum mechanics allows possibilities not known in classical physics. This has consequences for coherent transients, allowing them to exhibit nonintuitive effects unlike any discussed up to this point. An example that directly illustrates this point shows that two entangled atoms whose inversion and coherences decay exponentially can have an entanglement that does not decay similarly smoothly and reaches zero long *before* the atoms reach their final states. This shows that transients of an entangled pair of atoms can be very different from the transients affecting the atoms separately.

We imagine the situation sketched in Fig. 77.8, two two-level atoms A and B of the type discussed at length already,

Fig. 77.8 Illustration of a setup in which two partially excited atoms A and B are located inside two spatially separated cavities that are possibly very remote from each other. The two atoms are assumed to initially be entangled, but they have no interaction

prepared by an earlier interaction in a partially excited entangled mixed state and subsequently located remotely from each other, without further interaction. They each must eventually, because of spontaneous emission, come to their ground states, creating the final joint state $|g\rangle_A \otimes |g\rangle_B$, which is clearly not entangled, a factored simple product. The question is, what is the manner of evolution by which the entanglement of the pair evolves toward zero?

The standard master equation methods [15] for investigating spontaneous emission [16] can be applied to each atom separately since they are not interacting with each other. For any initial state $\rho^{AB}(0)$, the density operator at t can be expressed as

$$\rho^{AB}(t) = \sum_{\mu=1}^4 K_{\mu}(t)\rho^{AB}(0)K_{\mu}^{\dagger}(t), \quad (77.60)$$

where the so-called Kraus operators [17] $K_{\mu}(t)$ are available in closed form in this case [18].

For illustration purposes, we will choose a partially coherent initial state, expressed by a two-atom density matrix with a single free parameter a :

$$\rho^{AB}(0) = \frac{1}{3} \begin{pmatrix} a & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1-a \end{pmatrix}. \quad (77.61)$$

Here, the convention is to label the rows and columns in the “inverted” order ee, eg, ge, gg . That is, the probabilities are $a/3$ that both atoms are in state $|e\rangle$ at $t = 0$ and $(1-a)/3$ in state $|g\rangle$, and with probability $1/3$, they are in either one of the opposite pair states, with the sum equaling 1, of course. Local transient decay, e.g., of either atom’s inversion W , can be evaluated separately from their reduced density matrices, $\rho^A \equiv \text{Trace}_B\{\rho^{AB}\}$, etc. For example,

$$\begin{aligned} \rho^A &= {}_B\langle e|\rho^{AB}|e\rangle_B + {}_B\langle g|\rho^{AB}|g\rangle_B \\ &= \frac{1}{3} \begin{pmatrix} 1+a & 0 \\ 0 & 2-a \end{pmatrix}, \end{aligned} \quad (77.62)$$

and the upper level occupation of atom A can be found to decay exactly as expected: $\rho_{ee}^A(t) = \frac{a+1}{3} e^{-t/\tau_0}$, where τ_0 is the usual spontaneous emission lifetime.

For nonlocal transients, we need a time-dependent measure of entanglement, and there are several options [19], all related to the joint entropy of the two-atom system. We will use the concurrence $C(t)$ of Wootters [20], which has the convenient normalization $1 \geq C(t) \geq 0$, where $C = 1$ represents completely entangled atoms (such as in a pure Bell state, for example), and $C = 0$ denotes the complete absence of entanglement.

For the specific case $a = 1$, one finds for the state Eq. (77.61) the initial concurrence $C(0) = \frac{2}{3}$, indicating a state with partial two-party coherence (incomplete entanglement). At time t , one then finds:

$$C^{AB}(t) = \frac{2}{3} \max\{0, e^{-t/\tau_0} f(t)\}, \quad (77.63)$$

where $f(t) = 1 - \sqrt{2\omega^2 + \omega^4}$, and $\omega \equiv 1 - e^{-t/\tau_0}$. The strikingly nonintuitive consequence of this transient is that $C(t)$ reaches 0 abruptly after a finite time (disentanglement suffers a “sudden death”), if $2\omega^2 + \omega^4 \geq 1$. In fact, only a minor algebraic rearrangement shows that this strange condition must occur, and that the finite sudden death time t_0 is given by

$$\frac{t_0}{\tau_0} \equiv \ln \left[\frac{2 + \sqrt{2}}{2} \right] \approx 0.53. \quad (77.64)$$

The nonlocal coherent transient behavior of entanglement for the entire range of allowed a values [18] is shown in Fig. 77.9. This shows that the concurrence undergoes familiar smooth and infinitely long decay only for a values in the limited range $\frac{1}{3} > a \geq 0$. Otherwise, sudden (finite-time) death occurs sooner or later. In our example, nonlocal coherence becomes zero most abruptly after a finite time for $a = 1$, the case that was calculated in Eq. (77.63). It appears that these results are not exceptional. Sudden termination of entanglement has also been predicted for two-party continuum

Fig. 77.9 Effect of spontaneous emission on concurrence of two two-level atoms, given the initially entangled mixed state Eq. (77.61) depending on the single parameter $1 \geq a \geq 0$

states, as well as for qubit pairs experiencing only T_2 decay, in contrast to the combined T_1 and T_2 decay appropriate to spontaneous emission as treated here.

Abstract

The excitation of atoms by intense laser pulses can be divided into two broad regimes: the first regime involves relatively weak optical laser fields of long duration, and the second involves strong fields of short duration. In the first case, the intensity is presumed to be high enough for multiphoton transitions to occur. The resulting spectroscopy is not limited by the single-photon selection rules for radiative transitions. However, the intensity is still low enough for a theoretical description based on perturbations of field-free atomic states to be valid, and the time dependence of the field amplitude does not play an essential role. In the second case, the field intensities are too large to be treated by perturbation theory, and the time dependence of the pulse must be taken into account. In addition to a detailed picture of the two subjects described above, we include a discussion on the generation of attosecond pulses and applications of both high-order harmonic generation (HHG) and above-threshold ionization (ATI). Furthermore, we incorporate a brief summary about the incipient field of atto-nano physics.

78.1 Introduction

The excitation of atoms by intense laser pulses can be divided into two broad regimes determined by the characteristics of the laser pulse relative to the atomic response. The first regime involves relatively weak optical laser fields of long

duration (> 1 ns), and the second involves strong fields of short duration (< 10 ps). These will be referred to as the weak-long (WL) and strong-short (SS) cases, respectively.

In the case of atomic excitation by WL pulses, the intensity is presumed to be high enough for multiphoton transitions to occur. The resulting spectroscopy of absorption to excited states is potentially much richer than single-photon excitation because it is not limited by the single-photon selection rules for radiative transitions. However, the intensity is still low enough for a theoretical description based on perturbations of field-free atomic states to be valid, and the time dependence of the field amplitude does not play an essential role.

The SS case is fundamentally different in that the atomic electrons are strongly driven by fields too large to be treated by perturbation theory, and the time dependence of the pulse as it switches on and off must be taken into account. Atoms may absorb hundreds of photons, leading to the emission of one or more electrons, as well as photons of both lower and higher energy. Because the flux of incident photons is high, a classical description of the laser field is adequate, but the time-dependent Schrödinger equation (TDSE) must be solved directly to obtain an accurate representation of the atom–field interaction.

For SS pulses of optical wavelength, it is sufficient in most cases to consider only the electric dipole (E1) interaction term defined in Chap. 72. The atom–field interaction can then be expressed in either the length gauge or the velocity gauge [1] (Chap. 22). In the length gauge, the TDSE is

$$i\hbar \frac{\partial \Psi(\mathbf{r}, t)}{\partial t} = [H_0 + e\mathbf{r} \cdot \mathbf{E}(t)]\Psi(\mathbf{r}, t), \quad (78.1)$$

where H_0 is the field-free atomic Hamiltonian, \mathbf{r} the collective coordinate of the electrons, and $\mathbf{E}(t)$ the electric field of the laser given by

$$\mathbf{E}(t) = \mathcal{E}(t)[\hat{\mathbf{x}} \cos(\omega t + \varphi) + \epsilon \hat{\mathbf{y}} \sin(\omega t + \varphi)]. \quad (78.2)$$

Here, $\mathcal{E}(t)$ defines the envelope, φ is the so-called carrier envelope phase (CEP), and ϵ characterizes the polarization: linear if $\epsilon = 0$ and circular if $|\epsilon| = 1$. In the velocity gauge, the TDSE is

$$i\hbar \frac{\partial \psi(\mathbf{r}, t)}{\partial t} = \left[H_0 - \frac{ie\hbar}{mc} \mathbf{A}(t) \cdot \nabla + \frac{e^2}{2mc^2} A^2(t) \right] \psi(\mathbf{r}, t). \quad (78.3)$$

Here, $\mathbf{A}(t) = -c \int^t \mathbf{E}(t') dt'$ is the vector potential of the laser field. The solutions of Eqs. (78.1) and (78.3) are related by the phase transformation

$$\Psi(\mathbf{r}, t) = \exp \left[\frac{ie}{\hbar c} \mathbf{r} \cdot \mathbf{A}(t) \right] \psi(\mathbf{r}, t). \quad (78.4)$$

Since lasers must usually be focused to reach the strong-field regime, measured electron and ion yields include contributions from a distribution of field strengths. The photoemission spectrum, on the other hand, contains a coherent component due to the macroscopic polarization of all the atoms and is, therefore, sensitive also to the laser phase variations within the focal volume. In this chapter, methods for solving Eqs. (78.1) and (78.3) are discussed along with details of the atomic emission processes.

Three relevant books provide excellent introductions to this subject [1–3]. Further developments are well described in the proceedings of the International Conferences on Multiphoton Physics [4–7] and the NATO workshop on Super-Intense Laser-Atom Physics [8, 9].

78.2 Weak-Field Multiphoton Processes

78.2.1 Perturbation Theory

Since atomic ionization energies are generally $\gtrsim 10$ eV, while optical photons have energies of only a few eV, several photons must be absorbed to produce ionization, or even electronic excitation in the case of the noble gases. For WL pulses, the electronic states are only weakly perturbed by the electromagnetic field. The rate of an n -photon transition can then be calculated using the n -th order perturbation theory for the atom–field interaction. For an incident photon number flux ϕ of frequency ω , the rate is

$$W_{i \rightarrow f}^{(n)} = 2\pi \left(\frac{2\pi\alpha\phi\omega}{e^2} \right)^n \left| T_{i \rightarrow f}^{(n)} \right|^2 \delta(\omega_i + n\omega - \omega_f), \quad (78.5)$$

where

$$T_{i \rightarrow f}^{(n)} = \langle f | d G[\omega_i + (n-1)\omega] \times d G[\omega_i + (n-2)\omega] \cdots d G[\omega_i + \omega] d | i \rangle, \quad (78.6)$$

$|i\rangle$ is the i -th eigenstate of the field-free atomic Hamiltonian, $d = e\hat{\mathbf{e}} \cdot \mathbf{r}$, with $\hat{\mathbf{e}}$ the polarization direction, and

$$G(\omega) = \sum_j \frac{|j\rangle\langle j|}{(\omega - \omega_j + i\Gamma_j/2)}. \quad (78.7)$$

The sum over j includes an integration over the continuum for all sequences of E1 transitions allowed by angular momentum and parity selection rules. Methods for calculating cross sections and rates in the weak-field regime are described in [1, 10] and in Chap. 25.

78.2.2 Resonant-Enhanced Multiphoton Ionization

For multiphoton ionization, ω can be continuously varied because the final state in Eq. (78.5) lies in the continuum. If ω is tuned so that $\omega_i + m\omega \cong \omega_j$ for some contributing intermediate state $|j\rangle$ in Eq. (78.7), then in that state lies an integer m photons above the initial state, and the corresponding denominator vanishes (to within the level width Γ_j), producing a strongly peaked resonance. Since it takes $k = n - m$ additional photons for ionization, the process is called m, k resonant-enhanced multiphoton ionization (REMPI). Measurements of the photoelectron angular distribution are useful in characterizing the resonant intermediate state.

Calculations using the semi-empirical multichannel quantum defect theory to provide the needed matrix elements have been very successful in describing experimental results. This technique is discussed in more detail in Chap. 49.

The perturbation equation Eq. (78.5) indicates that the rate for nonresonant multiphoton ionization scales as ϕ^n for an n -photon process [11]. However, this is not the case for REMPI since the resonant transition saturates, and Eq. (78.5) no longer applies. Then the rate can be controlled either by the m -photon resonant excitation step or by the number of photons k needed for the ionization step.

78.2.3 Multielectron Effects

Multiply excited states can play a role in multiphoton excitation dynamics. These states are particularly important if their energies are below or not too far above the first ionization potential. Configuration expansions including these states have been used successfully in studies, for example, of the alkaline earth atoms, which have many low-lying doubly excited states. The presence of these states can also enhance the direct double ionization of an atom [12].

78.2.4 Autoionization

The configuration interaction between a bound state and an adjacent continuum leads to an absorption profile in the single photon ionization spectrum with a Fano lineshape. The actual lineshape reflects the interference between the two pathways to the continuum. Autoionizing states can also be probed via multiphoton excitation [13, 14]. Because, in the strong-field regime, coupling strengths and phases change with intensity, the lineshapes can be strongly distorted by changing the incident intensity. At particular intensities, the phases of the excited levels can be manipulated to prevent autoionization completely. Then a trapped population with energy above the ionization limit can be created [15].

78.2.5 Coherence and Statistics

Real laser fields exhibit various kinds of fluctuations and so are never perfectly coherent. The effects of such fluctuations on the complex electric field amplitude

$$E(t) = \mathcal{E}(t) \exp[-i\omega t + \varphi(t)] \quad (78.8)$$

can be modeled by a variety of stochastic processes [16], depending on the conditions [10, 17–20], as follows.

For continuum wave (CW) lasers, a phase diffusion model (PDM) is often used, for which $\mathcal{E}(t) = \mathcal{E} = \text{const.}$ and

$$\dot{\varphi}(t) = \sqrt{2b}F(t), \quad (78.9)$$

where $F(t)$ describes white noise by a real Gaussian function [16] characterized by the averaged values $\langle F(t) \rangle = 0$, $\langle F(t)F(t') \rangle = 2b\delta(t - t')$. The stochastic electric field then has an exponential autocorrelation function

$$\langle E(t)E^*(t') \rangle = \mathcal{E}^2 \exp[-b|t - t'| - i\omega(t - t')], \quad (78.10)$$

and a Lorentzian spectrum of width b . Far-off resonance, such a Lorentzian spectrum often gives unrealistic results, and the model Eq. (78.9) is then replaced by an Ornstein-Uhlenbeck process,

$$\ddot{\varphi}(t) = -\beta\dot{\varphi}(t) + \sqrt{2b\beta}F(t), \quad (78.11)$$

where the parameter β for $\beta \ll b$ plays the role of a cutoff of the Lorentzian spectrum.

A multimode laser with a large number M of independent modes has a field of the form $E(t) = \sum_{j=1}^M \mathcal{E}_j \exp[-i\omega_j t + i\varphi_j(t)]$, and according to the central limit theorem [16], can be described for large M as a complex Gaussian process defined to be a chaotic field,

$$\dot{E}(t) = -(b + i\omega)E(t) + \sqrt{2b|E(t)|^2}F(t), \quad (78.12)$$

where $F(t)$ is now a complex white noise, and ω is the central frequency of the field. The field, Eq. (78.12) has an exponential autocorrelation function and a Lorentzian spectrum of width b .

Various other stochastic models have been discussed in the literature. These include Gaussian fluctuations of the real amplitude of the field $\mathcal{E}(t)$; Gaussian chaotic fields with non-Lorentzian spectra; non-Gaussian, nonlinear diffusion processes (that describe for instance a laser close to threshold [16]); multiplicative stochastic processes (that describe a laser with pump fluctuations [18]) and jump-like Markov processes [21–23]. Statistical properties of laser fields can sometimes be controlled experimentally to a great extent [19, 20].

78.2.6 Effects of Field Fluctuations

Since the response of systems undergoing multiphoton processes is, in general, a nonlinear function of the field intensity (and, in particular, of the field amplitude), it depends in a complex manner on the statistics of the field. The enhancement of the nonresonant multiphoton ionization rate illustrates the point. According to the perturbation equation Eq. (78.5), the rate of an n -photon process is proportional to ϕ^n ; i.e., to I^n , where I is the field intensity. For fluctuating fields, the average response is thus

$$W_{i \rightarrow f}^{(n)} \propto \langle I^n \rangle \propto \langle |E(t)|^{2n} \rangle. \quad (78.13)$$

Phase fluctuations (as described by PDM) do not affect the average. On the other hand, for complex chaotic fields, the average is

$$\langle I^n \rangle \cong n! \langle I \rangle^n, \quad (78.14)$$

i.e., there exists a significant enhancement of the rate for $n > 1$.

Field fluctuations lead to more complex effects in resonant processes. Two well-studied examples are the enhancement of the AC Stark shift in resonant multiphoton ionization [24], and the spectrum of double optical resonance – a process in which the AC Stark splitting of the resonant line is probed by a slightly detuned fluctuating laser field [18]. Double optical resonance is very sensitive not only to the bandwidth of the probing field but also to the shape of its frequency spectrum.

78.2.7 Excitation with Multiple Laser Fields

The simultaneous application of more than one laser field produces interesting and novel effects. If a laser and its second (2ω) or third (3ω) harmonic are combined and the relative phase between the fields controlled, product state distributions and yields can be altered dramatically. The effects include reducing the excitation or ionization rates in the $\omega - 3\omega$ case [25] or altering the photoelectron angular distributions and the harmonic emission parity selection rules using a $\omega - 2\omega$ laser source [26].

A laser field can dress or strongly mix the field-free excited states, including the continuum, of an atom. This can produce a number of effects depending on how the dressed system is probed. By coupling a bound, excited state with the continuum, ionization strengths and dynamics are altered, resulting in new resonance-like structures where none existed before. This effect is called laser-induced continuum structure, or LICS [15, 27]. This general idea has been exploited to design schemes for lasers without

inversion [28] in which the dressed atom can have an inverted population, allowing gain, even though in terms of the undressed states, the lower level has the largest population. A laser can produce dramatic changes in the index of refraction of an atomic medium [29], creating, at specific frequencies, laser-induced transparency for a second, probe laser field. Multistep ionization, where each step is driven by a laser at its resonant frequency, has resulted in two useful applications. These are: efficient atomic isotope separation [23]; and the detection of small numbers of atoms in a sample, called single-atom detection. This technique is extremely sensitive because the use of exact resonance for each step yields very large cross sections for ionization, and the efficiency of collecting ions is high [30].

78.2.8 Waveforms

One step beyond would be to drive the atomic or molecular system with a so-called multicolor laser field, i.e., with a laser source created starting from different laser frequencies, not necessarily a multiple of each other (these sources are also known as waveforms or light-field transients). Waveform-controlled light transients with a bandwidth spanning almost two octaves have been demonstrated at microjoule energy and gigawatt peak power levels. These particular sources allow temporal confinement of optical radiation to less than 1 fs in subcycle waveforms. With their power substantially enhanced, these extreme waveforms may open up a new stage in nonlinear optics and attoscience. This is mainly due to, among other things, the feasibility of suppressing ionization up to unprecedented peak intensities and instantaneous ionization rates approaching optical frequencies, respectively. A prototypical three-color few-cycle system is already available, and it offers a conceptually simple route to scaling multioctave optical waveform synthesis to the multiterawatt regime (e.g., [31]). To this end, with the three channels delivering few-cycle pulses in the visible (VIS), $0.45 \approx 0.65 \mu\text{m}$, near-infrared (NIR), $0.7 \approx 1.3 \mu\text{m}$, and mid-infrared (MIR), $1.6 \approx 2.7 \mu\text{m}$, spectral ranges are recombined using a set of dichroic chirped mirrors to yield one single beam. Additionally, the feasibility of superoctave optical waveform synthesis was recently demonstrated in the NIR-VIS-ultraviolet (UV) spectral range by seeding a three-channel and, more recently, a four-channel, synthesizer consisting of broadband chirped mirrors with a continuum originating from a Ti:sapphire-laser-driven hollow-fiber/chirped-mirror compressor. Further degrees of freedom for waveform sculpting can be introduced by shaping the amplitude and phase of the spectra of the individual channels, e.g., via an acousto-optic pulse shaper and/or a spatial light modulator (for a recent review see, e.g., [32]).

78.3 Strong-Field Multiphoton Processes

Recently developed laser systems can produce very short pulses, some as short as a few to tens of femtoseconds, while at the same time maintaining the pulse energy so that the peak power becomes very high. In this regard, e.g., focused intensities up to 10^{19} W/cm² have been achieved. Because the pulses are short, atoms survive to much higher intensities before ionizing, making possible studies of laser–atom interactions in an entirely new regime [33]. A discussion of the status of short-pulse laser development is given in Chap. 75 and in [34].

With increasing intensity, higher-order corrections to Eq. (78.6) contribute to the transition rate. The next order correction comes from transitions involving two additional photons, one absorbed and one emitted, leading to the same final state. One effect of these terms is to shift the energies of the excited states in response to the oscillating field. This is called the dynamic or AC Stark shift. The AC Stark shift of the ground state tends to be small because of the large detuning from the excited states for long wavelength photons. On the other hand, in strong fields, the shift of the higher states and the continuum can become appreciable. Electrons in highly excited states respond to the oscillating field in the same manner as a free electron. Their energies shift with the continuum by the amount

$$U_p = \frac{(1 + \epsilon)e^2 \mathcal{E}^2}{4m\omega^2}, \quad (78.15)$$

where U_p is the cycle-averaged kinetic energy of a free electron in the field, and ϵ defines the polarization of the field Eq. (78.2); U_p is called the ponderomotive or quiver energy of the electron. For strong laser fields, U_p can be several eV or more, meaning that during a pulse, many states shift through resonance as their energies change by an amount larger than the incident photon energy. The resulting intensity-induced resonances can dominate the ionization dynamics.

Electrons promoted into the continuum acquire the ponderomotive energy, oscillating in phase with the field. In a linearly polarized field, the amplitude of the quiver motion of a free electron, given by $e\mathcal{E}/m\omega^2$, can become many times larger than the bound-state orbitals. If the initial velocity of an electron is small after ionization, it can be accelerated by the laser electric field and back into the vicinity of the ion core, when the field reverses its direction. The subsequent rescattering process, amongst other effects, changes the photoelectron energy and angular distributions, and allows the emission of high-energy photons [35, 36]. This simple dynamical picture forms the basis of the current understanding of many strong-field multiphoton processes.

78.3.1 Nonperturbative Multiphoton Ionization

The breakdown of perturbation theory for n th-order multiphoton processes occurs when the higher-order correction terms become comparable to the n -th-order term. Assuming that the dipole strength is $\propto ea_0$, where a_0 is the Bohr radius, and the detuning is $\delta \propto \omega$, the ratio of an $(n + 2)$ -order contribution to the n -th-order term from Eq. (78.6) is [1]

$$R_{n+2,n} \approx \left(\frac{2\pi\alpha\phi\omega}{e^2} \right) \left(\frac{ea_0}{\omega} \right)^2 = \left(\frac{I}{I_\gamma} \right) \left(\frac{\omega_a}{2\omega} \right)^2, \quad (78.16)$$

where $\hbar\omega_a \approx 27.2114$ eV is the atomic unit of energy e^2/a_0 , and $I_\gamma \approx 3.50945 \times 10^{16}$ W/cm² is the intensity corresponding to an atomic unit of field strength, given by $E_a = \alpha c(m/a_0^3)^{1/2} \approx 5.1422 \times 10^9$ V/cm. The atomic unit of intensity itself is defined by

$$I_a = \phi_a \hbar\omega_a = \alpha c E_a^2, \quad (78.17)$$

which is $6.436414(4) \times 10^{15}$ W/cm². Thus, $I_\gamma = I_a/(8\pi\alpha)$. For photon energies of 1 eV, $R_{n+2,n}$ becomes unity for $I \approx 10^{14}$ W/cm². Because of the large number of $(n + 2)$ -order terms, perturbation theory actually fails for $I > 10^{13}$ W/cm². Above this critical intensity, nonresonant n -photon ionization ceases to scale with the ϕ^n dependence predicted by perturbation theory.

78.3.2 Tunneling Ionization

At sufficiently high intensity and low frequency, a tunneling mechanism changes the character of the ionization process. For lasers in the infrared (IR) or optical range, a strongly bound electron can respond to the instantaneous laser field since the oscillating electric field varies slowly on the timescale of the electron. The Coulomb attraction of the ion core combines with the laser electric field to form an oscillating barrier through which the electron can escape by tunneling, if the amplitude of the laser field is large enough. The DC rate for this process is $e\mathcal{E}/\sqrt{2mI_p}$, where I_p is the ionization potential of the electron. When this rate is comparable to the laser frequency, tunneling becomes the most probable ionization mechanism [37–39]. The ratio of the incident laser frequency to the tunneling rate is called the Keldysh parameter and is given by

$$\gamma = \sqrt{I_p/2U_p}, \quad (78.18)$$

which is less than unity ($\gamma \ll 1$) when tunneling dominates and larger than unity ($\gamma \gg 1$) when multiphoton ionization

governs the laser–matter process. Interestingly, many experiments are carried out in an intermediate or *crossover* region, defined by $\gamma \approx 1$. Another way to interpret γ is to note that we can write $\gamma = \tau_T/\tau_L$, where τ_T is the Keldysh time (defined as $\tau_T = \sqrt{2I_p/F}$) and $\tau_L = 2\pi/\omega$ is the laser period. Hence, γ serves as a measure of nonadiabaticity by comparing the response time of the electron wavefunction to the period of the laser field.

78.3.3 Multiple Ionization

Excitation and ionization dynamics are dominated by single-electron transitions in the strong-field regime. Although atoms can lose several electrons during a single pulse, the electrons are released sequentially. There is no convincing evidence of significant collective excitation in atoms in strong fields, even though it has been extensively sought. Once one electron is excited in an atom, the remaining electrons have much higher binding energies. As a result, the laser field is unable to affect them significantly until it reaches a much higher intensity. By that time, the first electron has already been emitted.

Simultaneous ejection of two electrons occurs as a minor channel (< 1%) in strong-field multiple ionization. Although it is possible that doubly excited states of atoms could assist in the double ionization, in the helium and neon cases studied, these states are unlikely to be contributors [40].

Correlated multi-electron ionization became a very hot subject over the past 20 years. Various mechanisms were proposed and demonstrated theoretically and experimentally. Perhaps the most important is the recollision mechanism, in which one electron tunnels out and is driven back to the nucleus by the laser field, where it recollides and releases a second atomic or molecular electron [41].

78.3.4 Above Threshold Ionization

In strong optical and IR laser fields, electrons can gain more than the minimum amount of energy required for ionization. Rather than forming a single peak, the emitted electron energy spectrum contains a series of peaks separated by the photon energy. This is called above-threshold-ionization, or ATI [42–45]. The peaks appear at the energies

$$E_s = (n + s)\hbar\omega - I_p, \quad (78.19)$$

where n is the minimum number of photons needed to exceed I_p , and $s = 0, 1, \dots$ is called the number of excess photons or above threshold photons carried by the electron. Calculations in the perturbative regime for ATI are given for hydrogen in [11].

Peak Shifting

As the intensity approaches the nonperturbative regime, the AC Stark shift of the atomic states begins to play a significant role in the structure of the ATI spectrum. The first effect is a shift of the ionization potential, given roughly by the ponderomotive energy U_p . Additional photons may then be required in order to free the electron from the atom, i.e., enough to exceed $I_p + U_p$. If the emitted electron escapes from the focal volume while the laser is still on, it is accelerated by the gradient of the field. The quiver motion is converted into radial motion, increasing the kinetic energy by U_p and exactly canceling the shift of the continuum. In this situation, the electron energies are still given by Eq. (78.19). However, when U_p exceeds the photon energy, the lowest ATI peaks disappear from the spectrum. In this long pulse limit, no electron is observed with energy less than U_p . This is called peak shifting and names the situation where the dominant peak in the ATI spectrum moves to higher order as the intensity increases.

ATI Resonance Substructure

If the laser pulse is short enough (< 1 ps for the typical laser focus), the field turns off before the electron can escape from the focal volume. Then the quiver energy is returned to the field, and the ATI spectrum becomes much more complicated. The observed electron energy can now be computed by

$$E_s \text{ (short pulse)} = (n + s)\hbar\omega - (I_p + U_p), \quad (78.20)$$

which results shifted an amount U_p with respect to the long pulses case Eq. (78.19). Electrons from different regions of the focal volume are thus emitted with different ponderomotive shifts, introducing a substructure in the spectrum, which can be directly associated with AC Stark-shifted resonances [42, 43].

ATI in Circular Polarization

The above discussion is particularly appropriate for the case of linear polarization, where the excited states of the atom can play a significant role in the excitation. On the contrary, in a circularly polarized field, the orbital angular momentum L must increase one unit with each photon absorbed, so that multiphoton ionization is allowed only to states that have high L , and, hence, a large centrifugal barrier. The lower energy scattering states thus cannot penetrate into the vicinity of the initial state. Thus, the ATI spectrum in circular polarization peaks at high energy and is very small near threshold.

ATI Applications

In the few-cycle regime, a precise knowledge of the CEP is instrumental to adequately characterize the subsequent nonlinear laser–matter phenomena. Then, the CEP plays

a major role in, for instance, the production and control of single attosecond pulses and the investigation of nonsequential double-electron ionization [46–48], amongst others. Recently, experimental observations of ATI driven by few-cycle IR-laser pulses have demonstrated that using a so-called “stereo” technique measurement of electrons emitted on the left and on the right with respect to the linear laser polarization, it is possible to extract the CEP of the driving laser [49].

In addition, another important application is to use energetic rescattered ATI electrons to estimate the bond distance in molecules. For instance, recent measurements in acetylene (C_2H_2) [50] have proved that it is entirely possible to extract structural information of the chemical internuclear distance between the carbon atoms in the C–C pair and the carbon and hydrogen atoms in the C–H one, both with unprecedented high accuracy. This singular technique is named laser-induced electron diffraction (LIED) and promises to lead the time-resolved studies in complex molecules [51].

The two above-mentioned examples, namely the few-cycle CEP characterization and the LIED technique, show the capabilities of ATI to interrogate nature and answer fundamental questions about both the electron dynamics and molecular structure, just to name a few. Hence, ATI provides a powerful tool to not only give light about time-dependent atomic and molecular processes but also to configure an invaluable ally for extracting information of the driving laser itself [49].

78.3.5 High-Order Harmonic Generation

High-order harmonic generation (HHG) in noble gases is a rapidly developing field of laser physics [33, 52–54]. When an SS pulse interacts with an atomic gas, the atoms respond in a nonlinear way, emitting coherent radiation at frequencies that are integral multiples of the laser frequency. Due to the inversion symmetry of the atom, only odd harmonics of the fundamental are emitted. In the high-intensity ($> 10^{13}$ W/cm²), low-frequency regime, the harmonic strengths fall off for the first few orders, followed by a broad plateau of nearly constant conversion efficiency and then a rather sharp cutoff [52, 53]. The plateau extends to well beyond the hundredth order of the 800–1000 nm incident wavelengths, using the light noble gases as the active medium. Moreover, there has also been experimental evidence of HHG from ions. Considering the laser-induced electron dynamics behind HHG natively develops on a sub-fs timescale, HHG provides a source of very bright, short-pulse, coherent XUV radiation, which can have several advantages over the other known sources, such as the synchrotron.

Plateau and Cutoff

The well-known three-step model [35, 36], which in 2018 turned 25 years old and combines quantum and classical aspects of laser-atom physics, accounts for many strong-field phenomena. In this model, the electron first tunnels out [55] from the ground state of the atom through the barrier formed by the Coulomb potential and the laser field. Its subsequent motion can be treated classically, and primarily consists of oscillatory motion in phase with the laser field. If the electron returns to the vicinity of the nucleus with kinetic energy \mathcal{T} , it may recombine into the ground state with the emission of a photon of energy $(2n + 1)\hbar\omega \leq \mathcal{T} + I_p$, where n is an integer. (The relation of this recombination process to atomic photoionization is discussed briefly in Chap. 25.) The maximum kinetic energy of the returning electron turns out to be $\mathcal{T} \approx 3.2U_p$, resulting in a cutoff in the harmonic spectrum at the harmonic of order

$$N_{\max} \approx (I_p + 3.2U_p)/\hbar\omega. \quad (78.21)$$

Theoretical Methods

Calculation of harmonic strengths requires the evaluation of the time-dependent dipole moment of the atom,

$$\mathbf{d}(t) = \langle \Psi(t) | e\mathbf{r} | \Psi(t) \rangle. \quad (78.22)$$

The strength of harmonics emitted by a single atom are then related to the Fourier components of $\mathbf{d}(t)$, or more precisely, its second time derivative, $\ddot{\mathbf{d}}(t)$.

The induced dipole moment $\mathbf{d}(t)$ can be directly evaluated from the numerical [56] or Floquet [26] solutions of the TDSE. Good agreement with numerical and experimental data is also obtained using the strong-field approximation discussed below and a Landau–Dykhne formula. This latter approach can be considered to be a quantum mechanical implementation of the three-step model [57].

Propagation and Phase-Matching Effects

A single atom response is not sufficient to determine the macroscopic response of the atomic medium. Because different atoms interact with different parts of the focused laser beam, they feel different peak field intensities and phases (which actually undergo a rapid π shift close to the focus, due to geometrical effects). The total harmonic signal results from coherently adding contributions from single atoms, accounting for propagation and interference effects. The latter effects can wipe out the signal completely if a constructive phase matching does not take place.

The propagation and phase-matching effects in the strong-field regime [58] can be studied by solving Maxwell’s equations for a given harmonic component of the electric

field $\mathcal{E}_M(\mathbf{r})$ Eq. (72.23),

$$\nabla^2 \mathcal{E}_M(\mathbf{r}) + n_M(\mathbf{r}) \mathcal{E}_M(\mathbf{r}) = -\frac{1}{\epsilon_0} \left(\frac{M\omega}{c} \right)^2 \mathcal{P}_M(\mathbf{r}), \quad (78.23)$$

where $n_M(\mathbf{r})$ is the refractive index of the medium (which depends on atomic, electronic, and ionic dipole polarizabilities), while $\mathcal{P}_M(\mathbf{r})$ is the polarization induced by the fundamental field only. The latter can be expressed as

$$\mathcal{P}_M(\mathbf{r}) \propto N(\mathbf{r}) d_M M(\mathbf{r}) \exp[-iM\Delta(\mathbf{r})], \quad (78.24)$$

where $N(\mathbf{r})$ is the atomic density, $d_M(\mathbf{r})$ is the M -th Fourier component of the induced dipole moment, and $\Delta(\mathbf{r})$ is a phase shift coming from the phase dependence of the fundamental beam due to focusing. All of these quantities may have a slow time dependence, reflecting the temporal envelope of the laser pulse.

Typically, phase matching is the most efficient in the forward direction. In general, the strength and spatial properties of a harmonic depend in a very complex way on the focal parameters, the medium length, and the coherence length of a given harmonic. Propagation and phase-matching effects can lead to a shift of the location of the cutoff in the harmonic spectrum [59].

Harmonic Generation by Elliptically Polarized Fields

The three-step model implies that for harmonic emission it is necessary that the tunneling electrons return to the nucleus and recombine into their initial state. According to classical mechanics, there are many trajectories in a linearly polarized field that involve one or more returns to the origin. However, there are practically no such trajectories in elliptically polarized fields. As a result, the three-step model predicts a strong decrease of the harmonic strengths as a function of the laser ellipticity. This prediction has been already confirmed experimentally [60].

The Generation of Attosecond XUV Pulses

Manipulation of generated harmonics by allowing the temporal beating of superposed high-order harmonics can produce a train of intense and very short spikes, on the order of ≈ 100 as and shorter, where $1 \text{ as} = 10^{-18} \text{ s}$ [61–63]. The structural characteristics of the generated pulse trains depend on the relative phases of the harmonics combined. Employing driving pulses that were themselves only a few femtoseconds long, experimental groups in Vienna [64] and Paris [65] reported the first observations and measurements of such subfemtosecond UV/XUV light pulse trains. Very recently, a new world record was set in Florida, where a single 53-attosecond X-ray pulse, with a photon energy enough to reach the carbon K-edge, was measured [66]. The scientific

importance of breaking the femtosecond barrier is obvious: the timescale necessary for probing the motion of an electron in a typical bound, the valence state, is measured in attoseconds (atomic unit of time $\equiv 24$ as). Attosecond pulses will allow the study of the time-dependent dynamics of correlated electron systems by freezing the electronic motion, in essence exploring the structure with ultrafast snapshots. A crucial aspect for all attosecond pulse generation is the control of spectral phases. Measurements of the timing of the attosecond peaks relative to the absolute phase of the IR driving field have been accomplished [67]. This provides insight into the recollision, the key step in the harmonic generation process. Also, the control of the group velocity phase relative to the envelope of the few-cycle driving pulses allows the production of reproducible pulse trains [68]. Thus, the highly nonperturbative, nonlinear multiphoton interactions of very short IR or visible light pulses with atoms or molecules is becoming a novel, powerful, and unique source for studies of the fastest quantum electronic processes known to date.

HHG Applications

One of the singular aspects of HHG is the possibility to produce and control both trains of and single attosecond pulses. These ultrashort light sources are extremely important for the investigation of the ultrafast process in atomic and molecular systems. The Auger decay, the delay in the photoemission absorption via an XUV source and double-electron ionization are examples of phenomena that occur on the subfemtosecond time domain. HHG allows not only to get knowledge about the ultrafast electron dynamics inside atoms and molecules, but it also has also been demonstrated that it configures an indispensable tool to extract atomic and molecular structural information [69, 70].

The fascinating technological advances of pump-probe experiments, where attosecond pulses and delayed IR lasers are being employed to firstly trigger the system and later interrogate its dynamical time evolution, have allowed us to address unexplored questions on the above-mentioned processes. The extension of these techniques to more complex systems, such as solid structures and biological materials, is already in the pipeline.

HHG in Bulk Matter

So far, the cornerstone of attosecond science applications has been the HHG phenomenon in gases. However, there still exists a clear disadvantage of HHG due to its poor conversion efficiency—the ratio between the outgoing XUV and incoming IR photon fluxes. Recent advances in light sources within the mid-infrared (MIR) domain, $1.7 \approx 7 \mu\text{m}$, have opened a new avenue in the investigation of HHG using condensed matter materials [71]. In particular, the control of such MIR sources allows us to overcome the low-efficiency problem and substantially increase the photon flux per produced at-

tosecond pulse. This characteristic could lead to unexplored physical processes in that condensed matter phase.

As is known, in an insulator, there exists the concept of band energy dispersion for electrons in its valence or conduction bands. For instance, the HHG in semiconductors (dielectrics) is governed by electron or holes bound wavefunctions that are not spatially (or energetically) localized. Holes, in addition, also have the possibility to move on their own valance band while, on the other hand, the electron dynamics takes place entirely in the conduction band. This leads to two main contributions to the HHG process, namely, one dictated by an intraband oscillation and other by an interband electron–hole current [72, 73].

This emerging field is attracting the attention of both the attosecond science and condensed matter communities. Joint efforts are being carried out to address fundamental questions such as how particle collisions can be mimicked in a solid through HHG processes [74] or how Bloch oscillations might be observed in real time [75]. Additionally, questions related to topological insulators and how their features might affect the harmonic emissions were recently brought up [76, 77].

78.3.6 Stabilization of Atoms in Intense Laser Fields

It has been argued [78] that in very intense laser fields of high frequency, atoms undergo dynamical stabilization and do not ionize. The stabilization effect can be explained by gauge transforming the TDSE Eq. (78.1) to the Kramers–Henneberger (K–H) frame; i.e., a noninertial oscillating frame that follows the motion of the free electron in the laser field. The K–H transformation consists of replacing $\mathbf{r} \rightarrow \mathbf{r} + \boldsymbol{\alpha}(t)$, where, for the linearly polarized monochromatic laser field, $\boldsymbol{\alpha}(t) = \hat{\mathbf{x}}\alpha_0 \cos(\omega t - \varphi)$; $\alpha_0 = eE/(m\omega^2)$ is the excursion amplitude of a free electron, and $\hat{\mathbf{x}}$ is the polarization direction. The TDSE in the K–H frame is

$$i\hbar \frac{\partial \Psi(\mathbf{r}, t)}{\partial t} = \left\{ -\frac{\hbar^2 \nabla^2}{2m} + V[\mathbf{r} + \boldsymbol{\alpha}(t)] \right\} \Psi(\mathbf{r}, t), \quad (78.25)$$

i.e., it describes the motion of the electron in an oscillatory potential. In the high-frequency limit, this potential may be replaced by its time average

$$V_{\text{K-H}}(\mathbf{r}) = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} dt V[\mathbf{r} + \boldsymbol{\alpha}(t)], \quad (78.26)$$

and the remaining Fourier components of $V[\mathbf{r} + \boldsymbol{\alpha}(t)]$ treated as a perturbation. When α_0 is large, the effective potential Eq. (78.26) has two minima close to $\mathbf{r} = \pm \hat{\mathbf{x}}\alpha_0$. The corresponding wave functions of the bound states are centered

near these minima, thus exhibiting a dichotomy. The ionization rates from the K–H bound states are induced by the higher Fourier components of $V(\mathbf{r} + \boldsymbol{\alpha}(t))$. For large enough α_0 , the rates decrease, if either the laser intensity increases, or the frequency decreases.

Numerical solutions of the TDSE [79, 80] show that stabilization, indeed, occurs for laser field strengths and frequencies of the order of one atomic unit. More importantly, stabilization is possible even when the laser excitation is not monochromatic but, rather, is produced by a short laser pulse. Physically, free electrons in a monochromatic laser field cannot absorb photons due to the constraints imposed by energy and momentum conservation. Absorption is possible only in the vicinity of a potential, such as the Coulombic attraction of the nucleus. In the case of a strong excitation, i.e., when α_0 is much larger than the Bohr radius, the electron spends most of the time very far from the nucleus, and, therefore, does not absorb energy from the laser beam. Therefore, stabilization, as viewed from the K–H frame, has a classical analog. Other mechanisms of stabilization based on the quantum mechanical effects of destructive interference between various ionization paths have also been proposed [81].

Due to classical scaling (Sect. 78.3.8) stabilization is predicted to occur for much lower laser frequencies, if the atoms are initially prepared in highly excited states. If additionally, the initial state has a large orbital angular momentum corresponding to classical trajectories that do not approach the nucleus, stabilization is even more easily accomplished. For instance, the stabilization of a 5g Rydberg state of neon has been reported [82].

Although recently interest in stabilization in intense laser fields became very limited, the K–H transformation and the stabilization effect have been discussed in a completely different situation. In [83, 84], the stabilization of atoms in a shaken trap Bose–Einstein condensate was proposed. In fact, recently, a K–H trick was used to develop an experimental simulator of ultrafast processes in strong laser fields using ultracold trapped atoms [85].

78.3.7 Molecules in Intense Laser Fields

Molecular systems are much more complex than atoms because of the additional degrees of freedom resulting from nuclear motion. Even in the presence of a laser field, the electron and nuclear degrees of freedom can be separated by the Born–Oppenheimer approximation, and the dynamics of the system can be described in terms of motions on potential energy surfaces. In strong fields, the Born–Oppenheimer states become dressed, or mixed by the field, creating new molecular potentials. Because of avoided crossings between the dressed molecular states, the field induces new potential wells in which the molecules become trapped.

These states, known as laser-induced bound states, are stable against dissociation, but exist only while the laser field is present [86]. Their existence affects the spectra of photoelectrons, photons, and the fragmentation dynamics. If the field is strong enough, many electrons can be ejected from a molecule before dissociation, producing highly charged, energetic fragments [87]. Such experiments are similar to beam-foil Coulomb explosion studies of molecular structure. However, because of changes from the field-free equilibrium geometries in laser dissociation, the energies of the fragments lie systematically below the corresponding values from Coulomb explosion studies. Additionally to the latter, a similar phenomenon was intensively studied with atomic clusters [88].

78.3.8 Microwave Ionization of Rydberg Atoms

Similar phenomena appear in the ionization of highly excited hydrogen-like (Rydberg) atoms by microwave fields [89, 90], but the dynamical range of the parameters involved is different from the case of tightly bound electrons. Recent developments have greatly extended techniques for the preparation and detection of Rydberg states. Since, according to the equivalence principle, highly excited Rydberg states exhibit many classical properties, a classical perspective of ionization yields useful insights (Sect. 78.4.5).

Classical Scaling

The classical equations of motion for an electron in both a Coulomb field and a monochromatic laser field polarized along the z -axis are invariant with respect to the following scaling transformations:

$$\begin{aligned} p &\propto n_0^{-1} \tilde{p}, & r &\propto n_0^2 \tilde{r}, \\ t &\propto n_0^3 \tilde{t}, & \varphi &\propto \tilde{\varphi}, \\ \omega &\propto n_0^{-3} \tilde{\omega}, & \mathcal{E} &\propto n_0^{-4} \tilde{\mathcal{E}}. \end{aligned} \quad (78.27)$$

In the scaled units, the Hamiltonian $\tilde{H} = n_0^{-2} H$ of the system becomes

$$\tilde{H} = \frac{\tilde{p}^2}{2m} - \frac{1}{\tilde{r}} + \tilde{z} e \tilde{\mathcal{E}} \cos(\tilde{\omega} \tilde{t} + \tilde{\varphi}), \quad (78.28)$$

i.e., it depends only on $\tilde{\omega}$ and $\tilde{\mathcal{E}}$. In experiments, the principal quantum number n_0 of the prepared initial state typically ranges from 1 to 100.

Classical scaling extends to the fields of other polarizations and to pulsed excitations, provided that the number of cycles in the rise, top, and fall of the pulse is kept fixed. This scaling does not hold for a quantum Hamiltonian, unless one also rescales Planck's constant, $\tilde{\hbar} = \hbar/n_0$. In practice, increasing n_0 , keeping $\tilde{\mathcal{E}}$ and $\tilde{\omega}$ constant, corresponds to

a decrease in the effective \hbar toward the classical limit. In view of this classical scaling, experimental and theoretical results are usually analyzed in terms of the scaled variables. Since the classical dynamics generated by the Hamiltonian Eq. (78.28) exhibits chaotic behavior in some regimes, the dynamics of the corresponding quantum system is frequently referred to as an example of quantum chaos [91–93].

Regimes of Response

By varying the initial n_0 , several regimes of the scaled parameters can be covered. The experimentally measured response of Rydberg atoms in microwave fields can be divided into six categories:

The tunneling regime

For $\tilde{\omega} \leq 0.07$, the response of the system is accurately represented as tunneling through the slowly oscillating potential barrier composed of the Coulomb and microwave potentials.

The low-frequency regime

For $0.05 \leq \tilde{\omega} \leq 0.3$, the ionization probability exhibits distinct structures (bumps, steps, changes of slope) as a function of the field strength. The quantum probability curves might be lower or higher than the corresponding classical counterparts, calculated with the aid of the phase averaging method (Sect. 78.4.5).

The semiclassical regime

For $0.1 \leq \tilde{\omega} \leq 1.2$, the ionization probabilities agree well for most frequencies with the results obtained from the classical theory. In particular, the onset of ionization and appearance intensities (i.e., the intensities at which a given degree of ionization is achieved) coincide with the onset of chaos in the classical dynamics. In the ionization probabilities, resonances appear that correspond to the classical trapping resonances [91–94].

The transition region

For $1 \leq \tilde{\omega} \leq 2$, the differences between the quantum and classical results are visible. Quantum ionization probabilities are frequently lower and appearance intensities higher than their classical counterparts.

The high-frequency regime

For $\tilde{\omega} \geq 2$, quantum results for ionization probabilities are systematically lower and appearance intensities higher than their classical counterparts. This apparent stability of the quantum system has been attributed to three kinds of effects: quantum localization [94], quantum scars [95], and perhaps the stabilization of atoms in intense laser fields (Sect. 78.3.6).

The photoeffect regime

When the scaled frequency becomes greater than the single-photon ionization threshold, the system undergoes single-photon ionization (the photoeffect).

Quantum Localization

The classical dynamics changes as the field increases. Chaotic trajectories start to fill the phase space and, as the KAM tori (describing periodic orbits) [91–93] break down, the motion becomes stochastic, resembling a random walk. This process, in which the mean energy grows linearly in time, is termed diffusive ionization. In quantum theory, diffusion corresponds to a random walk over a ladder of suitably chosen quantum levels. However, both diagonal and off-diagonal elements of the evolution operator, which describe quantum mechanical amplitudes for transitions between the levels, depend in a quasi-periodic manner on the quantum numbers of the levels involved. Such quasiperiodic behavior is quite analogous to a random one. Electronic wave packets, which initially spread in accordance with the classical laws, tend to remain localized for longer times due to destructive quantum-interference effects. Quantum localization is an analog of the Anderson localization of electronic wave functions propagating in random media [94].

Quantum Scars

Even in the fully chaotic regime, classical phase space contains periodic, although unstable, orbits. Nevertheless, quantum mechanical wave-function amplitudes can become localized around these unstable orbits, resulting in what are called quantum scars. The increased stability of the hydrogen atom at $\tilde{\omega} \approx 1.3$ has, in fact, been attributed [95] to the effects of quantum scars. These effects are very sensitive to fluctuations in the driving laser field. Control of the laser noise, therefore, provides a powerful spectroscopic tool to study such quantal phenomena [96]. Using this tool, it has become possible to demonstrate the effects of quantum scars in the intermediate regime of scaled frequencies, i.e., for values less than but close to 1.

78.4 Strong-Field Computational Techniques

The SS pulse regime requires a nonperturbative solution of the TDSE. We describe here two of the most used approaches: the explicit numerical solution of the TDSE and the Floquet expansion technique. In addition to these, several approximate methods have been proposed.

78.4.1 Floquet Theory

The excitation and ionization dynamics of an atom in a strong laser field can be determined by turning the problem

into a time-independent eigenvalue problem [26, 97]. From Floquet's theorem, the eigenfunctions for a perfectly periodic Hamiltonian of the form

$$H = H_0 + \sum_{N \neq 0} H_N e^{-iN\omega t} \quad (78.29)$$

can be expressed as

$$\Psi(t) = e^{-iXt/\hbar} \sum_N e^{-iN\omega t} \psi_N. \quad (78.30)$$

Putting this into the time-dependent Schrödinger equation results in an infinite set of coupled Floquet equations for the harmonic components ψ_N . In the velocity gauge, the Floquet equations are

$$(X + N\hbar\omega - H_0)\psi_N = V_+ \psi_{N-1} + V_- \psi_{N+1}, \quad (78.31)$$

where, for a vector potential of amplitude \mathcal{A} ,

$$V_+ = -\frac{e}{2mc} \mathcal{A} \cdot \mathbf{p}, \quad (78.32)$$

and $V_- = V_+^\dagger$. The Eq. (78.31) has been solved, after truncation to a manageable number of terms, using many techniques to provide what are called the quasi-energy states of the laser-atom system. The eigenvalues X of these equations are complex, with $\text{Im}(X)$ giving the decay or ionization rate for the system. The generated rates are found to be very accurate as long as the pulse length of the laser field is not too short, at least hundreds of cycles. The eigenfunctions provide the amplitudes for the photoelectron energy spectra, and the time-dependent dipole of the state can be related to the photoemission spectrum of the system. Yields for slowly varying pulses can be constructed by combining the results from the individual, fixed-intensity calculations [26].

The Floquet method can be applied for any periodic Hamiltonian. In strong enough fields of high frequency, the Floquet equations can be truncated to a very small set in the K–H frame [78].

78.4.2 Direct Integration of the TDSE

Methods for the direct solution of the time-dependent Schrödinger equation (TDSE) are described in general in Chap. 8 and in [98, 99] for multiphoton processes. The wave functions are defined on spatial grids or in terms of an expansion in basis functions. The time evolution is obtained by either explicit or implicit time propagators. All these methods are capable of generating numerically exact results for an atom with a single electron in a short pulsed field for a wide range of pulse shapes, wavelengths, and intensities. The solutions are time-dependent wave functions for the electrons,

which can be analyzed to obtain excitation and ionization rates, photoelectron energies, angular distributions, and photoemission yields. The ability to generate an explicit solution of the TDSE allows the study of arbitrary pulse shapes and provides insight into the excitation dynamics.

For multielectron atoms, one generally has to limit the calculations to that for a single electron in effective potentials, which represent, as well as possible, the influences of the remaining atomic electrons. This approach is called the single-active electron (SAE) approximation, and it gives generally accurate results for systems with no low-lying doubly excited states, for example, the noble gases [98]. In these cases, the excitation dynamics is dominated by the sequential promotion of a single electron at a time.

78.4.3 Volkov States

A laser interacting with a free electron superimposes an oscillatory motion on its drift motion in response to the field. The wave function for an electron with drift velocity $\mathbf{v} = \hbar\mathbf{k}/m$ is given by

$$\begin{aligned} \Psi_V(\mathbf{r}, t) &= \exp\left(-\frac{i}{2m\hbar} \int^t \left[\hbar\mathbf{k} - \frac{e}{c}\mathbf{A}(t')\right]^2 dt'\right) e^{i[\mathbf{k} - e\mathbf{A}(t)/\hbar c] \cdot \mathbf{r}}, \end{aligned} \quad (78.33)$$

where $\mathbf{A}(t) = -c \int^t \mathbf{E}(t') dt'$ is the vector potential of the field; Ψ_V is called a Volkov state. In a linearly polarized field, the electron oscillates along the direction of polarization with an amplitude $\alpha_0 = e\hbar\mathcal{A}/(mc\omega)$. In the strong-field regime, this amplitude can greatly exceed the size of a bound-state orbital. Volkov states provide a useful tool that can be applied in various strong-field approximations discussed in Sect. 78.4.4.

78.4.4 Strong-Field Approximations

There have been several attempts to solve the TDSE in the strong-field limit using approximate but analytic methods. Such strong-field approximations (SFA) typically neglect all the bound states of the atom except for the initial state. In the tunneling regime ($\gamma < 1$), and a quasi-static limit ($\omega \rightarrow 0$), one can use a theory [55] in which the ionization occurs due to the tunneling through the Coulomb barrier distorted by the electric field of the laser. The wave function is constructed as a combination of a bare initial wave function of the electron (close to the nucleus) and a wave function describing a motion of the electron in a quasi-static electric field (far from the nucleus). In a second approach [37–39], the elements of the scattering matrix \hat{S} are calculated assuming that initially the

electronic wave function corresponds to a bare bound state. On the other hand, the final, continuum states of the electron are described by dressed wave functions that account for the free motion of the electron in the laser field. In the simplest case, such dressed states are Volkov states Eq. (78.33). Alternatively, the time-reversed \hat{S} -matrix is obtained by dressing the initial state and using field-free scattering states for the final state.

Yet another method consists of expanding the electronic continuum–continuum dipole matrix elements in terms corresponding to matrix elements for free electrons plus corrections due to the potential [57]. In the latter version of the SFA, the amplitude of the electronic wave function $b(\mathbf{p})$, corresponding to an outgoing momentum \mathbf{p} , is given by

$$b(\mathbf{p}) = i \int_0^{t_F} dt \mathbf{d}[\mathbf{p} - e\mathbf{A}(t)/c] \cdot \mathbf{E}(t) \exp[-iS(t_F, t)/\hbar]. \quad (78.34)$$

Here, $\mathbf{d}[\mathbf{p} - e\mathbf{A}(t)/c]$ denotes the dipole matrix element for the transition from the initial bound state to the continuum state in which the electron has the kinetic momentum $\mathbf{p} - e\mathbf{A}(t)/c$, t_F is the switch-off time of the laser pulse, and

$$S(t_F, t) = \int_t^{t_F} dt' \left[\frac{[\mathbf{p} - e\mathbf{A}(t')/c]^2}{2m} + I_P \right] \quad (78.35)$$

is a quasi-classical action for an electron that is born in the continuum at t and propagates freely in the laser field. The form of the expression Eq. (78.34) is generic to the SFA.

78.4.5 phase-space Averaging Method

The methods of classical mechanics are particularly useful in describing the microwave excitation of highly excited (Rydberg) atoms [89, 90] (Sect. 78.3.8), but have also been applied to describe HHG, stabilization of atoms in super-intense fields, and two-electron ionization [100–102].

The classical phase-space averaging method [103] solves Newton's equations of motion

$$\dot{\mathbf{r}} = \frac{\mathbf{p}}{m}, \quad (78.36)$$

$$\dot{\mathbf{p}} = -\nabla V(\mathbf{r}) - e\mathbf{E}(t), \quad (78.37)$$

for an electron interacting with an ion core and an external laser field. A distribution of initial conditions in phase space is chosen to mimic the initial quantum mechanical state of the system, and a sample of classical trajectories is generated. Quantum mechanical averages of physical observables are then identified with ensemble averages of those observables

over the initial distribution. Since the dynamics of multiphoton processes is very complex, the neglected phases in this approach generally cause negligible errors, and the results can be in quite good agreement with quantum calculations. Additionally, an examination of the trajectories provides details of the excitation dynamics, which are often difficult to extract from a complex time-dependent wave function.

78.5 Atto-Nano Physics

The interaction of ultrashort strong laser pulses with larger systems has recently received much attention; it has led to a consequent advance in our understanding of the attosecond to few-femtosecond electronic and nuclear dynamics. For instance, the interaction of atomic clusters with strong ultrafast laser fields has long been known to lead to the formation of nanoplasmas in which there is, on the one hand, a high degree of charge localization and ultrafast dynamics and, on the other hand, the emission of both very energetic (multiple keV) electrons and highly charged ions (in the MeV energy range). Interestingly, the most recent utilization of ultrashort few-cycle pulses (≈ 10 fs) to trigger the laser–matter processes has succeeded in isolating the electron dynamics from the longer ion dynamics timescale (which can essentially be considered as frozen) revealing a higher degree of fragmentation anisotropy in both electrons and ions compared to the isotropic distributions found from much longer (multicycle) pulses (100 fs).

Additionally, interactions of intense lasers with nanoparticles, such as micron and submicron scale liquid droplets, lead to hot plasma formation. An important role is found for enhanced local fields on the surface of these droplets, the so-called hot spots. Furthermore, studies of driving bound and free charges in larger molecules, e.g., collective electron dynamics in fullerenes and in graphene-like structures, proton migration in hydrocarbon molecules, charge migration in proteins and biomolecules, amongst others, could be included in this category. In addition, biological applications of atto-nano physics could be envisaged as well, e.g., to explain the DNA-protein interactions in solutions of living cells, study the induced covalent crosslink between aromatic amino acids and peptides, and characterize the protein–protein interactions in living cells. In turn, laser-driven broadband electron wavepackets have been used for static and dynamic diffraction imaging of molecules, obtaining structural information with subnanometer spatial and subfemtosecond temporal resolution (Sect. 78.3.4).

Tailored ultrashort and intense fields have also been used to drive electron dynamics and electron or photon emission from (nanostructured) solids (for a recent compilation: [104]). The extraordinary progress seen recently has been largely driven by advances in both experimental, e.g., laser technology, and engineering, e.g., nanofabrication, tech-

niques. Amongst the remarkable achievements in just the most recent years are the demonstration of driving electron currents and switching the conductivity of dielectrics with ultrashort pulses, controlling the light-induced electron emission from nanoparticles and nanotips, and the subcycle-driven photon emission from solids. Furthermore, the intrinsic electron propagation and photoemission processes have been investigated on their natural, attosecond timescales.

A key feature of light-nanostructure interactions is the enhancement, by several orders of magnitude, of the electric near-field and its local confinement on a subwavelength scale. From a theoretical viewpoint, this field localization presents a unique challenge: we have at our disposal strong fields that change on a comparable spatial scale of the oscillatory electron dynamics that are initiated by those same fields. This peculiar property entails profound consequences in the underlying physics of the conventional strong-field phenomena. In particular, it violates one of the main assumptions that the modeling of strong-field interactions is based upon: the spatial homogeneity of laser fields in the volume of the electronic dynamics under scrutiny (this hypothesis was *per se* considered in all the previous sections of this chapter).

Interestingly, an exponential growing attraction in strong-field phenomena induced by plasmonic-enhanced fields was sparked by the controversial work of Kim et al. [105]. These authors claimed having observed efficient HHG from noble-gas atoms driven by the plasmonic-enhanced field generated by bow-tie metallic nanostructures. Although later on the interpretation of the outcomes was demonstrated to be incorrect [106], Kim's paper definitively stimulated a steadily constant interest in the plasmonic-enhanced HHG and ATI. We should mention, however, a very recent result of the same group, which clearly seems to be well justified and, as such, opens new perspectives and ways toward efficient HHG using nanostructures [107]. In this recent contribution, the authors demonstrate experimentally plasmonic-driven HHG by devising a metal-sapphire nanostructure that provides a solid tip as the HHG emitter instead of gaseous atoms. Measured EUV spectra show odd-order harmonics up to 60-nm wavelengths, without the plasma atomic lines typically seen when using gaseous atoms as the HHG-driven media. This experimental data confirm that the plasmonic HHG approach is a promising way to make real coherent EUV sources for nanoscale near-field applications in spectroscopy, microscopy, lithography, and attosecond physics (for another recent related experiment, see, e.g., [108]).

Within the conventional assumption, both the laser electric field, $\mathbf{E}(\mathbf{r}, t)$, and the corresponding vector potential, $\mathbf{A}(\mathbf{r}, t)$, are spatially homogeneous in the region where the electron moves and only their time dependence is considered, i.e., $\mathbf{E}(\mathbf{r}, t) = \mathbf{E}(t)$ in Eq. (78.2) and $\mathbf{A}(\mathbf{r}, t) = \mathbf{A}(t)$ in Eq. (78.4). This is a genuine assumption considering the usual electron excursion α_0 is bounded roughly by a few nanometers in the NIR, for typical laser intensities, and sev-

eral tens of nanometers for MIR sources (note that $\alpha_0 \propto \mathcal{E}\lambda^2$, where λ is the wavelength of the driving laser and $\mathcal{E} = \sqrt{I}$, where I is the laser intensity). Hence, electron excursions are very small relative to the spatial variation of the field in the absence of local (or nanoplasmonic) field enhancement. On the contrary, the fields generated using surface plasmons are spatially dependent on a nanometric region. As a consequence, all the standard theoretical tools in the strong-field ionization toolbox described previously, ranging from purely classical to frequently used semiclassical and complete quantum mechanical descriptions, have to be reexamined. For a comprehensive review about atto-nano physics see, e.g., [109]

Abstract

Interactions of light with an atomic particle are accompanied by exchange of momentum between the electromagnetic field and the atom. Narrowband resonance radiation from tunable lasers enhances the ensuing mechanical effects of light to the extent that it is possible to stop atoms emanating from a thermal gas and to trap atoms with light. We will also discuss charged ions trapped by types of electromagnetic fields other than light, and possibly cooled with light. The emphasis is on basic theoretical concepts and experimental procedures. Cooling and trapping of atomic particles is now a basic tool and large swaths of modern AMO physics depend on it, so the discussion of applications is necessarily cursory.

At the time of writing, the book [1] appears to be the standard reference on cooling and trapping of atoms. Reviews of various vintages with a substantial component on trapped particles include [2–5]. Optical lattices binding atoms, discussed in a tutorial manner in [6], is presently a prominent frontier. Additional references ranging from pioneering works to representative recent examples are given as leads into specific topics. No assignment of credit or priority is implied.

spontaneous emission · Wigner function · trap particle · laser cool · Paul trap

79.1 Notation

In this chapter, the lower and upper states of an optical transition are denoted by the respective labels g and e , for *ground* and *excited*. The notation $J_g \rightarrow J_e$ stands for a transition in which the lower and upper levels have the angular momentum degeneracies $2J_g + 1$ and $2J_e + 1$. The resonance frequency of the transition is ω_0 .

The detuning of the driving monochromatic light of frequency ω from the atomic resonance is defined as

$$\Delta = \omega - \omega_0 . \quad (79.1)$$

Spontaneous emission is taken to be the sole mechanism of line broadening, so that the rate of spontaneous emission Γ and the half-width half-maximum (HWHM) linewidth of the transition are related by $\gamma = \Gamma/2$. The Rabi frequency is $\Omega = \mathcal{D}\mathcal{E}/\hbar$, where \mathcal{D} is the reduced dipole moment matrix element that would apply to a transition with unit Clebsch–Gordan coefficient, and \mathcal{E} is the electric field amplitude of the laser. The corresponding intensity scale is the saturation

Table 79.1 Laser cooling parameters for the lowest $S_{1/2}-P_{3/2}$ transition of hydrogen and most alkalis (the D_2 line). Also shown are the nuclear spin I and the ground state hyperfine splitting $\Delta\nu_{\text{hfs}}$

$\Delta\nu_{\text{hfs}}$	1420	228.2	803.5	1772	461.7	1286	3036	6835	9193	2π MHz

intensity

$$I_s = \frac{4\pi^2\hbar c\Gamma}{3\lambda^3}, \quad (79.2)$$

defined in such a way that the light intensity I satisfies

$$\Omega = \Gamma \Rightarrow I = I_s. \quad (79.3)$$

If multiple laser beams are explicitly mentioned, laser intensity and Rabi frequency are quoted for one of the equally intense beams.

The momentum of a photon with the wave vector \mathbf{k} is $\hbar\mathbf{k}$. The recoil velocity

$$v_r = \frac{\hbar k}{m} \quad (79.4)$$

equals the change of the velocity of an atom of mass m when it absorbs a photon with wave number $k = 2\pi/\lambda$. The kinetic energy of an atom with velocity v_r and the corresponding frequency,

$$E_r = \frac{1}{2}mv_r^2, \quad \varepsilon_r = \frac{E_r}{\hbar}, \quad (79.5)$$

are referred to as recoil energy and recoil frequency. Two temperatures, the Doppler limit T_D and the recoil limit T_r , are often cited in laser cooling. They are

$$T_D = \frac{\hbar\gamma}{k_B}, \quad T_r = \frac{E_r}{k_B}, \quad (79.6)$$

where k_B is the Boltzmann constant.

Table 79.1 lists numerical values of pertinent parameters for laser cooling and trapping using the D_2 line for most stable and long-lived alkali isotopes and hydrogen. Except for the spontaneous decay rates Γ (and the derived quantities T_D , I_s), data greatly exceeding the displayed precision are widely available. The spontaneous decay rate is taken either from [7] or [8].

79.2 Control of Atomic Motion by Light

79.2.1 General Theory

The Hamiltonian

The mechanical effects of light may be derived from the Hamiltonian

$$\hat{H} = \hat{H}_A + \hat{H}_{\text{CM}} + \hat{H}_F - \hat{\mathbf{d}} \cdot \hat{\mathbf{E}}(\hat{\mathbf{r}}), \quad (79.7)$$

where \hat{H}_A , \hat{H}_{CM} , and \hat{H}_F are the Hamiltonians for the internal degrees of freedom of the atom, center-of-mass (CM) motion of the atom, and free electromagnetic field. The quantized electric field is $\hat{\mathbf{E}}(\hat{\mathbf{r}})$, where $\hat{\mathbf{r}}$ is the CM position operator. The dipole operator $\hat{\mathbf{d}}$ acts on the internal degrees of freedom of the atom. Since the $\hat{\mathbf{d}} \cdot \hat{\mathbf{E}}(\hat{\mathbf{r}})$ term couples all degrees of freedom, the possibility of influencing CM motion by light immediately follows. The inclusion of the quantized CM motion is the essential ingredient not contained in traditional theories of light–matter interactions. For an atom with mass m trapped in a possibly anisotropic harmonic oscillator potential with frequencies ν_i ($i = x, y, z$), the CM Hamiltonian is

$$H_{\text{CM}} = \frac{\hat{\mathbf{p}}^2}{2m} + \sum_{i=x,y,z} \frac{m\nu_i^2 \hat{r}_i^2}{2}, \quad (79.8)$$

where $\hat{\mathbf{p}}$ is the CM momentum operator. For a free atom, $\nu_i = 0$.

Master Equation

With the aid of Markov and Born approximations, the vacuum modes of the electromagnetic field may be eliminated as described in Chap. 7.1.6. This gives a master equation for the reduced density operator $\hat{\rho}$ that contains the internal and CM degrees of freedom of the atom. Relaxation terms proportional to Γ and γ are all that is left of the quantized fields.

Consider as an example a two-state atom in a traveling wave of light with the electric field strength

$$E(\mathbf{r}, t) = \frac{1}{2}E e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)} + \text{c.c.} \quad (79.9)$$

Master equations are conveniently written using *Wigner functions* to represent the CM motion. Given the internal-state labels i and $j = g$ or e , and the three-dimensional variables \mathbf{r} , \mathbf{p} , the Wigner functions are defined as

$$\rho_{ij}(\mathbf{r}, \mathbf{p}) = \frac{1}{(2\pi\hbar)^3} \int d^3u e^{i\mathbf{u}\cdot\mathbf{p}/\hbar} \times \left\langle \mathbf{r} - \frac{1}{2}\mathbf{u} | \langle i | \hat{\rho} | j \rangle | \mathbf{r} + \frac{1}{2}\mathbf{u} \right\rangle. \quad (79.10)$$

The Wigner function is one of the quantum mechanical quasi-probability distributions, Chap. 82.5, with the special property that the marginal distribution of \mathbf{r} obtained by integrating over \mathbf{p} coincides with the correct quantum probability density function for position, and vice versa with \mathbf{r} and \mathbf{p} interchanged. In the rotating wave approximation, Chap. 72.3.2, the master equations are

$$\frac{d}{dt} \rho_{ee}(\mathbf{p}) = -\Gamma \rho_{ee}(\mathbf{p}) + i \frac{\Omega}{2} \left[e^{i\mathbf{k}\cdot\mathbf{r}} \hat{\rho}_{ge} \left(\mathbf{p} - \frac{1}{2}\hbar\mathbf{k} \right) - e^{-i\mathbf{k}\cdot\mathbf{r}} \hat{\rho}_{eg} \left(\mathbf{p} - \frac{1}{2}\hbar\mathbf{k} \right) \right], \quad (79.11)$$

$$\frac{d}{dt} \rho_{gg}(\mathbf{p}) = \Gamma \int d^2n W(\hat{\mathbf{n}}) \rho_{ee}(\mathbf{p} + \hbar\mathbf{k}\hat{\mathbf{n}}) - \frac{i\Omega}{2} \times \left[e^{i\mathbf{k}\cdot\mathbf{r}} \hat{\rho}_{ge} \left(\mathbf{p} + \frac{1}{2}\hbar\mathbf{k} \right) - e^{-i\mathbf{k}\cdot\mathbf{r}} \hat{\rho}_{eg} \left(\mathbf{p} + \frac{1}{2}\hbar\mathbf{k} \right) \right], \quad (79.12)$$

$$\frac{d}{dt} \hat{\rho}_{ge}(\mathbf{p}) = -(\gamma + i\Delta) \hat{\rho}_{ge}(\mathbf{p}) - \frac{i\Omega}{2} \times \left[e^{-i\mathbf{k}\cdot\mathbf{r}} \rho_{gg} \left(\mathbf{p} - \frac{1}{2}\hbar\mathbf{k} \right) - e^{i\mathbf{k}\cdot\mathbf{r}} \rho_{ee} \left(\mathbf{p} + \frac{1}{2}\hbar\mathbf{k} \right) \right], \quad (79.13)$$

$$\frac{d}{dt} \hat{\rho}_{eg}(\mathbf{p}) = -(\gamma - i\Delta) \hat{\rho}_{eg}(\mathbf{p}) + \frac{i\Omega}{2} \times \left[e^{i\mathbf{k}\cdot\mathbf{r}} \rho_{gg} \left(\mathbf{p} - \frac{1}{2}\hbar\mathbf{k} \right) - e^{-i\mathbf{k}\cdot\mathbf{r}} \rho_{ee} \left(\mathbf{p} + \frac{1}{2}\hbar\mathbf{k} \right) \right]. \quad (79.14)$$

Here, the convective derivative that describes the motion of the atom in the absence of light is

$$\frac{d}{dt} = \frac{\partial}{\partial t} + \frac{\mathbf{p}}{m} \cdot \frac{\partial}{\partial \mathbf{r}} - \sum_i m v_i r_i \frac{\partial}{\partial p_i}; \quad (79.15)$$

cf. H_{CM} in Eq. (79.8); $W(\hat{\mathbf{n}})$ is the angular distribution of spontaneous photons, and the integral runs over the unit

sphere. Representative expressions for $W(\hat{\mathbf{n}})$ are

$$W(\hat{\mathbf{n}}) = \frac{1}{4\pi}, \quad \frac{3}{8\pi} [1 - (\hat{\mathbf{e}} \cdot \hat{\mathbf{n}})^2], \quad \frac{3}{16\pi} [1 + (\hat{\mathbf{e}} \cdot \hat{\mathbf{n}})^2]. \quad (79.16)$$

These apply, respectively, for isotropic spontaneous emission, for spontaneous emission in a $\Delta m = 0$ transition, and in $\Delta m = \pm 1$ transitions; $\hat{\mathbf{e}}$ stands for the unit vector in the direction of the quantization axis for angular momentum. Only the \mathbf{p} dependence has been denoted explicitly in the Wigner functions, as the recoil effects displayed on the right-hand sides of Eqs. (79.11)–(79.14) take place at a fixed position \mathbf{r} .

Semiclassical Theory

Suppose that $v_{\text{CM}} \gg v_r$ and $\tau \ll \tau_{\text{CM}}$, where τ and τ_{CM} are the timescales for light-driven changes of the internal state and CM motion of the atom. Then the internal degrees of freedom may be eliminated adiabatically from the master equations in favor of the position-momentum distribution for the CM motion,

$$f(\mathbf{r}, \mathbf{p}, t) = \sum_i \rho_{ii}(\mathbf{r}, \mathbf{p}, t), \quad (79.17)$$

where the sum runs over the internal states of the atom. Technically, the recoil velocity v_r is treated as an asymptotically small expansion parameter. The result is the Fokker–Planck equation for the CM motion

$$\frac{d}{dt} f = -\frac{\partial}{\partial \mathbf{p}} \cdot (\mathbf{F} f) + \sum_{i,j} \frac{\partial^2}{\partial p_i \partial p_j} (D_{ij} f). \quad (79.18)$$

In this semiclassical theory, the CM motion of the atom is regarded as classical. The atom moves under the optical force $\mathbf{F}(\mathbf{r}, \mathbf{p}, t)$, which models the coarse-grained flow of momentum between the electromagnetic field and the atom; $D_{ij}(\mathbf{r}, \mathbf{p}, t)$, with $i, j = x, y, z$, is the diffusion tensor. Diffusion is an attempt to model quantum mechanics with a classical stochastic process, including discreteness of recoil kicks, random directions of spontaneous photons, and random timing of optical absorption and emission processes.

A general prescription exists for calculating the force and the diffusion tensor for an arbitrary atomic level scheme and light field [9]. However, the formally correct analysis of diffusion has not proven to be particularly useful, and here only the force is considered at length. Let $\hat{V}(\mathbf{r})$ be the dipole interaction operator coupling the driving field and the internal state for an atom at position \mathbf{r} . By assumption, $\hat{V}(\mathbf{r})$ has been rendered slowly varying in time with the aid of a suitable rotating wave approximation. To compute the force, one takes

an atom that travels along a hypothetical trajectory unperturbed by light in such a way that at time t it arrives at the phase space point (\mathbf{r}, \mathbf{p}) , whereupon the density operator of the internal degrees of freedom is $\hat{\rho}$. The force is then

$$F_i(\mathbf{r}, \mathbf{p}, t) = -\text{Tr}\left(\hat{\rho} \frac{\partial \hat{V}}{\partial r_i}\right). \quad (79.19)$$

Quantum Theory

When either $v_{\text{CM}} \lesssim v_r$ or $\tau \gtrsim \tau_{\text{CM}}$, the full quantum theory of cooling and trapping is needed. Master equations such as Eqs. (79.11)–(79.14) must then be solved without the assumption that v_r is small. For instance, a truncated basis of plane waves may be used to expand the CM state. Density matrix equations are then solved numerically either directly or by resorting to quantum Monte-Carlo simulations [10]. Such solutions for free ($v_i = 0$) particles are very few. Our approach and terminology are, therefore, semiclassical by default.

Qualitative origin of laser cooling

Velocity-dependent dissipative forces are needed for cooling. They arise because the evolution of the internal state of a moving atom has a finite response time τ . The atom conveys the memory of the field it has sampled over the length $\ell = v\tau$ on its past trajectory. If $\ell \ll \lambda$, a nonequilibrium component proportional to ℓ is present in the density operator of the internal state of the atom. Further interactions with light convert this component into a velocity-dependent force of the form

$$F = -m\beta v, \quad \beta \propto I\tau. \quad (79.20)$$

If the damping constant β is positive, Eq. (79.20) describes exponential damping of the velocity on the timescale β^{-1} . In the contrary case $\ell \gg \lambda$, when the atom travels many wavelengths during the memory time, linear dependence of force on velocity breaks down. The watershed is the critical velocity or velocity capture range

$$v_c \approx \frac{\lambda}{\tau}. \quad (79.21)$$

One-dimensional considerations

Most specific results cited here are one-dimensional. By default, the propagation direction of light and the direction of vector quantities other than light polarization is $\hat{\mathbf{e}}_x$. The relevant components of position, velocity, and momentum are denoted by x , v , and p .

The general one-dimensional Fokker–Planck equation for a particle trapped in a harmonic oscillator potential with a CM oscillation frequency ν is

$$\left(\frac{\partial}{\partial t} + \frac{p}{m} \frac{\partial}{\partial x} - mv^2 x \frac{\partial}{\partial p}\right) f = -\frac{\partial}{\partial p}(Ff) + \frac{\partial^2}{\partial p^2}(Df). \quad (79.22)$$

For the force in Eq. (79.20) with constant $\beta = \beta_0$ and $D(z, p) = D_0$, the steady state of the Fokker–Planck equation is a thermal distribution of the form

$$f(x, p) = K \exp\left[-\frac{\beta_0 m}{D_0} \left(\frac{p^2}{2m} + \frac{mv^2 x^2}{2}\right)\right], \quad (79.23)$$

where K is a normalization constant.

Since Wigner functions give correct quantum mechanical marginal distributions for \mathbf{r} and \mathbf{p} , expectation values of kinetic and potential energy may be calculated from the distribution function Eq. (79.23) as if it were a classical phase space density. For a free atom with $v = 0$, the temperature is directly proportional to the kinetic energy,

$$T = \frac{D_0}{\beta_0 m k_B}. \quad (79.24)$$

However, for a trapped particle with $v \neq 0$ the Fokker–Planck equation may be valid all the way to the quantum mechanical zero-point energy. Then, temperature and energy are no longer directly proportional to one another. For a trapped particle, the safe interpretation of Eq. (79.23) is that the total CM energy of the particle is

$$E = \frac{D_0}{\beta_0 m}. \quad (79.25)$$

79.2.2 Two-State Atoms

A two-state or two-level atom, discussed in detail in Chap. 72.3, stands for a closed (cycling) transition with one lower state and one excited state. In practice, a two-state system is often realized by driving a $J \rightarrow J + 1$ transition with circularly polarized light. This leads to optical pumping to the states with the maximal (or minimal) component of angular momentum along the quantization axis, say, to the transition $m = J \rightarrow m' = J + 1$.

Two types of force are generally distinguished: light pressure, or scattering force, or spontaneous force, and dipole, or gradient, or induced force. However, the distinction is neither exclusive, nor exhaustive. Here, the two types of force are approached by way of examples.

Traveling Waves

Light pressure

Consider a cycle of absorption and spontaneous emission. In the absorption, the atom receives a photon recoil kick in the direction of the laser beam, while in the spontaneous emission the recoil kick has a random direction and zero average. The atom is, on the average, left with a velocity change equal

to v_r . The rate of such processes equals $\Gamma\rho_{ee}$, which gives the force along \mathbf{k} and equal to

$$F = F_m \frac{\Omega^2/2}{\gamma^2 + \Delta^2(v) + \Omega^2/2} \quad (79.26)$$

in magnitude. Here, the maximum of light pressure force, a convenient scale for optical forces, is

$$F_m = \frac{1}{2} m v_r \Gamma, \quad (79.27)$$

and

$$\Delta(v) = \Delta - kv \quad (79.28)$$

is the effective detuning, which includes the Doppler shift experienced by the moving atom.

Diffusion

For a traveling wave, the diffusion coefficient accompanying light pressure is

$$\frac{D}{\hbar^2 k^2 \Gamma} = \frac{(1 + \alpha)\Omega^2}{4[\Delta^2(v) + \gamma^2 + \Omega^2/2]} - \frac{[\Delta^2(v) - 3\gamma^2]\Omega^4}{4[\Delta^2(v) + \gamma^2 + \Omega^2/2]^3}, \quad (79.29)$$

where

$$\alpha = \int d^2n W(\hat{\mathbf{n}})(\hat{\mathbf{e}}_x \cdot \hat{\mathbf{n}})^2 \quad (79.30)$$

depends on $W(\hat{\mathbf{n}})$, see Eq. (79.16). Representative values are $\alpha = 1/3$ for isotropic spontaneous emission, and $\alpha = 2/5$ ($\alpha = 3/10$) for spontaneous emission with $\Delta m = 0$ ($\Delta m = \pm 1$) with respect to a quantization axis that is perpendicular (parallel) to the direction $\hat{\mathbf{e}}_x$.

The expression Eq. (79.29) is the formally complete result from the expansion in recoil velocity. The first term on the right is easily obtained by computing the variance of the atomic momentum in a cycle of absorption and spontaneous emission and multiplying it by the rate of such processes $\Gamma\rho_{ee}$. The second term, rarely seen in theoretical analyses and henceforth ignored, is related to photon antibunching: The subsequent spontaneous emissions do not happen independently of one another at the rate $\Gamma\rho_{ee}$, but after an emission, there is some delay before the atom gets excited and can emit again.

Spontaneously emitted photons cover all of the 4π solid angle, and so do the directions of photon recoil kicks on the atom. Absorption from a light wave traveling in a particular direction leads to transverse diffusion also in the orthogonal directions, which is not accounted for by the one-dimensional Eq. (79.29).

Phenomenology in Multimode Fields

Doppler cooling in standing waves

Next, take an atom in two counterpropagating plane waves of light. At low intensity, $\Omega \ll \Gamma$, forces of the form Eq. (79.26) for the two beams may be added when averaged over a wavelength. For velocities well below the critical velocity

$$v_{c,D} = \frac{\Gamma}{k}, \quad (79.31)$$

the wavelength-averaged force is of the form of Eq. (79.20),

$$F = -m\bar{\beta}v, \quad \bar{\beta} = -\frac{4\Omega^2\gamma\Delta}{(\Delta^2 + \gamma^2)^2} \varepsilon_r. \quad (79.32)$$

When light is tuned below the atomic resonance (*red detuning* with $\Delta < 0$), exponential damping of the atomic velocity with the time constant $\bar{\beta}^{-1}$ ensues. No matter which way the atom moves, it is always Doppler tuned toward resonance with the light wave that propagates opposite to its velocity, and away from resonance with the light wave that propagates along its velocity. Net momentum transfer, therefore, opposes the motion of the atom. This is known as Doppler cooling.

Optical molasses

For three pairs of counterpropagating waves in three orthogonal directions, Eq. (79.32) is valid in all coordinate directions, and, hence, as a vector equation between the force \mathbf{F} and velocity \mathbf{v} . For $\Delta < 0$, an atom experiences an isotropic viscous damping force, as if it were moving in a thick liquid. Such a field configuration is dubbed optical molasses. Two counterpropagating beams make a one-dimensional optical molasses.

Limit of Doppler cooling

Under the conditions of Eq. (79.32), the diffusion coefficients for the two counterpropagating beams averaged over a wavelength may be added, and the $v = 0$ form suffices for slow atoms. This yields

$$\frac{\bar{D}(v=0)}{\hbar^2 k^2 \Gamma} = \frac{(1 + \alpha)\Omega^2}{2(\Delta^2 + \gamma^2)}. \quad (79.33)$$

The random diffusive motion of the atom corresponds to diffusive heating that competes with Doppler cooling. In equilibrium, the temperature is

$$T = \frac{\bar{D}(v=0)}{m\bar{\beta}k_B} = \frac{\hbar\gamma}{4k_B}(1 + \alpha) \left(\frac{|\Delta|}{\gamma} + \frac{\gamma}{|\Delta|} \right). \quad (79.34)$$

Equation (79.34) also applies to three-dimensional Doppler cooled molasses, provided one uses $\alpha = 1$ corresponding

to added transverse diffusion. The minimum temperature is reached at

$$|\Delta| = \gamma = \frac{\Gamma}{2}. \quad (79.35)$$

For three-dimensional molasses, the Doppler limit T_D of Eq. (79.6) is obtained.

For $\Omega > \Gamma$, the performance of Doppler cooling deteriorates. Qualitatively, power broadening increases the effective linewidth γ .

Dipole forces

Dipole forces are the resonant analog of the ponderomotive forces discussed in Chap. 78.3. They arise from successions of absorption and induced emission driven by photons with different momenta. Such processes occur only if there is more than one wave vector present in the field, i.e., if there is an intensity gradient. For a zero-velocity, two-state atom, the gradient force in a monochromatic field with the local total intensity $I(\mathbf{r})$ is

$$\mathbf{F}_g(\mathbf{r}) = -\frac{4\hbar\Delta\gamma^2}{\Delta^2 + \gamma^2[1 + 2I(\mathbf{r})/I_s]} \frac{\nabla I(\mathbf{r})}{I_s}. \quad (79.36)$$

The dipole force may be derived from the potential energy

$$V_g(\mathbf{r}) = 2\hbar\Delta \ln\left(1 + \frac{2\gamma^2 I(\mathbf{r})/I_s}{\Delta^2 + \gamma^2}\right). \quad (79.37)$$

The atoms are strong-field seekers for red detuning ($\Delta < 0$) and weak-field seekers for blue detuning ($\Delta > 0$).

Suppose the amplitude of the dipole moment induced on the atom equals $d = \alpha \mathcal{E}(\mathbf{r})$, where $\mathcal{E}(\mathbf{r})$ is a slowly varying (or stationary) local electric field amplitude, and α is the polarizability. This is true in the limit of a large detuning or a low light intensity, in the case when the response of the atom is isotropic. In the limit of large detunings, the dipole moment is also either in phase ($\Delta \rightarrow -\infty$) or π out of phase with the electric field, so the polarizability is real. Then, there is a general expression for the dipole force,

$$\mathbf{F}_g(\mathbf{r}) = \frac{1}{4}\alpha \nabla |\mathcal{E}(\mathbf{r})|^2, \quad (79.38)$$

with the obvious potential energy. For a CO₂ or Nd-YAG laser, the static polarizability of the atom serves as a practical approximation for α .

Optical trap and optical lattice

Dipole forces are utilized in an optical trap for atoms, and even molecules. A common configuration is the crossed-beam dipole force trap, two crossing laser beams tuned below resonance, and focused to the same spot. The frequencies of

the beams may be deliberately offset to average out extraneous standing wave patterns. Very intense lasers with a large detuning, including CO₂ and Nd-YAG, can be used. As the optical force and the rate of spontaneous emission scale, respectively, as I/Δ and I/Δ^2 , the heating from spontaneous emission may be negligible.

A standing wave of light makes a periodic array of optical traps called an optical lattice. Optical lattices may be set up in 1-D, 2-D, and 3-D configurations.

Induced diffusion

Random motion of atoms in velocity space owing to absorptions and induced emissions of photons with different momenta leads to induced diffusion. Contrary to diffusion in a traveling wave as in Eq. (79.29), induced diffusion does not saturate at high intensity. Instead, the diffusion coefficient continues to grow linearly with I . Induced diffusion is another reason why the lowest Doppler cooling temperatures are generally reached at low ($I < I_s$) light intensities.

Sisyphus effect

In a standing wave at high intensity and large detuning, another kind of optical force becomes important that cannot be categorized either as light pressure or gradient force.

As explained in Chap. 72.3.4, one may diagonalize the Hamiltonian to obtain the dressed atom-field states. Because the light field depends on position, so do the energies of the dressed states and their decompositions into plain atomic states. In Fig. 79.1 drawn for $\Delta > 0$, the dressed state with a minimum (maximum) at the field nodes coincides with the bare ground state (excited state) at the nodes. At the antinodes, the admixtures of ground and excited states are evened out to some extent.

The energy of a dressed state acts as potential energy for the CM motion of an atom residing in that particular state. In fact, the gradient force is the force derived from these potential energies, averaged over the occupation probabilities of the dressed states. The occupation probability is larger for the dressed state with a larger ground-state admixture. From Fig. 79.1 one, therefore, sees that the atom predominantly resides in the dressed state that has a minimum of energy at the antinodes. The atom is a weak-field seeker, as it should for $\Delta > 0$.

Spontaneous emission remains to be considered. It gives rise to transitions between the dressed states. These transitions may go both ways between the dressed states because the states are, in general, superpositions of the bare ground state and the excited state. The rate of spontaneous transitions from one dressed state to another increases (decreases) with the excited (ground) state admixture of the initial state.

In reference to Fig. 79.1, suppose that the atom is coming from the left in the upper dressed state. The probability that the atom makes a transition to the lower dressed state,

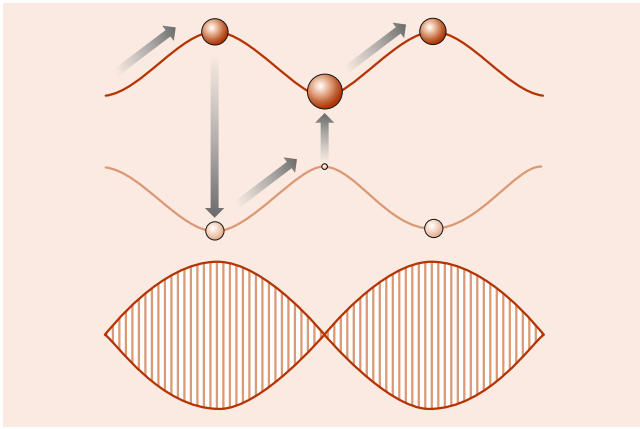

Fig. 79.1 Qualitative origin of the Sisyphus effect. The *hatched pattern* represents a standing light wave. The energies of the two dressed states are drawn as a function of position, along with a few *filled circles* representing the admixture of the ground state in each dressed state at selected field positions. *Larger circles* correspond to larger ground-state admixtures, and hence, larger equilibrium populations of the dressed state. This figure applies for tuning of the laser above the atomic resonance (blue detuning)

as marked by the downward vertical arrow, is largest at the antinode. If this transition takes place, near the next node the most probable transition is as shown by the upward vertical arrow. In this manner, the atom spends most of its time at an uphill climb against the potential, and is, therefore, slowed down. In reference to Greek mythology, this is called the Sisyphus effect. In the two-state model atom, cooling takes place when the laser frequency is higher than the atomic resonance frequency.

Semiclassical Versus Quantum Theory

When $\gamma \gg \varepsilon_r$, the root-mean-square (RMS) velocity of a cooled two-state atom is always $\gg v_r$, and semiclassical theory is valid. Under the same condition $\gamma \gg \varepsilon_r$, the Doppler-limit RMS velocity is also less than the critical velocity $v_{c,D}$ from Eq. (79.31). Velocity expansions such as in Eqs. (79.32) and (79.33) are then justified.

In the contrary case, $\gamma \lesssim \varepsilon_r$, the full quantum theory of trapping and cooling must be employed. The cooled velocity distribution cannot be expected to be thermal and temperature is ill defined, but on dimensional grounds, one expects that the minimum kinetic energy for cooled free atoms is comparable to the recoil energy E_r .

79.2.3 Multistate Atoms

Energy levels of atomic systems usually have angular momentum degeneracy. In addition, the polarization of light, in general, depends on position. A combination of these aspects leads to phenomena beyond the two-state atomic model.

Polarization Gradient Cooling

As explained in connection with Eq. (79.20), a finite memory time of the internal atomic state may lead to damping of the CM motion. For a two-state atom, internal equilibration arises from spontaneous emission. The timescale is $\tau_D \approx \Gamma^{-1}$, and Doppler cooling ensues. However, an atom whose ground state has angular momentum degeneracy is also subject to optical pumping. If the polarization of light varies as a function of position, optical pumping is needed to reach local equilibrium. The pumping timescale $\tau_p \propto I^{-1}$ then becomes relevant for a moving atom. The associated cooling is known as polarization gradient cooling. Its hallmark is that, for low I , the damping coefficient $\beta \propto I \tau_p$ is independent of intensity.

Two detailed mechanisms of polarization gradient cooling have been described [11], although in three-dimensional light fields they are intertwined. The Sisyphus effect works like the Sisyphus effect for a two-state atom, except that it relies on light shifts and optical pumping within the ground state manifold. Induced orientation cooling is analogous to Doppler cooling. Velocity dependence of optical pumping in counterpropagating waves leads to pumping to a state for which the force due to the wave propagating opposite to the atom exceeds the force due to the wave propagating along with the atom.

$\sigma^+ - \sigma^-$ molasses

As an example consider one-dimensional $\sigma^+ - \sigma^-$ molasses, which consists of two counterpropagating waves with opposite circular polarizations. The net polarization is linear everywhere, but the direction of polarization rotates as the point of observation is displaced along the propagation axis; hence the name corkscrew molasses. At low intensity and low velocity, the force on an atom with a $1 \rightarrow 2$ transition is

$$F = \frac{60}{17} \frac{\Delta \gamma}{5\gamma^2 + \Delta^2} \hbar k^2 v. \quad (79.39)$$

In this configuration, only induced orientation cooling contributes. Cooling again takes place for $\Delta < 0$, and the resulting temperature is

$$T = \frac{29\Delta^2 + 1045\gamma^2}{300(\Delta^2 + \gamma^2)} \left(\frac{2I\Gamma}{I_s|\Delta|} \right) T_D. \quad (79.40)$$

Experimental molasses

For $I\Gamma/I_s|\Delta| < 1$ and $|\Delta| \gg \Gamma$, the temperature Eq. (79.40) reduces to the form

$$T = C \frac{\hbar \Omega^2}{k_B |\Delta|} = C \frac{2I\Gamma}{I_s |\Delta|} T_D. \quad (79.41)$$

Under these conditions, the same I/Δ scaling is approximately observed also in three-dimensional, six-beam optical

molasses operating with atoms that have a degenerate ground state. The constant C depends on the degeneracy of the transitions and on the polarizations of the molasses beams. On dimensional-analysis grounds, one expects $C \approx 1$; values in the range $0.25 < C < 0.5$ have been reported [12].

Limit of cooling

While the expressions in Eqs. (79.40) and (79.41) suggest that T goes all the way to zero as $I \rightarrow 0$ or $\Delta \rightarrow -\infty$, in practice there is a lower limit of T reached in polarization gradient cooling. This is because the velocity capture range falls below the speeds of the would-be cooled atoms. The temperature eventually starts to rise abruptly when $|\Delta|$ is increased, or I is decreased. The empirical rule of thumb is that $T \approx 10 T_r$ is the lowest temperature one can expect.

Magneto-Optical Trap

Since spontaneous forces may be strong already at modest light intensities, $I \approx I_s$, the use of light pressure to trap neutral atoms appears desirable. However, the optical Earnshaw theorem states that (in the limit of low I) the spontaneous force on a two-state atom is sourceless. While confinement may be possible in some directions, escape routes for atoms remain open in others. Three-dimensional trapping of a two-state atom with light pressure is not possible.

A magneto-optical trap (MOT) defeats the Earnshaw theorem by relying on angular momentum degeneracy. Consider an atom with a $0 \rightarrow 1$ transition in a magnetic field \mathbf{B} that depends linearly on position around the zero at $x = 0$. Suppose that the gradient of \mathbf{B} is chosen in such a way that the $m = 1$ ($m = -1$) magnetic substate of the excited state has the higher (lower) energy for $x > 0$, and that the atom is illuminated by σ^\pm polarized beams propagating in the $\pm x$ -directions, tuned below resonance. When the atom is displaced from $x = 0$ in either direction, it is closer to resonance with the beam that pushes it back toward $x = 0$. This makes the restoring force responsible for trapping.

A magneto-optical trap can be set up also in three dimensions. A quadrupole magnetic field of the form

$$\mathbf{B}(\mathbf{r}) \approx \left. \frac{\partial B_z}{\partial z} \right|_{r=0} \left(z \hat{\mathbf{e}}_z - \frac{1}{2} x \hat{\mathbf{e}}_x - \frac{1}{2} y \hat{\mathbf{e}}_y \right) \quad (79.42)$$

is produced by reversing the direction of current in one of the two Helmholtz coils. Three orthogonal pairs of light beams, each in the $\sigma^+ - \sigma^-$ configuration, complete the trap. The magnetic field is sourceless. To compensate for the ensuing signs of the field gradients, one of the $\sigma^+ - \sigma^-$ corkscrews has the opposite handedness from the other two (with the $+x$, $+y$ and $+z$ -directions as the reference for handedness).

The mechanism of the magneto-optical trap for the $0 \rightarrow 1$ configuration is the same as the mechanism for Doppler cooling, except that position-dependent level shifts of the excited

states take the place of velocity-dependent Doppler shifts. The restoring force and the damping coefficient of Doppler cooling are closely related. For the coordinate directions $u = x, y, z$, the relation is

$$F_u = -\kappa_u u, \kappa_u = \beta \frac{mg_e \mu_B}{\hbar k} \left| \frac{\partial B_u}{\partial u} \right|, \quad (79.43)$$

where g_e is the Landé factor of the excited state.

A magneto-optical trap may similarly be based on the induced-orientation mechanism of polarization gradient cooling. This might actually be the mechanism of many magneto-optical traps.

Atoms in a well-aligned magneto-optical trap reside near the zero of \mathbf{B} , so that the magnetic field has little effect on polarization gradient cooling. Trapping and cooling are achieved simultaneously.

79.3 Magnetic Trap for Atoms

The magnitude $B(\mathbf{r})$ of a magnetic field may have a minimum in free space, as in Eq. (79.42). A particle with a magnetic dipole moment $\boldsymbol{\mu}$ then experiences a trapping potential $U(\mathbf{r}) = \boldsymbol{\mu} \cdot \mathbf{B}(\mathbf{r})$ if $\boldsymbol{\mu}$ and \mathbf{B} are antiparallel; $\boldsymbol{\mu}$ remains locked antiparallel to \mathbf{B} if the field seen by the moving dipole satisfies the adiabatic condition

$$\frac{1}{B} \left| \frac{dB}{dt} \right| \ll \frac{\mu B}{\hbar} \quad (79.44)$$

(cf. Sect. 77.5.4). However, if $B(\mathbf{r}) = 0$ at the minimum, the adiabatic condition is violated, and the dipole may flip (Majorana transition). The particle may end up in a repulsive potential and get expelled from the trap. This could become a problem at low temperatures, when the particles accumulate near the minimum of the potential. Trap configurations are, therefore, designed in which $B(\mathbf{r}) \neq 0$ at the minimum.

79.3.1 Evaporative Cooling

A magnetic trap is often combined with evaporative cooling. The most energetic atoms from the tail of the thermal distribution escape from the trap, whereupon the average energy of the remaining atoms decreases. The atoms then thermalize to a lower temperature. Successful operation of evaporative cooling requires a high enough rate of elastic collisions so that the atoms thermalize in a time short compared with the lifetime of the sample. In order to sustain the evaporation, the effective depth of the trap is typically lowered as the atoms cool.

79.4 Trapping and Cooling of Charged Particles

Since the potential $\Phi(\mathbf{r})$ of a static electric field satisfies Laplace's equation, $\Phi(\mathbf{r})$ cannot have an extremum in free space. A static electric field, therefore, cannot serve as an ion trap (Earnshaw's theorem). Paul and Penning traps circumvent this limitation by making use of an alternating electric field and a magnetic field, respectively. Cooling is often employed to assist trapping.

Before going any further, it should be noted that neutral atoms trapped in sufficiently deep far-off resonance optical dipole traps and optical lattices may behave essentially like ions in a Paul trap. They are, therefore, subject to similar cooling and detection methods.

79.4.1 Paul Trap

Trapping

Configuration

Consider an ideal trap whose surfaces are hyperboloids of revolution; see Fig. 79.2. The two *endcaps* and the intervening *ring* are equipotential surfaces of the quasi-static electric potential

$$\Phi(x, y, z) = \frac{\Phi_0(t)(2z^2 - x^2 - y^2)}{2\varrho_0^2}, \quad (79.45)$$

where ϱ_0 is the distance from the center to the ring, $z_0 = \varrho_0/\sqrt{2}$ is the distance to the endcaps, and $\Phi_0(t)$ is a voltage applied between the endcaps and the ring,

$$\Phi_0(t) = U - V \cos \tilde{\omega}t. \quad (79.46)$$

Motion of an ion

In the ideal three-dimensional Paul trap, Newton's equations of motion for the coordinates $u = x, y, \text{ or } z$ may be recast as Mathieu's equations,

$$\frac{d^2u}{d\tau^2} + (a_u - 2q_u \cos 2\tau)u = 0, \quad (79.47)$$

where $\tau = \tilde{\omega}t/2$ is a dimensionless quantity proportional to time, the parameters are

$$a_z = -2a_{x,y} = -\frac{8qU}{m\tilde{\omega}^2\varrho_0^2}, \quad (79.48)$$

$$q_z = -2q_{x,y} = -\frac{4qV}{m\tilde{\omega}^2\varrho_0^2}, \quad (79.49)$$

and m and q are the mass and charge of the particle. Stable trapping ensues when a_u and q_u are such that the motion

of the ion is stable in all directions. A Paul trap normally operates in the first stability region of Eq. (79.47).

Stable motion may be qualitatively divided into forced micromotion at the frequency $\tilde{\omega}$ of the external drive, and slower secular motion of the center of the micromotion. If $U = 0$, the secular motion takes place in an effective ponderomotive potential U_P , Sect. 78.3, equal to the cycle-averaged kinetic energy in the micromotion. Explicitly,

$$U_P(\mathbf{r}) = \frac{q^2 \mathcal{E}^2(\mathbf{r})}{4m\tilde{\omega}^2} = \frac{q^2 V^2 (x^2 + y^2 + 4z^2)}{4m\tilde{\omega}^2 \varrho_0^4}, \quad (79.50)$$

where $\mathcal{E}(\mathbf{r})$ is the AC field amplitude. This is an anisotropic harmonic oscillator potential characterized by the oscillation frequencies

$$\nu_z = 2\nu_{x,y} = \frac{\sqrt{2}qV}{m\tilde{\omega}\varrho_0^2}. \quad (79.51)$$

Quantization of CM motion

The separation of micromotion and secular motion is excellent, and the trap is stable, when $\nu_{x,y,z} \ll \tilde{\omega}$. Ignoring the micromotion, the CM motion of the ions in the potential $U_P(\mathbf{r})$ may be quantized readily. The energy of a state with $n_{x,y,z}$ quanta in the coordinate directions x, y, z is

$$E = \sum_{i=x,y,z} \hbar \nu_i \left(n_i + \frac{1}{2} \right). \quad (79.52)$$

Variations of the Paul trap

Usually, little practical advantage arises from realization of the ideal shape. Even a single electrode with an applied AC voltage may work as a Paul trap. A linear trap is basically a two-dimensional Paul trap with an added static longitudinal potential to prevent escape of the ions from the ends of the trap. A closed race track Paul trap is obtained by bending a linear trap into a ring.

Cooling

Origin of laser cooling

The Wigner function formalism in Eqs. (79.11)–(79.14) is exact as long as the trapping forces are harmonic, but occasionally it is more convenient to think in terms of harmonic oscillator eigenstates of a trapped particle instead of position and momentum. In this view, a plane wave of light can effect transitions between motional states because the position of the ion is regarded as a quantum mechanical operator. The coupling matrix element between two harmonic oscillator eigenstates n_1 and n_2 due to light is proportional to

$$K_{n_1 n_2} = \langle n_2 | e^{ik \cdot \hat{r}} | n_1 \rangle;$$

$|K_{n_1 n_2}|^2$ may be viewed as the Franck–Condon factor for the transition $n_1 \rightarrow n_2$.

Laser cooling in one dimension

Consider the motion of the ion in one of the principal-axis directions x, y, z , with ν denoting the corresponding CM frequency. In the common case where $\gamma \gg \nu$, Doppler cooling basically works as with a free atom. In the contrary case, $\nu \gg \gamma$, cooling may be achieved by tuning the laser to $\omega = \omega_0 - \nu$. Resonant photoabsorption starting with n quanta in the CM motion decreases the quantum number from n to $n - 1$, and the subsequent spontaneous emission, on the average, leaves the CM energy nearly untouched. The net effect is reduction of the CM energy by $\hbar\nu$ in such a Raman process. Since the oscillating ion sees a frequency-modulated laser with sidebands, this method of cooling is called sideband cooling. For one-dimensional motion of a two-state ion in a traveling light wave at low I , the velocity damping rate for tuning below resonance, $\Delta < 0$, is

$$\beta = \frac{2\Omega^2\gamma|\Delta|}{[(\Delta + \nu)^2 + \gamma^2][(\Delta - \nu)^2 + \gamma^2]} \varepsilon_r, \quad (79.53)$$

and the expectation value of the CM energy is

$$E = \frac{\hbar}{4|\Delta|} \times \left(\Delta^2 + \gamma^2 + \nu^2 + \alpha \frac{[(\Delta - \nu)^2 + \gamma^2][(\Delta + \nu)^2 + \gamma^2]}{\Delta^2 + \gamma^2} \right), \quad (79.54)$$

where α characterizes the angular distribution of spontaneous emission, see Eq. (79.30). The result in Eq. (79.54) is useful when either $\varepsilon_r \ll \gamma$ or $\varepsilon_r \ll \nu$. The case with $\varepsilon_r, \nu \ll \gamma$ is for Doppler cooling; the temperature from Eq. (79.54) coincides with Eq. (79.34) for a free atom. The case with $\varepsilon_r, \gamma \ll \nu$ corresponds to sideband cooling in the Lamb–Dicke regime, in which the cooled ion is confined to a region much smaller than λ .

In connection with sideband cooling, it is convenient to cite the expectation number of harmonic oscillator quanta $\langle n \rangle$ instead of energy or temperature; the latter are

$$E = \hbar\nu \left(\langle n \rangle + \frac{1}{2} \right), \quad T = \frac{\hbar\nu}{k_B} [\ln(1 + \langle n \rangle^{-1})]^{-1}. \quad (79.55)$$

For optimal sideband cooling, $\nu \gg \gamma$ and $\Delta = -\nu$, the result is

$$\langle n \rangle = \frac{1}{4}(1 + 4\alpha) \left(\frac{\gamma}{\nu} \right)^2 + O \left[\left(\frac{\gamma}{\nu} \right)^4 \right]. \quad (79.56)$$

In principle, by decreasing the linewidth γ , the ion may be put arbitrarily close to the ground state of the CM harmonic oscillator. Such a tuning of linewidth is not practical

in a given two-state system, but there is a workaround. After Doppler cooling on one transition, the experiment may switch to sideband cooling using another, narrower, transition. A narrow resonance may also be achieved by using the two-photon resonance in a three-state Λ configuration as an effective two-state system, see Chap. 77.8.2.

Laser cooling in three dimensions

Either by design or chance, no two of the ν_i are precisely degenerate. If the damping rate β and the trap frequencies ν_i satisfy

$$\beta \lesssim |\nu_i - \nu_j|, \quad i \neq j, \quad (79.57)$$

the motion of the ion in each principal axis direction of the trap is cooled independently of the other directions. For $\gamma \gg \nu_{x,y,z}$, a single laser beam propagating approximately in the direction $(1/\sqrt{3})(\hat{e}_x + \hat{e}_y + \hat{e}_z)$ suffices to cool all components of the secular motion.

Energy in micromotion

Possibly with the aid of compensating static electric fields, one cooled ion may be confined near the zero of the trapping AC electric fields. The energy in the micromotion is then comparable to the energy in the secular motion.

79.4.2 Penning Trap

Trapping

Configuration

A Penning trap might use the same hyperboloid-shape electrodes as an ideal Paul trap. However, a DC voltage U is applied between the endcaps and the ring, and a constant magnetic field \mathbf{B} in the direction of the trap axis z is added. The magnetic field forces an ion escaping toward the ring to turn back.

Motion of an ion

The motion of an ion is a superposition of three periodic components. For the hyperboloid-shape trap, Eq. (79.45) and Fig. 79.2, the three components are completely decoupled. Firstly, in the axial direction, the ion executes oscillations at the axial frequency

$$\nu_z = \left(\frac{2qU}{mQ_0^2} \right)^{1/2}. \quad (79.58)$$

Secondly, the ion undergoes cyclotron motion in the plane perpendicular to the trap axis. As a result of the electric field,

Fig. 79.2 Electrode configuration and voltages of an ideal hyperboloid Paul trap

the frequency of the cyclotron motion

$$\nu'_c = \frac{1}{2}\nu_c + \left(\frac{1}{4}\nu_c^2 - \frac{1}{2}\nu_z^2\right)^{1/2} \quad (79.59)$$

is displaced from the cyclotron frequency $\nu_c = qB/m$ of a free ion. Thirdly, the guiding center of cyclotron motion rotates about the trap axis at the magnetron frequency

$$\nu_m = \frac{1}{2}\nu_c - \left(\frac{1}{4}\nu_c^2 - \frac{1}{2}\nu_z^2\right)^{1/2}. \quad (79.60)$$

The frequencies typically satisfy

$$\nu_m \ll \nu_z \ll \nu'_c. \quad (79.61)$$

Magnetron motion has unusual properties. It takes up the majority of the electrostatic energy in the transverse directions, which in the absence of the magnetic field would lead to expulsion of the ion. Relative to a stationary ion at the trap center, the energy of the magnetron motion is bounded from above by zero. The radius, as well as velocity and kinetic energy of magnetron motion, decreases with increasing total energy. The energy for a state with n_c , n_z , and n_m quanta in the cyclotron, axial, and magnetron motions is, therefore,

$$E = \hbar\nu'_c\left(n_c + \frac{1}{2}\right) + \hbar\nu_z\left(n_z + \frac{1}{2}\right) - \hbar\nu_m\left(n_m + \frac{1}{2}\right). \quad (79.62)$$

Cooling

Laser cooling

For ions in a practical Penning trap, the frequencies ν'_c , ν_z and ν_m are $< \gamma$. If \mathbf{k} is not orthogonal to either the cyclotron motion or the axial motion, Doppler cooling proceeds

essentially as for a free atom. However, energy should be added to the magnetron motion in order to reduce the magnetron radius and velocity. The solution is to aim a finite-size laser beam off the center of the trap in such a way that an ion experiences a higher (lower) intensity over the part of its magnetron orbit in which it travels in the direction of (opposite to) the laser beam. With a proper choice of the parameters, the ensuing addition of energy overcomes Doppler cooling of the magnetron motion.

Other cooling methods

Precision measurements are carried out in Penning traps with objects that do not have an internal level structure suitable for laser cooling, and, thus, other cooling methods are used.

For light particles such as electrons, characteristic times of radiative damping of the cyclotron motion are in the sub-second regime, and, hence, so are the equilibration times with blackbody radiation. Cooling is accomplished by enclosing the trap in a low-temperature (e.g., liquid helium) environment. For protons and heavier particles, the equilibration times of the cyclotron motion with the environment are impracticably long, and the same applies to the axial and magnetron motions even for electrons.

A workable cooling scheme for the axial motion is based on the charges that the oscillating particle induces on the endcaps. The charges generate currents in an external circuit connecting the endcaps. The endcaps are coupled to a cooled resonant circuit tuned to the axial frequency, and axial motion relaxes to thermal equilibrium with the resonant circuit. A variant of this resistive cooling, in which the ring is split into electrically insulated segments, is used to cool the cyclotron motion of protons and heavier ions.

Magnetron motion of an electron or proton is cooled by sideband cooling. An electric field with components in both the z -direction and xy -plane, and tuned to $\omega = \nu_z + \nu_m$, drives transitions that may either increase or decrease the number of quanta in each mode. However, the matrix elements favor transitions with $\Delta n_z = 1$ and $\Delta n_m = -1$. Pumping of the axial motion is canceled by axial cooling, while an equilibrium with low kinetic energy ensues for the magnetron motion. Ideally, the ratio of kinetic energies becomes

$$\frac{\mathcal{T}_{\text{kin},m}}{\mathcal{T}_{\text{kin},z}} = \frac{\nu_m}{\nu_z}. \quad (79.63)$$

79.4.3 Collective Effects in Ion Clouds

As soon as there is more than one ion in the trap, Coulomb interactions between the ions profoundly shape the physics [13].

Ion Crystal

In the standard Paul trap, radio frequency heating [14] due to transfer of energy from micromotion to secular motion limits the number of ions that can be cooled efficiently by a laser. Nevertheless, if a low enough temperature is reached, the ions settle to equilibrium positions corresponding to a minimum of the joint trapping and Coulomb potentials and form a *crystal*.

Strongly Coupled Plasma

Cooling of a large number of ions is possible in a Penning trap. However, magnetron motion becomes uniform rotation of the entire cloud, and Coulomb interactions set a lower limit on the attainable radius of the cloud. This leads to a lower limit on the kinetic energy and second-order Doppler shift.

In a corotating frame, the ions behave like a one-component plasma on a neutralizing background. The characteristic parameter for a one-component plasma with charge per particle q and density n is

$$\Gamma_P = \left(\frac{4\pi n}{3} \right)^{1/3} \frac{q^2}{4\pi\epsilon_0 k_B T}, \quad (79.64)$$

essentially the ratio of the Coulomb energy between two nearest-neighbor ions divided by the thermal kinetic energy. $\Gamma_P > 1$ indicates a strongly coupled plasma; for $\Gamma_P > 2$ and $\Gamma_P > 170$ liquid and solid phases are expected in an infinite plasma. Experiments with a Penning trap have produced $\Gamma_P \gtrsim 300$. Concentric shells of ions or various more or less crystalline arrangements are seen, depending on the experimental conditions.

Sympathetic Cooling

In a trap that holds two or more species of charged particles, cooling of the motion of one species is transferred by the Coulomb interactions to the other species. This sympathetic cooling broadens the selection of species accessible to ion cooling methods.

79.5 Experimental

79.5.1 Free Particles

Historically, the focus has been on alkali metal vapors, to a large extent because the required laser frequencies can be generated using inexpensive diode lasers. Hyperfine structure of the ground state of the alkalis complicates experiments because the atoms may end up in an inert hyperfine level outside the active cooling/trapping transitions. To counteract this, appropriately tuned repumper light is added to

return such atoms to circulation. Other species such as alkaline earths (Sr) and lanthanides (Yb) are occasionally used. They offer very narrow optical transitions and isotopes with varying hyperfine structures (including none).

Originally the experiments often started with a longitudinal deceleration and cooling of an atomic beam by a counterpropagating laser beam. To compensate for the change of the Doppler shift of the atoms while they slowed down, the position-dependent magnetic field of a tapered solenoid shifted the transition frequency of the atoms to keep them near resonance while they moved down the solenoid. A magneto-optical trap then scooped up some atoms, cooled them further, and held them. Nowadays, this Zeeman slower is mostly supplanted by various schemes in which a MOT directly captures atoms from the low-velocity wing of the thermal distribution. Depths of neutral-atom traps are far below 1 K. Storage times in a MOT are typically on the order of seconds, limited at high densities by exothermic binary collisions and at low densities by collisions with the atoms of the background gas.

Absorption imaging of the atom cloud is the standard diagnostic tool, giving both (the projection to a plane of) the spatial distribution of the atoms, and after proper calibration, the number of the atoms. If cooling and trapping is suddenly turned off, the atom cloud flies apart ballistically, and the velocity distribution gets converted into a position distribution. Analysis of time-delayed absorption images, thus, gives the momentum distribution.

The evolution of the experimental techniques during the era of laser cooling and trapping has been nothing short of spectacular. Acousto-optic and electro-optic modulators enable control of temporal variations and frequencies of the light; the spatial shape of the light field may be tailored using spatial light modulators such as digital micromirror devices; by moving an optical trap of light around quickly, one can “paint” a nearly arbitrary time-averaged optical potential energy for the atoms [15]; it is possible to assemble an arbitrary defect-free 2-D array of atoms one atom at a time [16], and so on. Digital control of the apparatus, data acquisition, and data analysis is an indispensable element in the experiments.

79.5.2 Trapped Particles

Both Paul and Penning traps behave like a conservative potential and scatter rather than confine a particle coming from the outside. One method to load a trap is to generate the ions in situ, e.g., by letting a beam of atoms and electrons collide inside the trap. Time-dependent electric potentials are another loading method. The trapped species is injected through a hole in the endcap, and the opposing endcap is raised to an electric potential that makes the entering parti-

cles stop. The potential is then lowered before it ejects the particles. A single electron, positron, proton, antiproton, or ion may be loaded. Typical depths of ion traps are ≈ 1 eV or $\approx 10^4$ K. With the aid of cooling, the storage time may be made infinite for all practical purposes.

Trap frequencies are measured by observing the resonances excited by added AC fields. For instance, an electric field near the axial resonance frequency may be coupled between the ring and one endcap. A resonance circuit coupled between the ring and the other endcap is used to detect the resonance. Alternatively, ejection of the driven ions is monitored.

For an ion with a dipole-allowed resonance transition, fluorescence of a single ion is readily detected. Even absorption of a single ion may be measurable. Various methods of finding the temperature have been devised. At temperatures of 1 K and higher, Doppler broadening of a dipole-allowed optical transition is observable. The size of the single-ion cloud is a measure of temperature. Finally, motional sidebands in the absorption of a narrow transition ($\gamma \ll \nu$), not necessarily the same transition as the one used for cooling, may be measured to find $\langle n \rangle$. In the Lamb–Dicke regime, only the carrier absorption at $\Delta = 0$ and sidebands at $\Delta = \pm \nu$ are significant, and the ratios of the peak absorptions are

$$\alpha_- : \alpha_0 : \alpha_+ = \langle n \rangle \frac{\epsilon_r}{\nu} : 1 : (1 + \langle n \rangle) \frac{\epsilon_r}{\nu}. \quad (79.65)$$

Fluorescence carries similar information.

In an ion crystal, the ions have collective vibration modes akin to phonons, instead of the three vibration modes along the principal axes of the trap of a single ion. Doppler cooling and sideband cooling work for such collective modes much like they work for the vibration modes of a single ion.

Ion traps and optical dipole traps make it possible to isolate an individual atom scale particle for studies for a practically infinite time, which enables clean experiments on various fundamental aspects of quantum mechanics and quantum electrodynamics. Quantum jumps are a case in point. Suppose that, in addition to an optically driven two-level system, a single ion has a third “shelving” state. Suppose further that the ion infrequently makes a transition to the shelving state, stays there for a long time compared with the timescale of spontaneous emission of the active system, and then returns to the two-level system. When the ion makes a transition to the shelving state, fluorescence from the two-level system suddenly ceases, and the fluorescence reappears equally abruptly when the ion returns to the two-level system. These jumps in light scattering are the quantum jumps [17]. They are a method to detect a weak transition with an enormous amplification; a single transition to or from the shelving state may mean the difference between the presence or absence of billions of fluorescence photons.

79.6 Applications

Trapping and cooling offer increased interaction times between the atoms/ions and the light. This leads to reduced transit time broadening, and, indeed, to macroscopic (> 1 s) interaction times. Laser cooling in a magneto-optical trap routinely gives temperatures so low that the Doppler width is below the natural linewidth of the cooling transition. A homogeneously broadened atomic sample is thus prepared. Cooling also enables reduction of the second-order Doppler effect. Spectroscopy and various frequency measurements have traditionally been the primary beneficiary. Potential applications range from detection of the change of natural constants over time (Chap. 30) to such feats of technology as the Global Positioning System.

Another broad area drawing from low temperatures is experiments, and in the future possibly technologies, that rely on quantum mechanical behavior of either light or atoms. Nowadays, nearly all cutting-edge experiments in quantum optics start with laser cooling. Trapping and manipulation of individual atomic particles is also an established practice.

In this chapter we, by necessity, limit the discussion of applications to very few topics in which the interplay between the internal degrees of freedom and the CM motion is the central theme. At the moment, the most prominent broad application area of laser cooling and trapping is probably quantum gases under conditions when the particle statistics matters, such as the use of optical lattices as quantum simulators of condensed matter systems. These are taken up separately in Chap. 80.

79.6.1 Cold Molecules

Ultralow-temperature molecules may be produced by starting with an ultralow-temperature atomic gas or gases, and using photoassociation or Feshbach resonances to convert pairs of atoms into diatomic molecules [18]. Direct laser cooling of molecules was long thought impossible because of the proliferation of vibrational and rotational states. In general, there is no closed transition that allows enough cycles of absorption and spontaneous emission so that the net exchange of momentum between light and the molecules would be comparable to the momentum of a room-temperature molecule. However, in certain molecules, such as CaF and SrF, there are diagonal transitions between vibrational states with the Franck–Condon factor very close to unity, giving a simulacrum of a closed two-level system. One still has to compensate for the leakage from the almost-closed transition because the Franck–Condon factors of the unwanted transitions are not exactly zero, branching between hyperfine levels is possible as in atoms, and so on. A number of

laser frequencies may be needed to repump the molecule into the desired transition. Nonetheless, the basic program of laser cooling and trapping has been demonstrated for diatomic molecules [19]. One of the foreseeable goals is a Bose–Einstein condensate of polar molecules, a novel system because of the strong anisotropic long-range electric dipole interactions between the molecules.

79.6.2 Quantum Systems of Internal and CM States

A vibrational mode of a trapped ion and an effective two-state system for the internal degrees of freedom make a realization of the Jaynes–Cummings model (discussed in detail in Chap. 83.4.1) possible. Moreover, sideband cooling enables the experimenter to put the mode cleanly in its lowest quantum state. These observations have inspired quantum-state engineering with the objective of generating an arbitrary state of the vibrational motion of the ion [20]. In many-ion crystals, the collective vibration modes may be used to couple and entangle the internal degrees of freedom of two or more ions. As discussed in Chap. 85, quantum information processing has been demonstrated in this manner.

Fully coherent manipulation of joint internal and CM states of free atoms is also possible. For instance, two motional states of a ground-state atom with the velocities v and $v + 2v_r$ can be coupled by two light pulses with opposite propagation directions. If both pulses are off resonance from a transition between the ground and excited state of the atom, and their frequency difference matches the difference of the kinetic energies $\frac{1}{2}mv^2$ and $\frac{1}{2}m(v + 2v_r)^2$, a Raman scheme is set up that may transfer the atom between the two motional states. Variations of this Bragg diffraction technique have been used to coherently split an atomic wave packet to components with the velocities differing by tens of recoil velocities [21]. Recombining the wave packet makes an interferometer that is sensitive to the forces, real and inertial, that acted on the atom while the wave packet was split. Analogous atom interferometers are being developed for purposes such as gravimetry. The hope is improved sensitivity; in the literature one sees claims of fundamental scaling of the sensitivity between atom interferometers and light interferometers with $mc^2/\hbar\omega_0$.

More generally in the way of coupling between internal and CM degrees of freedom, a field called (in the atomic context maybe confusingly) spin–orbit coupling [22] emerged during the past decade and has inspired much theoretical and experimental work. In an elementary example, consider a two-level atom without damping moving in the x -direction in the plane wave of light with the amplitude proportional to e^{ikx} . Using the vector-matrix representation for the internal states $\{|e\rangle, |g\rangle\}$ and in the convention that the zero of the en-

ergy in the rotating frame lies halfway between the states, the Hamiltonian reads

$$H = \begin{bmatrix} \frac{\hat{p}_x^2}{2m} - \frac{\hbar\Delta}{2} & -\frac{\hbar\Omega}{2}e^{ikx} \\ -\frac{\hbar\Omega}{2}e^{-ikx} & \frac{\hat{p}_x^2}{2m} + \frac{\hbar\Delta}{2} \end{bmatrix}. \quad (79.66)$$

After a unitary transformation generated by

$$U = \begin{bmatrix} e^{-ikx/2} & 0 \\ 0 & e^{ikx/2} \end{bmatrix}, \quad (79.67)$$

the Hamiltonian may be written in terms of Pauli spin matrices as

$$H = \frac{1}{2m} \left(\hat{p}_x + \frac{\hbar k}{2} \sigma_z \right)^2 - \frac{\hbar\Omega}{2} \sigma_x - \frac{\hbar\Delta}{2} \sigma_z. \quad (79.68)$$

The term $\propto \hat{p}_x \sigma_z$ that arises from the expansion of the square is the spin–orbit coupling, seemingly a direct coupling between motional and internal states of the atom. A Raman scheme with two beams propagating in opposite directions and the intermediate state far-off resonance offers a potential realization. A main goal here, again, is clean AMO physics simulations of prominent systems in condensed matter physics. A similar topic, synthetic gauge fields that arise from coupling between internal and motional states of an atom, is discussed at some length in Chap. 80.

Abstract

The purpose of this chapter is to summarize the physics of dilute quantum degenerate gases. Given the broad activity in the field, many choices have to be made regarding the topics to include and the style of the discussion. Emphasis is on AMO physics, as opposed to condensed-matter physics. Two related choices are that virtually nothing is said about temperature dependence, and that the focus is on one-particle and mean-field theories as opposed to

strongly correlated systems. Inside AMO physics the approach is in the vein of quantum optics, as opposed to atomic/molecular structure and collisions. For the most part, the coverage is on elementary concepts and basic material. The exception is Sect. 80.6, where a few topical issues are addressed.

The article [1] has become the standard reference on the mean-field physics of a Bose–Einstein condensate (BEC), [2] is particularly explicit about the excitations of a BEC, and [3] reviews the basics of the concurrent condensed-matter approach to quantum degenerate gases. The monograph [4] is a recent broad overview of BEC physics. Here, references are usually not given for topics that are discussed in these sources or where a full discussion can be traced from them. Otherwise, references are meant to be entries to the literature. Assignment of credit or priority is never implied.

magnetic trap · optical trap · Feshbach resonance · phase space density · condensate wave function

80.1 Introduction

Bose–Einstein condensation in dilute alkali metal vapors has realized a source of atoms with properties analogous to the properties of laser light, and ultralow-temperature Fermi gases have also come under study. Quantum degenerate gases have become a main theme in AMO physics. Dilute-vapor systems are weakly interacting and subject to a degree of experimental control not seen before in traditional low-temperature condensed-matter systems. Ultralow-temperature gases thereby reinvigorated, say, investigations of superfluids. More recently, the main thrust has been to use AMO techniques to simulate experimentally condensed-

matter systems, some of which have been subject to much theoretical study in the past but have lacked clean implementations. This applies, in particular, to various lattice systems [5, 6].

80.2 Elements of Quantum Field Theory

A Bose–Einstein condensate and a degenerate Fermi gas are both consequences of particle statistics, exchange symmetries of the many-particle wave function. It is possible, in principle, to deal directly with the wave functions, but in practice, analyses of many-body systems are usually carried out using the methods of second quantization and field theory. In first quantization, the particles are labeled as if each one had a unique tag on it, and the wave function for more than one indistinguishable particle must be symmetrized explicitly. In second quantization, the question is how many particles are in a given one-particle state without any distinction between identical particles. The exchange symmetries are then taken care of automatically. Here, we briefly summarize [7] elementary features of quantum field theories for both bosons and fermions.

80.2.1 Bosons

Particles with an integer value of the angular momentum obey the Bose–Einstein statistics. The characteristic property is that a one-particle state can accommodate an arbitrary number of bosons.

State Space for Bosons

Specifically, first consider one particle whose states are completely specified by a set of quantum numbers k . As a notational device for the purposes of the present chapter, all of the quantum numbers are assumedly mapped in a one-to-one fashion to nonnegative integers, and, correspondingly, the quantum numbers are written $k = 0, 1, 2, \dots$. The quantum numbers incorporate a description of the state of the center-of-mass (CM) motion of the particle. We, therefore, have an orthonormal basis of wave functions to represent any state of a particle, $\{u_k(\mathbf{x})\}_k$, where \mathbf{x} stands for the CM coordinate.

Given the one-particle states, the postulate is that the Fock states $|n_0, n_1, \dots, n_\infty\rangle$ with $n_k = 0, 1, 2, \dots$ particles in the states $k = 0, 1, 2, \dots$ form an orthonormal basis for the many-body system.

Second-Quantized Operators for Bosons

The annihilation operator for the state k , a_k , is defined by

$$\begin{aligned} a_k |n_0, n_1, \dots, n_k, \dots, n_\infty\rangle \\ = \sqrt{n_k} |n_0, n_1, \dots, n_k - 1, \dots, n_\infty\rangle. \end{aligned} \quad (80.1)$$

Its Hermitian conjugate, the creation operator, behaves as

$$a_k^\dagger |\dots, n_k, \dots\rangle = \sqrt{n_k + 1} |\dots, n_k + 1, \dots\rangle. \quad (80.2)$$

It follows that

$$a_k^\dagger a_k |\dots, n_k, \dots\rangle = n_k |\dots, n_k, \dots\rangle, \quad (80.3)$$

and so $\hat{n}_k = a_k^\dagger a_k$ is called the number operator for the state k . Correspondingly,

$$\hat{N} = \sum_k a_k^\dagger a_k \quad (80.4)$$

is the operator for the total number of particles in the system. The annihilation and the creation operators have the usual boson commutators,

$$[a_k, a_{k'}] = [a_k^\dagger, a_{k'}^\dagger] = 0, \quad [a_k, a_{k'}^\dagger] = \delta_{kk'}. \quad (80.5)$$

The boson field operator is defined as

$$\hat{\psi}(\mathbf{x}) = \sum_k u_k(\mathbf{x}) a_k. \quad (80.6)$$

The commutator for the field operator,

$$[\hat{\psi}(\mathbf{x}), \hat{\psi}^\dagger(\mathbf{x}')] = \delta(\mathbf{x} - \mathbf{x}'), \quad (80.7)$$

follows from boson commutators and the completeness of the wave functions $\{u_k(\mathbf{x})\}_k$. The orthonormality of the wave functions gives the expression

$$\hat{N} = \int d^3x \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}(\mathbf{x}), \quad (80.8)$$

for the particle number operator. The positive operator

$$\hat{n}(\mathbf{x}) = \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}(\mathbf{x}) \quad (80.9)$$

evidently represents the density of the particles at the position \mathbf{x} .

The second-quantized operators introduced thus far can be used to express all observables acting on indistinguishable bosons. The most relevant here are the one and two-particle operators. One-particle operators, such as kinetic energy, act on one particle at a time, while two-particle operators, such as atom–atom interactions, refer to two particles. In first quantization, these are of the form

$$O_1 = \sum_n V(\mathbf{x}_n), \quad O_2 = \frac{1}{2} \sum_{n \neq n'} u(\mathbf{x}_n, \mathbf{x}_{n'}), \quad (80.10)$$

where the sums run over the labels of the particles. The corresponding second-quantized operators are

$$\hat{O}_1 = \int d^3x \hat{\psi}^\dagger(\mathbf{x}) V(\mathbf{x}) \hat{\psi}(\mathbf{x}), \quad (80.11)$$

$$\hat{O}_2 = \frac{1}{2} \int d^3x d^3x' \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}^\dagger(\mathbf{x}') u(\mathbf{x}, \mathbf{x}') \hat{\psi}(\mathbf{x}') \hat{\psi}(\mathbf{x}). \quad (80.12)$$

When the particles have internal degrees of freedom in addition to the CM motion, such as hyperfine and Zeeman states, it is convenient for the present purposes to regard particles in each internal state as a separate species. Thus, if the quantum number breaks up into $k \equiv \{p, \alpha\}$, where p stands for quantum numbers of the center of the mass and α for the quantum numbers of the internal state, it is expedient to define a quantum field for each species α as

$$\hat{\psi}_\alpha(\mathbf{x}) = \sum_p u_{p\alpha}(\mathbf{x}) a_{p\alpha}. \quad (80.13)$$

Mechanisms that cause transitions between the internal states couple the fields $\hat{\psi}_\alpha(\mathbf{x})$ with different α .

States of Bosons

To complete the transformation from wave function quantum mechanics to second quantization, the state of the system must be specified in second quantization. For instance, take the Hamiltonian \hat{H} and the particle number operator \hat{N} . According to statistical mechanics a system characterized by the temperature T and chemical potential μ is in the state with the density operator $\hat{\rho} = e^{-(\hat{H} - \mu\hat{N})/k_B T} / \mathcal{Z}$, where the grand partition function is $\mathcal{Z} = \text{Tr} e^{-(\hat{H} - \mu\hat{N})/k_B T}$.

Bose–Einstein Condensate

The state of a boson system of particular interest here is the BEC. In an ideal gas, condensation entails a macroscopic fraction of the particles occupying the ground state of the CM motion. Condensation is a phase transition that occurs when either the density of the gas is increased, or the temperature is lowered. In a homogeneous ideal Bose gas, the governing parameter is the phase space density ζ , defined in three spatial dimensions as

$$\zeta = \left(\frac{2\pi\hbar^2}{mk_B T} \right)^{3/2} n, \quad (80.14)$$

where m is the mass of the condensing atoms, T is the temperature, and n is the density of the condensing species. For the purposes of quantum degeneracy, each internal state of an atom behaves as a separate species. Bose–Einstein condensation takes place when the phase space density satisfies $\zeta = 2.612$. Depending on whether density or temperature is

regarded as a constant, Eq. (80.14) may be regarded as an equation for the critical temperature T_c or the critical density n_c for Bose–Einstein condensation.

80.2.2 Fermions

Particles with a half-integer angular momentum obey the Fermi–Dirac statistics. Each Fock state may then only have the occupation numbers $n_k = 0, 1$. The conventional definition of the annihilation operator contains a phase factor,

$$a_k |n_0, n_1, \dots, n_k, \dots, n_\infty\rangle \\ = n_k (-1)^{\sum_{p=0}^{k-1} n_p} |n_0, n_1, \dots, n_k - 1, \dots, n_\infty\rangle, \quad (80.15)$$

and fermion operators are governed by the anticommutator

$$[A, B]_+ \equiv AB + BA \quad (80.16)$$

rather than the commutator. For instance,

$$[a_k, a_{k'}]_+ = 0, \quad [a_k, a_{k'}^\dagger]_+ = \delta_{kk'}. \quad (80.17)$$

Except for the use of anticommutators in lieu of commutators, all formal expressions for field operators and one and two-particle operators written down for bosons in Sect. 80.2.1 remain valid as stated.

Degenerate Fermi Gas

A degenerate Fermi gas realized in a dilute atom vapor is the fermion counterpart of a BEC. The basic parameter of a free noninteracting Fermi gas is the Fermi energy, the chemical potential at zero temperature. It is given by

$$\epsilon_F = \frac{\hbar^2 k_F^2}{2m}; \quad k_F = (6\pi^2 n)^{1/3}, \quad (80.18)$$

where n once more is the density for the relevant fermion species. In the limit of zero temperature, the Fermi gas makes a Fermi sea; the states below the Fermi energy are filled with one particle each, the states above the Fermi energy are empty. The gas begins to show substantial deviations from the Maxwell–Boltzmann statistics and may be regarded as degenerate when the temperature is below the Fermi temperature, $T \lesssim T_F = \epsilon_F/k_B$. Except for a numerical factor, in terms of density and temperature, the condition $T = T_F$ is the same as the condition for Bose–Einstein condensation.

80.2.3 Bosons Versus Fermions

Isotopes of alkali metals with an odd mass number (${}^7\text{Li}$, ${}^{23}\text{Na}$, ${}^{39}\text{K}$, ${}^{85}\text{Rb}$, ${}^{87}\text{Rb}$, ${}^{133}\text{Cs}$) make Bose–Einstein gases,

while isotopes with an even mass number (${}^6\text{Li}$, ${}^{40}\text{K}$) make Fermi–Dirac gases. Atoms are composite particles consisting of fermions, and how they may act as bosons is a legitimate question. Whether a satisfactory formal answer to this question exists may be debated, but in practice, atoms seem to obey the correct statistics in processes that do not expose their individual constituents.

When two bosonic atoms with integer angular momenta combine into a molecule, the molecule has an integer angular momentum and behaves as a boson. On the other hand, two fermionic atoms also make a bosonic molecule. Models for the latter type of system are basically ad hoc since, at this point in time, no microscopic theory for such a rearrangement of the statistics appears to exist. Nonetheless, empirically, diatomic molecules formed by combining two fermionic atoms indeed appear to be bosons.

80.3 Basic Properties of Degenerate Gases

80.3.1 Atoms Are Trapped

Quantum degenerate alkali vapors are typically prepared in an atom trap. Close to the bottom almost every trap is a three-dimensional harmonic oscillator potential completely characterized by the principal-axis directions and the corresponding trap frequencies ω_i , the (angular) frequencies at which a single atom would oscillate back and forth in the given principal-axis direction. In the principal-axis coordinate system the trapping potential reads

$$V(\mathbf{x}) = \frac{1}{2} \sum_{i=1}^3 m \omega_i^2 x_i^2. \quad (80.19)$$

It is convenient to introduce the characteristic harmonic-oscillator frequency scale and the corresponding harmonic-oscillator length scale as

$$\bar{\omega} = (\omega_1 \omega_2 \omega_3)^{1/3}, \quad \ell = \sqrt{\frac{\hbar}{m \bar{\omega}}}. \quad (80.20)$$

80.3.2 Atom–Atom Interactions

At low temperatures/energies, only s -wave collisions are significant. In the theory of quantum degenerate gases, these are frequently represented by a pseudopotential tailored to give the correct s -wave phase shift. Except for a mathematical subtlety that is usually ignored, for two atoms the pseudopotential is

$$u(\mathbf{x}_1, \mathbf{x}_2) = \frac{4\pi \hbar^2 a}{m} \delta(\mathbf{x}_1 - \mathbf{x}_2), \quad (80.21)$$

where a is the s -wave scattering length. Qualitatively, the scattering length is positive (negative) if the interaction is repulsive (attractive).

80.3.3 Model Hamiltonian

Quantum field theory for a single-component Bose gas usually starts with the Hamiltonian

$$\hat{H} = \int d^3x \hat{\mathcal{H}}(\mathbf{x}), \quad (80.22)$$

where the Hamiltonian density is

$$\begin{aligned} \hat{\mathcal{H}}(\mathbf{x}) = & \hat{\psi}^\dagger(\mathbf{x}) \left[-\frac{\hbar^2}{2m} \nabla^2 + V(\mathbf{x}) \right] \hat{\psi}(\mathbf{x}) \\ & + \frac{2\pi \hbar^2 a}{m} \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}(\mathbf{x}) \hat{\psi}(\mathbf{x}). \end{aligned} \quad (80.23)$$

As in Sect. 80.2.1, $\hat{\psi}(\mathbf{r})$ is the boson field operator, the kinetic energy $-\hbar^2 \nabla^2 / 2m$ and trapping potential $V(\mathbf{x})$ are one-particle operators, and atom–atom interactions are governed by the two-particle operator u of Eq. (80.21). Analogous models can be written down for multicomponent boson and fermion fields, for conversion between atoms and molecules, and so on.

80.3.4 Bosons

Gross–Pitaevskii Equation

Mean-field approximation

Conventionally, the next step for bosons is to go over to the corresponding classical field theory. The result is referred to as mean-field theory or semiclassical theory.

Formally, one first writes down explicitly the Heisenberg equation of motion for the boson field $\hat{\psi}$,

$$i\hbar \frac{\partial}{\partial t} \hat{\psi}(\mathbf{x}, t) = [\hat{\psi}(\mathbf{x}, t), \hat{H}], \quad (80.24)$$

and then declares that in the equations of motion, $\hat{\psi} \rightarrow \psi$ is a classical field and no longer a quantum field. We call ψ the macroscopic wave function of the condensate. This approximation is precisely analogous to using the classical instead of the quantum description for the electric and magnetic fields of the light coming out of a laser.

Time-dependent Gross–Pitaevskii equation

The ensuing time-dependent Gross–Pitaevskii equation (GPE) is

$$i\hbar \frac{\partial}{\partial t} \psi(\mathbf{r}, t) = \left[-\frac{\hbar^2}{2m} \nabla^2 + V(\mathbf{r}) \right] \psi(\mathbf{r}, t) + \frac{4\pi\hbar^2 a}{m} |\psi(\mathbf{r}, t)|^2 \psi(\mathbf{r}, t). \quad (80.25)$$

This equation is nonlinear, and normalization of the macroscopic wave function ψ is important. Quantum mechanically, the particle number operator is given by Eq. (80.8), so the normalization for a system with N particles naturally reads

$$\int d^3x |\psi(\mathbf{x}, t)|^2 = N. \quad (80.26)$$

Time evolution under Eq. (80.25) preserves the normalization. Obviously, and in accordance with Eq. (80.9),

$$n(\mathbf{x}) = |\psi(\mathbf{x})|^2 \quad (80.27)$$

is the local density of the gas.

Time-independent Gross–Pitaevskii equation

Solutions to the time-dependent GPE of the form $\psi(\mathbf{x}, t) = \phi(\mathbf{x})e^{-i\mu t/\hbar}$ are stationary states with no time evolution in the physics. The analog μ of the energy of a stationary state in ordinary quantum mechanics is called chemical potential. The corresponding wave function ϕ satisfies the time-independent GPE

$$\mu\phi = \left(-\frac{\hbar^2}{2m} \nabla^2 + V \right) \phi + \frac{4\pi\hbar^2 a}{m} |\phi|^2 \phi. \quad (80.28)$$

Both GPEs are nonlinear variants of the Schrödinger equation, and in other contexts they are often referred to as nonlinear Schrödinger equations. The nonlinear term approximates the interaction energy of an atom with the other atoms in an averaged way based on the local density of the atoms, hence the term mean-field theory.

Sign of scattering length

The qualitative properties of a condensate, as per the GPE, depend on the sign of the scattering length. For repulsive atom–atom interactions or no atom–atom interactions, $a \geq 0$, both the time-dependent and the time-independent forms are mathematically well behaved. Unless otherwise noted, below the scattering length is always assumed nonnegative.

In the case of a negative scattering length, a BEC may, in principle, decrease its energy without a bound by collapsing to a point. Mechanisms such as three-body recombination and molecule formation would eventually set in as the density increases, and the collapse would stop, but the

condensate must then be presumed lost. In the absence of an external potential, a condensate with a negative scattering length is unconditionally unstable against collapse. For a bounded condensate, the increase in the kinetic energy coming with the decreasing size may hold off the collapse, provided the number of atoms in the condensate is sufficiently small. Simple dimensional-analysis arguments give the condition of stability in a harmonic trap as $N|a| \lesssim \ell$.

Behavior attributed to a collapse has been observed in ^7Li with a negative scattering length. By using a Feshbach resonance it is also possible to adjust the scattering length, see Eq. (80.66), which has led to further demonstrations of collapse-like physics.

Healing length

Consider the time-independent GPE Eq. (80.28) without an external potential and scale the various quantities:

$$\begin{aligned} \phi &= \sqrt{n} \bar{\phi}, \quad \mu = \bar{\mu} \frac{4\pi\hbar^2 n a}{m}, \\ \mathbf{x} &= \xi \bar{\mathbf{x}}; \quad \xi = \frac{1}{\sqrt{8\pi n a}}. \end{aligned} \quad (80.29)$$

Here, n is the density scale for the gas, and the length scale is ξ . In terms of these new variables, the time-independent GPE reads

$$\bar{\mu} \bar{\phi} = -\bar{\nabla}^2 \bar{\phi} + |\bar{\phi}|^2 \bar{\phi}. \quad (80.30)$$

There is a solution in all of space with $\bar{\mu} = 1$, $\bar{\phi} = 1$. If for some reason, such as an edge of the sample, the condensate wave function must vanish, the length scale over which the wave function grows back to one (in the scaled units) is on the order of unity. In fact, Eq. (80.30) has the solution $\bar{\phi}(\bar{\mathbf{x}}) = \tanh(\bar{z}/\sqrt{2})$ in the half-space $\bar{z} \geq 0$. The quantity ξ is the minimum length scale over which a condensate wave function can build up to the density n . It is called the healing length.

Thomas–Fermi approximation

Without atom–atom interactions, the ground state of the trapping potential $V(\mathbf{x})$ would be the lowest-energy (lowest μ) solution to Eq. (80.28). However, experience has shown that even modest repulsive atom–atom interactions ($a > 0$) spread out the macroscopic wave function of the condensate a great deal. With increasing size comes decreasing kinetic energy, according to the Heisenberg uncertainty principle. This suggests the Thomas–Fermi approximation, in which the kinetic energy term in Eq. (80.28) is simply ignored. The density of the gas is then easily solved to be

$$n(\mathbf{x}) = \begin{cases} \frac{m[\mu - V(\mathbf{x})]}{4\pi\hbar^2 a}, & \mu > V(\mathbf{x}) \\ 0, & \text{otherwise,} \end{cases} \quad (80.31)$$

an inverted image of the trapping potential. The normalization Eq. (80.26) can be used to find the relation between chemical potential and particle number, and all of the unknown quantities may, in principle, be found.

For a harmonic potential the Thomas–Fermi approximation can be worked out explicitly with the results

$$\begin{aligned} \mu &= \frac{1}{2} \hbar \bar{\omega} \left(\frac{15Na}{\ell} \right)^{2/5}, & R &= \ell \left(\frac{15Na}{\ell} \right)^{1/5}, \\ n(0) &= \frac{1}{8\pi\ell^3} \frac{\ell}{a} \left(\frac{15Na}{\ell} \right)^{2/5}. \end{aligned} \quad (80.32)$$

The quantity R represents the size of the condensate. In particular, it equals the radius of the spherical condensate if the trap is isotropic with $\omega_1 = \omega_2 = \omega_3$. Finally, $n(0)$ is the central, maximum, density of the atoms.

The relevant dimensionless parameter is Na/ℓ , which can easily be much larger than unity in the experiments. When the Thomas–Fermi approximation is accurate, the chemical potential exceeds the typical level spacing of the harmonic-oscillator trap, and the condensate is larger than the ground-state wave function of the harmonic oscillator would be. Ordinarily, the condensate is also much larger than the healing length.

Small Excitations in a BEC

Linearizing the GPE

The time-dependent GPE is nonlinear but may be linearized around a stationary solution. Consider the special case without a trapping potential, $V(\mathbf{x}) \equiv 0$. The stationary solutions are plane waves,

$$\phi(\mathbf{x}) = \sqrt{n} e^{i\mathbf{p}\cdot\mathbf{x}}. \quad (80.33)$$

This corresponds to a flow of the gas at the velocity $\mathbf{v} = \hbar\mathbf{p}/m$ and with a momentum $\hbar\mathbf{p}$ per atom. The chemical potential of such a mode is

$$\frac{\mu}{\hbar} = \epsilon_p + \frac{1}{2}\epsilon_0, \quad (80.34)$$

where

$$\epsilon_p = \frac{\hbar p^2}{2m}, \quad \epsilon_0 = \frac{mc^2}{\hbar}, \quad c = \frac{\hbar\sqrt{8\pi na}}{m} = \frac{\hbar}{m\xi} \quad (80.35)$$

are the dispersion relation of free atoms, a peculiar analog of the rest energy, and the speed of sound in the BEC.

The ansatz for small deviations from the stationary solution is written as

$$\psi(\mathbf{x}, t) = \sqrt{n} e^{i(\mathbf{p}\cdot\mathbf{x} - \frac{\mu}{\hbar}t)} \left[1 + u e^{i(\mathbf{q}\cdot\mathbf{x} - \nu t)} + v^* e^{-i(\mathbf{q}\cdot\mathbf{x} - \nu^* t)} \right], \quad (80.36)$$

where $\hbar\mathbf{q}$ and $\hbar\nu$ are the momentum and energy associated with the excitation relative to the momentum and energy of the original flow. The GPE mixes the field ψ and its complex conjugate ψ^* , so that two small amplitudes u and v are needed for the excitations. The ansatz Eq. (80.36) is a solution to the time-dependent GPE to the lowest nontrivial order in u and v if these amplitudes and the frequency of the excitation satisfy the eigenvalue equation

$$\begin{pmatrix} \epsilon_q + \epsilon_0 + \mathbf{q}\cdot\mathbf{v} & \epsilon_0 \\ \epsilon_0 & \epsilon_q + \epsilon_0 - \mathbf{q}\cdot\mathbf{v} \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} = \nu \begin{pmatrix} u \\ -v \end{pmatrix}. \quad (80.37)$$

The remaining problem is that the eigenvalue equation has two solutions for each \mathbf{q} , which gives twice as many small-excitation modes as there are degrees of freedom. The extra modes are the penalty one pays for the linearization of the GPE. The criterion $|u|^2 - |v|^2 > 0$ picks out the correct small-excitation modes. The corresponding dispersion relation for the excitations is

$$\nu(\mathbf{q}) = \mathbf{q}\cdot\mathbf{v} + \sqrt{\epsilon_q(\epsilon_q + 2\epsilon_0)}. \quad (80.38)$$

For a stationary BEC with $\mathbf{v} = 0$ and in the limit $q \rightarrow 0$, Eq. (80.38) gives $\nu \approx cq$. This confirms the identification of c as the speed of sound.

In the BEC experiments the condensates are usually trapped, but in principle the same analysis of small-excitation modes may be carried out both numerically and in a myriad of analytical approximations. The generic result is that the trap frequencies lend their frequency scale to small excitations. At low enough temperatures, excitation frequencies calculated in this way agree well with the experiments.

Within the mean-field approximation, small excitations may be analyzed similarly in all boson systems, for instance, in a multicomponent Bose–Einstein condensate or a joint atom–molecule condensate. The evolution frequencies may be complex, which signals a dynamical instability of the stationary configuration; there are small-excitation modes that grow exponentially. The instability of a free gas with a negative scattering length, which is apparent in Eq. (80.38) for $\epsilon_0 < 0$, is a simple example.

Bogoliubov theory

Bogoliubov theory is the many-body quantum version of the analysis of small excitations. The idea is to treat the condensate mode ψ_0 , containing n_0 atoms, separately in the field operator,

$$\hat{\psi} = \sqrt{n_0} \psi_0 + \delta\hat{\psi}, \quad (80.39)$$

expand the Hamiltonian in the lowest nontrivial (second) order in the remnant quantum field $\delta\hat{\psi}$, and diagonalize.

The result is small-excitation modes with the annihilation operators A_k , where k stands for the appropriate quantum numbers. It turns out that the core mathematics of Bogoliubov theory is the same as the mathematics of small excitations, but two features are added. First, Bogoliubov theory explicitly shows that the coefficients u and v in the analog of Eq. (80.37) need to satisfy $|u|^2 - |v|^2 = 1$ to ensure boson commutators for the operators A_k . Second, with quantum fluctuations, atom–atom interactions force atoms out of the condensate even at zero temperature. In a homogeneous (untrapped) condensate, in the limit $na^3 \ll 1$, at $T = 0$, the fraction of noncondensate atoms is

$$\frac{N - n_0}{N} = \frac{8}{3} \sqrt{\frac{na^3}{\pi}}. \quad (80.40)$$

When the so-called gas parameter na^3 is much smaller than unity, at low enough temperatures most of the atoms are in the condensate. Mean-field theory and the GPE are expected to apply, and empirically, they do.

Numerical Methods for GPE

Mathematical properties of the GPE

Let us momentarily assume that, by separation of variables or by some fiat, the problem of solving the time-independent GPE has been rendered one-dimensional. The ordinary Schrödinger equation is linear, and any constant multiple of a solution is also a solution. One parameter, e.g., the logarithmic derivative of the wave function at a given point in space, determines a stationary state completely. This does not hold for the corresponding GPE, for which the values of the wave function and its derivative can be specified independently at (almost) every fixed point in space. As a result of the added flexibility, and unlike the Schrödinger equation, the GPE has bounded solutions for continuous ranges of the values of the chemical potential μ .

However, the time-independent GPE Eq. (80.28) comes with the added normalization condition Eq. (80.26). Normalization quantizes the values of μ for the bound states. In practice one might, for instance, find a solution that satisfies the boundary conditions for a given μ with the shooting method, then adjust the value of μ until the normalization holds. Techniques used in the first numerical analyses of the time-independent GPE in the context of atom vapor condensates were variations of this theme. Such schemes are not feasible in spatial dimensions greater than one.

In general, there is one solution to the time-independent GPE that can be chosen to be positive everywhere, the ground state with the lowest chemical potential. Excited steady states exist, but only a few, such as the flowing states of Eq. (80.33) and vortices discussed in Sect. 80.5.1, have obvious physical meanings. As the GPE is nonlinear, excited states are not the same as small excitations.

Split-step Fourier method

The superposition principle does not hold for the solutions of the time-dependent GPE, and the excited states are usually not orthogonal to one another in any useful sense. Methods based on eigenstate expansions for solving the time-dependent GPE are cumbersome at best. Instead, one often simply integrates the GPE as a partial differential equation in time. A number of different methods are used, but here we only discuss an elementary split-step Fourier method [8]. This is an exceedingly popular algorithm for parabolic equations, which is easy to implement and with minor modifications also solves the time-independent GPE in any number of dimensions.

Thus, consider integration of Eq. (80.25) forward in time over a step from t to $t + \Delta t$. For this purpose, assume first that $|\psi|^2$ in the GPE were a constant equal to its value at time t , then the evolution over the time step Δt would be given by

$$\psi(\mathbf{x}, t + \Delta t) = \exp\left[-i\Delta t\left(-\frac{\hbar\nabla^2}{2m} + U(\mathbf{x})\right)\right]\psi(\mathbf{x}, t), \quad (80.41)$$

where $U(\mathbf{x})$ is a known function of position. In the algorithm the exponential is first split approximately, for instance, as

$$\begin{aligned} & \exp\left[-i\Delta t\left(-\frac{\hbar\nabla^2}{2m} + U(\mathbf{x})\right)\right] \\ & \approx \exp\left(i\frac{\Delta t}{2}\frac{\hbar\nabla^2}{2m}\right)\exp[-i\Delta t U(\mathbf{x})]\exp\left(i\frac{\Delta t}{2}\frac{\hbar\nabla^2}{2m}\right) \\ & \equiv \tilde{T}\tilde{U}\tilde{T}. \end{aligned} \quad (80.42)$$

The exponential of the kinetic-energy operator is diagonal in the Fourier representation. Consequently, carrying out the Fourier transformation \mathcal{F} and its inverse gives the split-step algorithm

$$\psi(t + \Delta t) = \mathcal{F}^{-1}\tilde{T}\mathcal{F}\tilde{U}\mathcal{F}^{-1}\tilde{T}\mathcal{F}\psi(t), \quad (80.43)$$

with an efficient implementation using the fast Fourier transformation. For the GPE, $U(\mathbf{x})$ includes the mean-field contribution that depends on the wave function ψ itself, so the question arises as to which approximation of ψ to use when one operates with \tilde{U} . The maybe surprising answer is that the very ψ that emerges from the first step $\mathcal{F}^{-1}\tilde{T}\mathcal{F}\psi(t)$ leads to the lowest order of error in Δt [9]. The split-step algorithm preserves the normalization of the macroscopic wave function, and features an accurate compact approximation of the exponential function of the kinetic-energy operator.

Integration in imaginary time

The split-step algorithm also provides a global method to find the ground state. To this end, the time-dependent GPE is integrated in imaginary time, i.e., replacing $\Delta t \rightarrow -i\Delta t$, starting

from a more or less random initial wave function and normalizing after every step. For the Schrödinger equation, this process would increase the amplitude of the lowest-energy component in the wave function with respect to the other components exponentially in the imaginary time, and eventually leave only the ground state. It is not clear that the same should hold for the nonlinear GPE, but often it does. However, in nonlinear problems split-operator methods often exhibit spurious behavior. Successful use of these techniques requires experience and skill in the art of numerical methods.

Local-Density Approximation

While an experimental BEC is usually trapped, it is often much easier to study the theory for a formally infinite homogeneous condensate. As long as the phenomena under investigation involve length scales much smaller than the size of the condensate, trapping cannot affect the behavior of the gas locally. Under such conditions, one may analyze the gas at each position \mathbf{x} as if it were homogeneous, and at the end of the calculations average over the density distribution. The unit-normalized distribution of the density of the gas used in the averaging is

$$P(\varrho) = \frac{\int \delta[\varrho - n(\mathbf{x})] n(\mathbf{x}) d^3x}{\int n(\mathbf{x}) d^3x}. \quad (80.44)$$

For instance,

$$P(\varrho) = \frac{15\sqrt{n(0) - \varrho} \varrho}{4[n(0)]^{5/2}} H(\varrho) H(n(0) - \varrho) \quad (80.45)$$

holds for the Thomas–Fermi approximation with the maximum density $n(0)$. The Heaviside step functions H restrict the density to the correct range $0 \leq \varrho \leq n(0)$. As an example, the average density in the Thomas–Fermi model is

$$\int \varrho P(\varrho) d\varrho = \frac{4}{7} n(0). \quad (80.46)$$

80.3.5 Meaning of the Macroscopic Wave Function

Here, the macroscopic wave function ψ has been introduced by replacing a boson field theory with a classical field theory.

The intuitive interpretation is that, for interacting particles, the atoms condense not to the ground state of the confining potential but to the one-body state whose wave function is the macroscopic wave function. This notion may be criticized on various grounds, but in practice it makes a useful picture.

A precise formal meaning of the macroscopic wave function, and of Bose–Einstein condensation for interacting systems, is found by considering the one-particle density matrix

$$\rho(\mathbf{x}, \mathbf{x}') = \langle \hat{\psi}^\dagger(\mathbf{x}) \hat{\psi}(\mathbf{x}') \rangle, \quad (80.47)$$

which is sufficient to determine the expectation value of any one-particle operator. This is the position representation of a positive operator with the trace equal to particle number (or technically, its expectation value) N . Therefore, an orthonormal set of eigenfunctions $\{\psi_k(\mathbf{x})\}_k$ and the corresponding nonnegative eigenvalues n_k with

$$\sum_k n_k = N \quad (80.48)$$

exist such that the one-particle density matrix may be put in the form

$$\rho(\mathbf{x}, \mathbf{x}') = \sum_k n_k \psi_k(\mathbf{x}) \psi_k(\mathbf{x}'). \quad (80.49)$$

The system is a BEC if in the thermodynamic limit at least one eigenvalue n_k is on the order of the number of particles (if the thermodynamic limit exists and is sensible). The usual case is that only one state, call it $k = 0$, has such a large eigenvalue. The macroscopic wave function is essentially the corresponding eigenfunction, $\psi \equiv \sqrt{n_0} \psi_0$, and n_0 gives the number of condensate atoms. If there is more than one macroscopic eigenvalue, the condensate is called fragmented.

Another interpretation of the macroscopic wave function comes from statistical mechanics. In a continuous (second-order) phase transition typically a symmetry of the system is spontaneously broken. For example, below the Curie temperature, a single-domain ferromagnet magnetizes in some specific direction, and the state has a lower symmetry than the rotationally invariant Hamiltonian of an isotropic ferromagnet. Any quantity that appears in a continuous phase transition and characterizes the breaking of the symmetry may be called an order parameter. The macroscopic wave function can be viewed as the order parameter associated with spontaneous breaking of the global phase or *gauge* symmetry of quantum mechanics. Specifically, in quantum mechanics, the state of the system is unchanged if the wave function is multiplied by an arbitrary complex phase factor $e^{i\varphi}$. However, to write the wave function as $\psi(\mathbf{x})$ already implies a preferred phase, and likewise even if the wave function is adorned with random but, for any given condensate, fixed phase, as in $e^{i\varphi} \psi(\mathbf{x})$.

For one condensate the random phase is inconsequential. Suppose, however, that two BECs with the wave functions $e^{i\varphi_1} \psi_1(\mathbf{x})$ and $e^{i\varphi_2} \psi_2(\mathbf{x})$ are combined. If the macroscopic

wave functions behave as wave functions should, the combination of two condensates displays the density $n(\mathbf{x}) = |e^{i\varphi_1}\psi_1(\mathbf{x}) + e^{i\varphi_2}\psi_2(\mathbf{x})|^2$. There should be an interference pattern between the condensates. Two BECs indeed produce an interference pattern when they are combined.

From the quantum optics viewpoint, a condensate is a given number of atoms in a given one-particle state, a number state, and cannot possess any phase at all. This seems to contradict the observations of an interference pattern. The resolution is that the process of measuring the phase difference in itself creates a phase difference, even if there initially was none [10].

80.3.6 Fermions

Static Fermi Gas

Thomas–Fermi approximation

Consider an ideal single-species Fermi gas of trapped atoms. The original Thomas–Fermi approximation (Chap. 21) was formulated for fermions, namely, electrons, and in the present case, it is modified as follows. For the atom density $n(\mathbf{x})$ at position \mathbf{x} , at a low temperature, the corresponding local chemical potential is approximated according to Eq. (80.18) as

$$\epsilon_F(\mathbf{x}) = \frac{\hbar^2 [6\pi^2 n(\mathbf{x})]^{2/3}}{2m}. \quad (80.50)$$

Given the trapping potential $V(\mathbf{x})$, the density of the gas adjusts in such a way that the sum of the external potential energy and the local chemical potential, the Fermi energy, is a constant across the gas,

$$V(\mathbf{x}) + \frac{\hbar^2 [6\pi^2 n(\mathbf{x})]^{2/3}}{2m} = \mu, \quad (80.51)$$

the global chemical potential. One may solve the density for a given chemical potential as

$$n(\mathbf{x}) = \begin{cases} \frac{\sqrt{2}m^{3/2} [\mu - V(\mathbf{x})]^{3/2}}{3\pi^2 \hbar^3}, & V(\mathbf{x}) < \mu; \\ 0, & \text{otherwise.} \end{cases} \quad (80.52)$$

Finally, the integral of the density over all space should equal the atom number, which gives an equation to determine the chemical potential μ .

For a harmonic trap, this program can be carried out exactly, analytically, with the result that

$$\mu = 6^{1/3} N^{1/3} \hbar \bar{\omega}, \quad R = 2^{2/3} 3^{1/3} N^{1/6} \ell, \quad (80.53)$$

$$n(0) = \frac{2\sqrt{N}}{\sqrt{3}\pi^2 \ell^3}.$$

The quantities $\bar{\omega}$, ℓ , R , and $n(0)$ have the same meaning as in the BEC case. The Thomas–Fermi approximation for fermions should be applicable whenever $N \gg 1$.

In a one-component Fermi gas at low temperature, atom–atom interactions are typically negligible for a multitude of reasons. There is no s -wave scattering, and the presence of the Fermi sea tends to suppress repulsive interactions. However, in the case of attractive interactions between two species, the Fermi sea may be thermodynamically unstable; the energy may be lowered by pairing fermions into Cooper pairs. This is the mechanism behind the BCS theory of superconductivity. BCS theory is a mean-field theory and also allows one to describe a superconductor or a fermion superfluid with a wave function.

Excitations in a Fermi Gas

If the interactions do not render a fermion system into a BCS superfluid, the elementary excitations of a degenerate weakly interacting Fermi gas with short-range interactions are basically atom–hole pairs. Both the static Fermi gas and its excitations have been major themes throughout the history of quantum physics, and we will not attempt a more detailed discussion.

80.4 Experimental

80.4.1 Preparing a BEC

In a trapped gas, the density $n(\mathbf{x})$ is self-determined from the atom number N , and the condition for a BEC in an ideal gas is most readily expressed in terms of the total number of atoms as

$$k_B T_c = 0.94 \hbar \bar{\omega} N^{1/3}. \quad (80.54)$$

In practice, at the bottom of the trap, the conditions on temperature and density for a BEC are similar to the conditions for a BEC in a free gas. In the thermodynamic limit, such that $\bar{\omega} \rightarrow 0$, $N \rightarrow \infty$ with $\bar{\omega} N^{1/3}$ held constant, below the critical temperature T_c , the fraction of condensate atoms behaves as a function of temperature T as

$$\frac{n_0}{N} = 1 - \left(\frac{T}{T_c}\right)^3. \quad (80.55)$$

The experimental realizations of alkali vapor condensates are based on techniques of laser cooling and trapping of atoms. The following discussion overlaps with, and is supplemented by, the material in Chap. 79.

A BEC in a dilute atomic gas is typically prepared using a two-stage process. First, a magneto-optical trap is used to capture a sample of cold atoms and to cool it to a temperature of the order of a few tens of microkelvin. The atoms are

then transferred to a magnetic or optical trap for evaporative cooling that leads to condensation.

A magnetic trap is based on a combination of two ideas. First, if an atom that starts out with its magnetic moment antiparallel to the magnetic field moves slowly enough in a position-dependent magnetic field, its magnetic moment remains adiabatically locked antiparallel to the magnetic field. The energy of the atom is then a minimum where the magnetic field is a minimum. Second, the absolute value of the magnetic field may have a minimum in free space. The minimum is then a trap for atoms whose magnetic moments are suitably oriented. The downside is that only atoms in the right magnetic (Zeeman) states are trapped.

While the atoms cool down, they accumulate at the center of the trap. The center should not be a zero of the magnetic field, because at zero field an atom would lose the lock between the directions of the magnetic moment and the magnetic field. In a time-orbiting potential (TOP) trap, a time-dependent magnetic field is added in such a way that the zero of the magnetic field orbits around the center of the trap. If the frequency at which the zero moves is high enough, the atoms see a time-averaged effective potential with a minimum at the center of the trap, and do not dwell around the zero of the magnetic field. Alternatively, it is possible to wind a coil in such a way that it makes a magnetic field whose absolute value has a minimum that is not zero. In this kind of Ioffe–Pritchard trap, the winding of the wire resembles the seams on a US baseball.

It is also possible to condense atoms trapped in a far-off resonant optical trap based on the dipole forces of light, instead of the magnetic trap. For tuning below the resonance, the atoms are strong-field seekers. An arrangement with two crossed laser beams focused to the same spot is typical. With extreme off-resonant light from, say, a CO₂ or a Nd:YAG laser, absorption of photons, and the associated photon recoil kicks and heating, may be negligible. The frequencies of the two beams may be made slightly different by using, for instance, an acousto-optic modulator, whereby a potentially harmful standing-wave pattern averages out. The advantage of a far-off resonant optical trap is that it is not particularly sensitive to the Zeeman state, so that it can hold atoms in many states.

The idea of evaporative cooling is that the most energetic atoms escape from the trap, and then the remaining atoms thermalize to a lower temperature. Some atoms are lost in the process, but with the decreasing temperature, the density at the trap center nonetheless tends to increase, and the phase space density increases even more due to the cooling.

Evaporative cooling is forced by actually or effectively lowering the depth of the trap. For instance, a radio frequency field is applied to the atoms. The transition frequency between the Zeeman states depends on the magnetic field and increases toward the edges of the trap. Atoms are re-

moved where the radio frequency (RF) is on resonance and drives transitions to untrapped Zeeman states. Thus, while the atoms cool and concentrate at the center, the radio frequency is swept down in such a way that the “RF knife” removing the atoms slides in from the edge of the trap. At some point along the evaporation, a condensate abruptly emerges. The temperature can be further lowered by continuing evaporative cooling, albeit at the expense of loss of atoms. A typical time needed to prepare a condensate is on the order of a second, and a condensate may live for tens of seconds in a good vacuum.

80.4.2 Preparing a Degenerate Fermi Gas

A single-species, very low-temperature Fermi gas is usually an uninteresting system, as the Fermi–Dirac statistics forbids *s*-wave interactions between the atoms, and the gas is nearly ideal. In the experiments the gas usually has two or more species, different states of the same atom. The interactions between the species are then comparable in strength to the interactions between bosonic atoms. Evaporative cooling works in a two-species gas and can be used to prepare a degenerate Fermi gas either in an optical or a magnetic trap. One can also use a gas of bosons, and, indeed, a BEC, as a refrigerator. The lowest attainable temperatures with direct cooling are on the order of $0.1 T_F$. In the quest toward lower temperatures, methods have been devised to reduce the entropy of the atoms rather than the energy.

80.4.3 Monitoring Degenerate Gases

Orders of Magnitude

As a rule of thumb, the trapping frequencies in a magnetic trap are $\bar{\omega} \approx 2\pi \times 10$ Hz, while the frequencies in an optical trap may reach into the kHz regime. A typical oscillator length is $\ell \approx 1$ μ m. A usual number of atoms is $N \approx 10^7$. Scattering lengths are of the order of $a \approx 10$ nm. The size of a degenerate gas is in the neighborhood of $R \approx 0.1$ mm, the maximum density is about $n(0) \approx 10^{15}$ cm⁻³, and the BEC transition temperature and the Fermi temperature are of the order of $T_c \approx T_F \approx 1$ μ K. However, much lower temperatures are readily reached in a BEC.

Time-of-Flight Imaging

Usually the observation of a degenerate gas in an experiment is by time-of-flight imaging. The trap is suddenly removed, whereupon the gas expands freely. After the atom cloud has grown to a size large enough compared to the wavelength of the resonant light used to monitor the gas, an absorption image of the cloud is taken. This gives the projection of the density of the gas onto a plane perpendicular to the direction

of propagation of the imaging light. Except for the effects of atom–atom interactions, after a sufficiently long time of free flight the density reflects the initial momentum distribution of the atoms. Time-of-flight images bear the signs of both condensation in a Bose gas and quantum degeneracy in a Fermi gas. Nontrivially, other features of interest such as vortex cores are also preserved and can be detected after the free expansion. The downside is that the time-of-flight method is destructive. After each snapshot, the sample will have to be prepared again.

80.5 BEC Superfluid

80.5.1 Vortices

Flow Velocity in a Superfluid

By manipulating the Heisenberg equations of motion for a Bose field under the Hamiltonian Eq. (80.22) it is easy to derive the equation of continuity for the atoms,

$$\frac{\partial}{\partial t} \hat{n} + \nabla \cdot \hat{\mathbf{j}} = 0, \quad (80.56)$$

$$\hat{n} = \hat{\psi}^\dagger \hat{\psi}, \quad \hat{\mathbf{j}} = i \frac{\hbar}{2m} (\hat{\psi} \nabla \hat{\psi}^\dagger - \hat{\psi}^\dagger \nabla \hat{\psi}). \quad (80.57)$$

This identifies \hat{n} and $\hat{\mathbf{j}}$ as the operators for atom density and atom current density. The corresponding mean-field quantities are again obtained when the boson fields are replaced with the corresponding classical fields. Writing the classical field in terms of the density $n(\mathbf{x}, t)$ and phase $\varphi(\mathbf{x}, t)$ in the form

$$\psi = \sqrt{n} e^{i\varphi}, \quad (80.58)$$

the local flow velocity $\mathbf{v} = \mathbf{j}/n$ becomes

$$\mathbf{v} = \frac{\hbar}{m} \nabla \varphi. \quad (80.59)$$

The velocity field is irrotational.

Quantization of Circulation

Integration of the flow velocity around an arbitrary loop gives

$$\oint d\mathbf{l} \cdot \mathbf{v} = \frac{\hbar}{m} \Delta\varphi = p \frac{2\pi\hbar}{m}, \quad (80.60)$$

$$p = 0, \pm 1, \pm 2, \dots,$$

since the change of the phase $\Delta\varphi$ around a closed loop must be an integer multiple of 2π . Equation (80.60) expresses the quantization of circulation in a superfluid. A medium described by a macroscopic wave function, such as a BEC, cannot sustain arbitrary flow velocities.

Vortices

As an example, in a fluid rotating as a whole at the angular velocity Ω , the line integral around a loop at the distance r from the axis of rotation would be $2\pi r^2 \Omega$, which is not permitted for an arbitrary r . Instead, upon an attempt to make a BEC rotate, the angular velocity will be carried by vortex lines. These are lines through the condensate, entering and exiting at the surface, such that each vortex carries a quantum of circulation. At the core of a vortex, the flow velocity should be infinite to sustain a finite circulation, which is physically impossible. Nature solves this problem by making the vortex core normal (not BEC), so that the macroscopic wave function does not apply. The diameter of the vortex core is of the order of the healing length ξ , given by Eq. (80.29).

When the trapping potential on the atoms is rotated, it is convenient to study the physics in the corotating frame. Given a frame rotating at the angular velocity Ω and the angular momentum operator $\mathbf{L} = \mathbf{x} \times \mathbf{p}$ per particle, transformation to the rotating frame adds the one-particle term

$$H_r = -\Omega \cdot \mathbf{L} \quad (80.61)$$

to the Hamiltonian. Any particular configuration of vortices is a thermodynamically stable equilibrium if it is the minimum of energy in the corotating frame. For a trapped condensate, at zero rotation velocity the state without vortices is the energy minimum, and increasing the rotation speed makes states with an increasing number of vortices the stable configuration. However, a vortex configuration may be metastable and live for a long time even if it is not the minimum of energy. Conversely, even the energy-minimum configuration of vortices must first be nucleated. Since the circulation can only have quantized values, it cannot change in a continuous process. It takes a zero condensate density somewhere to create or destroy a vortex.

These alternatives provide a large number of experimental scenarios involving rotation of the trap or stirring of the condensate, condensation of a rotating normal gas by taking it across the transition temperature, and so forth. For instance, when a trap containing a BEC is rotated, vortices are generated at the surface where they start their lives as dynamical instabilities. The vortices then drift in and form a regular vortex array. When the rotation is halted, the vortices drift out to the surface and disappear.

80.5.2 Superfluidity

A BEC also has the remarkable property that it may sustain persistent currents that are completely immune to viscosity. The qualitative reason may be seen from the dispersion relation of small excitations Eq. (80.38). As long as the flow

speed $|v|$ is less than the speed of sound c , all excitation energies are positive, so that the flowing state is the state of lowest energy and is thermodynamically stable. On the other hand, when the flow velocity exceeds the speed of sound, the system has excitations that lower the energy, $v(\mathbf{q}) < 0$ for some \mathbf{q} . The flowing state is then not a minimum of energy. The flow is not thermodynamically stable, and it decays when it interacts with an environment by sending off small excitations. The speed of sound gives the Landau critical velocity for superfluidity.

The critical velocity c tends to zero when the atom–atom interactions vanish with $a \rightarrow 0$. While the condensate wave function may be written down whether or not the atoms interact, superfluidity and persistent flows rely on the interactions. The same applies to vortices, as in the limit of a noninteracting gas the healing length and the radius of the vortex core tend to infinity.

The conventional picture is that superfluid flow in an inhomogeneous medium is thermodynamically unstable if the local flow velocity somewhere exceeds the local (density-dependent) speed of sound. In practice, in liquid He experiments and numerical simulations of dilute condensates, the supercurrent often dissipates by shedding vortices when it flows past an obstacle. Persistent flow in a toroidal geometry would be an ideal test case for superfluidity, and such experiments have, in fact, been carried out with dilute atomic condensates [11]. Nonetheless, no clear picture of the quantitative limits to the flow velocity of a superfluid has emerged from these experiments.

80.6 Optical Lattice as Quantum Simulator

Lattice models have been, and are, widely studied in condensed-matter physics. Even though they may look deceptively simple, quantum systems with interactions between the particles usually cannot be solved exactly even with massive numerical computations. Certain static properties of bosonic systems are accessible to quantum Monte Carlo methods even in fairly large models, but less so for fermions because of the notorious “sign problem” [12]; and exact numerical solutions of time dependence in, say, boson lattice models are restricted to the scale of about ten sites with ten particles. The thermodynamic limit of a strongly interacting system is typically addressed with in-principle uncontrolled approximations, such as a judicious mean-field theory.

However, progress in AMO physics has given us materially flawless optical lattices to hold the atoms, lattice parameters may be controlled by varying the parameters of the lattice lasers, and even the strength of the atom–atom interactions may be tuned using Feshbach resonances. In addition, it is possible to monitor the atoms with single-site resolution. In most experiments, the optical lattice is raised

adiabatically in a cold gas and captures atoms without undue heating of the CM motion, but with a random number of atoms at random lattice sites. Nevertheless, loading of the desired initial configuration atom by atom has also been demonstrated [13]. Such developments have lent credence to the idea of using an optical lattice system as a quantum simulator [5, 6, 14]—basically as an analog quantum computer.

80.6.1 Basics of the Optical Lattice

Dipole forces of standing-wave fields of light generate a periodic potential, an optical lattice, on the atoms [15]. If the light is detuned far enough from atomic resonances, absorption and spontaneous emission are negligible, and the potential is conservative. In one dimension, the prototypical potential energy for the motion of the atoms is of the form

$$V(x) = V_0 \sin^2 kx, \quad (80.62)$$

where k is the wave number of the lattice light, and the depth of the lattice V_0 can be inferred from the known parameters of the atoms and the light as explained in Chap. 79.2.2. With multiple laser beams propagating in different directions and having different polarizations, a wide variety of 2-D and 3-D optical lattices may be set up analogously.

As is usual with periodic potentials, the one-particle energy eigenstates are characterized by a quasimomentum or lattice momentum \mathbf{q} , and group into bands λ typically separated by bandgaps. In an experimental technique called band mapping, the lattice potential is adiabatically removed, whereupon such Bloch states get converted into eigenstates of ordinary momentum. Upon further free evolution, momenta get mapped into observable positions of the atoms. In this way, the distribution of the atoms among the quasimomenta and bands may be determined.

Bose–Hubbard Model

Consider as an example a 1-D optical lattice that holds spin-0 atoms, with the sites labeled by an integer n . The simplified Hamiltonian, the Bose–Hubbard model, reads

$$\frac{\hat{H}}{\hbar} = \frac{1}{2} \sum_n \left[-J (a_{n+1}^\dagger a_n + a_{n-1}^\dagger a_n) + U a_n^\dagger a_n^\dagger a_n a_n \right]. \quad (80.63)$$

The operator a_n annihilates and the operator a_n^\dagger creates an atom at the site n , so the terms $\propto J$ describe tunneling of the bosons from a site to a neighboring site. The term $\propto U$ models the interactions of the atoms that are in the same site. Boundary conditions ordinarily matter little for a long lattice; for convenience, we assume periodic boundary conditions for a lattice with L sites, so that the sites n and $n + L$ are

regarded as the same. This case could be physically realized by making a 1-D ring lattice.

The key consideration in the physics of the Bose–Hubbard model is the competition between tunneling $\propto J$ and atom–atom interactions $\propto U$.

Tuning of the Parameters

Without the interactions, the model Eq. (80.63) corresponds to the tight-binding approximation to the band structure of a 1-D solid, with the energies in the single Bloch band ranging from $-\hbar J$ to $\hbar J$. The wave functions of the states annihilated by a_n are the corresponding Wannier states $\phi_n(x)$. We use vector notation for the position since in reality the lattice is confined in the transverse directions, making a wave function in 3-D, and the atom–atom interactions depend on the volume density of the atoms anyway. For the standard contact interaction Eq. (80.21) characterized by the scattering length a , we have

$$U = \frac{4\pi\hbar a}{m} \int d^3x |\phi_n(x)|^4. \quad (80.64)$$

On the other hand, the exact band structure for the potential energy Eq. (80.62) of an optical lattice comes from the Mathieu equation. A comparison of the width of the first band with the tight-binding approximation gives the estimate

$$J = \frac{8}{\sqrt{\pi}} \frac{E_r}{\hbar} \left(\frac{V_0}{E_r} \right)^{3/4} \exp\left(-2\sqrt{\frac{V_0}{E_r}}\right), \quad (80.65)$$

where E_r is the photon recoil energy, and we assume that $V_0 \gtrsim E_r$. Since the depth of the optical lattice V_0 is proportional to the intensity of the lattice light and the tunneling amplitude J depends strongly on V_0 , J may be varied over a wide range by changing the intensity of the lattice light.

Near a Feshbach resonance at the magnetic field B_0 , the scattering length varies with the magnetic field applied to the atoms, B , as

$$a = a_0 \left(1 - \frac{\Delta B}{B - B_0} \right), \quad (80.66)$$

where a_0 , B_0 , and ΔB are constants depending on the atomic species and the Feshbach resonance in question. Under favorable conditions, it may be possible to vary the scattering length over a wide range, and even to change its sign, by varying the magnetic field applied to the atoms.

Discrete Nonlinear Schrödinger Equation

The mean-field counterpart of the Bose–Hubbard model is found in the usual way, by positing that in the Heisenberg equations of motion the operators a_n are no longer boson operators but instead complex numbers α_n . Furthermore, we

scale these numbers so that the average of $|\alpha_n|^2$ over the lattice equals 1, which brings in the average site occupation $\bar{n} = N/L$ for a total of N bosons in a lattice of length L . The result, an analog of the GPE,

$$\frac{d}{dt}\alpha_n = -\frac{1}{2}J(\alpha_{n+1} + \alpha_{n-1}) + \bar{n}U|\alpha_n|^2\alpha_n, \quad (80.67)$$

is often called the discrete nonlinear Schrödinger equation (DNLS).

DNLS has interesting properties of its own. For instance, for attractive ($a < 0$) atom–atom interactions, it may have solutions called gap solitons, clusters of atoms that propagate along the lattice (or stand still) while retaining their shape. They are “gap solitons” because formally their energies are outside of the energies of the Bloch bands, i.e., in the bandgaps.

80.6.2 Strongly Correlated Systems

Superfluid–Mott Insulator Transition

In generic terms, a many-body system that cannot be adequately described by a mean-field theory is called strongly correlated. In particular, the mean-field version of the Bose–Hubbard model Eq. (80.67) misses an essential piece of physics that emerges when the interactions become sufficiently strong. When tunneling dominates, the system is in what is referred to as the superfluid phase. Fluctuations of the atom number between the sites are relatively large. On the other hand, if atom–atom interactions dominate, fluctuations in atom number become costly in energy; a configuration with zero atoms in one site and two in the next site has a much higher energy than a configuration with one atom in both sites. The same number of atoms in each site corresponds to the Mott insulator phase. According to calculations carried out using the so-called Gutzwiller ansatz, the ground state of an optical lattice inserted in an atom trap then consists of regions with the same integer number of atoms at the lattice sites within each region [16]. When the parameters of the system are varied, in what is known as a quantum phase transition [17] the system should abruptly switch between the phases.

This superfluid–Mott insulator transition has been observed experimentally [18]. The observation of the transition is by means of phase coherence. In the superfluid phase, the system is characterized by a global macroscopic wave function. When the atoms are abruptly released from the lattice, atoms originating from different sites are capable of interference, and the interference pattern reflects the lattice structure. On the other hand, in the Mott insulator phase, the lattice sites are in number states with little phase coherence between them, and there is no interference pattern.

Quantum Gas Microscope

The superfluid–Mott insulator transition has established optical lattices as viable simulators of lattice models and has inspired much current following [5, 6, 14]. As an example of the ongoing technical advances, we describe cursorily the quantum gas microscope [19]. This is literally a microscope, one with an objective lens that has a very large (effectively 0.8) numerical aperture. This entails resolution close to a wavelength. The microscope views a 2-D lattice of the atoms. However, in this particular experiment, the lattice is not produced by added standing waves but by imaging a judiciously designed mask backwards through the objective to the plane of the atoms. The lattice is turned on slowly and collects cold atoms from a suitable trap. The physics experiment then commences.

After the experiment, the lattice is switched much deeper. It then confines the atoms to its individual potential wells, and facilitates a measurement of the number of the atoms at each lattice site; or at least the parity of the atom numbers, since the trapped atoms experience pairwise laser-assisted exothermic collisions and are lost from the trap until only one or zero atoms per site remains. Laser beams forming an optical molasses illuminate the atoms, and the atoms fluoresce. The deep confinement and a tuning of the laser conducive to cooling eliminate heating from photon recoil kicks, so that the atoms stay in place and send out a number of fluorescence photons. This improves the signal-to-noise ratio to the extent that an individual atom can be detected at the resolution of a single lattice site. Not only atom density, but also position correlations of the atoms can be recorded for comparison with theory. By making use of resonance spectroscopy, the spins of the atoms and the correlations of the spins between the sites may also be determined.

Phase Diagrams in Lattice Systems

There is, for all practical purposes, an infinity of lattice systems to study: different lattice structures; bosons versus fermions, various spins, real, or simulated with internal states of the atoms; short-range on-site interactions versus long-range coupling of the spins via magnetic or (for polar molecules) electric dipole interactions; and so on. A number of implementations relying on AMO techniques have been considered and are being considered. In the tradition of condensed-matter physics, the goal is to find the phases and phase diagrams; either to compare with existing theoretical arguments, or to discover new phases experimentally. We will say nothing further about this kind of work.

Time Dependence

As was mentioned already, time dependence in large, strongly interacting many-body quantum systems usually overwhelms the theoretical tools that we have available today, including exact numerical computations. Quench ex-

periments, in which a steady-state system is suddenly altered and then let evolve, have the potential to deliver reliable results not available in any other way.

The broad experience in physics is that, when left alone, a large system thermalizes and can then be described by statistical mechanics, at least to the extent permitted by the conserved quantities. The issue is, does this always happen, and how; especially in isolated systems when it is not possible to appeal to the interactions with the environment as the cause of the thermalization. Time evolution in well-controlled lattice systems [20] is an enterprise with potential for breakthroughs in our understanding of the foundations of statistical mechanics.

80.6.3 Topological Phases of Matter

As another current line of development, also a spin-off from condensed-matter physics, we discuss topological band structures and topological phases of matter [14, 21].

Phase of Tunneling in a Lattice

Consider as a preparatory example a static magnetic field acting on a charged free particle. In the minimum coupling substitution, the Hamiltonian reads

$$H = \frac{1}{2m} [\hat{p} - q\mathbf{A}(\mathbf{x})]^2. \quad (80.68)$$

If there actually is no magnetic field so that the vector potential satisfies $\mathbf{B} = \nabla \times \mathbf{A} = 0$, the vector potential may be “gauged away” with the canonical transformation

$$\psi(\mathbf{x}) \rightarrow \tilde{\psi}(\mathbf{x}) = \exp \left[\frac{iq}{\hbar} \int_{\mathbf{x}_0}^{\mathbf{x}} d\mathbf{l} \cdot \mathbf{A} \right] \psi(\mathbf{x}), \quad (80.69)$$

where \mathbf{x}_0 is an arbitrary reference point. With $\nabla \times \mathbf{A} = 0$, the integral is independent of the path. In particular, the integral vanishes over any closed path.

In contrast, if a magnetic field is present, the integral depends on the path, and the canonical transformation as written in Eq. (80.69) is ill defined. The integral becomes a phase factor $e^{i\Phi}$, where the phase $\Phi(P, \mathbf{x}_0, \mathbf{x})$ depends on the path P . If a wave packet ψ is split at \mathbf{x}_0 and the components are sent along two different paths to recombine at \mathbf{x} , they will have a phase difference modifying the interference

$$\Delta\Phi = \frac{q}{\hbar} \int_S d\Omega \cdot \mathbf{B} \quad (80.70)$$

proportional to the magnetic flux through an arbitrary surface S with the paths of the two wave packets as its edge. This is how the Aharonov–Bohm effect comes about.

By making use of the interplay between internal and CM degrees of freedom of an atom, it is possible to realize a Hamiltonian of the form Eq. (80.68) also for a neutral atom whose CM motion does not directly couple to electromagnetic fields, and even with $\nabla \times \mathbf{A} \neq 0$. This is the idea of synthetic gauge fields [22].

Suppose now that in a 1-D lattice, there is a change of phase φ of the wave function when an atom tunnels from site n to the site $n + 1$. The counterpart of the Bose–Hubbard model would be

$$\frac{\hat{H}}{\hbar} = \frac{1}{2} \sum_n \left[-J (e^{i\varphi} a_{n+1}^\dagger a_n + e^{-i\varphi} a_{n-1}^\dagger a_n) + U a_n^\dagger a_n^\dagger a_n a_n \right]. \quad (80.71)$$

A priori such a phase change is inconsequential, as one can remove it by redefining the inconsequential phases of the states corresponding to an atom at different sites n . However, if it is possible to have a closed loop among the lattice sites and the phase changes do not add up to an integer multiple of 2π along the way, the phases φ cannot be gauged away in this way. This could happen in a 1-D ring lattice. Among the consequences is a nontrivial ground state in which the atoms flow around the ring.

Here, the emphasis is on 2-D lattice systems. It could correspondingly happen, for instance, that in a square lattice the phase changes in a loop around a plaquette of the four atoms at the corners of a unit cell add up to something other than 0 or another integer multiple of 2π .

A phase change in tunneling can be engineered by having external light drive a transition between the sites, instead of the ordinary tunneling. This is because the phase of the light gets imprinted on the transition. In practice, complicated arrangements are needed [23, 24] to effect a nontrivial accumulation of phase around a closed loop, for one thing because the phase changes of a laser field itself add up to zero around a closed loop; but it has been achieved experimentally. Modulation of the lattice potential, e.g., by shaking the lattice, is another approach to the same effect [25, 26]. We do not go into the details of either type of idea, but stipulate that an effective magnetic field with a nontrivial phase accumulation can be achieved. The effective magnetic field can be enormous compared to the real magnetic fields that can be reached in a laboratory.

Topological Band Structure

As an example, we briefly consider a recent experiment [24]. The starting point here is (conceptually) a square lattice with a lattice constant a in the xy plane. The reciprocal lattice is also square, with the lattice constant $2\pi/a$, and so is the first Brillouin zone that contains the values of the lattice momenta \mathbf{q} for the lowest energy band. By using optical fields, an accumulated phase $\Delta\Phi = \pi/2$ is put in each loop around

a four-site plaquette. This means that the translation that leaves the lattice unchanged is not a , but $2a$. Since the unit cell has become two times as big, the Brillouin zone is half the size, and 1/4 in area. The result is that the original lowest band splits into (in principle) four energy bands.

Moreover, as a result of the accumulated phases, the topology of these bands may be nontrivial. The topology is characterized by an invariant called the Chern number. Suppose one first solves for the one-body Bloch states in an energy band, $u(q_x, q_y)$, and forms the Berry curvature

$$\Omega = i(\langle \partial_{q_x} u | \partial_{q_y} u \rangle - \langle \partial_{q_y} u | \partial_{q_x} u \rangle), \quad (80.72)$$

then the Chern number is computed as an integral over the first Brillouin zone,

$$C = \frac{1}{2\pi} \int \Omega d^2q. \quad (80.73)$$

The value would be zero for a topologically trivial band, while in the experiments actually three bands are found (one with twice as many states as the other two) with the Chern numbers 1, -2 , and 1.

It is not possible to modify the Hamiltonian continuously in such a way that the Chern number suddenly changes between integer values unless “something drastic” happens along the way. In this case, the drastic event is that the gap between bands closes. In the experiments, there is an auxiliary control variable to take the system across such a topological phase transition.

One way of detecting the Chern number is to apply a force that moves the atoms. As one might expect from the analogy between the engineered phases and a magnetic field, in an analog of the Hall effect, the atoms get translated also in the direction perpendicular to the applied force. This translation may be measured and is proportional to the Chern number (under the particular experimental conditions), which gives a measurement of the latter.

Significance of Topology

The circulation of a superfluid around the core of a vortex is a topological property, characterized by discrete values. A vortex is, therefore, resilient; it vanishes if the density of the superfluid vanishes, but small perturbations will not change its circulation. The same applies to the Chern number, which will not change unless the perturbations of the lattice are so drastic that a bandgap closes. The integer quantum Hall effect with a precisely determined quantized value of the Hall conductance occurs because the Hall conductance is equal to the product of a Chern number and a combination of natural constants [21].

In practice, there is no such thing as an infinite lattice. A finite 2-D lattice with a topologically nontrivial band structure is believed to have chiral edge modes. They are localized

at the edges of the lattice, are chiral in that the atoms propagate in one direction around the lattice only (in analogy with cyclotron motion), and are topologically protected, i.e., their character does not change in small perturbations of the lattice or of the edge.

From the AMO perspective, the long-term goal is to use topologically protected variables, hopefully insensitive to decoherence, for quantum computations.

Abstract

De Broglie optics concerns the propagation of quantum mechanical particle waves, their reflection, refraction, diffraction, and interference. The basic principles of De Broglie optics, which are quite similar to the principles of ordinary light optics, do not depend much on the specific nature of the sort of particles under consideration – electron, neutron, atom, ion, or molecule, but the focus in this chapter is on the De Broglie optics of atoms and molecules. This sort of particle comes with a variety of internal degrees of freedom, which are easily addressed and manipulated with electromagnetic fields, in particular laser fields, and thereby allow for quite a broad spectrum of different applications in lithography, imaging, and precision measurement.

Keywords

atomic beam · matter wave · Fresnel zone plate · Sagnac effect · atom optics

81.1 Wave-Particle Duality

The wave-particle duality of quantum mechanics states that freely traveling material particles of mass M and momentum p are properly described by a plane wave of wavelength $\lambda_{\text{dB}} = 2\pi\hbar/p$, named in honor of Prince Victor Louis De Broglie, and frequency $\omega = \hbar k^2/(2M)$, with k the wavenumber $k = 2\pi/\lambda_{\text{dB}}$.

Originally meant to account for the orbitals of a Coulomb-bound electron, the ultimate wave character of particles has meanwhile been confirmed for all fundamental particles, but also for the center-of-mass (CM) motion of composite particles like ions, atoms, and even large molecules. These waves have been dubbed matter waves, although they do not encode

a density variation or the like, but rather a probability amplitude for the center-of-mass degree of freedom of the particle under consideration.

The optics of matter waves comprises, among others, electron optics and electron microscopy [1], electron holography [2], neutron optics and neutron imaging [3], in particular neutron interferometry [4], and atom optics [5].

Being strongly driven by the progress of laser cooling – see Chap. 79 on cooling and trapping – but also nanofabrication, the subject of atom optics is relatively new, and applications are currently being developed in atom interferometry [6], atom lithography, [7] and atom imaging [8]. These days, the wave character of particles has been confirmed for molecules with more than 430 atoms [9], and atom optics is promoted as a competitive method for the determination of the gravitational redshift [10], a particle’s proper time [11], Newton gravitational constant [12], gravimetry [13], inertial sensing [14], and even the exploration of possible manifestations of dark energy [15]. Interference experiments with atoms and molecules have been suggested to explore the boundaries between quantum and classical mechanics [16, 17]. In this domain, processes called decoherence or localization are expected to change the behavior of particles; quantal features like superpositions and particle-wave duality are fading out, and the particles start to behave as expected from classical kinetic theory [18].

In terms of the Bohr radius a_0 , the fine-structure constant α , and the electron mass m_e ,

$$\lambda_{\text{dB}} = \frac{2\pi\alpha a_0}{(v/c)(M/m_e)} = 2\pi \left(\frac{E_h m_e}{2\mathcal{T} M} \right)^{1/2} a_0, \quad (81.1)$$

where $v = p/M$ is the velocity, $\mathcal{T} = (1/2)Mv^2$ is the kinetic energy, and E_h is the atomic unit of energy (Table 1.4 of Sect. 1.2). For electrons, $\lambda_{\text{dB}} \approx 1.226426 \text{ nm}/(\mathcal{T}/\text{eV})^{1/2}$.

For thermal samples, the mean kinetic energy is of the order of $k_B T$, and, thus, the mean momentum scales $\propto \sqrt{T}$, and Eq. (81.1) is replaced by the thermal De Broglie wavelength, which is defined in Eq. (81.76). In terms of the atomic mass unit u : $\lambda_{\text{th}} = 1.74(5) \text{ nm} (M/u)^{-1/2} (T/\text{K})^{-1/2}$. At room temperature, the thermal De Broglie wavelength of atomic samples is sub-Å, but for temperatures on the micro or nano-Kelvin scale, even in dilute samples the wavelength may well exceed the mean interparticle spacing, in which case, the quantum statistical effects of indistinguishability become manifest – see Chap. 80 on quantum degenerate gases.

However, even in the nondegenerate regime, the physics of de Broglie waves differs from that of light waves in a number of regards. First, the dispersion relation of free particles is quadratic in the wavenumber, giving rise to spatial spreading of wave packets even in one-dimensional configurations. Second, particles may be brought to rest, which is impos-

sible for photons. Finally, particles in beams are subject to pair interactions, giving rise to nonlinear optical phenomena. Electrons and ions, for example, experience a particle density-dependent Coulomb broadening in the focus of a lens (Boersch effect [2]). Similarly, atoms or molecules interact via short range interparticle van der Waals forces, giving rise to density-dependent nonlinear effects, see Sect. 81.2.4 “Atom Optical Nonlinearity”, below.

81.2 The Hamiltonian of de Broglie Optics

A typical de Broglie optical experiment involves a source, a beam of particles produced by that source, an array of optical elements, possibly a probe, other optical elements placed behind the probe, and, finally, a detector. Optical elements are collimators, apertures, lenses, mirrors, and beam splitters. A probe could be a crystal, a biological sample, or just another unknown optical element whose properties are to be investigated. To avoid proliferation of notation, we refer to any object placed in the beam path simply as an *optical element*.

Here, we shall assume that the particles are far from quantum degeneracy, and the effects of particle interactions can safely be ignored. A large class of optical elements is then well described by a Hamiltonian model in which the ensemble of particles is described by a wave function $\psi(\mathbf{x}, t) = \langle \mathbf{x} | \psi(t) \rangle$ whose time evolution is governed by the Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = H(t) |\psi(t)\rangle, \quad (81.2)$$

with a one-particle Hamiltonian of the generic form

$$H(t) = \frac{[\hat{\mathbf{p}} - \mathcal{A}(\hat{\mathbf{x}}, t)]^2}{2M} + \mathcal{U}(\hat{\mathbf{x}}, t). \quad (81.3)$$

Here, $\hat{\mathbf{p}}$ and $\hat{\mathbf{x}}$ denote the canonically conjugate operators of the center of mass momentum and position, respectively. The Cartesian components of $\hat{\mathbf{p}}$ and $\hat{\mathbf{x}}$ obey the fundamental commutation relation

$$[\hat{x}_i, \hat{p}_j] = i\hbar \delta_{ij}. \quad (81.4)$$

The vector potential $\mathcal{A}(\mathbf{x}, t)$ and scalar potential energy $\mathcal{U}(\mathbf{x}, t)$ account for the interaction of the particle with all the optical elements, probes, and samples that are placed between the source and the detector, including the effects of gravitation and rotation.

81.2.1 Gravitation and Rotation

All particles are subject to the influence of gravitation and rotation, which may both be viewed as being special cases

of an accelerated frame of reference. The effects of uniform gravitation are described by

$$\mathcal{U}(\mathbf{x}) = -M \mathbf{g} \cdot \mathbf{x}, \quad \mathcal{A}(\mathbf{x}) = 0, \quad (81.5)$$

where \mathbf{g} describes the direction and magnitude of gravitational acceleration. The effects of uniform rotation are described by

$$\mathcal{U}(\mathbf{x}) = -\frac{M}{2}(\boldsymbol{\Omega} \times \mathbf{x})^2, \quad \mathcal{A}(\mathbf{x}) = M(\boldsymbol{\Omega} \times \mathbf{x}), \quad (81.6)$$

where the direction and magnitude of $\boldsymbol{\Omega}$ refer to the orientation of the axis of rotation and the angular velocity, respectively. Here, $\mathcal{U}(\mathbf{x})$ is the potential of the centrifugal force, while $\mathcal{A}(\mathbf{x})$ is the potential of the Coriolis force.

81.2.2 Charged Particles

The interaction of charged particles (electrons, ions) with the electromagnetic field is described by

$$\mathcal{U}(\mathbf{x}, t) = q\Phi(\mathbf{x}, t), \quad \mathcal{A}(\mathbf{x}, t) = qA(\mathbf{x}, t), \quad (81.7)$$

where q is the particle charge ($q = -e$ for electrons), and A and Φ denote the gauge potentials of the electric field strength \mathbf{E} and magnetic induction \mathbf{B} , respectively,

$$\mathbf{E}(\mathbf{x}, t) = -\frac{\partial}{\partial t}A(\mathbf{x}, t) - \nabla\Phi(\mathbf{x}, t), \quad (81.8)$$

$$\mathbf{B}(\mathbf{x}, t) = \nabla \times A(\mathbf{x}, t). \quad (81.9)$$

The quantum mechanics of charged particles is invariant under a gauge transformation $A \mapsto A' = A + \nabla\chi$, $\Phi \mapsto \Phi' = \Phi - \dot{\chi}$ combined with a local phase transformation of the wave function, $\psi \mapsto \psi' = e^{iq\chi/\hbar}\psi$. In particular, all measurable quantities in the De Broglie optics of charged particles, including the phase shift in the Aharonov–Bohm effect, are independent of the gauge – see Sect. 81.6.1 “Aharonov–Bohm Effect” below.

81.2.3 Magnetic Moments

The interaction of a magnetic dipole moment $\hat{\boldsymbol{\mu}}$ with the electromagnetic field is described by

$$\begin{aligned} \hat{\mathcal{U}}(\mathbf{x}, t) &= -\hat{\boldsymbol{\mu}} \cdot \mathbf{B}(\mathbf{x}, t), \\ \hat{\mathcal{A}}(\mathbf{x}, t) &= \frac{\hat{\boldsymbol{\mu}} \times \mathbf{E}(\mathbf{x}, t)}{c^2}. \end{aligned} \quad (81.10)$$

Here, the vector potential is due to the motional correction of the magnetic dipole interaction. Usually, it is neglected. However, it does play an important role for the Aharonov–Casher effect (Sect. 81.6.1).

81.2.4 Atoms

Many optical elements in atom optics are based on the mechanical effects of the radiation interaction. In the electric dipole approximation, the interaction of a single atom with the electromagnetic field is described by

$$\begin{aligned} \hat{\mathcal{U}}(\mathbf{x}, t) &= -\hat{\mathbf{d}} \cdot \mathbf{E}(\mathbf{x}, t), \\ \hat{\mathcal{A}}(\mathbf{x}, t) &= \mathbf{B}(\mathbf{x}, t) \times \hat{\mathbf{d}}, \end{aligned} \quad (81.11)$$

where $\hat{\mathbf{d}}$ is the operator of electric dipole transition. The vector potential $\hat{\mathcal{A}}$ is due to the motional correction of the electric dipole interaction. Usually it is neglected; see however, the paragraph “Electric dipole phase” in Sect. 81.6.1.

For a monochromatic field of frequency ω

$$\mathbf{E}(\mathbf{x}, t) = \mathbf{E}^{(+)}(\mathbf{x})e^{-i\omega t} + \text{h.c.}, \quad (81.12)$$

where $\mathbf{E}^{(+)}(\mathbf{x})$ defines both polarization and spatial characteristics of the field. A standing-wave laser field with optical axis in the x -direction and linear polarization $\boldsymbol{\epsilon}$, for example, is described by

$$\mathbf{E}^{(+)}(\mathbf{x}) = \boldsymbol{\epsilon} \mathcal{E}_0 f(x, y, z) \cos(kx), \quad (81.13)$$

where \mathcal{E}_0 is the electric field amplitude, $k = \omega/c$ is the wavenumber, and the slowly varying function $f(x, y, z)$ accounts for the transverse profile of the laser field.

Essential state approximation

The electric dipole operator $\hat{\mathbf{d}}$ acts in the Hilbert space of electronic states of the atom. In the particular case that the polarization of the laser field is spatially uniform and that spontaneous emission does not play a role, two states are generally sufficient, and the atom may be modeled by a two-level atom with electronic levels $|e\rangle$ and $|g\rangle$ of energy E_e and E_g , respectively ($E_e > E_g$). With the pseudo-spin representation

$$|e\rangle \mapsto \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad |g\rangle \mapsto \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad (81.14)$$

the electric dipole operator assumes the form

$$\hat{\mathbf{d}} \mapsto d \boldsymbol{\epsilon}_d \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad (81.15)$$

where d is the matrix element of the dipole transition, and $\boldsymbol{\epsilon}_d$ denotes its polarization. The prefix “pseudo” of a pseudo spinor indicates that it does not transform in the spin-(1/2) representation of the physical rotation group.

The laser field is assumed to be near resonant with the $e \leftrightarrow g$ transition at $\omega_0 = (E_e - E_g)/\hbar$, and we denote by

$\Delta \equiv \omega_0 - \omega$ the atom-laser detuning. Using the rotating-wave approximation (Sect. 72.3.2) in an interaction picture with respect to the laser frequency, the Hamiltonian describing the atomic dynamics – both internal and center-of-mass – is given by

$$H = \frac{\hat{\mathbf{p}}^2}{2M} - \frac{\hbar}{2} \begin{pmatrix} -\Delta & \Omega_1(\hat{\mathbf{x}}) \\ \Omega_1^\dagger(\hat{\mathbf{x}}) & \Delta \end{pmatrix}, \quad (81.16)$$

where

$$\Omega_1(\mathbf{x}) = \frac{2d \boldsymbol{\epsilon}_d \cdot \mathbf{E}^{(+)}(\mathbf{x})}{\hbar} \quad (81.17)$$

is the spatially dependent bare Rabi frequency. In the field Eq. (81.13), $\Omega_1(\mathbf{x})$ is cosinusoidal with peak value $\Omega_0 = 2d\mathcal{E}_0/\hbar$.

The Hamiltonian Eq. (81.16) may be written in the form

$$H = \frac{\hat{\mathbf{p}}^2}{2M} + \frac{\hbar}{2} \boldsymbol{\Omega}(\hat{\mathbf{x}}) \cdot \hat{\boldsymbol{\sigma}}, \quad (81.18)$$

where $\hat{\boldsymbol{\sigma}}$ is the vector of Pauli matrices and

$$\boldsymbol{\Omega}(\mathbf{x}) = (-\text{Re}[\Omega_1(\mathbf{x})], \text{Im}[\Omega_1(\mathbf{x})], \Delta). \quad (81.19)$$

As it stands, the Hamiltonian Eq. (81.18) describes the precession and center-of-mass motion of the *atomic pseudo spin* in an external *fictitious magnetic field* $\boldsymbol{\Omega}(\mathbf{x})$ [Eq. (81.10)]. Spatial variations of this field give rise to the atom-optical Stern–Gerlach effect, i.e., the splitting of the atomic center of mass wave function (Sect. 81.5.3).

Adiabatic approximation

In the position representation, the Hamiltonian Eq. (81.16) acts on state vectors of the form of a pseudo spinor

$$\Psi(\mathbf{x}, t) = \begin{pmatrix} \psi_e(\mathbf{x}, t) \\ \psi_g(\mathbf{x}, t) \end{pmatrix}. \quad (81.20)$$

Alternatively, this state vector may be expanded in terms of the local eigenvectors $\alpha_\pm(\mathbf{x})$, $\beta_\pm(\mathbf{x})$ of the interaction matrix, also called dressed states,

$$\Psi(\mathbf{x}, t) = \psi_+(\mathbf{x}, t) \begin{pmatrix} \alpha_+(\mathbf{x}) \\ \beta_+(\mathbf{x}) \end{pmatrix} + \psi_-(\mathbf{x}, t) \begin{pmatrix} \alpha_-(\mathbf{x}) \\ \beta_-(\mathbf{x}) \end{pmatrix}, \quad (81.21)$$

where

$$\hat{\mathcal{U}}(\mathbf{x}) \begin{pmatrix} \alpha_\pm(\mathbf{x}) \\ \beta_\pm(\mathbf{x}) \end{pmatrix} = \pm \frac{\hbar \Omega(\mathbf{x})}{2} \begin{pmatrix} \alpha_\pm(\mathbf{x}) \\ \beta_\pm(\mathbf{x}) \end{pmatrix}, \quad (81.22)$$

with eigenvalues determined by the dressed Rabi frequency

$$\Omega(\mathbf{x}) = \sqrt{|\Omega_1(\mathbf{x})|^2 + \Delta^2}, \quad (81.23)$$

and coefficients (we suppress the \mathbf{x} -dependence for notational clarity)

$$\begin{pmatrix} \alpha_+ & \alpha_- \\ \beta_+ & \beta_- \end{pmatrix} = \begin{pmatrix} \cos \frac{\vartheta}{2} & -e^{-i\varphi} \sin \frac{\vartheta}{2} \\ e^{i\varphi} \sin \frac{\vartheta}{2} & \cos \frac{\vartheta}{2} \end{pmatrix} \equiv \hat{S}. \quad (81.24)$$

Here, the Stückelberg angle $\vartheta \equiv \vartheta(\mathbf{x})$ and phase angle $\varphi \equiv \varphi(\mathbf{x})$ are defined in terms of the polar representation of the fictitious magnetic field

$$\boldsymbol{\Omega} = \Omega (\cos \varphi \sin \vartheta, \sin \varphi \sin \vartheta, \cos \vartheta). \quad (81.25)$$

In the dressed state basis, the transformed Hamiltonian assumes the form

$$\tilde{H} \equiv \hat{S}^\dagger H \hat{S} = \frac{[\hat{\mathbf{p}} - \hat{\mathcal{A}}(\hat{\mathbf{x}})]^2}{2M} + \frac{\hbar}{2} \Omega(\hat{\mathbf{x}}) \sigma_3, \quad (81.26)$$

with matrix-valued vector potential

$$\hat{\mathcal{A}}(\mathbf{x}) = i\hbar S^\dagger(\mathbf{x}) [\nabla S(\mathbf{x})]. \quad (81.27)$$

This matrix is not diagonal; its off-diagonal elements describe nonadiabatic transitions between the dressed states. If the detuning is sufficiently large, and the atom moves sufficiently slowly, these nonadiabatic transitions may be neglected in a first approximation. In such an approximation, which is akin to the Born–Oppenheimer approximation in molecular physics, the dynamics of the atom is described by two decoupled Hamiltonians of the generic form Eq. (81.3), with scalar potentials \mathcal{U} given by

$$\mathcal{U}(\mathbf{x}) = \pm \frac{\hbar}{2} \Omega(\mathbf{x}), \quad (81.28)$$

and vector potentials $\mathcal{A}(\mathbf{x})$ given by the diagonal elements of Eq. (81.27). The vector potential is usually neglected. If included, it describes the Berry phase of the mechanical effects of the radiation interaction of a two-level atom.

The idea behind the adiabatic approximation is that the internal state of the atom, which is described by any of the locally varying dressed states, has enough time to adjust smoothly to the motion of the atom. For the important case of strong detuning $|\Delta| \gg |\Omega_1(\mathbf{x})|$, this assumption is usually well justified. In this case, an atom in the dressed ground state experiences a potential that is approximately given by

$$\mathcal{U}(\mathbf{x}) = -\frac{\hbar |\Omega_1(\mathbf{x})|^2}{4\Delta}. \quad (81.29)$$

For red detuning, we have $\Delta > 0$, in which case the atom is attracted towards regions of high intensity (high-field seeker). For blue detuning, the atom is repelled from such regions (low-field seeker). A potential similar to Eq. (81.29) also applies for complex particles like molecules whose transitions are detuned far from the light frequency. The potential is proportional to the dynamic polarizability $\alpha(\omega)$ and the field intensity.

Atom optical nonlinearity

In atom optics, nonlinear phenomena occur due to atom–atom interactions in the ensemble, the nature of which may be significantly influenced by laser light [19]. In the presence of laser light, atom–atom interactions mainly result from photon exchange, which, in most cases, leads to a repulsive interaction. Details of the microscopic basis of atom–atom interactions, in particular those concerning cold collisions, are presented in Chap. 54. Characteristic effects of nonlinear atom optics like four-wave mixing [20] and parametric amplification [21] have been observed with the highly dense samples provided by Bose–Einstein degenerate gases (Chap. 80).

81.3 Evolution of De Broglie Waves

Since the Schrödinger equation is a linear partial differential equation, de Broglie optics shares most of its principles with principles of other wave phenomena, and in particular with the optical principles of electromagnetic waves.

81.3.1 Light Optics Analogy

The analogy of de Broglie optics and light optics becomes particularly transparent for monoenergetic beams of scalar particles. Such beams are described by a time harmonic wave function $\psi(\mathbf{x}, t) = e^{-iEt/\hbar} \psi_E(\mathbf{x})$, where $\psi_E(\mathbf{x})$ obeys the stationary Schrödinger equation

$$H \psi_E = E \psi_E . \quad (81.30)$$

Setting $\mathcal{A}(\mathbf{x}) = 0$ in Eq. (81.3) for simplicity, this equation assumes the form

$$\left[\nabla^2 + k_0^2 \left(1 - \frac{U(\mathbf{x})}{E} \right) \right] \psi_E(\mathbf{x}) = 0 , \quad (81.31)$$

where the wavenumber k_0 is related to the energy E via the dispersion relation

$$E \equiv \frac{\hbar^2 k_0^2}{2M} . \quad (81.32)$$

If $U = 0$ at the entrance to the interaction region, E is the kinetic energy of the freely traveling de Broglie wave, and k_0 is the related wavenumber.

Comparing Eq. (81.31) with the scalar Helmholtz equation of electromagnetic theory and identifying

$$n_E(\mathbf{x}) \equiv \left[\frac{E - U(E)}{E} \right]^{1/2} \quad (81.33)$$

as an index of refraction for matter waves, one observes the complete analogy of scalar optics of stationary matter waves and monochromatic light waves. This analogy can be generalized for spinor-valued wave functions, which would correspond to vector wave optics in anisotropic index media. However, in contrast to light, spinor-valued wave functions do not obey a transversality condition.

In Eqs. (81.31)–(81.33), the parameter E describes the kinetic energy of the incoming beam. Thus, E is positive, and, therefore, $n_E < 1$ for positive values of the potential, while $n_E > 1$ for negative values of the potential. For neutrons, one generally has $n_E < 1$. This contrasts to the index of refraction for light waves, which is generally larger than 1. For electrons, ions, and atoms both $n_E < 1$ and $n_E > 1$ may be realized.

81.3.2 WKB Approximation

Waves are described by amplitude and phase. Particles are described by position and momentum. The link between these concepts is provided by Hamilton's ray optics. For scalar matter waves, a ray follows a classical trajectory. The optical signature of the ray is the phase associated with it. The quantum mechanical version of Hamilton's ray optics is obtained in the WKB (Wenzel, Kramers, and Brillouin) approximation of the stationary Schrödinger equation (Eq. (81.30)).

Any solution of Eq. (81.30) may be written in the form

$$\psi_E(\mathbf{x}) = A(\mathbf{x}) e^{iW(\mathbf{x})} , \quad (81.34)$$

with real-valued $A(\mathbf{x})$ and $W(\mathbf{x})$. In the WKB approximation, $A(\mathbf{x})$ is slowly varying, and

$$W(\mathbf{x}) = k_0 \int_{P_i}^P n_E(s) ds + \hbar^{-1} \int_{x_i}^x \mathcal{A}(\mathbf{x}') \cdot d\mathbf{x}' , \quad (81.35)$$

which is called eikonal in Hamilton's ray optics. In this expression, $n_E(s) \equiv n_E(\mathbf{x}(s))$, where $\mathbf{x}(s)$ denotes the classical trajectory of energy E connecting the point P_i with the point P , x_i and x are the coordinates of P_i and P , respectively, and $ds \equiv |d\mathbf{x}|$ is the element of arc length measured

along the classical trajectory. Note that the second contribution in Eq. (81.35) is generally gauge dependent. However, for closed loops, which are frequently encountered in interferometry, the gauge-dependence disappears by virtue of Stokes theorem, which transforms the path integral into an area integral over the rotor of \mathcal{A} .

The eikonal Eq. (81.35) may also be written in the form of a reduced action

$$W(\mathbf{x}) = \frac{1}{\hbar} \int_{x_i}^{\mathbf{x}} \mathbf{p}(\mathbf{x}') \cdot d\mathbf{x}' = \int_{x_i}^{\mathbf{x}} \mathbf{k}(\mathbf{x}') \cdot d\mathbf{x}', \quad (81.36)$$

where $\mathbf{p}(\mathbf{x})$ is the local value of the canonical momentum of the particle, $\mathbf{k}(\mathbf{x}) \equiv \mathbf{p}(\mathbf{x})/\hbar$ is the corresponding wave vector, and the integral is evaluated along the classical trajectory of the particle. Note that in the presence of a vector potential, $\mathbf{p}(\mathbf{x})$ and $d\mathbf{x}$ are no longer parallel as a result of the difference between canonical momentum \mathbf{p} and kinetic momentum $M d\mathbf{x}/dt \equiv \mathbf{p} - \mathcal{A}$.

The WKB approximation becomes invalid in the vicinity of caustics where neighboring rays intersect, and the amplitude $A(\mathbf{x})$ becomes large. There, connection formulae are used to find the proper phase factors picked up by the ray in traversing the caustics. Depending on the topology of the intersecting rays, different classes of diffraction integrals provide uniform approximations for the wave amplitude near caustics. For further details, see [22].

81.3.3 Phase and Group Velocity

The velocity of a particle that traverses a region of negative potential increases so that $p(\mathbf{x}) > p_0$, and the phase advances: $\delta W = \int [\mathbf{p}(\mathbf{x}) - \mathbf{p}_0] \cdot d\mathbf{x} > 0$. In quantum mechanics, the classical velocity corresponds to the group velocity, while the evolution of the phase is determined by the phase velocity. The phase and group velocities of de Broglie waves are given by

$$v_p(\mathbf{x}) \equiv \frac{E}{p(\mathbf{x})} = \frac{1}{n_E(\mathbf{x})} \sqrt{\frac{E}{2M}}, \quad (81.37)$$

$$v_g(\mathbf{x}) \equiv \frac{\partial E}{\partial p(\mathbf{x})} = n_E(\mathbf{x}) \sqrt{\frac{2E}{M}}, \quad (81.38)$$

respectively. Note that the product $v_p v_g = E/M$ is independent of $n_E(\mathbf{x})$.

81.3.4 Paraxial Approximation

The paraxial approximation is useful in describing the evolution of wave-like properties and/or distortion of wavefronts in the immediate neighborhood of an optical ray.

Let the z -axis be the central optical axis of symmetry along which the optical elements are aligned. Using the ansatz $\psi_E(\mathbf{x}) = e^{ik_0 z} \phi(x, y; z)$ and dropping $\partial^2 \phi / \partial z^2$ in a slowly varying envelope approximation one obtains

$$i\hbar v_0 \frac{\partial}{\partial z} \phi(x, y; z) = \left[-\frac{\hbar^2}{2M} \nabla_{\perp}^2 + \mathcal{U}(x, y; z) \right] \phi(x, y; z), \quad (81.39)$$

where $\nabla_{\perp}^2 = \partial^2 / \partial x^2 + \partial^2 / \partial y^2$, and $v_0 = \hbar k_0 / M$ is the longitudinal velocity of incoming particles. This equation has exactly the form of a time-dependent Schrödinger equation in two dimensions, with z/v_0 playing the role of a fictitious time t . With this interpretation, the spatial evolution of phase fronts along z can be analyzed in dynamical terms of particles moving in the xy -plane.

81.3.5 Raman–Nath Approximation

In the Raman–Nath approximation (also called the short-time, thin-hologram, or thin-lens approximation), the ∇_{\perp}^2 term in Eq. (81.39) is neglected. The potential $\mathcal{U}(x, y; z)$ then acts as a pure phase structure, and the solution of Eq. (81.39) becomes

$$\phi(x, y; z) = \exp \left[-\frac{i}{\hbar v_0} \int_{z_i}^z dz' \mathcal{U}(x, y; z') \right] \phi(x, y; z_i). \quad (81.40)$$

In terms of a classical particle moving under the influence of \mathcal{U} , the approximation loses validity for $(1/2)M v_{\perp}^2 \gtrsim \mathcal{U}$, which is just a quarter cycle for a harmonic oscillator.

81.4 Refraction and Reflection

Consider a particle beam of energy E incident on a medium with constant index of refraction n_E . The boundary plane at $z = 0$ in Fig. 81.1 divides the vacuum from the medium. At the boundary, the beam is partially reflected and partially transmitted, with the angles determined by Snell's law of refraction

$$\sin \alpha = n_E \sin \beta, \quad (81.41)$$

and the law of reflection

$$\alpha = \alpha'. \quad (81.42)$$

Fig. 81.1 Reflection geometry

The coefficients of reflectivity R , and transmittivity $T = 1 - R$ are given by the Fresnel formula

$$R = \left| \frac{\cos \alpha - n_E \cos \beta}{\cos \alpha + n_E \cos \beta} \right|^2. \quad (81.43)$$

For $n_E > 1$, the interface is *attractive*, and $R \ll 1$, with $R \rightarrow 1$ only for glancing incidence $\alpha \rightarrow \pi/2$. For $n_E < 1$, the interface is *repulsive*, and total reflection ($R = 1$) occurs for $\alpha \geq \tilde{\alpha}_c$, where $\tilde{\alpha}_c = \sin^{-1} n_E$ is the critical angle. For $\alpha > \tilde{\alpha}_c$, the de Broglie wave becomes evanescent, with $\psi_E(z > 0) \approx e^{-\kappa z}$ inside the medium ($z > 0$), where

$$\kappa = k_0 (\sin^2 \alpha - \sin^2 \tilde{\alpha}_c)^{1/2}. \quad (81.44)$$

If $E < \mathcal{U}$, then n_E is imaginary, and total reflection occurs for all α . In neutron optics, this total mirror reflection requires ultracold neutrons ($T \approx 0.5$ mK). It has important applications for the storage of ultracold neutrons in material cavities, and neutron microscopy using spherical mirrors. For details, see [3].

81.4.1 Atomic Mirrors

Inelastic processes, such as diffuse scattering and adsorption, inhibit coherent reflection of atoms from bare surfaces. The surface must, therefore, be coated either with material of low adsorptivity (noble gas), or electromagnetic fields (evanescent light or magnetic fields, see below).

Reflection of atoms by evanescent laser light

Evanescent light fields are produced by total internal reflection of a light beam at a dielectric–vacuum interface. In the vacuum ($z \geq 0$), the field decays exponentially away from the interface on a characteristic length κ^{-1} , where

$$\kappa = k(n^2 \sin^2 \theta_i - 1)^{1/2}. \quad (81.45)$$

Here, n is the light index of refraction of the dielectric, k is the wave number of the light beam in vacuo, and θ_i is its angle of incidence.

If the light is blue-detuned from the atomic resonance, an incident beam of ground state atoms experiences the repulsive potential

$$\mathcal{U}(x) = \frac{\hbar}{2} \left[(\Omega_0^2 e^{-2\kappa z} + \Delta^2)^{1/2} - |\Delta| \right]. \quad (81.46)$$

For $\alpha > \tilde{\alpha}_c$, the evanescent field acts as a nearly perfect mirror, the imperfections being due to nonadiabatic transitions into the *wrong* dressed state, possible spontaneous emission, and scattering off an inhomogeneous potential, inherited from the roughness of the dielectric–vacuum interface. Reflection of atoms by evanescent laser light was demonstrated by *Balykin et al.* [23] at grazing incidence and by *Kasevich et al.* [24] at normal incidence.

Reflection of atoms by magnetic near fields

Magnetic near fields are produced above substrates with a spatially modulated permanent magnetization or close to arrays of stationary currents. In the vacuum above the substrate, the field decays approximately exponentially over a length comparable to the scale of the magnetic modulation. The motion of atoms that cross such inhomogeneous magnetic fields sufficiently slowly is governed by the analog of the adiabatic potential described in Sect. 81.2.4

$$\mathcal{U}(x) = -\mu \frac{m_s}{s} |\mathbf{B}(x)|, \quad (81.47)$$

where μ is the magnetic moment, and m_s is the (conserved) projection of the atomic spin s onto the local magnetic field direction. A repulsive mirror potential is achieved for spin states with $\mu m_s < 0$; these weak field seekers are repelled from the strong fields close to the substrate.

Experiments have used magnetic recording media like magnetic tapes or hard disks, arrays of current-carrying wires, or amorphous magnetic substrates, see [25].

81.4.2 Atomic Cavities

Atomic reflections are used in the two kinds of cavities proposed so far: the trampoline cavity and bicolored traps.

The trampoline cavity, also called the gravito-optical cavity, consists of a single evanescent mirror facing upwards, the second mirror being provided by gravitation [26]. A stable cavity is realized with the evanescent laser field of a parabolically shaped dielectric–vacuum interface, see the experiment by *Aminoff et al.* [27]. A cavity with transverse confinement provided by a hollow blue-detuned laser beam was demonstrated by *Hammes et al.* [28]. By combining red and

blue-detuned beams guided by an optical fiber, one can form an array of traps, as shown by *Vetsch et al.* [29].

81.4.3 Atomic Lenses

De Broglie waves may be focused by refraction from a parabolic potential or by diffraction, e.g., by a Fresnel zone plate (Sect. 81.5.2). Consider focusing by the parabolic potential

$$\mathcal{U}(x, y; z) = \begin{cases} \frac{1}{2}M\omega_f^2(x^2 + y^2), & -w \leq z \leq 0 \\ 0, & \text{otherwise.} \end{cases} \quad (81.48)$$

For ground-state atoms, such a potential is realized in the vicinity of the node of a blue-detuned standing-wave laser field of transverse width w . In this case,

$$\omega_f = \Omega_0 \left(\frac{\omega_{\text{rec}}}{|\Delta|} \right)^{1/2}, \quad (81.49)$$

where $\omega_{\text{rec}} = \hbar k^2/2M$ is the recoil frequency.

The comparison of the Raman–Nath approximation Eq. (81.40) at $z = 0$ with the phase fronts of a spherical wave converging towards a point $\mathbf{x}_f = (0, 0, f)$, shows that \mathcal{U} describes a lens of focal length

$$f = \frac{v_0^2}{w\omega_f^2}. \quad (81.50)$$

The Raman–Nath approximation is only valid for a thin lens $w \ll f$ and breaks down for $w > w_{\text{RN}} = \pi v_0/2\omega_f$. In the latter case, oscillations of the particles in the harmonic potential become relevant, a phenomenon sometimes called channeling. Channeling may be used to realize thick lenses with focal length $f = w_{\text{RN}}$ corresponding to a quarter oscillation period.

Focusing of a metastable helium beam using the antinode of a large period standing-wave laser field has been demonstrated [30]. Such a field is produced by reflecting a laser beam from a mirror under glancing incidence. The standing wave forms normal to the mirror surface. Similar interference patterns provide arrays of thick lenses that have been exploited in atom lithography to focus an atomic beam onto a substrate [7].

81.4.4 Atomic Waveguides

Atomic waveguides can be realized with potentials that confine atoms in one or two dimensions [26, 31, 32]. These devices are key elements for integrated atom optics, a field

that has seen a rapid evolution recently [33]. A planar waveguide is provided by the one-dimensional confinement in an optical standing wave or an atomic mirror combined with gravity. The discrete nature of the waveguide modes in that case was demonstrated by lowering an absorbing object [34]. Linear waveguides can be modeled by the parabolic transverse potential Eq. (81.48) that now extends along the waveguide axis (the z -axis). Physical realizations include hollow, blue-detuned laser beams, hollow fibers whose inner wall is coated with blue-detuned evanescent light [35], interference patterns from three or four far-detuned beams (also known as optical lattices) [36], and magnetic field minima along current-carrying wires, possibly combined with homogeneous bias fields [37]. With typical thermal atomic ensembles, these waveguides operate in a multimode regime, and coherent operation has been demonstrated only with Bose–Einstein condensates. A strong transverse confinement that facilitates monomode operation, can be achieved with miniaturized wire networks deposited on a solid substrate. This approach has led to the fabrication of atom chips [38, 39], and integrated atomic interferometers were demonstrated in [40, 41].

81.5 Diffraction

The diffraction of matter waves is described by the solution of the Schrödinger equation (Eq. (81.30)) subject to the boundary conditions imposed by the diffracting object. For a plane screen Σ made of opaque portions and apertures, the solution in the source-free region behind the screen is given by the Rayleigh–Sommerfeld formulation of the Huygens principle

$$\psi_E(\mathbf{x}) = \frac{k_0}{i} \int_{\Sigma} \frac{d\xi d\eta}{2\pi} \frac{e^{ik_0 R}}{R} \times \left(1 + \frac{i}{k_0 R} \right) \frac{\mathbf{n} \cdot \mathbf{R}}{R} \psi(\xi), \quad (81.51)$$

where $\xi = (\xi, \eta, \zeta)$ denotes coordinates of points on Σ , \mathbf{n} is an inwardly directed normal to Σ at a point ξ , and $\mathbf{R} = \mathbf{x} - \xi$.

A diffraction pattern only becomes manifest in the diffraction limit $r \gg d$, where r is the distance to the observation point, and d is the length scale of the diffracting system. The two diffraction regimes are then the Fraunhofer limit $r \gg d^2/\lambda_{\text{dB}}$ and the Fresnel regime $r \approx d^2/\lambda_{\text{dB}}$, also called near-field optics.

81.5.1 Fraunhofer Diffraction

In the Fraunhofer limit, the field at position (x, y) on a screen at a distance L downstream from the diffracting object is

given by

$$\psi(x, y; L) = k_0 \frac{e^{ik_0 L}}{iL} \int \frac{d\xi d\eta}{2\pi} \times e^{-i(k_x \xi + k_y \eta)} \psi(\xi, \eta; 0), \quad (81.52)$$

where $k_x = k_0 x/L$, $k_y = k_0 y/L$. The field at the observation screen is thus given by the Fourier transform of the field in the object plane; i.e., the momentum representation of the diffracted state. Since most diffraction experiments in atom optics are performed in the Fraunhofer limit, most calculations are done in the momentum representation.

Atomic diffractions from microfabricated transmission gratings [42] and double slits [43] have been observed. Recent experiments have extended de Broglie wave diffraction to heavier, complex particles like fullerenes (C_{60}) [44] and even larger molecules [9].

81.5.2 Fresnel Diffraction

Typical applications of Fresnel diffraction are Fresnel zone plates and the effects of Talbot and Lau. Fresnel zone plates are microfabricated concentric amplitude structures that act like lenses. They are frequently employed in optics of α -particles and neutrons. In atom optics, focusing with a Fresnel zone plate was first demonstrated by *Carnal* et al. [45].

The Talbot effect and the related Lau effect refer to the self-imaging of a grating of period d , which appears downstream at distances that are integral multiples of the Talbot length $L = 2d^2/\lambda_{dB}$. For a discrete set of distances smaller than the Talbot length, images of the grating appear with smaller periods d/n , $n = 2, 3, \dots$ For applications in matter-wave interferometry, see [46].

81.5.3 Near-Resonant Kapitza–Dirac Effect

The near-resonant Kapitza–Dirac effect refers to the diffraction of two-level atoms from a standing-wave laser field with a spatially uniform polarization. The dynamics of the effect is described by the Hamiltonian Eq. (81.16) with the mode function of the laser field given by Eq. (81.13). Consider atoms traveling predominantly in the z -direction, i.e., orthogonal to the axis of the laser field, with energy $(1/2)Mv_0^2 \gg \hbar\Omega_0$ (Fig. 81.2). Kapitza–Dirac diffraction is then observed in transmission, which in the theory of diffraction is called Laue geometry. In the paraxial approximation (Sect. 81.3.4) for motion in the z -direction, and assuming that the laser profile is homogeneous in the y -direction, the description reduces to an effectively one-dimensional model for the quantum mechanical motion along the x -axis of the laser field.

Fig. 81.2 Geometry of the Kapitza–Dirac effect

Due to the periodicity of the standing-wave light field, the transverse momenta of the transmitted atom waves differ by multiples of $\hbar k$ from the transverse momentum of the undiffracted wave. For the important case of strong detuning, and assuming that the incoming atoms are in their electronic ground state moving with transverse momentum $p_x = 0$, the p_x -distribution of the outgoing wave is given in the Raman–Nath approximation (Sect. 81.3.5) by

$$\text{Prob}(p_x = 2n\hbar k) \propto \left| J_n \left(\frac{\Omega_0^2}{8|\Delta|} \tau \right) \right|^2, \quad (81.53)$$

where J_n is a Bessel function of order n , $\tau = w/v_0$ is an effective interaction time, w being the width of the laser field, and v_0 the longitudinal velocity of the atoms. The distribution Eq. (81.53) was observed by *Gould* et al. [47].

For $\tau \gtrsim \tau_{RN}$, where $\tau_{RN} = (\omega_{rec} \Omega_0^2 / |\Delta|)^{-1/2}$, the Raman–Nath approximation becomes invalid. As a result of Doppler related phase-mismatch, the momentum spread saturates and shows a sequence of collapse and revival as a function of τ .

If the detuning is too small to allow for a scalar description, the two-level character of the atoms must be taken into account. For the particular case of $\Delta = 0$, the ground state evolves into an equal superposition of the two diabatic states $1/\sqrt{2}(|e\rangle \pm |g\rangle)$ while entering the interaction region. Inside the interaction region, these states experience potentials that differ only by their sign. For atomic beams with a small spatial spread $\delta x \ll 2\pi/k$, the diabatic states experience opposite forces, leading to a splitting of the atomic beam called the atom-optical Stern–Gerlach effect [48].

Diffraction similar to the Kapitza–Dirac effect is also possible with other polarizable particles. Experiments with molecules have been demonstrated by *Gerlich* et al. [49].

81.5.4 Atom Beam Splitters

Beam splitters are optical devices that divide an incoming beam into two outgoing beams traveling in different direc-

tions. For thermal neutrons, beam splitters may be realized by diffraction from perfect crystals in Laue geometry. For atoms, they can be realized using diffraction from crystalline surfaces, microfabricated structures (Sect. 81.5.1), or by using diffraction from an optical standing wave.

The Kapitza–Dirac effect, for example, may be exploited to split an atomic beam coherently using Bragg reflection at the *lattice planes* provided by the periodic intensity variations of a standing-wave laser field [50]. This process is resonant for an incoming atomic beam traveling with transverse momentum $p_x = \hbar k$ because it is energetically degenerate with the diffracted beam traveling with transverse momentum $\bar{p}_x = -\hbar k$. This level degeneracy is lifted while the atoms enter the interaction region. In the Bragg regime, the lifting happens slowly enough that only the momentum states $|\pm \hbar k\rangle$ participate in the diffraction (two-beam resonance), and their populations show Pendellösung-type oscillations as a function of the transit time. The frequency of the oscillations is given by $\delta E/\hbar$, where δE is the energy splitting of the two beams inside the interaction region. For a transit time given by a quarter period of the Pendellösung, a 50% beam splitting is observed [50]. In principle, Bragg resonances may also be realized for higher diffraction order $p_x = n\hbar k \leftrightarrow \bar{p}_x = -n\hbar k$. However, in this case, intermediate momentum states become populated (multibeam resonance), which makes the higher-order Bragg resonances less suitable for beam splitting purposes.

More promising for the realization of an atomic beam splitter is the magneto-optical diffraction which refers to the diffraction of three-level atoms from a laser field with a periodic polarization gradient (lin \perp lin configuration) (Chap. 79), and a magnetic field aligned parallel to the optical axis of the laser field. This configuration realizes an interaction potential in the form of a blazed grating, i.e., a phase grating with an approximately triangular variation of phase. In an experiment by Pfau et al., transverse splitting of a beam of metastable helium by $42\hbar k$ was observed [51].

Diffraction from an evanescent standing wave involves Bragg reflection of atoms under glancing incidence from the periodic grating of a blue detuned evanescent standing-wave laser field [52]. Diffraction at normal incidence has been demonstrated with sufficiently slow atoms [53, 54] and can be described by a generalization of the Raman–Nath approximation (Sect. 81.3.5).

81.6 Interference

While the overall phase of a wave function ψ is not observable, interferometry makes detectable the relative phases of two components ψ_1, ψ_2 in a superposition $\psi = \psi_1 + \psi_2$. Two types of interferometers are most common: the Young double-slit as a paradigm for interferometers based on di-

vision of wavefront, and the Mach–Zehnder interferometer as a paradigm for interferometers based on division of amplitude. In de Broglie optics, the latter type is realized in the form of a three-grating interferometer, since division of amplitude is achieved by diffraction at gratings rather than by semitransparent mirrors. Experiments with this geometry have been reported for atoms [55] and recently for more massive, complex molecules [56].

81.6.1 Interference Phase Shift

From a fundamental point of view, any interferometer is a ring. At the entrance port of a three-grating interferometer displayed in Fig. 81.3, for example, the wave function is split into two coherent parts that evolve spatially along different paths and, subsequently, come together at the exit port where they are superimposed to produce two outgoing waves

$$\psi_{\pm} = \frac{1}{\sqrt{2}}(\psi_1 \pm \psi_2), \quad (81.54)$$

where the components from path 1 and 2 are given by

$$\begin{aligned} \psi_1 &= A_1 \exp(iW_1), \\ \psi_2 &= A_2 \exp(iW_2). \end{aligned} \quad (81.55)$$

For simplicity, assume $A_1 = A_2 = A_0/\sqrt{2}$. The relative flux of the outgoing waves is then

$$I_{\pm} = \frac{1}{2}(1 \pm \cos \chi), \quad (81.56)$$

where $\chi = W_1 - W_2$ is the relative phase of the two components. The sinusoidal variations of I_{\pm} with varying χ are called interference fringes, and $\chi/2\pi$ is called the fringe order number.

In the WKB approximation, the phases W_1 and W_2 are given by

$$W_i = W_0 + \int_i \mathbf{k}(\mathbf{x}) \cdot d\mathbf{x}, \quad i = 1, 2, \quad (81.57)$$

Fig. 81.3 Geometry of the three-grating interferometer

where the integrals extend over the classical paths 1 and 2, respectively, and $d\mathbf{x}$ is an element of displacement along the paths. Using Eq. (81.57), the relative phase is

$$\chi = \int_C \mathbf{k}(\mathbf{x}) \cdot d\mathbf{x} , \quad (81.58)$$

where C is the closed interferometer loop. Note that on path 2, the path element $d\mathbf{x}$ in Eq. (81.58) and \mathbf{k} are antiparallel.

Usually, the absolute value of χ is not measured, but only variations, called phase shifts, which result from displacements of the diffraction gratings or placement of optical elements into the beam path. Phase shifts come in two categories: dispersive and geometric. If a phase shift χ depends on v_0 , it is called dispersive, otherwise it is called geometric. Geometric phases depend only on the geometry of the interferometer loop. The Sagnac effect (see below), for example, may be geometric. A phase that depends neither on v_0 nor on the geometry of the interferometer loop is called topological. The Aharonov–Bohm effect (see below) is topological.

Using Eq. (81.35), χ becomes

$$\chi = \chi_0 + \chi\{\mathcal{U}\} + \chi\{\mathcal{A}\} , \quad (81.59)$$

where for weak potentials \mathcal{U} and \mathcal{A} ,

$$\chi_0 = \frac{Mv_0}{\hbar}(L_1 - L_2) , \quad (81.60)$$

$$\chi\{\mathcal{U}\} = -\frac{1}{\hbar v_0} \oint \mathcal{U}[\mathbf{x}(s)] ds , \quad (81.61)$$

$$\chi\{\mathcal{A}\} = \frac{1}{\hbar} \oint \mathcal{A}(\mathbf{x}) \cdot d\mathbf{x} , \quad (81.62)$$

and L_i is the geometric length of the path i . For a constant potential \mathcal{U}_0 intersecting the interferometer on a length w , $\chi\{\mathcal{U}\}$ is given by

$$\chi\{\mathcal{U}\} = -\frac{\mathcal{U}_0 w}{\hbar v_0} . \quad (81.63)$$

Using Stokes' theorem, $\chi\{\mathcal{A}\}$ may be written in the manifestly gauge-invariant form

$$\chi\{\mathcal{A}\} = \frac{1}{\hbar} \int [\nabla \times \mathcal{A}(\mathbf{x})] \cdot d\mathbf{a} , \quad (81.64)$$

where the integral extends over the area enclosed by the interferometer, and $d\mathbf{a}$ is an infinitesimal area element.

Dispersive phase shifts. Atom interferometers have been able to measure phase shifts of the form Eq. (81.61) due to, for example, the atomic level shift in an electric field (Stark effect) or to coherent forward scattering by background gas atoms, see [6].

Sagnac effect. The Sagnac effect refers to $\chi\{\mathcal{A}\}$ in a rotating interferometer. Inserting Eq. (81.6) into Eq. (81.64) and assuming that the axis of rotation is oriented perpendicular to the plane of the interferometer, the Sagnac phase shift is given by

$$\chi_{\text{Sa}} = \frac{4M\Omega A}{\hbar} , \quad (81.65)$$

where A is the geometric area enclosed by the interferometer loop; χ_{Sa} may be dispersive or geometric depending on the type of interferometer. In a Young double-slit, A is independent of energy, and χ_{Sa} is geometric. In a three-grating interferometer, the area is $A \approx \vartheta D^2$, where ϑ is the splitting angle; see Fig. 81.3. In this case, χ_{Sa} is dispersive because of the velocity dependence of $\vartheta \approx 2\hbar k / M v_0$. The Sagnac effect for de Broglie waves was first observed by *Werner et al.* [57] using a neutron interferometer.

Aharonov–Bohm effect. The Aharonov–Bohm effect refers to the $\chi\{\mathcal{A}\}$ of charged particles encircling a magnetic flux line [58]. Inserting \mathcal{A} from Eq. (81.7) into Eq. (81.64), and assuming the particles of charge q encircle a line of flux Φ once, one finds

$$\chi_{\text{AB}} = \frac{q\Phi}{\hbar} . \quad (81.66)$$

A characteristic feature of the Aharonov–Bohm effect is that the particles actually never *see* the magnetic field of the flux line, which is confined to some region inaccessible to the particles; χ_{AB} is strictly topological and only depends on the linking number of the interferometer loop and the flux line. Its appearance is characteristic for all gauge theories. For further details and a summary on its experimental verification, see [2].

Aharonov–Casher effect. The Aharonov–Casher effect refers to $\chi\{\mathcal{A}\}$ of a magnetic spin encircling an electric line charge [59]. Inserting \mathcal{A} from Eq. (81.10) into Eq. (81.64), one obtains for proper alignment of $\boldsymbol{\mu}$ and \mathbf{E} ,

$$\chi_{\text{AC}} = 2\pi \frac{|\boldsymbol{\mu}| r_0}{\mu_B \xi} , \quad (81.67)$$

where r_0 is the classical electron radius, μ_B is the Bohr magneton, $\xi = e/\rho_{\text{el}}$, ρ_{el} being the electric line charge density; χ_{AC} is topological only if the spin is aligned parallel to the electric line charge, and both are oriented perpendicular to the plane of the interferometer; χ_{AC} for atoms has been observed by *Sangster et al.* [60].

Electric dipole phase. Electric dipole phase refers to the $\chi\{\mathcal{A}\}$ of an electric dipole moment encircling a magnetic line charge [61]. Inserting \mathcal{A} from Eq. (81.11) into

Eq. (81.64), one obtains for proper alignment of \mathbf{d} and \mathbf{B}

$$\chi_{\text{dE}} = 2\pi \frac{|\mathbf{d}| a_0}{e a_0 \xi}, \quad (81.68)$$

where a_0 is the Bohr radius, and $\xi = \Phi_0/\varrho_{\text{mg}}$, Φ_0 being the magnetic flux unit, and ϱ_{mg} being the magnetic line charge density. In analogy to the Aharonov–Casher effect, χ_{dE} is topological, provided that \mathbf{d} is aligned parallel to the magnetic line charge, and both are oriented perpendicular to the interferometer plane. The electric dipole phase has been experimentally measured using atom interferometry [62].

81.6.2 Internal-State Interferometry

Manipulation of the internal state of atoms by means of electromagnetic fields makes it possible to realize interferometric setups that involve separation of paths in internal space rather than in real space. Examples of such interferometers are the optical Ramsey interferometer [63], the stimulated Raman interferometer [64], and interferometers using static electric and magnetic fields [65, 66].

81.6.3 Manipulation of Cavity Fields by Atom Interferometry

The entanglement of atomic states and quantized field states opens novel possibilities for manipulating and/or measuring nonclassical field states in a cavity. In the adiabatic limit, for example, and assuming sufficient detuning between the atom and the cavity field, the interaction and CM motion of an atom traversing a cavity is well described by the potential Eq. (81.29)

$$\mathcal{U}(\mathbf{x}) = -\hbar \frac{g^2}{\Delta} f(\mathbf{x})^2 a^\dagger a, \quad (81.69)$$

where g is the vacuum Rabi frequency, $f(\mathbf{x})$ is a cavity mode function, and a, a^\dagger denote cavity photon annihilation and creation operators, respectively (see Chap. 82).

Because of the presence of the photon-number operator $a^\dagger a$ in Eq. (81.69), the deflection and phase shift of an atom traversing the cavity is quantized, displaying essentially the photon number statistics in the cavity. The quantized deflection is sometimes called the inverse Stern–Gerlach effect.

Due to the entanglement of atom and cavity states, and the position dependence of the interaction strength, the phase shift induced by $\mathcal{U}(\mathbf{x})$ in a standing-wave cavity may be used to measure either the atomic position via homodyne detection of the cavity field or the photon statistics via atom interferometry. In a ring cavity, the entanglement of CM motion and cavity field may be used to measure the atomic

momentum via homodyne detection of the cavity field. For further details, see [67] and Chap. 82.

81.7 Coherence of Scalar Matter Waves

The general solution of the free Schrödinger equation (Eq. (81.2)) may be written in the form

$$\psi(\mathbf{x}, t) = \int d^3\mathbf{k} a(\mathbf{k}) e^{i(\mathbf{k}\cdot\mathbf{x} - \omega(\mathbf{k})t)}, \quad (81.70)$$

where $\omega(\mathbf{k}) \equiv E/\hbar = \hbar\mathbf{k}^2/2M$. If the coefficients $a(\mathbf{k})$ are known, the state represented by $\psi(\mathbf{x}, t)$ is called a pure state. Otherwise it is called a mixed state, and physical quantities are obtained by an ensemble average over the possible realizations of $a(\mathbf{k})$.

The degree of coherence of matter waves is described by the autocorrelation function of $\psi(\mathbf{x}, t)$

$$\Gamma(\mathbf{x}, t; \mathbf{x}', t') \equiv \overline{\psi(\mathbf{x}', t')^* \psi(\mathbf{x}, t)}, \quad (81.71)$$

where the overline ($\overline{\dots}$) denotes the ensemble average over the possible realizations of $a(\mathbf{k})$. In light optics, $\Gamma(\mathbf{x}, t; \mathbf{x}', t')$ is called the mutual coherence function. In particular, for equal times, $\Gamma(\mathbf{x}, t; \mathbf{x}', t)$ describes the spatial coherence, and for equal positions, $\Gamma(\mathbf{x}, t; \mathbf{x}, t')$ describes the temporal coherence.

For a beam of particles, coherence may be either longitudinal (measured along the beam) or transverse (measured across the beam). In contrast to light optics, there is no simple relation between longitudinal coherence and temporal coherence because the dispersion relation of matter waves is quadratic in the wavenumber.

The spatial coherence function is intimately related to the quantum mechanical density operator of the particles (Chap. 7)

$$\rho(t) = \overline{|\psi(t)\rangle\langle\psi(t)|}. \quad (81.72)$$

In the position representation, one has

$$\langle\mathbf{x}|\rho(t)|\mathbf{x}'\rangle \equiv \rho(\mathbf{x}, \mathbf{x}'; t) = \Gamma(\mathbf{x}, t; \mathbf{x}', t). \quad (81.73)$$

Longitudinal and temporal coherence of a particle beam is determined mainly by the source of the beam. The thermal fission reactors used in neutron optics and the ovens used in atom optics are analogous to black-body sources in light optics. In contrast, the transverse coherence is mainly determined by the way the particles are extracted from the oven to form a beam.

81.7.1 Atomic Sources

To describe thermal sources, consider a single particle in an oven of temperature T and volume V , assuming that $a(\mathbf{k})$ and $a(\mathbf{k}')$ are statistically independent

$$\overline{a(\mathbf{k})^* a(\mathbf{k}')} = \rho(k) \delta(\mathbf{k} - \mathbf{k}'), \quad (81.74)$$

where

$$\rho(k) = \frac{\lambda_{\text{th}}^3}{V} \exp\left(-\frac{\hbar^2 k^2}{2Mk_{\text{B}}T}\right) \quad (81.75)$$

accounts for the thermal distribution of wavenumbers, and

$$\lambda_{\text{th}} = \left(\frac{2\pi\hbar^2}{Mk_{\text{B}}T}\right)^{1/2} \quad (81.76)$$

denotes the thermal de Broglie wavelength.

Using Eqs. (81.74)–(81.76) in Eq. (81.71), the mutual coherence function becomes

$$\Gamma(\mathbf{x}, t; \mathbf{x}', t') = \frac{1}{V} \frac{1}{\{1 + i(t - t')/\tau_{\text{th}}\}^{3/2}} \times \exp\left\{-\pi \frac{(\mathbf{x} - \mathbf{x}')^2 / \lambda_{\text{th}}^2}{1 + i(t - t')/\tau_{\text{th}}}\right\}, \quad (81.77)$$

where

$$\tau_{\text{th}} = \frac{\hbar}{k_{\text{B}}T}, \quad (81.78)$$

is the thermal coherence time.

According to Eq. (81.77), the spatial coherence of a thermal state falls off in a Gaussian manner on a scale given by λ_{th} . The temporal coherence, in contrast, falls off algebraically on a timescale given by τ_{th} . Expressed in physical units, one has

$$\lambda_{\text{th}} = \frac{1.74(5) \text{ nm}}{\sqrt{(M/\text{u})(T/\text{K})}}, \quad \tau_{\text{th}} = \frac{7.63 \text{ ps}}{(T/\text{K})}, \quad (81.79)$$

where u is the atomic mass unit.

Atomic Beams

Effusive beams. Effusive beams are produced from thermal sources by a suitable set of collimators placed in front of the opening of the oven. This produces a Maxwell–Boltzmann distribution of atomic velocities in the longitudinal direction. The coherence properties in the transverse direction are described by the van Cittert–Zernike theorem [68]; for details see any textbook on classical optics.

Supersonic beams. Supersonic beams are produced by supersonic expansion of a high-pressure gas that is forced through an appropriately designed nozzle. The expansion produces a velocity distribution in the longitudinal direction, which is approximately Gaussian with a velocity ratio $v/\delta v \approx 10\text{--}20$.

Pulsed beams. Pulsed beams are produced by chopping any of the beams described above. Important applications for pulsed beams are the resolution of temporal coherence and the mapping of the relative phases of the $a(\mathbf{k})$ in matter-wave interferometry.

Laser-like source of atoms. In these sources, many atoms with integral spin (Bosons) occupy one and the same quantum state of motion. Their operational principle is rooted in the quantum statistical effects of indistinguishability. It may be viewed in close analogy to the operational principle of an ordinary laser (Chap. 74) and the mechanism underlying Bose–Einstein condensation (Chap. 80). Laser-like sources have, indeed, been achieved by letting a small current of atoms leak out of a trapped Bose–Einstein condensate [69].

81.7.2 Atom Decoherence

In any interferometer, the contrast of the interference fringes quantitatively measures the coherence of the wave involved. Partially coherent beams show an output flux given by

$$I_{\pm} = \frac{1}{2} [1 \pm \text{Re}(C e^{i\chi})], \quad (81.80)$$

instead of Eq. (81.56), with a complex number C . One has $|C| \leq 1$, with the maximum achieved for a pure state; the phase of C is measured by scanning the interferometer phase shift χ .

In de Broglie interferometry, coherence can be lost when the interfering matter wave gets entangled with other systems. This happens for atoms, for example, due to the emission or scattering of photons, as soon as the detection of these photons permits, in principle, the resolution of spatially separated paths in the interferometer. In fact, the width of $\Gamma(\mathbf{x}, t; \mathbf{x}', t)$ as a function of $\mathbf{x} - \mathbf{x}'$, also called the spatial coherence length, is reduced to the photon wavelength after a single scattering event; see [70]. Interference can be restored when the emitted photons are detected and correlated with the atom output [71, 72]. Collisions with background gas atoms between the optical elements of a three-grating interferometer also reduce coherence, as has been shown with fullerene molecules [73]. Furthermore, coherence is lost when atoms interact with random electromagnetic fields. This has become relevant for atom reflection from evanescent light because of the roughness of the dielectric surface

used [74]. The coherent operation of integrated atom optics near metallic surfaces is limited by thermally excited electromagnetic near fields [75], as shown in experiments by Harber et al. [76]. Finally, there are suggestions that decoherence may be ever more efficient for particles with larger masses, due to the interaction with the gravitational field or internal degrees of freedom [17, 18]. Interferometer experiments with large molecules [16] and nanoparticles [77] have been proposed to resolve this issue.

Abstract

This article focuses on the understanding of issues where the quantumness of the radiation field is important. To this end, we introduce the experimental signatures of the strict quantum character of the radiation field. Besides the fundamental interest in quantumness, we discuss the important consequences of it, especially in beating the standard quantum noise limit. The quantum character of the field can be used for achieving unprecedented sensitivity. This article is focused on the radiation field, but

many of these ideas are applicable to spin systems, two-level systems, and many other bosonic systems, like ionic motion and mechanical (phonon) degrees of freedom in optomechanical systems. An extensive discussion of the quantumness and its applications in quantum metrology can be found in the book [1]; the summary in this Handbook chapter is tailored along the lines of this book. We start with a historical introduction to the quantum theory of radiation.

82.1 Introduction

The quantum theory of light has its beginnings in the work of Max Planck in 1900. After a tedious struggle in explaining the black-body radiation, Planck found that in order to fit the thermal radiation curve, he had to assume the exchange of energy between a black body and the radiation fields with an undividable unit of energy, $\hbar\omega$, where $\hbar = 1.06 \times 10^{-34}$ J s is the Planck constant and ω is the circular frequency of the light. However, Planck did not regard light itself as being composed of particles with this unit energy. The idea of light quanta was proposed by Einstein in 1905. In studying the thermal dynamic properties of light, Einstein realized that the thermal dynamic equations of light allow a corpuscular theory of light, i.e., the energy of light is carried in discrete quantized packets.

Let us first see how the quantum nature of light affects its thermal statistical distribution. If light behaves like classical waves, the intensity distribution at a certain temperature is

$$P(I) = \frac{1}{\langle I \rangle} e^{-I/\langle I \rangle}, \quad (82.1)$$

where $\langle I \rangle$ is the average intensity. Quantum theory requires that the probability that the light field contains n photons is, given by the Bose–Einstein distribution,

$$p_n = \frac{1}{1 + \langle n \rangle} \left(\frac{\langle n \rangle}{1 + \langle n \rangle} \right)^n, \quad (82.2)$$

where Planck's law gives the average photon number $\langle n \rangle = 1/[\exp(\hbar\omega/k_B T) - 1]$ at the frequency ω with k_B the Boltzmann constant, and T is the temperature. In the large photon number limit, $\langle n \rangle \gg 1$,

$$p_n \approx \frac{1}{\langle n \rangle} \exp\left(-\frac{n}{\langle n \rangle}\right), \quad (82.3)$$

which is identical to Eq. (82.1) since $\langle I \rangle \propto \langle n \rangle$. However, in the low-temperature limit, when $\langle n \rangle \approx 1$ or smaller than 1, p_n drops to zero much faster than Eq. (82.1).

Another drastic difference is in the fluctuations of the fields. From Eq. (82.1), the variance of the intensity $\Delta I^2 = \langle I \rangle^2$, while the fluctuation in the photon numbers according to Eq. (82.2) is $\Delta n^2 = \langle n \rangle^2 + \langle n \rangle$. Einstein called $\langle n \rangle^2$ and $\langle n \rangle$ the particle and wave parts of the fluctuations, respectively. At the low-temperature limit, the fluctuation of the photon numbers is larger than that of the classical statistics. In a remarkable experiment [2], the moments of the Bose–Einstein distribution were measured down to the mean number of the order of unity with deviation in the second moment less than 10%.

The nature of the quantization of the electromagnetic field was not fully understood until Dirac found the second quantization after quantum mechanics was formulated by Heisenberg and Schrödinger in 1925–1926. The wave nature of the light is governed by the Maxwell equations, which give the mode function for the electromagnetic modes. In each of the modes, the amplitude of the field is quantized using the fact that photons obey Bose statistics.

82.2 Quantization of the Electromagnetic Field

According to the Maxwell equations, which characterize the wave nature of the electromagnetic fields, the electromagnetic fields in free space can be written with the vector potential \mathbf{A} ,

$$\mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t}, \quad \mathbf{B} = \nabla \times \mathbf{A}, \quad (82.4)$$

where \mathbf{E} and \mathbf{B} are the electric field and the magnetic field, respectively. We employ CGS units because the physics community uses these widely. In a volume V , \mathbf{A} can be

decomposed into plane waves with wave vector \mathbf{k} and polarization s ,

$$\mathbf{A} = \sum_{\mathbf{k}, s} \frac{A_{\mathbf{k}s}}{\sqrt{V}} \boldsymbol{\epsilon}_{\mathbf{k}s} e^{i\mathbf{k}\cdot\mathbf{r} - i\omega_{\mathbf{k}}t} + \text{c.c.}, \quad (82.5)$$

where the mode functions of the plane wave satisfy the orthogonal condition, $(1/V) \int_V d^3r e^{i\mathbf{k}\cdot\mathbf{r} - i\mathbf{k}'\cdot\mathbf{r}} = \delta(\mathbf{k} - \mathbf{k}')$.

The energy of the electromagnetic fields, $U = (1/8\pi) \int_V [E^2(\mathbf{r}, t) + B^2(\mathbf{r}, t)] d^3r$ can be written in terms of the vector potential,

$$U = \frac{1}{2\pi} \sum_{\mathbf{k}, s} \left(\frac{\omega_{\mathbf{k}}^2}{c^2} \right) |A_{\mathbf{k}s}|^2. \quad (82.6)$$

What was revealed in Planck's black-body radiation is that the above energy should be quantized, $U = \sum_{\mathbf{k}, s} n_{\mathbf{k}s} \hbar\omega_{\mathbf{k}}$, where $n_{\mathbf{k}s}$ is the number of quanta in the mode $\mathbf{k}s$. By making comparison between these two expressions of the energy, we realize the correspondence,

$$\frac{\omega_{\mathbf{k}}}{2\pi\hbar c^2} |A_{\mathbf{k}s}|^2 \leftrightarrow n_{\mathbf{k}s}. \quad (82.7)$$

This is the quantization of the field amplitudes. This quantization is done by introducing the annihilation and creation operators for the electromagnetic field, $a_{\mathbf{k}s}$ and $a_{\mathbf{k}s}^\dagger$, with the commutation relations

$$\begin{aligned} [a_{\mathbf{k}s}, a_{\mathbf{k}'s'}^\dagger] &= \delta_{\mathbf{k}, \mathbf{k}'} \delta_{s, s'}, \\ [a_{\mathbf{k}s}, a_{\mathbf{k}'s'}] &= 0. \end{aligned} \quad (82.8)$$

The number operator can be written as,

$$n_{\mathbf{k}s} = a_{\mathbf{k}s}^\dagger a_{\mathbf{k}s}. \quad (82.9)$$

From Eqs. (82.7) and (82.9), we can relate $A_{\mathbf{k}s} = \sqrt{2\pi\hbar c^2/\omega_{\mathbf{k}}} a_{\mathbf{k}s}$, and the vector potential can be rewritten as $\mathbf{A} = \sum_{\mathbf{k}, s} \boldsymbol{\epsilon}_{\mathbf{k}s} \sqrt{2\pi\hbar c^2/(\omega_{\mathbf{k}} V)} a_{\mathbf{k}s} e^{i\mathbf{k}\cdot\mathbf{r} - i\omega_{\mathbf{k}}t} + \text{H.c.}$, where H.c. stands for Hermitian conjugate. With \mathbf{A} , it is straightforward to write \mathbf{E} and \mathbf{B} in the form of a and a^\dagger . Most importantly, the total energy of the electromagnetic fields, i.e., the Hamiltonian can be written as

$$H = \sum_{\mathbf{k}, s} \hbar\omega_{\mathbf{k}} \left(n_{\mathbf{k}s} + \frac{1}{2} \right). \quad (82.10)$$

82.3 Quantum States

After the field is quantized, it is natural to ask what kind of quantum states photons can possess. In the following, we first introduce several photonic states that people frequently encounter, i.e., the Fock states, the coherent states and the thermal states.

The Fock state. The quantization of the electromagnetic field is most obviously represented by the quantized value of the number operator $a^\dagger a$, which is directly related to the Hamiltonian of the electromagnetic fields through Eq. (82.10). Fock states $|n\rangle$ are the eigenstates of the number operators,

$$a^\dagger a |n\rangle = n |n\rangle . \quad (82.11)$$

For a single mode, the commutation relation in Eq. (82.8) reduces to $[a, a^\dagger] = 1$. It is easy to find that $a |n\rangle$ is also an eigenstate of the number operator,

$$a^\dagger a a |n\rangle = (a a^\dagger - 1) a |n\rangle = (n - 1) a |n\rangle . \quad (82.12)$$

Therefore, $a |n\rangle = c |n - 1\rangle$ with c being a constant, which can be determined from the inner product $\langle n | a^\dagger a |n\rangle = \langle n - 1 | c^* c |n - 1\rangle$ that $c = \sqrt{n}$. This then leads to

$$|n\rangle = \frac{a^{\dagger n}}{\sqrt{n!}} |0\rangle . \quad (82.13)$$

Obviously, there is a lower limit of the number in the number states,

$$a |0\rangle = 0 . \quad (82.14)$$

Here, $|0\rangle$ is also called the vacuum state, which is also an eigenstate of the annihilation operator. Note that $\langle 0 | H |0\rangle = \hbar\omega/2$ for a single mode. This is called the zero-point energy of the mode. It diverges for infinitely many-mode fields. This cannot be measured, and hence no physical consequence exists. However, the differences of the zero-point energy are finite and are related to the Casimir force and the van der Waals force.

In the following, we are going to introduce a more general form of the eigenstate of the annihilation operator.

The coherent state. A coherent state is an eigenstate of the annihilation operator a ,

$$a |\alpha\rangle = \alpha |\alpha\rangle , \quad (82.15)$$

and in the basis of the number states,

$$|\alpha\rangle = \sum_n e^{-|\alpha|^2/2} \frac{\alpha^n}{\sqrt{n!}} |n\rangle . \quad (82.16)$$

The photon number distribution

$$p_n = e^{-\langle n \rangle} \frac{\langle n \rangle^n}{n!} , \quad (82.17)$$

is Poissonian with the mean value $\langle n \rangle = |\alpha|^2$. The variance is equal to its mean value,

$$\langle \Delta n^2 \rangle = \langle n^2 \rangle - \langle n \rangle^2 = \langle n \rangle . \quad (82.18)$$

One important property of the coherent state is that they form a complete set,

$$\frac{1}{\pi} \int d^2\alpha |\alpha\rangle \langle \alpha| = 1 , \quad (82.19)$$

where $\alpha = x + iy$ and $d^2\alpha = dx dy$ with x and y being real numbers. However, different from the complete set formed by the number states, the basis states of the coherent states are not orthogonal,

$$\langle \alpha | \beta \rangle = \exp\left(\alpha^* \beta - \frac{|\alpha|^2}{2} - \frac{|\beta|^2}{2}\right) . \quad (82.20)$$

The nonorthogonality of the coherent states leads to an important property of the coherent state, namely, we can represent a coherent state in the form of other coherent states,

$$|\alpha\rangle = \frac{1}{\pi} \int \langle \beta | \alpha \rangle |\beta\rangle d^2\beta . \quad (82.21)$$

Any coherent state can be generated by the displacement of the vacuum state,

$$|\alpha\rangle = D(\alpha) |0\rangle , \quad (82.22)$$

where $D(\alpha)$ is the displacement operator

$$D(\alpha) = \exp(\alpha a^\dagger - \alpha^* a) . \quad (82.23)$$

The displacement operator has the following important properties,

$$\begin{aligned} D^{-1}(\alpha) &= D^\dagger(\alpha) = D(-\alpha) , \\ D^\dagger(\alpha) G(a, a^\dagger) D(\alpha) &= G(a + \alpha, a^\dagger + \alpha^*) , \\ D(\alpha) D(\beta) &= D(\alpha + \beta) \exp[(\alpha\beta^* - \alpha^*\beta)/2] . \end{aligned} \quad (82.24)$$

Here, G is any function of annihilation and creation operators.

The thermal state. The Fock states and the coherent states are both pure states. In contrast, thermal states are mixed states and can only be represented by the density matrices,

$$\rho_T = \frac{\exp(-\beta \hbar \omega a^\dagger a)}{\text{Tr}[\exp(-\beta \hbar \omega a^\dagger a)]} , \quad (82.25)$$

where $\beta = 1/k_B T$. In terms of the Fock states,

$$\rho_T = \sum_{n=0}^{\infty} \frac{\langle n \rangle^n}{(1 + \langle n \rangle)^{n+1}} |n\rangle \langle n| , \quad (82.26)$$

where the average photon number $\langle n \rangle = 1/[\exp(\beta \hbar \omega) - 1]$, which is Planck's law.

82.4 Field Observables: Quadratures

The above three kinds of states are different in their quantum statistical properties, which can be measured by physical observables of the fields. However, the annihilation and creation operators are not Hermitian or directly measurable. Instead, the measurable quantities in experiments are, besides the photon number distributions, the amplitudes and phases of the fields, e.g., the real and imaginary parts of the electric fields. These are called in-phase and out-of-phase quadratures, which can be measured by homodyne detection. We can define two Hermitian quadrature operators, X and Y ,

$$X = \frac{a + a^\dagger}{\sqrt{2}}, Y = \frac{a - a^\dagger}{\sqrt{2}i}. \quad (82.27)$$

The commutation relation between X and Y is

$$[X, Y] = i, \quad (82.28)$$

analogous to the position-momentum commutation relation. Therefore, we can represent the operator Y with $Y = -i(\partial/\partial X)$. The Hamiltonian $H = \hbar\omega(a^\dagger a + 1/2)$ can be rewritten as $H = (X^2 + Y^2)/2$, which is similar to the one of the harmonic oscillators. The number state can be represented with variable X in a similar way as in the harmonic oscillator,

$$\Psi_n(X) = \langle X|n\rangle = (2^n n! \sqrt{\pi})^{-1/2} H_n(X) e^{-X^2/2}, \quad (82.29)$$

where $H_n(X)$ is the Hermite polynomial of degree n .

The variance of the quadratures reflects the fluctuations in the amplitudes and phases of the fields,

$$\begin{aligned} \langle \Delta X^2 \rangle &= \frac{\langle a^2 \rangle + \langle a^{\dagger 2} \rangle}{2} + \langle n \rangle + \frac{1}{2} - \frac{\langle a + a^\dagger \rangle^2}{2} \\ \langle \Delta Y^2 \rangle &= -\frac{\langle a^2 \rangle + \langle a^{\dagger 2} \rangle}{2} + \langle n \rangle + \frac{1}{2} + \frac{\langle a - a^\dagger \rangle^2}{2} \end{aligned} \quad (82.30)$$

For Fock states or thermal states, $\langle \Delta X^2 \rangle = \langle \Delta Y^2 \rangle = \langle n \rangle + 1/2$. For coherent states, $\langle \Delta X^2 \rangle = \langle \Delta Y^2 \rangle = 1/2$. The coherent states are the minimum uncertainty states as the product $\langle \Delta X \Delta Y \rangle$ takes the minimum value $1/2$.

82.5 Phase-Space Representations of the Light: P , Q , and Wigner Functions

The quantum nature of light is evidently represented by the number states. On the other hand, in classical electromagnetic theory, according to the Maxwell equations,

light can be represented by harmonic oscillations of the fields. Classically, we can describe the center of mass of a particle with its position and momentum. For an ensemble of particles, we can define a probability distribution $P(x, p)$ (phase-space distribution) to study their statistics. However, in quantum mechanics, x and p do not commute, and thus cannot have definite values at the same time. E. Wigner tried to incorporate quantum mechanics into the classical statistics. By doing this, the noncommutative nature in quantum mechanics is demonstrated by negative values of the Wigner quasi probability. The same problem exists in a probability description of the light field with respect to its amplitude and phase. In this section, we are going to introduce several representations of light in phase space.

P -representation. Glauber and Sudarshan proposed to use the coherent states as a basis to describe the light field [3, 4]. The coherent state basis, even though composed by states that are nonorthogonal, can represent any radiation field

$$\rho = \int P(\alpha) |\alpha\rangle \langle \alpha| d^2\alpha, \quad (82.31)$$

with the normalization condition $\int P(\alpha) d^2\alpha = 1$. This representation is called Glauber–Sudarshan P -representation. The $P(\alpha)$ is not necessarily positive, and thus cannot be simply regarded as a probability. For the Fock states, $\rho = |n\rangle \langle n|$, the P -function is highly singular,

$$P_n(\alpha) = e^{|\alpha|^2} \frac{1}{n!} \frac{\partial^{2n}}{\partial \alpha^n \partial \alpha^{*n}} \delta^2(\alpha). \quad (82.32)$$

For a coherent state $|\alpha_0\rangle$, the P -function is completely classical,

$$P_c(\alpha) = \delta^{(2)}(\alpha - \alpha_0). \quad (82.33)$$

Likewise for a thermal state $\rho_T = \exp(-\beta\hbar\omega a^\dagger a) / \text{Tr}[\exp(-\beta\hbar\omega a^\dagger a)]$, the P -function is classical [3],

$$P_T(\alpha) = \frac{1}{\pi \langle n \rangle} \exp\left(-\frac{|\alpha|^2}{\langle n \rangle}\right). \quad (82.34)$$

The P -representation is convenient to evaluate normally ordered quantities, such as

$$\langle a^{\dagger m} a^n \rangle = \int P(\alpha) \alpha^{*m} \alpha^n d^2\alpha. \quad (82.35)$$

We will use the singularity or negativity of the P -function to characterize the strict quantum nature of the field. This is because the experimentally measured observables correspond to the normally ordered moments like $\langle a^{\dagger m} a^n \rangle$.

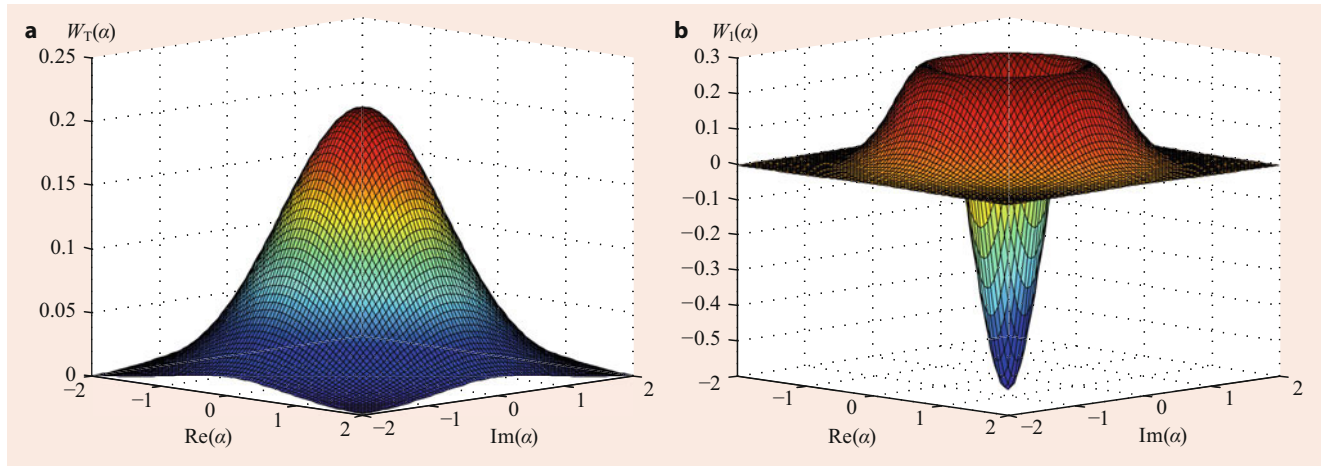

Fig. 82.1 The Wigner function of a thermal state (a) and single-photon state (b)

***Q*-representation.** Different from the *P*-functions, the *Q*-function has the properties of a classical probability distribution,

$$Q(\alpha) = \frac{1}{\pi} \langle \alpha | \rho | \alpha \rangle. \quad (82.36)$$

Q-functions are convenient to evaluate antinormally ordered moments of a and a^\dagger ,

$$\begin{aligned} \langle a^n a^{\dagger m} \rangle &= \text{Tr} \left(\frac{1}{\pi} \int a^n | \alpha \rangle \langle \alpha | a^{\dagger m} \rho d^2 \alpha \right) \\ &= \frac{1}{\pi} \int \alpha^n \alpha^{*m} \langle \alpha | \rho | \alpha \rangle d^2 \alpha \\ &= \int \alpha^n \alpha^{*m} Q(\alpha) d^2 \alpha. \end{aligned} \quad (82.37)$$

By substituting Eq. (82.31) in Eq. (82.36), we obtain the relation between the *P* and *Q*-functions,

$$Q(\alpha) = \frac{1}{\pi} \int P(\beta) \exp(-|\alpha - \beta|^2) d^2 \beta. \quad (82.38)$$

The *Q*-function of a thermal field is

$$Q_T(\alpha) = \frac{1}{\pi(1 + \langle n \rangle)} \exp\left(-\frac{|\alpha|^2}{1 + \langle n \rangle}\right), \quad (82.39)$$

which is Gaussian.

The *P* and *Q*-functions can be written as integrals of their characteristic functions,

$$\begin{aligned} P(\alpha) &= \frac{1}{\pi^2} \int d^2 \beta e^{-\beta \alpha^* + \beta^* \alpha} C_P(\beta), \\ Q(\alpha) &= \frac{1}{\pi^2} \int d^2 \beta e^{-\beta \alpha^* + \beta^* \alpha} C_Q(\beta), \end{aligned} \quad (82.40)$$

where $C_P(\beta) = \text{Tr}(e^{\beta \alpha^\dagger} e^{-\beta^* a} \rho)$ and $C_Q(\beta) = \text{Tr}(e^{-\beta^* a} e^{\beta \alpha^\dagger} \rho)$. Other phase-space representations can be

obtained by using different characteristic functions, such as the Wigner function in the following.

The Wigner representation. We next discuss the Wigner function. This function has great practical utility as it always exists and can be experimentally measured, and, thus, nonclassical aspects are easily accessible via the Wigner function. The Wigner function is defined as

$$W(\alpha) = \frac{1}{\pi^2} \int d^2 \beta \text{Tr}[\rho D(\beta)] e^{-\beta \alpha^* + \beta^* \alpha}, \quad (82.41)$$

where $D(\beta)$ is the displacement operator. The characteristic function of the Wigner function is $C_W = \text{Tr}[\rho D(\beta)]$. For a coherent state $|\gamma\rangle$, the Wigner function is

$$W_c(\alpha) = \frac{2}{\pi} \exp(-2|\alpha - \gamma|^2), \quad (82.42)$$

which is a Gaussian distribution with a width $1/2$. The Wigner function is related to the *P*-function,

$$W(\alpha) = \frac{2}{\pi} \int P(\gamma) \exp(-2|\alpha - \gamma|^2) d^2 \gamma. \quad (82.43)$$

The Wigner function of a thermal state is

$$W_T(\alpha) = \frac{1}{\pi(\langle n \rangle + 1/2)} \exp\left[-\frac{|\alpha|^2}{\langle n \rangle + 1/2}\right], \quad (82.44)$$

which is Gaussian as shown in Fig. 82.1a.

The Wigner function of a Fock state is more complicated,

$$W_n(\alpha) = \frac{2}{\pi} (-1)^n e^{-2|\alpha|^2} L_n(4|\alpha|^2), \quad (82.45)$$

where $L_n(x)$ is the n -th order Laguerre polynomial. Obviously, Wigner functions can be negative. Shown in Fig. 82.1b

is the Wigner function of the single-photon number state

$$W_1(\alpha) = \frac{2}{\pi} e^{-2|\alpha|^2} (4|\alpha|^2 - 1), \quad (82.46)$$

which is clearly maximally negative at $|\alpha| = 0$.

For an arbitrary state, the Wigner function at the zero point is used in many tests of nonclassicality,

$$W(0) = \frac{2}{\pi} \sum_{n=0}^{\infty} \rho_{nn} (-1)^n = \frac{2}{\pi} \langle \exp(i\pi a^\dagger a) \rangle, \quad (82.47)$$

which is related to the average value of the parity operator or $\exp(i\pi a^\dagger a)$. For a single-photon Fock state $W(0) = -2/\pi$. Another important property is that the Wigner function is square-integrable,

$$\text{Tr} \rho^2 = \pi \int d^2\alpha W^2(\alpha) \leq 1. \quad (82.48)$$

The negativity of the Wigner function at the origin has been used to test the nonclassicality. *Haroche* and collaborators [5] measured the negativity of the Wigner function for the Fock state $|1\rangle$ using cavity QED. More recently, this was measured for ionic motion (boson) [6]. Further, the negativity of the Wigner function for a set of states equivalent to non-Gaussian states including Fock states is measured [7].

82.6 Squeezed State

One of the most important nonclassical fields is the squeezed state, which was discovered by *Yuen* [8]. It only gained popularity after *Caves* proposed its great advantage in measurements beyond the standard quantum noise limit (SQL) [9]. The effectiveness of the squeezed states was first demonstrated by *Kimble's* group by a 3-dB sensitivity enhancement [10]. We will discuss this issue later. Here, we first discuss the measurable properties of the squeezed states.

Squeezing operator. We have shown that the coherent state can be generated by applying a displacement operator on the vacuum state. The squeezed state $|\xi\rangle$ can also be generated by applying a squeezing operator $S(\xi)$ on the vacuum state,

$$|\xi\rangle = S(\xi)|0\rangle, \quad (82.49)$$

where

$$S(\xi) = \exp(\xi a^{\dagger 2}/2 - \xi^* a^2/2), \quad (82.50)$$

and $\xi = r e^{i\phi}$ is a complex number.

The expansion of the squeezed state in the Fock-state basis is given by

$$|\xi\rangle = \frac{1}{\sqrt{\cosh r}} \sum_{n=0}^{\infty} e^{in\phi} (\tanh r)^n \frac{\sqrt{(2n)!}}{n! 2^n} |2n\rangle, \quad (82.51)$$

where all the Fock states with odd numbers are missing.

The action of the squeezing operator to the annihilation operator yields

$$a(\xi) = S^\dagger(\xi) a S(\xi) = a \cosh r + a^\dagger e^{i\phi} \sinh r. \quad (82.52)$$

Note that Eq. (82.52) also represents the Bogoliubov transformation. The squeezed state is the vacuum state of the transformed annihilation operator

$$a(-\xi)|\xi\rangle = 0. \quad (82.53)$$

To see the effect of squeezing, let us define a general quadrature X_θ ,

$$X_\theta = \frac{a e^{-i\theta} + a^\dagger e^{i\theta}}{\sqrt{2}}, \quad (82.54)$$

which is conjugate to $X_{\theta+\pi/2}$ and satisfies the commutation relation $[X_\theta, X_{\theta+\pi/2}] = i$. The variance of $X_{\phi/2}$ of a squeezed state $|\xi\rangle$ is

$$(\Delta X_{\phi/2})^2 = \frac{1}{2} e^{2r}, \quad (82.55)$$

while for the conjugate quadrature, $(\Delta X_{\phi/2+\pi/2})^2 = (1/2) e^{-2r}$. Therefore, the squeezed state has a squeezed quadrature $X_{\phi/2+\pi/2}$ and a stretched quadrature $X_{\phi/2}$. To see the nonclassicality of the squeezed state, we introduce the squeezing parameter [8]

$$S_\theta = \langle : (X_\theta)^2 : \rangle - \langle X_\theta \rangle^2, \quad (82.56)$$

where $::$ stands for the normal ordering of the operators between them; S is related to the variance of the quadrature by $S_\theta = (\Delta X_\theta)^2 - 1/2$. The negative value of S is a sufficient condition for nonclassicality. Obviously, for the squeezed state, $S_{\phi/2-\pi/2} = -(1 - e^{-2r})/2 < 0$, which is a signature of the nonclassicality of the squeezed vacuum.

The representation of the squeezed state in the quadrature- X space can be obtained from Eq. (82.53),

$$\Psi_\xi(X) = \Psi^{(0)} \exp\left(-\frac{1}{2} X^2 \frac{\cosh r - e^{i\phi} \sinh r}{\cosh r + e^{i\phi} \sinh r}\right), \quad (82.57)$$

which is a Gaussian wavefunction with chirped width (due to the complex parameter in the exponent).

Fig. 82.2 The Wigner function of a squeezed state with $r = 1$, $\phi = 0$ (a), and $\phi = \pi$ (b)

Phase-space representations. While the P -function of the squeezed states does not exist, the Q -function and Wigner function are

$$Q_{\xi}(\alpha) = \frac{1}{\pi \cosh r} \exp\left[\frac{\tanh r}{2}(e^{i\phi}\alpha^{*2} + e^{-i\phi}\alpha^2) - |\alpha|^2\right], \quad (82.58)$$

and

$$W_{\xi}(\alpha) = \frac{2}{\pi} \exp(-2|\alpha \cosh r - \alpha^* e^{i\phi} \sinh r|^2). \quad (82.59)$$

The Wigner functions of a squeezed state with the same squeezing amplitude but different squeezing angles are plotted in Fig. 82.2. The Wigner function for the squeezed states is Gaussian and does not exhibit a nonclassical nature, which is truly reflected by the P -function.

The squeezed coherent state. The squeezed coherent state is defined by first squeezing the vacuum state and then displacing it,

$$|\xi, \beta\rangle = D(\beta)S(\xi)|0\rangle. \quad (82.60)$$

The annihilation operator transforms under these two operations,

$$\begin{aligned} a(\xi, \beta) &= S^{\dagger}(\xi)D^{\dagger}(\beta)aD(\beta)S(\xi) \\ &= a \cosh r + a^{\dagger} e^{i\phi} \sinh r + \beta. \end{aligned} \quad (82.61)$$

The Q -function and Wigner function of $|\xi, \beta\rangle$ are

$$\begin{aligned} Q_{\xi\beta}(\alpha) &= Q_{\xi}(\alpha - \beta), \\ W_{\xi\beta}(\alpha) &= W_{\xi}(\alpha - \beta). \end{aligned} \quad (82.62)$$

The squeezed thermal state. The squeezed thermal state can be obtained by applying the squeezing operator to the thermal state density matrix,

$$\rho = S(\xi)\rho_T S^{\dagger}(\xi). \quad (82.63)$$

The Wigner function of the squeezed thermal state is

$$\begin{aligned} W_{\rho}(\alpha) &= \frac{2}{\pi(2\langle n \rangle + 1)} \\ &\times \exp\left(-\frac{2}{2\langle n \rangle + 1}|\alpha \cosh r - \alpha^* e^{i\phi} \sinh r|^2\right). \end{aligned} \quad (82.64)$$

Nonclassicality. To characterize the nonclassicality of the squeezed states, we need to introduce a physical quantity that can tell us its quantum feature. Mandel observed that the photon number distribution of the coherent state is Poissonian and realized that a state with narrower variance is the feature of a nonclassical field. He introduced the parameter [11],

$$Q_M = \frac{\langle (a^{\dagger}a)^2 \rangle - \langle a^{\dagger}a \rangle^2 - \langle a^{\dagger}a \rangle}{\langle a^{\dagger}a \rangle} \quad (82.65)$$

to quantify the nonclassicality of the field [12–15]. The P -function of a coherent field is a delta function, which is in accord with the classical probability distribution. The Q_M of a classical field is zero. In contrast, there are singularities in the P -function of the number states. The Q_M of a number state is -1 . The negativity of Q_M is a sufficient condition for a nonclassical field.

While the Mandel Q_M factor is super-Poissonian for a squeezed state, $Q_M(\xi) = 1 + 2 \sinh^2 r = 1 + 2\langle a^{\dagger}a \rangle$, the Q_M factor for a squeezed coherent state, e.g., with phase

Fig. 82.3 The Mandel Q_M -factor as a function of r and β for the squeezed coherent state $|\xi, \beta\rangle$, $\phi = \pi$

$\phi = \pi$,

$$Q_M(\xi, \beta) = \frac{\sinh^4 r + 2\beta^2 \sinh^2 r + \sinh^2 r \times \cosh^2 r - 2\beta^2 \sinh r \cosh r}{\beta^2 + \sinh^2 r}, \quad (82.66)$$

can be negative, as shown in Fig. 82.3.

82.7 Detection of Quantum Light by Array Detectors

In this section, we discuss only the array detectors that have recently become in vogue in the study of the statistics of quantum fields although photon counting devices have been extensively used in past. The characterization of quantum light requires the detection of photons. However, ideal photon-number-resolving measurement devices are typically not available. For example, avalanche photodiodes in the Geiger mode can only distinguish between the presence (“click” or “on”) and the absence (“no click” or “off”) of photons. To overcome this deficiency, different measurement schemes have been proposed and implemented. One of the most successful approaches is the multiplexed detection of photons [16]. In such a measurement layout, a beam of light is split into N beams with equal and reduced intensities. Subsequently, experimentally accessible on–off detectors, such as avalanche photodiodes, can be used to measure the resulting quantum light fields.

Typically, the photon-number distribution takes the form of a quantum version of a Poisson distribution. However, the theory of multiplexing layouts with N on–off detectors

yields statistics resembling a binomial distribution [17],

$$c_k = \frac{N!}{k!(N-k)!} \langle : \pi^{N-k} (1-\pi)^k : \rangle, \quad (82.67)$$

where $::$ denotes the normal ordering, k is the number of recorded clicks, and $\hat{\pi}$ describes the measurement operator for a click of a single on–off detector including its imperfections. In fact, coherent light, describing a classical radiation field, yields a true binomial distribution. Consequently, non-classical light can be identified via the binomial parameter as follows [18],

$$Q_B = N \frac{(\Delta k)^2}{\bar{k}(N-\bar{k})} - 1 < 0, \quad (82.68)$$

where \bar{k} and $(\Delta k)^2$ are the mean value and the variance of the click-counting distribution c_k , respectively. The binomial parameter generalizes the Mandel Q -parameter [11] to the case of measurements with on–off detectors. Moreover, in the limit of an infinite number of detectors, the binomial click statistics converges to the actual Poisson distribution of the photons.

As an example, let us consider the click-counting statistics of an n -photon state measured with N on–off detectors with a quantum efficiency η . This scenario yields $Q_B = (N-1)([1-2\eta/N]^n - [1-\eta/N]^{2n})(1-[1-\eta/N]^n)^{-1}[1-\eta/N]^{-n}$, which is negative for all efficiencies $\eta > 0$ ($N \geq 2$ and $n \geq 1$). This means that an n -photon state represents a sub-binomial, i.e., nonclassical, state of light [18]. For a large number of detectors ($N \gg 1$), we approach the well-known Mandel parameter for photons, $Q_B \approx -\eta(1-1/N)$, as was mentioned previously. This example demonstrates the direct application of the method for verifying quantum properties of quantized radiation fields, as shown in Fig. 82.4a. Furthermore, the click-counting theory can be directly employed to analyze data and characterize experiments [19–22].

Fig. 82.4 $Q_B < 0$ certifies the nonclassicality of n -photon states as a function of η for only two on–off detectors ($N = 2$)

Besides the applications to certify quantum properties based on the photon-number statistics, the click-counting theory additionally allows for more advanced techniques to characterize and manipulate quantum light. For example, employing multiplexing detectors in interferometers [23] uncovers the click-counting counterpart of squeezing [24]. In addition, click-counting detectors can be used to implement advanced multiphoton heralding, addition, and subtraction protocols to generate nonclassical quantum states [25]. For instance, the heralding is based on the conditional click-counting statistics of a two-mode light field, which has been experimentally compared with the joint click-counting statistics [26].

82.8 Two-Mode Squeezed States

The squeezing operator can be generated in parametric downconversion (PDC) into the same optical modes. More generally, if the generated modes are different, the PDC process results in the two-mode squeezing.

The two-mode squeezing operator. The two-mode squeezed state can be generated from the operator

$$S(\xi) = \exp(\xi a^\dagger b^\dagger - \xi^* ab), \quad (82.69)$$

where $\xi = r e^{i\phi}$ is a complex number. We apply $S(\xi)$ to the two-mode vacuum state $|0, 0\rangle$,

$$\begin{aligned} |\xi\rangle &= S(\xi)|0, 0\rangle = \frac{1}{\cosh r} \exp(e^{i\phi} \tanh r a^\dagger b^\dagger) |0, 0\rangle \\ &= \frac{1}{\cosh r} \sum_{n=0}^{\infty} e^{in\phi} (\tanh r)^n |n, n\rangle. \end{aligned} \quad (82.70)$$

The interesting property of the two-mode squeezed states is that the two modes must contain the same number of photons. The operators a and b transform under two-mode squeezing

$$\begin{aligned} a(\xi) &= S^\dagger(\xi) a S(\xi) = a \cosh r + b^\dagger e^{i\phi} \sinh r, \\ b(\xi) &= S^\dagger(\xi) b S(\xi) = b \cosh r + a^\dagger e^{i\phi} \sinh r, \end{aligned} \quad (82.71)$$

which is a two-mode Bogoliubov transformation. By introducing two linearly combinational modes of a and b ,

$$d = \frac{a+b}{\sqrt{2}}, \quad c = \frac{a-b}{\sqrt{2}}, \quad (82.72)$$

we obtain the two-mode squeezing operator

$$\begin{aligned} \exp(\xi a^\dagger b^\dagger - \xi^* ab) &= \exp\left(\frac{\xi}{2} d^{\dagger 2} - \frac{\xi^*}{2} d^2\right) \\ &\quad \times \exp\left(-\frac{\xi}{2} c^{\dagger 2} + \frac{\xi^*}{2} c^2\right), \end{aligned} \quad (82.73)$$

which is a product of two single-mode squeezing operators.

The Q -function of the two-mode squeezed states is

$$\begin{aligned} Q_\xi(\alpha, \beta) &= \frac{1}{\pi} |\langle \alpha, \beta | \xi \rangle|^2 \\ &= \frac{1}{\pi \cosh^2 r} \\ &\quad \times \exp\left[e^{i\phi} \tanh r \alpha^* \beta^* + \text{c.c.}\right] - |\alpha|^2 - |\beta|^2, \end{aligned} \quad (82.74)$$

which is a Gaussian distribution of $\text{Re}\alpha$, $\text{Re}\beta$, $\text{Im}\alpha$, and $\text{Im}\beta$.

The Wigner function of the two-mode squeezed vacuum is

$$\begin{aligned} W_\xi(\alpha, \beta) &= \frac{4}{\pi^2} \exp(-2|\alpha \cosh r - \beta^* \sinh r e^{i\phi}|^2 \\ &\quad - 2|-\alpha^* \sinh r e^{i\phi} + \beta \cosh r|^2). \end{aligned} \quad (82.75)$$

The quadrature representation is

$$\begin{aligned} \Psi(X_a, X_b) &= \langle X_a, X_b | \xi \rangle \\ &= \frac{1}{\cosh r} \sum_{n=0}^{\infty} e^{in\phi} \tanh^n r \frac{1}{2^n n! \sqrt{\pi}} \\ &\quad \times H_n(X_a) H_n(X_b) e^{-(X_a^2 + X_b^2)/2} \\ &= \frac{1}{\sqrt{(1-\eta^2)\pi \cosh^2 r}} \\ &\quad \exp\left[\frac{2X_a X_b \eta - (X_a^2 + X_b^2)\eta^2}{1-\eta^2} - \frac{1}{2}(X_a^2 + X_b^2)\right], \end{aligned} \quad (82.76)$$

where $\eta = e^{i\phi} \tanh r$. This distribution of the quadratures is plotted in Fig. 82.5.

Cauchy–Schwarz inequality. The nonclassicality of the two-mode squeezed states can be measured by the Cauchy–Schwarz inequalities. For two well-defined functions f and g , the Cauchy–Schwarz inequality is $\langle f^* f \rangle \langle g^* g \rangle \leq |\langle f^* g \rangle|^2$ if the average is made with positive probability distributions. Considering the P -representation of the two-mode density matrix $\rho = \int P(\alpha, \beta) |\alpha, \beta\rangle \langle \alpha, \beta| d^2\alpha d^2\beta$, letting $f = \alpha^* a$ and $g = \beta^* b$, the Cauchy–Schwarz inequality in phase-space distribution is

$$\langle a^{\dagger 2} a^2 \rangle \langle b^{\dagger 2} b^2 \rangle \leq |\langle a^\dagger a b^\dagger b \rangle|^2. \quad (82.77)$$

Fig. 82.5 Quadrature distribution of a two-mode squeezed state $|\Psi(X_a, X_b)|^2$ for $r = 1$ and $\phi = 0$

A violation of this inequality can be regarded as a sufficient condition of nonclassicality. We define a parameter [27–29]

$$I = \frac{\sqrt{\langle a^{\dagger 2} a^2 \rangle \langle b^{\dagger 2} b^2 \rangle}}{\langle a^{\dagger} a b^{\dagger} b \rangle} - 1 \quad (82.78)$$

to measure this deviation. The quantity I has been used to measure the nonclassicality of both photons [30–32] and matter waves [33]. More recently, such a violation of nonclassicality using Eq. (82.78) was studied in phonon–photon interactions [34]; obviously, for a coherent state $I = 0$. For the two-mode squeezed states,

$$I = -\frac{\langle a^{\dagger} a \rangle}{\langle (a^{\dagger} a)^2 \rangle} = -\operatorname{sech} 2r < 0. \quad (82.79)$$

Therefore, the two-mode squeezed state is essentially nonclassical.

82.9 Quantum Entanglement

The two-mode states that cannot be written as a direct product of two quantum states, such as the two-mode squeezed states $|\xi\rangle \neq |\Psi_a\rangle |\Psi_b\rangle$, are called entangled states. Historically, entanglement was proposed by *Einstein, Podolsky, and Rosen* to challenge the completeness of quantum theory [35]. The entangled nonseparable states indicate that the measurement of one particle will project the other particle to a certain quantum state, even if the other particle is far away. They suggested the existence of hidden variables to explain the “spooky action at a distance” between entangled particles. *Bell* proposed an inequality to distinguish the predictions between the theories of hidden variables and quantum entanglement [36]. Many experiments have been done, and the results overwhelmingly support the quantum theory [37–41].

Entanglement has been widely used in quantum information [42–44]. We briefly introduce the basic properties of entanglement in the following.

Using the Peres–Horodecki criterion [45, 46] on the negativity of the partial transpose of the density matrix, we can measure the entanglement by the logarithmic negativity,

$$E_N(\rho) = \log_2[1 + 2N(\rho)]. \quad (82.80)$$

Here, $N(\rho)$ is the absolute value of the sum of the negative eigenvalues of the partial transpose density matrix ρ^{PT} , which is obtained by taking the transpose of the operators associated with the mode b . In the following, we calculate the parameter $E_N(\rho)$ for the state in Eq. (82.70). The density matrix is

$$\rho = \sum_{nm} c_n c_m^* |nn\rangle \langle mm|. \quad (82.81)$$

Its partial transpose is

$$\rho^{\text{PT}} = \sum_{nm} c_n c_m^* |nm\rangle \langle mn|. \quad (82.82)$$

This matrix can be block-diagonalized within the basis states $|mn\rangle$ and $|nm\rangle$ for any combination $n \neq m$, and the eigenvalues are $\pm |c_n c_m|$. The negativity is

$$E_N(\rho) = \log_2 \left(1 + \sum_{n \neq m} |c_n c_m| \right) = \log_2 \left(\sum_n |c_n| \right)^2. \quad (82.83)$$

For the two-mode squeezed vacuum state $|c_n| = (\tanh r)^n / \cosh r$, we obtain

$$E_N(\rho) = \log_2(e^{2r}). \quad (82.84)$$

The entanglement is measured by the squeezing parameter.

The reduced density matrix of mode a after tracing over the mode b is

$$\rho^{(a)} = \operatorname{Tr}_b |\xi\rangle \langle \xi| = \frac{1}{\cosh^2 r} \sum_{n=0}^{\infty} \tanh^{2n} r |n\rangle \langle n|, \quad (82.85)$$

which is a thermal state. Therefore, by measuring one mode, we lose the nonclassicality of the other mode. In particular, if we measure b and obtain a Fock state $|n\rangle$, we immediately know that the a -mode is also in the state $|n\rangle$. This is extensively used in experiments of generating single photons, which is called the heralded source of single photons.

Parametric downconversion. We can use parametric downconversion to generate two-mode squeezed states by considering a three-wave mixing process with the Hamiltonian

$$H = \hbar(Gfa^\dagger b^\dagger + \text{H.c.}), \quad (82.86)$$

where the frequency of the mode f is $\omega_f = \omega_a + \omega_b$, G is related to $\chi^{(2)}$, and the geometric factors of the crystal. If $\omega_a = \omega_b$, the Hamiltonian is reduced to one containing the a^2 -term, which describes single-mode squeezing.

The squeezing parameter $r = gt$ is proportional to the interaction time t , and g is an effective coupling constant. The evolution of the two mode operators is described by Eq. (82.71). The evolution of the quadratures of the combinational mode operators c and d in Eq. (82.72) obeys,

$$\begin{aligned} \frac{d(t) \pm d^\dagger(t)}{\sqrt{2}} &= e^{\pm r} \frac{d \pm d^\dagger}{\sqrt{2}}, \\ \frac{c(t) \pm c^\dagger(t)}{\sqrt{2}} &= e^{\mp r} \frac{c \pm c^\dagger}{\sqrt{2}}. \end{aligned} \quad (82.87)$$

After having passed through the crystal, the operators are obtained by scaling the ones input into the crystal. No quantum noise terms are added. This property is useful in phase-sensitive amplifiers, since one quadrature is amplified, while the other quadrature is attenuated. The signal-to-noise ratio of the quadrature,

$$\frac{\langle X_d(t) \rangle}{\sqrt{\langle X_d^2(t) \rangle - \langle X_d(t) \rangle^2}} = \frac{\langle X_d \rangle}{\sqrt{\langle X_d^2 \rangle - \langle X_d \rangle^2}}, \quad (82.88)$$

where $X_d = (d + d^\dagger)/\sqrt{2}$ does not change with time.

Type II parametric downconversion is widely used to generate entangled photons. The Hamiltonian can be written as

$$H = i\hbar g(e^{i\phi_1} a_H^\dagger b_V^\dagger + e^{i\phi_2} a_V^\dagger b_H^\dagger - \text{H.c.}), \quad (82.89)$$

where the photons with orthogonal polarizations travel in different directions. To first order in the coupling, the photons generated are entangled,

$$|\psi\rangle = \frac{|H_1, V_2\rangle + e^{i\chi}|V_1, H_2\rangle}{2}, \quad (82.90)$$

where χ is a phase factor. Such entangled states have been realized in experiments for up to 10 photons [47, 48]. Currently, the entanglement is widely used in the fields of quantum information science and quantum technology.

82.10 Non-Gaussian Nonclassical States

In this section, we introduce the quantum properties of two important non-Gaussian nonclassical states: the cat state and the single-photon added state.

Cat states. In 1935, Schrödinger proposed a thought experiment, which contains a radioactive atom, a vial of cyanide, and a cat. The electron emitted during the decay of the atom can trigger some mechanical device, which finally results in the release of the cyanide and kills the cat. However, a quantum mechanical description of the atom allows a superposition of the decayed and undecayed states. Consequently, the cat is in a superposition of dead and alive states. This later became known as Schrödinger's cat and led to a lively debate over the completeness of quantum mechanics.

When the excitation number is large, a classical state of a harmonic oscillator is naturally described by a coherent state. A superposition of two different coherent states is, therefore, thought of as a superposition of two classical states and traditionally called the cat states,

$$|\alpha_0\rangle_c = N^{-1}(|\alpha_0\rangle + e^{-i\phi} |-\alpha_0\rangle), \quad (82.91)$$

where $N = (2 + 2e^{-2|\alpha_0|^2} \cos \phi)^{1/2}$ is a normalization factor. Typically, a nonlinear medium like the Kerr medium can produce such cat states provided that the nonlinearity is strong. The Kerr medium can also produce a superposition of many coherent states lying on a circle [49]. The strong Kerr interaction can be realized in cavity QED and related setups. Such cat states have been created in trapped ions [6], and cavity quantum electrodynamic systems [50] with a dispersive cavity [51]. Multicomponent cat states as a superposition of several coherent states have also been realized in superconducting qubit systems [52, 53].

The coherent superposition of the two states results in interference of the wavefunction in the quadrature space,

$$\begin{aligned} |\Psi_c(x)|^2 &= |\langle x|\alpha_0\rangle_c|^2 \\ &= N^{-2} \pi^{-1/2} \\ &\quad \times \left[e^{-(x-x_0)^2} + e^{-(x+x_0)^2} \right. \\ &\quad \left. + 2e^{-(x^2+x_0^2)} \cos(\phi - 2y_0x) \right], \end{aligned} \quad (82.92)$$

where we have written $\alpha_0 = (x_0 + iy_0)/\sqrt{2}$. The oscillation of the probability appears in the complementary way of x and y . When $y_0 = 0$, $\Psi_c(x)$ does not oscillate, but the wavefunction with the conjugate variable $\Psi_c(y)$ oscillates.

The nonclassicality of the cat states can be shown by its Wigner function,

$$\begin{aligned} W_c(\alpha) &= \frac{2N^{-2}}{\pi} \\ &\quad \times \left[e^{-2|\alpha-\alpha_0|^2} + e^{-2|\alpha+\alpha_0|^2} \right. \\ &\quad \left. + 2e^{-2|\alpha|^2} \cos(\phi + 4\text{Im}\alpha_0^* \alpha) \right], \end{aligned} \quad (82.93)$$

where the oscillation of the cosine function results in negativity of the Wigner function, as is shown in Fig. 82.6.

Fig. 82.6 The Wigner function of a cat state with $\alpha_0 = 2$ and $\phi = 0$

Single-photon-added states. If we add a photon to a classical state, we can generate a nonclassical state [54]. A simple example is the vacuum state. By adding a photon, it becomes a single-photon state, which is highly nonclassical. The density matrix of a single-photon-added state is related to the original density matrix by

$$\rho^{(a)} = \frac{a^\dagger \rho a}{\text{Tr}(a^\dagger \rho a)}. \tag{82.94}$$

The Q -function and P -function are related to the original one by

$$\begin{aligned} Q^{(a)}(\alpha) &= \frac{\langle \alpha | a^\dagger \rho a | \alpha \rangle}{\langle a a^\dagger \rangle} = \frac{|\alpha|^2}{\langle a a^\dagger \rangle} Q(\alpha), \\ P^{(a)}(\alpha) &= \frac{e^{|\alpha|^2}}{\langle a a^\dagger \rangle} \frac{\partial^2}{\partial \alpha \partial \alpha^*} P(\alpha) e^{-|\alpha|^2}. \end{aligned} \tag{82.95}$$

It is clear that the Q -function can become zero (for the vacuum state) and the P -function can become negative, even if the original functions are classical. For example, it is easy to calculate the P -function of the single-photon-added thermal state [55],

$$P_T^{(a)}(\alpha) = \frac{1 + \langle n \rangle}{\langle n \rangle^2} \left[|\alpha|^2 - \frac{\langle n \rangle}{1 + \langle n \rangle} \right] P_T(\alpha). \tag{82.96}$$

For $|\alpha|^2 < \langle n \rangle / (1 + \langle n \rangle)$, $P_T^{(a)}(\alpha) < 0$.

The P -function for a single-photon-added coherent state is singular. It is more convenient to use the Wigner function to characterize its nonclassical behavior. The general relation between the Wigner functions after adding the single photon is,

$$W^{(a)}(\alpha) = \frac{1}{\langle a a^\dagger \rangle} \left(\alpha^* - \frac{1}{2} \frac{\partial}{\partial \alpha} \right) \left(\alpha - \frac{1}{2} \frac{\partial}{\partial \alpha^*} \right) W(\alpha). \tag{82.97}$$

For a photon-added coherent state, the result is

$$\begin{aligned} W_c^{(a)}(\alpha) &= \frac{2}{\pi(1 + |\alpha_0|^2)} \\ &\times [4|\alpha|^2 - 2(\alpha^* \alpha_0 + \alpha \alpha_0^*) - 1 + |\alpha_0|^2] \\ &\times e^{-2|\alpha - \alpha_0|^2}, \end{aligned} \tag{82.98}$$

which can be negative.

The quadrature representation of the single-photon-added coherent classical state is

$$\Psi_c^{(a)}(x) = \frac{\langle x | a^\dagger | \alpha \rangle}{\sqrt{1 + |\alpha|^2}} = \frac{1}{\sqrt{2}} \frac{2x - \sqrt{2}\alpha}{\sqrt{1 + |\alpha|^2}} \Psi_c(x), \tag{82.99}$$

which has a zero at $x = \alpha / \sqrt{2}$. Here we have used $a^\dagger = (x - \partial/\partial x) / \sqrt{2}$.

The single-photon-added coherent states [56–58] and thermal states [59] have been realized in experiments, and several properties, as originally predicted [54, 55], have been measured. The negativity of the Wigner function mentioned above has been tested using the photon addition or subtraction on Gaussian states [60].

82.11 Beam Splitter, Interferometer, and Measurement Sensitivity

Beam splitter. At a beam splitter as shown in Fig. 82.7, the input modes a and b are transformed to the output modes c and d by

$$\begin{pmatrix} c \\ d \end{pmatrix} = \begin{pmatrix} t_1 & r_2 \\ r_1 & t_2 \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} = U \begin{pmatrix} a \\ b \end{pmatrix}, \tag{82.100}$$

where $r_{1,2}$ and $t_{1,2}$ are the two reflection and transmission coefficients at the two sides of the beam splitter. The lossless beam splitter has the requirement that U is unitary, which leads to,

$$|t_1|^2 + |r_1|^2 = |t_2|^2 + |r_2|^2 = 1, t_1^* r_2 + r_1^* t_2 = 0. \tag{82.101}$$

Fig. 82.7 Beam splitter

Fig. 82.8 The second-order correlation function as a function of the time delay (controlled by the position of the beam splitter) between the two single photons. Adopted from [61]

For a symmetric beam splitter, $r_1 = r_2$, $t_1 = t_2$, we can rewrite U as

$$U = \begin{pmatrix} \cos \theta & i \sin \theta \\ i \sin \theta & \cos \theta \end{pmatrix}. \quad (82.102)$$

When $\theta = \pi/2$, it is a 50–50 beam splitter.

A remarkable feature of the beam splitter is the Hong–Ou–Mandel effect [61]. Two photons incident at a 50–50 beam splitter simultaneously bunch together to come out from either one of the output modes. This can be easily seen by

$$\begin{aligned} |1, 1\rangle_{\text{out}} &= \frac{1}{2}(c^\dagger + id^\dagger)(d^\dagger + ic^\dagger)|0\rangle \\ &= \frac{i}{\sqrt{2}}(|2, 0\rangle + |0, 2\rangle). \end{aligned} \quad (82.103)$$

Two single photons get entangled to become a two-photon NOON state [62] at a beam splitter, i.e., two detectors cannot click at the same time, if the two single photons arrive at the beam splitter simultaneously. Note that a NOON state is one in which N photons can exist either in one mode or the other mode, i.e., it has the structure $(|N, 0\rangle + |0, N\rangle)/\sqrt{2}$. The second-order correlation function $g^{(2)}(\tau)$ as a function of the time delay between the two single-photon pulses was measured in the original Hong–Ou–Mandel experiment, as shown in Fig. 82.8.

However, if $n > 1$, we cannot obtain an n -photon NOON state, although the output state is still entangled.

Mach–Zehnder interferometer. The Mach–Zehnder interferometer is composed of two successive beam splitters. The two output modes of the first beam splitter are directed to the two input modes of the second beam splitter by two mirrors,

Fig. 82.9 Mach–Zehnder interferometer. Adopted from [1]

as shown in Fig. 82.9. In one of the two split light paths, we have a tunable phase ϕ . The output fields at detectors D_1 and D_2 are,

$$\begin{aligned} a_{\text{out}}(D_1) &= \frac{1}{\sqrt{2}} \left(-\frac{a+ib}{\sqrt{2}} - ie^{-i\phi} \frac{b+ia}{\sqrt{2}} \right) \\ &= (-ie^{-i\phi/2}) \left(a \sin \frac{\phi}{2} + b \cos \frac{\phi}{2} \right), \\ b_{\text{out}}(D_2) &= \frac{1}{\sqrt{2}} \left(-e^{-i\phi} \frac{b+ia}{\sqrt{2}} - i \frac{a+ib}{\sqrt{2}} \right) \\ &= (-ie^{-i\phi/2}) \left(a \cos \frac{\phi}{2} - b \sin \frac{\phi}{2} \right). \end{aligned} \quad (82.104)$$

If one of the input modes, e.g., b , is the vacuum state, the output photon numbers are

$$\begin{aligned} \langle a_{\text{out}}^\dagger a_{\text{out}} \rangle &= \sin^2 \frac{\phi}{2} \langle a^\dagger a \rangle, \\ \langle b_{\text{out}}^\dagger b_{\text{out}} \rangle &= \cos^2 \frac{\phi}{2} \langle a^\dagger a \rangle. \end{aligned} \quad (82.105)$$

Therefore, the phase can be measured by the detectors.

Sensitivity of the interferometer. Now we calculate the sensitivity of the Mach–Zehnder interferometer with respect to the phase ϕ . We take the signal to be the difference between the intensities of the a_{out} and b_{out} modes. We assume that mode a is in a coherent state $|\alpha\rangle$, and the mode b is either in vacuum or squeezed vacuum state, then

$$\begin{aligned} S &= \langle b_{\text{out}}^\dagger b_{\text{out}} \rangle - \langle a_{\text{out}}^\dagger a_{\text{out}} \rangle \\ &= (\langle b^\dagger b \rangle - |\alpha|^2) \cos \phi \\ &\approx \delta\phi (|\alpha|^2 - \langle b^\dagger b \rangle), \end{aligned} \quad (82.106)$$

for small $\delta\phi$ around $\phi = \pi/2$, i.e., $\phi = \pi/2 + \delta\phi$. We next calculate the noise in the measured signal

$$(\Delta S)^2 = \langle S^2 \rangle - \langle S \rangle^2. \quad (82.107)$$

The calculation based on the properties of the squeezed vacuum and coherent states shows that

$$\begin{aligned} (\Delta S)^2 &= (|\alpha|^2 \langle (be^{i\theta} + b^\dagger e^{-i\theta})^2 \rangle + \sinh^2 r) \\ &= (|\alpha|^2 e^{-2r} + \sinh^2 r), \quad \alpha = |\alpha| e^{-i\theta}. \end{aligned} \quad (82.108)$$

We chose the phases such that the quadrature $be^{i\theta} + b^\dagger e^{-i\theta}$ is squeezed. Thus, the signal-to-noise ratio becomes

$$\begin{aligned} \frac{S}{N} &= \frac{\langle b^\dagger b - a^\dagger a \rangle}{\sqrt{\langle (b^\dagger b - a^\dagger a)^2 \rangle - \langle b^\dagger b - a^\dagger a \rangle^2}} \\ &= \frac{(|\alpha|^2 - \sinh^2 r) \delta\phi}{(|\alpha|^2 e^{-2r} + \sinh^2 r)^{1/2}}, \end{aligned} \quad (82.109)$$

which for $r = 0$ is $(S/N) = |\alpha| \delta\phi$ leading to the shot noise limit or the standard quantum noise limit (SQL) of the phase sensitivity $\delta\phi = 1/(|\alpha|)$. Clearly, the above equation, Eq. (82.109), shows that with squeezed light applied to one of the ports, the phase sensitivity improves considerably

$$\delta\phi \approx \frac{1}{|\alpha| e^r} \quad \text{if } |\alpha|^2 \gg \sinh^2 r. \quad (82.110)$$

We say that we have sensitivity better than the SQL.

For 3-dB squeezing of the field $e^{-2r} = 1/2$, the SQL is beaten by a factor $\sqrt{2}$. This was the proposal of *Caves* [9], first experimentally implemented by *Kimble* [10]. The great utility of using squeezed light in advanced LIGO has been extensively considered [63]. *Schnabel's* group reported a direct measurement of 15-dB squeezed vacuum states of light at 1064 nm from a doubly resonant, type I optical parametric amplifier operated below threshold. They managed to push down the noise levels from various contributing sources [64].

Heisenberg limited sensitivity. Thus, the discussion above shows that the SQL can be beaten by illuminating the vacuum port in conventional interferometer by squeezed vacuum. In addition, we can have the interferometer where both input ports are illuminated with two-mode squeezed vacuum. This leads to several advantages, as shown both theoretically [65] and experimentally [66]. Besides beating the SQL it is also possible to achieve Heisenberg limited sensitivity, i.e.,

$$\delta\phi \approx \frac{1}{|\alpha|^2} \quad (82.111)$$

by using the SU(1,1) interferometers [67–69].

Fig. 82.10 Mach-Zehnder interferometer with two OPAs as the beam splitter

Instead of half-reflection mirrors, we use two optical parametric amplifiers (OPAs) (Fig. 82.10) to mix the fields in the two interfering paths. The same pumping field pumps the two OPAs. The idler fields and signal fields after the first OPA is,

$$\begin{aligned} a_1 &= \mu a_0 + \nu b_0^\dagger, \\ b_1 &= \mu b_0 + \nu a_0^\dagger, \end{aligned} \quad (82.112)$$

with $\mu = \cosh r$ and $\nu = e^{i\phi} \sinh r$. The object in one of the interfering paths brings a phase factor, $a_2 = e^{i\chi} a_1$ and $b_2 = b_1$. The second OPA transforms a_2 and b_2 to

$$\begin{aligned} a_f &= \mu a_2 - \nu b_2^\dagger, \\ b_f &= \mu b_2 - \nu a_2^\dagger. \end{aligned} \quad (82.113)$$

There is a relative phase π between the two OPA transformations. The relation between the input fields and output fields is

$$\begin{aligned} a_f &= e^{i\chi} (A a_0 + B b_0^\dagger), \\ b_f &= A b_0 + B a_0^\dagger, \end{aligned} \quad (82.114)$$

where $A = \mu^2 - |\nu|^2 e^{-i\chi}$ and $B = \mu\nu(1 - e^{-i\chi})$. Since $|A|^2 - |B|^2 = 1$, the input fields and the output fields are related by a Bogoliubov transformation, which is dependent on χ . If the input field is a vacuum state, we obtain,

$$\langle a_f^\dagger a_f \rangle = \langle b_f^\dagger b_f \rangle = |B|^2. \quad (82.115)$$

We define the signal as

$$S \equiv \langle a_f^\dagger a_f + b_f^\dagger b_f \rangle = 8|\mu|^2 |\nu|^2 \sin^2\left(\frac{\chi}{2}\right). \quad (82.116)$$

The variance of the signal is

$$\Delta S = \sqrt{\langle (a_f^\dagger a_f + b_f^\dagger b_f)^2 \rangle - S^2} = 2\sqrt{|B|^2 + |B|^4}. \quad (82.117)$$

At the point $\chi = 0$, we obtain the sensitivity

$$\Delta\chi = \frac{\Delta S}{|\partial S / \partial \chi|} = \frac{1}{2|\mu\nu|}. \quad (82.118)$$

Since the average photon number in each OPA arm is around $|\nu\mu|$, this result yields the Heisenberg limited sensitivity. This interferometer was realized by *Jing et al.* [70]. The SU(1,1) interferometer and its variants are currently gaining momentum in the ultrasensitive measurements of phase [71, 72]. Besides being of great utility, the two-mode squeezed states in metrology may also turn out to be of special importance in bioimaging. Two-photon excitation microscopy (TPEM) is the most widely used technique for optically imaging tissues at depths up to several cell layers below the surface. However, because two-photon absorption is such a weak effect, and scattering in biological tissues is so strong, TPEM requires excitation with high-power lasers that can damage or disrupt biological function. It is known that the use of entangled light leads to two-photon absorption that is proportional to intensity [73–75]. *Goodson's* group reported that two-photon absorption in some molecules can be significantly enhanced when the two incident photons are energy-time entangled with one another [76]. Clearly, the real advantages of entangled photon excitation are just beginning to appear now [77, 78] and should have far-reaching consequences for bioimaging.

We mention that the nonclassical states for atoms like squeezed states and cat states have been introduced [79–81]. The review by *Pezzè et al.* [82] discusses in detail the metrological applications of the nonclassical states of atoms.

We also note that many of the ideas of nonclassicality from the radiation field are being applied to general bosonic degrees of freedom. An important example of mesoscopic systems is the optomechanical interactions involving mechanical mirrors in high-quality cavities. Squeezing of mechanical mirrors and Fock states of mirrors have been realized [83, 84]. The entanglement of mirrors has also been reported [85, 86]. The field of optomechanics is likely to remain very active in the nonclassical properties of mechanical mirrors.

Acknowledgments GSA thanks Barnabas Kim and Jan Sperling for help in preparing this article. He also thanks his collaborators who worked on nonclassical aspects of the radiation fields, two-level systems, and general bosonic systems. DWW thanks Wei Feng for technical help and support. Abstract

Although the concept of a *free atom* is of use as a first approximation, a full quantum description of the interaction of atoms with an omnipresent electromagnetic radiation field is necessary for a proper account of spontaneous emission and radiative level shifts such as the Lamb shift. This chapter is concerned with the changes in the atom–field interaction that take place when the radiation field is modified by the presence of a cavity. An atom in the vicinity of a plane perfect mirror serves as an example of cavity quantum electrodynamics [1–5].

The interaction between atom and intracavity light field can significantly change the spontaneous and stimulated emission of light and induce transitions of the atom between different quantum states. In the case of strong coupling, it also becomes possible for a single atom to control the transmission of light through the cavity, and for a single photon to deterministically change the state of the atom.

Lower row: the spectral signature of exponential decay is a Lorentzian line shape (c), while the so-called vacuum Rabi splitting (d) is observed in the strong coupling case

83.1 Introduction

In the weak coupling regime, the coupling of an excited atom to a broad continuum of radiation modes leads to exponential decay (Fig. 83.1a), as first described by *Weisskopf* and *Wigner* [6]. Spontaneous emission may be enhanced or suppressed in structures such as waveguides or *bad* cavities. Cavities also introduce van der Waals forces and the subtle Casimir level shifts [7].

In the strong coupling regime, the excited atom is strongly coupled to an isolated resonant cavity mode. In the absence of damping, an oscillatory exchange of energy between the atom and the field replaces exponential decay (Fig. 83.1b) with a coherent evolution in time. Experimental investigations of these effects began [8] with the development of suitable resonators and techniques for producing atoms with long-lived excited states and strong dipole transition moments.

83.2 Atoms and Fields

83.2.1 Two-Level Atoms

Most of the essential features of cavity QED can be elucidated by the two-level model atom discussed in Chaps. 72, 74, and 81 (also [9]). A ground state $|g\rangle$ and an excited state $|e\rangle$ are coupled to the radiation field by a dipole interaction. Using the formal equivalence to a spin-1/2 system, the Pauli

spin operators are

$$\begin{aligned}\sigma_x &= \sigma_+ + \sigma_-, \\ \sigma_y &= -i(\sigma_+ - \sigma_-), \\ \sigma_z &= \sigma_+\sigma_- - \sigma_-\sigma_+ = [\sigma_+, \sigma_-],\end{aligned}\quad (83.1)$$

with $\sigma_+ = |e\rangle\langle g|$ and $\sigma_- = |g\rangle\langle e|$. The quadratures (out-of-phase components) of the atomic polarization are given by σ_x and σ_y , while σ_z is the occupation number difference. The free atom Hamiltonian is

$$\mathcal{H}_{\text{atom}} = \frac{1}{2}\hbar\omega_0\sigma_z, \quad (83.2)$$

where $\hbar\omega_0 = E_e - E_g$ is the transition energy.

83.2.2 Electromagnetic Fields

Classical Fields

Classical electromagnetic fields have longitudinal and transverse components

$$\mathbf{E}(\mathbf{r}, t) = \mathbf{E}^l(\mathbf{r}, t) + \mathbf{E}^t(\mathbf{r}, t). \quad (83.3)$$

In the Coulomb gauge, the longitudinal part is the instantaneous electric field. The transverse part is the radiation field that obeys the wave equation

$$\left(\nabla^2 - \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\right)\mathbf{E}^t(\mathbf{r}, t) = \frac{1}{\epsilon_0 c^2}\frac{\partial}{\partial t}\mathbf{j}(\mathbf{r}, t). \quad (83.4)$$

In empty space, the driving current density $\mathbf{j}(\mathbf{r}, t)$ vanishes, and the field may be expanded in a set of orthogonal modes as

$$\mathbf{E}^t(\mathbf{r}, t) = \sum_{\mu} E_{\mu}(t)e^{-i\omega_{\mu}r}\mathbf{u}_{\mu}(\mathbf{r}) + \text{c.c.}, \quad (83.5)$$

with slowly varying amplitudes $E_{\mu}(t)$. The spatial distributions $\mathbf{u}_{\mu}(\mathbf{r})$ obey the vector Helmholtz equation

$$\left[\nabla^2 + \left(\frac{\omega_{\mu}}{c}\right)^2\right]\mathbf{u}_{\mu}(\mathbf{r}, t) = 0, \quad (83.6)$$

depending on geometric boundary conditions as imposed by conductive or dielectric mirrors, waveguides, and resonators. In free space, plane wave solutions $\mathbf{u}_{\mu}(\mathbf{r}, t) = \mathbf{u}_{\epsilon}e^{i\mathbf{k}\cdot\mathbf{r}}$ have a continuous index $\mu = (\mathbf{k}, \epsilon)$ with wave vector \mathbf{k} and an index ϵ for the two independent polarizations. The orthogonality relation

$$\frac{1}{V}\int_V \mathbf{u}_{\mu} \cdot \mathbf{u}_{\nu}^* d^3\mathbf{r} = \delta_{\mu\nu} \quad (83.7)$$

applies. For a closed cavity, V is the resonator volume. In waveguides and free space, an artificial boundary is introduced and then increased to infinity at the end of a calculation, such that the final results do not depend on V . Many of the properties of cavity QED can be described by a classical theory [10] where the classical fields interact with electric dipoles via the so-called dipole approximation.

Quantum Fields

The quantum analog of the classical transverse field in Eq. (83.4) is obtained through a quantization of its harmonic modes leading to a number state expansion. Field operators obey standard commutation relations $[a_\mu, a_\nu^\dagger] = \delta_{\mu,\nu}$, and for a single mode with index μ , the amplitude E_μ in Eq. (83.5) is replaced by the corresponding operator

$$E_\mu(t) = \mathcal{E}_\mu a_\mu e^{-i\omega t}, \quad E_\mu^\dagger(t) = \mathcal{E}_\mu^* a_\mu^\dagger e^{i\omega t}. \quad (83.8)$$

The normalization factor \mathcal{E}_μ is chosen such that the energy difference between number states $|n\rangle_\mu$ and $|n+1\rangle_\mu$ in the volume V is $\hbar\omega_\mu$, giving

$$\mathcal{E}_\mu \mathcal{E}_\mu^\dagger = \frac{\hbar\omega_\mu}{2\epsilon_0 V}. \quad (83.9)$$

The Hamiltonian of the free field is

$$\mathcal{H}_{\text{Field}} = \sum_\mu \hbar\omega_\mu \left(a_\mu^\dagger a_\mu + \frac{1}{2} \right). \quad (83.10)$$

In the Coulomb gauge, the vector potential $\mathbf{A}(\mathbf{r})$ is related to the electric field $\mathbf{E} = -\partial\mathbf{A}/\partial t$ by

$$\mathbf{A}_\mu(\mathbf{r}, t) = -\frac{\mathcal{E}_\mu}{\omega_\mu} \left(a_\mu e^{-i\omega t} + a_\mu^\dagger e^{i\omega t} \right) \mathbf{u}_\mu(\mathbf{r}). \quad (83.11)$$

The ground state $|0\rangle_\mu$ is called the vacuum state. While the expectation value $\langle n|\mathbf{E}|n\rangle = 0$ for a number state, the variance is not zero, since $\langle n|\mathbf{E}\mathbf{E}^*|n\rangle > 0$, giving rise to non-vanishing *fluctuations* of the free electromagnetic field.

83.2.3 Dipole Coupling of Fields and Atoms

The combined system of atoms and fields can be described by the product quantum states $|a, n\rangle$ of atom states $|a\rangle$ and field states $|n\rangle$. The interaction Hamiltonian \mathcal{H}_I of the atom and the radiation field is given by (The A^2 -term plays an important role in energy shifts and can only be neglected when radiative processes involving energy exchange are considered.)

$$\mathcal{H}_I = -\frac{q}{m} \mathbf{p} \cdot \mathbf{A}(\mathbf{r}) + \frac{q^2}{2m} A^2(\mathbf{r}). \quad (83.12)$$

This interaction causes the atom to exchange energy with the radiation field. In the dipole approximation, the interaction can be reduced to the commonly used form of $\mathbf{p} \cdot \mathbf{E}$ [11], with the coupling strength proportional to the component of the atomic dipole moment $\mathbf{d}_{eg} = q\langle e|\mathbf{r}_{eg}|g\rangle$ along the electric field. The coupling constant

$$g_\mu(\mathbf{r}) = |\mathbf{d}_{eg} \cdot \mathbf{u}_\mu(\mathbf{r}) \mathcal{E}_\mu|/\hbar. \quad (83.13)$$

In the rotating-wave approximation (RWA) (Chaps. 72 and 74),

$$\mathcal{H}_{\text{RWA}} = \sum_\mu \hbar \left(g_\mu \sigma_+ a_\mu + g_\mu^* a_\mu^\dagger \sigma_- \right), \quad (83.14)$$

where we have used the atomic operators of Eq. (83.1).

For the simplest scenario of a two-level atom interacting with a monomode cavity, the Hamiltonian under RWA reduces to the Jaynes–Cummings (JC) model

$$\mathcal{H}_{\text{JC}} = \frac{1}{2} \hbar\omega_0 \sigma_z + \hbar\omega_C a^\dagger a + \hbar(g\sigma_+ a + g^* a^\dagger \sigma_-), \quad (83.15)$$

where ω_C denotes the cavity mode frequency, and the zero-point energy of the field is neglected. Note that the JC model is valid only if the RWA can be employed to describe the coherent dipole interaction between the atom and the field mode. This usually requires that the coupling constant g is relatively much smaller than the energy scales of ω_0 and ω_C . Research beyond the RWA has been conducted in the regime where the coupling constant g is comparable with the atomic and field frequencies.

In a continuous electromagnetic spectrum, the atom interacts with a large number of modes having quantum numbers μ , yielding exponential decay of an excited atomic level at the rate [6]

$$\Gamma_{eg} = \frac{2\pi}{\hbar^2} \sum_{\tilde{\mu}} \sum_{\mathbf{k}} |g_\mu|^2 \delta(\omega_\mu - \omega_0). \quad (83.16)$$

Here, we have separated the discrete ($\tilde{\mu}$) and the continuous part (wave vector \mathbf{k}) of the mode index μ . If g_μ Eq. (83.13) does not vary much across a narrow resonance, then

$$\Gamma_{eg} \simeq 2\pi |g_\mu(\omega_0)|^2 \sum_{\tilde{\mu}} \rho_{\tilde{\mu}}(\omega_0). \quad (83.17)$$

The density of states corresponding to the continuous mode index \mathbf{k} of dimension ν can be evaluated on a ν -dimensional fictitious volume $V^{(\nu)}$ as

$$\rho_{\tilde{\mu}} = \sum_{\mathbf{k}} \delta(\omega_{\tilde{\mu},\mathbf{k}} - \omega) \rightarrow \frac{V^{(\nu)}}{(2\pi)^\nu} \int_0^\infty d^\nu k \delta(\omega_{\tilde{\mu},\mathbf{k}} - \omega), \quad (83.18)$$

provided that $\omega(\mathbf{k})$ is known, and by converting the sum over plane wave vectors \mathbf{k} into an integral. (This is formally accomplished by taking the limit of $\Delta k = 2\pi/l$ for large l , where l is a linear dimension of an artificial resonator, and the resonator volume is $V = l^3$. If the relation between mode spacing Δk and geometric dimension is nonlinear in a more complex geometry, this analysis can be very complicated.)

The Rate of Spontaneous Emission

In free space [$\omega(\mathbf{k})^2 = (c\mathbf{k})^2$], the sum in Eq. (83.17) contributes a factor of 2, due to polarization, to the total density of states in free space, $\rho_{\text{free}}(\omega) = V\omega^2/\pi^2c^3$. When the vector coupling of atom and field Eq. (83.13) is replaced by its average in isotropic free space, that is, by 1/3, the result

$$\Gamma_{eg} = A_{eg} = \frac{e^2 r_{eg}^2 \omega^3}{3\pi\epsilon_0 \hbar c^3} \quad (83.19)$$

is obtained for the decay rate A_{eg} as measured by the natural linewidth Γ_{eg} .

83.3 Weak Coupling in Cavity QED

The regime of weak cavity QED generally applies when an atom is coupled to a continuum of radiation modes. This is always the case with mirrors, waveguides, or bad cavities. The signatures of weak cavity QED are modifications of the rate of spontaneous emission, as well as the existence of van der Waals and Casimir forces. Formally, this regime is well described by perturbation theory.

83.3.1 Radiating Atoms in Waveguides

Within the continuous spectrum of a waveguide, the radiative decay of an excited atomic level remains exponential, and Γ_{eg} may be determined as in the preceding section. We now consider the modifications of spontaneous decay in a parallel plate waveguide. According to Eq. (83.17), the theoretical problem is reduced to a geometric evaluation of mode densities. Between a pair of mirrors it is convenient to distinguish TE_{nk} and TM_{nk} modes, where n is the number of half-waves across the gap of width d . The dispersion relation $\omega(\mathbf{k})$ reflects the discrete standing-wave part ($n\pi/d$) and a running-wave part as in free space,

$$\omega_{n,k}^2 = c^2(|\mathbf{k}|^2 + n\pi/d)^2 \quad \begin{array}{l} n = 0, 1, 2, \dots \quad \text{TM} \\ n = 1, 2, \dots \quad \text{TE} \end{array} \quad (83.20)$$

The average mode density [$d\mathbf{u} = 1$, Eq. (83.13)] is evaluated [Eq. (83.18), $\nu = 2$] with an appropriate quantization volume

Fig. 83.2 Modification of the average vacuum spectral density ($\rho^{\text{TE}} + \rho^{\text{TM}}$) in a parallel plate cavity (thick line) compared with free space (thin line)

containing the area of the plates, $V = Ad$, giving

$$\begin{aligned} \rho^{\text{TE}}(\omega) &= \frac{\omega_c[\omega]}{2\omega_c^2} \rho_{\text{free}}(\omega_c), \\ \rho^{\text{TM}}(\omega) &= \frac{\omega_c[\omega + 1]}{2\omega_c^2} \rho_{\text{free}}(\omega_c), \end{aligned} \quad (83.21)$$

where $[x]$ is the largest integer in x , and $\omega_c = \pi c/d$ gives the waveguide cutoff frequency. Below ω_c , the TE-mode density clearly vanishes and, with the pictorial notion of turning off the vacuum introduced by Kleppner [12], inhibition of radiative decay is obvious. Figure 83.2 shows the calculated mode density for a parallel plate waveguide. The decay rate can be calculated from Eq. (83.17), with the spatial variation of g_μ included. This configuration was used for the first experiments, which showed the suppression of spontaneous emission in both the microwave and the near optical frequency domain [13, 14] with atomic beams.

83.3.2 Trapped Radiating Atoms and Their Mirror Images

Boundary conditions imposed by conductive surfaces may also be simulated by appropriately positioned image charges. Inspired by classical electrodynamics, this image charge model can be successfully used to determine the modifications of radiative properties in confined spaces. In the simplest case, an atom is interacting with its image produced by a plane mirror. Trapped atoms and ions allow one to control their relative position with respect to a mirror to distances below the wavelength of light. Hence they are ideal objects for studying the spatial dependence of the mirror-induced modifications of their radiative properties. In an experiment with a single trapped ion (Fig. 83.3), its radiation field was

Fig. 83.3 Sinusoidal variation of the $\lambda = 493$ nm spontaneous emission rate of a single trapped Ba ion caused by self-interference from a retroreflecting mirror. The experimental arrangement is sketched at the bottom [15]

superposed onto its mirror image [15, 16], yielding a sinusoidal variation of both the spontaneous decay rate and the mirror-induced level shift with excellent contrast.

83.3.3 Radiating Atoms in Resonators

Resonators

In a resonator, the electromagnetic spectrum is no longer continuous, and the discrete mode structure can also be resolved experimentally. While a resonator is only weakly coupled to external electromagnetic fields, it still interacts with a large thermal reservoir through currents induced in its walls. The total damping rate is due to resistive losses in the walls (κ_{wall}) and also due to transmission at the radiation ports, $1/\tau_{\mu} = \kappa_{\mu} = \kappa_{\text{wall}} + \kappa_{\text{out}}$. An empty resonator stores energy for times

$$\tau_{\mu} = \frac{Q}{\omega_{\mu}}, \quad (83.22)$$

and the power transmission spectrum is a Lorentzian with width $\Delta\omega_{\mu} = \omega_{\mu}/Q_{\mu}$. The index μ , for instance, represents the TE_{lm} and TM_{lm} modes of a *pillbox* microwave cavity, or the TEM_{klm} modes of a Fabry–Perot (FP) interferometer (Fig. 83.4).

When cavity damping remains strong, $\Gamma_{\mu} \gg \Gamma_{eg}$, the atomic radiation field is *immediately* absorbed, and Weisskopf–Wigner perturbation theory remains valid. In this so-called bad cavity limit, resonator damping can be accounted

Fig. 83.4 Two frequently used resonator types for cavity QED: (a) open Fabry–Perot (FP) optical cavity; (b) closed *pillbox* microwave cavity

for by an effective mode density of Lorentzian width $\Delta\omega_{\mu}$ for a single isolated mode,

$$\rho_{\mu}(\omega) = \frac{1}{\pi} \frac{\omega_{\mu}/2Q_{\mu}}{(\omega - \omega_{\mu})^2 + (\omega_{\mu}/2Q_{\mu})^2}. \quad (83.23)$$

Bad and Good Cavities

The modification of spontaneous decay is again calculated from Eq. (83.17). For an atomic dipole aligned parallel to the mode polarization, and right at resonance, $\omega_{\mu} = \omega_0$, the enhancement of spontaneous emission is found to be proportional to the Q -value of a selected resonator mode

$$\frac{\Gamma_{eg}^{\text{cav}}}{\Gamma_{eg}^{\text{free}}} = \frac{\rho_{\mu}|\mathbf{u}(\mathbf{r})|}{\rho_{\text{free}}} = \frac{3Q\lambda^3}{4\pi^2V} |\mathbf{u}(\mathbf{r})|^2 = \frac{3Q\lambda^3}{4\pi^2V_{\text{eff}}}, \quad (83.24)$$

where the effective mode volume is $V_{\text{eff}} = V/|\mathbf{u}(\mathbf{r})|^2$. The lowest possible value $V_{\text{eff}} \simeq \lambda^3$ is obtained for ground modes of a closed resonator. For an atom located at the waist of an open FP cavity with length L , it is much larger. Special limiting cases for concentric and confocal cavities are $V_{\text{eff}}^{\text{conc}} = \lambda^2 L(R/D)$ and $V_{\text{eff}}^{\text{conf}} = \lambda L^2/2\pi$, respectively, where (R/D) gives the ratio of mirror radius to cavity diameter.

At resonance, the atomic decay rate Γ_{μ} grows with Q_{μ} , whereas the resonator damping time constant κ_{μ} is reduced. Eventually, the energy of the atomic radiation field is stored for such a long time that reabsorption becomes possible. Perturbative Weisskopf–Wigner theory is no longer valid in this good cavity limit, which is separated from the regime of bad cavities by the more formal condition

$$\Gamma_{eg}^{\text{cav}} > \kappa_{\mu}. \quad (83.25)$$

The strong coupling case is considered explicitly in Sect. 83.4.

Antenna Patterns

Since the reflected radiation field of an atomic radiator is perfectly coherent with the source field, the combined radiation pattern modifies the usual dipole distribution of a radiating atom. The new radiation pattern can be understood in terms of antenna arrays [17]. For a single atomic dipole in front of a reflecting mirror, for example, one finds a quadrupole-type pattern due to the superposition of a second, coherent image antenna. In some of the earliest experimental investigations on radiating molecules in cavities, modifications of the radiation pattern were observed [18].

83.3.4 Radiative Shifts and Forces

When the radiation field of an atom is reflected back onto its source, an energy or radiative shift is caused by the corresponding self-polarization energy. An atom in the vicinity of a plane mirror (Fig. 83.5) again makes a simple model system. Since the energy shift depends on the atom wall separation z , it is equivalent to a dipole force F_{dip} whose details depend on the role of retardation. Here, we distinguish between the two cases where no radiation energy is exchanged between the atom and the field (van der Waals, Casimir forces), and where the atomic radiation causes forces by self-interference.

The Unretarded Limit: van der Waals Forces

When the radiative round-trip time $t_r = 2z/c$ is short compared with the characteristic atomic revolution period $2\pi/\omega_{\text{eg}}$, retardation is not important. In this quasi-static limit, van der Waals energy shifts for decaying atomic dipoles vary as z^{-3} with the atom–wall separation. Such a shift is also present for a nonradiating atom in its ground

state. In perturbation theory, the van der Waals energy shift of an atomic level $|a\rangle$ is

$$\Delta_{\text{vdW}} = -\frac{\langle a|q^2[(\mathbf{d}^2 \cdot \hat{\mathbf{x}}_1)^2 + 2(\mathbf{d}^2 \cdot \hat{\mathbf{z}})^2]|a\rangle}{64\pi\epsilon_0 z^3}. \quad (83.26)$$

Since the van der Waals force is anisotropic for electronic components parallel ($\hat{\mathbf{z}}$) and perpendicular ($\hat{\mathbf{x}}_1$) to the mirror normal, the degeneracy of magnetic sublevels in an atom is lifted near a surface. The total energy shift is ≈ 1 kHz for a ground-state atom at $1 \mu\text{m}$ separation and is very difficult to detect. However, the energy shifts grow as n^4 since the transition dipole moment scales as n^2 . With Rydberg atoms, van der Waals energy shifts have been successfully observed in spectroscopic experiments [19].

The Retarded Limit: Casimir Forces

At large separation, retardation becomes relevant, since the contributions of individual atomic oscillation frequencies in Eq. (83.26) cancel by dephasing, thus reducing the Δ_{vdW} . A residual Casimir–Polder [20] shift may be interpreted as the polarization energy of a slowly fluctuating field with squared amplitude $\langle E^2 \rangle = 3\hbar c/64\epsilon_0 z^4$ originating from the vacuum field noise

$$\Delta_{\text{CP}} = -\frac{1}{4\pi\epsilon_0} \frac{3\hbar c \alpha_{\text{st}}}{8\pi z^4}, \quad (83.27)$$

where α_{st} is the static electric polarizability. The vacuum field noise Δ_{CP} replaces Δ_{vdW} at distances larger than characteristic wavelengths and is even smaller. Only indirect observations have been possible to date, relying on a deflection of polarizable atoms by this force [21, 22]. The Casimir–Polder force can also be regarded as an ultimate, cavity-induced consequence of the mechanical action of light on atoms [23]. It is an example of the conservative and dispersive dipole force, which is even capable of binding a polarizable atom to a cavity [24].

Radiative Self-Interference Forces

Spontaneous emission of atoms in the vicinity of a reflecting wall also provides an example of cavity-induced modification of the dissipative type of light forces, or radiation pressure. If the returning field is reabsorbed, the spontaneous emission rate is reduced, and a recoil force directed away from the mirror is exerted. If the returning radiation field causes enhanced decay, a recoil towards the mirror occurs due to stimulated emission.

If the photon is detected at some angle with respect to the normal vector connecting the atom with the mirror surface, two paths for the photon are possible: it can reach a detector directly or following a reflection off the wall. At small atom–mirror separation, these paths are indistinguishable, the atom is thus left in a superposition of two recoil momentum states.

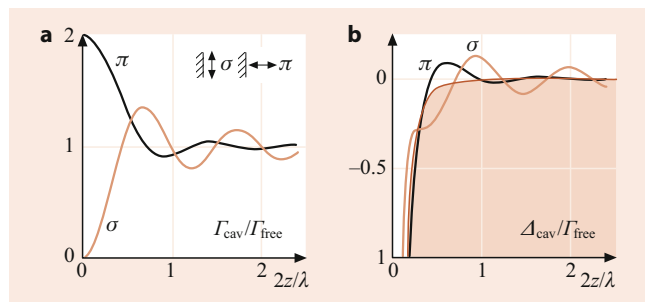

Fig. 83.5 (a) Normalized rate of modified spontaneous emission in the vicinity of a perfectly reflecting wall for σ and π orientation of the radiating dipole. (b) Corresponding energy shift of the resonance frequency. The shaded area indicates contribution of static van der Waals interaction

83.3.5 Experiments on Weak Coupling

Perhaps the most dramatic experiment in a weak coupling cavity QED is the total suppression of spontaneous emission. For the experiments that were carried out with Rydberg atoms and for a low-lying near-infrared atomic transition [13, 14], it is essential to prepare atoms in a single decay channel. In addition, the atoms must be oriented in such a way that they are only coupled to a single decay mode (see the model waveguide in Fig. 83.4). This may be interpreted as an anisotropy of the electromagnetic vacuum or as a specific antenna pattern.

An important problem in detecting the modification of radiative properties – changes in emission rates as well as radiative shifts – arises from their inhomogeneity due to the dependence on atom–wall separation. This difficulty has been overcome by controlling the atom–wall separation at microscopic distances through light forces [19], or by using well localized trapped ions [15, 16]. Furthermore, spectroscopic techniques that are only sensitive to a thin layer of surface atoms [25] have been used to clearly detect van der Waals shifts.

An atom emitting a radiation field in the vicinity of a reflecting wall will experience an additional dipole optical force caused by its radiation field. This force has been observed as a modification of the trapping force holding an ion at a fixed position with respect to the reflector [26].

Conceptually most attractive and experimentally most difficult to detect is the elusive Casimir interaction. Only for atomic ground states is this effect observable, free from other much larger shifts. The influence of the corresponding Casimir force on atomic motion was observed in a variant of a scattering experiment, confirming the existence of this force in neutral atoms [21, 22].

The success of this experiment shows that spectroscopic techniques involving the exchange of photons are not suitable for the Casimir problem. A notable exception could be Raman spectroscopy of the magnetic substructure in the vicinity of a surface. In general, scattering or atomic interferometry experiments are more promising methods. The experiment by Brune et al. [27] may be interpreted in this way.

83.3.6 Cavity QED and Dielectrics

There are two variants of dielectric materials employed to study light–matter interaction in confined space: conventional materials, such as glass or sapphire, and artificial materials called photonic materials or metamaterials.

While dielectric materials are theoretically more difficult to treat than perfect mirrors, since the radiation at least partially enters the medium, they have a similar influence on radiative decay processes. One new aspect is, however, the

coupling of atomic excitations to excitations of the medium, which was observed for the case of a surface-polariton in [28].

Cavities with dimensions comparable to the wavelength promise the most dramatic modification of radiative atomic properties, but micrometer-sized cavities for optical frequencies with highly reflecting walls are difficult to manufacture. So-called whispering gallery modes of spherical microcavities [29] have been intensely studied, but no simple way of coupling atoms to these resonator modes has yet been found.

On the other hand, dielectric materials with a periodic modulation of the index of refraction may exhibit photonic bandgaps in analogy with electronic bandgaps in periodic crystals [30, 31]. Electronic phenomena of solid-state physics can then be transferred to photons. For example, excited states of a crystal dopant or a quantum dot cannot radiate into a photonic bandgap, the radiation field cannot propagate, and the excitation energy remains localized. The bandgap behaves like an empty resonator, and if a resonator structure is integrated into the device, the regime of strong coupling [32, 33] can be achieved with such photonic structures. An overview of suitable systems can be found in [34].

83.4 Strong Coupling in Cavity QED

Strong coupling of atoms and fields is realized in a good cavity when $\Gamma_\mu < \Gamma_{eg}$ Eq. (83.25). The Hilbert space of the combined system is then the product space of a single two-level atom and the countable set of Fock states of the field,

$$\mathcal{H} = \mathcal{H}_{\text{atom}} \otimes \mathcal{H}_{\text{field}}, \quad (83.28)$$

which is spanned by the states

$$|n; a\rangle = |n\rangle|a\rangle. \quad (83.29)$$

The interaction of a single-cavity mode with an isolated atomic resonance is now characterized by the Rabi nutation frequency, which gives the exchange frequency of the energy between atom and field. For an amplitude \mathcal{E} corresponding to n photons,

$$\Omega(n) = g_\mu \sqrt{n+1}. \quad (83.30)$$

This is the simplest possible situation of a strongly coupled atom–field system. The new energy eigenvectors are conveniently expressed in the dressed-atom model [35]

$$\begin{aligned} |+, n\rangle &= \cos \theta |g, n+1\rangle + \sin \theta |e, n\rangle, \\ |-, n\rangle &= -\sin \theta |g, n+1\rangle + \cos \theta |e, n\rangle, \end{aligned} \quad (83.31)$$

with $\tan 2\theta = 2g_\mu \sqrt{n+1}/(\omega_0 - \omega_\mu)$. The separate energy structures of free atom and empty resonator are now replaced

Fig. 83.6 Level diagram for the combined states of noninteracting atoms and fields (*left*) which are degenerate at resonance. Degeneracy is lifted by strong coupling of atoms and fields (*right*) yielding new dressed eigenstates

by the combined system of Fig. 83.6. At resonance, the new eigenstates are separated by $2\hbar\Omega_R$, where $\Omega_R = g_\mu$ is the vacuum Rabi frequency.

83.4.1 The Jaynes-Cummings Model

In a microscopic laser, simple atoms are strongly coupled to a single mode of a resonant or near-resonant radiation field. Collecting atomic and field operators from Eqs. (83.2), (83.10), and (83.14), this situation is described by the Jaynes–Cummings model Hamiltonian Eq. (83.15) [36, 37]

$$\begin{aligned} \mathcal{H}_{\text{JC}} &= \mathcal{H}_{\text{atom}} + \mathcal{H}_{\text{field}} + \mathcal{H}_{\text{RWA}} \\ &= \frac{1}{2}\hbar\omega_0\sigma_z + \hbar\omega_\mu a_\mu^\dagger a_\mu + \hbar(g_\mu\sigma_+ a_\mu + g_\mu^* a_\mu^\dagger \sigma_-). \end{aligned} \quad (83.32)$$

The JC model Eq. (83.32) represents the most basic and, at the same time, the most informative model of strong coupling in quantum optics. It consists of a single two-level atom interacting with a single mode of the quantized cavity field. The time evolution of the system is determined by

$$i\hbar\frac{\partial\psi}{\partial t} = H\psi. \quad (83.33)$$

This model can be solved exactly due to the existence of the additional constant of motion

$$N = a^\dagger a + \sigma_z + 1, \quad (83.34)$$

i.e., conservation of the *number of excitations*. Its eigenvalues are the integers N , which are twofold degenerate except for $N = 0$. The simultaneous eigenstates of H and N are the pairs of dressed states defined in Eq. (83.31), which are

not degenerate with respect to the energy H . The initial state problem corresponding to Eq. (83.33) is solved by elementary methods in terms of the expansion

$$|\Psi(t)\rangle = \sum_{n=0}^{\infty} \sum_{j=1}^2 C_n^j(t) |n, j\rangle, \quad (83.35)$$

where the expansion coefficients are

$$\begin{aligned} C_n^1(t) &= \left(C_n^1(0) \left\{ \cos[\Omega(n)t] - i \frac{\delta}{2\Omega(n)} \sin[\Omega(n)t] \right\} \right. \\ &\quad \left. - i \frac{\sqrt{n}g_\mu}{\Omega(n)} C_{n-1}^2(0) \sin[\Omega(n)t] \right) \\ &\quad \times \exp\left[-i\omega_\mu\left(n - \frac{1}{2}\right)t\right] \end{aligned} \quad (83.36)$$

and

$$\begin{aligned} C_n^2(t) &= \left(C_n^2(0) \left\{ \cos[\Omega(n+1)t] \right. \right. \\ &\quad \left. \left. + i \frac{\delta}{2\Omega(n+1)} \sin[\Omega(n+1)t] \right\} \right. \\ &\quad \left. - i \frac{g_\mu\sqrt{n+1}}{\Omega(n+1)} C_{n+1}^1(0) \sin[\Omega(n+1)t] \right) \\ &\quad \times \exp\left[-i\omega_\mu\left(n + \frac{1}{2}\right)t\right], \end{aligned} \quad (83.37)$$

with $\delta = \omega_\mu - \omega_0$ the detuning between the atom and cavity, and $\Omega(n) = (1/2)(\delta^2 + 4g_\mu^2 n)^{1/2}$ is the generalized Rabi frequency. The coefficients $C_n^j(0)$ are determined by the initial preparation of atom and cavity mode. The result simplifies considerably for $\delta = 0$ to

$$\begin{aligned} |\Psi(t)\rangle &= \sum_{m=0}^{\infty} \left\{ C_m^1(0) e^{-i\omega_\mu(m-1/2)t} \right. \\ &\quad \times [\cos(g_\mu\sqrt{m}t)|m; 1\rangle \\ &\quad \left. - i \sin(g_\mu\sqrt{m}t)|m-1; 2\rangle] \right. \\ &\quad \left. + C_m^2(0) e^{-i\omega_\mu(m+1/2)t} \right. \\ &\quad \times [\cos(g_\mu\sqrt{m+1}t)|m; 2\rangle \\ &\quad \left. - i \sin(g_\mu\sqrt{m+1}t)|m+1; 1\rangle] \right\}. \end{aligned} \quad (83.38)$$

The coefficients $C_n^j(0)$ represent any initial state of the system, from uncorrelated product states to entangled states of atom and field. There exist numerous generalizations of this model that include more atomic levels and several coherent fields.

83.4.2 Fock States, Coherent States, and Thermal States

We now illustrate the properties of the Jaynes–Cummings model by specifying the initial state. Assume that the atom and field are brought into contact at time $t = 0$ and that all correlations that might exist due to previous interactions are suppressed.

Rabi Oscillations

If the atom is initially in the excited state, and the field contains precisely m quanta, then

$$C_n^j(t=0) = \delta_{n,m} \delta_{j,2}. \quad (83.39)$$

The solution of Eq. (83.33) assumes the form

$$\begin{aligned} |\Psi(t)\rangle &= e^{-i\omega_\mu(m+1/2)t} \\ &\times \left[\cos(g_\mu \sqrt{m+1}t) |m; 2\rangle \right. \\ &\quad \left. - i \sin(g_\mu \sqrt{m+1}t) |m+1; 1\rangle \right]. \end{aligned} \quad (83.40)$$

The occupation probabilities of the atomic states evolve in time according to

$$\begin{aligned} n_2(t) &= \langle \Psi(t) | 2 \rangle \langle 2 | \Psi(t) \rangle \\ &= \cos^2(g_\mu \sqrt{m+1}t), \end{aligned} \quad (83.41)$$

$$\begin{aligned} n_1(t) &= \langle \Psi(t) | 1 \rangle \langle 1 | \Psi(t) \rangle \\ &= \sin^2(g_\mu \sqrt{m+1}t). \end{aligned} \quad (83.42)$$

The photon number and its variance are

$$\begin{aligned} \langle n(t) \rangle &= \langle \Psi(t) | a^\dagger a | \Psi(t) \rangle \\ &= m + \sin^2(g_\mu \sqrt{m+1}t), \end{aligned} \quad (83.43)$$

$$\begin{aligned} \langle \Delta^2 n \rangle &= \langle \Psi(t) | (a^\dagger a - \langle a^\dagger a \rangle)^2 | \Psi(t) \rangle \\ &= \frac{\sin^2(2g_\mu \sqrt{m+1}t)}{4}. \end{aligned} \quad (83.44)$$

In the limit of large m , $g_\mu \sqrt{m+1}$ is proportional to the field amplitude, and the classical Rabi oscillations in a resonant field are recovered. The nonclassical features of the states are characterized by Mandel's parameter

$$Q_M = \frac{\langle \Delta^2 n \rangle - \langle n \rangle}{\langle n \rangle} \geq -1. \quad (83.45)$$

For the present example,

$$Q_M = -1 + \frac{1}{4} \frac{\sin^2(2g_\mu \sqrt{m+1}t)}{m + \sin^2(g_\mu \sqrt{m+1}t)}; \quad (83.46)$$

$Q_M \geq 0$ indicates the classical regime, while $Q \leq 0$ can only be reached by a quantum process.

The Coherent State

Consider the case where the field is initially prepared in a coherent state

$$|\alpha\rangle = \exp(\alpha a^\dagger - \alpha^* a) |0\rangle = e^{-|\alpha|^2/2} \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} |n\rangle, \quad (83.47)$$

while the atom starts from the excited state

$$C_n^j(0) = e^{-|\alpha|^2/2} \frac{|\alpha|^n}{\sqrt{n!}} \delta_{j,2}. \quad (83.48)$$

In this case, the general solution specializes to

$$\begin{aligned} |\Psi(t)\rangle &= \sum_{n=0}^{\infty} \frac{\alpha^n}{\sqrt{n!}} e^{-i\omega(n+1/2)t} e^{-|\alpha|^2/2} \\ &\times \left[\cos(g_\mu \sqrt{n+1}t) |n; 2\rangle \right. \\ &\quad \left. - i \sin(g_\mu \sqrt{n+1}t) |n+1; 1\rangle \right], \end{aligned} \quad (83.49)$$

and the occupation probability of the excited state is

$$n_2(t) = \frac{1}{2} \left[1 + \sum_{n=0}^{\infty} \frac{|\alpha|^{2n}}{n!} e^{-|\alpha|^2} \cos(2g_\mu \sqrt{n+1}t) \right]. \quad (83.50)$$

From here, detailed quantitative results can only be obtained by numerical methods [38]. However, if the coherent state contains a large number of photons $|\alpha|^2 \gg 1$, the essential dynamics can be determined by elementary methods. Initially, the population oscillates with the Rabi frequency $\Omega_1 \approx g_\mu |\alpha|$, which is proportional to the average amplitude of the field, as expected from its classical counterpart. With increasing time, the coherent oscillations tend to cancel due to the destructive interference of the different Rabi frequencies in the sum

$$n_2(t) = \frac{1}{2} \left[1 + \cos(2g_\mu |\alpha| t) e^{-(g_\mu t)^2/2} \right]. \quad (83.51)$$

However, strictly aperiodic relaxation of $n_2(t)$ is impossible since the exact expressions, Eqs. (83.35) and (83.36), represent a quasi-periodic function which, given enough time, approaches its initial value with arbitrary accuracy.

For short times, the oscillating terms in the sum cancel each other due to the slow evolution of their frequency with n . However, consecutive terms interfere constructively for larger times t_r , such that the phases satisfy

$$\phi_{n+1}(t_r) - \phi_n(t_r) = 2\pi. \quad (83.52)$$

For $|\alpha|^2 \gg 1$, the increment of the arguments is

$$\phi_{n+1} - \phi_n = \frac{g_\mu t_r}{|\alpha|}, \quad (83.53)$$

and, therefore, the first revival of the Rabi oscillations occurs approximately at $t_r = \pi |\alpha| / g_\mu$. A clear distinction of Rabi

Fig. 83.7 Rabi oscillations, dephasing, and quantum revival

oscillation, collapses, and revivals requires a clear separation of the three timescales

$$t_1 \ll t_2 \ll t_3, \quad (83.54)$$

where $t_1 \approx (g_\mu |\alpha|)^{-1}$ for Rabi oscillation, $t_2 \approx g_\mu^{-1}$ for collapse, and $t_3 \approx |\alpha|/g_\mu$ for revival.

The discovery of the collapse and revival of Rabi oscillations is one of the key demonstrations of photons [38–40]. The typical features of the transient evolution starting from a coherent state are shown in Fig. 83.7. With time increasing even further, revivals of higher order occur, which spread in time and finally can no longer be separated order by order. It is also proposed that by carefully manipulating the initial states and atom–light coupling during evolution, arbitrary Fock states can be created with prechosen evolution time [41].

The Thermal State

Consider a microwave resonator brought into thermal contact with a reservoir, inducing loss on a timescale κ^{-1} and thermal excitation. The dissipative time evolution is described by the master equation

$$\begin{aligned} \dot{\rho} &= (L_0 + L)\rho \\ &\equiv \frac{i[H, \rho]}{\hbar} + \kappa(n_{\text{th}} + 1)\{[a, \rho a^\dagger] + [a\rho, a^\dagger]\} \\ &\quad + \kappa n_{\text{th}}\{[a^\dagger, \rho a] + [a^\dagger \rho, a]\}, \end{aligned} \quad (83.55)$$

where $n_{\text{th}} = [\exp(\beta\hbar\omega) - 1]^{-1}$, at $T = k_B\beta^{-1}$, is the equilibrium population of the cavity mode, L_0 symbolizes the unitary evolution according to the Jaynes–Cummings dynamics, and L is a dissipation term.

The solution of this model can be expressed in terms of an eigenoperator expansion of the equation

$$L\rho = -\lambda\rho. \quad (83.56)$$

The eigenvalues λ that determine the relaxation rates, as well as the eigenoperators, are known in closed form for the case

of vanishing temperature [42]. Since energy is exchanged between the nondecaying atom and the decaying cavity mode, cavity damping is modified in a characteristic way due to the presence of the atom. The technical details can be found in [43].

83.4.3 Vacuum Splitting

In the classical case, the eigenvalues of the interaction-free Hamiltonian are degenerate at resonance. The atom–field interaction splits the eigenvalues and determines the Rabi frequency of oscillation between the two states. One consequence is the existence of sidebands in the resonance fluorescence spectrum [44]. In the quantum case, the field itself is treated as a quantized dynamical variable determined from a self-consistent solution for the complete system of atom plus field. The vacuum Rabi frequency $\Omega_{\text{vac}} = g_\mu$ remains finite and accounts for the spontaneous emission of radiation from an excited atom placed in a vacuum. In the limiting case of a single atom interacting with the quantized field, the photon number n can only change by ± 1 , and the population oscillates with the frequency $\Omega(n)$ given by Eq. (83.30). For an ensemble of N atoms, n can, in principle, change by up to $\pm N$. However, if the field and atoms are only weakly excited, the collective frequency of the ensemble is determined by the linearized Maxwell–Bloch equations. The eigenfrequencies are given by

$$\lambda^\pm = \frac{1}{2} \left[i(\gamma_\perp + \kappa) \pm \sqrt{4g_\mu^2 N - (\gamma_\perp - \kappa)^2} \right], \quad (83.57)$$

where γ_\perp^{-1} is the phase relaxation time of the atom and κ^{-1} the decay time of the resonator. This is the polariton dispersion relation in the neighborhood of the polariton gap. The spectral transmission

$$T(\omega) = T_0 \left| \frac{\kappa[\gamma + i(\omega_0 - \omega)]}{(\omega - \lambda^+)(\omega - \lambda^-)} \right|^2 \quad (83.58)$$

of an optical cavity containing a resonant atomic ensemble of N atoms reveals the internal dynamics of the coupled system and a splitting of the resonance line occurs; T_0 is the peak transmission of the empty cavity. The splitting increases either with the number of photons, approaching $\sqrt{n+1}$ in the presence of a single atom or with the number of atoms, approaching \sqrt{N} in the resonator when the field is weak. The latter case is demonstrated in Fig. 83.8 [45] for an optical resonator with 1–10 atoms interacting with a field that contains, on average, much less than a single photon.

83.4.4 Strong Coupling in Experiments

In order to achieve strong coupling experimentally, it is necessary to use a high- Q resonator in combination with a small

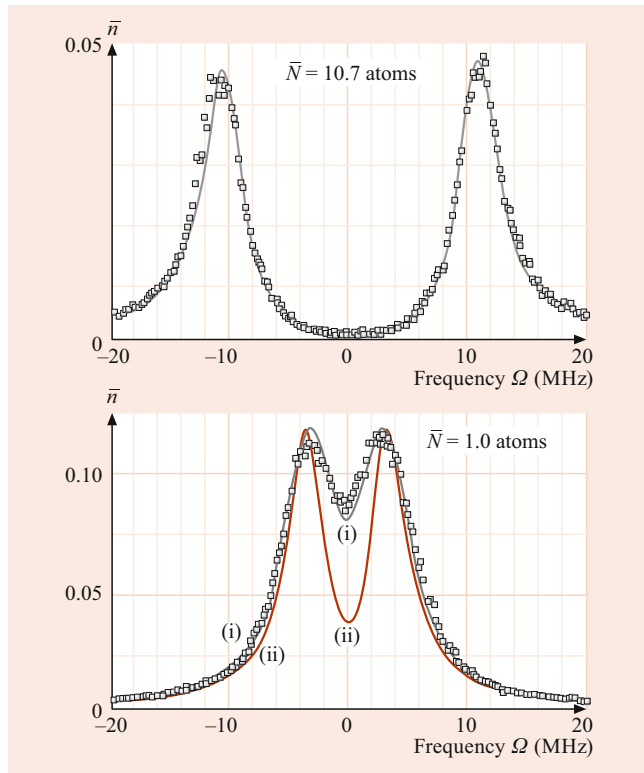

Fig. 83.8 Intracavity photon number (measured from a transmission experiment, [45]) as a function of probe frequency detuning, and for two values of N , the average number of atoms in the mode. *Thin lines* give theoretical fits to the data, including atomic number and position fluctuations. *Curve (ii)* in the lower graph is for a single intracavity atom with optimal coupling g_μ

effective mode volume. This condition was first realized for ground modes of a closed microwave cavity [8] and later also for open-cavity optical resonators (Fig. 83.6) [45]. It is interesting to control the interaction time of the atoms with the cavity field. In earlier experiments, this was typically achieved by selecting the passage time for an atom transiting the cavity. The advancement of atom-trapping methods has also led to the observation of a truly one-atom laser at optical frequencies [46].

More recently, this situation has also been realized for artificial atoms including superconducting systems [47, 48] and quantum dots [32, 33].

Rydberg Atoms and Microwave Cavities

At microwave frequencies, very low-loss superconducting niobium cavities are available with $Q \approx 10^{10}$. Resonator frequencies are typically several tens of GHz and can be matched by atomic dipole transitions between two highly excited Rydberg states. By selective field ionization, the excitation level of Rydberg atoms can be detected, and hence it is possible to measure whether a transition between the levels involved has occurred. The efficiency of this method approaches unity, so that experiments can be performed at

the single-atom level. The interaction or transit time T is usually much shorter than the lifetime τ_{Ry} of the Rydberg states involved. For this reason, circular Rydberg states with quantum numbers $l = m = n - 1$ are particularly suitable.

Rydberg atoms [49] are prepared in an atomic beam, selectively excited to an upper level, and then sent through a microwave cavity where the upper and lower levels are coupled by the electromagnetic field. If the atom is detected in the lower of the coupled levels as it leaves the resonator, the excitation energy has been stored in the resonator field. Thus, the evolution of the resonator field is recorded as a function of the atomic interaction.

A microwave cavity in interaction with a single or a few Rydberg atoms is called a micromaser (formerly a one-atom maser) [8]. The experimental conditions may be summarized as

$$g_\mu > \frac{1}{T} > \frac{1}{\tau_{\text{Ry}}} > \kappa_\mu. \quad (83.59)$$

Strong Coupling in Open Optical Cavities

At optical wavelengths, a cavity with small V_{eff} in Eq. (83.24) is clearly more difficult to construct than at centimeter wavelengths. However, dielectric coatings that allow very low damping rates ω_μ/Q_μ for optical cavities are now available. Very high finesse $\mathcal{F} \simeq 10^7$ (which is a more convenient measure for the damping rate of an optical FP interferometer) has been achieved. By reducing the volume of such a high- Q cavity mode, strong coupling of atoms and fields at optical frequencies has been demonstrated [45].

In open structures, the atoms can still decay into the continuum states with a rate γ . Therefore, the condition for strong coupling in such systems is usually given as

$$\frac{g_\mu^2}{\kappa_\mu \gamma} > 1. \quad (83.60)$$

83.5 Micromasers

Sustained oscillations of a cavity mode in a microwave resonator can be achieved by a weak beam of Rydberg atoms excited to the upper level of a resonant transition. For a cavity with a $Q \approx 10^{10}$, much less than a single atom at a time, on average, suffices to balance the cavity losses. Operation of a single atom maser has been demonstrated [8]. The atoms enter the cavity at random times, according to the Poisson statistics of a thermal beam, and interact with the field only for a limited time. In order to restrict the fluctuations of the atomic transit time, the velocity spread is reduced. This is achieved either by Fizeau chopping techniques or by making use of Doppler velocity selection in the initial laser excitation process. Since most of the time no atom is present, it is natural to separate the dynamics into two parts [50]:

1. For the short time while an atom is present, the state evolves according to the Jaynes–Cummings dynamics, where H is defined in Eq. (83.32),

$$\dot{\rho}(t) = \frac{i[H, \rho]}{\hbar}, \quad (83.61)$$

and damping can safely be neglected. The formal solution is abbreviated by $\rho(t) = F(t - t_0)\rho(t_0)$.

2. During the time interval between successive atoms, the cavity field relaxes freely toward the thermal equilibrium according to Eq. (83.55) with $L_0 = 0$

$$\dot{\rho}(t) = L\rho, \quad (83.62)$$

with the formal solution $\rho(t) = \exp[L(t - t_0)]\rho(t_0)$.

The time development of the micromaser, therefore, consists of an alternating sequence of unitary $F(t)$ and dissipative $e^{(Lt)}$ evolutions. Atoms enter the cavity one by one at random times t_i . Until the next atom enters at time t_{i+1} , the evolution t_i is given by

$$\rho(t_{i+1}) = \exp(Lt_p)F(\tau)\rho(t_i), \quad (83.63)$$

where $t_p = t_{i+1} - t_i - \tau$, and τ is the transit time. If $\tau \ll t_{i+1} - t_i$ on average, then $t_p \approx t_{i+1} - t_i$. After averaging Eq. (83.63) over the Poisson distribution $P(t) = R \exp(-Rt_p)$ for t_p , where R is the injection rate, the mean propagator from atom to atom is

$$\langle \rho(t_{i+1}) \rangle = \frac{R}{R - L} F(\tau) \langle \rho(t_i) \rangle. \quad (83.64)$$

After excitation, the reduced density matrix of the field alone becomes diagonal after several relaxation times κ^{-1}

$$\langle n | \text{Tr}_{\text{atom}}(\rho) | m \rangle = P_n \delta_{n,m}. \quad (83.65)$$

Due to the continuous injection of atoms, the field never becomes time independent but may relax toward a stroboscopic state defined by

$$\langle \rho(t_{i+1}) \rangle = \langle \rho(t_i) \rangle. \quad (83.66)$$

The state of the cavity field can be determined in closed form by iteration

$$P_n = N \prod_{k=1}^n \frac{n_{\text{th}}\kappa + A_k}{(n_{\text{th}} + 1)\kappa}, \quad (83.67)$$

where N guarantees normalization of the trace, and $A_k = (R/n) \sin^2(g_\mu \tau \sqrt{n})$, and exact resonance between cavity mode and atom is assumed. Since all off-diagonal elements vanish in steady state, Eq. (83.67) provides a complete description for the photon statistics of the field.

Fig. 83.9 Average photon number as a function of the normalized transit time defined by Eq. (83.69)

83.5.1 Maser Threshold

The steady-state distribution determines the mean photon number of the resonator as a function of the operating conditions

$$\langle n \rangle = \sum_{n=0}^{\infty} n P_n. \quad (83.68)$$

A suitable dimensionless control parameter is

$$\Theta = \frac{1}{2} g_\mu \tau \sqrt{\frac{R}{\kappa}}. \quad (83.69)$$

For $\Theta \ll 1$, the energy input is insufficient to counterbalance the loss of the cavity, effectively resulting in a negligible photon number. With increasing pump rate R , a threshold is reached at $\Theta \simeq 1$, where $\langle n \rangle$ increases rapidly with R . In contrast to the behavior of the usual laser, the single-atom maser displays multiple thresholds with a sequence of minima and maxima of $\langle n \rangle$ as a function of Θ [51]. This can be related to the rotation of the atomic Bloch vector. When the atom undergoes a rotation of about π during the transit time τ , a maximum of energy is transferred to the cavity, and $\langle n \rangle$ is maximized. The converse applies if the average rotation is a multiple of 2π . This behavior is shown in Fig. 83.9. The minima in $\langle n \rangle$ are at $\Theta \simeq 2n\pi$.

83.5.2 Nonclassical Features of the Field

Fluctuations can be of classical or of quantum origin. The variance of the photon number

$$\sigma^2 = (\langle n^2 \rangle - \langle n \rangle^2) \quad (83.70)$$

Fig. 83.10 Variance normalized on the average photon number $\sigma^{2(n)}/\langle\sigma\rangle$. Values below unity indicate regions of nonclassical behavior

is a measure of the randomness of the field intensity. Classical Poisson statistics require that $\sigma^2 \geq \langle n \rangle$. A value below unity indicates quantum behavior, which has no classical analog. In Fig. 83.10, the variance is plotted as a function of Θ . Regions of enhanced fluctuations $\sigma^2 > \langle n \rangle$ alternate with regions with sub-Poissonian character $\sigma^2 < \langle n \rangle$ [52]. When $\langle n \rangle$ approaches a local maximum, it is accompanied by large fluctuations, while at points of minimum field strength, the fluctuations are reduced below the classical limit. This feature is repeated with a period of $\Theta \simeq 2\pi$ but finally washes out at large values of Θ .

The large variance of n is caused by a splitting of the photon distribution P_n into two peaks, which gives rise to bistability in the transient response [53]. The sub-Poissonian behavior of the field is reflected in an increased regularity of the atoms leaving the cavity in the ground state.

83.5.3 Trapping States

If cavity losses are neglected, operating conditions exist which lead directly to nonclassical, i.e., Fock states. If the cavity contains precisely n_q photons, an atom that enters the resonator in the excited state leaves it again in the same state provided the condition [54]

$$g_\mu \tau \sqrt{n_q + 1} = 2q\pi \quad (83.71)$$

is satisfied, i.e., the Bloch vector of the atom undergoes q complete rotations. Such a photon Fock state $|n_q\rangle$ is referred to as a trapping state in the literature of maser. Note that the same term is also used in other contexts with very different definitions. If the maser happens to reach a trapping state $|n_q\rangle$, the photon number n_q can no longer increase irrespective of the flux of pump atoms. With the inclusion of cavity damping

at zero temperature, n_q still represents an upper barrier that cannot be overcome, since damping only causes downward transitions. Even in the presence of dissipation, generalized trapping states exist with a photon distribution that vanishes for $n > n_q$ and has a tail towards smaller photon numbers $n \leq n_q$. However, thermal fluctuations at finite temperatures destabilize the trapping states since they can momentarily increase the photon number and allow the distribution to jump over the barrier $n = n_q$. Nevertheless, even for $n_{\text{th}} < 10^{-7}$, remnants of the trapping behavior persist and can be seen in the transient response of the micromaser (Sect. 83.5.4).

83.5.4 Atom Counting Statistics

Direct measurements of the field in a single-atom maser resonator are not possible because detector absorption would drastically degrade its quality. However, the field can be deduced from the statistical signature of the atoms leaving the resonator.

The probability $P(n)$ of finding n atoms in a beam during an observation interval t is given by the classical Poisson distribution

$$P(n) = \frac{(Rt)^n e^{-Rt}}{n!}. \quad (83.72)$$

Information on the field inside is then revealed by the conditional probability $W(n, |g\rangle, m, |e\rangle, T)$ of finding n atoms in the ground state and m atoms in the excited state during a time t . Since there are only two states, it is sufficient to determine the probability

$$W(n, |g\rangle, t) = \sum_{m=0}^{\infty} W(n, |g\rangle, m, |e\rangle, t) \quad (83.73)$$

for being in the ground state [55]. For $n = 0$, the probability of observing no atom in the ground state during the period t is

$$\begin{aligned} W(0, |g\rangle, t) &= \text{Tr}(\rho_{\text{stst}} \exp\{L + R[O_{|g}\rangle + (1 - \eta)O_{|e}\rangle - 1]t\}) , \\ & \quad (83.74) \end{aligned}$$

where $O_{|j}\rangle = \langle j | F(\tau) | j \rangle$ Eq. (83.61) and ρ_{stst} is the steady state of the maser field. This probability is closely related to the waiting time statistic $P_2(0, |g\rangle, t)$ between two successive ground-state atoms, a property that is easily determined in a start–stop experiment. For an atom detector with finite quantum efficiency η for state selective detection, the waiting time probability is

$$\begin{aligned} P_2(0, |g\rangle, t) &= \frac{\text{Tr}(\rho_{\text{stst}}) O_{|g}\rangle \exp[L + R[O_{|g}\rangle + (1 - \eta)O_{|e}\rangle - 1]T] O_{|g}\rangle}{[\text{Tr}(\rho_{\text{stst}}) O_{|g}\rangle]^2} . \\ & \quad (83.75) \end{aligned}$$

Fig. 83.11 Waiting time probability for atoms in the ground state while the cavity is operated at the vacuum trapping-state condition

How a specific field state is reflected in the atom counting statistics will be illustrated for two situations: the region of sub-Poisson statistics and the region where the trapping condition is satisfied. Increased regularity of the cavity field $Q_M \leq 0$ manifests itself in increased regularity of ground-state atoms in the beam. The statistical behavior exhibits *antibunching*, i.e., $P_2(0, |g), t$ has a maximum at finite t , indicating *repulsion* between successive atoms in comparison with a Poissonian beam. If the transit time τ is chosen in such a way that $g\tau \simeq 2\pi$, the chance of observing an initially excited atom in the ground state is negligible. At some point, however, an unlikely thermal fluctuation occurs, adding a photon. The rotation angle of the Bloch vector suddenly increases to $2\pi\sqrt{2} \simeq 3\pi$, and the atoms tend to leave the cavity in the ground state. After a typical cavity lifetime, the field decays, and the trapping condition is restored again. Under this operation condition, the statistics of ground-state atoms is governed by two time constants:

1. A short interval, in which successive atoms leave the cavity in the ground state after a thermal fluctuation
2. A long time interval, in which the trapping condition is maintained, and all atoms leave the resonator in their excited state until the next fluctuation occurs.

The probability $P_2(0, |g), t$ is plotted in Fig. 83.11. The plot clearly shows the two time regimes that govern the imperfect trapping situation.

83.6 Cavity Cooling

In previous sections, we presented some important aspects of cavity QED by examining the effect of coupling between a single-cavity photon and the atomic (pseudo-)spin degree of freedom. However, an experimental realization and a perfect control of such coupling requires very cold atoms

trapped at a specific position. Thus, the external degree of freedom associated with the kinetic motion of atoms needs to be taken into account to achieve a complete description of the system. As an example, the cavity modes can exert light forces on moving atoms and induce a significant effect in transmission spectroscopy measurements [56–58].

Another important example and one of the most promising applications of the cavity QED dynamics involving atomic motion is the realization of cavity cooling, i.e., the dissipation of kinetic energy through the cavity photon-loss channel in a controlled manner. The realization of cavity cooling has been proved to be an essential step for the experimental achievement of strongly coupled cavity QED systems with sufficiently long interaction times and precise control of atomic motion. In the weak coupling regime, the atom can be cooled by coupling with cavity photons if the pumping is red-detuned with $\omega_p - \omega_C < 0$, in which case the average frequency of emitted photons is higher than that of the pumping laser due to the increase of mode density around the cavity frequency. The energy, hence, has to be compensated by the loss in kinetic energy of the atomic center-of-mass (CM) motion. In the strong-coupling regime, however, the atom–light scattering process becomes complicated with the nonnegligible photon reabsorption. For a high-finesse FP cavity, the dynamic cavity cooling effect in this case can be interpreted in the frequency domain with a Sisyphus-type mechanism using the dressed-state picture [59]. For the case of a ring cavity, the intuitive photon scattering picture can still be used but with a full velocity dependence on the radiation pressure [60].

83.6.1 Master Equation

As a simplest example, we consider a system of a single two-level atom trapped in a single-mode optical cavity, which is driven by a monochromatic pumping laser. Under the dipole approximation and the RWA, the Hamiltonian of the system can be written as

$$\mathcal{H} = \mathcal{H}_{\text{GJC}} + \mathcal{H}_{\text{CoM}} + \mathcal{H}_{\text{pump}}. \quad (83.76)$$

The generalized Jaynes–Cummings (GJC) term is similar to the JC model in Eq. (83.15)

$$\begin{aligned} \mathcal{H}_{\text{GJC}} = & \frac{1}{2} \hbar \omega_0(\mathbf{r}) \sigma_z + \hbar \omega_C a^\dagger a \\ & + \hbar [g f(\mathbf{r}) \sigma_+ a + g^* f^*(\mathbf{r}) a^\dagger \sigma_-], \end{aligned} \quad (83.77)$$

where the atomic frequency $\omega_0(\mathbf{r})$ acquires explicit dependence on the CM coordinate \mathbf{r} of the atom owing to a differential AC-Stark shift induced by a far-detuned external trapping potential exerted on the atom. Besides, the

atom–photon coupling strength is spatially modulated with a function $f(\mathbf{r})$ according to the electric field strength of cavity mode. For a standing-wave mode in an FP cavity, the coupling modulates in magnitude with $f(\mathbf{r}) = \cos(kx)$, while for a propagating-wave mode in a ring cavity, the coupling modulates in phase with $f(\mathbf{r}) = e^{i\pi kx}$. In both cases, the intracavity mode is assumed without loss of generality to be along the x -direction. The motion of the atomic CM degree of freedom is described by the term

$$\mathcal{H}_{\text{CoM}} = \frac{\mathbf{p}^2}{2m} + V_{\text{trap}}(\mathbf{r}), \quad (83.78)$$

where m is the atomic mass, and $V_{\text{trap}}(\mathbf{r})$ denotes the trapping potential. If pumped by a driving laser at frequency ω_p , the pumping Hamiltonian takes the form

$$\begin{aligned} \mathcal{H}_{\text{pump}} = & i\hbar\eta(a^\dagger - a)e^{-i\omega_p t} \\ & + i\hbar\Omega_p(\mathbf{r})e^{-i\omega_p t}(\sigma_+ - \sigma_-), \end{aligned} \quad (83.79)$$

where the first term describes a pumping laser applied along the cavity direction to couple the cavity mode with amplitude η , and the second corresponds to a driving directly on the atomic spin degree of freedom at a position-dependent Rabi frequency $\Omega_p(\mathbf{r})$.

The dynamics of the system can be described by the density operator ρ , which satisfies the master equation

$$\frac{d\rho}{dt} = -\frac{i}{\hbar}[\mathcal{H}, \rho] + \mathcal{L}_{\text{cav}}\rho + \mathcal{L}_{\text{atom}}\rho, \quad (83.80)$$

where the Liouville operators are introduced to describe the dissipation of cavity photons and atoms. If the environment is Markovian, this photon decay can be approximated by

$$\mathcal{L}_{\text{cav}}\rho = -\kappa(a^\dagger a \rho + \rho a^\dagger a - 2a\rho a^\dagger), \quad (83.81)$$

with κ the cavity decay rate. Another decay channel of the system is the spontaneous decay of atom from the excited to the ground state, accompanied by the emission of a photon into the environment. This process takes the form

$$\begin{aligned} \mathcal{L}_{\text{atom}}\rho = & -\gamma[\sigma_+\sigma_-\rho + \rho\sigma_+\sigma_- \\ & - 2\int d^2\hat{\mathbf{r}}_\perp h(\hat{\mathbf{r}}_\perp)\sigma_-\epsilon^{-ik_0 r_\perp}\rho\epsilon^{ik_0 r_\perp}\sigma_+], \end{aligned} \quad (83.82)$$

where γ is the spontaneous decay rate, $\hat{\mathbf{r}}_\perp$ is the directional unit vector in the transversal plane, $r_\perp = \mathbf{r} \cdot \hat{\mathbf{r}}_\perp$ is the projection, and $k_0 = \omega_0/c$ is the recoil wave vector of the atom. The function $h(\hat{\mathbf{r}}_\perp)$ is present to describe the directional distribution of spontaneous decay of specific atomic transition.

In general, it is not possible to solve the master equation (83.80) analytically, even for a single atom. If the population of the atomic excited state is negligible, one

can significantly simplify the Hamiltonian Eq. (83.76) by adiabatically eliminating the atomic excited state. This approximation is valid provided that the atomic transition between the two internal spin states is far detuned from the pumping laser or has a large spontaneous decay rate. In either case, the atomic operator can be approximated as

$$\sigma_- \approx \frac{gf(\mathbf{r})a + \Omega_p(\mathbf{r})}{-i(\omega_p - \omega_0) + \gamma}. \quad (83.83)$$

By substituting the expressions of σ_- and $\sigma_+ = \sigma_-^\dagger$ back into Eq. (83.76), we obtain an effective Hamiltonian in which the CM motion of the atom is coupled to the cavity mode

$$\begin{aligned} \mathcal{H}_{\text{eff}} = & \frac{\mathbf{p}^2}{2m} + V_{\text{trap}}(\mathbf{r}) \\ & - \hbar[(\omega_p - \omega_C) - U_0|f(\mathbf{r})|^2]a^\dagger a \\ & + \hbar\eta_{\text{eff}}(\mathbf{r})[f^*(\mathbf{r})a^\dagger + f(\mathbf{r})a], \end{aligned} \quad (83.84)$$

where the position-dependent effective pumping strength is given by

$$\eta_{\text{eff}}(\mathbf{r}) = \frac{(\omega_p - \omega_0)g\Omega_p(\mathbf{r})}{(\omega_p - \omega_0)^2 + \gamma^2}. \quad (83.85)$$

In this effective model, one can see clearly that the cavity photons provide a trapping potential $\hbar U_0|f(\mathbf{r})|^2 a^\dagger a$ to the atomic CM motion with

$$U_0 = \frac{g^2(\omega_p - \omega_0)}{(\omega_p - \omega_0)^2 + \gamma^2}. \quad (83.86)$$

The gradient of this effective potential acts as a force exerted on the atom. This force acquires an explicit dependence on the amplitude of the cavity mode, which depends not only on the momentary position of the atom but has a memory effect owing to the finite decay rate κ . The force, hence, becomes velocity dependent, which, in a semiclassical theory of atomic motion, leads to an effective viscous friction that can cool the atom.

83.6.2 Cavity Cooling Experiments

Cavity cooling of single atoms was first demonstrated with ^{85}Rb atoms trapped in an FP cavity [61]. In this experiment, the trapping field was red-detuned with respect to the atom, while the cooling laser was a blue-detuned probing field with frequency $\omega_p > \omega_0$. From Eqs. (83.84) and (83.86), the interaction between the probing laser and the atom induces to a blueshift of the cavity frequency by an amount of $U_0|f(\mathbf{r})|^2$, which then leads to an increase of the energy stored in the cavity field with a cost of kinetic energy

of the atoms. The cooling effect was demonstrated via the observation of extended storage times and improved localization of ^{85}Rb atoms from time-resolved measurement of the cavity transmission signal. As a result, a cooling rate of $\beta/m = 21$ kHz is achieved, which exceeds the estimated value of 4 kHz for blue-detuned Sisyphus cooling of a two-level atom in free space, or with the Doppler cooling rate of 1.5 kHz at equivalent atomic saturation.

With the advanced progresses of free-space laser cooling and trapping, other achievements have been obtained in the exploration and applications of single-atom cavity QED systems. These include the high-precision measurements demonstrated the basic cavity QED model in the optical domain [62, 63], the quantum anharmonic domain of the Jaynes–Cummings spectrum [64, 65], the generation of squeezed light [66], the development of a deterministic single-photon source [67, 68], the realization of the long-time sought atom–photon quantum interface [69, 70] and single-atom quantum memory [71], and the realization of electromagnetically induced transparency with a single atom [72].

83.7 Cavity QED for Cold Atomic Gases

Another new research direction in cavity QED is about the hybrid system of cold and ultracold atomic ensembles and high-finesse optical resonators. With the common coupling of atoms to the cavity field, there exists a long-range interatomic interaction mediated by coherent scattering of cavity photons, an ingredient which is usually absent in free-space cold atom experiments. As a result, this strongly interacting many-body system can present novel quantum phenomena with strong correlation. Besides, the coupling between the cavity mode and the atomic motion can induce a frequency shift of the cavity frequency and its backaction on mechanical motion, which may lead to a self-organization of atoms and an implementation of cavity optomechanics.

83.7.1 Atomic Ensembles in a Cavity

The interatomic interaction in a cavity is mediated by the cavity mode by its direct coupling to the atomic electric-dipole moments. However, the nature is inherently different from the induced dipole–dipole interaction, i.e., the van der Waals interaction in free space. In a cavity, the interaction strength does not decay with the interatomic separation and depends only on the local coupling of the atoms to the cavity field. More importantly, the interaction is a global coupling with the ensemble of atoms collectively coupling to the cavity field and experiencing the resulting backaction. Thus, even in cases where the interaction between a single atom and cavity mode is not strong enough, the collective interac-

tion energy can still be enhanced coherently within an atomic ensemble. Next, we discuss the character of the cavity-mediated interatomic interaction in two different pumping geometries, namely, pumping the cavity either directly or indirectly via light scattering off the laser-driven atoms.

In the case of cavity pumping, the detuning between the driving laser and the dispersively shifted cavity resonance depends on the position of all atoms, which, in turn, experience the optical dipole force of the intracavity field. Under the adiabatic approximation with small atomic velocities and low saturation, the interaction potential among the ensemble of N atoms takes the form [73]

$$V(\mathbf{r}_1, \dots, \mathbf{r}_N) = \frac{\hbar(\omega_p - \omega_0)|\eta|^2}{(\omega_p - \omega_0)\kappa + (\omega_p - \omega_C)\gamma} \times \tan^{-1} \frac{\gamma\kappa - (\omega_p - \omega_0)(\omega_p - \omega_C + g_{\text{eff}}^2)}{(\omega_p - \omega_0)\kappa + (\omega_p - \omega_C)\gamma}. \quad (83.87)$$

The collective coupling strength g_{eff} depends on the spatial distribution of the N atoms. This cavity-mediated long-range interatomic interaction gives rise to an asymmetric deformation of the normal-mode splitting, which has been observed experimentally [74].

The situation drastically changes if the system is atom pumped by a driving laser from a direction perpendicular to the cavity axis. In this case, photons are Rayleigh scattered by atoms into the cavity mode. Photons scattered from different atoms will interfere either destructively or constructively, depending on the relative positions of the atoms. Consider as a simple example, two atoms trapped in a cavity. If the two atoms are separated by odd integer multiples of the half-wavelength, the photons scattered into the cavity have the same magnitude but opposite signs, resulting in destructive interference and a vanishing cavity field intensity. On the other hand, if the two atoms are separated by even integer multiples of the half-wavelength, the photons scattered off the two atoms interfere constructively to yield a fourfold enhancement of the field intensity. This collective enhancement of scattering photons from multiple atoms is referred to as superradiance [75, 76].

Approximately, in the limit of $U_0 \rightarrow 0$, the collective potential of the atomic ensemble reads

$$V(\mathbf{r}_1, \dots, \mathbf{r}_N) = \frac{\hbar(\omega_p - \omega_C)|\eta_{\text{eff}}|^2}{(\omega_p - \omega_C)^2 + \kappa^2} \times \left[\sum_{j=1}^N \cos(kx_j) \cos(kz_j) \right]^2. \quad (83.88)$$

Here, we assume that the cavity mode and the pumping laser are both standing waves along the x and z -directions, respectively. Notice that if one moves along the cavity direction

over a wavelength, the potential varies from its maximal value to zero, leading to a contrast of unity regardless of the atom–cavity coupling constant g . This is clearly distinct from the case of cavity pumping, where the atoms cause only a small modulation of the cavity intensity as $g \rightarrow 0$. This observation suggests that significant many-body effects can be encountered even in the weak-coupling regime in the atom pumping geometry.

The long-range interaction between atoms is the origin of various collective dynamical effects. As an example, a thermal cloud of cold atoms interacting with a single-mode FP cavity shows a phase transition upon tuning the atomic pumping power P from a direction perpendicular to the cavity axis [77, 78]. For pumping power less than a critical value P_{cr} , the atoms distribute uniformly to minimize its kinetic energy. The light scattered from atoms in different positions then interferes destructively, and the average intensity of the cavity field is zero. When the pumping power $P > P_{\text{cr}}$, however, the atoms arrange themselves to form a checkerboard pattern to compensate the long-range interaction energy, so that the light interferes constructively to achieve a macroscopic cavity field.

The self-organization of atoms in a transversally driven FP cavity was first demonstrated in 2003 [79]. In that experiment, a total of $N \approx 10^7$ Cs atoms prepared at a temperature of 6 μK were pumped by a strong enough red-detuned laser to achieve collective emission of light into the cavity. As a result, the emission rate exceeded the free-space single-atom Rayleigh scattering rate by a factor of up to 10^3 , and the spatial configuration of atoms featured a spontaneous symmetry breaking into either the odd or even sites of a checkerboard pattern, which was revealed by measuring π jumps in the phase of emitted cavity field relative to the pumping laser. In a ring-cavity with two propagating-wave modes, the self-organization of atoms was also observed with transverse pumping [80]. However, the system spontaneously breaks a continuous translational symmetry rather than a discrete \mathbb{Z}_2 symmetry as in the FP cavity.

83.7.2 Bose–Einstein Condensate in a Cavity

As compared to a thermal cloud of cold atoms, the system of a Bose–Einstein condensate (BEC) coupling with an optical cavity is of particular importance as it corresponds to some conceptually fundamental models of atoms coupling to a single-mode light field. When the atoms are Bose condensed into a single motional quantum state, the number of degrees of freedom required to describe the system can be substantially reduced. Therefore, the experimental platform can be used to mimic some model Hamiltonians of matter–light interaction, including the Tavis–Cummings or the Dicke

model, as well as the generic model for cavity optomechanics.

Under the mean-field approximation, which is valid in the presence of a cavity-mediated global coupling among all atoms, the condensate wave function and the cavity field are assumed by their amplitudes of expectation

$$\begin{aligned}\Psi(\mathbf{r}, t) &\rightarrow \sqrt{N_c} \phi(\mathbf{r}, t), \\ a(t) &\rightarrow \alpha(t),\end{aligned}\quad (83.89)$$

where N_c is the number of condensed atoms, and $\phi(\mathbf{r})$ is the normalized wave function. These mean fields for atoms and cavity field satisfy the Gross–Pitaevskii-like equations

$$\begin{aligned}i\hbar\partial_t\phi(\mathbf{r}, t) &= \left\{ -\frac{\hbar^2\nabla^2}{2m} + V_{\text{trap}}(\mathbf{r}) \right. \\ &\quad + N_c g_{\text{atom}} |\phi(\mathbf{r}, t)|^2 + \hbar U_0 |\alpha(t)|^2 \cos^2(kz) \\ &\quad \left. + \hbar\eta_{\text{eff}} [\alpha(t) + \alpha^*(t)] \cos(kx) \cos(kz) \right\} \phi(\mathbf{r}, t), \\ i\partial_t\alpha(t) &= [\omega_C - \omega_p + N_c U_0 \langle \phi | \cos^2(kz) | \phi \rangle - i\kappa] \alpha(t) \\ &\quad + i\eta + N_c \eta_{\text{eff}} \langle \phi | \cos(kx) \cos(kz) | \phi \rangle,\end{aligned}\quad (83.90)$$

where the interatomic contact interaction $g_{\text{atom}} = 4\pi\hbar^2 a_s/m$ with a_s the s -wave scattering length. On the one hand, the dynamics of the cavity field involves spatial averages over the condensate density distribution. On the other hand, the atoms are also affected by the backaction from the cavity field according to the potential-like terms, which depend on the amplitude α and intensity $|\alpha|^2$ of the cavity field in the Gross–Pitaevskii equation for atoms. The mean-field equations are usually solved numerically to obtain the time-evolution of the system and the steady-state solutions for both atoms and cavity field [81].

As in a thermal atomic ensemble, the BEC trapped inside a cavity can also self-organize to emit an intracavity field collectively. The key difference in the case of BEC is that the atomic motion is also quantized, and the transition is now between a uniform distribution and a periodic array of atoms in the cavity-induced lattice potential. As a consequence, the transition point is determined by the competition of kinetic energy and potential energy associated with the spatial modulation of atomic density.

Under the mean-field approximation, the steady state of the system can be determined by the numerical solutions of the Gross–Pitaevskii-like equations for both the cavity field α and the atomic mode $\phi(\mathbf{r})$. By assuming for simplicity that the atomic motion is only along the cavity axis and the cavity pumping $\eta = 0$, one can define an order parameter $\Theta = \langle \phi | \cos(kx) | \phi \rangle$, which describes the nonuniform spatial

Fig. 83.12 The steady-state order parameter Θ plotted as a function of the effective cavity pumping strength η_{eff} , indicating the self-organization of a Bose–Einstein condensate in an FP cavity [81]

modulation of the atoms. As can be seen from a typical result of the numerical solution shown in Fig. 83.12, the order parameter takes a nonzero value beyond a critical pumping strength η_{eff} , indicating self-organization of the density of atoms.

Self-organization of a BEC was experimentally achieved in 2010 [82]. In that experiment, a BEC of about 10^5 atoms was trapped inside a high-finesse FP cavity and was illuminated from a transversal direction by a far red-detuned standing-wave laser beam. By gradually increasing the power of the transverse laser beam beyond a critical value, a sharp rise of the intracavity field intensity and a macroscopic populations in the atomic momentum states $(px, pz) = (\pm\hbar k, \pm\hbar k)$ were observed, indicating a transition to the self-organization phase. Above this critical pump power, the relative phase $\Delta\phi$ between pump field and cavity field was observed to stay constant, which demonstrates that the system reached a steady state.

Self-organization of a laser-driven BEC in an optical cavity can also be considered as a realization of the Dicke quantum-phase transition in an open system, where the quantized atomic motion acts as a macroscopic spin, which strongly couples to the cavity field. The Dicke model, or equivalently, the Tavis–Cummings model, is proposed to study the collective interaction between a set of two-level atoms and a single light mode

$$\mathcal{H}_{\text{Dicke}} = \frac{1}{2}\hbar\omega_0 \sum_{j=1}^N \sigma_z^{(j)} + \hbar\omega_C a^\dagger a + \hbar g \sum_{j=1}^N (\sigma_+^{(j)} a + a^\dagger \sigma_-^{(j)}), \quad (83.91)$$

which contains a sum over all atoms with index j that couple to the field mode. It is instructive to introduce the collective spin operators

$$S_z = \frac{1}{2} \sum_{j=1}^N \sigma_z^{(j)},$$

$$S_\pm = \sum_{j=1}^N \sigma_\pm^{(j)}, \quad (83.92)$$

together with the total spin operator $\mathbf{S} = (S_x, S_y, S_z)$, where N is the number of atoms, $S_\pm = S_x \pm iS_y$, and $\sigma^{(j)}$ are the Pauli spin operators for the j -th atoms. In this notation, the Dicke Hamiltonian becomes

$$\mathcal{H}_{\text{Dicke}} = \hbar\omega_0 S_z + \hbar\omega_C a^\dagger a + \hbar g (S_+ a + a^\dagger S_-). \quad (83.93)$$

Here, we assumed that all atoms have the same frequency ω_0 and that they are coupled with the same strength g . Note that the eigenstates of the Dicke Hamiltonian are highly degenerate, reflecting the fact that there are many possible ways to accommodate a fixed number of excitations.

The eigenstates of the Dicke Hamiltonian, usually referred to as Dicke states, can be labeled by the quantum numbers of the spin operators $S^2|J, M\rangle = J(J+1)|J, M\rangle$ and $S_z|J, M\rangle = M|J, M\rangle$, where $J = 0, 1, \dots, N/2$, and $M = -J, -J+1, \dots, J$. In the weak excitation limit of $J+M \ll N$, the Dicke states behave like a harmonic oscillator, as can be seen from

$$|\langle J, M+1|S_+|J, M\rangle|^2 = (J+M+1)(J-M) \approx (J+M+1)N. \quad (83.94)$$

Thus, in this regime, the Dicke model can be regarded as a pair of harmonic oscillators coupled at a rate of $\sqrt{N}g$. If there is only one excitation in the system, the eigenstate is equivalent to that of the JC model, except that the coupling strength is collectively enhanced by a factor of \sqrt{N} . However, for the case of more than one excitation, the energy spectrum acquires a significant difference of anharmonicity.

For the case of large number of excitations, the Dicke Hamiltonian has been investigated extensively in the context of superradiance, during which process a macroscopic number of the atomic ensemble decays collectively and emits a large pulse of radiation. This can be seen from

$$S_+ S_- |J, M\rangle = (J+M)(J-M+1)|J, M\rangle, \quad (83.95)$$

which is proportional to the spontaneous emission rate of the ensemble. For the case of $M=J$, the emission rate is proportional to N as $J=N/2$. For the case of $M=0$, however, it is proportional to N^2 . This increase can be understood as

a result of strong correlations between the atoms in the ensemble during the emission process.

The self-organization of a BEC-cavity system can be regarded as the Dicke model by considering a pair of motional states as two pseudo-spin states [82, 83]. The two motional states are given by the uniform condensate mode $|p_x, p_z\rangle = |0, 0\rangle$ and the coherent superposition of the four momentum states $|\pm\hbar k, \pm\hbar k\rangle$, where x and z denote the cavity and pump directions, respectively. Coherent light scattering between the transverse pump beam and the cavity mode couples these two momentum states via two distinguishable Raman channels, resulting in a tunable interaction between the cavity mode and the corresponding collective spin degree of freedom. Experimentally, the phase boundary was mapped out as a function of pump-cavity detuning $\omega_p - \omega_C$ as shown in Fig. 83.13 [82].

83.7.3 Cavity Optomechanics with Cold Atoms

The hybrid atom-cavity system can also be used to study an important model of cavity optomechanics, where a harmonically suspended mechanical element interacts with an intracavity single-mode field. In certain limiting cases, where the motional degrees of freedom of atoms can be reduced to a single-mode harmonic oscillator [84], the effective Hamiltonian of Eq. (83.84) can be significantly simplified, leading to a generic form of the cavity optomechanics Hamiltonian

$$\mathcal{H}_{\text{OM}} = \hbar\omega_m c^\dagger c - \hbar \left[(\omega_p - \omega_C) - \frac{G}{2}(c^\dagger + c) \right] a^\dagger a + i\hbar\eta(a^\dagger - a), \quad (83.96)$$

where c^\dagger and c denote creation and annihilation operators of the mechanical oscillator at frequency ω_m , G is the dispersive shift of the cavity frequency induced by the atomic density modulation, and η is the pumping strength along the cavity axis.

The key ingredient of the experimental realization of the cavity optomechanics Hamiltonian Eq. (83.96) is that the cavity field must affect and sense predominantly a single collective motional mode of the atomic ensemble, which hence can be regarded as the harmonically suspended mechanical element. One possible way to realize this condition is to trap ultracold atoms in a far-detuned intracavity lattice potential such that the atoms form a stack of tightly confined atom clouds [85]. Each atom cloud is harmonically suspended with oscillation frequency ω_m and extends along the cavity axis by only a fraction of the optical wavelength. A cavity mode, whose periodicity differs from that of the trapping lattice potential, couples strongly to a single collective center-of-mass mode of the atomic stack. All remaining collective modes are

detuned from the cavity field and hence contribute as a heat bath.

Another route to realize the cavity optomechanics Hamiltonian is reported in 2008 [86]. In that experiment, a BEC is prepared in an external harmonic trapping potential, extending over several periods of the cavity standing-wave mode structure. Initially, all condensate atoms are prepared in the zero-momentum state $|p = 0\rangle$. The dispersive interaction with the cavity field diffracts atoms into the symmetric superposition of momentum states $|\pm 2\hbar k\rangle$ along the cavity axis. If the diffraction into higher-order momentum modes can be neglected, the dynamics of the coupled system can be well described by the optomechanics Hamiltonian Eq. (83.96).

83.8 Applications of Cavity QED

83.8.1 Quantum Nondemolition (QND) Counting of Photons

When the object of interest consists of only a few atoms and a few photons, the puzzling consequences of quantum mechanical measurement become visible. In the case of the micromaser, the information on the state of the field is imprinted in a subtle way on the atomic beam. While photon counting is normally a destructive operation, the dispersive part of the photon-atom interaction may be used to determine the photon number inside a resonator without altering it on average. Dispersive effects shift the phase of an oscillating atomic dipole without changing its state.

The phase shift due to the field in the resonator can be measured in a Ramsey-type experiment [87]. Consider an atom with two transitions $|g\rangle \rightarrow |e\rangle$ and $|e\rangle \rightarrow |i\rangle$. The first is far from resonance with the cavity, and the second is close to resonance but with a detuning $\delta_{ie} = \omega - \omega_{ie}$ large enough so as not to change the cavity photon number as the atom passes through. The dynamic Stark effect of the $|g\rangle \rightarrow |e\rangle$ transition frequency due to state $|i\rangle$ is then

$$\Delta\omega_{eg} = \frac{[g_{ie}\sqrt{n+1}]^2}{\delta_{ie}}. \quad (83.97)$$

If the resonator is now placed between the two Ramsey cavities, which are tuned to $\omega_R \approx \omega_{eg}$, such that the polarization of the $|e\rangle \rightarrow |g\rangle$ transition is rotated by $\approx \pi/2$, then the additional phase shift $\Delta\omega_{eg}\tau$ and, hence, the photon number n can be measured. Here, τ is the transit time through the optical resonator. Since Rydberg states have a large coupling constant g_μ , the phase shift due to a single atom is detectable [87].

This proposal was demonstrated experimentally in 2007 at ENS [88]. With the ability of developing super high-

Fig. 83.13 Dicke-model phase diagram. The mean-intracavity photon number is finite in the superradiant phase with large pumping power and small pump-cavity detuning [82]

quality microwave cavity, the experimental group successfully performs a QND measurement on single photons via dispersive interaction of single atoms in circular Rydberg states. The atoms have a high principal quantum number $n = 50$, and the highest possible angular and magnetic quantum numbers ($l = n - 1$, $|m_l| = n - 1$), hence acquire a life time of the order $\tau = 30$ ms. The experiment can witness the birth, life, and death of a photon nondestructively.

A complete measurement of n requires a sequence of N atoms because a single Ramsey measurement only determines whether the atom is in state $|e\rangle$ or $|g\rangle$, and hence $\Delta\omega_{eg}\tau$ to within $\pm\pi/2$. Since each measurement provides one binary bit of information, a sequence of N measurements can, in principle, distinguish 2^N possible Fock states for the photon field. However, with a monoenergetic beam, integral multiples of 2π remain undetermined. A distribution of velocities, and hence transit times, is, therefore, desirable. An entropy reduction strategy for selecting an optimal velocity distribution, based on the outcome of previous measurements, is described in [89]. The experimental demonstration was also reported in 2007 by the same group at ENS [90], where the experimental setup was refined to distinguish states with photon number $n \leq 7$.

As a consequence of the uncertainty principle, a measurement of the photon number destroys all information about the phase of the field. In the present case, the noise in the conjugate variable (the phase) is prevented from coupling back on the measured one, and hence the measurement is called a quantum nondemolition experiment. Many other aspects of phase diffusion, entangled states, and quantum measurements in the micromaser are discussed in [91].

83.8.2 Detecting and Trapping Atoms Through Strong Coupling

One of the key ingredients of cavity QED experiments is to deterministically localize atoms at desired positions in a cavity, where the atom–photon coupling can be well calculated and tuned. From Fig. 83.8 it is obvious that an atom traveling through the cavity will modify the transmission properties of this cavity. The ability of tuning strong coupling, thus, enables the experimenter to detect the presence of a single atom dispersively by monitoring cavity transmission or reflection. Laser-cooled atoms have low velocities and spend sufficient time in the cavity even in free flight to generate the transmission signal shown in Fig. 83.14. The signals correspond to individual atom transits, and the shape depends on the detuning of the probe laser from the resonantly interacting cavity–atom system [56, 92]. Thus, the strongly coupled cavity QED system can work as a sensitive single-atom detector, and can help us to extract the temperature and the statistical properties of cold atoms, which have great potential in time-resolved atom–cavity microscopy and in tracking single-atom trajectories.

The same scheme can also be applied to monitor a specific collective motion in an atomic ensemble [85, 93, 94]. In these experiments, the cavity mode is shifted in frequency by the strong interaction with the center-of-mass motion of the atomic ensemble. This provides the ability to realize continuous nondestructive measurement of a quantum many-body system.

The strong coupling between atom and cavity mode can also be used to trap atoms at specified positions. If an atom

Fig. 83.14 Transmission of a strongly coupled cavity for individual atom transits. Cesium atoms and cavity are in perfect resonance at $\lambda = 852$ nm, while the probe laser is increasingly detuned to the red side of the resonance from top to bottom [125]

absorbs a photon inside the cavity, a strong dipole force can be exerted due to the inhomogeneous field distribution of the cavity mode. Trapping of atoms with a single photon was achieved [92], and from the time variation of the cavity transmission, a reconstruction of atomic trajectories became possible. A similar mechanism is also implemented in a hybrid system of ion trap and optical cavity to localize single ions [95, 96]. This has allowed for very long trapping times of more than 90 min, as well as excellent control over the position of trapped ions within a subwavelength precision [97]. Recently, position control was also demonstrated individually for two ions trapped in the same cavity [98].

83.8.3 Single-Photon Sources

Coherent laser fields are considered the ultimate source of classical radiation fields, and they are characterized by the random arrival time of photons. Nonclassical light sources with, for instance, a regularized stream of photons offer interesting properties for low-noise measurement applications.

Cavity-QED systems offer an attractive light–matter process for the generation of such *photon-bit-streams*, or single-photon sources [99]. In such devices, a single-photon state can, for instance, be created by Raman processes involving a classical field, which serves as the control parameter for the process, and the vacuum field of the optical resonator. The Raman process leaves a single photon in the cavity, which only weakly interacts with the atom. If the resonator has suitable transmission properties, this photon will then escape with predetermined frequency, shape, and propagation direction. Deterministic single-photon sources have been realized with quantum dots [100, 101], single molecules [102], and also with slow [103, 104] or trapped [105, 106] cold atoms and ions [97, 107] inside optical cavities.

The high efficiency of photon sources also paves the route towards quantum memory and quantum network, which is essential for providing cluster states in one-way quantum computing [92] and for the quantum simulation of complex solid-state systems [93]. Successive operations of photon generation, photon storage, and photon retrieval were successfully demonstrated in a hybrid atom–cavity system [71].

83.8.4 Generation of Entanglement

In the middle of the 1990s, it was realized that fully controlled quantum systems can be used to implement a revolutionary type of information processing, now called quantum computing [108]. From the beginning, cavity QED has conceptually played an important role for experimental realizations, since it offers a route to manipulate, in principle, all physical parameters of a coherently interacting system. With the well-established microwave-cavity–Rydberg–atom system, it was proven that the generation of correlated and nonlocal, so-called *entangled* quantum states, is possible [109].

The first *application* of cavity QED was the transfer of the strong coupling idea to the combined internal and motional quantum states of trapped ions [110]. Here, the harmonic oscillation of the ion replaces the electric field of the conventional cavity-QED system. This quantum gate was realized with a system of two trapped ions coupled to each other by Coulomb forces [111].

Ideas about how to use the strong coupling of atoms and photons [112–114] for the generation of atom–photon, photon–photon, or atom–atom systems (by insertion of more than one atom) abound and become possible with the aid of experimental capabilities in the preparation and control of atoms in high-finesse cavities.

Atom–Photon Entanglement

A key advantage of the hybrid atom–cavity QED system is the potential to work as a quantum interface through which

the quantum state can be faithfully transferred from one medium to another. By driving a vacuum-stimulated Raman adiabatic passage into a superposition of two atomic ground states, for example with different orientations of the atomic spin of ^{87}Rb atoms [70], the internal state of a single atom can be entangled with the polarization state of a single photon.

Photon–Photon Entanglement

Starting from the atom–photon entangled state, one can drive another vacuum-simulated Raman adiabatic passage into a single atomic ground state with a well-defined spin orientation to map the quantum state of the atom into a second single photon. This process disentangles the atom and the light and creates an entangled photon pair. The two photons are emitted one after the other into the same spatial mode, hence have never overlapped with each other [115].

Atom–Atom Entanglement

By reversing the role of field and atom, the atom–photon entanglement can also be transferred to a second atom to create atom–atom entanglement. Multiparticle entanglement is considered as a crucial resource of quantum simulation, quantum computation, and quantum-enhanced metrology. The largest number of atoms ever to be entangled in an FP cavity is about 3000 [116] and is more than 40 in an optical fiber cavity [117]. The entanglement between two ions and two atomic ensembles via coupling to cavity mode were also demonstrated in experiments [118, 119].

Quantum Network

Using the aforementioned atom–photon entangled state as building blocks, an elementary quantum network can be implemented with two fiber-linked optical cavities, each containing a single trapped atom as a stationary quantum node. This scheme offers a clear perspective of both addressability and scalability because the atoms are trapped in their corresponding cavities, and more constituent cavities can be added to an existing network without much apparent complication. Besides, the component cavities can, in principle, be arranged in any geometry and two-party links can be established at will, both in time and space.

Elementary quantum network links implementing teleportation protocols between remote trapped atoms and atom–photon quantum-gate operations have been demonstrated in experiments [115, 120–122]. Besides, quantum networking between two cavities has also been experimentally demonstrated with atomic ensembles [123, 124]. These achievements represent a big step towards the goal of realizing an elementary quantum network and a feasible quantum computing system.

Qiongyi He Qiongyi He received her PhD from Jilin University in Changchun, China in 2007 and then worked at the University of Queensland in Brisbane, at Swinburne University of Technology in Melbourne, Australia, and at Peking University in China. She now works on quantum optics and information, with a focus on quantum entanglement, nonlocality, and quantum information applications.

Wei Zhang Wei Zhang received his PhD from Georgia Institute of Technology in 2006 and then worked at the University of Michigan at Ann Arbor and at Renmin University of China. He now works on quantum simulation and computation in artificial quantum systems, including cold quantum gases, optical microcavities, and trapped ions.

Dieter Meschede Professor Dieter Meschede teaches at the Institute for Applied Physics in Bonn. After his studies in Hanover and Cologne and having been awarded his Dr rer nat in Munich in 1984, he first worked at Yale University. Then he became Senior Scientist at the MPI for Quantum Optics, Garching. He has been Professor of Physics since 1990, first in Hanover and since 1994 in Bonn.

Axel Schenzle Professor Schenzle worked on various aspects of theoretical quantum optics, the description of classical and quantum-mechanical noise in microscopic and mesoscopic systems, Bose–Einstein condensation, quantum information theory, and quantum computing and decoherence. He was Deputy Rector of the University of Munich and Dean for many years. He passed away in 2016.

Abstract

Quantum mechanics began with the solution of the problem of blackbody radiation by Planck's quantum hypothesis: in the interaction of light with matter, energy can only be exchanged between the light in a cavity, and the atoms in the walls of the cavity by the discrete amount $E = h\nu$, where h is Planck's constant, and ν is the frequency of the light. Einstein, in his treatment of the photoelectric effect, reinterpreted this equation to mean that a beam of light consists of particles ("light quanta") with energy $h\nu$. The Compton effect supported this particle viewpoint of light by demonstrating that photons carried momentum, as well as energy. In this way, the wave-particle duality of quanta made its first appearance in connection with the properties of light.

It might seem that the introduction of the concept of the photon as a particle would necessarily also introduce the concept of locality into the quantum world. However, in view of observed violations of Bell's inequalities, exactly the opposite seems to be true. Here, we review some

recent results in quantum optics, which elucidate nonlocality and other fundamental issues in physics.

84.1 Introduction: The Photon Hypothesis

In spite of the successes of quantum electrodynamics, and of the standard model in particle physics, there was for a time considerable resistance to the concept of the photon as a particle. Many papers have been written trying to explain all optical phenomena semiclassically, i.e., with the light viewed as a classical wave, and the atoms treated quantum mechanically [1–4]. We first present some quantum optics phenomena that exclude this semiclassical viewpoint.

In an early experiment, Taylor reduced the intensity of a thermal light source in Young’s two-slit experiment, until, on the average, there was only a single photon passing through the two slits at a time. He then observed a two-slit interference pattern, which was identical to that for a more intense classical beam of light. In Dirac’s words, the apparent conclusion is that “each photon then interferes only with itself” [5]. However, a coherent state, no matter how strongly attenuated, always remains a coherent state (Sect. 83.4.2); since a thermal light source can be modeled as a statistical ensemble of coherent states, a stochastic classical wave model yields complete agreement with Taylor’s observations. The one-by-one darkening of grains of film can be explained by treating the matter alone quantum mechanically [2]; consequently, the concept of the photon need not be invoked, and the claim that this experiment demonstrates quantum interference of individual photons is unwarranted [6].

This weakness in Taylor’s experiment can be removed by the use of nonclassical light sources; as discussed by Glauber [7], classical predictions diverge from quantum ones only when one considers counting statistics or photon *correlations*. In particular, two-photon light sources, combined with coincidence detection, allow the production of single-photon ($n = 1$ Fock) states with near certainty. In the first such experiment [8], two photons, produced in an atomic cascade within nanoseconds of each other, impinged on two beamsplitters and were then detected in coincidence by means of four photomultipliers placed at all possible exit ports.

In a simplified version of this experiment [9], one of the beamsplitters and its two detectors are replaced with a single detector D_1 (Fig. 84.1). We define the anticorrelation parameter

$$\alpha \equiv N_{123}N_1/N_{12}N_{13}, \quad (84.1)$$

where N_{123} is the rate of triple-coincidences between detectors D_1 , D_2 , and D_3 ; N_1 is the singles rate at D_1 ; and N_{12} and N_{13} are double-coincidence rates. Then from Schwarz’s inequality [6, 9, 10], $\alpha \geq 1$ for any classical wave. In essence, since the wave divides smoothly, the coincidence rate between D_2 and D_3 is never smaller than the “accidental” coincidence rate, even when measurements are conditioned on an event at D_1 . (The Hanbury-Brown and Twiss experiment [11] can be explained classically, because thermal fluctuations lead to “bunching”, or a mean coincidence rate, which is *greater* than the mean accidental rate; cf. Sect. 74.4.) By contrast, the indivisibility of the photon leads to strong anticorrelations between D_2 and D_3 , making α arbitrarily small. In agreement with this quantum mechanical picture, Grangier et al. observed a 13-standard-deviation violation of the inequality [9], corroborating the notion of the “collapse of the wave packet” as proposed by Heisenberg [12].

84.2 Quantum Properties of Light

84.2.1 Vacuum Fluctuations: Cavity QED

The above considerations necessitate the quantization of the electromagnetic field, which in turn leads to the concept of vacuum fluctuations [4] (Sect. 82.2). Difficulties with this idea, such as the implied infinite zero-point energy of the universe, have led some researchers to attempt to dispense with this concept altogether, along with that of the photon, in every explanation of electromagnetic interactions with matter. Of course, it is impossible to explain all phenomena, such as spontaneous emission and the Lamb shift, without some kind of fluctuating electromagnetic fields (Chap. 70), but one can go a long way with an *ad hoc* ambient classical electromagnetic noise-field filling all of space, in conjunction with the radiation reaction [1, 4].

In particular, even the Casimir attraction between two conducting plates can be explained semiclassically in terms of dipole forces between electrons in each plate as they undergo zero-point motion and induce image charges in the other plate. Nevertheless, the effects of cavity QED (Chap. 71) [13, 14], including the influence of cavity-induced

Fig. 84.1 Triple-coincidence setup of Grangier et al. [9]

boundary conditions on energy levels and spontaneous emission rates, are most easily unified via quantization of the electromagnetic field.

By coupling highly excited Rydberg atoms to photons in a high-finesse superconducting microwave cavity, *Brune et al.* observed single-photon-driven Rabi oscillations [15] and used these to study decoherence effects [16], atom-photon entanglement [17], and quantum nondemolition measurements [18] (Sect. 84.5.2). *Kimble et al.* [19] and *Rempe et al.* [20] performed similar experiments, coupling atoms to small optical cavities, and even trapping the atoms with light fields at the single-photon level [21, 22]. By monitoring the amplitude of the light transmitted through the cavity (which depends on the precise location of the atom inside the cavity volume), the trajectory of the atom can be determined with ultrahigh resolution, much smaller than an optical wavelength [23, 24].

84.2.2 Two-Photon Light Sources

The quantum aspects of electromagnetism are made more striking with a two-photon light source, for example, when two highly correlated photons are produced in spontaneous parametric downconversion, or parametric fluorescence [25–27], or four-wave mixing. In this process, a “pump” photon produced in a laser spontaneously decays inside a crystal with a $\chi^{(2)}$ nonlinearity into two highly correlated lower energy photons, conventionally called the “signal” and the “idler” (Sect. 76.3.6). (The quantum state of the light is more correctly written as $|\psi\rangle \propto |\text{vacuum}\rangle + \epsilon|1\rangle_s|1\rangle_i + \epsilon^2|2\rangle_s|2\rangle_i$, but since the amplitude of the downconversion process itself is very weak (ϵ is of order 10^{-4} to 10^{-6}), one often neglects the terms containing two or more pairs. However, recent experiments have begun to exploit these higher-order terms, e.g., to investigate multiphoton quantum entangled states of up to 10 and 12 photons [28].). As shown in Fig. 84.2, a rainbow of colored cones is produced around an axis defined by the direction of the pump beam (for the case of type-I phase-matching), with the correlated downconversion photons always emitted on opposite sides of the pump (Sect. 76.2.2). Their emission times are within femtoseconds of each other, so that detection of one photon implies with near certainty that there is exactly one quantum present in the conjugate mode [29]. In type-I phase-matching, the correlated photons share the same polarization, while in type-II phase-matching, they have orthogonal polarizations (Sect. 76.2.2). We will see below (Sect. 84.6.5) how both of these can enable the production of photons that are entangled in polarization, as well as in other degrees of freedom. Downconversion can only take place in a crystal having inversion symmetry; otherwise $\chi^{(2)} = 0$. However, the next order nonlinearity ($\chi^{(3)}$) can occur in any optical material, although it

Fig. 84.2 Conical emissions of downconversion from a nonlinear crystal. Photon energy depends on the cone opening angle, and conjugate photons lie on opposite sides of the axis, e.g., the inner “circle” orange photon is conjugate to the outer “circle” deep-red photon, etc.

is a weaker effect. Using this third-order nonlinearity, it is possible to create a correlated signal and idler photon pair through the annihilation of two pump photons in a process known as four-wave mixing.

84.2.3 Squeezed States of Light

The creation of correlated photon pairs is closely related to the process of quadrature-squeezed light production (Sect. 82.6 and the review in [30]). For example, when the gain arising from parametric amplification in a downconversion crystal becomes large, there is a transition from spontaneous to stimulated emission of pairs. This gain is dependent on the phase of amplified light relative to the phase of the pump light. As a result, the vacuum fluctuations are reduced (“squeezed”) below the standard quantum limit in one quadrature but increased in the other, in such a way as to preserve the minimum uncertainty-principle product [31]. This periodicity of the fluctuations at 2ω is a direct consequence of the fact that the light is a superposition of states differing in energy by $2\hbar\omega$ – the quadrature-squeezed vacuum state

$$|\xi\rangle = \exp\left(\frac{1}{2}\xi^*aa - \frac{1}{2}\xi a^\dagger a^\dagger\right)|0\rangle \quad (84.2)$$

represents a vacuum state transformed by the creation ($a^\dagger a^\dagger$) and destruction (aa) of photons two at a time. Essentially any optical processes operating on photon pairs (e.g., four-wave mixing [32, 33]) can also produce such squeezing.

Amplitude squeezing involves preparation of states with a well-defined photon number, i.e., states lacking the Poisson fluctuations of the coherent state. The possibility of producing such states (e.g., via a constant-current-driven semiconductor laser [34], or more recently a quantum dot-based source [35–38]) demonstrates that “shot noise” in photodetection should not be thought of as merely the result of the probabilistic (à la Fermi’s Golden Rule; Sect. 73.5) excitation of quantum mechanical atoms in a classical field but

as representing real properties of the electromagnetic field, accessible to experimental control. This longstanding field of fundamental research has at long last begun to be applied to gravitational-wave detection (Sect. 84.8) and to quantum metrology [39].

84.3 Nonclassical Interference

84.3.1 Single-Photon and Matter-Wave Interference

The first truly one-photon interference experiment [9] used the cascade source discussed in Sect. 84.1. One of the photons was directed to a “trigger” detector, while the other, thus prepared in an $n = 1$ Fock state, was sent through a Mach–Zehnder interferometer. The output photon, detected in coincidence with the trigger photon, showed fringes with a visibility $> 98\%$. Dirac’s statement that a single photon interferes with itself is thus verified.

The pioneering atomic matter-wave interferometry experiments of Pritchard used standing-light gratings and nanofabricated diffraction gratings to construct Mach–Zehnder-type interferometers for sodium atoms [40] and molecules [41] from a supersonic source. Chu and Kasevich significantly advanced the field by the use of STIRAP (stimulated Raman pulses) to produce coherent beamsplitters for cold atomic beams, also in a Mach–Zehnder-type interferometer, but whose source were cesium atoms cooled in and launched from a magneto-optical trap (MOT) [42]. Matter-wave interferometry has since been applied to precision measurements of the acceleration g due to Earth’s gravity [43], gravity gradiometry [44], and Sagnac matter-wave gyroscopes [45, 46].

To date some of the largest molecular systems to display quantum interference of this sort are large molecules like carbon 60 (“buckyball”) and carbon 70 [47]. These are significant in that the average de Broglie wavelength of the molecules, emitted from an oven, was 2.8 pm, actually about 350 times *smaller* than the molecule itself. Multislit diffraction has also been demonstrated with the biological molecule porphyrin and with fluorofullerenes ($C_{60}F_{48}$) [48]. With a mass of 1632 amu, the latter are currently the largest single objects to display interference. *Marshall, Simon, Penrose*, and *Bouwmeester* separately suggested that it may be possible to put a micron-scale mirror (with $\approx 10^{14}$ atoms) into a superposition of resolvable spatial locations [49] – the mirror, part of a high-finesse optical cavity forming one arm of a Michelson interferometer, could be mounted on a high-quality mechanical oscillator, whereby the interaction with a single photon would change the frequency of the oscillator. During the last decade, progress along these lines has been dramatic. The quantum optical control of nano and micromechanical devices through motional coupling to optical cavity

fields or superconducting circuits, i.e., quantum optomechanics, has now been firmly established [50–52]. Recent examples include ground-state laser cooling of the center of mass motion of a micromechanical device comprising up to 10^{11} atoms [53], as well as the generation of quantum-squeezed states [54–56] and of non-Gaussian states [57, 58] of motion. Regarding interference phenomena, Ramsey interference has been observed with a micromechanical device coupled to a superconducting qubit [57], and quantum entanglement comprising one [59] and two [60–62] mechanical resonators has been demonstrated, including the violation of a Bell inequality [63]. Still, while masses of these solid-state resonators comprise the collective motion of up to 10^{15} atoms, the displacement involved in the demonstrated interference experiments is minute (specifically, on the order of one or a few mechanical quanta, which translates to nuclear-scale spatial displacements). Larger spatial displacements may be possible using levitated solid-state systems coupled to cavities [64], which is now becoming a focus of intense research and which holds even the promise of matter-wave interference in this extreme large-mass regime [65, 66].

Two other systems, demonstrating Bose–Einstein condensation (BEC), have also produced evidence of macroscopic quantum coherence. In the experiments of *Andrews* et al., atoms from two different atomic vapor BEC clouds were allowed to fall onto the same detection region, and displayed interference fringes [67] (more recently interference from an array of 30 independent BECs was observed [68]). In some ways, this is the matter-wave equivalent of the famous Pflieger–Mandel experiment [69], in which light from two separate lasers displays interference, even when attenuated to the single-photon level. The explanation in terms of the indistinguishability of the underlying processes is that one cannot ascertain from which laser source a given photon originated. However, this explanation must be applied carefully to the situation of the two atomic BECs; unlike the lasers, the BEC clouds can – at least in principle – be prepared with a definite number of atoms, and it would therefore seem that one could, in principle, determine which cloud emitted a given detected atom. However, this determinacy is rapidly lost after a few atoms are detected [70]. Once the number becomes uncertain, a well-defined relative phase of the two BECs is established, according to the number-phase uncertainty relation $\Delta(N_2 - N_1)\Delta(\phi_2 - \phi_1) \geq 1/2$.

Finally, quantum coherence (although not explicitly spatial interference as in the previous examples) has been detected in the operation of a Josephson-junction linked superconducting loop. Specifically, the group of Mooij was able to prepare a superposition of clockwise and counter-clockwise circulating electrical currents [71]. The $\approx 0.5 \mu\text{A}$ currents corresponded to the motion of millions of Cooper pairs. This superconducting system has become a major focus of quantum computing efforts (Chap. 85), with many groups and

companies around the world making rapid progress with superconducting quantum bits [72–83].

84.3.2 “Nonlocal” Interference Effects and Energy-Time Uncertainty

The energy-time uncertainty principle, $\Delta E \Delta t \geq \hbar/2$ has been tested in a downconversion interference experiment [84]. The downconversion process conserves energy and momentum:

$$\hbar\omega_0 = \hbar\omega_1 + \hbar\omega_2, \quad (84.3)$$

$$\hbar\mathbf{k}_0 \approx \hbar\mathbf{k}_1 + \hbar\mathbf{k}_2, \quad (84.4)$$

where $\hbar\omega_0$ ($\hbar\mathbf{k}_0$) is the energy (momentum) of the parent photon, and $\hbar\omega_1$ ($\hbar\mathbf{k}_1$) and $\hbar\omega_2$ ($\hbar\mathbf{k}_2$) are the energies (momenta) of the daughter photons; \mathbf{k}_1 and \mathbf{k}_2 sum to \mathbf{k}_0 to within an uncertainty given by the reciprocal of the crystal length [85]. Since there are many ways of partitioning the parent photon’s energy, each daughter photon may have a broad spectrum, and hence a wave packet narrow in time; indeed, detecting one of the photons with a fast detector will localize the other to a narrow pulse. However, $\omega_1 + \omega_2 = \omega_0$ is extremely well defined, so that the *difference* in the daughter photons’ arrival times and the *sum* of their energies can be simultaneously known to high precision. Thus, the daughter photons of a parent photon of sharp energy E_0 are in an energy-entangled state, a nonfactorizable sum of product states [86]:

$$|\Psi\rangle = \int_0^{E_0} dE A(E) |E\rangle |E_0 - E\rangle, \quad (84.5)$$

where $A(E)$ is the probability amplitude for the production of two photons of energies E and $E_0 - E$. Measuring the energy of one of the photons to be E_1 “collapses” the system to the state $|E_1\rangle |E_0 - E_1\rangle$, implying an instantaneous increase of the width of the other photon’s wave packet. In the experiment, one photon was used as a trigger, while the other was sent into an adjustable Michelson interferometer (Fig. 84.3) used to measure its coherence length. If the trigger photon was detected after passing through an interference filter F1 of narrow width ΔE , then the conjugate photon occupied a broad wave packet of duration $\Delta t \approx \hbar/\Delta E$ and displayed interference. When there was no trigger, no fringes were observed, implying a much shorter wave packet. This is a nonlocal effect in that the photons can be arbitrarily far away from each other when the collapse occurs.

84.3.3 Two-Photon Interference

In the above experiments, interference occurs between two paths taken by a *single* photon. An early experiment to

Fig. 84.3 The energy–time uncertainty relation and wave-function collapse were studied by investigating the effect of various filters before the detectors in a single-photon interference experiment [9, 84]

demonstrate *two*-photon interference using the downconversion light source was performed by Ghosh and Mandel [88]. They looked at the counting rate of a detector illuminated by both of the twin beams. No interference was observed at the detector, because although the sum of the phases of the two beams emitted in parametric fluorescence is well defined (by the phase of the pump), their *difference* is not, due to the number-phase uncertainty principle. However, when Ghosh and Mandel looked at the rate of *coincidence* detections between two such detectors whose separation was varied, they observed high-visibility interference fringes. Whereas in the standard two-slit experiment, interference occurs between the two paths a single photon could have taken to reach a given point on a screen, in this case, it occurs between the possibility that the signal photon reached detector 1 and the idler photon detector 2, and the possibility that the reverse happened. This experiment provides a manifestation of quantum nonlocality; interference occurs between alternate global histories of a system, not between local fields. At a null of the coincidence fringes, the detection of one photon at detector 1 excludes the possibility of finding the conjugate photon at detector 2.

Such interference becomes clearer in the related interferometer of Hong, Ou, and Mandel [89] (Fig. 84.4). The identically polarized conjugate photons from a downconversion crystal are directed to opposite sides of a 50–50 beamsplitter, such that the transmitted and reflected modes overlap. If the difference in the path lengths ΔL prior to the beamsplitter is larger than the two-photon correlation length (of the order of the coherence length of the downconverted light), the photons behave independently at the beamsplitter, and coincidence counts between detectors in the two output ports are observed half of the time – the other half of the time, both photons travel to the same detector. However, when

Fig. 84.4 Simplified setup for a Hong–Ou–Mandel (HOM) interferometer [89]. Coincidences may result from both photons being reflected or both being transmitted. When the path lengths to the beamsplitter are equal, these processes destructively interfere, causing a null in the coincidence rate. In a modified scheme, a half-waveplate in one arm of the interferometer (at “A”) serves to distinguish these otherwise interfering processes, so that no null in coincidences is observed. Using polarizers before the detectors one can “erase” the distinguishability, thereby restoring interference [108]. (Sections 84.4.2 and 84.6.5)

$\Delta L \approx 0$, such that the photon wave packets overlap at the beamsplitter, the probability of coincidences is reduced, in principle to zero if $\Delta L = 0$. One can explain the coincidence null at zero path-length difference using the Feynman rules for calculating probabilities: add the probability amplitudes of *indistinguishable* processes that lead to the same final outcome, and then take the absolute square. The two indistinguishable processes here are both photons being reflected at the beamsplitter (with Feynman amplitude $r \cdot r$) and both photons being transmitted (with Feynman amplitude $t \cdot t$). The probability of a coincidence detection is then

$$P_c = |r \cdot r + t \cdot t|^2 = \left| \frac{i}{\sqrt{2}} \cdot \frac{i}{\sqrt{2}} + \frac{1}{\sqrt{2}} \cdot \frac{1}{\sqrt{2}} \right|^2 = 0, \quad (84.6)$$

assuming a real transmission amplitude, and where the factors of i come from the phase shift upon reflection at a beamsplitter [90, 91].

The possibility of a perfect null at the center of the dip is indicative of a nonclassical effect. Indeed, classical field predictions allow a maximum coincidence-fringe visibility of only 50% [92]. The tendency of the photons to travel off together at the beamsplitter can be thought of as a manifestation of the Bose–Einstein statistics for the photons [93]. In practice, the bandwidth of the photons, and hence the width of the null, is determined by filters and/or irises before the detectors [85]. Widths as small as $5 \mu\text{m}$ have been observed, corresponding to time delays of only 15 fs [94]. Consequently, one application is the determination of single-photon propagation times with extremely high time resolution (Sect. 84.7). The dependence of the dip visibility on the indistinguishability of the photons is now commonly used to characterize quantum light sources [95–98].

84.4 Complementarity and Coherence

84.4.1 Wave-Particle Duality

The complementary nature of wave-like and particle-like behavior is frequently interpreted as follows: due to the uncertainty principle, any attempt to measure the position (particle aspect) of a quantum leads to an uncontrollable, irreversible disturbance in its momentum, thereby washing out any interference pattern (wave aspect) [99, 100]. This picture is incomplete though; no “state reduction”, or “collapse”, is necessary to destroy interference, and measurements that do not involve reduction can be reversible. One must view the loss of coherence as arising from an *entanglement* of the system wave function with that of the measuring apparatus (MA) [101]. Previously interfering paths can thereby become distinguishable, such that no interference is observed. Consider the simplest experiment, a Mach–Zehnder interferometer with a 90° polarization rotator in arm 1. If horizontally polarized light is input, the state before the recombining beamsplitter is $(|1\rangle|V\rangle + |2\rangle|H\rangle)/\sqrt{2}$, where $|1\rangle$ and $|2\rangle$ label the path of the photon. Because the polarization – playing the role of the MA – labels the path, no interference is observed at the output. Englert [102] has introduced a generalized relation quantifying the interplay between the wave-like attributes of a system (as measured by the fringe visibility V) and the particle-like character (as measured by the distinguishability D of the underlying quantum processes):

$$V^2 + D^2 \leq 1. \quad (84.7)$$

The equality holds for *pure* input states. This relation has now been well verified in optical systems like that described above [103], as well as in atom interferometry (Sect. 81.6) [104]. In the latter, the role of the polarization was played by internal energy states of an atom diffracted off a standing light wave.

84.4.2 Quantum Eraser

The interference lost to entanglement may be regained if one manages to “erase” the distinguishing information. This is the physical content of quantum erasure [105, 106]. The primary lesson is that one must consider the total physical state, including any MA with which the interfering quantum has become entangled, even if that MA does not allow accessible which-path information [107]. If the coherence of the MA is maintained, then interference may be recovered.

Fig. 84.5 Experimental data and scaled theoretical curves (adjusted to fit observed visibility of 91%) with polarizer 1 at 45° and polarizer 2 at various angles. Far from the dip, there is no interference, and the angle is irrelevant [108]

The first demonstration of a quantum eraser was based on the interferometer in Fig. 84.4 [108]. A half-waveplate inserted into one of the paths before the beamsplitter serves to rotate the polarization of light in that path. In the extreme case, the polarization is made orthogonal to that in the other arm, and the $r \cdot r$ and $t \cdot t$ processes become distinguishable; hence, the destructive interference that led to a coincidence null does not occur. The distinguishability can be erased, however, by using polarizers just before the detectors. In particular, if the initial polarization of the photons is horizontal, and the waveplate rotates one of the photon polarizations to vertical, then polarizers at 45° before both detectors restore the original interference dip. If one polarizer is at 45° and the other at -45° , interference is once again seen but now in the form of a peak instead of a dip (Fig. 84.5). There are four basic measurements possible on the MA (here the polarization) – two of which yield which-path information, one of which recovers the initial interference fringes (here the coincidence dip), and one of which yields interference antifringes (the peak instead of the dip). In some implementations, the decision to measure wave-like or particle-like behavior may even be delayed until *after detection* of the original quantum, an irreversible process [114, 115]. However, in all cases, one must correlate the results of measurements on the MA with the detection of the originally interfering system. This requirement precludes any possibility of superluminal signaling. This is an extension of the original delayed-choice discussion by *Wheeler* [109] and the experiments by *Hellmuth et al.*, *Alley et al.*, *Jacques et al.*, and *Kim et al.* [110–113], in which the decision to display wave-like or particle-like aspects in a light beam may be delayed until after the beam has been split by the appropriate optics.

Fig. 84.6 Setup used in [117]. The idler photons from the two crystals are indistinguishable; consequently, interference fringes may be observed in the signal singles rate at detector D_s . Additional elements at A and B can be used to make a quantum eraser

84.4.3 Vacuum-Induced Coherence

A somewhat different demonstration [116, 117] of complementarity involves two downconversion crystals, NL1 and NL2, aligned such that the trajectories of the idler photons from each crystal overlap (Fig. 84.6). A beamsplitter acts to mix the signal modes. If the path lengths are adjusted correctly, and the idler beams overlap precisely, there is no way to tell, even in principle, from which crystal a photon detected at D_s originated. Interference appears in the signal *singles* rate at D_s , as any of the path lengths is varied. If the idler beam from crystal NL1 is prevented from entering crystal NL2, then the interference vanishes, because the presence or absence of an idler photon at D_i then “labels” the parent crystal. Thus, one explanation for the effect of blocking this path is that coherence is established by the idler-mode *vacuum* field seen by both crystals.

Experiments have also been performed in which a *time-dependent* gate is introduced in the idler arm between the two crystals [118]. As one expects, the presence or absence of interference depends on the earlier state of the gate, at the time when the idler photon amplitude was passing through it.

84.4.4 Suppression of Spontaneous Parametric Downconversion

A modification [119] of this two-crystal experiment uses only a single nonlinear crystal (Fig. 84.7). A given pump photon may downconvert in its initial rightward passage through the crystal or in its left-going return trip (or not at all, the most likely outcome). As in the previous experiment, the idler modes from these two processes are made to overlap; moreover, the signal modes are also aligned to overlap. Thus, the left-going and right-going production processes are indistinguishable and interfere. The result is that fringes are observed in all of the counting rates (i.e., the coincidence rate and both singles rates) as any of the mirrors is translated. A different interpretation is as a change in the spontaneous emission of the downconverted photons, akin to the suppression of spon-

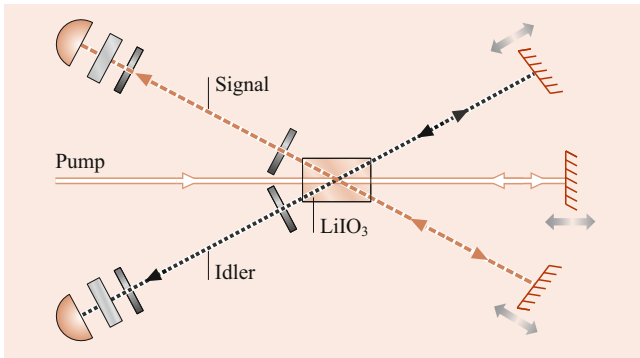

Fig. 84.7 Experiment to demonstrate enhancement and suppression of spontaneous downconversion [119]

taneous emission in cavity QED demonstrations, discussed in Sects. 84.2.1 and 83.3. Subsequent work has shown that, in a sense, there are always photons between the downconversion crystal and the mirrors, even in the case of complete suppression of the spontaneous emission process [120]. This same conclusion should also apply in the atom case, although in contrast to that system, for the downconversion experiment, the distances to the mirrors are much longer than the coherence lengths of the spontaneously emitted photons.

One recent application of this phenomenon is to study effective nonlinearities at the single-photon level [121]. Finally, with the inclusion of waveplates to label the photons' paths and polarizers to erase this information, an improved quantum eraser experiment was also completed, in which the which-path information for one photon was carried by the other photon [115].

84.5 Measurements in Quantum Mechanics

84.5.1 Quantum (Anti-)Zeno Effect

A strong measurement of a quantum system will project it into one of its eigenstates [101]. If the system evolves slowly out of its initial state: $|\Psi(t=0)\rangle = |\Psi_0\rangle \rightarrow \sqrt{1-t^2/\tau^2}|\Psi_0\rangle + t/\tau|\Psi_1\rangle$, then repeated measurements with an interval much less than τ can inhibit this evolution. If there are N total measurements within τ , then the probability for the system to still be in the initial state is $P(\tau) = (1 - (\tau/N)^2/\tau^2)^N \rightarrow 1$ as $N \rightarrow \infty$. This phenomenon, known as the quantum Zeno effect [122], has been experimentally observed using three levels in a ${}^9\text{Be}^+$ ion [123]. The ion was prepared in state $|i\rangle$ and weakly coupled to state $|f\rangle$ via RF radiation that induced a slow Rabi oscillation between the two states. Thus, in the absence of any intervening measurements, the ion evolved sinusoidally into state $|f\rangle$. When rapid measurements were made (by a laser strongly coupling state $|f\rangle$ to readout state $|r\rangle$, hence leading to strong fluorescence only if the atom was in state $|f\rangle$), the effect was to inhibit the $|i\rangle \rightarrow |f\rangle$ transition.

Note that here it was the *absence* of fluorescent photons that projected the state at each measurement back into the state $|i\rangle$.

Kofman and Kurizki pointed out that the above inhibition phenomenon depends on there being a bounded number of final states (the ion example had only one). If, instead, the measurement process actually *increases* the number of accessible final states $|f\rangle$, then one obtains the “anti-Zeno” effect, in which the $|i\rangle \rightarrow |f\rangle$ rate is enhanced rather than suppressed by frequent measurements [124]. For example, in the ion example, this would be the case if the $|i\rangle \rightarrow |f\rangle$ transition were spontaneous (allowing all frequencies) instead of driven (proceeding only at the driving Rabi frequency). The anti-Zeno effect has been observed by monitoring the survival time (against tunneling escape) of atoms trapped in an accelerating far-detuned standing wave of light [125].

84.5.2 Quantum Nondemolition

The uncertainty principle between the number of quanta N and phase ϕ of a beam of light,

$$\Delta N \Delta \phi \geq 1/2, \quad (84.8)$$

implies that to know the number of photons exactly, one must give up all knowledge of the phase of the wave. In theory, a *quantum nondemolition* (QND) process is possible [126]: without annihilating any of the light quanta, one can count them. It might seem that this would make possible successive measurements on noncommuting observables of a single photon, in violation of the uncertainty principle; it is the unavoidable introduction of phase uncertainty by any number measurement that prevents this.

QND schemes [127] often employ the intensity-dependent index of refraction arising from the optical Kerr effect (Sect. 76.4.3) – the change in the index due to the intensity of the “signal” beam changes the optical phase shift on a “probe” beam [128–131]. Other proposals include using the Aharonov–Bohm effect to sense photons via the phase shift their fields induce in passing electrons [132, 133]. Two classic experimental realizations [18] of a QND measurement – of the photon number in a microwave cavity – were performed by passing Rydberg atoms [134, 135] in a superposition of ground and excited state through the cavity. The interaction with the cavity photon is equivalent to a 2π -pulse (Sect. 83.8). The result is that, in the absence of any photon, the quantum state of the atoms after the cavity was unchanged; with a photon in the cavity, the ground state acquired an extra relative phase of π , which was then detected by measuring the atom's quantum state. Using similar schemes, successful nondemolition measurements have now been performed on microwave photons in microwave circuits [136, 137].

84.5.3 Quantum Interrogation

The previous section described techniques to measure the presence of a photon without absorbing it. Now we discuss a method – quantum interrogation – to optically detect the presence of an object without absorbing or scattering a photon. The possibility that the *absence* of a detection event – a “negative-result” measurement – can lead to wave-packet reduction was first discussed by *Renninger* [138] and later by *Dicke* [139]. Here, we consider the *gedanken* experiment proposed by *Elitzur* and *Vaidman*, a simple single-particle interferometer, with particles injected one at a time [140]. The path lengths are adjusted so that all the particles leave a given output port (A) and never the other (B). Now suppose that a nontransmitting object is inserted into one of the interferometer’s two arms – to emphasize the result, we consider an infinitely sensitive “bomb”, such that interaction with even a single photon will cause it to explode. By classical intuition, any attempt to check for the presence of the bomb involves interacting with it in some way, and by hypothesis this will inevitably set it off.

Quantum mechanics, however, allows one to be certain some fraction of the time that the bomb is in place, *without* setting it off. After the first beamsplitter of the interferometer, a photon has a 50% chance of heading towards the bomb and, thus, exploding it. On the other hand, if the photon takes the path without the bomb, there is no more interference, since the *nonexplosion* of the bomb provides *welcher Weg* (“which way”) information (Sect. 84.4.1). Thus, the photon reaches the final beamsplitter and chooses randomly between the two exit ports. Some of the time (25%), it leaves by output port B, something that never happened in the absence of the bomb. This immediately implies that the bomb (or some object) is in place – even though (since the bomb is unexploded) it has not interacted with any photon; *Elitzur* and *Vaidman* termed this an “interaction-free measurement”. (We prefer the more general description “quantum interrogation”, which then includes cases – e.g., detecting a semitransparent or quantum object – where it may not be possible to logically exclude the possibility of an interaction.) It is the possibility that the bomb *could* have interacted with a photon that destroys interference. An initial experimental implementation of these ideas [141] used downconversion to prepare the single photon states (Sect. 84.1) and a single-photon detector as the “bomb”. Subsequently, the technique was implemented incorporating focusing lenses, which would enable the image (more correctly, the silhouette) of an object to be determined with less than one photon per “pixel” being absorbed [142].

By adjusting the beamsplitter reflectivities in the above example, one can achieve at most a 50% fraction of measurements that are interaction free. An improved method, relying on the quantum Zeno effect [122] (Sect. 84.5.1), was discovered with which one can, in principle, make this fraction

arbitrarily close to 1 [141]. For example, consider a photon initially in cavity #1 of two identical cavities coupled by a lossless beamsplitter whose reflectivity $R = \cos^2(\pi/2N)$. If the photon’s coherence length is shorter than the cavity length, after N cycles, the photon will with certainty be located in cavity #2, due to an interference effect. However, if cavity #2 instead contains an absorbing object (e.g., the ultrasensitive bomb), at each cycle there is only a small chance ($= 1 - R$) that the photon will be absorbed; otherwise, the *nonabsorption* projects the photon wave packet entirely back onto cavity #1. After all N cycles, the total probability for the photon to be absorbed by the object is $1 - R^N$, which goes to 0 as N becomes large. In practice, unavoidable losses in the system limit maximum number of cycles and, hence, the achievable performance [143]. The photon effectively becomes trapped in cavity #1, thus indicating unambiguously the presence of the object in cavity #2.

This quantum-Zeno version of interrogation was first implemented using the inhibited rotation of a photon’s polarization (the object to be detected blocked one arm of a polarizing interferometer through which the photon was repeatedly cycled), achieving an efficiency of 75% [143]. A cavity-based implementation, in which the presence of the absorbing object inside a high-finesse cavity vastly increased the reflection off the cavity [144], detected the presence of the object with only 0.15 photons on average being absorbed or scattered [145].

84.5.4 Weak Measurements

Aharonov, *Albert*, and *Vaidman* extended quantum measurement theory by introducing “weak measurement”, a procedure that determines a physical property of a quantum system belonging to an ensemble that is both preselected and *postselected* [146, 147]. In the standard theory, a quantum system is measured by entangling its eigenstates with distinguishable pointer states of a measurement device, completely resolving the observable spectrum. The measurement can be weakened by increasing the overlap of the pointer states, consequently reducing the resolution of the eigenstates. When performed between two measurements this can give surprising results – in contrast to ordinary expectation values, the pointer can lie *outside* the range of the eigenvalue spectrum of the measured observable \mathbf{O} . The “weak value” $\mathbf{O}_w = \langle \Psi_{\text{fin}} | \mathbf{O} | \Psi_{\text{ini}} \rangle / \langle \Psi_{\text{fin}} | \Psi_{\text{ini}} \rangle$ between preselected $|\Psi_{\text{ini}}\rangle$ and postselected $|\Psi_{\text{fin}}\rangle$ states completely characterizes the outcome of the weak measurement. Weak measurements do not disturb each other, so that the weak values of noncommuting observables can be measured simultaneously [148].

Weak measurements have played an important role in addressing many fundamental issues in quantum mechanics, from the tunneling time [149, 150] (Sect. 84.7) to Hardy’s

paradox [151, 152] (Sect. 84.6.8) to the role of momentum disturbance in complementarity experiments [153] to verification of Ozawa's precision-disturbance relationship [154], which shows that a measurement need not disturb a system as much as predicted by a naive reading of the Heisenberg relation [155]. They have also permitted the study of negative kinetic energies [156], by postselecting a particle in a classically forbidden region, the direct reconstruction of the Bohmian trajectories of particles in a two-slit experiment [157], and a demonstration that a single postselected "shutter" can block two slits at once [158].

One other potentially powerful application of weak measurements is the amplification of weak signals, which was first demonstrated by amplifying the birefringence-induced small displacement of optical fields [159]. More recently it was used to detect very small deflections of an optical beam ($< \text{frad}$), much less than the intrinsic spread of the beam [160]. While it is true that weak amplification does not give a signal-to-noise ratio better than an optimal strong projection measurement if a system is quantum noise limited [161, 162], weak measurements can be advantageous in the typical case of dominant systematic noise [163, 164]. Recently, it was shown that the nonlinear effect of a single properly postselected photon on a probe beam could be amplified by a factor of 8, based on this principle [165]. Additionally, one could amplify a 5 nm displacement to 5 μm , which could then be easily observed, even if the measuring device measures an intrinsic jitter of 500 nm (ten times larger). Weak measurements also arise naturally in fiber optics telecom networks, due to polarization-mode dispersion and polarization-dependent losses [166].

84.5.5 Direct Measurements of a Wave Function

One particularly fundamental use of weak measurement is to directly measure an arbitrary unknown quantum wave function $|P s i_{\text{ini}}\rangle$ [167]. Here, one weakly measures whether the particle is at a particular position $X = x$, i.e., observable $\pi = |x\rangle\langle x|$, and then subsequently measures momentum, P . In the subset of trials that have outcome $P = p$, the weak value is $\pi_w = \langle p|x\rangle\langle x|\Psi_{\text{ini}}\rangle / \langle p|\Psi_{\text{ini}}\rangle$. For $p = 0$, this reduces to $\pi_w = C \langle x|\Psi_{\text{ini}}\rangle = \Psi_{\text{ini}}(x)$, where C is a complex constant that is independent of x , which can be found through calibration or normalization [167]. Hence, the weak value is directly proportional to the position wave function. In contrast to the standard method of quantum-state estimation, quantum tomography, a mathematical reconstruction or fitting is not required. Instead, the pointer directly indicates the real and imaginary parts of the wave function. An experiment used this concept to demonstrate the measurement of the transverse spatial wave function of a photon [167].

The concept has since been extended to general (e.g., mixed) quantum states [168–170]. More generally, this is an example of the aforementioned use of weak measurement to jointly measure complementary observables, and, thus, applies to any quantum system, whether it be discrete or continuous. Experiments have gone on to demonstrate the direct measurement of discrete states such as photon polarization [171] and orbital angular momentum [172]. In this context, the quantum-state estimation of systems with a high dimensionality d is greatly simplified, as has been experimentally demonstrated [173, 174]. Whereas tomography typically requires measurements in d different bases, this procedure requires only two (e.g., x and p). This advantage is multiplied when the direct measurement is applied to estimating processes [175], which would require d^2 experimental settings with tomography.

84.6 The EPR Paradox and Bell's Inequalities

84.6.1 Generalities

Nowhere is the nonlocal character of the quantum mechanical entangled state as evident as in the "paradox" of *Einstein, Podolsky, and Rosen* (EPR) [176], the version of *Bohm* [177], and the related inequalities by *Bell* [178, 179]. Consider two photons traveling in opposite directions, described by the entangled state

$$|\psi^-\rangle = (|H_1, V_2\rangle - |V_1, H_2\rangle) / \sqrt{2}, \quad (84.9)$$

where the letters denote horizontal (H) or vertical (V) polarization, and the subscripts denote photon propagation direction. This state, analogous to the singlet state of a pair of spin-1/2 particles, has the same form regardless of what polarization basis is used to describe it. Measurement of any polarization component for one of the particles will yield a count with 50% probability; individually, each particle is unpolarized. Nevertheless, if one measures the polarization component of particle 1 in any basis, one can predict with certainty the polarization of particle 2 in the same basis – either both photons will pass through their respective (aligned) polarizers or both will be reflected. Quantum mechanics predicts that this will happen no matter how far apart the polarizers are separated. According to EPR, to prevent faster-than-light influences between the two particles, there must be some extra information or variables that the photons carry locally with them that correlates their polarization state in every basis. These variables may be hidden or inaccessible to us, and are, therefore, referred to as local hidden variables (LHV). Quantum mechanics is a statistical theory that does not include in its formulation any such LHV, and, therefore, EPR argued that quantum theory is an incomplete description

of reality. For two entangled particles, a local hidden variable (LHV) theory can be made, which correctly describes perfect correlations or anticorrelations (i.e., measurements made in the same polarization basis). It was thought for many years that LHV theories and quantum mechanics yield the same predictions, and, consequently, the choice of an LHV theory versus quantum mechanics was a purely philosophical choice and not a physical one. However, in 1964 *John Bell* [178] discovered that QM gives different statistical predictions than does any LHV theory, for situations of imperfect correlations (i.e., analyzers at intermediate angles). Bell's inequality (BI) constrains various joint probabilities given by any local realistic theory and was later generalized to include any model incorporating locality [180, 181], and also extended to apply to real experimental situations [182, 183], and to systems with higher dimensionality [184–188]. Bell's theorem means that there is an experimental method to test whether local hidden variables are a fundamental aspect of nature.

84.6.2 Bell's Inequalities as a Game

A Bell test can be thought of as a game that two parties, Alice and Bob, play. Alice and Bob are isolated from one another and given a sequence of particles (e.g., photons in our case) to independently measure. Their goal is to correlate their outcomes in the way demanded by the rules of the game as much as possible. While they cannot communicate during the game, they are allowed to devise a shared secret strategy beforehand to try to maximize the number of times they win. Such a strategy can be thought of as a local hidden variable model (local in the sense that Alice and Bob are isolated from one another and must act independently).

In photonic Bell tests, it is often convenient for Alice and Bob to measure the polarization degree of freedom of their individual photons. To perform their measurements, Alice and Bob each have a polarizer that is randomly switched between two different angles every time they receive a photon. Alice has her polarizer set randomly to either angle a or a' , while Bob's polarizer is set to angles b or b' . Alice and Bob cannot know ahead of time what each other's polarizer setting is. If a particle is transmitted through the polarizer, a $+$ is recorded, and if it is reflected, a $-$ is recorded. This leaves four possible joint measurement settings ($ab, ab', a'b,$ and $a'b'$) as well as four possible measurement outcomes for each setting ($++, +-, -+,$ and $--$). The game proceeds in the following way. To win, we demand that if Alice and Bob happen to choose settings ab, ab' , or $a'b$, they report a correlated result (either $++$ or $--$), and if they choose setting $a'b'$ that they report an anticorrelated result (either $+-$ or $-+$). Each time they report a correct outcome for their particular measurement setting they receive a score of $+1$, but if they are wrong, they receive a score of -1 . Alice and Bob

play the game many times and then tabulate their joint score. To keep track of the score, we look at the average correlation as a function of the settings. For a given setting xy , the normalized correlation function $E(xy)$ is:

$$E(xy) = \frac{N_{++}(xy) - N_{+-}(xy) - N_{-+}(xy) + N_{--}(xy)}{N(xy)}, \quad (84.10)$$

where, for example, $N_{+-}(xy)$ is the number of times that Alice records a $+$ and Bob records a $-$ outcome when Alice sets her polarizer to $x \in a, a'$ and Bob sets his polarizer to $y \in b, b'$. This score is normalized by the total number of occurrences, $N(xy)$, resulting in the term $E(xy)$ taking on a value that ranges from -1 to 1 . The total joint correlation score, S , between Alice and Bob is then:

$$S = E(ab) + E(ab') + E(a'b) - E(a'b'). \quad (84.11)$$

This form of a Bell inequality was first proposed by *Clauser, Horne, Shimony, and Holt* (CHSH) [182, 183].

There are many optimal hidden variable strategies, but one of the simplest optimal approaches is for each photon to always be detected as $+$ regardless of the measurement setting. Therefore, Alice and Bob will report the correct result for three of the four possible settings' choices, but give the incorrect result when they perform the setting $a'b'$, resulting in an average score of 2 ($= 1 + 1 + 1 - 1$). The problem is that when Alice chooses to measure in setting b' , she does not know whether Bob is setting his polarizer to angle a or a' , and, therefore, is not sure whether to report a correlated or anticorrelated result. In general, for any local hidden variable model, the average score from Eq. (84.11) is bounded between $|S| \leq 2$. This form of Bell's inequalities was formulated in 1969 by Clauser, Horne, Shimony, and Holt (CHSH) and holds for any set of polarizer angles that Alice and Bob choose.

Surprisingly, if Alice and Bob are instead sent a pair of polarization-entangled photons, such as the singlet state in Eq. (84.9), and choose the appropriate measurement angles, then it is possible for them to achieve a maximum score of $2\sqrt{2}$. This means that quantum mechanics predicts correlations that are stronger than those permitted by local hidden variables. A Bell test is an experiment designed to test this contradiction. If a value of $S > 2$ is observed, this rules out any local hidden variable description of the experiment. Strictly speaking, in a Bell test, we are never able to prove that quantum mechanics is correct, but rather we are only trying to falsify the notion that local hidden variables are fundamental to nature. The stronger correlations in quantum systems not only have important philosophical implications about the structure of reality but are part of the reason why emerging technologies like quantum computers should have

a massive performance advantage over classical computers in certain situations. It should also be noted that, in principle, the maximum achievable score in this Bell game is 4 for a perfectly correlated system, which is even greater than what quantum mechanics allows for. While we do not have any evidence that the universe permits correlations stronger than quantum mechanics, models of such systems, known as PR boxes [189], can serve as a useful theoretical tool.

84.6.3 Loopholes in Bell Tests

To unambiguously violate a Bell inequality one must experimentally satisfy several conditions. The first experiments to violate Bell's inequalities were carried out by *John Clauser* [190] and later by *Aspect* and colleagues [191], but due to technological limitations needed to make additional assumptions. These extra assumptions open up “loopholes” that could allow a local hidden variable theory to replicate the stronger correlations predicted by quantum mechanics. Strictly speaking, these experiments could only rule out a subset of local hidden variable models. If Alice and Bob are close together, then there is the possibility that hidden variables controlling Alice and Bob's photons could signal one another to coordinate their outcomes. To prevent this, Alice and Bob must be far enough apart so that their measurements can be individually completed before any such signals traveling at the speed of light could influence the outcomes. If this condition is not satisfied, it opens the so-called “locality loophole”. There is a subset of the locality loophole, sometimes referred to as “freedom of choice”, where Alice and Bob must assume that their measurement choices are independent of one another and the source of photons. This is usually addressed through the use of independent random number generators at Alice and Bob, but strictly speaking they can never guarantee that something in their shared past light cones did not correlate their settings choices. The extreme example of this is “superdeterminism”, the idea that the universe is deterministic with its entire history set in stone at beginning of time. Such theories are not testable, and therefore exist outside the realm of experimental physics.

Because a Bell test is statistical in nature, if there is too much loss, it is possible for a local hidden variable to appear to violate a Bell inequality. A local hidden variable could bias the observed correlations by preferentially discarding, through nondetection, certain outcomes. In this way, the detected events would appear to violate Bell's inequalities, but the total ensemble of detected and undetected events would not. To prevent this, at least 2/3 of the photons sent to Alice and Bob must be detected. If this efficiency threshold cannot be met, then one must assume that the detected events are fairly sampled from the total ensemble leading to the “fair-sampling” loophole (also known as the “detector loop-

hole”). All of the experiments discussed above that closed the locality loophole were unable to simultaneously close the fair-sampling loophole. In order to understand the detection loophole, it is convenient to consider the Clauser–Horne (CH) form of the Bell inequality [183]. This form of the inequality incorporates loss directly and is convenient because it only requires Alice and Bob to use one detector each. Now Alice and Bob must report either the detection of a photon (+) or no detection (0) every trial (any – outcomes are now just mapped to 0). The CH inequality is:

$$N_{++}(a, b) + N_{++}(a, b') + N_{++}(a', b) - N_{++}(a', b') \leq N_+(a) + N_+(b). \quad (84.12)$$

The left-hand side of this equation is the number of coincidence events where in a given trial Alice and Bob both detect a photon. The term $N_+(a)$ ($N_+(b)$) on the right-hand side represent the total number of photons Alice (Bob) detects while in setting a (b) irregardless of what the other party measures. For certain choices of a , a' , b , and b' , quantum mechanics predicts that the left-hand side of the CH inequality can exceed the right-hand side. However, in practice, this is very difficult to observe, since the probability of detecting a coincidence falls as η^2 (η is the detection efficiency), compared to the singles counts on the right-hand side, which fall only as η . For a maximally entangled state, such as the one described in Eq. (84.9), a detection efficiency $\eta \geq 83\%$ is required to violate the CH inequality [192]. If one uses a nonmaximally entangled state of the form:

$$|\Psi\rangle = \cos(\theta)|H_1, V_2\rangle - \sin(\theta)|V_1, H_2\rangle, \quad (84.13)$$

then the required detection efficiency may be reduced to 67% as θ goes to 0 for the appropriate analysis settings [193, 194]. Finally, the CH inequality in Eq. (84.12) can be converted into a “hypothesis test”. Doing so can prevent additional forms of potential statistical manipulation. For example, if Alice and Bob normalize their correlations by the total number of counts, they are implicitly making the assumption that every trial was independent and identical. Instead, by using an appropriate hypothesis-testing framework it is possible to avoid these subtle analysis assumptions. In the hypothesis-testing framework, a p-value is reported which is the probability that, if local realism is true, it would be able to produce a violation of the Bell inequality greater than or equal to the observed violation.

84.6.4 Closing the Loopholes in Bell Tests

In 1982, *Aspect* et al. used entangled photons from an atomic cascade to perform the first Bell test where Alice and Bob were separated far enough apart (12 m) that their measurement outcomes satisfied the locality constraints [191]. This

was followed up by a first attempt to have Alice and Bob vary their measurement settings while the photons were in flight towards the measurement stations (early experiments used passive components that could be interpreted as allowing the photons to make the decisions as to how they would be measured). In this experiment, function generators at Alice and Bob produced a periodic voltage to drive home-built acoustic optic modulators that switched the incoming photons between two different measurement setups. However, because the generators used to drive the measurement switching were periodic, the locality loophole could not be fully addressed. In 1998, Weihs et al. were able to fully close the locality loophole by using entangled photons generated by the process of spontaneous parametric downconversion along with fast random number generators that drove electronic polarization analyzers. The photons were sent to measurement stations 400 m apart, and while they were in flight, the measurement basis was randomly and independently set to ensure space-like separated observers [195]. However, in that experiment, the detection efficiency was less than 5%. Currently, the locality loophole has been closed on a continental scale—in 2018, Yin et al. performed a Bell test with Alice and Bob separated by 1203 km using an entangled source of photons on board a satellite in low Earth orbit [196].

The first experiment to close the detection loophole was the entangled-ion experiment of Rowe et al. [197] in 2001. In this experiment the entangled variables were the hyperfine energy levels of ${}^9\text{Be}^+$ ions. By employing a cycling transition that leads to the emission of many photons if the atom is in one of the states, a detection efficiency in excess of 98% was achieved, allowing an $8\text{-}\sigma$ Bell inequality violation. However, because the ions were separated by only $3\ \mu\text{m}$ in the same linear Paul trap, and in fact were measured using the same laser pulse, there was no possibility of closing the locality loophole. A decade later the detection loophole was finally closed using photons in two experiments [198, 199] that utilized superconducting transition edge detectors with efficiencies $> 98\%$. These detectors use a superconducting material operating near the transition point to measure the energy deposited by one or more photons. However, in these experiments the detectors used for Alice and Bob were cooled in the same cryostat, preventing the locality loophole from being closed.

It wasn't until 2015, 51 years after Bell's original paper, that three groups were able to independently close these loopholes at the same time in the same experiment. At TU Delft Hensen et al. used entangled spins in Nitrogen-vacancies in diamonds separated by 1.3 km to violate a Bell inequality with a value of $S = 2.42 \pm 0.20$ [200]. This corresponds to a p-value of 0.039 for refuting local realism. The other two experiments were performed using entangled photons. At the National Institute of Standards and Technologies in Boulder, Shalm et al. were able to close

all the loopholes with $> 5\sigma$ confidence, and violate a Bell inequality with a p-value of 5.3×10^{-9} [201], while in Vienna a loophole-free Bell test was conducted at the Hofburg Imperial Palace by Giustina et al., measuring a p-value of 3.74×10^{-31} [202]. In 2016 a fourth loophole-free Bell test used entangled Rb^{87} atoms separated by 398 m by Rosenfeld et al. in Munich to obtain a violation of $S = 2.221 \pm 0.033$, corresponding to a p-value of 2.57×10^{-9} [203].

While in principle it is not possible to close the freedom-of-choice loophole due to super determinism, with some additional assumptions one is able to push back the earliest time that a local hidden variable could have correlated Alice's and Bob's measurement choices by using light from distant stars or quasars to choose the measurement settings used. This requires the assumption that the detectors, telescopes, and other electronic equipment used by Alice and Bob are not correlated with one another, and that the mechanisms that produce the light in the stellar objects are short-lived. For example, it might take a photon 100,000 years to escape the deep plasma core of a star due to the short mean-free path [204, 205], but an unimpeded neutrino could escape at a much earlier time to carry the information to the Earth. Recently, in 2018 Li et al. were able to perform a loophole-free Bell test using polarization entangled photons that used the random arrival times of light from nearby stars to make Alice and Bob's measurement choices. This pushes the earliest point at which Alice's and Bob's measurement choices could be correlated to 11 years in the past [206]. A similar experiment, albeit not loophole-free, used high-redshifted light from distant quasars to choose Alice's and Bob's settings, and pushing back the earliest time a local hidden variable model could have exerted an influence to approximately 7.8 billion years ago (corresponding to 96% of the space-time volume in the past light cone of the experiment) [207]. Taken together these experiments provide convincing proof that local realism is not a viable theory of nature.

84.6.5 Polarization-Based Entangled Sources

The process of downconversion (see Sect. 76.3.6) provides a convenient way to generate entangled pairs of polarization-entangled photons. To create entangled photons, two different processes need to interfere with one another. For example, consider two identical type-I phase-matched crystals placed back-to-back, but with the second crystal rotated by 90° . The first crystal will downconvert a H -polarized pump into V -polarized pairs while the second crystal downconverts a V -polarized pump into H -polarized pairs. By coherently pumping the two crystals with light polarized at $|45\rangle = (|V\rangle + |H\rangle)/\sqrt{2}$, there is an equal probability of producing a pair of photons in either the first or second crystal. Since there is no knowledge of which process took place,

one obtains the entangled state $(|HH\rangle + e^{i\varphi}|VV\rangle)/\sqrt{2}$ [208]. More generally, pumping $\alpha|V\rangle + e^{i\varphi}\beta|H\rangle$ produces arbitrary nonmaximally entangled states of the form $\alpha|HH\rangle + e^{i\varphi}\beta|VV\rangle$ [209].

Using type-II phase-matching one also can produce polarization entanglement from a single crystal [210]. One member of each downconversion pair is emitted along an ordinary polarized cone while the other is emitted along an extraordinary polarized cone. If the photons happen to be emitted along the intersection of the two cones, neither photon will have a definite polarization – they will be in the state $(|HV\rangle + |VH\rangle)/\sqrt{2}$. This entanglement source has now been used in a variety of quantum investigations, including Bell inequality tests [195, 210], quantum cryptography [211, 212] (Sect. 85.2.1) and teleportation [213, 214], and as a resource for studying entanglement of more than two photons [215–218].

84.6.6 Other Entanglement Sources for Bell Tests

The advent of parametric downconversion has also led to the appearance of several nonpolarization-based BI tests, using, for example, an entanglement of the photon momenta (Fig. 84.8) [219]. By the use of small irises (labeled ‘A’ in Fig. 84.8), only four downconversion modes are examined: 1s, 1i, 2s, and 2i. Beams 1s and 1i correspond to one pair of conjugate photons; beams 2s and 2i correspond to a different pair. Photons in beams 1s and 2s have the same wavelength, as do photons in beams 1i and 2i. With proper alignment, after the beamsplitters there is no way to tell whether a pair of photons came from the 1s-1i or the 2s-2i paths. Consequently, the coincidence rates display interference, although the singles rates at the four detectors indicated in Fig. 84.8 remain constant. This interference depends on the difference of phase shifts induced by rotatable glass plates P_i and P_s in paths 1i and 2s, respectively, and is formally equivalent to the polarization case considered above, in which it is the difference of polarization-analyzer angles that is rele-

Fig. 84.8 Outline of apparatus used to demonstrate a violation of a Bell’s inequality based on momentum entanglement [219]

vant. By measuring the coincidence rates for two values for each of the phase shifters – a total of four combinations – the experimenters were able to violate an appropriate BI. One interpretation is that the paths taken by a given pair of photons are not elements of reality.

Momentum conservation in the downconversion process (Eq. (84.4)) also leads to entanglement directly in the spatial modes in the correlated photons. For example, *Zeilinger et al.* [220, 221] and *Langford et al.* [222] demonstrated entanglement between the *orbital* angular momentum of the photons, of the form $(|+1, -1\rangle + \epsilon|0, 0\rangle + |-1, +1\rangle)$, where 0 and ± 1 , respectively, denote modes with no orbital angular momentum (Gaussian spatial profiles) and $\pm\hbar$ (Laguerre–Gauss vortex modes). Note that this enables one to investigate correlations for degrees of freedom that reside in larger Hilbert spaces than do the two-level systems (e.g., polarization) discussed above. The nonlocal spatial correlations of the downconversion photons have also given rise to many interesting experiments in the area of quantum imaging [223–226], where one is able to obtain spatial resolution beyond that predicted by the usual \sqrt{N} shot-noise limitations.

Several groups [227, 228] have implemented a different BI proposal [229], based on energy-time entanglement of the photons. One member of each downconverted pair is directed into an unbalanced Mach–Zehnder-like interferometer, allowing both a short and a long path to the final beamsplitter; the other photon is directed into a separate but similar interferometer. There arises interference between the indistinguishable processes (“short-short” and “long-long”), which could lead to coincidence detection. Using fast detectors to select out only these processes, the reduced state (Eq. (84.9)) is

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|S_1, S_2\rangle - e^{i\phi}|L_1, L_2\rangle), \quad (84.14)$$

where the letters indicate the short or the long path, and the phase is the sum of the relative phases in each interferometer. Although no fringes are seen in any of the singles count rates, the high-visibility coincidence fringes (Fig. 84.9) lead to a violation of an appropriate BI. One conclusion is that it is incorrect to ascribe to the photons a definite time of emission from the crystal, or even a definite energy, unless these observables are explicitly measured. A more general interpretation, applicable to all violations of Bell’s inequalities, is that the predictions of QM cannot be reproduced by any completely local theory. It must be that the results of measurements on one of the photons depend on the results for the other, and these correlations are not merely due to a common cause at their creation [230, 231].

This same sort of arrangement, modified to work with a pulsed pump, has been used to demonstrate a violation of local realism with photons separated by 10.9 km [232].

Fig. 84.9 High-visibility coincidence fringes in a Franson dual-interferometer experiment [229] for two values of the phase in interferometer 2 as the phase in interferometer 1 is slowly varied. The curves are sinusoidal fits

In a related experiment, a similar system was used to place limits on the “speed of collapse” of the two-photon wave function, i.e., how fast a nonlocal “signal” would need to propagate from one side of the experiment to the other to account for the measured nonclassical correlations. Depending on some assumptions about the detection process and which inertial frame of reference is considered, the nonlocal influence speed was constrained to be at least 10^4c to 10^7c [233]. In one interesting variant, the researchers arranged to have *moving* detectors, such that in the local reference frame of each detector, it was the *other* detector that initiated the collapse. Due to the experimental difficulty of accelerating actual detectors to high velocities, a rapidly rotating absorbing disk was placed close to one output port of a polarizing beamsplitter; following ideas discussed in Sect. 84.5.3, the *nonabsorbance* of the photon by the absorber was deemed sufficient to cause a reduction of the wave function. As expected, the measured correlations were in no way reduced, but this experiment did rule out one alternative theory of nonlocal collapse [234].

Finally, by using more than two possible creation times, one can also demonstrate entanglement in higher dimensional Hilbert spaces. For instance, using a mode-locked pulsed laser, *Gisin’s* group demonstrated entanglement for a two-photon state at least of dimension 11 [235].

84.6.7 Advanced Experimental Tests of Nonlocality

The previously described tests of Bell’s inequality actually have little to do with quantum mechanics per se, other than that it is quantum correlations that enable a violation; the conclusions of such a violation only say that no local realistic description is sufficient to explain the results. Just as the

CHSH inequality [183] bounds the observable correlations of a local realistic description to $|S| \leq 2$, *Tsirelson* [236] showed that, according to quantum theory, $|S|$ has an upper bound of $2\sqrt{2} \approx 2.82843$. One immediate question is how close experimental realizations have come to reaching this value. The loophole-free experiments discussed in Sect. 84.6.4 have values of S that, while larger than the local realistic bound of 2, are still far from the maximum possible value permitted by quantum mechanics. A recent experiment [237] that did not attempt to close the detection and locality loopholes provides the best test of the upper bound to date, using photon pairs in a maximally entangled state of polarization to obtain $S = 2.82759 \pm 0.00051$.

Other generalizations to the Bell inequality have been studied and have obtained some counterintuitive results. For example, one modified Bell inequality has the property that the maximum quantum violation can only be obtained using partially entangled states [238], and another cannot be violated at all by a maximally entangled state. Experimental violations [239] of these modified inequalities have been observed, with results matching the (quantum) theoretical predictions extremely well, thus illustrating the phenomenon of “more nonlocality with less entanglement” [238, 240, 241].

In fact, the four correlation functions that make up S (Eq. (84.11)) are each bounded by 1, and *Popescu* and *Rohrlich* showed that the no-signaling principle that prevents superluminal communication is compatible with values up to $S = 4$ [242]; a theoretical ultra-nonlocal construct that enables one to achieve this maximal value is called a “PR box” after its originators. A 2.828 maximal quantum violation of the CHSH inequality could, thus, be interpreted as arising from a 41% contribution of a PR box and a 59% contribution from a local theory: $2\sqrt{2} = (0.59 \times 2) + (0.41 \times 4)$, where the 2 and 4 represent the maximum values for S attainable with a local theory or nonsignaling nonlocal theory, respectively. One can instead consider a “chained Bell inequality” [243, 244] in which the usual two measurement settings on either side are replaced by a value $n > 2$; in this case, as n increases, the quantum violation approaches the bound imposed by the no-signaling principle. Consequently, one can place a stronger bound on the “nonlocal” content that would be required to achieve the observed results. In the experiment reported in [239], nonlocal resources (such as PR boxes) would be needed in $87.4 \pm 0.1\%$ of the experimental rounds in order to match the observed chained Bell inequality violation; this represents the most nonlocal correlations ever produced experimentally (this experiment did not attempt to close the detector or locality loophole). A subsequent experiment using ${}^9\text{Be}^+$ ions closed the detection loophole in a chained-Bell inequality while certifying that the nonlocal content consistent with their results was at least 67.3% [245]. A remaining challenge is performing a fully loophole-free chained Bell inequality.

Fig. 84.10 A three-particle gedankenexperiment to demonstrate the inconsistency of quantum mechanics and any local realistic theory. All beamsplitters are 50–50 [116]

84.6.8 Nonlocality Without Inequalities

In the above experiments for testing nonlocality, the disagreement between quantum predictions and Bell’s constraints on local realistic theories are only statistical. Greenberger, Horne, and Zeilinger (GHZ) pointed out that in some systems involving *three* or more entangled particles [246, 247], a contradiction could arise even at the level of perfect correlations. A schematic of one version of the GHZ *gedankenexperiment* is shown in Fig. 84.10. The source at the center is posited to emit trios of correlated particles. Just as the Rarity-Tapster experiment selected two pairs of photons (Fig. 84.8), the GHZ source selects two trios of photons; these are denoted by abc and $a'b'c'$. Hence, the state coming from the source may be written as

$$|\psi\rangle = (|abc\rangle + |a'b'c'\rangle)/\sqrt{2}. \quad (84.15)$$

After passing through a variable phase shifter (e.g., ϕ_a), each primed beam is recombined with the corresponding unprimed beam at a 50–50 beamsplitter. Detectors (denoted by Greek letters) at the output ports signal the occurrence of triple coincidences. The following simplified argument conveys the spirit of the GHZ result.

Given the state Eq. (84.15), one can calculate from standard QM the probability of a triple coincidence as a function of the three phase shifts:

$$P(\phi_1, \phi_2, \phi_3) = \frac{1}{8}[1 \pm \sin(\phi_a + \phi_b + \phi_c)], \quad (84.16)$$

where the plus sign applies for coincidences between all unprimed detectors, and the minus sign for coincidences between all primed detectors. For the case in which all phases

are 0, it will occasionally happen (1/8-th of the time) that there will be a triple coincidence of all primed detectors. Using a “contrafactual” approach, we ask what would have happened if ϕ_a had been $\pi/2$ instead. By the locality assumption, this would not change the state from the source, nor the fact that detectors β' and γ' went off. However, from Eq. (84.16), the probability of a triple coincidence for primed detectors is zero in this case; therefore, we can conclude that detector α would have “clicked” if ϕ_a had been $\pi/2$. Similarly, if ϕ_b or ϕ_c had been $\pi/2$, then detectors β or γ would have clicked. Consequently, if all the phases had been equal to $\pi/2$, we would have seen a triple coincidence between unprimed detectors. However, according to Eq. (84.16), this is impossible: the probability of triple coincidences between unprimed detectors when all three phases are equal to $\pi/2$ is strictly zero! Hence, if one believes the quantum mechanical predictions for these cases of perfect correlations, it is not possible to have a consistent local realistic model.

Downconversion experiments have enabled the production of three and four-photon GHZ states, with results in good agreement with theory (the all-or-nothing arguments given above become inequalities in any real experiment) [215, 216, 248]. In 2014, Erven et al. were able to close the locality loophole while violating the Mermin inequality by $9\text{-}\sigma$, although they were unable to close the detector loophole simultaneously.

By similar arguments, *Hardy* has shown the inconsistency of quantum mechanics and local realism in a *gedankenexperiment* with just two particles [249, 250]. When the arguments are suitably modified to deal with real experiments, inequalities once again result; these have also been experimentally violated, using nonmaximally entangled states from downconversion [251, 252], underscoring the vast disagreement between quantum theory and locality.

84.6.9 Connection to Quantum Information

The properties of entangled photons and the nonlocal correlations they share play a critical role in many quantum information applications. The information carried by photons cannot be cloned perfectly, which has led to protocols for securely exchanging one-time pads for use in cryptography [211, 212, 253–260]. The stronger correlations present between entangled photon-pairs can also be exploited to transfer two bits of information using a single photon [261–263], a process known as superdense coding. Since it is not possible to perfectly clone a quantum state, techniques have been devised to use an entangled pair of photons to instead “teleport” or move quantum information from one location to another through the use of Bell state measurements and classical communications [213, 264–267]. This process of teleportation may form a fundamental building block in fu-

ture quantum networks, allowing quantum information to be transmitted over long distances [268]. Such a network would enable networked quantum computing, connecting quantum circuits based on solid-state or matter quantum bits using light. Finally, loophole-free Bell tests are a fundamental component in new types of security protocols. A hacker or attacker who wishes to control or predict the outcome of a Bell test has at their disposal a set of tools equivalent to those of a hidden-variable theory. They are hoping to use their added knowledge, perhaps hidden from the experimenter, to manipulate the results. However, if a loophole-free Bell violation can be obtained, one can rule out the influence of such an attacker even if they control part of the equipment used. For this reason, protocols based on loophole-free Bell tests are referred to as being “device-independent” [269–273]. In 2017, the first fully device-independent protocol was carried out to generate certifiably secure random numbers using the loophole-free Bell test developed at NIST in Boulder, CO [274]. As the technology behind loophole-free Bell tests improves, a wider-range of device-independent applications promises to become more prevalent.

As an indicator of the importance of these fundamental tests of (non)locality, the 2022 Nobel prize in physics was awarded to John F. Clauser, Alain Aspect, and Anton Zeilinger “for experiments with entangled photons, establishing the violation of Bell inequalities and pioneering quantum information science,” i.e., based on the research described above [182, 183, 190, 191, 195, 213, 268].

84.7 Single-Photon Tunneling Time

84.7.1 An Application of EPR Correlations to Time Measurements

In this section, we discuss experiments involving the quantum propagation of light in matter. Due to the sharp time correlations of the paired photons from spontaneous downconversion, one can use the HOM interferometer (Sect. 84.3.3, Fig. 84.4) to measure very short relative propagation delay times for the signal and idler photons. One early application was, therefore, to confirm that single photons in glass travel at the group velocity [94]. At least until recently, the only quantum theory of light in dispersive media was an *ad hoc* one [275]. The shift of the interference dip resulting from a medium introduced into one of the interferometer arms can be accurately measured by determining how much the path lengths must be changed to compensate the shift and recover the dip. This result suggests that when looking for a microscopic description of dielectrics, it is unnecessary to consider the medium as being polarized by an essentially classical electric field due to the collective action of all photons present, and reradiating accordingly. Linear di-

electric response is not a collective effect in this sense – each photon interferes only with itself (as per Dirac’s dictum) as it is partially scattered from the atoms in the medium. The single-photon group velocity thus demonstrates “wave-particle unity”.

The standard limitation for measurements of short-time phenomena is that to have high time-resolution, one needs short pulses (or at least short coherence lengths), but these, in turn, require broad bandwidths and are, therefore, very susceptible to dispersive broadening. It is a remarkable consequence of the EPR energy correlations of the downconversion photons (Sect. 84.3.2) that time measurements made with the HOM interferometer are essentially immune to such broadening [94, 276, 277]. In effect, the measurement is sensitive to the *difference* in emission times while the broadening is sensitive to the *sum* of the frequencies. While frequency and time cannot both be specified for a given pulse, the crucial feature of EPR correlations such as those exhibited by downconverted photons is that this difference and this sum correspond to commuting observables and both may be arbitrarily well defined. The photon that reaches detector 1 could either have traversed the dispersive medium and been transmitted or traversed the empty path and been reflected, leaving its twin to traverse the medium. The medium, thus, samples *both* of the (anticorrelated) frequencies, leading to an automatic cancelation of any first-order (and in fact, all odd-order) dispersive broadening. Measurements can be more than five orders of magnitude more precise than would be possible via electronic timing of direct detection events, and in principle, better than those performed with nonlinear autocorrelators (which rely on the same fundamental physics as downconversion but do not benefit from a cancelation of dispersive broadening).

84.7.2 Superluminal Tunneling Times

Another well-known problem in the theory of quantum propagation is the delay experienced by a particle as it tunnels. There are difficulties associated with calculating the “duration” of the tunneling process, since evanescent waves do not accumulate any phase [278–280]. First, the kinetic energy in the barrier region is negative, so the momentum is imaginary. Second, the transit time of a wave-packet peak through the barrier, defined in the stationary phase approximation by

$$\tau^{(\phi)} \equiv \partial[\arg t(\omega)e^{ikd}]/\partial\omega, \quad (84.17)$$

tends to a constant as the barrier thickness diverges, in seeming violation of relativistic causality. It is shown in [91] that such saturation of the delay time is a natural consequence of time-reversal symmetry, and in [281] that one can deduce

from the principle of causality itself that *every* system possesses a superluminal group delay, at least at the frequency where its transmission is a minimum. For example, the transmission function for a rectangular barrier,

$$t(k, \kappa) = \frac{e^{-ikd}}{\cosh \kappa d + i \frac{\kappa^2 - k^2}{2k\kappa} \sinh \kappa d}, \quad (84.18)$$

leads in the opaque limit ($\kappa d \gg 1$) to a traversal time of $2m/\hbar k \kappa$, independent of the barrier width d . The same result applies to photons undergoing frustrated total internal reflection [91], when the mass m is replaced by $n^2 \hbar \omega / c^2$, and similar results apply to other forms of tunneling.

Some researchers have, therefore, searched for some more meaningful “interaction time” for tunneling, which might accord better with relativistic intuitions and perhaps have implications for the ultimate speed of devices relying on tunneling [282]. The “semiclassical time” corresponds to treating the *magnitude* of the (imaginary) momentum as a real momentum. This time is of interest mainly because it also arises in Büttiker and Landauer’s calculation of the critical timescale in problems involving oscillating barriers, which they take to imply that it is a better measure of the duration of the interaction than is the group delay [278]. The Larmor time [283] is one of the early efforts to attach a “clock” to a tunneling particle, in the form of a spin aligned perpendicular to a small magnetic field confined to the barrier region. The basic idea is that the amount of Larmor precession experienced by a transmitted particle is a measure of the time spent by that particle in the barrier. This clock turns out to contain components corresponding both to the distance-independent “dwell time” and the linear-in-distance semiclassical time. Experiments are being done with cold atoms, which have begun to resolve these two contributions [284]. Curiously, the most common theories for tunneling times become superluminal in certain cases anyway, whether or not they deal with the motion of wave packets. Pioneering tests of tunneling times included both optical and solid-state approaches [285]. In recent years, new experimental results have begun to appear both in attosecond strong-field ionization measurements and in cold-atoms experiments [286–289], but there is still disagreement about their interpretation. Below, in Sect. 84.7.4, we discuss theoretical status of different tunneling-time proposals.

Here, we will restrict ourselves to discussing the time of appearance of a peak of a single-photon wave packet. Optical tests offer certain unique advantages [290], including the ease of construction of a barrier with no dissipation, very little energy dependence, and a superluminal group delay. The transmitted wave packets suffer little distortion and are essentially indistinguishable from the incident wave packets. At a theoretical level, the fact that photons are described by Maxwell’s (fully relativistic) equations is an important argu-

ment against interpreting superluminal tunneling predictions as a mere artifact of the nonrelativistic Schrödinger equation. Also, one is denied the recourse suggested by some workers [291] of interpreting the superluminal appearance of transmitted peaks to mean that only the high-energy components (which, for matter waves, traveled faster even before reaching the barrier [292]) were transmitted.

84.7.3 Tunneling Delay in a Multilayer Dielectric Mirror

A suitable optical tunnel barrier can be a standard multilayer dielectric mirror. The alternating layers of low and high index material, each one quarter-wave thick at the design frequency of the mirror, lead to a photonic bandgap [293] analogous to that in the Kronig–Penney model of solid state physics (Sect. 83.3.6). The gap represents a forbidden range of energies, in which the multiple reflections will interfere constructively so as to exponentially damp any incident wave. The analogy with tunneling in nonrelativistic quantum mechanics arises because of the exponential decay of the field *envelope* within the periodic structure, i.e., the imaginary value of the quasi momentum. The same qualitative features arise for the transmission time: for thick barriers, it should saturate at a constant value, as was verified in a recent experiment employing short *classical* pulses [300]. A more direct analogy, that of waveguides beyond cutoff, yielded similar results in a classical microwave experiment [294], while another paper reported superluminal effects related to the penetration of diffracted or “leaky” microwaves into a shadow region [295]. All these experiments involve very small detection probabilities, just as in *Chu* and *Wong*’s pioneering experiment on propagation within an absorption line [296]. However, it has been predicted that superluminal propagation could occur *without* high loss or reflection [297–299] by operating outside the resonance line of an *inverted* medium (Sect. 74.1). One can understand the effect as off-resonance “virtual amplification” of the leading edge of a pulse.

The phenomenon was investigated at the single-photon level by using the high time-resolution techniques discussed in Sect. 84.7.1 to measure the relative delay experienced by downconversion photons [301] when such a tunnel barrier (consisting of 11 layers) was introduced into one arm of a HOM interferometer. The transmissivity of the barrier was relatively flat throughout the bandgap (extending from 600 to 800 nm; Fig. 84.11), with a value of 1% at the gap center (700 nm), where the experiment was performed. The HOM coincidence dip was measured both with the barrier (and its substrate) and with the substrate alone (Fig. 84.12). Each dip was subsequently fitted to a Gaussian, and the difference between their centers was calculated. When several such runs

Fig. 84.11 Transmission probability for the tunnel barrier used in [301] (light solid curve); heavy, dashed, and dotted curves show group delay, Larmor time, and semiclassical time; $d/c = 3.6$ fs is shown for comparison

Fig. 84.12 Coincidence profiles with and without the tunnel barrier map out the single-photon wave packets. The lower profile shows the coincidences with the barrier; this profile is shifted by ≈ 2 fs to negative times relative to the one with no barrier (upper curve): the average particle which tunnels arrives earlier than the one which travels the same distance in air

were combined, it was found that the tunneling peak arrived 1.47 ± 0.21 fs earlier than the one traveling through air, in reasonable agreement with theoretical prediction of approximately 1.9 fs. Taking into account the $1.1 \mu\text{m}$ thickness of the barrier, this implies an effective photon tunneling velocity of $1.7c$. The results exclude the “semiclassical” time but are consistent with the group delay. A recent investigation of the energy dependence of the tunneling time was performed by angling the dielectric mirror, thus shifting its bandgap [150]. The data confirm the group delay in this limit as well and rule out identification of Büttiker’s Larmor time with a peak propagation time.

84.7.4 Interpretation of Tunneling Time

Even though a wave-packet peak may appear on the far side of a barrier sooner than it would under allowed propagation, it is important to stress that no information is transmitted faster than c , nor, on average, is any energy. These effects occur in the limit of low transmission, where the transmitted wave packet can be considered as a “reshaped” version of the leading edge of the incident pulse [285, 296, 302, 303]. At a physical level, the reflection from a multilayer dielectric is due to destructive interference among coherent multiple reflections between the different layers. At times before the field inside the structure reaches its steady-state value, there is little interference, and a nonnegligible fraction of the wave is transmitted. This preferential treatment of the leading edge engenders a sort of “optical illusion”, shifting the transmitted peak earlier in time. A signal, such as a sharp onset, relies on high-frequency components, which would not benefit from this illusion but instead travel more slowly than c . Even for a smooth wave packet, no energy travels faster than light; most is simply reflected by the barrier. Only if one considers the Copenhagen interpretation of quantum mechanics, with its instantaneous collapse, does one find superluminal propagation of those particles that happen to be transmitted. This leads to the question of whether it is possible to ask which part of a wave packet a given particle comes from.

In one paper it was argued that transmitted particles do, in fact, stem only from the leading edge of the wave packet [304]. While it is true that the transmission only depends on causally connected portions of the incident wave packet, further analysis revealed that simultaneous discussion of such particle-like questions and the wave nature of tunneling ran afoul of the complementarity principle [305]. In essence, labeling the initial positions of a tunneling particle destroys the careful interference by which the reshaping occurs (as in the quantum eraser). However, one picture in which the transmitted particles really do originate earlier is the Bohm–de Broglie model of quantum mechanics [306, 307]. This theory considers Ψ to be a real field (residing, however, in configuration space, thus incorporating non-locality) that guides point-like particles in a deterministic manner. It reproduces all the predictions of quantum mechanics without incorporating any randomness; the probabilistic predictions of QM arise from a range of initial conditions. Bohm’s equation of motion has the form of a fluid-flow equation, $\mathbf{v}(\mathbf{x}) = \hbar \nabla \arg \Psi(\mathbf{x}) / m$, implying that particle trajectories may never cross, as velocity is a single-valued function of position. Consequently, all transmitted particles originate earlier in the ensemble than all reflected particles [305, 308]. This approach yields trajectories with well-defined (and generally subluminal) dwell times in the barrier region. However, the fact that the mean tunneling delay of Bohm particles diverges as the incident bandwidth becomes

small, along with other interpretational issues [309, 310], leaves open the question of whether time scales as defined by the Bohm model have any physical meaning.

The “weak measurement” approach of Aharonov et al. [146, 147] or equivalently, complex conditional probabilities obeying Bayes’s theorem [149, 311], can be used to address the question of tunneling interaction times in an experimentally unambiguous way. The real part of the resulting complex times determines the effect a tunneling particle would have on a “clock” to which it coupled, while the imaginary part indicates the clock’s backaction on the particle. They unify various approaches such as the Larmor and Büttiker–Landauer times, as well as Feynman path methods. In addition, they allow one to discuss separately the *histories* of particles that have been transmitted or reflected by a barrier, rather than discussing only the wave function as a whole. Interestingly, these calculations do *not* support the assertion that transmitted particles originate in the leading edge of a wave packet.

84.7.5 Other Fast and Slow Light Schemes

In addition to the case of tunneling described already, apparently superluminal propagation was observed in a Bessel beam geometry [312], and in the case of an inverted medium [313], as described in [297–299]. While the former case may be explained geometrically, the latter – in which superluminal group velocities occur without significant gain, loss, or distortion – raises difficult questions about the speeds of propagation of both energy and information. For two contrasting perspectives, see [314] and [315]. Much more work has followed [313], including theoretical treatments of the role of quantum noise in preventing superluminal information transfer [316] and attempts to experimentally compare the velocity of information transfer with the group velocity [317]. The latter work seemed to verify the claim, previously tested only in an electronic analog [318], that even in the regime of superluminal propagation, new information was limited to causal speeds. Some dispute has persisted [319], and it seems clear that a more rigorous definition of information velocity is required; somewhere between the idealized extremes of infinitely sharp signal fronts and strictly finite signal bandwidths lies the real world, and neither the front velocity nor the group velocity should be expected to completely describe the behavior of actual information-carrying pulses. At the same time, the definition of the energy velocity in active media cannot be resolved without reviving the long-standing conundrum about how to apportion energy between the propagating field and energy stored in the medium [320, 321].

Since 1999 there has actually been much more excitement over so-called “slow light” than over “fast light” [322].

Building on the concepts of electromagnetically induced transparency [323], two groups succeeded in that year in utilizing the steep dispersion curves that can be generated by extremely narrow holes in absorption lines to slow light by a remarkable factor, to speeds as low as 17 m/s [324, 325]. Two experiments succeeded in bringing light to a *standstill* [326, 327] 2 years later. This can be understood in terms of a “dark-state polariton” model, in which the propagating photon is adiabatically converted into a (stationary) metastable atomic excitation. In addition to the obvious possibilities for storage of optical pulses [328, 329], there have been several proposals and demonstrations of generating extremely strong optical nonlinearities at the single-photon level that may be directly applicable to quantum information processing [330–337]. For a review on anomalous optical propagation velocities, see [338].

84.8 Gravity and Quantum Optics

84.8.1 Gravitational Wave Detection

According to general relativity, gravitational waves can be produced and detected by moving mass distributions [339–341]. However, gravitational waves are coupled only to time-varying mass *quadrupole* moments in lowest order, since the mass dipole moment is $\sum_j m_j \mathbf{r}_j = M \mathbf{R}_{\text{cm}}$ and \mathbf{R}_{cm} , for a closed system can only exhibit uniform rectilinear motion. Current efforts focus on detecting gravitational waves (typically at 100 Hz to 1 kHz) from astrophysical sources, such as supernovae or collapsing binary stellar systems. For example, it is expected that in the nearby Virgo cluster of galaxies, several such events should occur per year, each yielding a fractional strain ($\Delta L/L$) of 10^{-21} on Earth.

The first major effort to detect gravitational waves began in the 1960s and utilized a large cylindrical mass (sometimes known as a “Weber bar”, after its inventor) whose fundamental mode of acoustical oscillation is resonantly excited by time-varying tidal forces produced by the passage of a gravitational wave [341]. However, these devices were not sensitive enough to detect gravitational waves. More recently, a large amount of research has been devoted to using optical interferometry to detect gravitational waves. A passing gravitational wave alters the relative path length in the arms of a Michelson interferometer, thereby slightly shifting the output fringes. Although the effective gravitational mass of the light is much smaller than that of the Weber bar, very long interferometer arms (2–4 km, with a Fabry–Perot cavity in each arm to increase the effective length) more than make up for this disadvantage. The signal-to-noise ratio for the detection of a fringe shift depends on the power of the light. The US initiative, called Advanced LIGO (Laser Interferometer Gravitational-Wave Observatory [342]) uses 20 W

from a Nd:YAG laser and an additional external mirror to recirculate the unmeasured light, thus increasing the stored light power up to 100 kW. There are three LIGO interferometers, located in Hanford, Washington (with both a 2-km and a 4-km version), and Livingston, Louisiana (4-km version), respectively. The registration of coincident events at the separated interferometers allows one to rule out terrestrial artifacts, but many problems involving seismic and thermal isolation, absorption and heating, intrinsic thermal noise, and optical quality had to be addressed. In September 2015, both the Louisiana and Hanford LIGO interferometers registered the first direct terrestrial observation of gravitational waves. The signal, which was coincident at both detection site, swept up from 35 Hz to 250 Hz, and corresponded to a peak gravitational strain of 1.0×10^{-21} [343]. The gravitational waves were most likely produced by the merger of two black holes that converted ≈ 3 solar masses worth of energy into gravitational waves. This discovery was awarded the 2017 Nobel prize. Since then several other binary black hole mergers have been detected, and in August 2017 gravitational waves were detected from the inspiral of two binary neutron stars [344]. Currently, a world-wide network of gravitational wave detectors is coming online with operational locations in Italy (VIRGO) and Germany (GEO600), along with planned detectors in Japan (KAGRA) and India (IndIGO).

Because the standard quantum noise limit of these detectors is ultimately determined by the vacuum fluctuations incident on the unused input ports of the interferometers, it is, in principle, possible to achieve reduced noise levels by using *squeezed* vacuum instead [341, 345] (Sect. 84.2.3). Currently, at lower frequencies, it is the radiation pressure of the circulating light in the interferometers at LIGO that set the noise floor—adding more power to the laser will not lead to a simple gain in sensitivity. Using squeezed light instead could circumvent this problem by yielding increased sensitivity at current power levels. At the GEO600 gravitational detector in Hanover, Germany, squeezed light has been used to improve the observable volume of the universe by approximately a factor of 2 [346], and plans are underway to incorporate this technology in future versions of LIGO [347]. A more ambitious project aims to establish an interferometric gravitational wave detector in space using a network of satellites, where the fundamental baseline can be several million kilometers long, allowing the device to detect gravity waves with much lower frequencies than ground-based systems [348].

It has also been suggested that matter waves that interact with gravity waves inside a matter-wave interferometer (Sect. 84.3.1) could lead to a sensitive method to detect gravitational waves [349]. Such a “Matter-Wave Interferometric Gravitational-Wave Observatory” (MIGO) may allow the detection of primordial gigahertz gravity waves arising from the Big Bang [350]. Moreover, quantum mechanical detec-

tors based on the use of macroscopically coherent entangled states may enable quantum transducers that can interconvert between electromagnetic and gravitational waves, based on time-reversal symmetry [351].

84.8.2 Gravity and Quantum Information

A fundamental connection between black holes and quantum information was suggested recently [352–354]. The basic idea is that every physical object, including a black hole, can be thought of as a computer that unitarily transforms input states to output states; i.e., “in” quantum bits (“qubits”) can always be *reversibly* interconverted into “out” qubits, thus obeying time-reversal symmetry. Hawking blackbody radiation from a black hole, thus, contains as much information in an evaporating black hole as originally fell into it, when this process is viewed as a *reversible* quantum-scattering problem. To resolve the paradox of the apparent loss of information of matter falling into a black hole, Lloyd and Ng propose that pairs of entangled photons can materialize at the event horizon of a black hole. One member of the photon pair flies outward to become the Hawking radiation; the other falls into the black hole and hits the singularity together with the matter that formed the hole. The annihilation of the infalling photon acts a measurement on the infalling matter in a quantum teleportation-like process, transporting the information contained in the infalling matter to the outgoing Hawking radiation, using the Horowitz–Maldacena mechanism [355].

L. Krister Shalm Krister is a Sr. Research Associate at the University of Colorado, Boulder and an Associate of the National Institute of Standards and Technologies. He uses photons to study quantum networking as well as perform fundamental tests of quantum mechanics. When he isn't in the lab he can be found swing dancing.

Paul G. Kwiat Paul G. Kwiat is the Bardeen Chair in Physics, at the University of Illinois, in Urbana-Champaign. A Fellow of the American Physical Society and the Optical Society of America, he studies the phenomena of entanglement, quantum interrogation, quantum erasure, and optical implementations of quantum information protocols. He can't resist a good swing dance.

Aephraim M. Steinberg Aephraim Steinberg works on experimental quantum optics and laser cooling, with specific emphasis on foundational questions in quantum mechanics (especially quantum measurement) and on quantum information. His obsession is with tunneling times; in 1994, and in 2005, he demonstrated (with Kwiat and Chiao) the superluminal tunneling of photons; he is starting an experiment to probe tunneling times for Bose-condensed atoms through optical barriers.

Raymond Y. Chiao Professor Chiao was awarded his PhD by MIT in 1965. He has been Professor of Physics at Berkeley since 1977. His research interests are nonlinear and quantum optics, low-temperature physics as applied to astrophysics, and the relationship between general relativity and macroscopic quantum matter. He is writing a book with J.C. Garrison on quantum optics.

Abstract

Since its inception over a century ago, quantum mechanics has been an indispensable tool for understanding atomic structure and has been used very successfully in the calculation energy levels, natural lifetimes, and cross sections; but for the most part, the philosophical interpretation of quantum mechanics has been left to others. However, after the work of Bell in the 1960s showed that the peculiarly nonlocal nature of quantum correlations could be tested in the lab, a number of atomic physicists turned to the experimental study of entanglement and quantum measurement. By the mid 1990s, it was becoming increasingly apparent that the peculiar quantum correlations and quantum superpositions might be exploited in *quantum information processing*, and that practical devices to exploit this potential might well be within the grasp of current experimental techniques. This led to an explosive growth of the subject over the past 25 years, fueled by the long-term prospects of quantum computing, quantum-enhanced metrology, and quantum cryptography. Today, quantum information is a vast area, embracing physics, chemistry, electrical engineering, material science, mathematics, and computer science. In this chapter, we introduce some of the basics of the subject, with an emphasis on atomic, molecular, and optical physics.

Keywords

entangled state · quantum teleportation · quantum information processing · quantum gate · dense coding

The fundamental resource in quantum information processing is generally considered to be *entanglement* between spatially separated subsystems. Entanglement is a quantum-mechanical effect and has led to numerous speculations about the validity of quantum mechanics itself for its apparent paradoxical implications. Most, if not all, of these difficulties have been resolved and can be mostly attributed

to the simple fact that paradoxical behavior is incompatible with common sense or everyday experience. These quantum-mechanical correlations have numerous applications in quantum key distribution (QKD), quantum communication, dense coding, and act as the main resource in quantum computing. We will briefly touch upon some mathematical issues concerning separability and quantification of entanglement before describing how quantum key distribution and teleportation work. After that, a brief discussion of single-qubit and two-qubit quantum gates follows, before we describe some simple quantum algorithms. The issues of error correction and fault tolerant computation as well as DiVincenzo's checklist (which any realization should satisfy) provide the background for the discussion of some physical implementations, of which we will pay most attention to those involving atomic, molecular, and atomic physics.

We are acutely aware of the fact that we can give only a brief introduction into what has become a major field of investigation over the last quarter-century. There are a number of textbooks available that cover the vast literature on this subject. Perhaps the most well-known is the widely cited quantum information textbook by *Nielsen and Chuang* [1]; a number of more recent works are also recommended as starting points for more in-depth study [2–7].

85.1 Entanglement and Information

As was already noted, entanglement comes about if a quantum-mechanical system can be divided into two or more distinguishable parts. (Distinguishability of the subsystems is important for applications of entanglement and is implicit in Schrödinger's original definition of the term [8]; systems such as the two-electron ground state of helium form a spin-singlet system, but the two electrons are not distinguishable, thus strictly speaking are not entangled.) As an example, consider a two-photon emission process from a spin-zero particle by which two photons escape in opposite directions. Given that the photons are spin-one particles, their spin projections onto some axis must be mutually opposite. As there is no prior information about the actual orientation of the spin, the part of the photon wave function associated with the spin degree is, therefore,

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle). \quad (85.1)$$

The striking feature of this type of quantum state is that it describes correlations of two spatially separated particles. If the polarization state of one photon is measured in any basis (e.g., linear polarization, circular polarization, etc.), the state of the other photon, which can be far away, is then instantly predetermined. This nonlocal correlation of purely quantum

origin is called entanglement. (Classical entanglement, i.e., an electromagnetic field, which is nonfactorizable in some representation, has received some attention in the last few years ([9] and references therein); although there are interesting parallels with quantum entanglement, the key difference is the significance of the quantum wavefunction and the collapse of multipartite states due to measurement, which is fundamentally quantum mechanical.) An important and inviolable principle of special relativity is that no information can be transmitted faster than the speed of light. Because the (classical) information concerning the measurement result on one particle needs to be transmitted via a causal classical channel, this experiment respects the letter of the law; however, the instantaneous collapse of the distant photon's state can be said to violate the spirit of the law. This issue of nonlocality has been seen as a vital part in understanding the foundations of quantum mechanics itself (Chap. 84). In 1935, *Einstein, Podolsky, and Rosen* argued on the basis of entangled states that quantum mechanics is incomplete [10]. They were most concerned about the existence of elements of reality within strongly correlated quantum systems and initiated the debate on quantum nonlocality. The nonexistence of so-called local hidden variable theories for the description of states like Eq. (85.1) was demonstrated by *John Stewart Bell* [11]. He showed that maximally entangled states violate certain inequalities (now called Bell's inequalities), which local hidden variable models would have obeyed. Later experiments showed the correctness of Bell's demonstration [12–16].

In classical information theory, the unit of information is called a bit, which can be defined as the amount of information contained in a yes–no question. As a matter of fact, “bit” is the abbreviation for “binary digit” and refers to Boolean algebra in which the allowed states of a system are the logical 0 and the logical 1. Therefore, by abuse of language, one bit (as a unit) is the information carried by one bit (as a binary digit) [18].

In quantum mechanics, however, due to its inherent linearity, two “quantum bits” (or “qubits” – this word, which has now been included the *Oxford English Dictionary*, seems to have been first used in [17] can be in superpositions of the logical states $|01\rangle$ and $|10\rangle$ (or $|\uparrow\downarrow\rangle$ and $|\downarrow\uparrow\rangle$, as in the example above). This typical example of an entangled state shows that quantifying the amount of information contained in a quantum state is different from what is known in classical information theory because of the superposition property.

85.1.1 Testing for and Quantifying Entanglement

From the above it is clear that entangled states play a major role in defining the differences between classical and

quantum information. Thus, it is clearly useful to be able to determine whether or not a particular state is entangled. Consider a quantum state of two distinct subsystems A and B . Note that these subsystems themselves might consist of ensembles of particles, in which case we are looking at a bipartite cut through the whole system. Suppose subsystem A is described by an orthonormal basis set $\{|\alpha_i\rangle, i = 1, 2, \dots, N_A\}$ and subsystem B by an orthonormal basis set $\{|\beta_k\rangle, k = 1, 2, \dots, N_B\}$, then the most general state of the bipartite system can be written as

$$|\Psi_{AB}\rangle = \sum_{i=1}^{N_A} \sum_{k=1}^{N_B} c_{ik} |\alpha_i\rangle |\beta_k\rangle, \quad (85.2)$$

where c_{ik} are probability amplitudes, which form the elements of a $N_A \times N_B$ matrix. Using the singular value decomposition on this matrix [19], the state may be rewritten in a simpler manner known as the Schmidt decomposition, i.e.,

$$|\Psi_{AB}\rangle = \sum_{n=1}^N \sqrt{p_n} |u_n\rangle |v_n\rangle, \quad (85.3)$$

where $\{p_n, n = 1, 2, \dots, N\}$ are real, positive valued constants, such that $\sum_{n=1}^N p_n = 1$; $\{|u_n\rangle, n = 1, 2, \dots, N\}$ and $\{|v_n\rangle, v = 1, 2, \dots, N\}$ are sets of orthonormal vectors in subsystems A and B , respectively. The constants p_n and the vectors $\{|u_n\rangle\}$ are, respectively, the eigenvalues and the eigenvectors of the $N_A \times N_A$ Hermitian, positive-definite matrix $\mathcal{A}_{ij} = \sum_{k=1}^{N_B} c_{ik} c_{jk}^*$, and N is the number of nonzero eigenvalues; similarly, the $N_B \times N_B$ Hermitian, positive-definite matrix $\mathcal{B}_{kl} = \sum_{i=1}^{N_A} c_{ik} c_{il}^*$ has eigenvectors $\{|v_n\rangle\}$; the eigenvalues of \mathcal{A}_{ij} and \mathcal{B}_{kl} are identical, hence if $N_B < N_A$, then some of the eigenvalues of \mathcal{B}_{kl} will be zero, and vice versa). The Schmidt number must be greater than or equal to 1, and at most, equal to the smaller of the two subsystem dimensions N_A and N_B . If (and only if) the Schmidt number of the state is 1 the state of the combined system can be written as a simple product of a state of subsystem A and a state of subsystem B ; such states are called *separable*. If the Schmidt number is greater than 1, no such factorization exists, and the state is then *entangled*.

In order to find some notion of the extent of the entanglement of a state, let us now suppose we were to discard subsystem B and concentrate our attention on subsystem A . How could we describe the state of this system? If we assume that the Schmidt number is greater than 1, then there can be no pure state description, and one must consider the reduced density operator for subsystem A , viz.

$$\begin{aligned} \hat{\rho}_A &= \text{Tr}_B\{|\Psi_{AB}\rangle\langle\Psi_{AB}|\} = \sum_{i,j=1}^N \mathcal{A}_{ij} |\alpha_i\rangle\langle\alpha_j| \\ &= \sum_{n=1}^N p_n |u_n\rangle\langle u_n|, \end{aligned} \quad (85.4)$$

where, to account for the uncertainty of the state of subsystem B , we have averaged out all its possible states; mathematically this is described by taking a partial trace over subsystem B . A simple and useful measure of how mixed a state is given by the trace of the square of its density matrix, called the *purity*, defined as

$$P(\hat{\rho}) = \text{Tr}\{\hat{\rho}^2\}. \quad (85.5)$$

The purity has the maximum value of 1, corresponding to pure states; its smallest value is $1/N$, (where N is the dimensionality of $\hat{\rho}$), corresponding to maximally mixed states. As we have seen, a pure reduced density matrix implies a separable state, for which the entanglement is zero; for a maximally entangled state, we would expect the reduced density matrix to be maximally mixed, corresponding to complete randomness. In this case, the entanglement is so strong and comprehensive that discarding subsystem B has resulted in a completely random state for subsystem A . Hence, it is natural to define a measure of entanglement for the pure state $|\Psi_{AB}\rangle$ as:

$$\begin{aligned} C(\Psi_{AB}) &= \sqrt{\frac{N}{N-1}(1 - P(\hat{\rho}_A))} \\ &= \sqrt{\frac{N}{N-1} \left(1 - \sum_{n=1}^N p_n^2\right)}. \end{aligned} \quad (85.6)$$

This quantity is called the *concurrence* [20, 21]. By definition, it takes values between 0 (separable states) and 1 (maximally entangled states). For the simplest nontrivial case, that of two qubits, the concurrence of the state $|\Psi_{AB}\rangle = \alpha|\downarrow\downarrow\rangle + \beta|\downarrow\uparrow\rangle + \gamma|\uparrow\downarrow\rangle + \delta|\uparrow\uparrow\rangle$ is given by $C = 2|\alpha\delta - \beta\gamma|$; for the state Eq. (85.1), $C = 1$, implying that it is maximally entangled.

We have concentrated here on bipartite entanglement of pure states. This is a major simplification and ignores a great body of work on the entanglement both of mixed states and of multipartite states. The fundamental issue when dealing with mixed states is that one must somehow separate the inherent mixture of the state as a whole from the mixture induced by discarding one of the subsystems; for pure states, the former is zero. Since quantum information usually assumes devices that are prepared in pure states, and their performance rapidly degrades as their systems undergo decoherence, the taxonomy of mixed-state entanglement measures, while fascinating, is at best tangential to the main thrust of this article; the interested reader should consult some of the recent review articles on the topic [22, 23].

85.2 Simple Quantum Protocols

In this section, we describe the historically first and simplest quantum protocols – quantum key distribution and quantum teleportation – that make use of inherently “quantum” properties of quantum-mechanical systems. These are either entanglement or, in the case of the simplest version of quantum key distribution, properties of the quantum-mechanical measurement process. We should mention here the pioneering work of *Holevo* [24], who showed that there are fundamental limits on the amount of information that can be extracted by measurements. The application of his ideas to channel capacity and communication [25, 26] are well described in [1], and space limitations prevent us from elaborating on it in this chapter.

85.2.1 Quantum Key Distribution

Historically, the earliest protocol that used quantum-mechanical features in order to realize some specific task that could not have been performed classically was a protocol for secure distribution of a key in cryptography, known as the BB84 protocol after its inventors *Bennett* and *Brassard* and the year of its invention [27]. Although it is commonly referred to as the first example of quantum information processing, it does not make use of entanglement; an entanglement-based method for quantum key distribution was introduced some years later by *Ekert* [28]. The BB84 protocol works in the following way. The sender, generically called Alice, prepares a random sequence (or string) of single photons in a polarization state, which is chosen out of a set of four basis states, horizontally and vertically (H and V) polarized, and diagonal (45°) and antidiagonal (135°) (D and A) polarized. In each of the two basis sets $\{H, V\}$, $\{D, A\}$, one of the states is used to encode the logical value 0 (say in H and D), and the other states encode the logical value 1 (V and A). The random sequence is sent to the receiver, Bob, who performs measurements on the sequence of signals by randomly choosing analogous basis states. The result will be another string of 0’s and 1’s that generically does not coincide with the original string. To rectify this problem, sender and receiver communicate over a classical public channel, where the sender announces the sequence of basis sets in which the photon states were prepared. The receiver compares its sequence of randomly chosen basis states with the announced string and keeps all measurement results for which the choice of basis had been the same. In that way, a common secret key is established (Table 85.1).

The security against eavesdropping of this simple protocol comes from the fact that even by knowing the measurement basis (say $\{H, V\}$) no information has been revealed about the choice of the actual bit value (H or V). Hence, it

Table 85.1 BB84 protocol for secret key distribution. “Alice” sends information encoded in either of two basis sets. “Bob” randomly chooses a measurement basis that is publicly communicated. For those cases when sender and receiver chose the same basis, the receiver’s measurement yields a secure bit

Sender (Alice)	Receiver (Bob)	Generated key
D	$\{H, V\}$	None
V	$\{H, V\}$	0
A	$\{H, V\}$	None
H	$\{H, V\}$	1
D	$\{D, A\}$	0
V	$\{D, A\}$	None
A	$\{D, A\}$	1
H	$\{D, A\}$	None

is the quantum-mechanical measurement process itself that provides security of the protocol. Nor can any eavesdropper (generically known as Eve) hope to intercept the signal without being detected: individual photons can neither be split in a beam splitter (the photon will either go to Bob, so Eve cannot see it, or to Eve, in which case Bob does not receive it), nor can it be cloned by some device [29] without inducing a detectable increase in the error rate. The first quantum key distribution experiments were reported in [30]. However, imperfections in the generation and detection of photons, transmission losses, and polarization drift cause an actual experimental realization to be far from ideal. In practice, encodings other than polarization may be used (for example, a time-binned interferometric basis). Despite these error sources, unconditionally secure quantum key distribution has been demonstrated and implemented over distances of up to 100 km in both fibers and free space. For reviews of theoretical and experimental aspects of quantum cryptography, see [31, 32].

85.2.2 Quantum Teleportation

An important utilization of entanglement as a necessary resource can be found in quantum teleportation. The task of teleportation is to transmit the complete information of an arbitrary unknown quantum state to a spatially different location with the aim of recreating it. The simplest and most obvious way to perform this task would be to take the quantum object that is prepared in the original state and physically transport it to a different location. However, sometimes this is not possible because, for example, an ion needs to be stored in a trap and cannot be moved. The next obvious thing to do would be to measure the quantum state and to recreate it at a different position using the classical information obtained during the measurement. However, single measurements on a quantum system yield only partial information and multiple measurements on many identically prepared copies would have to be performed.

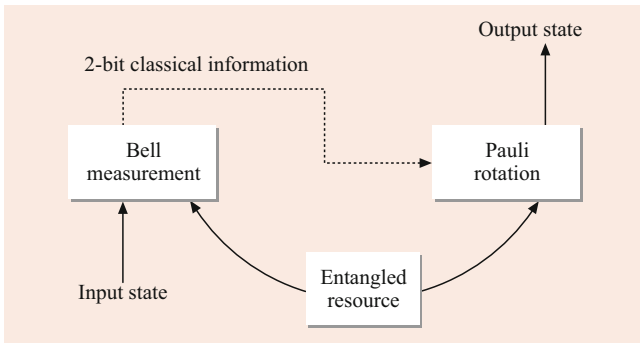

Fig. 85.1 Outline of an ideal teleportation protocol

The protocol (Fig. 85.1), which was originally proposed in [33], makes use of the existence of maximally entangled states. Let the unknown quantum state that is to be teleported be a qubit superposition state of the form:

$$|\psi\rangle = \alpha|0\rangle + \beta|1\rangle, \quad |\alpha|^2 + |\beta|^2 = 1. \quad (85.7)$$

Then one prepares a maximally entangled state $|\Psi^+\rangle = (1/\sqrt{2})(|01\rangle + |10\rangle)$, which is one of the four orthonormal Bell states, defined by

$$\begin{aligned} |\Psi^\pm\rangle &= \frac{1}{\sqrt{2}}(|01\rangle \pm |10\rangle), \\ |\Phi^\pm\rangle &= \frac{1}{\sqrt{2}}(|00\rangle \pm |11\rangle). \end{aligned} \quad (85.8)$$

We then form the tensor product state $|\psi_A\rangle|\Psi_{BC}^+\rangle$ as

$$\begin{aligned} |\psi_A\rangle|\Psi_{BC}^+\rangle &= \frac{1}{\sqrt{2}}(\alpha|0_A0_B1_C\rangle + \alpha|0_A1_B0_C\rangle \\ &\quad + \beta|1_A0_B1_C\rangle + \beta|1_A1_B0_C\rangle), \\ &= \frac{1}{2} [|\Psi_{AB}^+\rangle(\alpha|0_C\rangle + \beta|1_C\rangle) \\ &\quad + |\Psi_{AB}^-\rangle(\alpha|0_C\rangle - \beta|1_C\rangle) \\ &\quad + |\Phi_{AB}^+\rangle(\alpha|1_C\rangle + \beta|0_C\rangle) \\ &\quad + |\Phi_{AB}^-\rangle(\alpha|1_C\rangle - \beta|0_C\rangle)], \end{aligned} \quad (85.9)$$

where we have explicitly indexed the relevant subsystems. After performing a joint measurement on subsystems A and B in the Bell basis (this is called a Bell-state measurement), one obtains one of four possible results. If the measurement result was $|\Psi_{AB}^+\rangle$, then the subsystem C is, indeed, prepared in the original unknown quantum state $|\psi\rangle$, and hence the state has been “teleported” from subsystem A to C . For all other measurement results the outcome is not exactly the same quantum state as intended, but the difference is just a unitary transformation, which is uniquely determined by the outcome of the Bell measurement. For example, measuring $|\Psi_{AB}^-\rangle$ means one has to perform a $\hat{\sigma}_z$ -operation on qubit

C , that flips the sign of the state $|1\rangle$, whereas on obtaining $|\Phi_{AB}^+\rangle$ or $|\Phi_{AB}^-\rangle$ the operations to be applied have to be $\hat{\sigma}_x$ or $\hat{\sigma}_z\hat{\sigma}_x = i\hat{\sigma}_y$, respectively.

Note that this quantum teleportation protocol works with perfect fidelity only if a maximally entangled state has been used. In the course of the Bell measurement, the quantum information is used up, and two classical bits of information (the measurement result) have to be communicated to C in order to restore the original quantum state. In this sense, entanglement can be regarded as a resource or “fuel” for certain tasks in quantum information processing.

The first experimental demonstrations of teleportation of qubits were performed using photons as qubits by the groups of *Zeilinger* in Vienna and *De Martini* in Rome [34, 35], although these could not implement a complete Bell-state measurement (i.e., they could only distinguish one or two of the four Bell states). The first experiments to demonstrate full teleportation with highly entangled states, strong projective measurement, and complete state reconstruction were performed by the groups of *Blatt* at Innsbruck, Austria and, independently, *Wineland* at Boulder in Colorado USA, both using trapped ions [36, 37]. Since then, it has been implemented on other systems and over longer distances; in 2017 a collaboration headed by *Pan* demonstrated the teleportation of photons over distances of up to 1400 km from a ground station to a satellite in low Earth orbit [38].

85.3 Quantum Logic

As we have seen, quantum information relies on devices consisting of qubits. In order to perform any quantum information processing task, one must implement unitary operations on them collectively, in order to create the desired quantum state. For a large number of qubits, this would seem a task daunting in its complexity; fortunately, it has been demonstrated that all unitary operations on a large qubit register can be broken down into single-qubit operations and operations involving pairs of qubits.

85.3.1 Single-Qubit Operations

It is instructive to give an example of how to classify all possible unitary operations that can act on a single qubit. A unitary operation acting upon the basis states $\{|0\rangle, |1\rangle\}$ can be represented by a unitary (2×2) -matrix, and hence is a matrix that represents an element of the unitary group $U(2)$. This group has four generators, the identity matrix and the three Pauli matrices. All unitary (2×2) -matrices are linear combinations of those four matrices. Given the way they

act upon basis states, they can be written as

$$\begin{aligned} \hat{I} &= |0\rangle\langle 0| + |1\rangle\langle 1| \\ \hat{\sigma}_x &= |0\rangle\langle 1| + |1\rangle\langle 0| \\ \hat{\sigma}_z &= |0\rangle\langle 0| - |1\rangle\langle 1| \end{aligned} \tag{85.10}$$

and, by virtue of the commutation rules for $U(2)$ -generators, $\hat{\sigma}_y = i\hat{\sigma}_x\hat{\sigma}_z$. Sometimes, the short-hand notation $\hat{X} = \hat{\sigma}_x$, etc., is used.

A particularly useful single-qubit gate that is not just one of the Pauli operators is the Hadamard gate \hat{H} . In terms of Pauli operators, it is defined as $\hat{H} = (1/\sqrt{2})(\hat{X} + \hat{Z})$. Its purpose is to transform each basis state into equal superpositions of basis states, i.e., $|0\rangle \rightarrow (1/\sqrt{2})(|0\rangle + |1\rangle)$ and $|1\rangle \rightarrow (1/\sqrt{2})(|0\rangle - |1\rangle)$. The Hadamard gate is used to initialize an equal superposition of all possible N -qubit basis states from the state $|0\rangle^{\otimes N}$ (i.e., the tensor product of N qubits in state $|0\rangle$). Hence,

$$\bigotimes_{i=1}^N \hat{H}_i |0\rangle^{\otimes N} = \frac{1}{\sqrt{2^N}} \sum_k |x_k\rangle, \tag{85.11}$$

where the $|x_k\rangle$ are all 2^N possible N -digit binary numbers.

85.3.2 Two-Qubit Operations

Similarly to the single-qubit case, one can write down all possible unitary operations on two qubits by noting that they constitute a representation of $U(4)$; the 16 generators of this group can be found by forming the tensor products of pairs the four generators of $U(2)$, listed above; all possible two-qubit operators can be written as a linear combination of these generators.

Particular examples of nontrivial two-qubit gates are the controlled-NOT and the controlled-phase gate, defined in terms of Pauli operators as

$$\begin{aligned} \hat{C}_{12} &= |0_1\rangle\langle 0_1| \otimes \hat{I}_2 + |1_1\rangle\langle 1_1| \otimes \hat{X}_2, \\ \hat{P}_{12} &= |0_1\rangle\langle 0_1| \otimes \hat{I}_2 + |1_1\rangle\langle 1_1| \otimes \hat{Z}_2, \end{aligned} \tag{85.12}$$

where in both cases, qubit 1 acts as the ‘‘control’’ and qubit 2 acts as the ‘‘target’’ (Fig. 85.2). The net effect of the

Fig. 85.2 Symbol and truth table of the controlled-NOT gate. The target qubit is flipped depending on the state of the control qubit

controlled-NOT gate is to interchange the states $|10\rangle \leftrightarrow |11\rangle$, whereas the controlled-phase gate changes the phase of the basis state $|11\rangle$ by π and leaves all other states unchanged. The controlled-NOT gate has an interpretation as a sum gate in that it performs a mapping $|x, y\rangle \rightarrow |x, x \oplus y\rangle$, where the addition has to be taken modulo 2. Moreover, it acts as an entangling gate when acting on tensor products of superpositions.

85.3.3 Multiqubit Gates and Networks

To realize a unitary operation on many qubits for a particular algorithm one would need a network of single-particle and multiparticle quantum gates. Quantum networks enable a prepared input state to be transformed by the appropriate unitary operator to a final state, which is then measured. Deutsch’s model of quantum networks enables us to decompose the network into component gates in diagrammatic form [39]. The task is then to optimize the sequence of gates. One can treat quantum gates acting on N qubits as being elements of the group, which has generators. This, however, is not a particularly transparent or useful way of looking at these gates. Much more useful, and of immense practical importance, is a result essentially from linear algebra, which states that every N -qubit gate can be generated by a network that consists only of very few elementary building blocks consisting of one or two-qubit operations, the so-called universal set of quantum gates [40]. This set contains all possible single-qubit rotations and one nontrivial two-qubit gate, such as the controlled-NOT or controlled-phase gate mentioned above.

85.3.4 Cluster-State Quantum Computing

The original paradigm for a quantum computer was a register of qubits, on which unitary operations would be performed, and eventually the answer would be read out by performing a measurement on some or all of the qubits. A system of N qubits in a pure entangled state would be a quantum system of 2^N dimensions; however the readout could at most procure N bits of information. This indicates both the potential and the drawbacks of the scheme: a quantum computer has an enormous memory on which parallel operations might be performed most efficiently; however, only a small amount of the information present in that memory can ever be accessed.

An important new paradigm for quantum computing was introduced by *Raussendorf* and *Briegel* in 2001 [41]. Cluster-state quantum computing (also called one-way quantum computing, or measurement-based quantum computing) envisions the initial creation of an entangled state of a very

large number of qubits, called a cluster state. If the algorithm one wishes to implement requires N register qubits to store information and M quantum gates to process it, then the size of the cluster state needs to be $N \times M$ physical qubits. The quantum algorithm may then be implemented by measurements of a subset of the qubits, followed by a series of single-qubit operations conditioned on the outcome of those measurements, followed by another series of measurements and conditional single-qubit operations, and so on. The resultant final state can be shown to be equivalent to the output state of a traditional, circuit-based quantum computer.

85.4 Quantum Algorithms

The search for algorithms that would run faster on a quantum computer than on any classical computer is a formidable task. By “faster”, we actually mean that the number of elementary tasks required to perform a given computation should be drastically reduced. The hope is that eventually one will find algorithms that provably run exponentially faster on a quantum computer compared to a classical computer. Here, we briefly discuss three well-known algorithms; investigation of other useful quantum algorithms remains an area of intense on-going research (for reviews: [42–44]).

85.4.1 Deutsch–Jozsa Algorithm

Let us give a particularly instructive example due to *Deutsch* and *Jozsa* [45]. Suppose one is given a function $f(x)$, which is Boolean (i.e., $f(x)$ has only two possible values: 0 or 1), and whose argument is a N -bit number, (i.e., $x \in \{0, 1, \dots, 2^N - 1\}$). From the start it is assumed $f(x)$ is either constant (i.e., it always has the value 0 or 1) or that it is balanced, (i.e., it returns the value 0 and 1 with equal probability). The task is to find out whether $f(x)$ is constant or balanced.

Although this seems a contrived problem, it serves to illustrate the potential power of quantum computers. Classically, to be certain of getting the correct answer, one needs to evaluate the function at least $2^{N-1} + 1$ times to find the answer (i.e., half of the possible values of x , plus 1). With a quantum computer, only a single evaluation of the function is required. First, N qubits are prepared in a superposition of all possible input states, using the Hadamard gate from Eq. (85.11); and a single qubit is prepared in the state $|y\rangle = (1/\sqrt{2})(|0\rangle - |1\rangle)$; then a unitary operator that evaluates the function $f(x)$ is applied, i.e., $\hat{U}_f|x\rangle|y\rangle = |x\rangle|y \oplus f(x)\rangle$. Since the N qubits containing the value of the argument x are in a superposition of all possible values, a single evaluation of the function suffices (Fig. 85.3). The following state

Fig. 85.3 Gate network for implementing the Deutsch–Jozsa algorithm

is the result:

$$\begin{aligned} & \frac{1}{\sqrt{2^{N+1}}} \sum_k |x_k\rangle (|f(x_k)\rangle - |1 \oplus f(x_k)\rangle) \\ & = \left(\frac{1}{\sqrt{2^N}} \sum_k (-1)^{f(x_k)} |x_k\rangle \right) |y\rangle, \end{aligned} \quad (85.13)$$

where we have used the fact that $f(x)$ can only take the value 0 or 1 in order to simplify the result. The final step is to repeat the Hadamard single-qubit unitaries of the argument register qubits and perform a measurement on all of these qubits; the probability of all the output qubits being in state $|0\rangle$ can be shown to be $|(1/\sqrt{2^N}) \sum_k (-1)^{f(x_k)}|^2$, which will be 1 if the function is constant, and 0 if it is balanced. Thus, a measurement outcome other than 0 on any of the N argument qubits then tells that the function $f(x)$ is balanced.

This quantum parallelism is at the heart of the increase in speed that occurs in quantum computation. The Deutsch–Jozsa algorithm involving a few qubits has been implemented on various platforms, most compellingly using ion traps [46].

85.4.2 Grover’s Search Algorithm

In contrast to the preceding example, which always gives the desired answer after exactly one trial, the quantum search algorithm by *Grover* [47] uses a procedure that amplifies the sought after result by a method called “inversion about average”. The goal of Grover’s algorithm is to search an unsorted database with $2N$ entries out of which only one entry fulfills a given criterion; for example, searching through an alphabetic telephone directory to find the person who has some specific telephone number. As in the Deutsch–Jozsa algorithm described above, the query is simultaneously run on all 2^N possible N -qubit basis states, being prepared in an equal superposition. It is assumed that the state that satisfies the search criterion will acquire a phase shift of π . After this step, the inversion about average is carried out. It is represented by a diffusion operator $\hat{D} = 2\hat{P} - \hat{I}$, where \hat{I} is the identity operator, and \hat{P} is a projection operator that averages each input vector with respect to its components. Compared to the previous average value of probability amplitudes, after each of

these steps, the magnitude of the desired state increases by $O(2^{-N/2})$. This procedure is repeated, and after only $O(2^{N/2})$ steps, a projective measurement yields the desired result with probability of $O(1)$, or more precisely, of more than a half. This is a quadratic increase in speed compared to classical search algorithms, which need $O(2^N)$ steps.

85.4.3 Shor's Factor-Finding Algorithm

Suppose one were given an integer n known to be the product of two primes, a and b . A systematic way to determine a and b would be to attempt to divide n by all the prime numbers less than \sqrt{n} . If n , written in binary, has L digits (i.e., $L = \lceil \log_2(n) \rceil$), then the prime number theorem [48, p. 47] implies that one must perform this division $O(2^{(L/2)+1}/L)$ times; in other words, the complexity of finding factors is exponential in the size of the number to be factored. While more efficient algorithms exist, they all have this unfortunate exponential scaling. This mathematical fact is central to the security of public-key encryption systems [48, pp. 212–217], and thus an algorithm that can find factors more efficiently will have far-reaching implications.

Shor's algorithm for quantum computers provides just such an algorithm [49]. The basic idea is to exploit conventional number theory to convert the factor finding to finding the period of particular modular exponential function. While a conventional computer would require multiple evaluations to determine the period of a function, a quantum computer, using the sort of parallelism we have already seen in the Deutsch–Jozsa algorithm, would require a single evaluation. A quantum Fourier transform (analogous to the fast Fourier transform executed on quantum registers) followed by measurement allows the period of the function to be determined with high probability. Once the period of this modular exponential function is determined, the factors of n may be deduced straightforwardly. The total number of operations required is a polynomial function of the number of bits L in the number to be factored.

Implementation of simplified versions of Shor's algorithm, using various tricks and short-cuts, have been reported using various platforms [50–53]; the first potentially scalable experimental demonstration (albeit on a small scale, i.e., factoring 15, using 5 qubits) was reported by Blatt and co-workers in 2016 using trapped ions [54].

85.4.4 Other Algorithms

Other algorithms that are attracting considerable attention and are being pursued both theoretically and experimentally include *quantum simulations* [55, 56], i.e., the use of quantum devices to emulate physical systems with prescribed

microscopic interactions to study the emergence of macroscopic behavior ([57, 58], for some recent experiments); the efficient calculations of molecular energy spectra in *Quantum Chemistry* [59–61]; *Boson Sampling*, the interference of harmonic oscillator modes in nonclassical states (typically single-photon states) in a large interferometer, the output of which can be shown to be related to computational intractable problems such as the calculation of permanents of matrices [62–64]; and *Quantum Machine Learning* [65], plus many others.

A significant milestone in the development of viable quantum computing was passed in 2019 with the demonstration of *quantum supremacy* using a 53 qubit quantum processor developed by the team at Google led by John Martinis [66]. They carried out a calculation in about 200 seconds which, had a conventional computer been used, would have required 10 000 years.

85.5 Error Correction

As we have discussed, the essence of quantum information processing is the use of quantum superpositions, interference, and entanglement. However, quantum interference is fragile. It appears in practice that it is very difficult to maintain a superposition of states of many particles in which each particle is physically separated from all the others. Entanglement turns out to be incredibly delicate. The reason for this is that all systems, quantum or classical, are not isolated; they interact with everything around them: local fluctuating electromagnetic fields, the presence of impurity ions, coupling to unobserved degrees of freedom of the system containing the qubit, etc. These fluctuations destroy quantum interference. A simple analogy is the interference of optical waves in Young's double-slit experiment. In that apparatus, waves from two spatially separated portions of a beam are brought together. If the two parts of the beam have the same phase, then the fringe pattern remains stable. However, if the phase of one part of the beam is drifting with respect to the other, then the fringe pattern will be washed out. And the more slits there are in the screen, the lower the visibility for the same amount of phase randomization per pair of slits. The sensitivity of an N -qubit register to decoherence is even worse, as a maximally entangled N -particle state decoheres at a rate N times faster than a single particle [67], one of the reasons why the world around us appears so classical. A single bit of information lost to an unobserved degree of freedom will result in the reduction of the quantum superposition to a mixed state. Yet, correcting errors due to environmental interactions is essential if a quantum computer is to be constructed; to do "fault tolerant" computing we need to be able to execute many gate operations coherently within the decoherence time

if we are to have a chance of building a scalable quantum register [68].

It might appear that the problem of stabilizing a register of qubits is hopeless, like trying to balance several pencils on their tips on the deck of a ship in a storm. Yet, amazingly, quantum mechanics provides a way to solve this problem, through the use of even higher levels of entanglement. In 1996, *Steane* and, independently, *Shor* and coworkers, showed that encoding information in entangled sets of qubits offered the opportunity to execute quantum error correction [69, 70]. That one can do this is a remarkable consequence of entanglement. In classical information processing, inevitable environmental noise is dealt with by error correction. In its simplest form, this involves repeating the message transmission or calculation until a majority result is obtained.

However, there are more efficient ways, for example, the use of a parity check on a block of bits. It turns out that a similar notion can be applied to a quantum register. However, the application is not straightforward because the contents of a register cannot be measured without destroying the superposition state encoded in it. The problem then is to determine what errors might be present in a quantum register without looking at the qubits. The elegant solution is to entangle the qubits in question with those in an ancillary register and measure the ancillary register. Because the two registers are correlated, the results of the measurement of the ancilla reveal any errors present in the processing register without destroying any coherent superpositions in the processing register itself.

The first experimental demonstration of quantum error correction used liquid-state nuclear magnetic resonance (NMR) techniques [71]; but given the highly mixed nature of the “pseudo-pure” quantum states in NMR, which precludes the existence of any entanglement [72], this work had limited implications for quantum information processing. In 2004, *Wineland’s* group in Boulder succeeded in implementing quantum error correction in an entangled system using trapped ions [73, 74]; since then, multiple, repetitive error correction has been demonstrated by *Blatt’s* group. Another way to prevent the register coherence from falling apart is to know a little about the sort of noise that is acting on it. If the noise has some very slow components (or those with very long wavelengths), then it is sometimes possible to find certain combinations of qubit states for which the noise on one qubit exactly cancels the noise on another. These qubit states live in a “decoherence-free subspace” (DFS) [75–77]. A computer will then be immune to environmental perturbations if all the computational states lie in this DFS. Decoherence-free subspaces were first realized experimentally using photonic qubits by *Kwiat* and coworkers in 2000 [78].

A remarkable result, which has important implications for the long-term viability of quantum information processing, is the quantum threshold theorem, which states in essence that

if a qubit can be realized with a high enough degree of protection against environmental errors, then through the process of concatenation (i.e., encoding one logical qubit using noisy qubits; each of which might be encoded on another set of qubits, and so on), quantum computations can be performed with arbitrary accuracy [79]. As in the field of quantum algorithms, fault-tolerant quantum computing remains a highly active area of research ([80], for a recent overview).

85.6 The DiVincenzo Checklist

So much for the theory of what we would like to with quantum computers; there remains the vexatious topic of how they might be realized in practice. The short answer is that no one knows for certain how (or, indeed, if) practical quantum computers might be realized. *DiVincenzo* has given a list of requirements that a physical implementation must fulfill in order to qualify as a sensible candidate for an implementation of quantum information processing [81]; we will review these here and then use them to assess how various technologies are developing. We will concentrate on those implementations that currently seem the most promising, rather than discuss every proposal that initially seem promising but has over the years fallen by the wayside.

85.6.1 Qubit Characterization, Scalability

Each physical implementation must be tested upon how qubits should be encoded. For a qubit being essentially a two-level system, this task is generally not too difficult. Several candidates, such as electronic or nuclear spin, photon polarization, and choice of path in an interferometer, degenerate ground states of an atom or ion, charge or flux states in superconducting quantum interference devices (SQUIDS), or exciton population, have all been explored. Much more challenging will be the question as to whether there are fundamental or technological limitations of having many of those qubits being operated upon separately, hence whether the system can be scaled up to contain potentially many qubits.

85.6.2 Initialization

Once the qubits have been specified, each quantum information processing or quantum computation task needs to be able to start from a well-defined state. This can be basically any quantum state of the many-qubit system as long as it is a product state and can be prepared error-free. Commonly, this state is then called the ground state and is denoted by $|0\rangle^{\otimes N}$.

85.6.3 Long Decoherence Times

In order to ensure error-free computation without loss of purity of quantum superpositions, the decoherence times that are relevant for the quantum operation should be much longer than the gate operation time itself. In most situations, decoherence limits the number of qubits that can be worked on simultaneously, thus affecting the scalability of the system. Typical examples of decoherence processes are heating mechanisms in ultracold systems, such as ion-trap or atom-chip experiments, spin relaxation in NMR-type experiments, or absorption in linear optical elements. Generally, decoherence is unavoidable due to the basic principles upon which quantum information processing is supposed to work. Avoiding decoherence means isolating the system from the outside world, the environment. However, controlling the interaction between subsystems always has the negative effect of bringing the system in contact with the environment and, therefore, necessarily introduces decoherence. Once one has accepted that decoherence is unavoidable, ways have to be found to guard against it. Several error-correction schemes have been proposed that can correct for certain small amounts of decoherence as described in Sect. 85.5.

85.6.4 Universal Set of Quantum Gates

A necessary prerequisite for quantum information processing and quantum computing is the ability to generate a set of quantum gates that can be considered universal. With such a set, it will then be possible to generate all other quantum gates by concatenating them to form suitably arranged networks. The choice of which set out of the many possible is taken depends on the physical implementation itself. Basically, it is determined by the operations that are intrinsically simple for the given interaction Hamiltonian. In some applications, such as the ion-trap experiments, the controlled-NOT gate is preferred as the nontrivial two-qubit gate, whereas in linear optical networks, one rather works with the controlled-phase gate.

85.6.5 Qubit-Specific Measurement

The last requirement is to be able to read out the result of the computation. That is, there has to be a way of providing a selective projective measurement. This proves to be a major challenge in most proposals for implementing quantum computing. Examples of the challenges involved are the necessity to provide photon-number resolving photodetectors, single-electron charge measurement devices, or single-spin measurements.

85.7 Physical Implementations

Over the past quarter of a century, a number of architectures capable of attempting an assault on the rigors of the DiVincenzo criteria have been proposed and tested; many have fallen by the wayside, a few have persevered. In general, atomic and optical systems based on nonclassical light (e.g., single photons) [82] or cold trapped atoms [83, 84] have led the way, since these had been studied for many years for their intrinsic scientific interest, and had already the proven capability to produce entangled quantum states and/or the high degree of protection against environmental decoherence necessary for quantum computation. In what follows, we will concentrate our attention on these. However, they possess a decided *disadvantage* as a scalable architecture for a full-scale quantum computer with say 10^5 qubits and capable of performing useful tasks: in order that computation technology be robust and durable, it is taken for granted that a solid-state-based architecture will ultimately be necessary. Such architectures, based on quantized magnetic flux in superconducting circuits [85, 86] or on individual spin impurities in a semiconductor host [87, 88], have also shown considerable promise. In such a rapidly developing field, the relative merits of the various technological implementations may well reverse themselves within the space of a few years.

85.7.1 Linear Optics

The use of photons as carriers of quantum information seems to be a straightforward matter: they are easy to produce in numbers; much of the technology to store and to manipulate photons in mature due to its dominance in conventional telecommunications; they show both spin-like behavior (i.e., polarization) and boson-like behavior, making them versatile quantum systems. The first serious proposal for a quantum logic gate was made using photons as qubits in 1989 [89]. The major drawback for photons as qubits is the lack of strong nonlinearities at the single-photon level needed to implement two-qubit logic gates.

However, a different approach, based on a generalization of the well-known quantum-optical Hong–Ou–Mandel interference effect [90], was proposed in 2001 [91, 92]. In this scheme, information is encoded in number states (also called *Fock states*): one photon can be in one of two distinct modes of free space or of a photonic waveguide. Since photons are bosons, there is a natural tendency to bunch together in interference experiments, which in a sense is a nonlinearity on the level of single or few photons. The trick is to use conditional measurements or measurement-induced nonlinearities. The idea was first realized experimentally in [93], where a polarization encoding was used. Fig. 85.4 shows the schematic

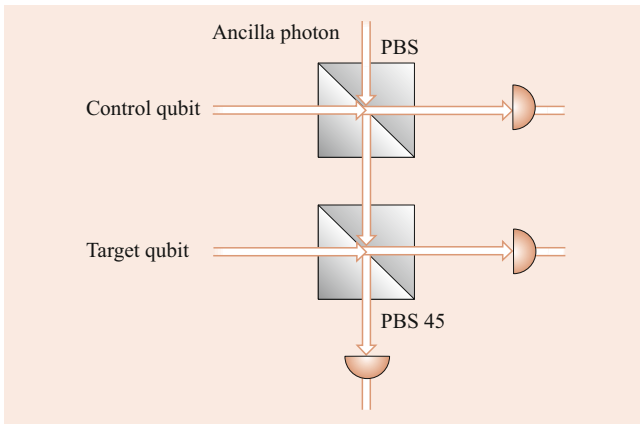

Fig. 85.4 Setup of an all-optical controlled-NOT gate. Control and target qubits are encoded in the polarization of single photons. These are fed into polarizing beam splitters (PBS), one of which is rotated by 45°

setup of a simplified version of a controlled-NOT gate with one single ancilla photon (after [94]).

Measurement-induced nonlinearities make use of the fact that unitary transformations in a larger Hilbert space, e.g., with added auxiliary photon modes combined with photodetection, can yield effective nonlinearities [95]. The drawback is, however, that the wanted nonlinearity is conditioned on the appearance of a certain measurement pattern, which means that these schemes work only with a certain probability [96].

The set of quantum gates that can be considered fundamental differs slightly from most other physical implementations. Within the qubit encoding in photon number states, the gates that can actually be implemented efficiently are those that act within Fock layers (subspaces of fixed total photon number), such as the controlled-phase gate, or the swap gate. Other gates that do not fall into this class require excessively more resources unless other types of qubit encodings are used simultaneously. Gate operation times can be very fast and are only limited by the gating times of the photodetectors. Other attractive features of this approach are that devices can work at room temperature and can readily be integrated into photonic waveguides. However, a major experimental challenge is mode matching in larger networks and interferometric setups, as well as scalability [96]. The cluster state approach discussed above (Sect. 85.3.4) is actively being pursued using linear optical implementations.

85.7.2 Trapped Ions

The most advanced method of quantum information processing in terms of the number of qubits and the number of gates

that have been unequivocally demonstrated is the ultracold-ions scheme proposed by *Cirac* and *Zoller* in 1995 [97]. The ions are stored in a linear Paul trap, in which radio frequency electric quadrupole fields are used to generate confining potentials [98, 99]. The ions are cooled into their motional ground states by Doppler cooling [100] and further cooled to the quantum ground state by resolved sideband cooling [101]. Since the ions are strongly coupled by their mutual Coulomb repulsion, their oscillations are resolved into a number of normal modes, rather like pendulums connected by springs [102]; each of these normal modes are quantum harmonic oscillators that interact with all of the ions in the trap, enabling a quantum data bus to connect the ion qubits.

The qubits are encoded into two long-lived electronic states of individual ions, either transitions to metastable excited states (i.e., with lifetimes of a second or more, since decays are dipole forbidden) or Raman coupling between sublevels of the ground state, thereby avoiding the decoherence that an upper-state lifetime, or laser phase drift can generate. Lasers focused on individual ions are then used to control both the internal states of individual qubits and, by detuning, to couple the qubits to the quantum oscillation modes of the ions, thereby enabling two-qubit quantum logic gates. Readout is performed by observation of fluorescence from individual ions. To date 20 qubits have been trapped, cooled, coherently manipulated, and shown to be entangled [103].

85.8 Outlook

We have discussed the basic ideas behind quantum information and described a few possible applications. However, the immense wealth of ideas and possible routes have barely been touched upon. In the past few years, the field has generated tremendous excitement, with many new strands of investigation evolving rapidly. Quantum key distribution is becoming a commercial technology. For quantum computing, only one or two dozen qubits have been entangled and manipulated experimentally so far, and a deployable quantum computer remains decades away, although new algorithm research suggests that demonstrations of the quantum advantage in computation may be a reality in a much shorter time.

Daniel James Daniel James was born in Manchester, UK. He received his PhD from the University of Rochester in 1992, supervised by Professor Emil Wolf. He was a staff member in the Theoretical Division, Los Alamos National Laboratory (1994–2005), after which he joined the faculty of the University of Toronto. He has been engaged in quantum information research since 1995.

Peter Knight Peter Knight is Emeritus Professor at Imperial, a past President of the Institute of Physics, 2004 President of the Optical Society of America, Chair of the UK National Quantum Technology Programme Strategy Advisory Board and chairs the Quantum Metrology Institute at the National Physical Laboratory. His research centres on quantum technology.

Stefan Scheel Stefan Scheel received his PhD (Dr rer nat) from the Friedrich Schiller University, Jena, Germany, in 2001. He worked in the Quantum Optics and Laser Science Group at Imperial College London until 2012, when he moved to Rostock, Germany as a Full Professor. His research interests include QED in dielectrics, fluctuation-induced phenomena, integrated waveguide quantum optics, and Rydberg physics with atoms and semiconductor excitons.

Part G
Applications

Part G is concerned with the various applications of atomic, molecular, and optical physics. A summary of the processes that take place in photoionized gases, collisionally ionized gases, the diffuse interstellar medium, molecular clouds, circumstellar shells, supernova ejecta, shocked regions, and the early universe are presented. The principal atomic and molecular processes that lead to the observed cometary spectra, as well as the needs for basic atomic and molecular data in the interpretation of these spectra, are focused on. The basic methods used to understand planetary atmospheres are given. The structure of atmospheres and their interac-

tion with solar radiation are detailed, with an emphasis on ionospheres. Atmospheric global change is then studied in terms of the applicable atomic and molecular processes responsible for these changes. Various applications of atomic and molecular physics to phenomena that occur at surfaces are reviewed; particular attention is placed on the application of electron-atom and photon-atom scattering processes to obtain surface specific structural and spectroscopic information. The effect of finite nuclear size on the electronic energy levels of atoms is also detailed; and conversely, the electronic structure effects in nuclear physics are discussed.

Applications of Atomic and Molecular Physics to Astrophysics

Abstract

The range of physical conditions of density, temperature, and radiation fields encountered in astrophysical environments is extreme and can rarely be reproduced in a laboratory setting. It is not only reliable data on known processes that are needed but also a deep understanding so that the relevant processes can be identified and the influence of the conditions in which they occur fully taken into account.

We present here a summary of the processes that take place in photoionized gas, collisionally ionized gas, the diffuse interstellar medium, molecular clouds, circumstel-

lar shells, supernova ejecta, shocked regions, and the early universe.

Keywords

charge exchange · dielectronic recombination · early universe · molecular cloud · photoionization · planetary nebula · radiative association · recombination · supernova remnant · three-body recombination · Wilkinson microwave anisotropy probe

86.1 Introduction

Almost all our information about the universe reaches us in the form of photons, though neutrinos, cosmic rays, and, recently, gravitational waves provide additional insight. Traditional observational astronomy is based on measurements of the distribution in frequency and intensity of the photons that are emitted by astronomical objects and detected by instrumentation on ground-based and space-borne telescopes. Information about the earliest stages in the evolution of the universe before galaxies and stars had formed is carried to us by blackbody background photons that attended the beginning of the universe. The photons that are the signatures of astronomical phenomena are the result of a plethora of physical and chemical processes reaching into a host of disciplines, including nuclear physics; plasma physics; solid-state physics or surface sciences; and atomic, molecular, and optical physics. The processes that modify the photons on their journey from distant origins through intergalactic and interstellar space to the Earth belong mostly to the domain of atomic, molecular, and optical physics, as do the instruments that detect and measure the arriving photons and their spectral distribution. The spectra are used to classify galaxies and stars and to identify other astronomical entities and phenomena such as quasars, active galactic nuclei, gravitational lensing, jets and outflows, pulsars, supernovae, novae, supernova remnants, nebulae, masers, protostars, shocks,

molecular clouds, circumstellar shells, accretion disks, protoplanetary disks (PPDs), galaxy clusters, and black holes.

Quantitative analyses of the spectra of astronomical sources of photons and of the atomic, molecular, and optical processes that populate the atomic and molecular energy levels and give rise to the observed absorption and emission require accurate data on transition frequencies and wavelengths, oscillator strengths, cross sections for electron impact, rate coefficients for radiative, dielectronic, and dissociative recombination, and cross sections for heavy-particle collisions involving charge transfer, excitation, ionization, dissociation, fine structure and hyperfine transitions, collision-induced absorption, and line broadening. Data on ion–molecule and neutral particle reaction rate coefficients are central to the interpretation of measurements of chemical composition in molecular clouds, circumstellar shells, PPDs, and supernova ejecta.

The range of physical conditions of density, temperature, and radiation fields encountered in astrophysical environments is extreme and can rarely be reproduced in a laboratory setting. It is not only reliable data on known processes that are needed but also a deep understanding of the microphysics so that the relevant processes can be identified and their influence on the environments in which they occur fully taken into account.

We present here a summary of the processes that take place in photoionized gas, collisionally ionized gas, the diffuse interstellar medium, molecular clouds, circumstellar shells, PPDs, supernova ejecta, kilonovae, shocked regions, and the early universe.

86.2 Photoionized Gas

The universe contains copious sources of energetic photons, most often due to radiation from hot stars. As a consequence, much of the baryonic material of the universe exists as photoionized gas. Photoionized gas produces the visible emission from emission nebulae, planetary nebulae, nova shells, starburst galaxies, and probably active galactic nuclei [1].

Emission nebulae are extended regions of luminosity in the sky. They arise from the absorption of stellar radiation by the gas surrounding one or more hot stars. The gas is ionized by the photons and excited and heated by the electrons released in the photoionizing events. A succession of ionization zones is created in which highly ionized regions give way to less ionized gas with increasing distance from the central star as the photon flux is diminished by geometrical dilution and by absorption. The outer edge of a nebula is a front of ionization pushing out into the neutral interstellar gas. The densities are typically between 100 and 10,000 cm⁻³, with temperatures between 5000 and 15,000 K. Nebulae are also called HII regions. At low densities, the lu-

minosity is low, but the ionized regions can still be detected by radio observations.

Planetary nebulae are smaller in extent and denser. They have a passing similarity in appearance to planets. Planetary nebulae are produced by the photoionization of shells of gas that have been ejected from the parent star as it evolved to its final white dwarf stage. Because the core of the parent star is very hot, the irradiated gas is more highly ionized than are emission nebulae and has a distinctive spectrum.

Photoionized gas is also found around novae. Novae are stars that have undergone spasmodic outbursts, and they are surrounded by faint shells of ejected gas, photoionized and excited by the stellar radiation. Some supernova remnants, which are what remains after a massive star has exploded, have spectra that also appear to be emanating from photoionized gas. The source of ionization may be synchrotron radiation. Figure 86.1 shows the X-ray emission spectrum of a supernova remnant.

The nuclei of starburst galaxies have spectra like those of emission nebulae. They result from gas photoionized by radiation from hot stars created in a period of rapid star formation. Active galactic nuclei, such as quasars, have a different spectrum characterized by broad lines indicating a large range of velocities. Photoionized gas is the most likely interpretation, although the ionizing source may be an accretion disk around a compact object, such as a black hole.

The ionization structure in a photoionized gas is determined by a balance of photoionization

and radiative

and dielectronic

recombination, while in plasmas with a significant population of neutral hydrogen and helium, charge transfer recombination

may also play a role. Many detailed calculations of the ionization structure of photoionized regions have been carried out [1].

The ionizing source spectra of hot stars can be obtained from calculations of stellar atmospheres; see Sect. 86.6. Approximate values of cross sections for photoionization for a wide range of atomic and ionic systems in many stages of ionization are available [3–6]. Calculations of higher precision and reliability that incorporate the contributions

Fig. 86.1 X-ray spectrum of the supernova remnant Puppis A as observed by the Einstein satellite. Note the high level of ionization with hydrogen-like ions of oxygen and neon, suggesting a high temperature. After [2]

from autoionizing resonance structures exist for specific systems [7]. They are undergoing continual improvements as increasingly more powerful computational techniques are brought to bear on the calculations.

The cross sections for radiative recombination are obtained by summing the cross sections for capture into the ground and excited states of the recombining system, typically by applying detailed balance to the state-resolved photoionization cross sections. Because of the contribution from highly excited states that are nearly hydrogenic, the rate coefficients are similar for different ions of the same excess nuclear charge. They vary slowly with temperature. In contrast, dielectronic recombination is a specific process whose efficiency depends on the energy level positions of the resonant states. For nebular temperatures, the rate coefficients vary exponentially with temperature. Explicit calculations have been carried out for many ionic systems [8–10]. Because the photoionization cross sections of the major cosmic gases hydrogen and helium diminish rapidly at high frequencies, multiply charged ions and neutral gas coexist in cosmic plasmas produced by energetic photons and charge-transfer recombination may control the ionization structure. For multiply charged ions with excess charge, greater than 2, charge transfer is rapid. For doubly charged and singly charged ions, the cross sections are sensitive to the details of the potential energy curves of the quasi molecule formed in the approach of the ion and the neutral particle and the interaction mechanism. Few reliable data exist. Some recent calculations may be found in the papers [11–13].

Photoionized gas is heated by collisions of the energetic photoelectrons and cooled by electron impact excitation of metastable levels, principally of O^+ and O^{2+} , N^+ and N^{2+} ,

and S^+ and S^{2+} , followed by emission of photons that escape from the nebula. Considerable attention has been given to the determination of the rate coefficients [14]. The resulting cooling rates increase exponentially with temperature and keep the temperature of the gas between narrow limits. Some contribution to cooling occurs from recombination and from free-free emission by electrons moving in the field of the positive ions.

The luminosity of the photoionized gas comes from the photons emitted in the cooling processes and from radiative and dielectronic recombination. The radiative recombination spectrum of hydrogen extends from the $Ly \alpha$ line at 121.6 nm to radio lines at meter wavelengths.

The recombination spectrum can be predicted to high accuracy, and calculations for a wide range of temperature, density, and radiation environments have been carried out for diagnostic purposes [15–18]. Electron impact and proton impact-induced transitions are important in determining the energy-level populations and the resulting spectrum. Stimulated emission often affects the intensities of the radio lines, especially those from extragalactic sources. Comparisons of the predicted intensities in the visible and infrared with theoretical predictions yield information on interstellar extinction in the nebula and along the line of sight.

The relative intensities of the lines emitted by different metastable levels depend exponentially on the temperature. The relative intensities of the lines at 500.7 and 436.3 nm originating in the 1D_2 and 1S_0 levels of O^{2+} vary as $\exp(33,170/T)$, and are commonly used to derive the temperature T .

The electron density can be inferred from the lines emitted from neighboring levels with different radiative lifetimes

for which there occurs a competition between spontaneous emission and quenching by impact with thermal electrons. There are many possible combinations of lines. The lines at 372.89 and 372.62 nm emitted by the $^2D_{3/2}$ and $^2D_{5/2}$ levels of N^+ are readily observable, and their relative intensity can be used to estimate the electron density.

Radiative and dielectronic recombination lines are often seen in the spectra, as are a few lines due to charge transfer recombination. Fluorescence of starlight and resonance fluorescence of lines emitted in the nebula, called Bowen fluorescence by astronomers, also contribute to the spectra of photoionized gases. A large variety of data are needed to adequately interpret the observations.

Two X-ray satellites, Chandra and XMM-Newton, both launched in 1999, have greatly increased our ability to detect hot ionized gas in stars, supernova remnants, active galaxies, and other regions [19]. In particular, Chandra has allowed us for the first time to directly observe the hot gas between galaxies [20]. The state of modeling photoionized clouds has been reviewed by *Ferland* [21]. He also highlights the great need for atomic and molecular data for analyzing these clouds.

86.3 Collisionally Ionized Gas

Hot gas is found in the coronae of stars and, particularly, the Sun, and in young supernova remnants, in the hot phase of the interstellar medium, and in intergalactic space. In a hot gas, the ionization is produced by impact ionization due to the fast thermal electrons and removed by recombination, both radiative and dielectronic [22]. The rate coefficients for electron impact ionization and for recombination for any given ionization stage are functions only of temperature, and hence so is the resulting ionization distribution. When ionization and recombination balance, coronal equilibrium is attained, in which the ionization structure is specified by the temperature.

Recombination at high temperatures is dominated by dielectronic recombination. At high temperatures, dielectronic recombination is stabilized by transitions in which the core electrons are the active electrons. The associated emission lines lie close in frequency to that of the resonant transition of the parent ion, resulting in so-called satellite lines. Together with lines generated by electron impact excitation, they provide a powerful diagnostic probe of density and temperature. In many circumstances, such as in supernova remnants, coronal equilibrium does not hold, and the ionization and recombination must be followed as functions of time, a situation referred to as nonequilibrium ionization. The temperature also evolves as the hot plasma is cooled by electron impact excitation and ionization.

The recombining gas produces X-rays and extreme UV radiation, which modify the ionization structure. There is a par-

Fig. 86.2 Total emissivity and emissivity by element as a function of temperature in coronal equilibrium. The *heavy solid curve* is total emissivity, and the *lighter lines* are contributions from individual elements. After [23]

ticular need for more reliable data on high-energy photoionization cross sections, on collision cross sections for electrons and positive ions, and on the energy levels and transition probabilities of highly stripped complex ions. In particular, for M-shell ions, dielectronic recombination becomes important at low temperatures, but the reliability of theoretical rate coefficients are uncertain due to a large number of near threshold resonances. Currently, available atomic data have been used to update coronal ionization equilibrium calculations [24]. Figure 86.2 shows the emissivity of coronal gas.

86.4 Diffuse Molecular Clouds

Diffuse molecular clouds are intermediate between the hot phase of the galaxy and the giant molecular clouds where much of the gas resides. They are called diffuse because they have optical depths of order unity, or less, allowing photons to penetrate from outside the cloud and affect the chemical composition. The atoms and molecules are observed in absorption against background stars. Translucent clouds, defined to have optical depths between about 2 and 5 are intermediate between diffuse and dark clouds where photons from the outside still affect the chemistry. They can be observed both in absorption against a background source or in emission in the radio.

The gas temperature is 100–200 K at the edges of a diffuse cloud with a density of about 100 cm^{-3} . In a typical diffuse cloud, the temperature decreases to about 30 K at the center, while the density increases to about $300\text{--}800 \text{ cm}^{-3}$. The chemistry is driven by ionization from interstellar UV photons and from cosmic rays, composed mostly of high-energy protons.

Interstellar UV photons ionize species that have ionization potentials less than that of atomic hydrogen. Atomic hydrogen is so pervasive in the galaxy that UV photons with energies higher than 13.6 eV are absorbed near the source. The UV flux is a very important parameter in determining the composition of a diffuse cloud. Photodissociation provides destruction that limits the buildup of more complex species, and so diffuse clouds are typically dominated by simpler diatomic species. However, a number of polyatomic molecules, including SO₂, H₂CO, and C₃H₂, have been observed in diffuse clouds, while the so-called diffuse interstellar bands suggest the presence of large organic molecules. Understanding the origin of these large molecules in diffuse clouds remains an important area of research [25].

Species with ionization potentials greater than hydrogen are mainly ionized by cosmic rays. Cosmic rays are high-energy nuclei that stream through the galaxy. The cosmic-ray ionization rate, the number of cosmic-ray ionizations per second per particle, is an important parameter in interstellar chemistry. A lower limit to the cosmic-ray ionization rate may be set by measured high-energy cosmic rays reaching Earth, giving an ionization rate of $\approx 10^{-17} \text{ s}^{-1}$. More realistic estimates of the cosmic-ray ionization rate from looking at recombination lines suggest values of a few $\times 10^{-17} \text{ s}^{-1}$. Earlier work by studying recombination lines suggests values of a few $\times 10^{-17} \text{ s}^{-1}$. However, more recent studies based on observations of molecular ions in the galactic disk indicate a much higher rate of $\approx 5.3 \times 10^{-16} \text{ s}^{-1}$, although with only marginal evidence for a decrease in the rate with extinction into diffuse clouds [26].

On the other hand, the hydroxyl radical OH is produced in a manner similar to that discussed below in Sect. 86.6 and removed by photodissociation. Thus, in diffuse clouds, OH may be used to measure the cosmic-ray ionization rate, subject to uncertainties in the OH photodissociation rate and the H₃⁺ dissociative recombination rate. The OH abundances give rates of several $\times 10^{-17} \text{ s}^{-1}$ for many diffuse clouds.

The carbon chemistry begins with the ionization of C by UV photons:

The carbon ion cannot react directly with H₂ by

as this reaction is endothermic by 0.4 eV. Instead, the chemistry proceeds by the slow radiative association process

The CH₂⁺ ion may either dissociatively recombine

or react with molecular hydrogen

The CH₃⁺ then undergoes dissociative recombination

where the products are listed in order of decreasing likelihood. The CH is removed by photodissociation

and by photoionization

CH may also be removed by reactions with oxygen or nitrogen atoms to form CO and CN, respectively.

One of the outstanding problems in diffuse clouds is to understand the large abundance of CH⁺ relative to CH. The difficulty is in finding a mechanism that can produce sufficient CH⁺ without producing additional CH. Since most reaction paths go through reaction Eq. (86.7), this is the most likely candidate. What is needed is some extra energy to overcome the endothermicity. This energy must come from either hot C⁺ or from hot or vibrationally excited H₂. The most popular model is gas heated by a shock, possibly a magnetic shock, in which ions stream relative to the neutrals, giving a high effective energy. Unfortunately, although these shock models can reproduce the CH⁺ abundances, they also predict relative velocities between the CH⁺ and CH, which are not often observed. Recently, there have been suggestions that turbulence in the cloud could account for the CH⁺ abundance.

The most comprehensive models of diffuse clouds are by *van Dishoeck and Black* [27]. A collection of photodissociation rates and photoionization rates is given by *Roberge et al.* [28], and a more recent compilation has been made by *Heays et al.* [29].

The UV flux is predominantly from stars and may be as much as 10⁵ times larger near an HII region (Sect. 86.2) than it is in the general interstellar medium. Regions in which the chemistry is dominated by photons are referred to as *photon-dominated regions* or *photodissociation regions* (PDRs) [30]. In the presence of high UV flux, the cloud is much warmer than in a typical diffuse cloud. Temperatures may reach 1000 K near the edge of the cloud and 100 K far into the cloud. The chemistry differs from traditional diffuse cloud chemistry in that the high temperatures allow endothermic reactions to proceed. *Sternberg and Dalgarno* [31] have published a comprehensive model of photodominated regions.

86.5 Dark Molecular Clouds

Much of the mass of the galaxy is in the form of dark molecular clouds. The molecular clouds are sites of new star formation. They are composed primarily of hydrogen, with about 10% helium and trace amounts of heavier elements. They have densities of approximately 10^3 or 10^4 cm^{-3} and temperatures between 10 and 20 K, and often contain denser clumps. The clouds are optically thick, and so photons from the outside are absorbed on the surface of the clouds. The interiors are heated and ionized by cosmic rays that penetrate deep into the cloud.

The temperatures are too low to sustain much neutral chemical activity in the clouds, and cosmic-ray ionization is important in driving the chemistry. In dense clouds, the cosmic rays both initiate the chemistry and limit it through the production of He^+ and through cosmic-ray induced photons.

Currently, about 200 molecules have been detected in the interstellar medium, many of which have also been found in other galaxies. Table 86.1 gives a partial list, ranging from simple diatomics to the largest being C_{70} . Most molecules, except H_2 , are formed in the gas phase by ion–molecule reaction sequences initiated by a cosmic-ray ionization. The fact that isomers, such as HCN and HNC, are seen in approximately equal abundances suggests a low density gas phase environment. Reactions on surfaces and the formation of grains are not well understood but are surely important. It does appear that many complex organic molecules, such as dimethyl ether, are primarily formed on ice mantles [32]. The Infrared Space Observatory (ISO) has provided a tremendous amount of data on cold regions in our own galaxy and allowed us to directly observe the icy mantles of dust grains [33].

The chemistry of molecular clouds is dominated by ion–molecule reactions driven by cosmic-ray ionization. The cosmic rays primarily ionize H_2 :

producing both H_2^+ and fast electrons. The fast electrons produce additional ionizations. The H_2^+ quickly reacts with H_2 to form H_3^+ ,

The H_3^+ reacts with other species by proton transfer, which then drives much of the interstellar chemistry.

As an example of the production of more complex molecules in interstellar chemistry, we examine the reaction networks leading to the production of water H_2O and the hydroxyl radical OH. The H_3^+ ions formed by cosmic-ray ionization react with atomic oxygen to form OH^+

Table 86.1 Molecules observed in interstellar clouds

H_2	Hydrogen
CH^+	Methylidyne ion
C_2	Carbon
CO	Carbon monoxide
NH	Amidogen
CS	Carbon monosulfide
SO	Sulphur monoxide
NS	Nitrogen sulfide
PN	Phosphorus nitride
SiN	Silicon nitride
H_2O	Water
HCN	Hydrogen cyanide
HCO	Formyl
N_2H^+	Protonated nitrogen
HNO	Nitroxyl
SO_2	Sulfur dioxide
C_2O	Carbon suboxide
N_2O	Nitrous oxide
H_2CO	Formaldehyde
NH_3	Ammonia
HNCO	Isocyanic acid
C_3H	Propynylidyne
C_3S	Tricarbon sulfide
C_2H_2	Acetylene
HCNH^+	Protonated hydrogen cyanide
CH_4	Methane
HCOOH	Formic acid
HC_3N	Cyanoacetylene
HCCNC	Ethynyl isocyanide
NH_2CH	Cyanamide
CH_2NH	Methanimine
H_2CCCC	Butatrienylidene
C_5H	Pentynylidyne
CH_3OH	Methyl alcohol
NH_2CHO	Formamide
CH_2CHCN	Vinyl cyanide
C_6H	Hexatrienyl
CH_3CHO	Acetaldehyde
$\text{CH}_3\text{C}_3\text{N}$	Methyl cyanoacetylene
$(\text{CH}_3)_2\text{O}$	Dimethyl ether
HC_7N	Cyanoheptatriyne
HC_9N	Cyano-nonaheptatriyne

which quickly reacts with H_2 to form H_3O^+ in an abstraction sequence

The H_3O^+ then undergoes dissociative recombination to form water and OH

Table 86.1 (Continued)

CH	Methylidyne
OH	Hydroxyl
CN	Cyanogen
CO ⁺	Carbon monoxide ion
NO	Nitric oxide
SiO	Silicon monoxide
SO ⁺	Sulfur monoxide ion
SiS	Silicon sulfide
HCl	Hydrogen chloride
NH ₂	Amino radical
C ₂ H	Ethynyl
HNC	Hydrogen isocyanide
HCO ⁺	Formyl ion
H ₂ S	Hydrogen sulfide
OCS	Carbonyl sulfide
HCS ⁺	Thioformyl ion
C ₂ S	Dicarbon sulfide
H ₂ CN	Methylene amidogen
H ₂ CS	Thioformaldehyde
HCNS	Isothiocyanic acid
HOCO ⁺	Protonated carbon dioxide
C ₃ N	Cyanoethynyl
C ₃ O	Tricarbon monoxide
H ₃ O ⁺	Hydronium ion
C ₃ H ₂	Cyclopropenylidene
H ₂ CCC	Propadienylidene
CH ₂ CO	Ketene
HNCCC	Cyanoacetylene isomer
C ₄ H	Butadynyl
CH ₂ CN	Cyanomethyl radical
CH ₃ CH	Methyl cyanide
CH ₃ SH	Methyl mercaptan
HCC ₂ HO	Propynal
HC ₃ NH ⁺	Protonated cyanoacetylene
CH ₃ C ₂ H	Methyl acetylene
HC ₅ N	Cyanodiacetylene
CH ₃ NH ₂	Methylamine
HCOOCH ₃	Methyl formate
CH ₃ C ₄ H	Methyl diacetylene
CH ₃ CH ₂ CN	Ethyl cyanide
CH ₃ CH ₂ OH	Ethyl alcohol
HC ₁₁ N	Cyano-decapenta-yne

The water is removed by reactions with neutral or ionized carbon, which eventually lead to the production of CO. OH is primarily removed by reactions with atomic oxygen, leading to O₂. The CO and O₂ are removed by reactions with He⁺. The He⁺, generated by cosmic-ray ionization of helium, does not react with H₂ and is available to remove species by reactions such as

Water and OH are also removed by UV photons generated within the cloud. The clouds are too thick for external UV

photons to penetrate, but cosmic rays excite H₂ into electronically excited states that decay through emission of UV photons. These internally generated photons play an important role in determining the composition of the cloud. *Gredel et al.* [34] compiled a list of the photodissociation and photoionization rates for cosmic-ray induced photons.

Modern chemical networks for molecular clouds include several hundred species and several thousand reactions. Standard sets of reaction rates are provided by the UMIST (University of Manchester Institute of Science and Technology) dataset [35, 36] and the KInetic Database for Astrochemistry (KIDA) [37]. The datasets may be obtained from the UMIST Astrochemistry (udfa.ajmarkwick.net) and KIDA (kida.obs.u-bordeaux1.fr) home pages.

The clouds also contain dust particles as evidenced by the extinction curves with the observed depletions of heavier elements. The importance of surface chemistry on these dust particles to interstellar clouds is still uncertain. Dust particles are the best candidates for the sites of molecular hydrogen formation because known gas phase reactions fail to produce H₂ in the quantities observed.

86.6 Circumstellar Shells and Stellar Atmospheres

The continuum emission from a star is very nearly that of a blackbody at the photosphere. This emission is then absorbed and redistributed by the atmosphere of the star. The spectrum of the star is, thus, determined by its atmosphere. In the hottest stars, most of the material is ionized, and the absorption lines are predominantly those of ions, while in the coldest stars, molecular lines are prominent. *Kurucz* has calculated models with continuum spectra and the inclusion of a large number of absorption lines [38]. There are two major projects for calculating the required atomic data. In 1984, an international collaboration named the *Opacity Project* was set up to calculate accurate atomic data needed for opacity calculations [39, 40]. The other earlier project is called OPAL. The two sources of data are compared in [41, 42]. The Opacity Project data was updated by *Badnell et al.* [43], while another set of opacity data is available from Los Alamos [44].

Low and intermediate mass stars eject circumstellar envelopes in their red giant phase near the end of their evolution. Circumstellar envelopes are an important part of astronomy, and they are a likely location for dust formation. They provide an interesting environment for studying molecules because they represent a transition between very high-density stellar atmosphere environments to low-density interstellar environments. These objects evolve to become planetary nebulae (Sect. 86.2).

We are fortunate in having one example, IRC +10216, which is very close to the Sun. The brightest 10 μm source

beyond the solar system, IRC +10216 is a carbon-rich star surrounded by the dust and gas it ejected in a strong stellar wind. The central star is so shielded that it is almost undetectable at optical wavelengths and was not discovered until the 2 μ m survey. IRC +10216 is where most of the circumstellar molecules are detected and has greatly increased our understanding of circumstellar envelopes.

The envelopes are ejected by the red giant in its final phase of evolution, the asymptotic giant branch (AGB). The mass loss rates increase to $\approx 10^{-4}$ solar masses per year, and temperatures in the envelope are of order 1000 K. Close to the star, the density is high, and the chemistry is characteristic of thermal equilibrium. The situation is quite unlike any interstellar environments. For example, in IRC +10216, the HNC is over 100 times less abundant than HCN, whereas in molecular clouds, they have about the same abundance.

If the star is oxygen-rich, such as the AGB star IK Tau, large amounts of H₂O are formed, and if it is carbon-rich, C₂H₂ and other hydrocarbons are abundant. This high-temperature environment forms both molecules and grains. The high obscuration of the central source indicates that grains are formed in these envelopes. Polycyclic aromatic hydrocarbons (PAHs) or similar carbonaceous species, are observed in carbon-rich planetary nebulae. These large molecules must have been produced when the object was in the AGB phase.

As the material flows out from the star, the density and temperature decrease. As the density becomes lower, three-body reactions become less important, and at some point the products of these reactions are frozen out in a similar manner to the evolution of molecules in the early universe (Sect. 86.12). In the outermost portions of the circumstellar envelope, molecules are dissociated by interstellar UV photons. The penetrating UV radiation is shielded by dust, H₂, and CO. The relative abundances can vary rapidly with radius, and observations provide abundances and radial distributions, a wealth of data for modelers. Circumstellar chemistry was reviewed by *Omont* [45], and recent chemical models are given in [46–48].

86.7 Supernova Ejecta

A supernova, the explosion of a massive star following core collapse, is one of the most spectacular displays in the universe. The explosion occurs when the iron core of a massive star collapses to form a neutron star, and the rebound shock and neutrino flux eject the outer portion of the star. The ejected portions of the star are rich in heavy elements produced in the interior of the progenitor star.

We are fortunate to have had in our lifetime a supernova that was close and in an unobscured line of sight. Supernova 1987A, the first supernova observed in 1987, went off in the

Large Magellanic Cloud, a small satellite galaxy close to our own. It was the first supernova visible to the naked eye in nearly 400 years (since the Kepler supernova in 1604). Using the full range of modern astronomical instruments has allowed us to get detailed spectra of the evolving ejecta, which has greatly increased our knowledge of supernovae. We will use SN1987A as an example of supernova ejecta.

Initially the temperature of the ejecta of SN1987A was high, $\approx 10^6$ K, but it quickly cooled through adiabatic expansion and radiation from the photosphere. The temperature leveled off at several thousand degrees because of heating by radioactive nuclei, first ⁵⁶Ni and then ⁵⁶Co, formed in the explosion. The dynamics is homologous free expansion: the velocity scales linearly with the radius $r(t) = vt$, where v is the velocity and t the time since the explosion.

The ejecta were at first optically thick, and the spectrum resembled that of a hot-star continuum with absorption lines from the surface. After a few days, the temperature dropped, but the ejecta remained optically thick and continued to show strong continuum emission. As the ejecta expanded, the temperature dropped, the ejecta became optically thin, and the resulting spectrum was dominated by strong emission lines, superficially resembling an emission nebula (Sect. 86.3). The emission is dominated by neutral atoms and singly ionized species.

The gas is heated and ionized by gamma rays from radioactive decay. The gamma rays Compton scatter, producing X-rays and fast electrons. The X-rays further ionize the gas and produce multiply charged ions through the Auger process. These multiply charged ions recombine through charge transfer with neutral atoms. Further charge transfer determines the relative ionization of different species, with the lowest ionization potential species more ionized than the higher ionization potential species. The development of the infrared and optical spectrum of Supernova 1987A was reviewed by *McCray* [49].

One of the great surprises in the spectrum of Supernova 1987A was the discovery of molecules in the infrared region. CO, SiO, and possibly H₃⁺ have been identified. In the absence of grains, molecules must be formed through either three-body or radiative processes. In the supernova ejecta, the densities are too low for three-body processes to be effective, and molecules are formed through radiative association reactions. The molecules are removed by reactions with He⁺, and the molecular abundances put a constraint on how much helium can be mixed back into the region with carbon and oxygen [50].

Since the detection of molecules in SN 1987A, there have been many more observations of CO molecules in Type II supernova, and they may even occur in every Type II [51]. CO has also been observed in a Type Ic supernova [52]. It remains a puzzle as to why the molecules are not rapidly removed by helium ions. A calculation of the O + He⁺

system [53] found that radiative charge transfer is much faster than direct charge transfer for temperatures below 10^6 K but still too slow to significantly reduce the helium ion abundance in supernova ejecta. The most likely explanation remains that mixing is not complete in supernova ejecta, and the molecules survive in regions of relatively low helium abundance. More recent observations have detected H_2 [54], and the Atacama Large Millimeter/submillimeter Array (ALMA) has also detected HCO^+ and SO , which are discussed in Sect. 86.10.

86.8 Shocked Gas

Shock waves occur in compressible fluids when the pressure gradients are large enough to generate supersonic motion, or when a disturbance is propagating through the fluid at supersonic velocities. Because information about the disturbance cannot propagate upstream in the fluid faster than the speed of sound, the fluid cannot respond dynamically until the shock arrives. The shock then compresses, heats, and accelerates the fluid. The boundary separating the hot compressed gas and the upstream gas is the shock front in which the energy of directed motion of the shock is converted to random thermal energy.

Shocks are ubiquitous in the interstellar medium where they are driven by the ionization fronts of expanding HII regions or nebulae, by outflowing gas accompanying stellar birth and evolution, and by supernova explosions. If the shock velocity is above 50 km/s, the shock gas is excited, dissociated, and ionized. The subsequent recombination and cooling radiation produces photons that may ionize and dissociate the gas components ahead of and behind the shock. This precursor radiation modifies the effects of the shock and influences its dynamical and thermal evolution. Fast shocks destroy all molecules by dissociating H_2 by collisions with H, H_2 and He and with electrons. Exchange reactions with H atoms destroy the other molecular species. At low densities, radiative stabilization occurs, and dissociation is less efficient. Molecules reform in the cooling postshock gas. Slower shocks do not cause ionization or dissociation, but the chemical composition and the ion composition are modified by reactions taking place in the warm gas. The response of the interstellar gas to slow shocks is significantly affected by the presence of a magnetic field. In some ionization conditions, a magnetic precursor may occur in which a magnetosonic wave carries information about the shock, and the ionized and neutral components of the gas react differently to the shock. Many different kinds of shocks have been identified [55].

A very fast shock with a velocity of hundreds of km/s, such as are driven by supernova explosions, creates a hot dilute cavity in the interstellar medium with a temperature of millions of degrees. The density is low, and the gas cools and

recombines slowly. Overlapping supernova-induced cavities may be responsible for the hot gas that occupies a considerable volume of the interstellar medium in the Galaxy and in some external galaxies. The conditions are far from coronal equilibrium as the gas cools more rapidly than it recombines. The cooling radiation appears as soft X-rays and UV emission lines with a characteristic spectrum.

As the gas cools below 10,000 K, molecular formation occurs. Molecular hydrogen is formed on the surfaces of grains as in molecular clouds and by the negative ion sequence that is effective in the early universe (Sect. 86.9). With the formation of H_2 in a still warm gas, the chemistry is driven by exothermic and endothermic reactions with H_2 . Thus, OH is produced by the reaction of O atoms, and H_2O by the further reaction of OH with H_2 . Enhanced abundances of other neutral and ionic molecules are the products of subsequent reactions with OH. The reactions of S^+ and S with OH lead to SO^+ and SO , and their simultaneous presence may be an indicator of a dissociative shock. There are, in addition, physical indicators of shocks, such as asymmetric line profiles indicating high velocities.

In a nondissociative shock in a molecular gas, reactions with warm H_2 dominate the chemistry as it does in the cooling zone of a dissociative shock. The composition is controlled by the post shock temperature and the H/ H_2 ratio. The warm H_2 changes the ionic composition by converting C^+ into CH^+ . Evidence for a nondissociative shock is the infrared emission from H_2 . The thermal emission from collisionally excited vibrational levels in shock-heated gas is readily distinguished from that discussed in Sect. 86.4 arising from UV pumping in a PDR. Emission from H_2 has been detected in numerous objects in the Galaxy and in many distant external galaxies. In external galaxies, X-rays may contribute to the H_2 infrared spectrum through heating the gas and through excitation by photoelectron pumping to excited states followed by a downward cascade [56, 57].

86.9 The Early Universe

Molecules appeared first in the universe after the adiabatic expansion had reduced the matter and radiation temperature to a few thousand degrees, and recombination occurred, creating a nearly neutral universe. The small fractional ionization that remained was essential to the formation of molecules. Molecular hydrogen formed through the sequences

and

Fig. 86.3 Diagram showing the important reactions in the production of hydrogen molecules in the early universe

the protons and electrons acting as catalysts. Many other atomic and molecular processes occurred (Fig. 86.3), some involving excited hydrogen atoms. Thus,

was a source of H_3^+ .

The universe contained trace amounts of deuterium and ${}^7\text{Li}$ nuclei with which heteronuclear molecules could be made. Molecules with dipole moments may leave an imprint on the cosmic blackbody background radiation that permeates the universe. The deuterated molecule HD forms from

and H_2D^+ from

and

Lithium hydride is formed through

There are many destruction processes, of which

may be the most severe, although its rate coefficient is uncertain. The chemistry of the early universe is summarized in [58].

The formation of molecules was a crucial step in the fragmentation of the first gravitationally collapsing objects,

which separated out of the cosmic flow. Three-body recombination reactions such as

[59] and

were likely major sources of molecules as the density increased.

The Wilkinson Microwave Anisotropy Probe (WMAP) has given us the best map of the universe at the time of recombination and given us general confirmation of the big bang model. Perhaps the most surprising result is that stars seem to have formed much sooner than would have been expected, about 180 million years after the big bang [60]. This makes it even more difficult to understand how the universe evolves from the relative uniformity at the time of recombination to the collapse and formation of the first objects so quickly, a problem that is certainly controlled by atomic and molecular processes. The relevant atomic and molecular processes have been reviewed by the authors [61].

86.10 Atacama Large Millimeter/Submillimeter Array

Breakthroughs in astronomy are often driven by major improvements in instrumentation [62]. The Atacama Large Millimeter/Submillimeter Array (ALMA) provides angular resolution and sensitivity improvements of over an order of magnitude leading to quicker and better resolved spectra for many astrophysical environments. To fully interpret these spectra will require additional work in laboratory astrophysics so that breakthroughs in understanding may occur. It is expected that ALMA will revolutionize our understanding of astrophysical environments. Some early ALMA results are highlighted in this section.

By using the improved spatial resolution of ALMA, observations were able to resolve the dust production and show that Supernova 1987A produced about 0.2 solar masses of dust [63]. These observations demonstrated that the dust was formed in the inner ejecta and has not yet been processed through the shock front. If the dust survives the processing of the shock, then supernova are an important cosmological source of dust. In addition, a molecular line survey for Supernova 1987A detected both HCO^+ and SO in the ejecta of a supernova for the first time [64]. The spectral resolution of the molecular survey is also helping to understand the mixing that occurs in the expanding ejecta.

Using ALMA astronomers were able to resolve the millimeter size dust grains around a young A-type star Oph IRS

48 [65]. By comparing this strongly asymmetric distribution of millimeter grains to that of smaller dust particles and molecules, both of which are symmetric about the orbit, the authors infer that the larger grains may be trapped. In their model, the trapping is due to a larger preexisting planet in the system. This trap could allow the dust grains to keep growing to sizes that allow for additional planet formation.

With improved sensitivity, ALMA has detected additional building-blocks-of-life molecules in the interstellar medium, including iso-propyl cyanide [66] in the star-forming region of Sagittarius B2 and methyl isocyanate in the solar-type protostar IRAS16293-2422 B [67]. The detection of these potential precursors to biological molecules is interesting and hints at the proposed idea that life and self-replicating molecules formed first in the interstellar medium and then rained down on the surfaces of planets. With its increased sensitivity, ALMA may give insight into this idea for the appearance of life.

86.11 Recent Developments

In 2015, a new era opened up when gravitational waves from a binary black hole merger were detected for the first time [68]. More recently, a merger between two neutron stars was observed [69]. The neutron star merger, known as a kilonova, was also observed as a gamma-ray burst, and transient emission was observed in several electromagnetic bands [70]. The observations confirmed a long standing prediction that the violent collision between neutron stars could lead to gamma-ray bursts and the production of heavy elements [71]. This start to multimessenger astronomy, combining the electromagnetic and gravitational waves along with recent theoretical studies [72], suggests that a binary neutron star merger is a major source for production of gold and other heavy elements.

The Herschel Space Observatory, a far infrared and submillimeter telescope active 2009 through 2013, greatly increased our knowledge of molecular astrochemistry. A special issue of *Astronomy and Astrophysics* was released in 2010 with Herschel's first results with papers on observations of the solar system, star formation, interstellar medium, galaxy evolution, and cosmology [73]. Herschel had four main objectives: to study the formation of galaxies in the early universe, the creation of stars and their interaction with the interstellar medium, the observation of chemical composition of solar system objects, and the molecular chemistry in the universe. The observatory made the first multiline detection of molecular oxygen in space [74, 75].

Another rapidly expanding field involves planets outside our solar system. The detection and characterization of molecules in exoplanets will be critical to understanding how they formed, and what the planets are like. It will be an im-

portant factor in the search for life on these planets. So far, CO and H₂O have been detected [76], as well as TiO [77]. However, further detections should be forthcoming, particularly with the launch of the James Webb Space Telescope. A database of molecular line lists for species that might be detected in exoplanet atmospheres is currently being maintained and updated [78].

In summary, satellite data along with continued ground observations continually raise new astrophysical puzzles, puzzles that are controlled and probed by atomic and molecular processes. The astrophysical community owes a great debt to both atomic and molecular laboratory measurements and theoretical models of energy levels, reaction rates, and transition probabilities. In order to continue to progress in our understanding of the universe we will need to continue to fund the work needed for the understanding of the atomic and molecular processes that control it.

86.12 Other Reading

Astronomy is one of the oldest sciences and one of the fastest evolving. Advances in technology are rapidly increasing the sensitivity and resolution of our instruments, and so new observations and more sophisticated models lead to an ever greater understanding of the universe. This means that books will often be somewhat dated when they appear. However, the series *Annual Review of Astronomy and Astrophysics* is a good source of recent review articles.

In addition, the following books are recommended as good introductions or overviews of a particular field [1, 79–86]:

- *Astrophysical Quantities* by Allen
- *Astrophysical Formula* by Lang
- *Interstellar Chemistry* by Duley and Williams
- *Physical Processes in the Interstellar Medium* by Spitzer
- *Astrophysics of Gaseous Nebula and Active Galactic Nuclei* by Osterbrock and Ferland
- *Spectroscopy of Astrophysical Environments* edited by Dalgarno and Layzer
- *Molecular Astrophysics* edited by Hartquist
- *The Physics and Chemistry of the Interstellar Medium* by Tielens
- *The Physics of the Interstellar and Intergalactic Medium* by Draine.

Many sources of atomic and molecular data are listed and discussed in a special issue of *Revista Mexicana de Astronomia y Astrofisica*, 23 March 1992 [7]. For details on atomic spectroscopy, the books [87, 88]:

- *The Theory of Atomic Structure and Spectra* by Cowan
- *Atomic Spectra and Radiative Transitions* by Sobelman.

For details on molecular spectroscopy, the books [89, 90]:

- *Molecular Spectra and Molecular Structure* by Herzberg
- *Spectra of Atoms and Molecules* by Bernath.

Abstract

Prior to spacecraft missions to comets, beginning with the *Giotto* and *Vega* spacecraft to comet 1P/Halley (the *P* signifies a periodic comet) in March 1986, determinations of the volatile composition of a cometary coma were derived from spectroscopic analyses. Detailed modeling was then used to infer the volatile composition of the cometary nucleus. Since then there have been additional missions, including *Deep Impact* (2005), *Stardust* (2006), *EPOXI* (2010), and most recently, *Rosetta*, that flew along with comet 67P/Churyumov-Gerasimenko for over 2 years, that have greatly advanced our knowledge of the physics, chemistry, and geology of comets. Only a few comets have been studied this way, but the results provide a framework, or “ground truth”, for remote observations from Earth and spaceborne observatories, both past and future. This chapter focuses on the principal atomic and molecular processes that lead to the observed spectrum as well as the needs for basic atomic and molecular data in the interpretation of these spectra. The largely collision-

less and low-density coma, with no gravity or magnetic field, is a unique spectroscopic laboratory, and in recent decades, observations of comets have expanded over the entire electromagnetic spectrum, from X-ray to the submillimeter and millimeter. Although *Rosetta* has elucidated many key questions, issues concerning the basic molecular composition and the elemental abundances of both the volatile and refractory components of the cometary nucleus, as well as the comet-to-comet variation (particularly between *new* and evolved periodic comets) of these quantities still remain to be solved. A recent (although slightly out-of-date) compendium covering all aspects of cometary science is the *Comets II* book [1], while a review of coma chemistry is given by *Mumma* and *Charnley* [2].

comets · cometary coma · spectroscopy · ultraviolet · fluorescence

87.1 Introduction

Comets are small bodies of the solar system believed to be remnants of the primordial solar disk. As long-period comets are believed to have formed near the orbits of Uranus and Neptune and were subsequently ejected into an *Oort cloud* of some 40,000 AU in extent, these objects likely preserve a record of the volatile composition of the early outer solar system and so are of great interest for the physical and chemical modeling of solar system formation. The comets arrive in the inner solar system as a result of galactic perturbations. The cometary volatiles are vaporized as their orbits bring them closer to the Sun, and it is solar radiation that initiates all of the processes that lead to the extended coma. Gas vaporization also leads to the release of dust into the coma, and the scattering of sunlight by dust is the major source of the visible coma and dust tail of comets. Somewhat fainter, and much more extended, is the plasma tail, resulting from

photoionization by solar extreme UV radiation of the neutral volatiles and their subsequent interaction with the solar wind.

87.2 Observations

In a review in 1965, *Arpigny* [3] summarized the known molecular and atomic emissions detected in the visible region of the spectrum (here defined as 3000 to 11,000 Å) as follows:

radicals:	OH, NH, CN, CH, C ₃ , C ₂ , and NH ₂ ,
ions:	OH ⁺ , CH ⁺ , CO ₂ ⁺ , CO ⁺ , and N ₂ ⁺ ,
metals:	Na, Fe.

The only known atomic feature was the O I forbidden red doublet at 6300 and 6364 Å. From the radicals and ions, one could infer the presence of their progenitor *parent* molecules such as H₂O, NH₃, HCN, CO, and CO₂, directly vaporizing from the comet's nucleus. The metals, seen only in comets passing close to the Sun, were assumed to come from the vaporization of refractory grains. The inventory of metals was soon expanded to include K, Ca⁺, Ca, V, Cr, Mn, Ni, and Cu, from observations of the Sun-grazing comet Ikeya-Seki (C/1965 S1) [4, 5], and H₂O⁺ was identified in comet Kohoutek (C/1973 E1). This latter comet was also the first to be extensively studied at wavelengths both shortward and longward of the visible spectral range.

The first parent molecule to be directly identified was CO, which fluoresces in the Fourth Positive system ($A^1\Pi_u - X^1\Sigma^+$) in the VUV [6]. In principle, the molecular species should be detectable through their radio and sub-mm rotational transitions or through the detection of vibrational bands or individual rovibrational lines in the near IR. Water was first directly detected through rovibrational lines near 2.7 μm in comet Halley and in many subsequent comets [7]. The detection of species such as H₂CO, H₂S and CH₃OH was made possible by the development of more sensitive instrumental techniques. More than two dozen parent molecules have been identified spectroscopically [8, 9]. Many more parent species, including O₂ and N₂, were detected by the ROSINA mass spectrometer on *Rosetta* [10]. Isotope ratios, particularly the D/H ratio, in molecules such as HDO have been determined from IR and submillimeter observations [11].

The ultimate result of solar photolysis (and to a lesser degree, the interaction with the solar wind) is the reduction of all of the cometary volatiles to their atomic constituents. The atomic inventory is somewhat easier to derive as the resonance transitions of the cosmically abundant elements H, O, C, N, and S all lie in the VUV and, in principle, the total content of these species in the coma can be determined by an instrument with a suitably large field of view. Of course, a fraction of the atomic species of each element will be pro-

duced directly in ionic form and will not be counted using this approach. In addition, another fraction exists in the coma in the solid grains, and this component will not be included either, except for a small amount volatilized by evaporation or sputtering by energetic particles. The composition of the grains, although not the absolute abundance, has been determined from in situ measurements made by the Halley encounter spacecraft [12] and can be inferred, although not unambiguously, from reflection spectroscopy of cometary dust in the 3–5 μm range.

The advent of spaceborne platforms for observations in the VUV has produced a wealth of new information about the volatile constituents of the coma. The $A^2\Sigma^+ - X^2\Pi$ (0, 0) band of the OH radical at ≈ 3085 Å was well known from ground-based spectroscopic observations, but as this wavelength lies very close to the edge of the atmospheric transparency window, the strength of this feature (relative to that of other species) was not appreciated until 1970, when comet Bennett (C/1969 Y1) was observed from space by the Orbiting Astronomical Observatory (OAO-2). The OAO-2 spectrum also showed a very strong, broadened H I Ly- α emission from H, the other principal dissociation product of H₂O. The broad shape of Ly- α seen in the OAO-2 spectrum is due to the large spatial extent of the atomic H envelope, the result of a high velocity acquired in the photodissociation process and a long lifetime against ionization. Later, at the apparition of comet Kohoutek (C/1973 E1), atomic O and C were identified in the spectra, and direct UV images of the H coma, as well as of the O I and C I emissions, were obtained from sounding rocket experiments.

Between 1978 and 1996, over 50 comets were observed spectroscopically over the wavelength range 1200–3400 Å by the International Ultraviolet Explorer (IUE) satellite observatory [13, 14]. Most of the spectra were obtained at moderate resolution ($\Delta\lambda = 6$ – 10 Å), although high-dispersion echelle spectra ($\Delta\lambda = 0.2$ – 0.3 Å) are useful for some studies, particularly those of fluorescence equilibrium (Sect. 87.3.2). The launch of the *Hubble Space Telescope* (HST) in 1990, together with subsequent enhancements to the spectroscopic instrumentation that were made on-orbit, marked another advance in sensitivity as well as the ability to observe in a small field-of-view very close to the nucleus. This yielded the first detection of CO Cameron band emission, a direct measure of CO₂ being vaporized from the nucleus [15]. Both the *Space Telescope Imaging Spectrograph*, installed in 1997, and the *Cosmic Origins Spectrograph*, installed in 2009, enabled high-resolution observations of the CO Fourth Positive System [16, 17]. An example of a STIS (Space Telescope Imaging Spectrograph) spectral image of the region of the CO Fourth Positive system is shown in Fig. 87.1 [16]. The geocentric distance of comet 153P/Ikeya-Zhang was 0.43 AU so that the image, top to bottom, spans 2800 km on either side of the nucleus.

Fig. 87.1 STIS spectral image of comet 153P/Ikeya-Zhang, showing the brightness variations along the slit. The spectral region containing the strong geocoronal H I λ 1216 and O I λ 1302 has been excluded. The carbon multiplets at 1561 Å and 1657 Å are the strongest features and appear relatively constant, as they are dissociation products extending far into the coma. The zero point in the vertical direction marks the location of the nucleus. From [16]

The launch of the *Far Ultraviolet Spectroscopic Explorer* (FUSE) in 1999 provided access to the spectral region between 900 and 1200 Å at very high spectral resolution and has led to the detection of H₂ (Sect. 87.3.4), upper limits on Ar and N₂, and some three dozen emission lines identified as solar Lyman- α pumped H₂ fluorescence from vibrationally excited H₂ resulting from the photodissociation of H₂CO. [18, 19].

Several other satellite observatories have contributed unique cometary observations in the UV and sub-mm spectral windows. The *Solar and Heliospheric Observatory* (SOHO) has two valuable instruments: the SWAN (Solar Wind Anisotropies) instrument provides sky maps in H I Ly- α at 1° resolution and has observed over 20 comets since 1996 [20]. The UVCS (Ultraviolet Coronagraph Spectrometer) provides far-UV spectra and images of comets close to the Sun, where HST and FUSE are prohibited from observing, and has recently detected C²⁺ in the tail of comet C/2002 X5 (Kudo-Fujikawa) [21]. The direct detection of H₂O in the fundamental rotational line at 557 GHz in sev-

eral comets was made by the *Submillimeter Wave Astronomy Satellite* (SWAS) [22], the *Odin satellite* [23], and the *Herschel* observatory [24]. This line cannot be observed from ground-based telescopes because of the strong absorption by water vapor in the terrestrial atmosphere.

Prior to 1996, X-rays had not been detected in comets, and the conventional wisdom was that they were unlikely to be produced in the cold, rather thin cometary atmosphere. The discovery of soft X-ray emission ($E < 2$ keV) from comet Hyakutake (C/1996 B2) by the *Röntgen Satellite* (ROSAT) thus came as a surprise [25]. Since then, X-ray emission has been detected from over a dozen comets using ROSAT and four other space observatories, the *Extreme Ultraviolet Explorer*, *BeppoSAX*, the *Chandra X-ray Observatory* (CXO), and *Newton-XMM* [26]. The earliest observations were at very low spectral resolution, making it difficult to select amongst the possible excitation mechanisms: charge exchange, scattering of solar photons by attogram dust particles, energetic electron impact and bremsstrahlung, collisions between cometary and interplanetary dust, and solar X-ray scattering and fluorescence. The more recent CXO observations, at higher spectral resolution, favor the charge exchange of energetic minor solar wind ions such as O⁶⁺, O⁷⁺, C⁵⁺, C⁶⁺, and others, with cometary gas, principally H₂O, CO, and CO₂, as the primary mechanism. This mechanism would explain why the X-ray intensity appears to be independent of the gas production rate of the comet, and that the peak emission is offset from the location of the comet's nucleus. This conclusion is also supported by recent laboratory work on the charge transfer of highly ionized species with cometary molecules [27] and by theoretical calculations of state-specific cascades [28]. The X-ray emission thus tells us more about the solar wind than about the gaseous composition of comets.

87.3 Excitation Mechanisms

87.3.1 Basic Phenomenology

Coma abundances may be derived from spectrophotometric measurements of either the total flux or the surface brightness in a given spectral feature. The uncertainty in the derived abundances includes not only the measurement uncertainty, but also uncertainties in the atomic and molecular parameters and, in the case of surface brightness measurements, uncertainties in the model parameters used. Thus, relative abundances, derived from observations of different comets with the same instrument and under similar geometrical conditions, are often more reliable.

Atoms and ions in the cometary coma emit radiation primarily by means of resonance re-radiation of solar photons. For the cosmically abundant elements H, C, N, O, and S, their

strongest resonance transitions are in the VUV. The few exceptions are noted below. Assume that the coma is optically thin in these transitions. The total number of species i in the coma is

$$M_i = Q_i \tau_i(r), \quad (87.1)$$

where Q_i is the production rate (atoms or molecules s^{-1}) of species i , and $\tau_i(r)$ is its lifetime at heliocentric distance r , $\tau_i(r) = \tau_i(1 \text{ AU})r^2$. The r dependence arises from photolytic destruction processes induced by solar UV radiation and to a lesser degree by the solar wind, as described in Sect. 87.4.1.

The luminosity, in photons s^{-1} , in a given transition at wavelength λ , is then

$$L_{i\lambda} = M_i g_{i\lambda}(r), \quad (87.2)$$

where the fluorescence efficiency, or g -factor, $g_{i\lambda}(r) = g_{i\lambda}(1 \text{ AU})r^{-2}$, is

$$g_{i\lambda}(1 \text{ AU}) = \frac{\pi e^2}{mc^2} \lambda^2 f_\lambda \pi F_\odot \tilde{\omega} \quad \text{photons s}^{-1} \text{atom}^{-1}, \quad (87.3)$$

where f_λ is the absorption oscillator strength, πF_\odot is the solar flux per unit wavelength interval at 1 AU, and $\tilde{\omega}$ is the albedo for single scattering, defined for a line in an atomic multiplet as

$$\tilde{\omega} = \frac{A_j}{\sum_j A_j}, \quad (87.4)$$

where A_j is the decay rate. If a given multiplet is not resolved, then $\tilde{\omega} = 1$. For diatomic molecules, fluorescence to other vibrational levels becomes important, and the evaluation of $\tilde{\omega}$ depends on the physical conditions in the coma, as discussed in Sect. 87.3.2. Thus, for a comet at a geocentric distance Δ , the total flux from the coma for the transition is

$$F_{i\lambda} = \frac{L_{i\lambda}}{4\pi\Delta^2} = \frac{Q_i g_{i\lambda}(r) \tau_i(r)}{4\pi\Delta^2}, \quad (87.5)$$

and the product $g_{i\lambda}(r) \tau_i(r)$ is independent of r .

Unfortunately, the scale lengths (the product of lifetime and outflow velocity) of almost all of the species of interest in the UV are $\approx 10^5$ – 10^6 km at 1 AU. Thus, total flux measurements require fields of view ranging from several arc-minutes to a few degrees. This has been done only in the case of a few isolated sounding rocket experiments. Most information about the UV spectra comes from observations made by orbiting satellite observatories whose spectrographs have small apertures (e.g., $10'' \times 20''$ for IUE) and, thus, sample only a very small part of the total coma. In this case, again assuming an optically thin coma, the measured flux $F'_{i\lambda}$ in the aperture can be converted to an average surface brightness $B_{i\lambda}$ (in units of Rayleighs):

$$B_{i\lambda} = 4\pi 10^{-6} F'_{i\lambda} \Omega^{-1}, \quad (87.6)$$

where Ω is the solid angle subtended by the aperture. The brightness, in turn, is related to \bar{N}_i , the average column density of species i within the field of view by

$$B_{i\lambda} = 10^{-6} g_{i\lambda}(r) \bar{N}_i. \quad (87.7)$$

The evaluation of Q_i from \bar{N}_i requires the use of a model of the density distribution of the species i (Sect. 87.4.2).

A similar treatment can be applied to the excitation of the near-infrared vibrational transitions of cometary parent molecules since the direct pumping by solar IR radiation far exceeds the indirect pumping of ground state vibrational levels through electronic transitions excited by the solar UV flux [8]. However, this does not apply to the rotational transitions, which are controlled by collisional excitation, primarily collisions with H_2O . In this case, the observed rotational temperature may be regarded as a reliable measure of the kinetic temperature of the coma gas.

87.3.2 Fluorescence Equilibrium

In the case of low-resolution spectroscopy, where an atomic multiplet or molecular band is unresolved, the evaluation of the g -factor Eq. (87.3) does not require knowledge of the population of either atomic fine structure levels or molecular rotational levels in the ground state of the transition. Furthermore, the assumption that the solar flux does not vary over the multiplet or band allows us to use the total transition oscillator strength. This assumption is more often than not invalid because of the Fraunhofer structure of the solar spectrum in the near-UV and visible region and the emission line nature of the spectrum below 2000 Å. For high-resolution spectra, the g -factors for each individual line must be calculated separately, and the relative populations of the ground state levels must be included. There are three cases to be considered:

1. The g -factor, or probability of absorption of a solar photon, is less than the probability that the species will be dissociated or ionized, i.e., $g_{i\lambda} < (\tau_i)^{-1}$. In this case, the ground-state population is not affected by fluorescence, and a Boltzmann distribution at a suitable temperature (typically ≈ 200 K at 1 AU) corresponding to the production of the species may be used. This is often the case in the far-UV, where the solar flux is low, such as for the Fourth Positive band system of CO. For atomic transitions from triplet ground states, such as is found with O, C and S, downward fine-structure transitions are fast enough to effectively depopulate all but the lowest fine structure level.
2. The species undergoes many photon absorption and emission cycles in its lifetime, and the ground-state population is determined (usually after five or six cycles) by the fluorescence branching ratios. This is the condition of

fluorescence equilibrium, which applies for almost all radicals observed in the visible and near-UV regions. The general procedure is to solve a set of coupled equations of the form

$$\frac{dn_a}{dt} = -n_a \sum_{b=1}^N p_{ab} + \sum_{b=1}^N n_b p_{ba}, \quad (87.8)$$

where n_a is the relative population of level a , and p_{ab} and p_{ba} are transition rates out of and into this level, respectively. The n_a are normalized to unity. The steady state, obtained after many cycles, is given by $dn_a/dt = 0$. Since the downward transition rates are determined only by quantum mechanics, while the absorption rates depend on the magnitude of the solar flux, the steady-state population varies with distance from the Sun with higher rotational levels (as for the case of CN [3]) populated closer to the Sun. In some cases, where only a few cycles occur, the equations are integrated numerically. As the g -factor varies with time, it also effectively varies with the position of a species in the coma. Care must also be taken when spectra taken with small apertures are analyzed, as the transit time for an atom or molecule to cross the aperture may be $\lesssim g_{i\lambda}(r)^{-1}$. In practice, these considerations are often not important.

3. The same as 2., except that the density is sufficiently high that collisional transitions must be included in addition to the radiative transitions between levels. However, as the collisional rates are poorly known, in practice a *collision sphere* is defined such that a molecule traveling radially outward from this sphere suffers only one collision with other molecules or atoms. Outside this sphere, fluorescence equilibrium is assumed to hold, while inside, a thermal distribution of ground-state levels is used. A rough estimate of the radius R_c of the collision sphere, based on the radial outflow model of Sect. 87.4.2, is given by [29, 30]

$$R_c = 10^3 \frac{Q}{10^{29}} \text{ km}, \quad (87.9)$$

where Q is the total production rate in molecules s^{-1} .

87.3.3 Swings and Greenstein Effects

Swings [31] first pointed out that because of the Fraunhofer absorption lines in the visible region of the solar spectrum, the absorption of solar photons in a molecular band would vary with the comet's heliocentric velocity \dot{r} , leading to differences in the structure of a band at different values of \dot{r} when observed at high resolution. In Eq. (87.8), this corresponds to evaluating the $p_{ba} = p_{ba}(\dot{r})$. For typical comets observed near 1 AU, \dot{r} can range from -30 to

Fig. 87.2 OH (0,0) band g -factor as a function of heliocentric velocity. After [32]

+30 km/s, while in certain cases of comets with small perihelia, the range can be twice as large. This effect of the Doppler shift between the Sun and the comet is commonly referred to as the *Swings effect*. Even for observations at low resolution, the Swings effect must be taken into account in the calculation of the total band g -factor, and this has been done for a number of important species such as OH, CN, and NH. A particularly important case, that of the OH $A^2\Sigma^+ - X^2\Pi$ (0,0) band at $\approx 3085 \text{ \AA}$, which is often used to derive the water production rate of a comet, is illustrated in Fig. 87.2, which also shows the dependence of fluorescence equilibrium on heliocentric distance [32].

While this effect was first recognized in the spectra of radicals in the visible range, a similar phenomenon occurs in the excitation of atomic multiplets below 2000 \AA , where the solar spectrum makes a transition to an emission line spectrum. For example, the three lines of the O I $\lambda 1302$ multiplet have widths of $\approx 0.1 \text{ \AA}$, corresponding to a velocity of $\approx 25 \text{ km/s}$, so that knowledge of exact solar line shapes is essential for a reliable evaluation of the g -factor for this transition [33]. A similar effect occurs for the Si I multiplets at 1429 and 1479 \AA [17].

A differential Swings effect occurs in the coma since atoms and molecules on the sunward side of the coma, flowing outward towards the Sun, have a net velocity that is different from those on the tailward side, and so, if the absorption of solar photons takes place on the edge of a line, the g -factors will be different in the two directions. Differences of this type appear in long-slit spectra in which the slit is placed along the Sun–comet line (the *Greenstein effect* [34]). Again, an analogue in the far-UV has been observed in the case of O I $\lambda 1302$ [35]. Although it is also possible to explain the observation by nonuniform outgassing, this was considered unlikely, as all of the other observed emissions had symmetric spatial distributions. The measurement of the

Greenstein effect immediately leads to a determination of the mean outflow velocity of the given species.

87.3.4 Bowen Fluorescence

For heliocentric velocities > 30 km/s, the Doppler shift reduces the solar flux at the center of the absorption line to a very small value, so that the O I $\lambda 1302$ line is expected to appear weakly, if at all, in the observed spectrum. Thus, it was a surprise that this line appeared fairly strongly in two comets, Kohoutek (C/1973 E1) and West (C/1975 V1), whose values of \dot{r} were both > 45 km/s at the times of observation. The explanation invoked the accidental coincidence of the solar H I Ly- β line at 1025.72 \AA with the O I $^3\text{D}-^3\text{P}$ transition at 1025.76 \AA , cascading through the intermediate ^3P state to the ^3S upper level of the 1302 \AA multiplet [33]. This mechanism, well known in the study of planetary nebulae, is referred to as *Bowen* fluorescence [36]. The g -factor due to Ly- β pumping is an order of magnitude smaller than that for resonance scattering but is sufficient to explain the observations and to confirm that H₂O is the dominant source of the observed oxygen in the coma.

Ly- β is also coincident with the P1 line of the (6,0) band of the H₂ Lyman system ($B^1\Sigma_u^+ - X^1\Sigma_g^+$) leading to fluorescence in the same line of several (6, v'') bands, the strongest being that of the (6,13) band at 1608 \AA [37]. This line is, however, difficult to observe because of the nearby strong CO Fourth Positive bands. Recently, the shorter wavelength (6,1), (6,2), and (6,3) bands have been detected in three comets using FUSE, and the derived H₂ column abundance was found to be consistent with a water photodissociation source [18]. Another interesting example occurs for Ne I, where the second resonance transition at 629.74 \AA coincides with the strong solar O V line at 629.73 \AA . This line was used to set a sensitive upper limit on the Ne abundance in the coma of comet Hale-Bopp (C/1995 O1) [38].

87.3.5 Electron Impact Excitation

The photoionization of parent molecules and their dissociation products leads to the formation of a cometary ionosphere whose characteristics are only now known as a result of measurements by the Rosetta Plasma Consortium [39]. In principle, electron impact excitation, which is often the dominant source of airglow in the atmospheres of the terrestrial planets, also contributes to the observed emissions, particularly in the UV, and so must be accounted for in deriving column densities from the observed emission brightnesses. However, one can use a very simple argument, based on the known energy distribution of solar UV photons, to demonstrate that electron impact excitation is only a minor source for the principal

emissions. Since the photoionization rate of water (and of the important minor species such as CO and CO₂) is $\approx 10^{-6} \text{ s}^{-1}$ at 1 AU, and the efficiency for converting the excess electron energy into excitation of a single emission is of the order of a few percent, the effective excitation rate for any emission will be $\approx 10^{-8} \text{ s}^{-1}$ or less at 1 AU [40]. Since the efficiencies for resonance scattering or fluorescence for almost all the known cometary emissions are much larger, electron impact may be safely neglected except in a few specific cases.

The cases of interest are those of forbidden transitions, where the oscillator strength, and consequently the g -factor, is very small. The primary example is the O I $^5\text{S}_2 - ^3\text{P}_{2,1}$ doublet at 1356 \AA , which was observed faintly in several bright comets such as Hyakutake and Hale-Bopp. This emission appeared very conspicuously in measurements of the coma of 67P/Churyumov-Gerasimenko made by the Alice far-ultraviolet spectrograph on *Rosetta* and was found concentrated within a few km of the nucleus, a region usually not resolvable from Earth-based observations [41]; O I $\lambda 1356$ is produced by dissociative electron impact of the principal molecular species H₂O, CO₂, and O₂, with the brightness of this multiplet relative to O I $\lambda 1304$, C I $\lambda 1657$, and H I Ly- β , diagnostic of the composition of the near-nucleus coma [42]. However, calculations of excitation rates require electron impact cross sections at energies where the electron flux is high, usually near threshold [39], and these are poorly known.

87.3.6 Prompt Emission

In cases where the dissociation or ionization of a molecule leaves the product atom or molecule in an excited state, the decay of this state with the prompt emission of a photon provides a useful means for tracing the spatial distribution of the parent molecule in the inner coma. The products of interest for the water molecule are described in Sect. 87.4.1. Prompt emission includes both allowed radiative decays (such as from the $A^2\Sigma^+$ state of OH) as well as those from metastable states such as O(¹D), since the latter will move ≈ 150 km (for a comet at a geocentric distance of 1 AU, 1 arc-second corresponds to a projected distance of 725 km) in its lifetime. The O I $^1\text{D} - ^3\text{P}$ transition at 6300 and 6364 \AA has been used extensively as a ground-based monitor of the water production rate with the caveat that other species such as OH, CO and CO₂ may also contribute to the observed red line emission. In addition, when the density of H₂O is sufficient to produce observable red line emission, it is also sufficient to produce collisional quenching of the ¹D state, and this must also be considered in the interpretation of the observations. The analogous $^1\text{D} - ^3\text{P}$ transitions in carbon occur at 9823 and 9849 \AA and provide similar information about the production rate of CO. Carbon atoms in the ¹D state, whose lifetime is ≈ 4000 s, are known to be present from the observation of the resonantly

scattered $^1\text{P}^0 - ^1\text{D}$ transition at 1931 Å [43], and the 9849 Å line has been detected in comet Hale-Bopp [44].

The OH $A^2\Sigma^+ - X^2\Pi$ prompt emission competes with that produced by the resonance fluorescence of OH and is difficult to detect, except close to the nucleus (inside 100 km) where the density of water molecules exceeds that of OH by a few orders of magnitude [45]. Again, the reason is that at the wavelengths below the threshold for simultaneous dissociation and excitation, the Sun has much less flux than at the resonance wavelength. On the other hand, only a few rotational lines are excited in fluorescence equilibrium [32], while the prompt emission is characterized by a very *hot* rotational distribution, so in principle the two components may be separated although observations at very high spatial and spectral resolution are required. OH prompt emission has also recently been detected in the infrared at 3.28 μm [46].

87.3.7 OH Level Inversion

An important consequence of fluorescence equilibrium in the OH radical is the UV pumping of the hyperfine and Λ -doublet levels of the $X^2\Pi_{3/2}(J = 3/2)$ ground state, which results in a deviation of the population from statistical equilibrium [32]. Depending on the heliocentric velocity, this departure may be either *inverted* or *anti-inverted*, giving rise to either stimulated emission or absorption against the galactic background at 18-cm wavelength. This technique has been used extensively since 1974 to monitor the OH production rate in comets, even of those that appear close to the Sun [47]. The resulting radio emissions are easily quenched by collisions with molecules and ions, the latter giving rise to a fairly large R_c that must be accounted for in interpreting the derived OH column density. Nevertheless, the radio and UV measurements give reasonably consistent results [47].

87.4 Cometary Models

87.4.1 Photolytic Processes

As an example of the photolytic destruction processes occurring in the coma, consider the dominant molecular species, water. Water vapor is assumed to leave the surface of the nucleus with some initial velocity v_0 and flow radially outward, expanding into the vacuum, and increasing its velocity according to thermodynamics [48]. Even though collisions are important at distances typically up to 10^4 km (depending on the density and, consequently, on the total gas production rate), the net flow of H_2O molecules is radially outward, such that the density varies as R^{-2} near the nucleus, where R is the cometocentric distance. This is the basis for spherically symmetric coma models (the number of particles flowing through

a spherical surface is conserved), which assume isotropic gas production but appears to hold equally well for the case of Halley, which clearly was not outgassing uniformly over its surface [49].

The photolysis of H_2O can proceed by:

<i>a</i>	$\text{H}_2\text{O} + h\nu \rightarrow \text{OH} + \text{H}$	2424.6 Å
<i>a'</i>	$\rightarrow \text{OH}(A^2\Sigma^+) + \text{H}$	1357.1 Å
<i>b</i>	$\rightarrow \text{H}_2 + \text{O}(^1\text{D})$	1770 Å
<i>b'</i>	$\rightarrow \text{H}_2 + \text{O}(^1\text{S})$	1450 Å
<i>b''</i>	$\rightarrow \text{H} + \text{H} + \text{O}(^3\text{P})$	1304 Å
<i>c</i>	$\rightarrow \text{H}_2\text{O}^+ + \text{e}^-$	984 Å
<i>d</i>	$\rightarrow \text{H} + \text{OH}^+ + \text{e}^-$	684.4 Å
<i>e</i>	$\rightarrow \text{H}_2 + \text{O}^+ + \text{e}^-$	664.4 Å
<i>f</i>	$\rightarrow \text{OH} + \text{H}^+ + \text{e}^-$	662.3 Å

The right-hand column gives the energy threshold for each reaction, in wavelength units. The products are subsequently removed by:

<i>g</i>	$\text{OH} + h\nu \rightarrow \text{O} + \text{H}$	2823.0 Å
<i>h</i>	$\rightarrow \text{OH}^+ + \text{e}^-$	928 Å
<i>i</i>	$\text{H}_2 + h\nu \rightarrow \text{H} + \text{H}$	844.79 Å
<i>j</i>	$\rightarrow \text{H}_2^+ + \text{e}^-$	803.67 Å
<i>k</i>	$\rightarrow \text{H} + \text{H}^+ + \text{e}^-$	685.8 Å
<i>l</i>	$\text{O} + h\nu \rightarrow \text{O}^+ + \text{e}^-$	910.44 Å
<i>m</i>	$\text{H} + h\nu \rightarrow \text{H}^+ + \text{e}^-$	911.75 Å

Reactions *l* and *m* can also occur by resonant charge exchange with solar wind protons. Reactions *a'*, *b*, and *b'* correspond to the production of prompt emission, as discussed in Sect. 87.3.6. The determination of column densities of H, O, and OH simultaneously was convincing evidence that the dominant volatile species in the cometary nucleus was H_2O , long before the direct infrared detection of this species in the coma.

Detailed cross sections for the absorption of UV photons by each of the reactants, including proper identification of the final product states, is necessary for the evaluation of the photodestruction rate in the solar radiation field of each of the above reactions. These rates are evaluated at 1 AU using whole disk measurements of the solar flux by integrating the cross section

$$J_d = \int_0^{\lambda_{\text{th}}} \pi F_{\odot} \sigma_d d\lambda. \quad (87.10)$$

Another quantity of interest in coma modeling is the excess velocity (or energy) of the dissociation or ionization

products, and this requires knowledge of the partitioning of energy between internal and translational modes for each reaction [50].

Qualitatively, the photodissociation and photoionization rates can be estimated from the threshold energies given in the table above, since the solar flux is decreasing very rapidly to shorter wavelengths. It is customary to specify the lifetime against photodestruction τ_i , of species i , which is just

$$(\tau_i)^{-1} = \sum_j (J_d)_j, \quad (87.11)$$

where the sum is over all possible reaction channels, as well as the lifetimes into specific channels. Processes with thresholds near 3000 Å have lifetimes $\approx 10^4$ s, those with thresholds near 2000 Å an order of magnitude longer, while those with thresholds below Ly- α , such as most photoionization channels, have lifetimes $\approx 10^6$ s, all at 1 AU. In addition to uncertainties in the details of the absorption cross sections, further uncertainty is introduced into the calculation of J_d by the lack of knowledge of the solar flux at the time of a given observation due to the variability of the solar radiation below 2000 Å, and most importantly, below Ly- α , where there have not been continuous space observations for more than a decade. The solar UV flux is known to vary considerably both with the 27-day solar rotation period and with the 11-year solar activity cycle. Also, at any given point in its orbit, a comet sees a different hemisphere of the Sun than what is seen from Earth. Huebner et al. [51] have compiled an extensive list of useful photodestruction rates using mean solar fluxes to represent the extreme conditions of solar minimum and solar maximum. They also include the excess energies of the dissociation products. A detailed analysis of the rates for H₂O and OH, using surrogate solar indices such as the 10.7 cm solar radio flux, or the equivalent width of the He I line at 1.083 μ m, is in good agreement with observations [52]. Similar analyses still remain to be carried out for other important species, such as CO and NH₃.

87.4.2 Density Models

For parent molecules produced directly by sublimation from the surface of the comet, a spherically symmetric radial outflow model is often adopted. Such a model assumes a steady-state gas production rate Q_i and a constant outflow velocity v , and gives rise to a density distribution as a function of cometocentric distance R given by

$$n_i(R) = \frac{Q_i}{4\pi v R^2} e^{-R/\beta_i}, \quad (87.12)$$

where $\beta_i = v\tau_i$ is the scale length of species i . The basic validity of this model was demonstrated by the *Giotto* neutral mass spectrometer measurements of H₂O and CO₂ [49],

although detailed analysis revealed that the velocity of the water molecules increased from 0.8 km/s at about 1000 km from the nucleus to 1.1 km/s at a radial distance of 10,000 km. The dependence of outflow velocity on heliocentric distance remains uncertain, although Delsemme [53] has suggested an $r^{-1/2}$ -dependence based on thermodynamic arguments. Submillimeter observations of H₂O have sufficient spectral resolution to permit the mapping of outflow velocities along various lines-of-sight to the comet [23].

For the dissociation products, the modeling is more complex. The simplest model assumes continued radial outflow, although at a different velocity, such as to maintain a constant flux of the initial particle across an arbitrary spherical surface surrounding the nucleus [54]. This model, which is valid only at distances equal to a few β_i , is widely used, as the densities can be easily expressed in analytical form. However, as surface brightness measurements are often made with small fields of view close to the nucleus, this model can lead to a factor of 2 error from the neglect of the dissociation kinematics. Since the solar photodissociation often leaves the product fragments with 1–2 eV of kinetic energy [50, 51], the resultant motion (which is assumed to be isotropic in the parent molecule's rest frame), will contain a large non-radial component. Several approaches have been developed to account properly for the kinematics; notably, the vectorial model of Festou [55] and the average random walk model (a Monte Carlo method) of Combi and Delsemme [56]. The latter model has been extended to include time-dependent gas kinetics so as to properly account for regions of the coma where the gas is not in local thermodynamic equilibrium [57].

In addition to the photodestruction chains, chemical reactions, particularly ion–molecule reactions, can alter the composition within the collision zone defined in Sect. 87.3.2. While such reactions may produce numerous minor species, they do not erase the signatures of the original parent molecules. In fact, detailed chemical models have clearly demonstrated the need for complex molecules to serve as the parents of the observed C₂ and C₃ radicals in the coma, strengthening the connection between comet formation and molecular cloud abundances. Thus, the photochemical chains provide a valid means of relating the coma composition to that of the nucleus.

87.4.3 Radiative Transfer Effects

The results of a model calculation for the density of a species must be integrated over the line of sight to obtain the column density at a given projected distance from the nucleus and then integrated over the instrumental field of view for comparison with the observed average surface brightness or derived average column density \overline{N}_i . This assumes that the

coma is optically thin, and that all atoms or molecules have an equal probability of absorbing a solar photon. In practice, this is true for all molecular emissions except perhaps within 1000 km of the nucleus (i.e., for observations made at better than 1'' resolution). Since the cross sections at line center can be very large for an atomic resonance transition, the optical depth for the abundant species can exceed unity, and radiative transfer along both the line of sight to the Sun and that to the Earth must be considered. This is not a trivial problem, as the velocity distribution of the atoms, particularly the component due to the excess energy of the photodestruction process, must be well known, as must be the shape of the exciting solar line. The most thoroughly studied case to date is that of H I Ly- α , whose angular extent, in direct images, can exceed several degrees on the sky [58].

An interesting case arises for resonance transitions between an excited 3S_1 state and the ground $^3P_{2,1,0}$ state, as for O and S, particularly the latter, as its concentration near the nucleus can be quite large due to the rapid decay of one of its parents, CS₂. For S I the three lines at 1807, 1820, and 1826 Å are not observed to have their statistical intensity ratio of 5 : 3 : 1, except at large distances from the nucleus. This is explained by noting that fine structure transitions will lead to all of the S atoms reaching the $J = 2$ ground state in a time short compared with that for absorbing a solar photon, and that the emitted 1807 Å photons will be reabsorbed and can then branch into the other two lines. The detailed solution to this problem has led to the conclusion that H₂S was the primary source of sulfur rather than CS₂, whose other product, CS, was simultaneously observed in the UV [59]. Millimeter and submillimeter observations of comet Hale-Bopp (C/1995 O1) subsequently showed that SO, SO₂, and OCS were also minor sources of atomic sulfur, comparable in abundance to CS₂ [60]. Another minor source is S₂, initially observed in only one comet, IRAS-Araki-Alcock (C/1983 H1) [61], but recently seen in three additional comets by HST. The origin of S₂ in the cometary nucleus has been discussed in the context of *Rosetta* mass spectrometer measurements of this species [62].

87.5 Summary

This brief chapter can only hint at the wealth of observational data spanning the entire electromagnetic spectrum now routinely acquired at almost every comet apparition allowing for a statistically significant assessment of comet diversity and formation scenarios. The *Rosetta* mission has revolutionized our knowledge of comets [63] and will serve as a benchmark for inferring the properties of comets from remote observations. Nevertheless, since space missions to comets are rare, Earth-based observations of comets will continue to play an important role in understanding the physical and chemical

environments of these objects left over from the formation of the solar system, as well as the diversity of comets, as spacecraft missions are not able to visit long-period comets.

Abstract

We describe here the neutral and ionic structures of atmospheres, including the processes that determine the atmospheric layers, the distributions of the species, and the temperature profiles. We focus on the upper atmosphere, which comprises the thermosphere and the ionosphere, two regions that overlay and interact with each other. We describe the interaction of near and extreme ultraviolet solar photons and energetic electrons with the atmosphere and their role in ionization and dissociation of

atmospheric species. We also review the production and loss processes that are important in the formation of the different layers of the dayside and nightside ionospheres, including ion and neutral diffusion. The processes that determine the neutral, ion, and electron temperatures are discussed. We review the processes that are important in the production of the luminosity of the upper atmospheres, including dayglow, nightglow, and auroras. Finally, we describe atmospheric escape processes, including thermal and nonthermal mechanisms.

88.1 Basic Structure of Atmospheres

88.1.1 Introduction

In a stationary atmosphere, the force of gravity is balanced by the plasma pressure gradient force in the vertical direction, and the variation of pressure $P(z)$ with altitude above the surface z is governed by the hydrostatic relation

$$\frac{dP(z)}{dz} = -\rho(z)g(z), \quad (88.1)$$

where $\rho(z) = n(z)m(z)$ is the mass density, $n(z)$ is the number density, and $m(z)$ is the weighted average mass of the atmospheric constituents. In general, variables such as P , T , ρ , g , n , and even m are functions of altitude, although it will often not be shown explicitly in the equations that follow for the sake of compactness. The acceleration of gravity g is usually taken to be the vector sum of the gravitational attraction per unit mass and the centrifugal acceleration due to the rotation of the planet

$$g(r) = \frac{GM}{r^2} - \omega^2 r \cos^2 \phi, \quad (88.2)$$

J. L. Fox (✉)

e-mail: jane.fox@wright.edu

where $r = r_0 + z$ is the distance from the center of the planet, r_0 is the planetary radius, M is the planetary mass, $G = 6.670 \times 10^{-8} \text{ dyn cm}^2 \text{ g}^{-2}$ is the gravitational constant, ϕ is the latitude, and ω is the angular velocity of the planet.

When the hydrostatic relation Eq. (88.1) is combined with the ideal gas law in the form

$$P = nk_{\text{B}}T, \quad (88.3)$$

where k_{B} is Boltzmann's constant, and T is the temperature, and integrated, the barometric formula

$$P(z) = P_0 \exp\left(-\int_{z_0}^z \frac{1}{H(z')} dz'\right), \quad (88.4)$$

for the pressure $P(z)$ above a reference level (denoted by the subscript 0) as a function of altitude results. The pressure scale height $H(z)$ is defined as

$$H(z) = \frac{k_{\text{B}}T}{mg}. \quad (88.5)$$

In the lower and middle atmosphere, the mass m in Eq. (88.5) is the weighted average mass of the atmospheric constituents.

When the ideal gas law Eq. (88.3) is substituted into the barometric formula Eq. (88.4), the altitude distribution

$$n(z) = n_0 \frac{T_0}{T(z)} \exp\left(-\int_{z_0}^z \frac{1}{H(z')} dz'\right), \quad (88.6)$$

for the number density $n(z)$ above a reference altitude is obtained. Integration of Eq. (88.1) or Eq. (88.6) from z to infinity shows that the column density above that altitude is approximately $N(z) = n(z)H(z)$. Thus, the scale height can be thought of as the effective thickness of the atmosphere.

Throughout the atmosphere, gravity exerts a force on each particle that is proportional to its mass. Below the homopause, however, the tendency of the species to separate out under the force of gravity is overpowered by large scale mixing processes, such as turbulence and/or convection. Thus in its lower and middle regions, the homosphere, the atmosphere is well-mixed. The upper boundary of this region is called the homopause (or turbopause). Above this level, the major transport process is diffusion, and each species is distributed according to its own scale height. The homopause is defined as the level at which the time constants for mixing and diffusion are equal, and usually occurs at $n(z) \approx 10^{11} - 10^{13} \text{ cm}^{-3}$, depending on the strength of vertical mixing for a given planet. Since molecular diffusion coefficients vary from one species to another, the exact altitude of the homopause is species-dependent, with smaller species (or those that have smaller momentum transfer colli-

sion frequencies) having lower homopause altitudes. It must also be borne in mind that the homopause is not a sharp boundary, and that the transition from mixing to diffusion occurs gradually. In the terrestrial atmosphere, the homopause is near 100 km at $n(z) \approx 10^{13} \text{ cm}^{-3}$. Below the homopause, the mixing ratios (or fractions by number) of the constituent gases, apart from those minor or trace species whose density profiles are determined by photochemistry or physical loss processes, are fairly constant with altitude. Characteristics of the homopauses of the planets are presented in Table 88.1.

88.1.2 Atmospheric Regions

The division of atmospheres into regions is based on the temperature structure of the terrestrial atmosphere, which is shown in Fig. 88.1. In the troposphere of a planet, above the boundary layer, T decreases at close to the adiabatic lapse rate (Γ) for the constituent gases from the surface to the tropopause. For an atmosphere that is a mixture of ideal gases, $\Gamma = g/c_p$, where c_p is the specific heat of the gas mixture at constant pressure. The presence of a condensible constituent, such as water vapor in the terrestrial troposphere and that of other planets, such as Mars and the outer planets, and ammonia, C_2 - or higher hydrocarbons in the atmospheres of the outer planets and satellites, decreases Γ because upward motion leads to cooling and condensation, which releases latent heat. On Earth, the dry adiabatic lapse rate is about 10 K km^{-1} , and the moist adiabatic lapse rate is about $4-6 \text{ K km}^{-1}$ in the lower to middle troposphere. The average lapse rate is about 6.5 K km^{-1} , and the altitude of the tropopause varies from about 9 to 16 km from the poles to the equator. The composition of the lower atmosphere of the Earth is given in Table 88.2.

Above the terrestrial tropopause lies the stratosphere, a region of increasing T that is terminated at the stratopause, near 50 km. This increase in T is caused by absorption of solar near-UV radiation by ozone in the Hartley bands and continuum (200–310 nm). In the terrestrial mesosphere, which lies above the stratosphere, T decreases again to an absolute minimum at the mesopause, where $T \approx 180 \text{ K}$ and $n(z) \approx 10^{14} \text{ cm}^{-3}$. Above the mesopause, in the thermosphere, T increases rapidly to a constant value, the exospheric temperature, T_{∞} . The value of T_{∞} in the terrestrial atmosphere depends on solar activity and is usually between about 700 and 1500 K. Figure 88.1a also shows altitude profiles of the noon and midnight thermospheric temperature for four values of the $F_{10.7}$ index (the 2800 MHz flux in units of $10^{-22} \text{ W m}^{-2} \text{ Hz}^{-1}$ at 1 AU), which represent different levels of solar activity. Analogous temperature profiles of other planetary bodies as a function of pressure are shown in Fig. 88.1b. It can be seen that the temperature profiles above some of the tropopauses do not reach a maximum value that signals the stratopause. In

these atmospheres, the region between the tropopause and the mesopause is usually called the mesosphere for the inner planets and the stratosphere for the outer planets.

The exosphere is assumed to be a nearly collisionless region of the thermosphere that is bounded from below by

a level called the “exobase”. The assumption involved in deriving the altitude of the exobase is that a particle traveling upward at or above the exobase will, with high probability, escape from the gravitational field of the planet. The exobase on Earth is located at about 450–500 km, depending upon solar activity. The properties of the classical exobase will be discussed in the context of escape of species from atmospheres in Sect. 88.7.

The surface P and T on Mars are about 6 mbar and 230 K, respectively. Due to the effect of dust storms, the extent of the Martian troposphere is highly variable, with a lapse rate that is 2–3 K km^{−1} compared with the adiabatic lapse rate of 4.5 K km^{−1} and a variable thickness of 20–50 km [11]. The atmosphere of Mars, like many planetary atmospheres, does not have a stratopause. A roughly isothermal mesosphere extends from the tropopause to the base of the thermosphere at about 90 km. Sometimes a peak in the temperature between the tropopause and the mesosphere is caused by the absorption of solar radiation by dust that is lifted to high altitudes by dust storms, which are most common at perihelion. The thermospheric T is sensitive to solar activity and, since Mars has a very eccentric orbit, to heliocentric distance; T_∞ varies from about 180 to 350 K. Near the surface of Venus, $T \gtrsim 700$ K, and $P \approx 95$ bar; T decreases with a mean lapse rate of 7.7 K km^{−1},

Fig. 88.1 (a) Vertical distribution of temperature in the terrestrial atmosphere. The altitudes of the tropopause, stratopause, and mesopause are indicated. The thermospheric temperatures depend on solar activity, and profiles are shown for four values of the $F_{10.7}$ index, from 75 (low solar activity) to 250 (high solar activity). The *solid* and *dashed curves* are for noon and midnight, respectively. After the MSIS model of Hedin [9]. (b) Vertical distribution of neutral temperatures of planets and satellites plotted on a common pressure scale. The regions of the atmospheres that are analogous to the terrestrial atmosphere are shown. From Strobel [10]

compared with the adiabatic lapse rate of 8.9 K km^{-1} , from the surface to about 50 km. The region from 50 to 60 km contains the major cloud layer, and the tropopause is usually considered to be at about 60 km. In the mesosphere, between about 60 and 85 km, T decreases slowly from about 250 to 180 K

and is nearly constant from 85 km to the mesopause at 100 km. The daytime exospheric temperature is only weakly dependent on solar activity, varying from about 230 to 300 K from low to high solar activity. The slow retrograde rotation of the planet, which results in a period of darkness that lasts 58 Earth days, leads to the relative isolation of the nightside thermosphere, where T is found to decrease above the mesopause to a constant value of $T_{\infty} \approx 100 \text{ K}$. Because of this, the nightside Venus thermosphere has been called the *cryosphere*. The compositions of the lower atmospheres of Mars and Venus are given in Table 88.3.

The giant planets, Jupiter, Saturn, Uranus, and Neptune do not have solid surfaces, so their atmospheric regions are defined either in terms of pressure, altitude above the cloud tops, or more commonly, altitude above the 1 bar level. The temperature structures of all but Uranus are influenced by internal heat sources that the terrestrial planets do not possess. The temperature structures near the tropopause can be determined from IR observations and radio occultation data, and at thermospheric altitudes from ultraviolet solar and stellar occultations performed by various spacecraft.

Below 300 mbar on Jupiter, the lapse rate is close to adiabatic (1.9 K km^{-1}); T at 1 bar is about 165 K, and the tropopause occurs near 140 mbar, where $T \approx 110 \text{ K}$. At 1 mbar, T again reaches 160–170 K. Temperature inversions

have been reported in the stratosphere and are probably due to absorption of solar radiation by dust or aerosols. Temperatures derived from the Voyager UV stellar and solar occultations show that T increases from about 200 K near 1 μ bar to an exospheric value of about 1000 K [22].

For $P > 500$ mbar on Saturn, the lapse rate approaches the adiabatic value of 0.9 K km^{-1} , and the tropopause, near the 100 mbar level, is characterized by $T \approx 80$ K. Above the tropopause, the temperature increases to about 140 K near a $P \approx 1$ mbar, and above this altitude, the temperature is essentially constant. Above 1000 km, T increases to a $T_{\infty} \approx 400\text{--}500$ K, e.g. [22]; T_{∞} appears to increase with latitude (Vervack, Jr. and Moses [5]). The mixing ratios of the species in the lower atmospheres of Jupiter and Saturn are given in Table 88.4.

The tropopauses on both Uranus and Neptune occur near 100 mbar, where $T \approx 50$ K. The lapse rates in the troposphere are 0.7 and 0.85 K km^{-1} for Uranus and Neptune, respectively. The temperatures in the Uranus thermosphere range from 500 K near 10^{-7} bar (about 1000 km above the 1 bar level) to an exospheric value of about 700–800 K. In the range 300 to 600 km on Neptune, T is characterized by a nearly constant value of 160–180 K. Above 600 km, where $P \approx 1 \mu$ bar, T increases again to a value that is probably about 700 K [26, 27]. The compositions of the lower atmospheres of Uranus and Neptune are given in Table 88.5.

Titan, which is a satellite of Saturn, has an N₂/CH₄ atmosphere of intermediate oxidation state. The mixing ratios of components of the lower atmosphere are given in Table 88.6. The surface P and T are 1.5 bar and 94 K, respectively; T decreases above the surface to about 70 K at the tropopause, which occurs at an altitude of 42 km and

a pressure of 128 mbar. A reanalysis of the Voyager 1 solar occultation experiment showed that, above the tropopause, the temperature increases to a peak value of about 176 K at an altitude of about 300 km. The temperature then decreases to a T_{∞} of 153–158 K [29]. The Huygens Atmospheric Structure Instrument (HASI) on the Cassini spacecraft measured temperature profiles that exhibited wave-like structure in the range 200–1400 km (Fulchignoni et al. [30]). A review of the thermal structure and dynamics of the upper atmosphere of Titan has been presented by Yelle et al. [31].

Triton is a satellite of Neptune. It also has an N₂ atmosphere with small amounts of methane, CO, H₂, H, N, C, and HCN. The mixing ratios at 10 km are given in Table 88.7. The surface P is about 19 μ bar, and the surface temperature is about 37 K. Methane in the troposphere is in equilibrium with a surface methane frost at about 38–50 K. The temperature decreases with a lapse rate of about 0.1 K km^{-1} from the surface to the tropopause. The tropopause temperature is about 36 K, and occurs in the 8–12 km region. The middle

atmosphere is isothermal with a temperature of about 52 K from 25 to 50 km, increasing to 78 K near 150 km [34]; T then rises to a constant maximum T_∞ in the range 80–100 K above 450 km.

Mercury does not have a troposphere, mesosphere, or stratosphere; the surface of the planet is the exobase. Nevertheless, several atomic species and ions have been identified previous to and during the recent MESSENGER mission. They are listed in Table 88.8. Among the possible sources of atmospheric species are interactions with the incoming solar wind, dust, and meteoroids. There are also a number of sources that act to release of atoms from the surface and include radiation pressure, thermal desorption, impact vaporization, photon-stimulated desorption, ion sputtering, and chemical sputtering (*Killen et al.* [35]; *McClintock et al.* [36]). Ions produced by photoionization of neutrals may be picked up by the solar wind and lost from the atmosphere.

The dwarf planet Pluto forms a binary system with its satellite Charon. The radius of Pluto is 1190 km, and that of Charon is about 617 km. The atmosphere of Pluto is mostly N₂, with small amounts of methane, the C-2 hydrocarbons C₂H₂, C₂H₄, and C₂H₆, and haze (Table 88.9), which were detected by the solar occultations carried out by the New

^d At surface. From *Lellouch et al.* [38]

Horizons spacecraft (e.g., *Young et al.* [8]). The appearance of haze is common to atmospheres in which methane is present, even in small abundance; it signals the presence of higher hydrocarbons, including benzene, and for Pluto, Titan, and Triton, large nitrogen-containing organic compounds. The mixing ratio of CO was measured as ≈ 515 ppm and is evenly mixed in the atmosphere of Pluto; HCN was detected by the interferometer on the ALMA (Atacama Large Millimeter Array). Below 100 km, a mixing ratio for HCN of 0.01–0.1 ppm was found, rising to 40 ppm at 800 km (*Lellouch et al.* [38]). H₂O with an abundance of 0.1 ppm at the surface was inferred in order to explain the observed temperature profile (*Strobel and Zhu* [7]).

The surface pressure and temperature on Pluto are ≈ 11.5 μbar and ≈ 45 K, respectively. The thermal structure of the atmosphere is influenced by the large thermal escape flux at the top of the atmosphere, by adiabatic cooling, and by H₂O rotational cooling. The temperature profile shows a shallow (if any) troposphere, above which T increases to a maximum (stratopause) temperature of about 110 K at an altitude of ≈ 30 km, due to absorption of solar UV radiation. Above that altitude, T decreases to form a broad minimum of about 63 K, before rising to an exospheric temperature of ≈ 70 K. Charon has no apparent atmosphere.

88.2 Density Distributions of Neutral Species

88.2.1 The Continuity Equation

The density distribution of a minor neutral species j in an atmosphere is determined by the continuity equation

$$\frac{\partial n_j}{\partial t} + \nabla \cdot \Phi_j = P_j - L_j, \quad (88.7)$$

where Φ_j is the flux of species j , and P_j and L_j are the chemical production and loss rates, respectively. If only the

vertical direction is considered, the divergence of the flux becomes $\partial\Phi_j/\partial z$, and $\Phi_j = n_j w_j$, where w_j is the vertical velocity of the species, and n_j is its number density. In one-dimensional models, transport due to turbulence and other macroscopic motions of air masses is often parametrized like molecular diffusion, using an eddy diffusion coefficient K in place of the molecular diffusion coefficient D_j . The total transport velocity w_j is then the sum of the diffusion velocity w_j^D and the eddy diffusion velocity w_j^K

$$w_j = w_j^D + w_j^K. \quad (88.8)$$

If there are no net flows of major constituents, w_j^D and w_j^K satisfy the equations

$$w_j^D = -D_j \left(\frac{1}{n_j} \frac{dn_j}{dz} + \frac{1}{H_j} + \frac{(1 + \alpha_j^T)}{T} \frac{dT}{dz} \right), \quad (88.9)$$

$$w_j^K = -K \left(\frac{1}{n_j} \frac{dn_j}{dz} + \frac{1}{H_{\text{avg}}} + \frac{1}{T} \frac{dT}{dz} \right). \quad (88.10)$$

In these expressions, α_j^T is the thermal diffusion factor (the ratio of the thermal diffusion coefficient to the molecular diffusion coefficient), and the pressure scale height H_{avg} for a mixed atmosphere is given by Eq. (88.5) with $m = m_{\text{avg}}$, the average molecular mass.

For a stationary atmosphere, if molecular diffusion greatly exceeds eddy diffusion, and if photochemistry can be neglected, then $w_j^D = 0$. The resulting number density distribution is called diffusive equilibrium, and is given by

$$n_j(z) = n_j(z_0) \left(\frac{T_0}{T} \right)^{(1+\alpha_j^T)} \exp \left(- \int_{z_0}^z \frac{dz'}{H_j} \right). \quad (88.11)$$

When mixing processes dominate, and $w_j^K = 0$, the distribution is given by Eq. (88.6), with $m = m_{\text{avg}}$ in the definition of the scale height H (Eq. (88.5)).

88.2.2 Diffusion Coefficients

In the thermosphere of a planet, above the homopause, the major transport mechanism is diffusion or transport by random molecular motions. The characteristic time τ_D for molecular diffusion is approximately H_j^2/D_j . The diffusion coefficient for a species j in a multicomponent mixture is usually taken as a weighted mean of inverse binary diffusion coefficients D_{jk}

$$\frac{1}{D_j} = \sum_{k \neq j} \frac{f_k}{D_{jk}}, \quad (88.12)$$

where f_k is the mixing ratio of species k . The binary diffusion coefficient can be expressed as

$$D_{jk} = \frac{3k_B T}{16n_t \mu_{jk} \Omega_{jk}}, \quad (88.13)$$

where μ_{jk} is the reduced mass

$$\mu_{jk} = \frac{m_j m_k}{m_j + m_k}, \quad (88.14)$$

and $n_t = n_j + n_k$ is the total number density. The collision integral Ω_{jk} is given by

$$\Omega_{jk} = \frac{1}{2\pi^{1/2}} \left(\frac{\mu}{2k_B T} \right)^{5/2} \times \int_0^\infty Q^D(v) v^5 \exp \left(\frac{-\mu v^2}{2k_B T} \right) dv, \quad (88.15)$$

where v is the relative velocity of the particles, $Q^D(v)$ is the diffusion or momentum transfer cross section

$$Q^D(v) = 2\pi \int_0^\pi \sigma_{jk}^{\text{el}}(\theta, v) (1 - \cos \theta) \sin \theta d\theta, \quad (88.16)$$

and $\sigma_{jk}^{\text{el}}(\theta, v)$ is the differential cross section for elastic scattering of species j and k through angle θ in the center-of-mass frame. In practice, D_{jk} is often expressed as b_{jk}/n_t , where n_t is the total number density, and b_{jk} is the binary collision parameter, which is usually given in tabulations in the semiempirical form $b = AT^s$. Here, A and s ($0.5 \lesssim s \lesssim 1.0$) are parameters that are fitted to the data. The binary collision parameter appears, for example, in the expression for the diffusion limited flux of a light species to the “exosphere” of a planet (e.g., *Hunten* [40]) (Sect. 88.7).

88.3 Interaction of Solar Radiation with the Atmosphere

88.3.1 Introduction

The source for all atmospheric processes is ultimately the interaction of solar radiation, either photons or particles, with atmospheric gases. Since visible photons arise from the photosphere of the sun, which is characterized by $T \approx 6000$ K, the solar spectrum in the visible and IR is similar to that of a black body at 6000 K. At longer (radio) and shorter (UV and X-ray) wavelengths, the photons arise from parts of the chromosphere and corona where the temperatures are higher ($10^4 - 10^6$ K). Thus, the photon fluxes differ substantially from those that would be predicted for a 6000 K black body. Photons in the extreme and far UV regions of the spec-

Fig. 88.2 Solar fluxes in units of $10^6 \text{ photons cm}^{-2} \text{ s}^{-1} \text{ Å}^{-1}$ at 1 AU for 1–3000 Å at a resolution of 1 Å. From *Eparvier* [41]. See also *Chamberlin et al.* [39]

trum are absorbed in the terrestrial thermosphere and X-rays in the lower thermosphere and mesosphere. The solar Lyman α line at 1216 Å penetrates through a window in the O_2 absorption cross sections to about 75 km. Near-UV photons are absorbed by ozone in the stratosphere, and visible radiation is not appreciably attenuated by the atmosphere.

The wavelength ranges that are most important for aeronomy are the UV and X-ray regions. A solar spectrum in the UV and X-ray regions at moderate solar activity ($F_{10} = 120$) is presented in Fig. 88.2. The ratio of high solar activity fluxes to low solar activity fluxes is near unity at wavelengths longward of 2000 Å but increases to factors that range between 2 and 3 over much of the extreme UV. At wavelengths between about 100 and 550 Å, the ratio of high to low solar activity fluxes reaches values as high as 100. The fluxes at X-ray wavelengths arise principally from solar flares and can increase by orders of magnitude from low to high solar activity.

The sun also emits a stream of charged particles, the solar wind, which flows radially outward in all directions, and consists mostly of protons, electrons, and alpha particles. The average number density of solar wind protons is about 5 cm^{-3} , and the average speed is about 400–450 km s^{-1} at Earth orbit (1 AU). The interaction of these particles with the magnetic field (either induced or intrinsic) of a planet, and ultimately with the atmosphere, is the source of auroral activity. Terrestrial auroras arise mostly from precipitation of electrons with energies in the kilovolt range, although measured spectra vary widely. An example of a primary electron auroral spectrum is shown in Fig. 88.3. Terrestrial auroral emissions maximize in the midnight sector, but dayside cusp auroras are produced by lower energy electrons, and diffuse proton auroras are also observed.

Since charged particles are constrained to move along magnetic field lines, for planets with intrinsic dipole fields,

auroras are usually found in an oval around the magnetic poles, where the dipole field lines enter the atmosphere. On Venus and Mars, diffuse and variable auroras are observed on the nightside. Since Mars has a remanent crustal magnetic field, discrete auroras are also seen on the nightside. On Earth, low-latitude auroras, which arise from heavy particle precipitation, have also been observed. The primary particles that are responsible for the Jovian aurora may be electrons, protons, or heavy ions originating from its satellite Io. The latter source produces a well-defined “footprint” near the auroral oval. Due to charge transfer, heavy particles spend part of their lifetime as neutral species, and their paths may then diverge from magnetic field lines. In any case, a large fraction of the effects of auroral precipitation is due to secondary electrons, regardless of the identity of the primary particles. In addition to producing emissions of atmospheric species in the visible UV and IR portions of the spectrum, auroral particles ionize and dissociate atmospheric species and contribute to heating the neutrals, ions, and electrons.

88.3.2 The Interaction of Solar Photons with Atmospheric Gases

The number flux of solar photons in a small wavelength interval around λ at an altitude z can, for the most part, be computed from the Beer–Lambert absorption law

$$F_\lambda(z) = F_\lambda^\infty \exp[-\tau(\lambda, z)], \quad (88.17)$$

where F_λ^∞ is the solar photon flux outside the atmosphere, and $\tau(\lambda, z)$ is the optical depth which, in the plane parallel approximation, is given by

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z') \sigma_j^a(\lambda) \sec \chi \, dz'. \quad (88.18)$$

Here, $\sigma_j^a(\lambda)$ is the absorption cross section of species j at wavelength λ , and the solar zenith angle χ is the angle of the sun with respect to the local vertical.

For χ greater than about 75° , the variation of the solar zenith angle (SZA) along the path of the radiation cannot be neglected; the optical depth must be computed by numerical integration along this path in spherical geometry. For $\chi \leq 90^\circ$, the optical depth is

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z') \sigma_j^a(\lambda) \times \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz'. \quad (88.19)$$

Fig. 88.3 Sample of energy spectrum of precipitating auroral electrons and ions (protons) as measured by the Defense Meteorology Satellite Program (DMSP) satellite. The abscissa is log (base-10) of the energy in electron-volts, and the ordinates are log (base 10) of the energy fluxes of the electrons (*top*) and protons (*bottom*). Also shown are the universal time (UT) geographic latitude (LAT) and longitude (LON), magnetic latitude (MLAT) and longitude (MLT), the integrated energy flux (Electron JE) and ion flux (Ion JE), and average energy (Avg E) of the electrons and ions. From Paxton [42]

For χ larger than 90° , the optical depth is given by

$$\tau(\lambda, z) = \sum_j \left\{ 2 \int_{z_s}^{\infty} n_j(z') \sigma_j^a(\lambda) \times \left[1 - \left(\frac{r_o + z_s}{r_o + z'} \right)^2 \sin^2 90^\circ \right]^{-0.5} dz' - \int_z^{\infty} n_j(z') \sigma_j^a(\lambda) \times \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz' \right\}, \quad (88.20)$$

where z_s is the tangent altitude, the point at which the solar zenith angle is 90° for the path of solar radiation through the atmosphere. Of course, we need not write $\sin 90^\circ$ explicitly in Eq. (88.20), but its inclusion helps to elucidate the origin of the equation.

In a one-species atmosphere, the rate of absorption of solar photons of wavelength λ is

$$q^a(\lambda) = F_\lambda \sigma^a(\lambda) n. \quad (88.21)$$

For an isothermal atmosphere in which $H(z)$ is approximately constant, the absorption maximizes where $\tau(\lambda, z) = 1$. This is a fairly good approximation even for regions of the atmosphere where the $H(z)$ is not constant. The altitude of unit optical depth is shown for wavelengths from X-rays to

the near UV for overhead sun in the terrestrial atmosphere in Fig. 88.4a. Note the accidental window in the O_2 photoabsorption cross sections at Lyman alpha (1216 \AA), which was mentioned above.

Similar plots for Venus, Mars, Jupiter, and Saturn are shown in Fig. 88.4b–e, respectively. N_2 does not absorb longward of about 105 nm, so in the terrestrial atmosphere, O_2 and O_3 are the primary absorbers between 100 and 220 nm, while ozone dominates the absorption for wavelengths in the range 220–320 nm. On Venus and Mars, CO_2 is the main absorber of FUV and EUV radiation, although at wavelengths less than about 100 nm, N_2 , CO, and O also contribute.

On Jupiter and Saturn, H_2 absorbs radiation in the 842–1116 \AA range in discrete transitions to rovibrational levels of excited states, which decay either to rovibrational levels or to the continuum of the ground state. Since the cross sections vary by several orders of magnitude, this leads to oscillations in the depths of penetration, especially in the wings of the lines and gaps between groups of lines. The photons are abruptly stopped near the methane homopause, when the hydrocarbon densities are large enough to absorb the photons.

Similarly, in the thermospheres of Titan and Pluto, absorption by N_2 in the range 850–1020 \AA is like that of H_2 ; it undergoes discrete line absorption to predissociating states. Methane and hydrocarbon hazes are the primary absorbers of UV radiation between 1600 \AA and the effective absorption threshold of N_2 of about 12.14 eV (Strobel and Zhu [7]; Zhang et al. [45]). The threshold for photoabsorption of CH_4 is effectively near 1600 \AA , above which the cross sections are very small (e.g., Huebner et al. [46]). Higher hydrocarbons,

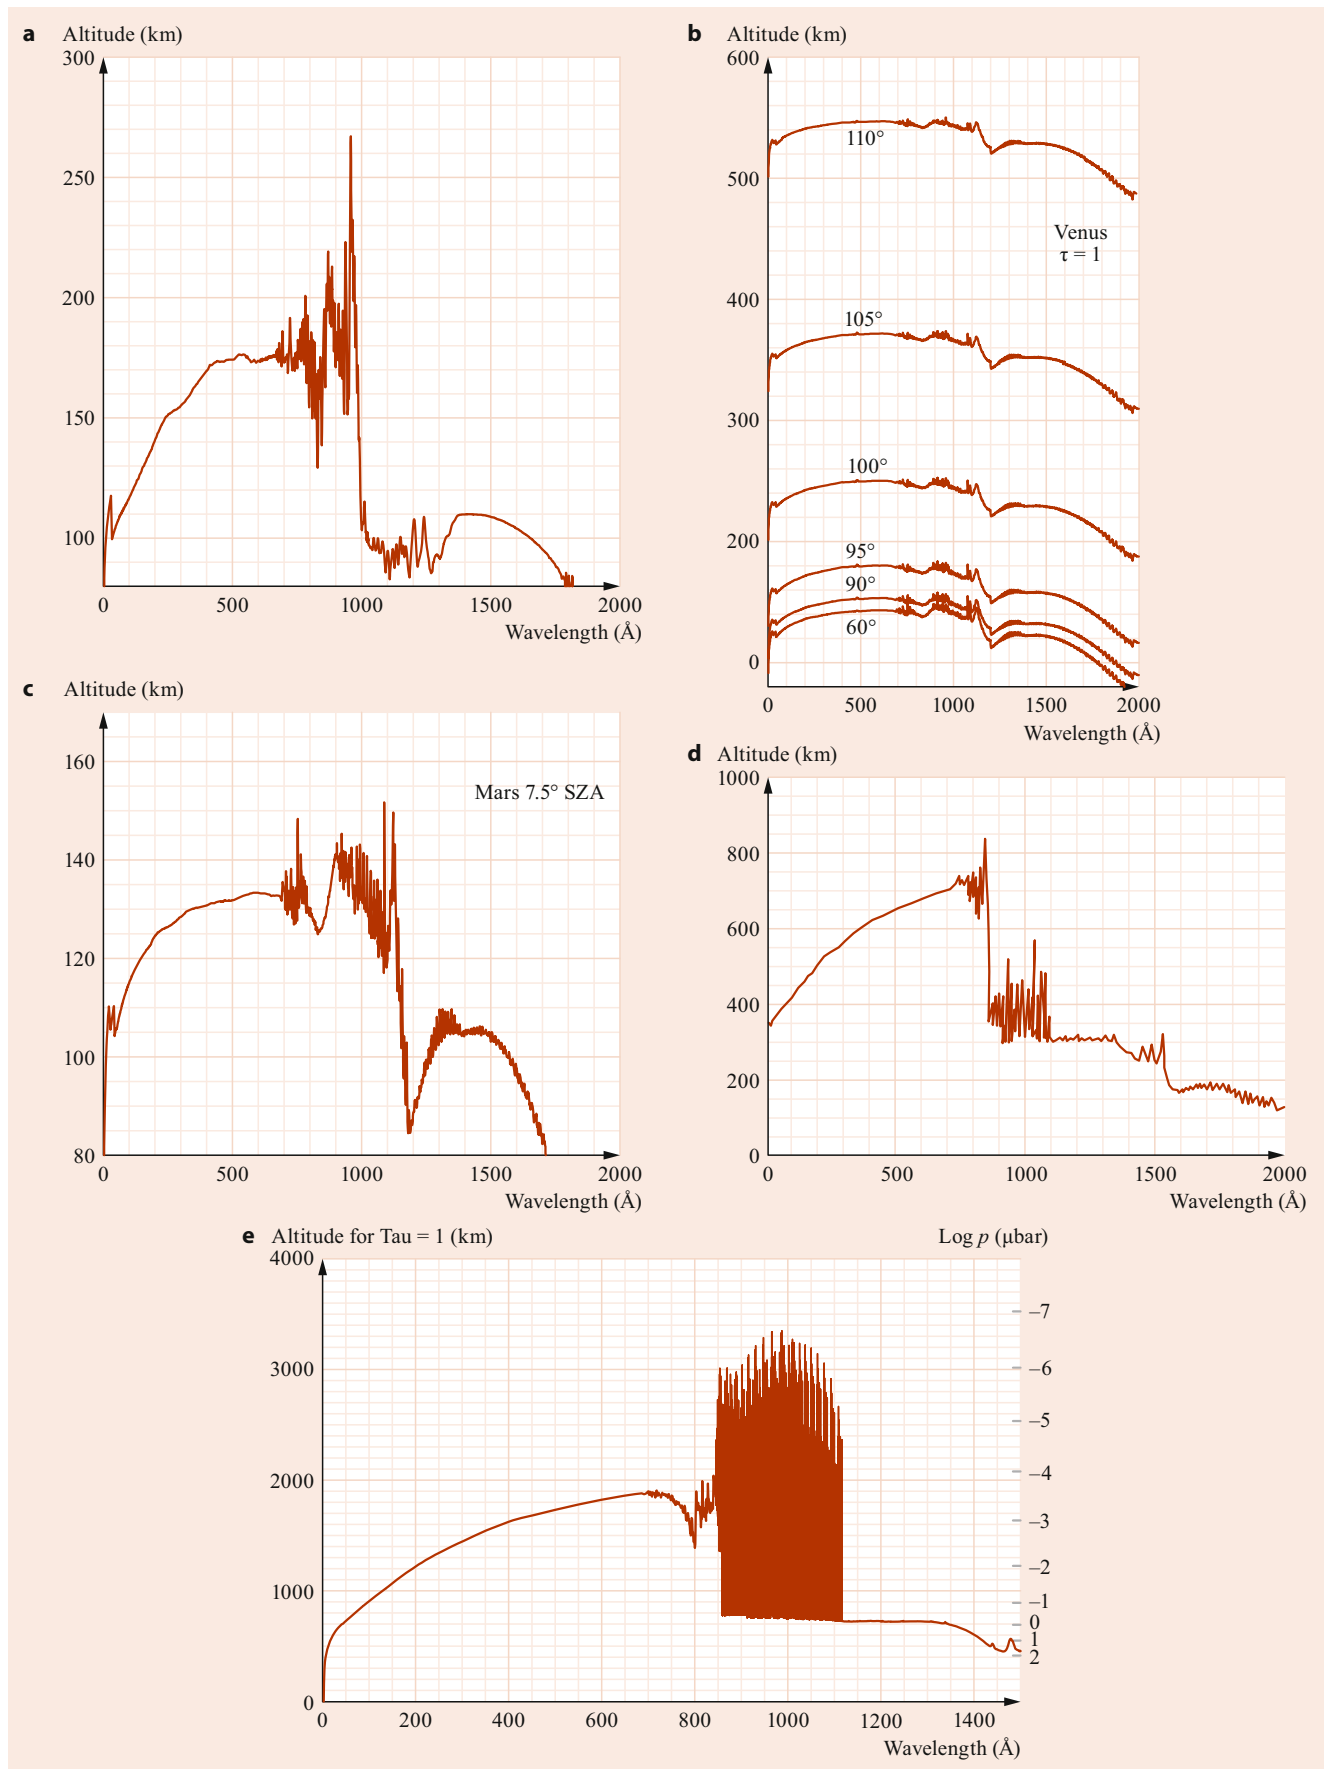

Fig. 88.4 The altitude where $\tau = 1$ versus wavelength: (a) Earth, (b) Venus. The optical depths for various solar zenith angles (SZA) from 60° to 110° . The solar zenith angle is the angle that the line of sight to the sun makes with the vertical. (c) Mars, for near-subsolar conditions (SZA = 5° – 10°) and moderate solar activity, (d) Jupiter [43], (e) Saturn, wavelength range 1–1500 Å, high-resolution values for SZA = 27° . The oscillations in the 842–1116 Å range are characteristic of the high-resolution photoabsorption cross sections of H₂. In this region, the photons can be seen to penetrate to the region of hydrocarbon absorption, where they are abruptly absorbed. Soft X-rays with wavelengths in the range 40–150 Å are absorbed in the altitude range of 700–1000 km above the 1-bar level, from Kim et al. [44] ◀

however, such as C₂H₂, C₂H₄, and C₂H₆, which are formed chemically subsequent to photoabsorption of methane, absorb longward of 1600 Å.

The interaction of UV photons with atmospheric gases produces ions and photoelectrons through photoionization, which may be represented as

and photodissociative ionization

In these equations, X represents any atmospheric species; A is either an atom or a molecular fragment, and AB is a molecule. The energy of the photoelectron in reaction Eq. (88.22) is given by

$$E_{pe} = h\nu - I_X - E_{ex}, \quad (88.24)$$

and in reaction Eq. (88.23) it is

$$E_{pe} = h\nu - E_d - I_A - E_{ex}, \quad (88.25)$$

where I_j is the ionization potential of species j , E_d is the dissociation energy of molecule AB, and E_{ex} is the sum of the internal energy states of the products. Neutral fragments, which may be reactive radicals, are also produced in photodissociation

The rate of ionization of a species j by a photon of wavelength λ at an altitude z is given by

$$q_j^i(\lambda, z) = F_\lambda(z)\sigma_j^i(\lambda)n_j(z), \quad (88.27)$$

where $\sigma_j^i(\lambda)$ is the photoionization cross section. The rate for photodissociation is given by a similar expression, with the photoionization cross section replaced by the photodissociation cross section. The expression above must be integrated over the solar spectrum to give the total rate. In addition, it is often necessary to take into account ionization and/or dissociation to different final internal states of the products, so the partial cross sections or yields are needed.

In the atmospheres of magnetic planets, photoelectrons may travel upward along the magnetic field lines to the conjugate point, where the field line re-enters the atmosphere. In

order to model this effect, the differential (with respect to angle) cross sections for photoionization $\sigma_j^i(\lambda, \theta)$ are necessary. The differential cross section is sometimes expressed as

$$\sigma_j^i(\lambda, \theta) = \frac{\sigma_j^i(\lambda)}{4\pi} \left[1 - \frac{1}{2}\beta(\lambda)P_2(\cos\theta) \right], \quad (88.28)$$

where θ is the angle between the incident photon beam and the ejected electron, P_2 is a Legendre polynomial, and β is an asymmetry parameter.

88.3.3 Interaction of Energetic Electrons with Atmospheric Gases

Suprathermal electrons, which are here denoted e^{*-} and include both energetic photoelectrons and auroral primary electrons, can also ionize species through electron-impact ionization

and electron-impact dissociative ionization

In these reactions, e^- represents the energy degraded photoelectron or primary electron, and e'^- the secondary electron. The energy of the secondary electron $E_{e'}$ in an electron-impact ionization process Eq. (88.29) is given by

$$E_{e'} = E_{e^*} - I_X - E_{ex} - E_e, \quad (88.31)$$

where E_{e^*} is the energy of the primary or photoelectron, E_e is the energy of the degraded primary or photoelectron, and E_{ex} is the internal excitation energy of the product ion or neutral fragments. For the dissociative ionization process Eq. (88.30) the dissociation energy of the molecule must also be subtracted as well.

Energetic electrons can also dissociate atmospheric species. In this process,

the energy of the degraded electron is

$$E_e = E_{e^*} - D_{AB} - E_{ex}, \quad (88.33)$$

where D_{AB} is the dissociation energy of molecule AB. Collisions with suprathermal electrons can also promote species to excited electronic, vibrational, or rotational states

where the dagger denotes internal excitation. The energy lost by the electron is, thus, the excitation energy of the species.

In determining the rate of ionization, dissociation, and excitation by photoelectrons, the local energy loss approximation, that is, the assumption that the electrons lose their energy at the same altitude where they are produced, is fairly good near the altitude of peak photoelectron production. The mean free path of an electron near 150 km on Earth is about 30 m. Substantially above the altitude of peak production of photoelectrons, transport of electrons from below is important, and use of the local energy loss assumption causes the excitation, ionization, and dissociation rates to be underestimated. For keV auroral electrons, the computation of the energy deposition of the electrons must consider their transport through the atmosphere. Thus, the elastic total and differential cross sections for electrons colliding with neutral species must be employed, as well as the inelastic cross sections, and the angles through which the electrons scatter must be taken into account.

In general, the excitation rate $q_j^k(z)$ of a species j to an excited level k with a threshold energy E_k at an altitude z by electron impact is given by

$$q_j^k(z) = n_j(z) \int_{E_k}^{\infty} \sigma_j^k(E) \frac{dF(z, E)}{dE} dE , \quad (88.35)$$

where $\sigma_j^k(E)$ is the excitation cross section at electron energy E , and $dF(z, E)/dE$ is the differential flux of electrons (between energies E and $E + dE$). The ionization rate $q_j^i(z)$ of a species with ionization potential I_j due to electron impact is given by

$$q_j^i(z) = n_j(z) \int_{I_j}^{\infty} \int_0^{(E-I_j)/2} \frac{d\sigma_j^i(E)}{dW_s} \frac{dF(z, E)}{dE} dW_s dE , \quad (88.36)$$

where $d\sigma_j^i(E)/dW_s$ is the differential cross section for production of a secondary electron with energy W_s by a primary electron with energy E . The integral over secondary energies W_s terminates at $(E - I_j)/2$ because the secondary electron is by convention considered to be the one with the smaller energy. Since the average energy of photoelectrons is less than 20 eV, the error incurred in cutting off the integrals in Eqs. (88.35) and (88.36) at 200 eV or so, rather than

$(E - I_j)/2$, is not serious, although for high-energy auroral electrons, a larger upper limit may be required.

An estimate of the number of ionizations in a gas produced by a primary electron with energy E_p is E_p/W_{ip} , where W_{ip} is the energy loss per ion pair produced, which approaches a constant value as the energy of the electron increases. This constant is also found to increase as a function of fractional ionization because of the larger amount of energy lost to thermal electrons as the fractional ionization increases. Empirical values are available for W_{ip} for many gases, and usually fall in the range 30–40 eV [47].

The total loss function or stopping cross section for an electron with incident energy E in a gas j is given by the expression

$$L_j(E) = \sum_k \sigma_j^k(E) W_j^k + \int_0^{(E-I_j)/2} (I_j + W_s) \frac{d\sigma_j^i(E)}{dW_s} dW_s , \quad (88.37)$$

where W_j^k is the energy loss associated with excitation of species j to excited state k . The differential cross section is usually adopted from an empirical formula that is normalized so that

$$\sigma_j^i(E) = \int_0^{(E-I_j)/2} \frac{d\sigma_j^i(E)}{dW_s} dW_s , \quad (88.38)$$

where $\sigma_j^i(E)$ is the total ionization cross section at primary electron energy E . One formula in common use is that employed by *Opal* et al. [48] to fit to their data

$$\frac{d\sigma_j^i(E)}{dW_s} = \frac{A(E)}{1 + (W_s/\bar{W})^{2.1}} , \quad (88.39)$$

where $A(E)$ is a normalization factor, and \bar{W} is an empirically determined constant, which has been found to be equal to within a factor of about 50% to the ionization potential for a number of species.

For energy loss due to elastic scattering by thermal electrons, an analytic form of the loss function such as that proposed by *Swartz* et al. [49] may be used

$$L_e(E) = \frac{3.37 \times 10^{-12}}{E^{0.94} n_e^{0.03}} \left(\frac{E - k_B T_e}{E - 0.53 k_B T_e} \right)^{2.36} , \quad (88.40)$$

where T_e is the electron temperature and n_e is the number density of ambient thermal electrons.

For high-energy auroral electrons, the rate of energy loss per electron per unit distance over the path s of the electrons

in the atmosphere can be estimated using the continuous slowing down approximation (CSDA) as

$$-\frac{dE}{ds} = \sum_j n_j(z) L_j(E) \sec \theta + n_e(z) L_e(E) \sec \theta, \quad (88.41)$$

where θ is the angle between the path of the primary electron s and the local vertical. In the CSDA, all the electrons of a given energy are assumed to lose their energy continuously and at the same rate. The rate of energy loss ($-dE/ds$) is integrated numerically over the path of the electron, which degrades in energy until it is thermalized. In this approximation, inelastic processes are assumed to always scatter the electrons forward, so cross sections that are differential in angle are not required. Because electrons actually lose energy at different rates, however, and because elastic and inelastic scattering processes do change the direction of the electrons, the CSDA gives an estimate for the rates of electron energy loss processes that is increasingly inaccurate as the energy of the electron decreases.

In practice, discrete energy loss of electrons can be easily treated numerically if the local energy loss approximation is valid. The spectrum of electrons must be divided into energy bins that are smaller than the energy losses for the processes, and the integrals in Eqs. (88.35) and (88.36) are replaced by sums over energy bins. Since elastic scattering of electrons by neutrals changes mostly the direction of the incident electron, and not its energy, only inelastic processes need be considered. In order to compute excitation and dissociation rates, only integral cross sections are required; the scattering angle is unimportant. For ionization, of course, the energy distribution of the secondary electrons must be considered but not the scattering angles of either the primary or secondary electrons. Below the lowest thresholds for excitations, energetic electrons lose their energy in elastic collisions with thermal electrons. The process of energy loss to thermal electrons is often approximated as continuous, rather than discrete.

The collision frequency ν_j^k for a discrete electron-impact excitation process k of a species j is given by

$$\nu_j^k(E) = n_j(z) v_e(E) \sigma_j^k(E). \quad (88.42)$$

For energy loss due to elastic scattering from thermal electrons, a pseudo-collision frequency ν_e may be defined as

$$\nu_e(E) = \frac{1}{\Delta E} \left(-\frac{dE}{dt} \right), \quad (88.43)$$

where ΔE is the grid spacing in the calculation, and the energy loss rate is

$$-\frac{dE}{dt} = \nu_e(E) n_e L_e(E), \quad (88.44)$$

where L_e is taken from, for example, Eq. (88.40).

Since the energy bins should be smaller than the typical energy loss in order to obtain accurate rates for the excitation processes, it is often convenient to treat rotational excitation also as a continuous process, with a pseudo-collision frequency similar to that for elastic scattering from ambient electrons Eq. (88.43) with

$$-\frac{dE}{dt} = \nu_e(E) n_j L_j^{\text{rot}}(E), \quad (88.45)$$

where the loss function for rotational excitation is given by

$$L_j^{\text{rot}}(E) = \sum_J \eta_j^J \sum_{J'} \sigma_j^{J,J'}(E) W_j^{J,J'}. \quad (88.46)$$

In this expression, η_j^J is the fraction of molecules j in the rotational level J , and $\sigma_j^{J,J'}$ is the measured or computed cross section for electron-impact excitation of species j from rotational state J to rotational state J' , and $W_j^{J,J'}$ is the associated energy loss.

The slowing down of high energy auroral primary or the concomitant high energy secondary electrons arises from both elastic and inelastic scattering processes and cannot be treated using the local energy loss approximation. In solving the equations for electron transport, the angle through which the primary electron is scattered, as well as the change in energy of the primary electron and the production of any secondaries, must be taken into account. Thus, differential cross sections for the elastic and inelastic scattering of electrons by neutral species are required. The detailed equations for electron transport have been presented by, for example, *Rees* [50].

Several methods for approximating the energy deposition of auroral electrons are currently in use. The CSDA has already been discussed, but it provides only a rough approximation to the depth of penetration of the electrons, and the rates of excitation, ion production, and other energy loss processes. In the two-stream approximation, the electrons are assumed to be scattered in either the forward or the backward direction [51]. Implementation of this method requires only the backscattering probabilities, rather than complete differential cross sections. The method has been generalized to multistream models, in which the solid angle range of the electrons is divided into 20 or more intervals, so more or less complete differential cross sections are required [52, 53]. Monte Carlo methods have also been used to model auroral electron precipitation [54].

88.4 Ionospheres

88.4.1 Ionospheric Regions

The division of the dayside ionosphere into regions is based on the structure of the terrestrial ionosphere, which consists of overlapping layers of ions. These layers are the result of

Fig. 88.5 Ionospheric regions and primary ionization sources. After Bauer [55]

changes both in the composition of the thermosphere and in the sources of the ionization, and are shown schematically in Fig. 88.5. The major molecular ion layer is the F_1 layer, which is produced by absorption of EUV (100–1000 Å) photons by the major thermospheric species, and occurs where the ion production maximizes. The E layer is below the F_1 layer and is produced by shorter and longer wavelength photons that are absorbed deeper in the atmosphere: soft X-rays and Lyman β , which can ionize O_2 and NO (Fig. 88.4a). In the D region, the densities of negative ions become appreciable, and large densities of positive cluster ions appear. These ions are produced by harder X-rays, with $\lambda \lesssim 10$ Å, and Lyman α , which penetrates to about 75 km, where it ionizes NO . The highest altitude peak in the terrestrial ionosphere is the F_2 peak, which occurs near or slightly below 300 km, where the major ion is O^+ . In the ionospheres of the outer planets, an F_2 peak is formed from H^+ . The F_1 region is formed from H_3^+ , and near or below that layer by hydrocarbon ions, as shown for Saturn in Fig. 88.10e. The peak density in the F_2 region occurs where the chemical lifetime of the (atomic) ion is comparable to the characteristic time for transport by diffusion ($\approx H^2/D$).

88.4.2 Sources of Ionization

As discussed in Sect. 88.3, ionization can be produced either by solar photons and photoelectrons during the daytime or

Fig. 88.6 Primary photoelectron spectrum for the terrestrial atmosphere at 172 km (near the F_1 peak) and at 100 km. The spectrum at 100 km is significantly harder than that at 172 km

by energetic particles and secondary electrons during auroral events. Photoelectrons have sufficient energy to carry out further ionization if they are produced by photons with $\lambda \lesssim 500$ Å. These photons penetrate further and exhibit larger solar activity variations than longer-wavelength ionizing photons. Thus, the ionization rate due to photoelectrons peaks below the main photoionization peak. Primary flux spectra of photoelectrons produced near the F_1 peak (172 km) and below the ion peak (100 km) are shown in Fig. 88.6. The primary spectrum at the ion peak consists mostly of lower-energy electrons, whereas at 100 km, the lower-energy electrons are depleted, and there are relatively larger fluxes of electrons with $E \gtrsim 50$ eV. Figure 88.7 shows the primary and steady-state photoelectron spectra near the ion peaks on Venus and Titan.

The major ions produced in the ionospheres of the Earth and planets are usually those from the major thermospheric species: N_2^+ , O_2^+ , and O^+ on Earth; CO_2^+ , O^+ , N_2^+ , and CO^+ on Venus and Mars; H_2^+ , H^+ , CH_4^+ , and He^+ on the outer planets; N_2^+ , N^+ , and CH_4^+ (and higher hydrocarbon ions) in the ionospheres of Titan and Pluto; and N_2^+ , N^+ , CH_4^+ , and C^+ in the ionosphere of Triton. In the presence of sufficient neutral densities, however, ion–molecule reactions transform ions whose parent neutrals have high ionization potentials to ions whose parent neutrals have low ionization potentials. This is a rigorous rule only for charge transfer reactions, but it applies more often than not in other ion–molecule reactions as well.

Because of transformations by ion–molecule reactions, the major ions in the F_1 regions of the dayside ionospheres of Earth, Venus, and Mars are O_2^+ and NO^+ , despite the large differences in composition between the thermosphere of the Earth and the thermospheres of Venus and Mars. A diagram illustrating the ion chemistry in the ionospheres of the terrestrial planets is shown in Fig. 88.8. The vertical positions of the ions in this figure represent the relative ionization po-

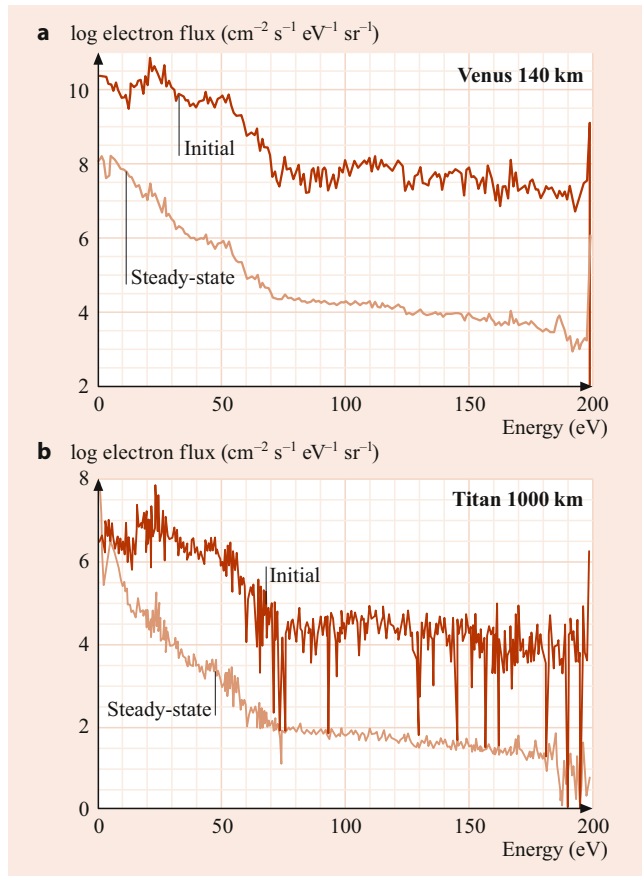

Fig. 88.7 Computed primary and steady-state spectra for photoelectrons near the F_1 peak on Venus at 1 eV resolution (a), and Titan at 0.5 eV resolution (b). For Titan, no precipitation of electrons from Saturn's magnetosphere is assumed. The steady-state spectra are averaged over three intervals in both plots

tentials of the parent neutrals. In regions where there are sufficient neutral densities the ionization flows downward.

Table 88.10 shows ionization potentials (I_p) for several major and minor species present in planetary thermospheres. Major atmospheric species generally have $I_p \gtrsim 12\text{--}16$ eV ($\lambda < 775\text{--}1000$ Å). Only a few species can be ionized by the strong solar Lyman alpha line (1216 Å, 10.2 eV), including NO, and a few hydrocarbon radicals and stable species, such as CH₃, C₂H₅, C₄H₂, and benzene. Metal atoms, which are produced in the lower thermospheres and mesospheres of planets from ablation of meteors, have very low ionization potentials, and some can be ionized by photons with wavelengths longer than 2000 Å.

In ionospheres where hydrogen and sufficient neutral densities are present, ionization flows from protonated species whose parent neutrals have small proton affinities to species formed by protonation of neutrals that have large proton affinities. There are no *in situ* measurements of the ion composition of the outer planets, but models predict that H₃⁺ and hydrocarbon ions dominate the lower ionospheres. In regions where meteor ablation occurs, metal ions may also be found.

Table 88.10 Ionization potentials (I_p) of common atmospheric species (computed with data taken from [56], except as noted)

High I_p		Medium I_p		Ionized by Ly α	
Species	I_p (eV)	Species	I_p (eV)	Species	I_p (eV)
He	24.59	H ₂ O	12.612	C ₄ H ₂	10.18
Ne	21.56	CH ₄	12.51	CH ₃	9.73
N ₂	15.58	O ₂	12.07	NO	9.264
H ₂	15.43	C ₂ H ₆	11.52	C ₂ H ₅	8.13
N	14.53	C ₂ H ₂	11.40	HCO	8.10
CO	14.01	C	11.26	C ₃ H ₇	8.09
CO ₂	13.76	C ₃ H ₈	10.95	Mg	7.65
O	13.62	CH	10.64	<i>trans</i> -HCNH	7.0 ^a
H	13.60	C ₂ H ₄	10.51	<i>cis</i> -HCNH	6.8 ^a
HCN	13.60	CH ₂	10.40	Ca	6.11
OH	13.00	S	10.35	Na	5.14

^a From [57]

Many ion–molecule reactions proceed at or near gas kinetic (or collision) rates. The interaction of an ion with a nonpolar molecule is dominated by the ion–induced dipole interaction, for which the interaction potential is $-\frac{1}{2}\alpha_d q^2/r^4$, where α_d is the polarizability of the neutral, q is the charge on the ion, and r is the distance between the particles. The Langevin–Gioumousis–Stevenson (LGS) or merely the Langevin rate coefficient, k_L , is then given by

$$k_L = 2\pi q \left(\frac{\alpha_d}{\mu} \right)^{1/2}, \quad (88.47)$$

where μ is the reduced mass of the two species. For a singly charged ion, with α_d in Å³ and μ in atomic mass units, this formula reduces to $2.34 \times 10^{-9}(\alpha_d/\mu)^{1/2}$. The rate coefficient for an ion with a polar molecule is

$$k_d = \frac{2\pi q}{\mu^{1/2}} \left[\alpha_d^{1/2} + c\mu_d \left(\frac{2}{\pi k_B T} \right)^{1/2} \right], \quad (88.48)$$

where μ_d is the dipole moment, and c is a constant that is unity in the locked dipole approximation and is about 0.1 in the average dipole orientation (ADO) theory. The value of c has been shown to be a function of $\mu_D/\alpha^{1/2}$ and can be determined either experimentally or graphically, as proposed by *Su* and *Bowers* [58]. Proton transfer reactions in particular have been shown to proceed at rates that are close to the Langevin (or capture) rates. Theories for ion–quadrupole interactions have also been developed, and the resulting formulas can be found in, for example, the review by *Su* and *Bowers* [58]. Measured rate coefficients for ion–molecule reactions have been compiled by *Anicich* et al. [59], *Ikezo* et al. [60], and *Anicich* [61].

Loss of ionization in planetary atmospheres proceeds mainly by dissociative recombination of molecular ions, which may be represented by

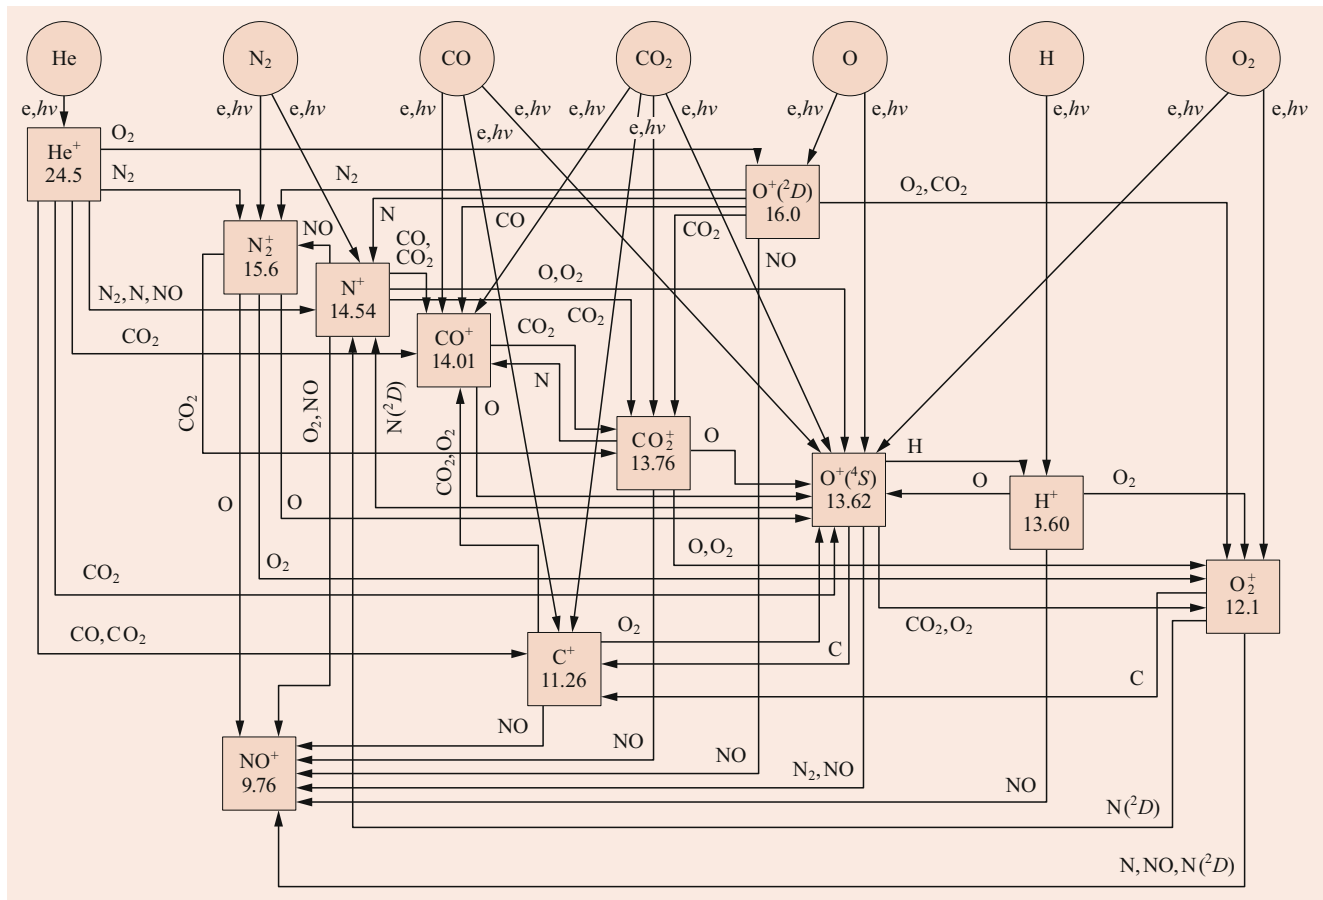

Fig. 88.8 Ion chemistry in the ionospheres of the terrestrial planets. The numbers under the names of the ions indicate the ionization potentials of the parent neutral. In the presence of sufficient neutral densities, the ionization flows downward, and the importance of dissociative recombination for the molecular ions increases as the ionization potentials of the parent neutrals decrease

Dissociative recombination coefficients are characteristically large, about $10^{-7} \text{ cm}^3 \text{ s}^{-1}$, at the electron temperatures T_e typical of planetary ionospheres, which are usually within a factor of a few of the neutral $T \approx 150\text{--}800 \text{ K}$ near the molecular ion density peak. Daytime peak electron densities tend to be in the range $10^4\text{--}10^6 \text{ cm}^{-3}$; fractional ionizations are small, about 10^{-5} , near the F_1 peak.

The relative importance of ion–molecule reactions and dissociative recombination in the destruction of a particular ion is determined by the relative densities of electrons and neutrals with which the ions can react. In general, molecular ions whose parent neutrals have high I_P are transformed by ion–molecule reactions preferentially to loss by dissociative recombination, and their peak densities occur higher in the atmosphere. Ions for which dissociative recombination is an important loss mechanism near the ion peaks of the terrestrial planets include NO^+ and O_2^+ , and in the atmospheres of the outer planets, H_3^+ and hydrocarbon ions. For ions whose parent neutrals have very high I_P , such as N_2^+ and H_2^+ , dissociative recombination is rarely important as a loss process, except at very high altitudes. They may, however, be im-

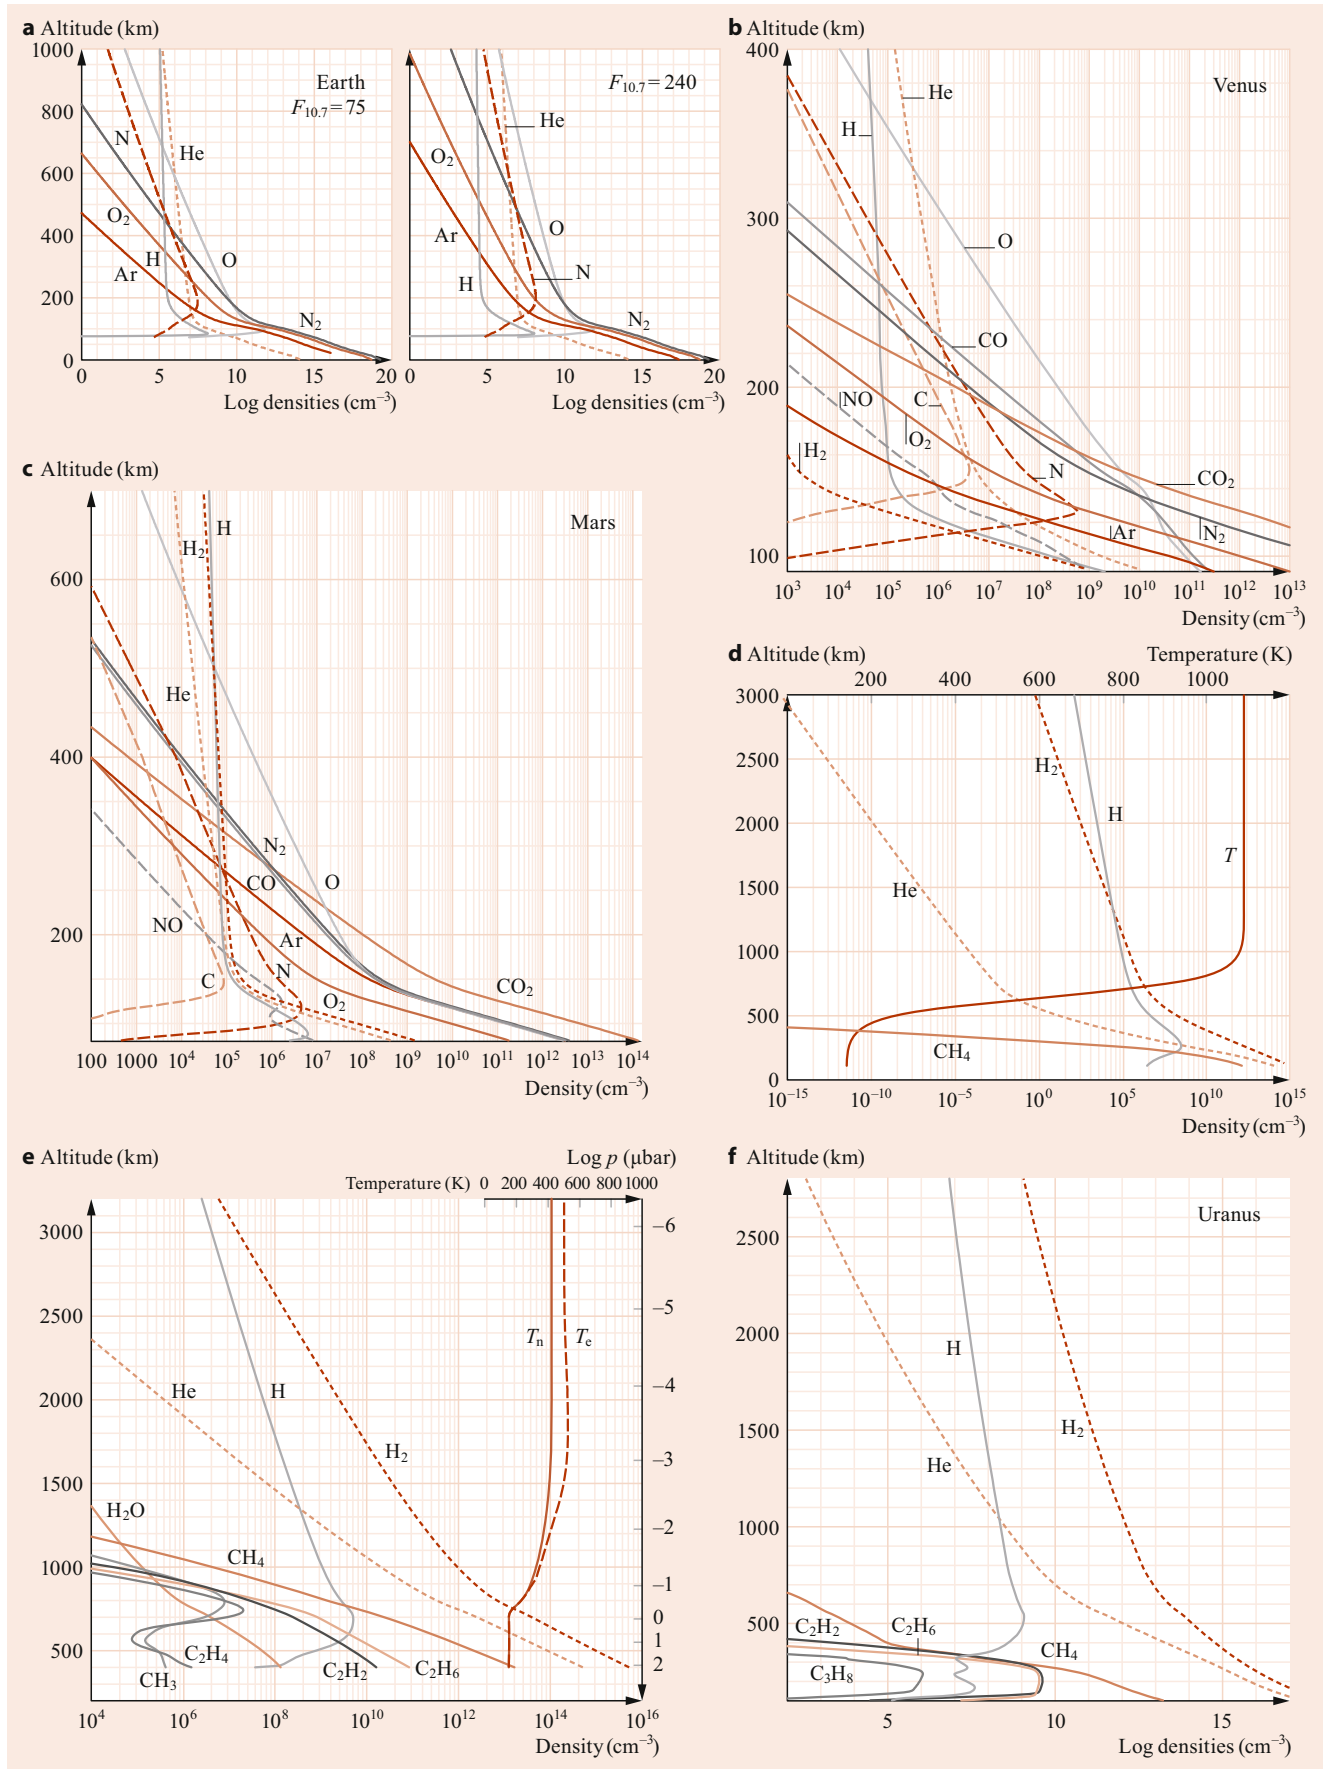

portant as a source of vibrationally or electronically excited fragments or hot atoms.

Atomic ions may be destroyed by radiative recombination

but the rate coefficients are small, less than $10^{-12} \text{ cm}^3 \text{ s}^{-1}$ at the typical T_e of planetary ionospheric peaks [62], and decrease with increasing electron temperature. Atomic ions may dominate at high altitudes, where neutral densities are low, but in such regions, loss by diffusion may be more important than chemical recombination. The ions diffuse downward to altitudes where the neutral densities are higher and are then destroyed in ion–molecule reactions. The major ions in the topside ionospheres of the planets tend to be atomic ions: O^+ in the ionospheres of Earth and Venus and H^+ in the ionospheres of the outer planets. On Mars, however, the O^+ peak density appears not to exceed that of O_2^+ even at high altitudes.

Model thermospheres for Earth and selected planets and satellites are shown in Fig. 88.9a–j. Measured or computed

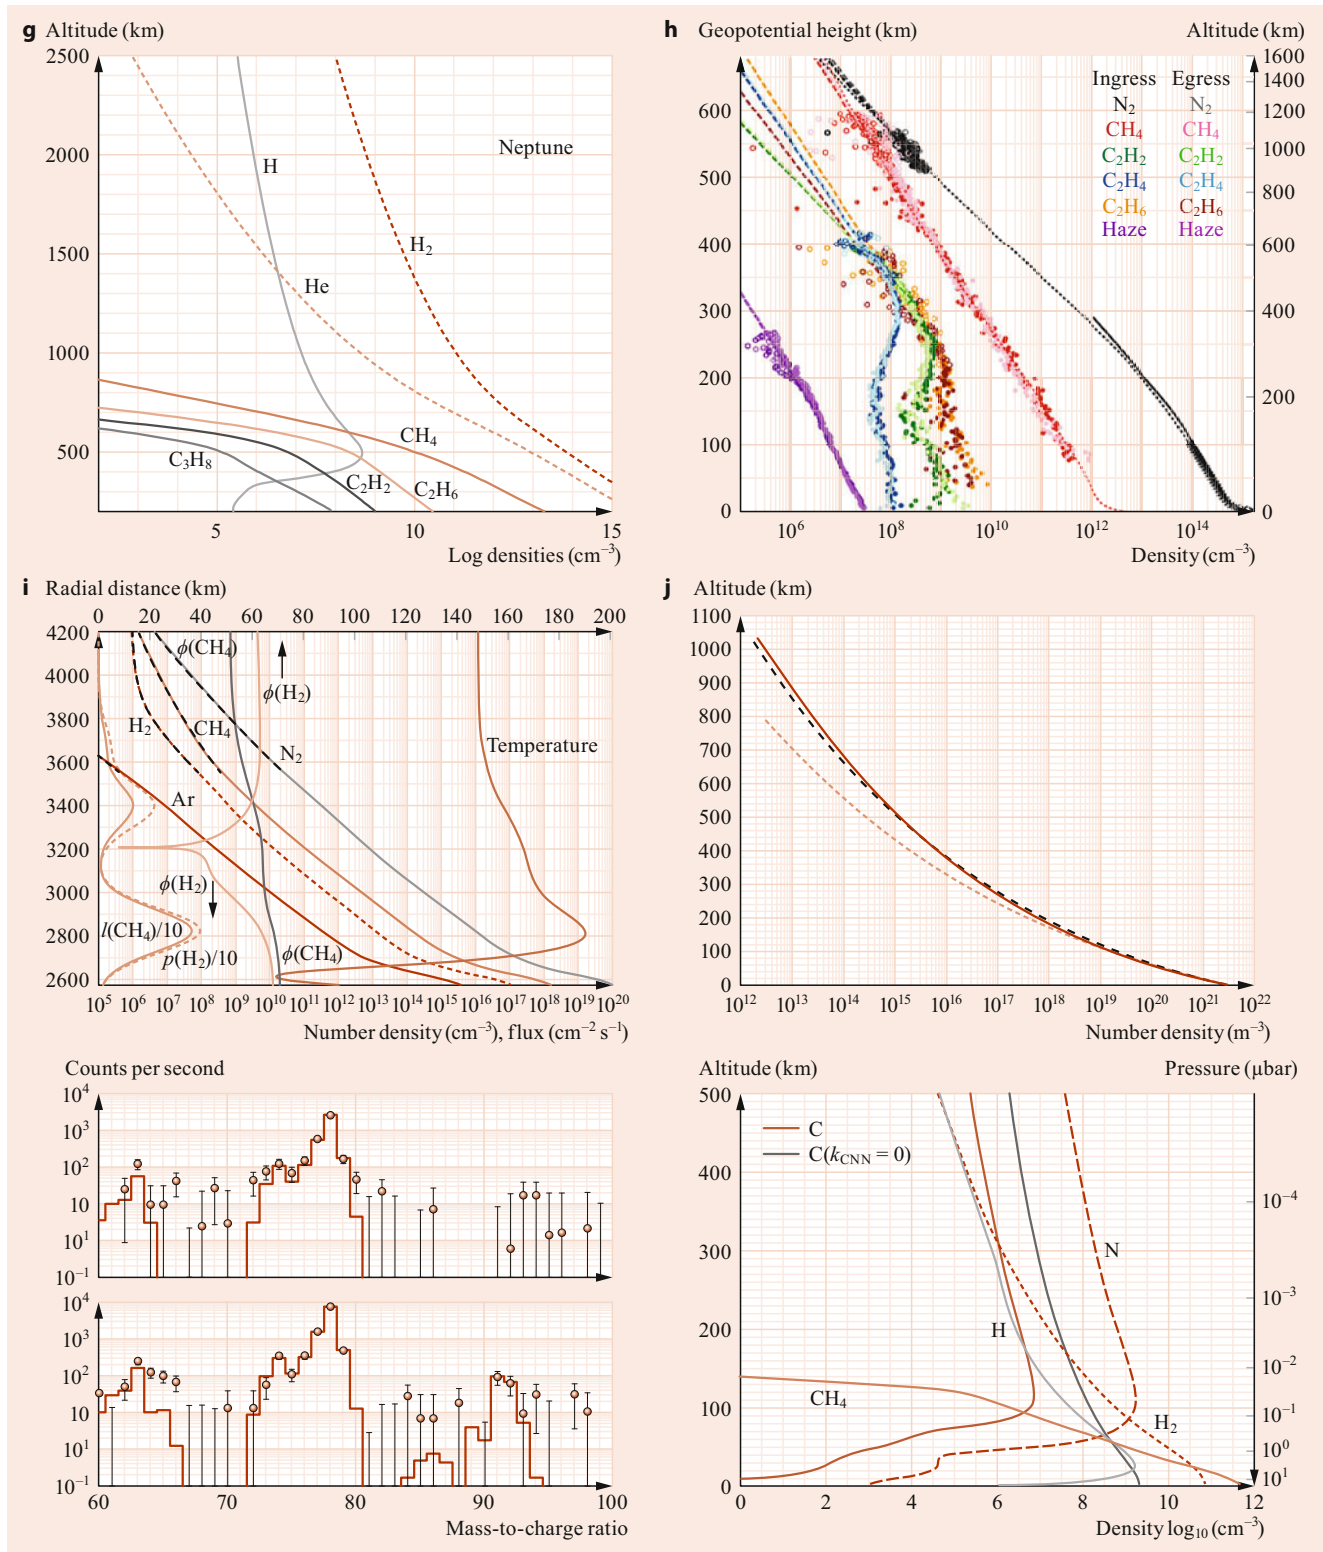

Fig. 88.9 Model thermospheres for the Earth, planets, and satellites. The curves are number density profiles and are labeled by the species they represent. (a) Earth, based on the NRLMSIS model of [9] for a latitude of 0° and a local time of noon for low (*left*) and high (*right*) solar activities. (b) High solar activity model of Venus, based on the model of [2] for 15° N latitude 15:00 LT. (c) Moderate ($F_{10.7} = 120$) solar activity model of Mars, based on MAVEN NGIMS (Neutral Gas and Ion Mass Spectrometer) measurements that are averaged over 5 km bins from March, April, and May 2015 for the SZA range of 5° – 10° . The CO_2 , O, N_2 , CO, Ar, and He profiles (*solid curves*) are fitted to data. The N, C, and NO profiles (*dashed curves*) are computed self-consistently from a model, as are the H and H_2 profiles. (d) Jupiter, basic JGITM (Jupiter Global Ionosphere-Thermosphere Model) after Egert et al. [63]. (e) Saturn, after Kim et al. [44] from the model from Vervack and Moses [5]. The neutral and electron temperatures are also shown, as well as C-1 and C-2 hydrocarbons and H_2O . (f) Uranus, plotted with model data from Moses and Poppe [64]. (g) Neptune, plotted with model data from Moses and Poppe [64]. (h) Pluto. Densities of species derived from line-of-sight integrated densities obtained from solar occultations of the New Horizons spacecraft as a function of geopotential height and altitude. The species are labeled by the color-coded names in the upper right corner. The circles are from data, and the dashed curves, as well as the dotted curves for N_2 and CH_4 are from a model. The N_2 densities at altitudes below about 110 km are from the radio occultation profiles carried out by the New Horizons REX instrument. Also shown (in purple) are the extinction coefficients multiplied by 10^{15} of the hazes. Both ingress and egress values are shown. From Young et al. [8]. (i) (top) Titan model, after Strobel [65]. The measured densities of N_2 , Ar, CH_4 , and H_2 are shown with dashed curves for radial distances above about 3500 km. (The radius of the surface is 2575 km.) The solid curves of these species' densities are from a model. Also shown are the upward fluxes of CH_4 and upward and downward fluxes of H_2 , denoted by $\phi(\text{CH}_4)$, and $\phi(\text{H}_2)$, respectively, and the adopted temperature profile. The loss rates of methane and production rates of H_2 are also shown in units of $\text{cm}^{-3} \text{s}^{-1}$ divided by 10. (bottom) The diversity of neutral species with mass/charge ratios of 60–99, in counts s^{-1} found in the atmosphere of Titan by the Ion and Neutral Mass Spectrometer (INMS) instrument on the Cassini spacecraft. The range of mass/charge is adapted for investigations of benzene and its derivatives. Masses less than 60 amu are not shown but are also present due to the presence of higher hydrocarbons that are ultimately formed from photolysis of methane. The points are the averaged values over the 960–980 km range, and the solid line is from a model. From Vuitton et al. [66]. (j) (top) Triton total neutral densities (largely N_2) as a function of altitude, after Strobel and Zhu [7]. The three curves represent models with different neutral temperature profiles. The red (solid), black (long dashes), and brown (short dashes) curves are those for exospheric temperatures of 97, 90, and 75 K, respectively. Note that the units of number density are SI units of m^{-3} rather than the traditional cm^{-3} . (bottom) Density profiles of minor species on Triton, including H_2 , N, H, and CH_4 . The two profiles that represent C densities are for slight differences in the chemistry ◀

ion density profiles for the Earth and selected planets and satellites are shown in Fig. 88.10a–j.

88.4.3 Nightside Ionospheres

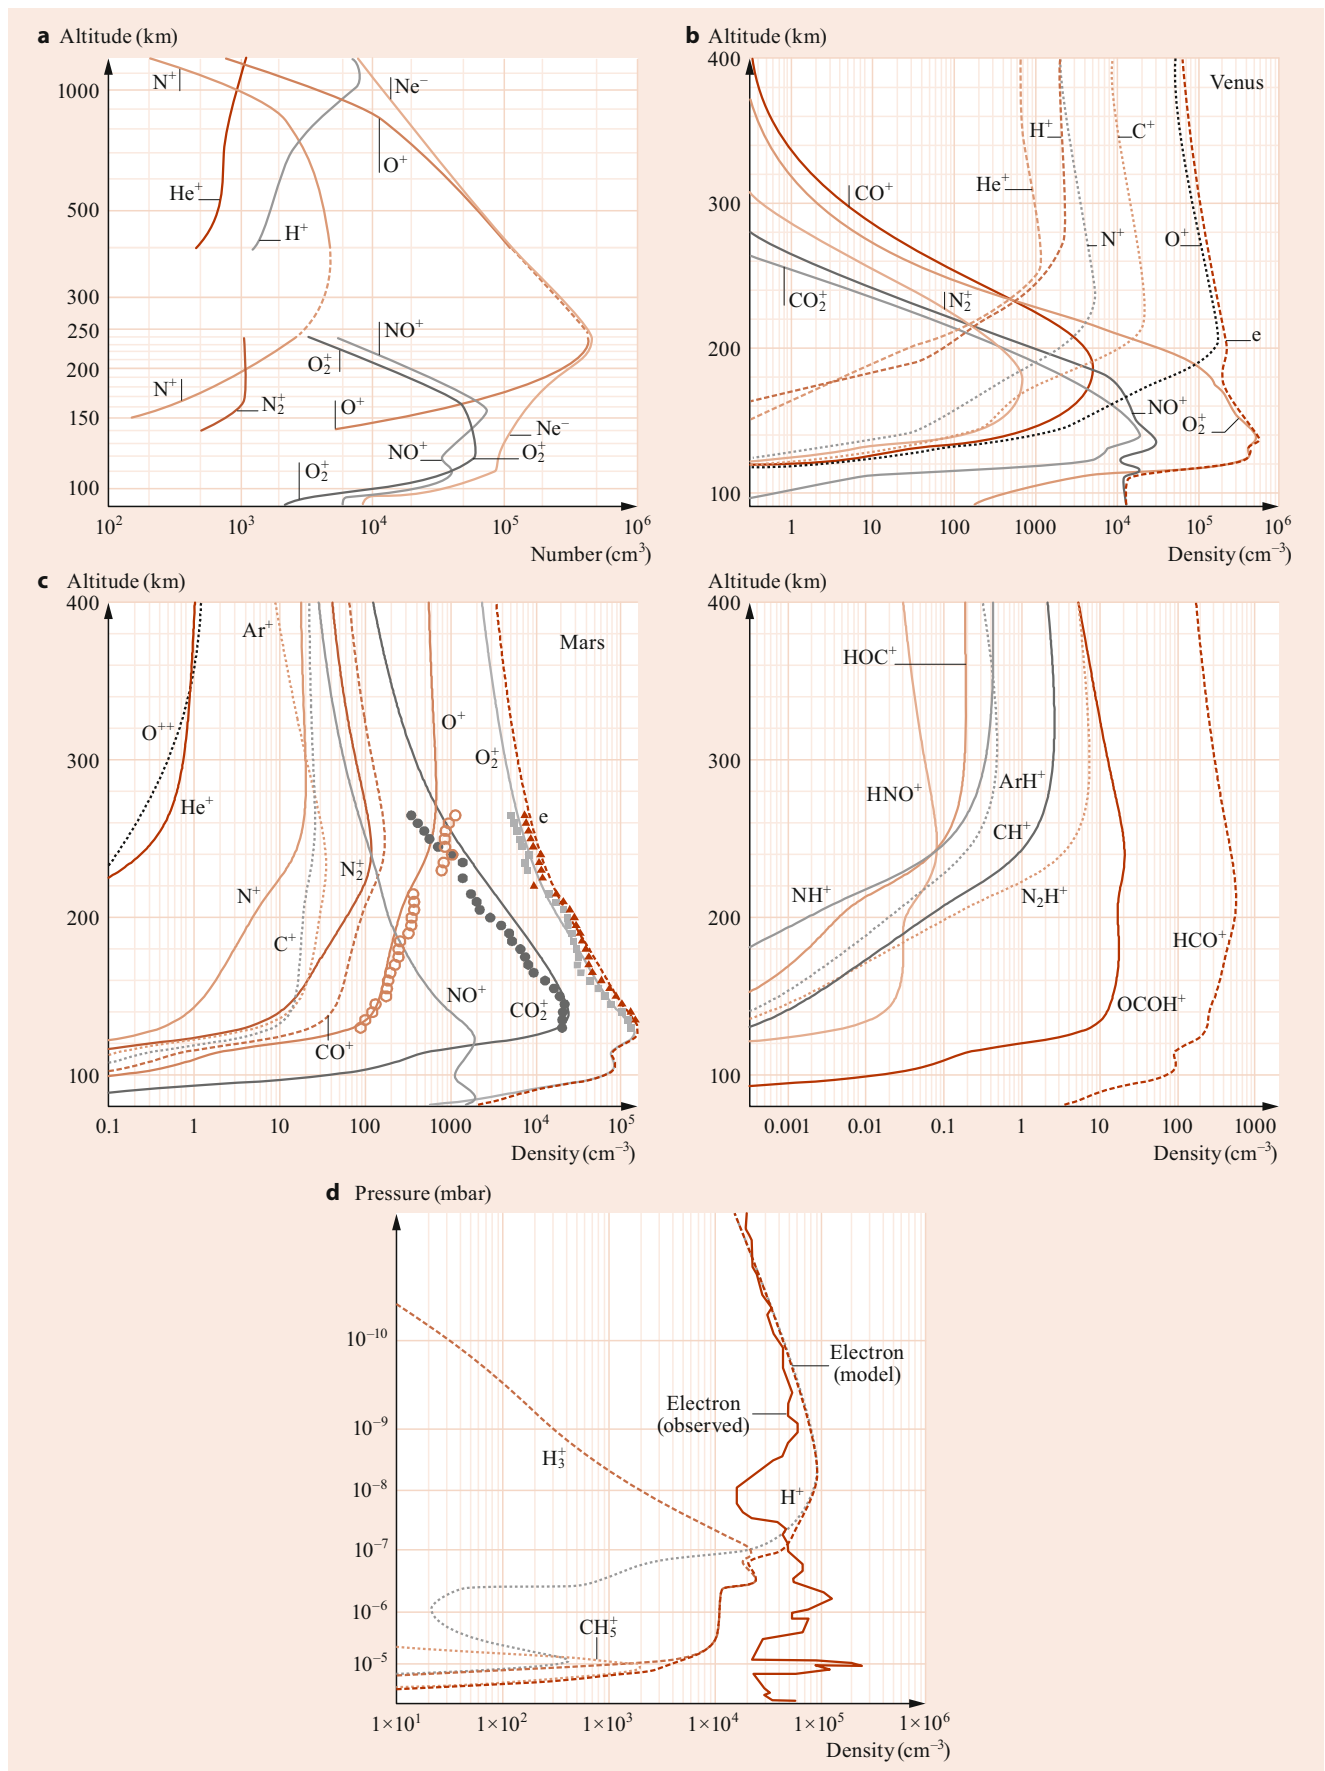

Nightside ionospheres can result from several sources, including remnant ionization from the dayside, like O^+ in the terrestrial ionosphere. While the lower molecular ion layers recombine, the F_2 peak persists through the night, although it rises, and the peak density is reduced by a factor of 10. Electron density profiles for day and night at high and low solar activities are shown in Fig. 88.11. In the auroral regions of the Earth, the precipitating electrons may also produce significant ionization, which maximizes in the midnight sector of the auroral oval.

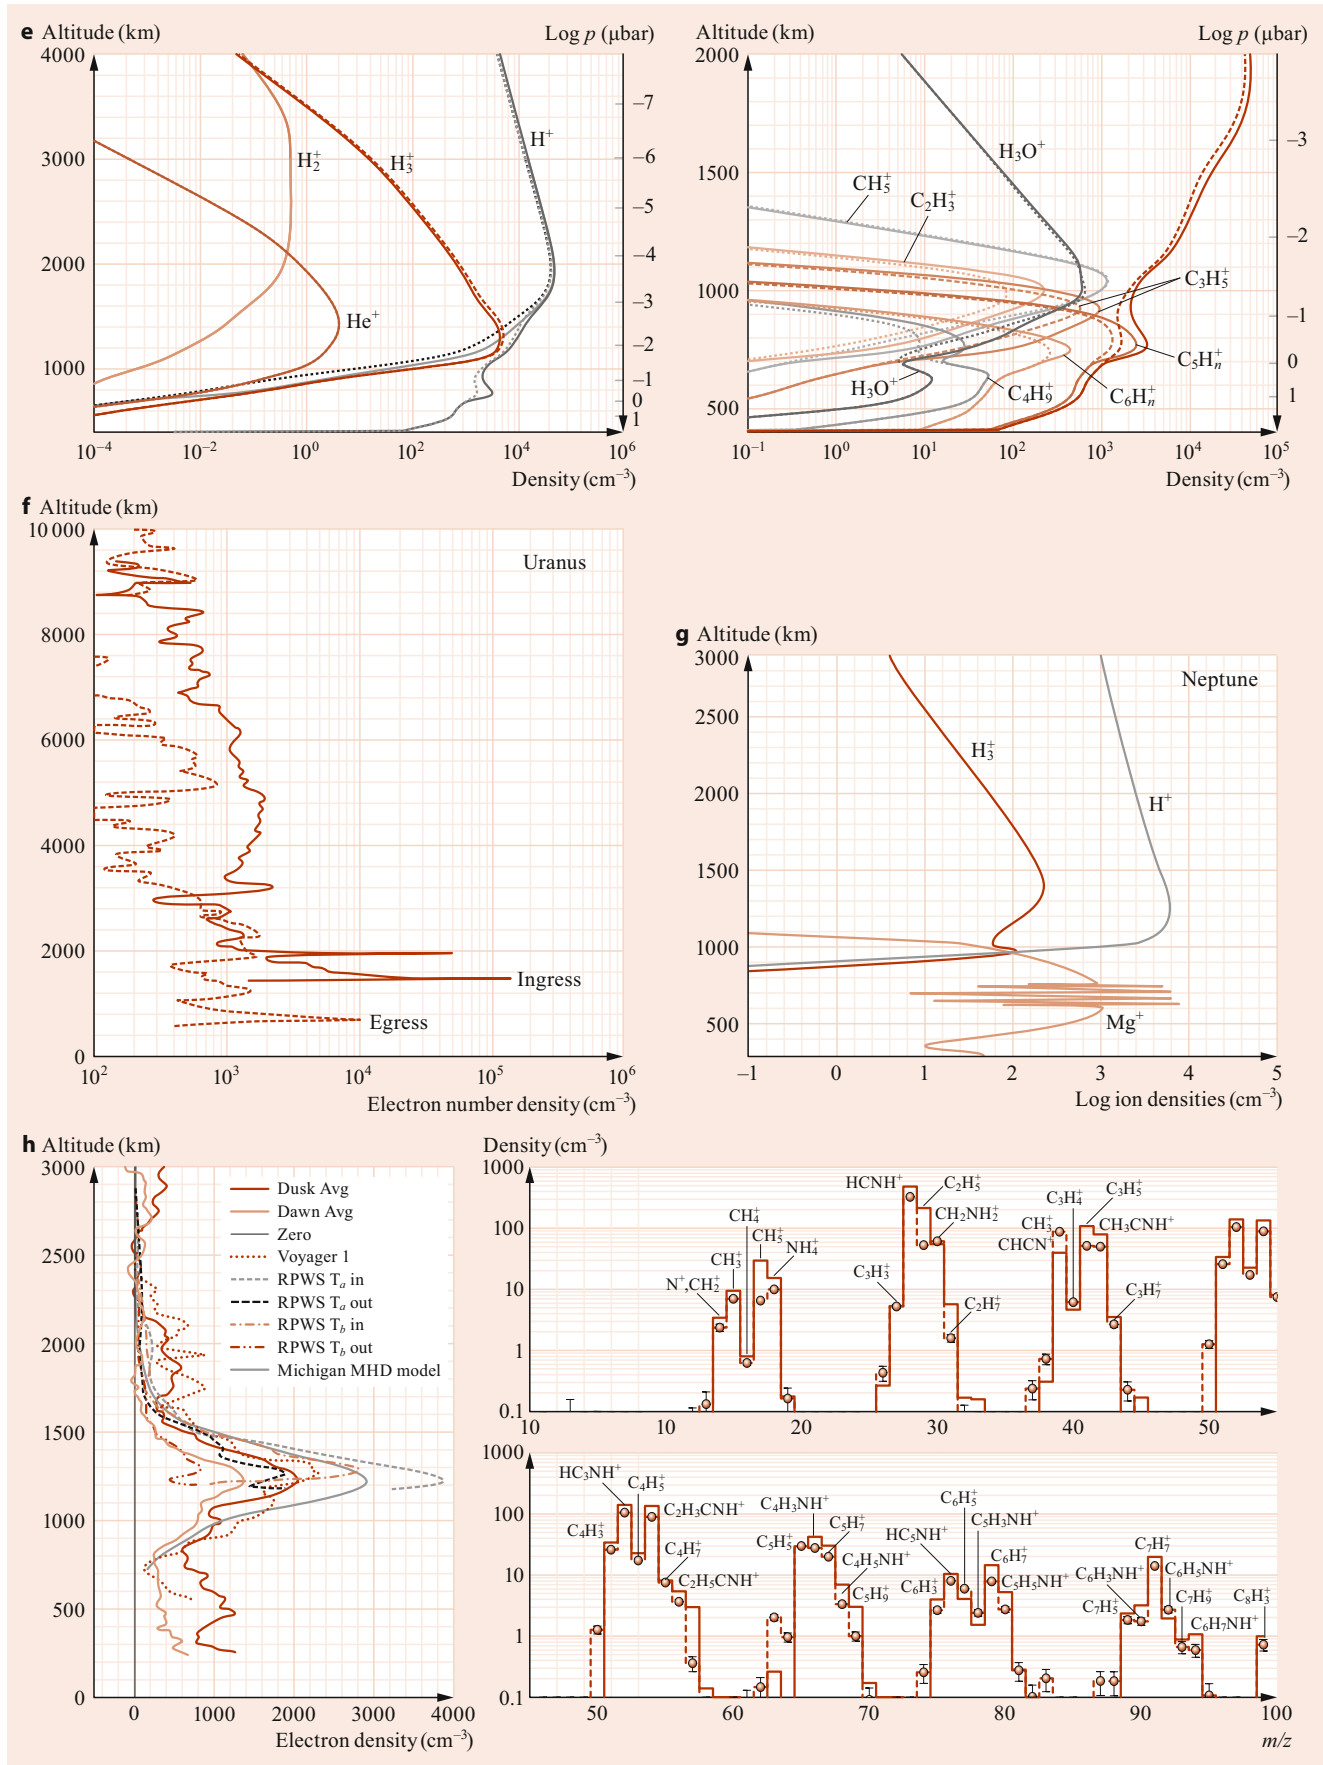

The nightside ionosphere of Venus is highly variable but has been shown to contain the same ions as the dayside ionosphere. The ion and electron densities are, however, smaller by factors of 10 or more than those of the dayside ionosphere, and the average peak in the electron density profile is about $(1\text{--}2) \times 10^4 \text{ cm}^{-3}$. It is produced by a combination of precipitation of suprathermal electrons that have been observed at high altitudes in the umbra, and transport of atomic ions (mostly O^+) at high altitudes from the dayside. For Mars, geometry limits the solar zenith angle probed by radio occultation (RO) measurements beyond the terminator of the nightside to values of about 130° . The

ionosphere is sunlit to about 105° SZA. The nightside ionosphere has been probed by radio occultation experiments on the Mariner 9 orbiter, the Viking spacecraft [76], and by the Mars Global Surveyor (MGS) spacecraft radio sciences (RS) experiment [77]. Until recently, there was no composition information about the nightside ionosphere of Mars.

More recently, however, the Neutral Gas and Ion Mass Spectrometer (NGIMS) on the MAVEN spacecraft has measured ion densities in situ on Mars from periapsis of about 150 km (with occasional “deep dips” down to 125–130 km) to ≈ 500 km at all SZAs, including the nightside. On both the dayside and the nightside of Mars, in addition to the major ions found on the dayside, populations of protonated species, including water-group ions, that is, those that contain only H and O were measured (e.g., Benna et al. [78]; Fox [79]; Fox et al. [80]).

The nightside ion densities for SZAs from 110° to 120° were shown to be smaller by an order of magnitude or more than those of the near-terminator dayside 75° – 80° SZA, and the composition in the lower ionosphere changed from O_2^+ and CO_2^+ to O_2^+ , NO^+ , and HCO^+ , the latter three of which have longer chemical lifetimes than CO_2^+ . For long-lived molecular ions, the major loss process is usually dissociative recombination, but the dissociative recombination coefficient of HCO^+ is particularly uncertain. As for all the known nightside ionospheres, the nightside ion densities have been shown to be quite variable (Girazian et al. [81]).

Fig. 88.10 Ionospheric density profiles. (a) Measured ion density profiles for Earth [67]. (b) Computed ion density profiles for Venus, for high solar activity and a solar zenith angle of 45° . (c) Ion density profiles for Mars, for moderate solar activity ($F_{10.7} = 120$) and a SZA range of 5° – 10° . (Left) major ions and (right) protonated species. The model densities of the major ions O_2^+ , O^+ , and CO_2^+ are compared to the MAVEN NGIMS measurements. Not shown are the density profiles of water ions (H^+ , H_2^+ , H_3^+ , OH^+ , OH_2^+ , H_3O^+). The model has no ambient water other than that produced through ion chemistry. (d) Jupiter, precomet impact model without hydrocarbon ion chemistry. After *Maurellis and Cravens* [68]. (e) Saturn, after *Kim et al.* [44], who adopted the model of *Vervack, Jr. and Moses* [5]. The total electron density profiles are shown with a thick curve. The SZA is 27° , and the magnetic dip angle is 45° . (Left) model density profiles of the H-containing ions and He^+ . (Right) model density profiles of hydrocarbon ions and H_3O^+ . (f) Uranus. Voyager 2 radio occultation electron density profiles for ingress and egress. From *Lindal et al.* [69]. (g) Neptune. From a model of *Lyons* [70], also [71]. (h) (Left) Titan. Electron density profiles measured by various instruments including the Voyager 1 radio occultation and in situ measurements of electron densities by the Cassini RPWS (Radio and Plasma Wave Science) LP (Langmuir probe) on the first two flybys, Ta and Tb, along with the dawn and dusk averages from the Cassini radio occultations, and one model. From *Kliore et al.* [72]. (Right) Titan. Cassini INMS (Ion and Neutral Mass Spectrometer) ion density measurements compared to a model at 1100 km. The abscissa is the mass/charge ratios from 0 to 55 is shown on the upper panel, and those from 45 to 100 are shown on the lower panel. From the review by *Vuitton et al.* [73]. (i) Triton. From the model of *Strobel and Summers* [74]. (j) Pluto. Upper limits to electron density profiles from a model (*Hinson et al.* [37]). That for the subsolar point (SZA = 0°) is shown in red, and that for the terminator region is in orange. No ionosphere was detected, however, by the New Horizons' radio science experiment

On satellites whose trajectories take them into the magnetospheres of the planet that they orbit, such as Titan around Saturn, or Triton around Neptune, ionization on the dayside or nightside may be produced by the impact of energetic electrons from these magnetospheres. The nightside ion densities of Titan have been shown to be a factor of ≈ 4 smaller than those of the dayside (*Ågren et al.* [82]).

At this time, there is no information available about the nightside ionospheres of the outer planets. Radio occultations can only probe the near-terminator ionospheres because of geometrical considerations. Just as on the dayside, only modeling can predict the identity of the major ions.

88.4.4 Ionospheric Density Profiles

Density profiles of molecular ions have often been approximated as idealized Chapman layers. A Chapman layer of ions is one in which the ions are produced by photoionization and

lost locally by dissociative recombination. The ionization rate q^i in a one-species Chapman layer for monochromatic radiation is given by

$$q^i = F\sigma^i n, \quad (88.51)$$

where σ^i is the ionization cross section, and $F = F^\infty \exp[-\tau(z)]$ is the local solar flux. For an isothermal atmosphere, the scale height is approximately constant and, therefore, $n = n_0 \exp(-z/H)$. Sometimes an ionization efficiency η^i is defined such that

$$\sigma^i = \eta^i \sigma^a. \quad (88.52)$$

Near threshold, the ionization efficiency for molecules is usually about 0.3–0.7, but it increases rapidly to 1.0 at shorter wavelengths, usually less than $\approx 600 \text{ \AA}$.

Since the maximum ionization rate in an isothermal atmosphere occurs where the optical depth ($\tau = nH\sigma^a \sec \chi$)

Fig. 88.11 Typical midlatitude ionospheric electron density profiles for sunspot maximum and minimum, day and night. After *Richmond* [75]

is unity and, therefore, $n = 1/(\sigma^a H \sec \chi)$, the maximum ionization rate in a Chapman layer is

$$q_{\max,\chi}^i = \frac{F^\infty}{e} \frac{\sigma^i}{\sigma^a H \sec \chi} = \frac{q_{\max,0}^i}{\sec \chi}. \quad (88.53)$$

If the altitude of maximum ionization for overhead sun is defined as $z = 0$, then $n_0 = (\sigma^a H)^{-1}$, and, expressing F^∞ in terms of $q_{\max,0}^i$, the ionization rate is

$$q^i(z) = q_{\max,0}^i \exp\left(1 - \frac{z}{H} - \sec \chi e^{-z/H}\right). \quad (88.54)$$

It is apparent that at high altitudes ($z \rightarrow \infty$), the ionization profile follows that of the neutral density, and below the peak ($z \rightarrow -\infty$), the ionization rate rapidly approaches zero. As the solar zenith angle increases, the peak rises, and the magnitude of the density maximum decreases. Figure 88.12 shows a production profile for an idealized Chapman layer on both linear and semilog plots. The asymmetry with respect to the maximum is more obvious for the semilog plot.

If photochemical equilibrium prevails, the production rate of the major molecular ion is equal to the loss rate due to dissociative recombination

$$q^i(z) = \alpha_{\text{dr}} n_i n_e = \alpha_{\text{dr}} n_i^2, \quad (88.55)$$

where α_{dr} is the dissociative recombination coefficient, n_i is the ion density, and n_e is the electron density. Therefore, the

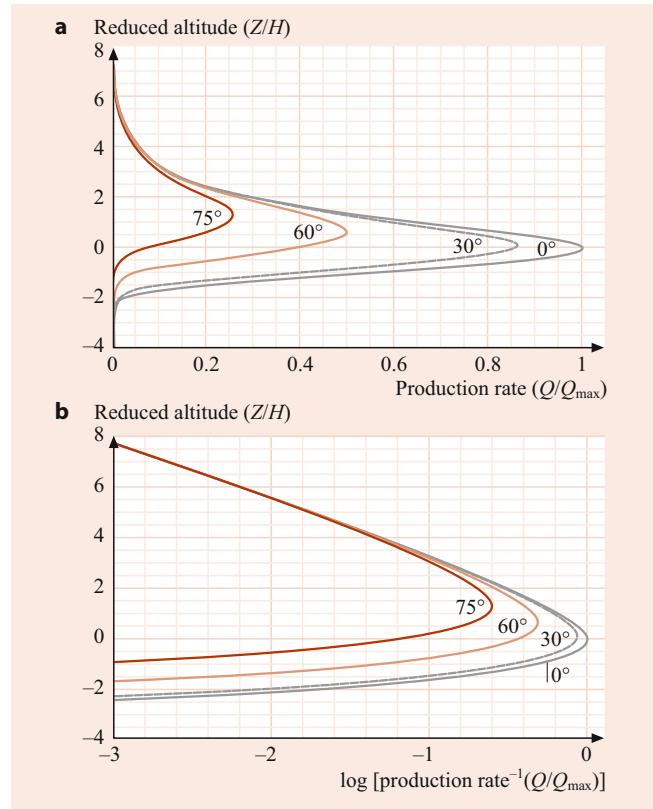

Fig. 88.12 Chapman production profile as a function of altitude on linear (a) and semilog plots (b). The production rate is divided by the maximum production rate and the altitude by the scale height H , which is assumed to be constant. The origin on the altitude scale corresponds to the point of maximum absorption for overhead sun

density of an ion in a Chapman layer (in the photochemical equilibrium region) is given by

$$\begin{aligned} n_i(z) &= \left(\frac{q^i(z)}{\alpha_{\text{dr}}}\right)^{1/2} \\ &= \left(\frac{q_{\max,0}^i}{\alpha_{\text{dr}}}\right)^{1/2} \exp\left(\frac{1}{2} - \frac{z}{2H} - \frac{1}{2} \sec \chi e^{-z/H}\right). \end{aligned} \quad (88.56)$$

Actual ion density profiles differ from the idealized Chapman profile for several reasons. First, ionization is produced by photons over a range of wavelengths, which do not all reach unit optical depth at the same altitude. Second, thermospheres are usually not isothermal near the altitude of peak ion production. Third, photoionization is supplemented by photoelectron-impact ionization, which peaks lower in the atmosphere. Fourth, the major ion produced is often transformed by ion–molecule reactions before it can recombine dissociatively; finally, the underlying neutral atmosphere undergoes changes with SZA. Nonetheless, the idealized concept of the Chapman profile is useful in attaining a general understanding of the shape of ion profiles and their behavior as the solar zenith angle changes. In addition, ion

layers produced by auroral precipitation may take on a similar appearance to a Chapman-type layer, although energetic electrons are not extinguished, as are photons, in ion production. Although attempts have been made to express real ionospheric profiles in terms of Chapman layer theory, ion layers rarely, if at all, fit true, or even slightly modified Chapman layers.

88.4.5 Ion Diffusion

Above the photochemical equilibrium layer of the ionosphere, upward and downward transport of ions must be considered. The motions of ions, neutrals, and electrons are coupled, and the momentum equation, which determines the fluxes or velocities of the ions must take into account these interactions. The interaction of an ion, denoted by a subscript i , with a neutral species denoted by a subscript n , is through the ion-induced dipole attraction or, for the diffusion of an ion through its parent neutral, by resonant charge transfer. For the former process, the ion-neutral diffusion coefficient is given by

$$D_{in} = \frac{k_B T}{m_i \bar{v}_{in}}, \quad (88.57)$$

where m_i is the mass of the ion, and the ion-neutral momentum transfer collision frequency

$$\bar{v}_{in} = 2.21 \pi \frac{n_n m_n}{m_i + m_n} \left(\frac{\alpha_n e^2}{\mu_{in}} \right)^{1/2}, \quad (88.58)$$

where α_n is the polarizability of the neutral species (*Dalgarno et al. [83], Schunk and Nagy [84]*). For the resonant charge transfer interaction, the diffusion coefficient is

$$D_{in}^{ct} = \frac{3(\pi/2)^{1/2}}{8n_n \bar{Q}_{in}^{ct}} \left(\frac{k_B T_i}{m_i} \right)^{1/2} \frac{1}{(1 + T_n/T_i)^{1/2}}, \quad (88.59)$$

where \bar{Q}_{in}^{ct} is the average charge transfer cross section [85]. It should be noted that the forgoing effect does not apply to accidental resonances, since it arises from the indistinguishability of the nuclei.

The momentum transfer collision frequency for Coulomb interactions between an ion i and another ion or electron denoted by the subscript s is

$$\bar{v}_{is} = \frac{16\pi^{1/2}}{3} \frac{n_s m_s}{m_i + m_s} \left(\frac{\mu_{is}}{2k_B T_{is}} \right)^{3/2} \frac{e_i^2 e_s^2}{\mu_{is}^2} \ln \Lambda, \quad (88.60)$$

where e_s is the charge on species s , $\ln \Lambda$ is related to the Debye shielding length, and $T_{is} = (m_s T_i + m_i T_s)/(m_i + m_s)$

is a reduced temperature. Numerically, $\ln \Lambda$ is about 15, and the collision frequency is approximately [84]

$$\bar{v}_{is} = 1.27 \frac{Z_i^2 Z_s^2 \mu_{is}^{1/2} n_s}{m_i T_{is}^{3/2}}, \quad (88.61)$$

where Z is the species charge number, μ and m are in amu, and the number density is in units of cm^{-3} .

The ion densities can be computed by solving the ion continuity equation, which is similar to Eq. (88.7) for neutral species, and in one dimension is

$$\frac{\partial n_i}{\partial t} + \frac{\partial \Phi_i}{\partial z} = P_i - L_i, \quad (88.62)$$

where the ion flux is given by $\Phi_i = n_i w_i$. In general, it is impossible to solve the momentum equation for the ion diffusion velocity w_i in closed form, except for the special cases of a single major ion and of a minor ion moving through a dominant ion species. If only motion of the ions parallel to magnetic field lines is considered, the vertical velocity of a dominant ion (for which $n_i \approx n_e$) moving through a stationary neutral atmosphere is

$$w_i = -D_a \sin^2 I \times \left(\frac{1}{n_i} \frac{dn_i}{dz} + \frac{m_i g}{k(T_e + T_i)} + \frac{1}{T_e + T_i} \frac{d(T_e + T_i)}{dz} \right), \quad (88.63)$$

where I is the magnetic dip angle, and the ambipolar diffusion coefficient is defined as

$$D_a = \frac{k_B(T_e + T_i)}{m_i \bar{v}_{in}}. \quad (88.64)$$

For a minor ion i diffusing through a major ion species j , its velocity is given by

$$w_i = -\frac{k_B T_i / m_i}{\bar{v}_{ij} + \bar{v}_{in}} \times \left(\frac{1}{n_i} \frac{dn_i}{ds} + \frac{T_e / T_i}{n_e} \frac{dn_e}{ds} + \frac{m_i g}{k_B T_i} + \frac{1}{T_i} \frac{d(T_e + T_i)}{ds} \right) - \frac{\bar{v}_{ij} w_j}{\bar{v}_{ij} + \bar{v}_{in}}. \quad (88.65)$$

For regions in which there are large gradients in the ion or electron temperatures, thermal diffusion may also be important in determining the ion density profiles, especially those of light ions such as H^+ and He^+ . Equations for ion distributions in which thermal diffusion is included have been presented by, for example, *Schunk and Nagy [84]*; see also references therein.

88.5 Neutral, Ion, and Electron Temperatures

The temperature distribution in planetary thermospheres/ionospheres can be modeled by solving the equation for conservation of energy, which, in a simplified form in the vertical direction is

$$n_m \frac{\mathcal{N}}{2} k_B \frac{\partial T_m}{\partial t} - \frac{\partial}{\partial z} \left(\kappa_m \frac{\partial T_m}{\partial z} \right) = Q_m - L_m \quad (88.66)$$

where \mathcal{N} is the number of degrees of freedom (three for an atom and five for a diatomic molecule), the subscript m refers to the neutrals, ions or electrons, κ_m is the thermal conductivity, Q_m is the volume heating rate, and L_m is the volume cooling rate. If horizontal variations are considered, the model becomes multidimensional, and advective terms must be added to the equations. The values of T_m are also affected by compression or expansion due to subsidence or upwelling, respectively. Viscous heating may be a factor where there are local regions of intense energy input, such as in auroral arcs. These terms are not shown in the energy equation above but may be found in standard aeronomy texts, such as *Banks and Kockarts* [85], *Whitten and Popoff* [86], *Rees* [50], and *Schunk and Nagy* [87]. For planets with intrinsic magnetic fields, the electrons and ions are constrained to move along magnetic field lines, and the second term on the left-hand side of Eq. (88.66) must be multiplied by a factor $\sin^2 I$.

The neutral thermospheres of planets are mostly heated by absorption of solar radiation in the 10–2000 Å range, although on planets with powerful auroras, electron precipitation may be an important source of heat. Absorption of EUV radiation (100–1000 Å) largely results in ionization of the major thermospheric species, in which most of the excess energy is carried away by the photoelectron. The photoelectron, however, may produce further dissociation or excitation of neutral species along the path to thermalization, and these processes may result in neutral heating. Photons near and longward of ionization thresholds in the FUV may lose their energy in photodissociation, in which the excess energy of the photon appears as kinetic or internal energy of the fragments.

Chemical reactions that follow ionization or dissociation release much of the absorbed solar energy as heat. Although the partitioning of kinetic energy released between the product species can easily be determined by conservation of energy and momentum, the fraction of energy that appears as internal or kinetic energy must be determined by measurements or theoretical calculations. If vibrationally or electronically excited states are produced in these interactions, however, the energy may be radiated to space, thus producing cooling. This may occur promptly if the radiative lifetime is short, or subsequent to an energy transfer process from a long-lived metastable species to a species for which radiation to a lower state is allowed. If the metastable species is quenched, however, its energy can also appear as

heat. Thus, the energy partitioning in chemical reactions and in the interactions of photons and photoelectrons with atmospheric species is important in understanding the temperature structure of thermospheres.

A heating efficiency ϵ is often defined as the fraction of energy absorbed at a given altitude that appears locally as heat. The heating efficiencies are in the range 30%–40% in the terrestrial lower thermosphere. Above 200 km, the heating efficiency decreases because the energy of the important metastable species $O(^1D)$ is lost as radiation rather than by quenching [88]. The heating efficiencies in the thermospheres of Venus and Mars are about 20% from 100 to 200 km [89, 90], and on Titan, they range from 20% to 30% from 800 to 2000 km. A column averaged heating efficiency for the Jovian thermosphere has been computed as 53% [91].

On Venus and Mars, CO_2 is the major absorber of far UV radiation, whereas on the Earth, O_2 plays that role. In the F_1 regions of the ionospheres of the terrestrial planets, dissociative recombination of molecular ions tends to be the major source of heating. Below the F_1 peak, photodissociation and neutral–neutral reactions, including quenching of metastable species, dominate. Since CH_4 is a very strong absorber, the major heating mechanisms in the thermosphere of Titan are photodissociation and neutral–neutral reactions, both above and below the F_1 peak. The few data that exist suggest that electron-impact dissociation is unimportant as a source of neutral heating, although further measurements would certainly be of benefit. Profiles of the heat sources in the terrestrial thermosphere and those of Mars and Titan are also shown in Fig. 88.13.

Important cooling processes in planetary thermospheres include downward transport of heat by molecular and eddy conduction and infrared cooling from rotational and vibrational excitation of IR active species such as NO, CO, and CO_2 . Excitation of the fine structure levels of atomic oxygen and subsequent emission at 63 and 147 μm also plays a role in cooling the neutral species in the thermospheres of the terrestrial planets. In the outer planets and their satellites, hydrocarbon molecules such as CH_4 and C_2H_2 are the primary thermospheric IR radiators. The global circulation may play a role in redistributing the heat that is deposited in the dayside or auroral thermosphere [95, 96].

In order to model heating rates, cross sections for processes in which solar photons or photoelectrons interact with neutral species, and rate coefficients and product yields for chemical reactions of ions and neutral atmospheric species are necessary. In addition, it is necessary to know, for example, how much of the energy released appears as internal energy of the products in chemical reactions and how much appears as kinetic energy of the products. Knowledge of energy transfer processes, including vibration–vibration (V–V) and translation–vibration (T–V) transfer between atmospheric species is also important. For example, a particularly

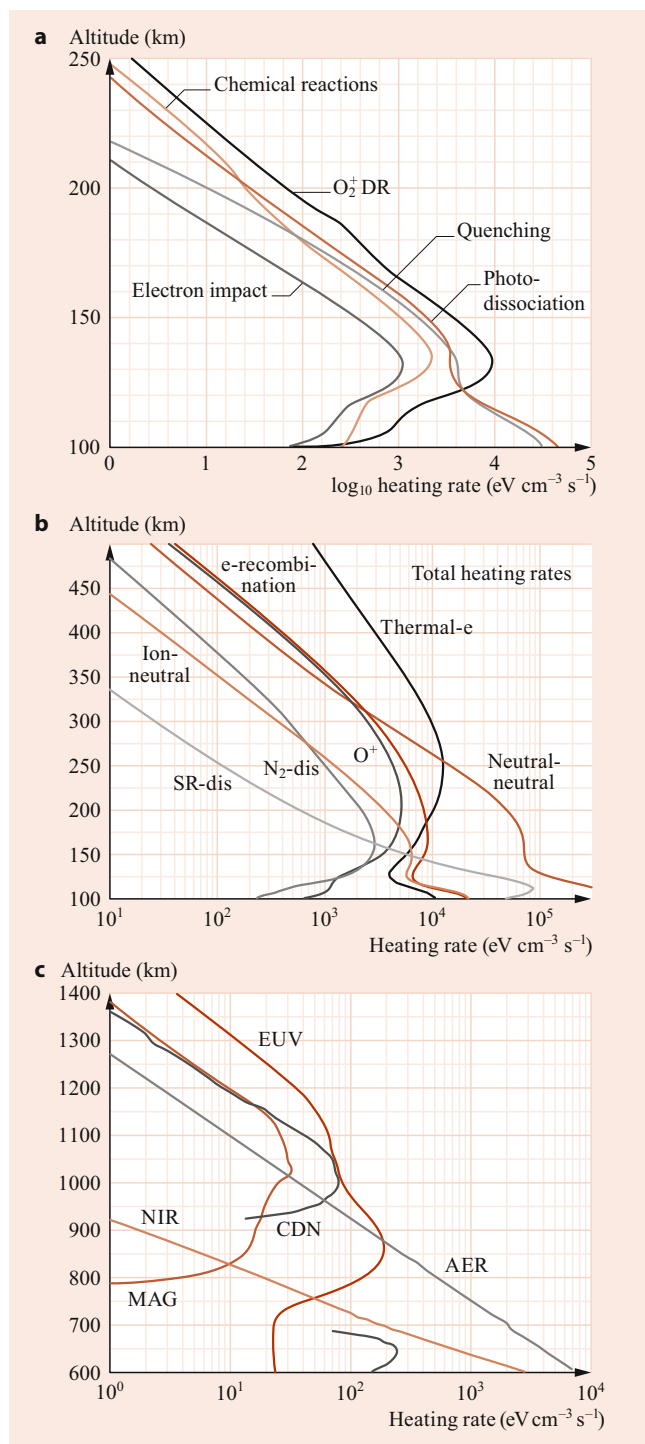

Fig. 88.13 Heating rates for the thermospheres of (a) Mars, (b) Earth, and (c) Titan. In (b), the curve labeled “Thermal-e” is the heating rate due to collisions between the neutrals and electrons, “O⁺” is the heating rate due to reactions of O⁺ with neutrals; “ion-neutral” is the heating rate due to other exothermic neutral-ion reactions. “Neutral-neutral” is the heating rate due to neutral-neutral chemical reactions; “e-recombination” is the heating rate due to dissociative recombination reactions; N₂-dis is the heating rate due to dissociation of N₂; SR-dis is the heating rate due to absorption by O₂ in the Schuman–Runge bands and continuum. From Richards [92]. In (c), the heating rates in the atmosphere of Titan due to five sources are shown. EUV represents solar heating, CDN represents heating due to thermal conduction, AER represents heating by aerosols, MAG is the heating due to magnetospheric ion precipitation, NIR is the heating due to absorption of the near infrared bands of CH₄. After Snowden [93]; see also Snowden and Yelle [94] ◀

important cooling process for the thermospheres of the terrestrial planets is excitation of the CO₂ 15 μm ν₂ bending mode in collisions with energetic O, and subsequent radiation [97]. The deexcitation rate coefficient is several percent of gas kinetic, which is anomalously large for a V–T process [98].

In the lower ionosphere, the electrons and ions are in thermal equilibrium with the neutral species, but at higher altitudes the plasma temperatures deviate from the neutral tem-

peratures. Near the F₁ peak, T_e is usually larger than T_i, but T_i begins to diverge from T_e at higher altitudes. The source for the energetic electrons on the dayside is largely photoionization, which, as discussed above, produces photoelectrons with average energies in the 15–20 eV range. In slowing down, these electrons lose their energy in inelastic processes with neutrals until E ≈ 1–2 eV. At this point, elastic scattering by the thermal electron population becomes the dominant energy loss process for the suprathermal electrons and the major source of heat for the thermal electrons. Other heating mechanisms for thermal electrons include deactivation of electronically or vibrationally excited species, and, for the terrestrial planets, quenching of the fine structure levels of O.

As for the neutrals, heat in the electron gas is redistributed by conduction at a rate that depends on the electron thermal conductivity. This quantity is inversely proportional to the sum of the momentum transfer collision frequencies of electrons with ions, neutrals, and ambient electrons. Cooling mechanisms for thermal electrons include Coulomb collisions with ions, rotational excitation of molecules, and, for the terrestrial planets, excitation of the fine structure levels of O. Because of the large mass difference, elastic collisions between neutrals and electrons are not effective in transferring kinetic energy.

In the ionosphere, T_i is elevated above T_n at high altitudes principally because of Coulomb collisions of ions with energetic electrons. Another potentially important source of heat input to the ions near the ion peak is exothermic ion–neutral reactions, including quenching of metastable ions, such as O⁺(²D), by neutrals. In the presence of electric fields, Joule heating may be important and can cause T_i to exceed T_e.

The ions cool in elastic collisions and resonant charge transfer with neutral species, which are characterized by lower temperatures than the ions. The cooling rate for elastic collisions is

$$L_{\text{in}} = -2n_i \frac{m_i}{m_i + m_n} \bar{v}_{\text{in}} \frac{3}{2} k_B (T_i - T_n). \quad (88.67)$$

Collisions between ions and neutrals (other than their parents) are dominated by the ion-induced dipole interaction. The momentum transfer collision frequency $\bar{\nu}_{in}$ is, thus, given by Eq. (88.58). Resonant charge transfer between an ion and its parent neutral, such as

leads to very effective ion cooling, which dominates at sufficiently high temperatures.

Examples of T_i and T_e profiles are shown in Fig. 88.14a–f for various bodies, including Earth, Venus, Mars, Titan, and Saturn. The International Reference Ionosphere (IRI) temperature profiles for the terrestrial thermosphere show the close coupling between the electrons, ions, and neutrals at low altitudes and the ions and electrons at high altitudes; T_i increases with increasing solar activity at low altitudes and approaches T_e at high altitudes. The values of T_e and T_i are about 2000–3000 K at 1000 km on the dayside and slightly smaller on the nightside [105]. Electron and ion temperatures in the terrestrial ionosphere have been discussed by Rees [50], Banks and Kockarts [85], Whitten and Popoff [86], and Schunk and Nagy [106].

In the Venus atmosphere, T_e and T_i were measured by instruments on the PVO, including the Langmuir Probe (LP) (e.g., Brace et al. [107]) and the Retarding Potential Analyzer (ORPA) (e.g., Miller et al. [99]). The values of T_i were found to be in the range 2000–2500 K at high altitudes and to be insensitive to the solar zenith angle, except beyond about 150° SZA, where T_i increases to values of 5000–6000 K [99]. Measured values of T_e do not vary appreciably with the solar zenith angle; the high altitude values are in the range 4000–6000 K [108].

The STATIC (Superthermal and Thermal Ion Composition) experiment on the MAVEN spacecraft found that T_i on Mars decouples from the T_n near 180–200 km and approaches values of about 1000–1200 K at high altitudes (McFadden [100]). The electron temperatures on Mars have been measured by the LPW (Langmuir Probe and Waves) instrument on the MAVEN spacecraft (e.g. Ergun et al. [101]); T_e is predicted to diverge from the T_n in the lower ionosphere (120–130 km) and has been found to approach values of 3000–4000 K at high altitudes.

The plasma temperatures on Titan have been measured and predicted by models. Electrons from Saturn's magnetosphere may interact with the Titan ionosphere during the part of its orbit that is within Saturn's magnetosphere. In this case, T_e is predicted to increase to values that are about 5000 K near 2000 km. The models of Richard et al. [103] showed that the predicted altitude profiles of the ion and electron temperatures depend greatly on the magnetic field orientation near a given location. Their computed results are shown in Fig. 88.14d and e. They deviate significantly from the val-

ues measured by the Cassini Plasma Spectrometer (CAPS) and the Radio and Plasma Wave Science/Langmuir Probe (RPWS/LP) on the Cassini spacecraft (Ågren et al. [82]; Crary et al. [102]).

88.6 Luminosity

The luminosity that originates in the atmospheres of the planets is generally classified as dayglow, nightglow, or aurora. Dayglow is the luminosity of the dayside atmosphere that occurs as a more or less direct result of the interaction of solar radiation with atmospheric gases. Among the sources of dayglow are photodissociative excitation and simultaneous photoionization and excitation. Dayglow may also include scattering of solar radiation by processes that are selective, such as resonance scattering by atoms and fluorescent scattering by molecules, but the term generally excludes nonselective scattering processes, such as Rayleigh scattering.

In resonance scattering, the absorption of a photon by an atom in the ground state causes a (usually dipole allowed) transition to a higher electronic state

followed by the emission of a photon as the state decays back to the ground state

The wavelength of the emitted radiation is very nearly the same as that of the radiation absorbed. The cross section for absorption of a line in the solar spectrum is

$$\sigma_{12}^a(\nu) = \frac{\varpi_2}{\varpi_1} \frac{c^2}{8\pi\nu^2} A_{21} \phi(\nu), \quad (88.71)$$

where the subscript 1 indicates the lower state and 2 the upper state, ϖ is the statistical weight of the state, and $\nu = c/\lambda$ is the frequency of the transition; A_{21} is the Einstein A coefficient for the transition, and $\phi(\nu)$ is the lineshape function, which in this equation is normalized so that the integral over all frequencies is unity.

If the linewidth is determined by the spread of velocities of the species, the lineshape $\phi(\nu)$ is a Doppler (Gaussian) profile

$$\phi_D(\nu) = \frac{c}{u\nu_0\sqrt{\pi}} \exp\left[-\left(\frac{\nu - \nu_0}{\nu_0}\right)^2 \frac{c^2}{u^2}\right], \quad (88.72)$$

where ν_0 is the frequency at the line center. The variable $u = (2k_B T/m)^{1/2}$ is the modal velocity of a gas in thermal

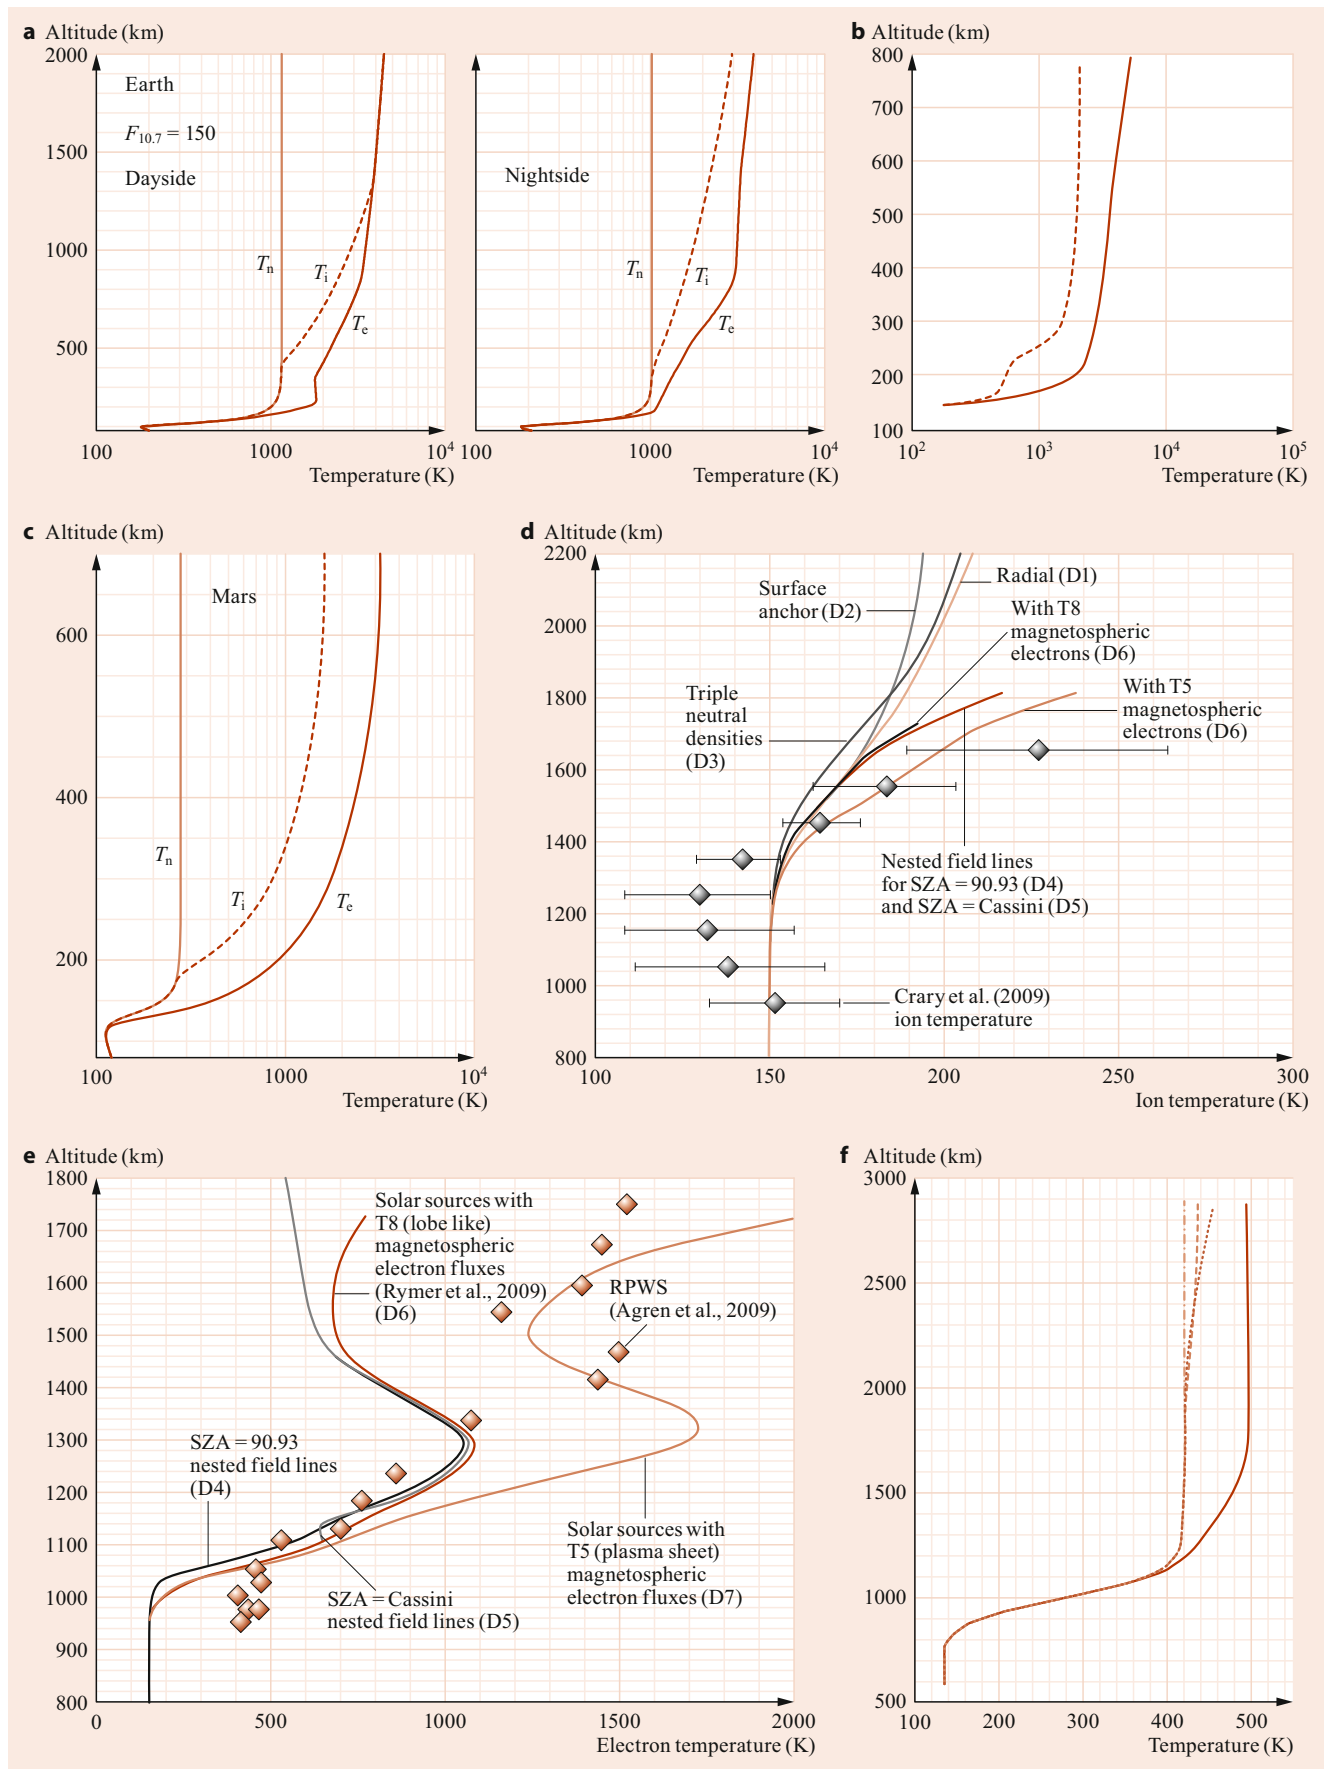

Fig. 88.14 Neutral (T_n), ion (T_i), and electron (T_e) temperature profiles for selected planets. (a) For the dayside terrestrial ionosphere from the International Reference Ionosphere (IRI) for equinox, noon, and moderate solar activity ($F_{10.7} = 150$). (Left) dayside; (right) nightside. The T_e is found to not vary substantially with SZA. Downloaded from the IRI website irmodel.org. (b) Smoothed median ion (dashed curve) and electron (solid curve) temperatures in the Venus ionosphere as measured by the Pioneer Venus (PV) retarding potential analyzer and the Langmuir probe, respectively. The electron temperature profile is essentially constant with the solar zenith angle. The ion temperature profile applies to solar zenith angles between 0 and 90°. After [99]. (c) Mars. Temperatures fit to the MAVEN model for $F_{10.7} = 120$; T_n is fit to the CO₂ density profile; T_i is fit to the ion temperatures at 200 km and at high altitudes *McFadden* [100]. It is assumed to deviate smoothly from the neutral temperature profile at 180 km. The T_e profile is based on that of *Ergun et al.* [101] at 200 km and above and adjusted smoothly to converge with the value of T_n at 125 km. (d) Titan T_i dayside models for various magnetic field configurations compared to measurements of the Cassini spacecraft (*Cravay et al.* [102]). From *Richard et al.* [103]. (e) Titan (T_e) dayside models for various magnetic field configurations compared to measurements of the Cassini RPWS/LP (*Ågren et al.* [82]). From *Richard et al.* [103]. (f) Saturn, T_n , T_i , and T_e for 07:00 LT (local time). The dash-dot curve is the T_n profile. The solid curve is the T_e profile, and the dotted and dashed curves are for H⁺ and H₃⁺, respectively. From *Moore et al.* [104] ◀

equilibrium at temperature T . The width of the line at half maximum, $\Delta\nu_D$ is

$$\Delta\nu_D = \frac{2\nu_0 u}{c} (\ln 2)^{1/2}. \quad (88.73)$$

If the linewidth is determined by the natural lifetime, the profile is a Lorentzian

$$\phi_L(\nu) = \frac{\Delta\nu_L/2\pi}{(\nu - \nu_0)^2 + (\Delta\nu_L/2)^2}, \quad (88.74)$$

where $\Delta\nu_L = \Gamma_R/2\pi$ is the linewidth at half-maximum, and

$$\Gamma_R = \Gamma_2 + \Gamma_1, \quad (88.75)$$

where Γ_2 and Γ_1 are the inverse radiative lifetimes of the levels 2 and 1, respectively. Collisional broadening also results in a Lorentzian lineshape. If both Doppler and natural broadening mechanisms are important, the lineshape is a convolution of the two profiles, called a Voigt profile

$$\phi_V(\nu) = \int_{-\infty}^{\infty} \phi_D(\nu') \phi_L(\nu - \nu') d\nu'. \quad (88.76)$$

The absorption cross section σ_{12}^a integrated over all frequencies is proportional to the absorption oscillator strength f_{12}

$$\int_0^{\infty} \sigma_{12}^a(\nu) d\nu = \frac{\pi e^2}{m_e c} f_{12}, \quad (88.77)$$

where m_e is the mass of the electron; A_{21} is related to the oscillator strength through

$$A_{21} = \frac{\omega_1}{\omega_2} \frac{8\pi^2 e^2 \nu^2}{m_e c^3} f_{12} = \frac{\omega_1}{\omega_2} \frac{8\pi^2 e^2}{m_e c \lambda^2} f_{12}. \quad (88.78)$$

The excitation rate q_2 of an upper level 2 by resonance scattering is given by

$$q_2 = F(\nu) \frac{\pi e^2}{m_e c} f_{12} = F(\lambda) \frac{\omega_2}{\omega_1} \frac{\lambda^4}{8\pi c} A_{21}, \quad (88.79)$$

where $F(\nu)$ is the solar flux in units of photons $\text{cm}^{-2} \text{s}^{-1} \text{Hz}^{-1}$, and $F(\lambda)$ is the flux in units of photons $\text{cm}^{-2} \text{s}^{-1}$ per unit wavelength interval. It should be noted that for radiative transfer purposes, the photon flux that we have called $F(\nu)$ is sometimes denoted $\pi F(\nu)$. It is customary in aeronomy to define a *g-factor*, which is the probability per atom that a photon will be resonantly scattered in a particular transition

$$g_{21} = \frac{q_2 A_{21}}{\sum_i A_{2i}}, \quad (88.80)$$

where the sum in the denominator is over all the lower states i that are accessible from the upper state 2. The *g-factor* for unattenuated solar radiation is often quoted at the mean sun–Earth distance or at a particular planet. The volume emission rate $\varepsilon_{21}(z)$ for resonance scattering of a solar photon is then given by

$$\varepsilon_{21}(z) = g_{21} n_1(z), \quad (88.81)$$

where $n_1(z)$ is the number density of atoms in level 1.

In fluorescent scattering, a photon is absorbed by a molecule in a vibrational state ν producing an excited electronic state with a vibrational quantum number ν'

This is followed by emission, at wavelengths that are usually the same as or longer than that of the absorbed photon, to a range of vibrational levels ν'' of a lower state

The volume emission rate of a transition from a level ν' of the upper electronic state to a vibrational level ν'' of a lower electronic state at an altitude z is given by

$$\varepsilon_{\nu'\nu''}(z) = n(z) g_{\nu'\nu''} = n(z) q_{\nu'} \frac{A_{\nu'\nu''}}{\sum_{\nu} A_{\nu'\nu}}, \quad (88.84)$$

where $A_{\nu'\nu''}$ is the transition probability, $n(z)$ is the number density of the molecular species at altitude z , and $q_{\nu'}$ is the

excitation rate of vibrational level v' of the upper electronic state from a range of lower states v . The latter quantity is

$$q_{v'} = \sum_v \eta_v F(\lambda) \frac{\pi e^2}{m_e c^2} \lambda^2 f_{vv'} , \quad (88.85)$$

where η_v is the fraction of molecules in the v vibrational level. A pedagogical review of these quantities and the relationships between them can be found in *Hilborn* [109] (erratum in *Hilborn* [110]).

Dayglow also includes emissions that are the result of the interaction of atmospheric species with the photoelectrons produced in solar photoionization, either by direct excitation

or by simultaneous dissociation and excitation

or ionization and excitation

Electron impact processes are particularly important in producing excited states that are connected to the ground state by dipole forbidden transitions, whereas resonance and fluorescent scattering are largely limited to transitions that are dipole allowed. Dayglow emissions may also result from prompt chemiluminescent reactions, which occur when fragments or ions produced by dissociation or ionization recombine with the emission of a photon.

As an example, the dayglow spectrum of the Earth from 1200 to 9000 Å is shown in Fig. 88.16. An ultraviolet spectrum of Mars as measured by the MAVEN Imaging Ultraviolet Spectrometer (IUVS) is shown in Fig. 88.17a; that of Saturn as measured by the Ultraviolet Imaging Spectrograph (UVIS) on Cassini (Fig. 88.17b); the UV dayglow of Saturn and Uranus, which were measured by the Voyager spacecraft, are compared in Fig. 88.17c; and the dayglow of N₂, along with NII and NI lines on Titan in Fig. 88.17d.

Nightglow arises from chemiluminescent reactions of species whose origin can be traced to species produced during the daytime or that have been transported from the dayside. For example, on Venus, O and N produced on the dayside are transported by the subsolar to antisolar circulation to the nightside, where they subside and radiatively associate

producing emission in the δ and γ bands of NO (e.g., *Stewart et al.* [119]). The point on the disk of maximum intensity is

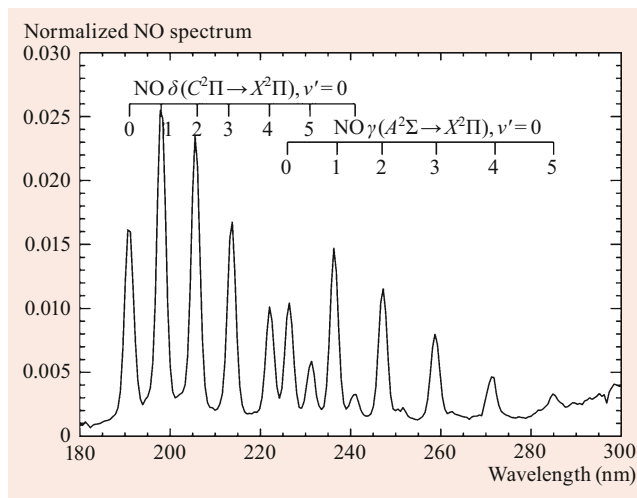

Fig. 88.15 Far ultraviolet NO nightglow spectrum of Venus obtained with the SPICAV (Spectroscopy for the Investigation of the Characteristics of the Atmosphere of Venus) instrument on the Venus Express spacecraft. Show is an average of 771 spectra obtained during orbit 516 when the tangent altitude was between 90 and 120 km. The sum of all the intensities is normalized to 1. The NO δ ($C^2\Pi \rightarrow X^2\Pi$) and γ ($A^2\Sigma \rightarrow X^2\Pi$) bands are shown. From *Royer et al.* [118]

a tracer of day-to-night transport and is found near 2 am just south of the equator. The normalized NO nightglow spectrum as measured by the SPICAV (Spectroscopy for the Investigation of the Characteristics of the Atmosphere of Venus) instrument on the Venus Express is shown in Fig. 88.15 (*Royer et al.* [118]). Similar phenomena have recently been observed by the ultraviolet spectrometer on the Mars Express spacecraft [120], and by the MAVEN UVIS, but the circulation seems to be mostly pole to pole, or equator to pole, depending upon the season. In any case, the day-to-night circulation seems to be much more complicated than that of Venus.

Auroral emissions are defined here as those produced by the impact of particles other than photoelectrons. Although auroras are usually thought of as confined to the polar regions of the Earth and the outer planets, Venus, which does not have an intrinsic magnetic field, exhibits UV emissions on the nightside that are highly variable and cannot be explained as nightglow. It has been proposed that the emissions are produced by precipitation of soft electrons into the nightside thermosphere, and the auroras are seen as diffuse and variable emissions on the nightside of the planet [121]. Mars, which has only a remanent crustal magnetic field, mostly in the southern hemisphere, exhibits discrete emissions that are concentrated over magnetic field anomalies, and more diffuse auroral emissions, which are seen over more extended regions. The SPICAM instrument on the Mars Express (e.g., *Bertaux et al.* [122], *Gérard et al.* [123]), and the IUVS instrument on the MAVEN spacecraft (*Schneider et al.* [124]) have observed both diffuse and discrete aurorae.

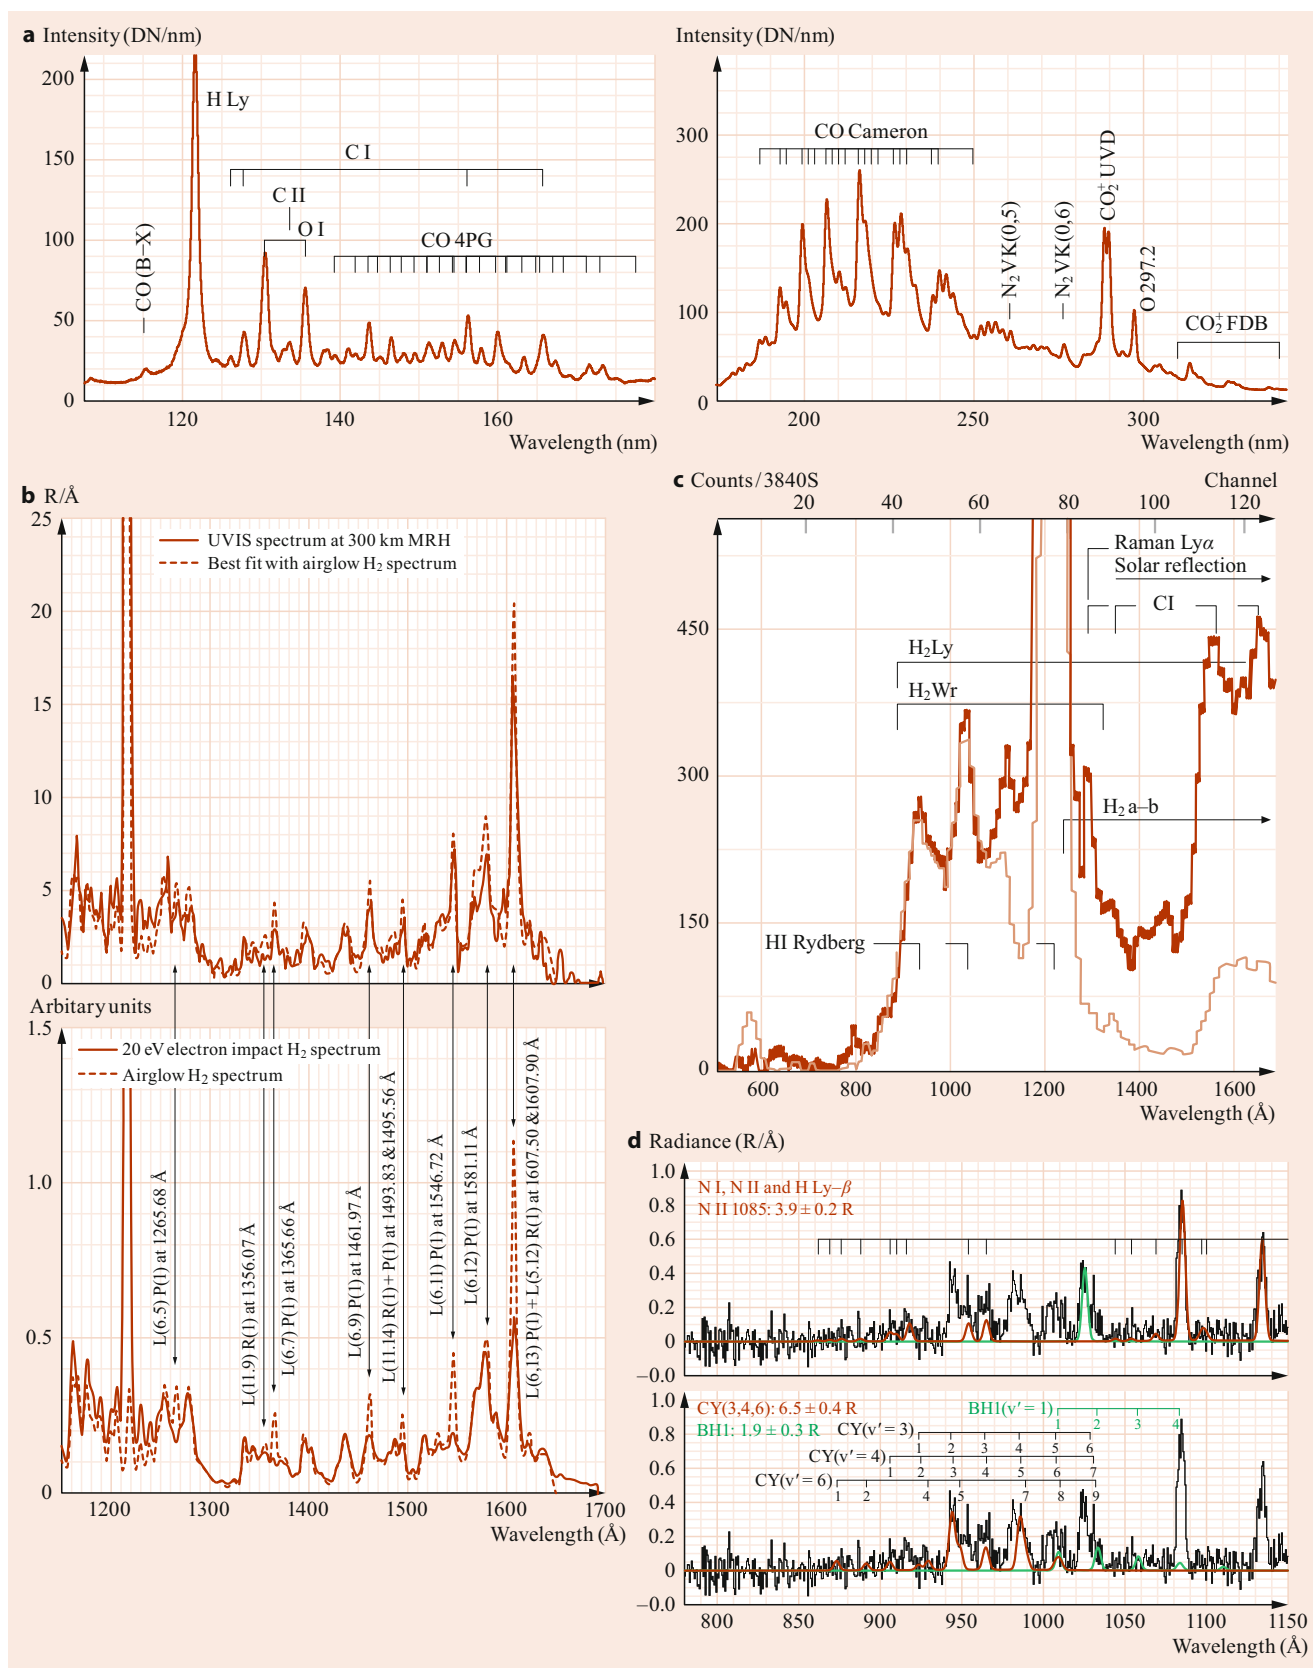

Fig. 88.17 Dayglow spectra of selected planets. **(a)** Martian dayglow spectrum (intensity as a function of wavelength) in the FUV to NUV, as measured by the MAVEN IUVS. The major features are labeled on the plot. From *Jain* [113, 114]. **(b)** (Top) Saturn airglow spectrum, as measured by the Cassini UVIS at a minimum ray height (MRH) of 300 km, compared to a fitted airglow H₂ spectrum. (Bottom) spectrum produced by the impact of 20 eV electrons compared to the airglow spectrum. From *Gustin* et al. [115]. **(c)** Comparison of dayglow spectra from Uranus (heavy line) and Saturn (thin line) recorded by Voyager 2 [116]. **(d)** Titan. Ultraviolet airglow of Titan in the wavelength range from about 780 to 1150 Å. (Top) Some atomic lines of NI, NII, and Lyman-beta are identified. (Bottom) Some bands of the N₂ Carroll-Yoshino (CY) and Birge-Hopfield 1 (BHI) systems. From *Stevens* et al. [117]

Fig. 88.18 (a) Spectra of the northern aurora (*heavy line*) and the equatorial airglow of Jupiter (*light line*) taken by the UVIS spectrometer the Cassini spacecraft on closest approach on 30 December 2000. In both spectra, the Lyman and Werner bands of molecular hydrogen are prominent. They are excited by photoelectron impact in the airglow and by primary and secondary auroral electrons. Locations of some of the brighter bands are indicated by *dotted lines*. Also shown are the Lyman-alpha and beta lines of atomic hydrogen. At wavelengths longer than 1550 Å, the airglow spectrum is swamped by reflected UV sunlight; some solar lines are indicated. At shorter wavelengths, UV sunlight is absorbed by methane and acetylene, rather than reflected. The solar signal is much weaker in the auroral spectrum than in the equatorial, due to the higher angles of incidence and emission in the former [125]. (b) Auroral synthetic spectrum of Saturn as predicted for the Cassini Ultraviolet Imaging Spectrograph in the EUV (*left*) and FUV (*right*); H₂ bands and H emissions are shown. From Esposito et al. [126]

The intensities of airglow and aurora are usually measured in units of brightness called Rayleighs. One Rayleigh is an apparent column emission rate at the source of 10^6 photons $\text{cm}^{-2} \text{s}^{-1}$ integrated over all angles or $10^6/4\pi$ photons $\text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}$. A comparison of auroral and dayglow emissions as measured by the Cassini UVIS as the spacecraft flew by Jupiter is shown in Fig. 88.18a (Stewart [125]).

A discussion of terrestrial airglow and auroral emissions can be found in Rees [50]. Meier [127] has reviewed

spectroscopy and remote sensing of the terrestrial ultraviolet emissions. The airglows of Mars and Venus have been reviewed by Barth [11], Fox [128], and Paxton and Anderson [129]. Airglow and auroral emissions on the outer planets have been reviewed by Atreya et al. [130], Atreya [22], and Strobel [116]. Airglow in the atmospheres of the planets has been reviewed by Slanger and Wolven [131]. Airglow and aurorae of solar system bodies have been reviewed by Slanger et al. [132].

88.7 Planetary Escape

The escape of species from atmospheres can occur by thermal and nonthermal mechanisms. Thermal processes include Jeans escape and hydrodynamic escape. Jeans escape is essentially evaporation of the energetic tail of the Maxwell–Boltzmann distribution, while hydrodynamic escape is a large-scale expansion of the atmosphere that occurs when the average molecular velocity is near or above the escape velocity. Although Jeans escape still occurs for light species in the thermospheres of small solar system bodies, until recently, hydrodynamic escape was thought to have been operative only in the early history of the smaller solar system bodies when the solar flux in the UV was higher. Now, hydrodynamic escape has been postulated to occur for light species in the atmospheres of comets, or, for example, for H₂ escape from Titan (*Strobel* [133]). There is an intermediate region between Jeans and hydrodynamic escape called “slow hydrodynamic escape”. The transition from hydrodynamic to Jeans escape is discussed by *Volkov et al.* [134]. Nonthermal escape mechanisms, which dominate for heavy species on smaller bodies such as Mars and Titan and for all species on Venus and Earth, include both photochemical and mechanical processes. A pedagogical discussion of escape processes can be found in *Chamberlain and Hunten* [135].

Because of the exponential rate of change of density with altitude in thermospheres, escape is sometimes assumed to occur only in the exosphere, that is, at or above an altitude historically called the “exobase” or “critical level”. The classically defined exobase is the altitude where the mean free path of a species, $l = (n\sigma^c)^{-1}$ (where σ^c is the collision cross section), is equal to the atmospheric scale height. The probability that a particle, moving upward from the exobase with sufficient velocity will actually escape without suffering another collision is then $1/e$. The condition $l = H$, therefore, reduces to $nH\sigma^c = 1$ or, equivalently, to $N = (\sigma^c)^{-1}$, where N is the column density. A typical collision cross section has been assumed to be about 3×10^{-15} cm², which places the “exobase” at the altitude above which the column density is about 3.3×10^{14} cm⁻³. Thus, the “exosphere” defined in this way is not a truly collisionless region.

Whether the trajectory of a particle moving upward at a given altitude is ballistic (bound) or escaping (free) in a collision-free region is determined by its total energy E , which is the sum of its kinetic and potential energies

$$E = \frac{1}{2}mv_c^2 + \int_{\infty}^{r_c} \frac{mGM}{r^2} dr, \quad (88.90)$$

where the symbols have the same meaning as in Eq. (88.2), and the subscript c refers to the critical level, the base of the assumed collision-free region. If $E < 0$, the particle is bound.

Equation (88.90) reduces to

$$E = \frac{1}{2}mv_c^2 - mg_c r_c, \quad (88.91)$$

where g_c is the gravitational acceleration at the critical level. The escape velocity at the exobase, v_{esc} , is then defined by the condition $v_{esc} = (2g_c r_c)^{1/2}$. In the “exobase” approximation, particles with velocities greater than the escape velocity are assumed to escape if their velocity vectors are oriented in the upward hemisphere and if they undergo no further collisions. In this approximation, the angular distribution of the products of collisions is assumed to be isotropic, and therefore half of the sufficiently energetic particles meet this criterion. The exobase approximation has been shown not to be valid for photochemical escape mechanisms by, for example, *Fox and Hač* [136].

In reality, the elastic and inelastic cross sections for collisions of different pairs of species vary over nearly an order of magnitude and are functions of energy in the relevant hyperthermal energy region (≈ 1 –10 eV), however, and thus the location of the exobase should vary from species to species. In addition, for similar mass species pairs, the angular differential cross sections in the center-of-mass frame for the hyperthermal energy region are also strongly forward peaked, and escape of atoms, such as O from the Martian thermosphere, originate over a large range of altitudes that extends from well below to above the theoretical exobase. Measurements of angular differential cross sections, however, show that the collisions of comparable mass particles are strongly forward-peaked, so the nonthermal escape of a given species occurs over a range of altitudes, which varies from several scale heights above to well below the “exobase”. Use of the exobase approximation has been shown to be in error for photochemical escape of O, C, and N on Mars (e.g., *Fox and Hač* [136]) but may have some relevance for thermal escape mechanisms. It also useful as a reference altitude that shows the escape region to within several scale heights above and below it. The radius, gravitational acceleration, escape velocity, and scale heights at the equatorial “exobases” of the planets are given in Table 88.11.

In the thermal Jeans process, escape occurs when particles in the high-energy tail of the Maxwellian distribution attain the escape velocity. The escape flux, Φ_J is given by

$$\Phi_J = \frac{n_c u}{2\sqrt{\pi}} (1 + \lambda_c) \exp(-\lambda_c), \quad (88.92)$$

where $u = (2k_B T/m)^{1/2}$ is the modal velocity, and λ is the gravitational potential energy in units of $k_B T$

$$\lambda = \frac{GMm}{rk_B T} = \frac{mgr}{k_B T} = \frac{r}{H}. \quad (88.93)$$

Sometimes, a correction factor is applied to the expression for the escape flux to account for the suppression of the tail

Table 88.11 Exobase properties of solar system bodies

Planet	r_c^a (km)	g_c^a (cm s^{-2})	$v_{\text{esc},c}^a$ (km s^{-1})	$H_{\text{avg}}^{a,b}$ (km)
Mercury ^c	2440	371	4.25	–
Venus ^d	6250	831	10.2	17
Earth ^e	6878	841	10.8	71

of the distribution due to the escape of the energetic particles [138, 139].

Photochemical processes that produce energetic fragments include photodissociation and photodissociative ionization, photoelectron impact dissociation and dissociative ionization, as well as exothermic chemical reactions. The most important example of the latter are dissociative recombination reactions, which are very exothermic and tend to produce neutral fragments with large kinetic energies. Charge transfer processes such as

or

can produce fast neutrals if the ion temperature is larger than the neutral temperature, as is usually the case at altitudes well above the exobase of a planet, or if solar wind heavy ions, including protons, directly impact the atmosphere. In modeling these processes, the kinetic energy distribution (in the laboratory frame) of the product species is important, as well as the cross sections or reaction rates.

Physical or collisional escape mechanisms include sputtering and *knock-on*. Sputtering can occur when a heavy ion

picked up by the solar wind (the projectile) collides with an atmospheric species (the target) and in the process produces a *back-splash* in which the accelerated neutral may be ejected from the atmosphere. Since for comparably sized species, there is no backscattering in the laboratory frame, either the collision must be glancing or the process must involve multiple collisions. The sputtering phenomenon has been described in detail in the monograph by *Johnson* [140]. In knock-on, hot atmospheric neutral species, such as O atoms produced in exothermic chemical reactions at sufficiently high altitudes can collide with a (usually) lighter species, such as H, imparting sufficient kinetic energy to allow it to escape. Modeling these processes requires knowledge of the ion–neutral and neutral–neutral elastic, inelastic, and angular differential collision cross sections.

The escape rate of a light species from a planetary atmosphere may be limited by diffusion of the species from the lower atmosphere to the exosphere, rather than by the escape process itself [141]. The limiting upward flux, ϕ_i of a species i with mixing ratio f_i can be estimated as

$$\phi_i \approx \frac{b_i f_i}{H_a}, \quad (88.96)$$

where H_a is the scale height that is based on the average mass of the constituents of the thermosphere at the homopause, and b_i is the binary collision parameter introduced in Sect. 88.2.2. Equation (88.96) above is usually evaluated at the homopause, with the mixing ratio taken from a suitable altitude in the middle atmosphere, but above the cold trap (where the species condenses, if one exists). The limiting flux obtains, if and only if the mixing ratio is constant with altitude. The effect of photochemistry can be accounted for if all chemical forms of the species are considered in the calculation of f_i (*Hunten* [40]). For example, on Titan, H_2 sometimes escapes hydrodynamically and sometimes by Jeans escape at the diffusion limit, but CH_4 escapes at 75% of its diffusion limiting rate. On Triton, the mixing ratio of CH_4 near the surface is much smaller than that in the lower atmosphere of Titan. It is chemically destroyed in the lower atmosphere before it can escape (e.g., *Strobel* [65]). On Pluto, CH_4 escapes with significant rates, exceeding 10^{25} s^{-1} ; H and H_2 escape at their diffusion limit (*Strobel* [10]).

Even if energetic particles released near the exobase of a planet do not have enough energy to escape, they may travel to great heights along ballistic orbits before falling back to the atmosphere. These particles are said to form hot atom coronas. Hot H and O coronas surround Earth, Venus, and Mars (Fig. 88.19). In addition, hot C and hot N coronas have been detected or predicted to surround Venus and Mars. Since the escape velocities of the giant planets are so large (tens of km s^{-1}), escape of even H is not possible. Non-thermal processes at high altitudes may, however, lead to the formation of hot H coronas. Reviews of the H and O coronas

Fig. 88.19 Spectrum of the oxygen green line taken on the nightside of Venus by the Keck/HIRES on 20 November 1999. The individual terrestrial and Doppler-shifted Venusian components are shown by the dashed lines (from *Slanger et al.* [142])

of Venus have been presented by *Fox and Bougher* [96] and by *Nagy et al.* [143]. The exospheres of various solar system bodies and the coronas of Mars, Venus, and Titan have been reviewed by *Futaana et al.* [144]. See *Chamberlain and Hunten* [135] for a detailed discussion of planetary coronal population processes.

Abstract

While there has been a general understanding and appreciation of the science involved in both global warming and stratospheric ozone depletion by atmospheric scientists for some time, a detailed understanding and rigorous proof have often been lacking. Over the last 20 years, there have been many advances made in filling in the

details, and there will continue to be rapid advances in the future. This means that any article or book discussing this topic becomes out of date as soon as it is written. Nevertheless, several recent references on these topics are recommended [1–3].

Atomic and molecular structure and spectroscopy, as well as collision processes involving atoms, molecules, ions and electrons, are important to the study of all planetary atmospheres.

polar vortex · sulfate aerosol · ozone layer · total ozone column · ozone monitoring instrument · air quality · global warming · greenhouse effect · stratospheric ozone depletion

89.1 Overview

89.1.1 Global Change Issues

Over the last several decades there has been increasing concern about the global environment and the effect of human perturbations on it. This whole area, which involves a wide range of scientific disciplines, has become known as *global change*. Knowledge of processes taking place in the atmosphere, oceans, land masses, and plant and animal populations, as well as the interactions between these various Earth–system components is essential to an overall understanding of global change – both natural and human induced.

The processes of atomic and molecular physics find greatest application in the area of atmospheric global change. The three major issues that have received significant attention in both the media and the scientific literature are: (1) global warming, due to the buildup of infrared-active gases; (2) stratospheric ozone depletion due to an enhancement of de-

structive catalytic cycles; and (3) air quality and tropospheric pollution. These three problems are thought to be largely caused by atmospheric pollutants due to industrialized human society. However, the general problem of air pollution and its direct effects on plant and animal populations will not be addressed here.

89.1.2 Structure of the Earth's Atmosphere

The vertical temperature structure of the Earth's atmosphere shown in Fig. 89.1 provides an important nomenclature that is widely used [4]. The atmosphere is divided into regions called “-spheres”, in which the sign of the temperature gradient with respect to altitude, dT/dz , is constant. The regions in which the temperature gradient changes sign are called “-pauses”. The precise altitude pertaining to each of these regions can vary depending upon latitude and the time of year.

In the troposphere, covering the range from 0 to ≈ 15 km above the Earth surface. The temperature steadily decreases with altitude. This is the most complex region of the atmo-

sphere, as it interacts directly with plant and animal life, land masses, and the oceans. It is the region in which weather occurs.

The change in sign of the temperature gradient at the tropopause to a positive dT/dz in the stratosphere is due to heating by absorption of solar ultraviolet radiation, which photodissociates O_2 and O_3 . The stratosphere, extending from ≈ 15 to 50 km above the Earth, contains the ozone layer, which shields the Earth's surface from harmful ultraviolet radiation in the range 280–320 nm.

At the stratopause, the heating processes have become too weak to compete with the cooling processes, and throughout the mesosphere, approximately 50–85 km, the temperature again decreases with increasing altitude. Cooling processes, which will be discussed in Sect. 89.2.2, involve collisional excitation of molecular vibrational modes, which decay by radiating to space. The coldest temperatures in the atmosphere are found at the mesopause, where the temperature gradient once again becomes positive. From approximately 70 km upward, a very diffuse plasma called the ionosphere exists due to photoionization of atoms and molecules by short wavelength (UV and EUV) solar radiation.

Fig. 89.1 Vertical temperature profile of the atmosphere

Throughout the thermosphere, which extends from approximately 90 km upward, heating occurs because the atmosphere has become so thin that there are very few collisions and, thus, inefficient equilibration of the highly translationally excited atoms and ions with the molecular species, which can radiate in the infrared. This “bottleneck” for energy loss causes increased heating. In the thermosphere and ionosphere, the thermal inertia is very small, and there are huge temperature variations, both diurnally and with respect to solar activity.

The densities are low enough in the thermosphere, ionosphere, and mesosphere that the primary processes determining the chemical and physical characteristics of these regions are two-body processes and “half-collision events” discussed elsewhere in this volume: dissociative recombination, photoionization, photodissociation, charge transfer, and collisional excitation of molecular rotation and vibration. As the altitude decreases, the density increases. Then, three-body interactions, interactions on surfaces (of aerosols and ices), and complex chemical cycles together with dynamical effects such as winds determine the chemical and physical characteristics of the stratosphere and troposphere.

89.2 Atmospheric Models and Data Needs

While models are absolutely essential to the study of any system as complex as the Earth’s atmosphere, they play a particularly fundamental role in exploring global change issues. Models not only provide predictions of future changes but also allow exploration of sensitivities to particular parameters. Comparing the results of a model with observations ultimately tests and challenges scientific understanding. Of critical importance is the atomic and molecular data that goes into the models.

Generally, atmospheric models become increasingly complex as altitude decreases. General circulation models (GCMs), incorporating thousands of chemical reactions, global wind patterns, and abundances of large numbers of trace species, require supercomputers in order to model aspects of the troposphere and stratosphere [5]. Tropospheric chemistry and transport models, such as GEOS-CHEM [6], and CAM-Chem [7] model the sources, evolution, transport, and sinks of pollution, as well as the oxidative capacity of the troposphere.

89.2.1 Modeling the Thermosphere and Ionosphere

The data necessary for modeling of the thermosphere and ionosphere are described here. The primary components of

such a model include: a solar spectrum of photon fluxes as a function of wavelength, concentrations of neutral species, and photoabsorption, photodissociation, and photoionization cross sections as functions of wavelength. The computer code brings all these elements together, calculating opacity as the solar radiation propagates downward through the atmosphere, keeping track of ion production and electron production. Additional steps are required to calculate the abundances of trace species such as NO^+ , necessitating the inclusion of all relevant ion–neutral reactions. Electron energy degradation can be tracked by including inelastic collisions of electrons with ions, atoms, and molecules.

The primary neutral species are N_2 , O_2 , O , and He . Below about 100 km, the atmosphere is fully mixed by turbulence in the ratio 78% N_2 , 21% O_2 , and 1% trace species such as O_3 and CO_2 . Above 100 km, turbulence dies out, and the atmospheric species are in diffusive equilibrium, distributed by their molecular weight, with atomic oxygen dominating above ≈ 150 km and He dominating much higher. The major ions are N_2^+ , O_2^+ , O^+ , and NO^+ .

89.2.2 Heating and Cooling Processes

In the upper atmosphere, heating occurs through absorption of short wavelength solar radiation to produce ionization and dissociation and is mediated by collisions between electrons, ions, and neutrals. Ions and electrons are created during the daytime and to a great extent disappear during the night with the absence of solar radiation. Processes such as dissociative recombination, the primary electron loss mechanism, heat the gas:

Cooling takes place when the kinetic energy of the gas is transformed through collisions into internal energy, which can then be radiated away. The primary coolant above ≈ 200 km is the fine structure transition of atomic oxygen, $\text{O}(^3\text{P}_1) \xrightarrow{h\nu} \text{O}(^3\text{P}_2)$, which is excited by thermal collisions and radiates at $63 \mu\text{m}$. From approximately 120 to 200 km, the fundamental band of NO , $v = 1 \rightarrow v = 0$, which is excited by collisions with atomic oxygen and radiates at $5.3 \mu\text{m}$, dominates the cooling. Below 120 km and throughout the mesosphere and stratosphere, the primary coolant is the ν_2 band of CO_2 radiating at $15 \mu\text{m}$. This transition is excited by collisions of CO_2 and atomic oxygen. Cooling throughout most of the atmosphere is accomplished through trace species because the major molecular species, N_2 and O_2 , are not infrared active.

89.2.3 Atomic and Molecular Data Needs

Knowledge of rate coefficients for ion–neutral and neutral–neutral reactions as functions of vibrational and rotational excitation of the reactants is becoming increasingly important, as there is recent evidence of more internal excitation of molecular species than had previously been thought [8]. Accurate photoabsorption, photodissociation, and photoionization cross sections as functions of wavelength for all the relevant species are important parameters determining the reliability and ultimate accuracy of an atmospheric model. Compilations of data, such as that by *Conway* [9] and *Kirby et al.* [10] are very useful but can rapidly become outdated. The Smithsonian Astrophysical Observatory maintains the world standard database, HITRAN, for molecular line parameters and absorption cross sections from the microwave through the ultraviolet for analysis of atmospheric spectra [11]. Discussions of the needs for atomic and molecular data in the context of space astronomy, but including applications to atmospheric physics, can be found in a book edited by *Smith and Wiese* [12]. Atomic and molecular data are available at the Virtual Atomic and Molecular Data Center Consortium [13].

89.3 Tropospheric Warming/Upper Atmosphere Cooling

89.3.1 Incoming and Outgoing Energy Fluxes

The overall temperature of a planet is determined by a balance between incoming and outgoing energy fluxes. In a steady state, the planet must radiate as much energy as it absorbs from the sun. The Earth, radiating as a black body at an effective temperature T_E , obeys the Stefan–Boltzmann law in which the energy emitted is expressed as $\sigma T_E^4 4\pi R_E^2$, with σ the Stefan–Boltzmann constant, and R_E the radius of the Earth. An equation expressing the equality of energy absorbed and energy emitted can be written as [14]

$$F_s \pi R_E^2 (1 - A) = \sigma T_E^4 4\pi R_E^2, \quad (89.3)$$

where A is the albedo of the Earth (the fraction of solar radiation reflected from, rather than absorbed by, the Earth), F_s is the solar flux at the edge of the Earth’s atmosphere, and πR_E^2 is the Earth’s area normal to the solar flux. Solving this equation for T_E , one obtains $T_E \approx 255 \text{ K}$ (-18°C).

The sun, which has a surface temperature of approximately 6000 K, emits most of its radiation in the 0.2–4.0 μm region of the spectrum (200–4000 nm). The upper atmosphere of the Earth (thermosphere, ionosphere, mesosphere, and stratosphere) absorbs all the solar radiation shortward of 320 nm. The atmosphere of the Earth absorbs only weakly in the visible region of the spectrum where the solar flux peaks.

The Earth, with an effective radiating temperature of 255 K, emits mainly long-wavelength radiation in the 4–100 μm region. Molecules naturally present in the atmosphere in trace amounts, such as carbon dioxide, water, and methane, absorb strongly in this wavelength region [15]. Radiation coming from the Earth is thus absorbed, reradiated back to the surface and thermalized through collisions with the ambient gas. This trapping of the radiation produces an additional warming of 33 K. Thus, the mean surface temperature of the Earth is 288 K, not 255 K as found for T_E above. This effect of the Earth’s atmosphere is known as the greenhouse effect. The greenhouse effect is what makes Earth habitable for life as we know it. Gases, both natural and manmade, which absorb strongly in the 4–100 μm region, are known collectively as greenhouse gases.

89.3.2 Tropospheric “Global” Warming

According to the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5) the “globally averaged combined land and ocean surface temperature data as calculated by a linear trend, show a warming of 0.85 [0.65 to 1.06] $^\circ\text{C}$, over the period 1880 to 2012.” The IPCC has also concluded that “Human influence on the climate system is clear. This is evident from the increasing greenhouse gas concentrations in the atmosphere, positive radiative forcing, observed warming, and understanding of the climate system” [16]. The Arctic region has warmed by an estimated 1 $^\circ\text{C}$ in the past two decades, leading to substantial changes in the cryosphere. Antarctic sea ice was stable from 1840 to 1950 but has since declined sharply. The extent of sea ice shows a 20% decline since about 1950 [17, 18].

From air bubbles trapped at different depths in polar ice, it is possible to determine carbon dioxide and methane concentrations several thousand years ago. In 2011, CO_2 levels reached 390.5 ppm, 40% greater than in 1750 [19]. In 2013, CO_2 levels passed the 400 ppm threshold for the first time. Over the next century, the total amount of CO_2 in the atmosphere since 1900 is expected to double to as much as 600 ppm [20]. This increase is due primarily to the burning of fossil fuels.

Although methane is present at levels several orders of magnitude less than CO_2 , it is increasing much more rapidly. Methane concentrations have more than doubled over the last 200 years due to industrial processes, fuels, and agriculture [19].

The manmade chlorofluorocarbons (CFCs), which have been widely used as refrigerants and in industry, increased in the atmosphere at a rate of over 5% per year between the 1970s and the 1990s. Due to the Montreal Protocol there has been a reduction or inversion of this trend [21].

Ozone, which is a primary component of chemical smog, is a pollutant when it occurs in the troposphere and an ef-

fective greenhouse gas. It has been increasing worldwide as well. This buildup of CO₂, CH₄, CFCs, and tropospheric O₃ causes a problem. In much of the spectral region from 5–100 μm, there is 100% absorption of radiation by the atmosphere – due mainly to naturally occurring water vapor. There is, however, a region of rather weak absorption, from ≈ 7–15 μm, known as the “atmospheric window”. Increased concentrations of the greenhouse gases strengthen the absorption in this region, tending to “close” this window, thus increasing the infrared opacity of the atmosphere. The increased opacity causes an immediate decrease in the thermal radiation from the planet–atmosphere system, forcing the temperature to rise until the energy balance is restored [22].

It is difficult to prove that the buildup of greenhouse gases is the cause of the observed temperature rise. Other possible causes include slight changes in solar activity and irradiance, and changes in ocean currents, which may have a profound effect on global temperature and climate. These are areas of active research.

Given the increase in concentrations of greenhouse gases that has occurred and is predicted to continue, the change in radiative heating of the troposphere can be calculated. Models generally predict an increase in tropospheric temperatures ranging from 1.5 to 5 °C, considering different emission scenarios over the next century [23]. The 3.5 °C range in temperature is due to the ways that different models incorporate climate feedbacks. Climate feedbacks include water vapor, snow and sea ice, and aerosols and clouds. Rising temperatures increase the concentration of water vapor, which is itself a greenhouse gas, producing further warming. Rising temperatures reduce the extent of reflective snow and ice, thus reducing the Earth’s albedo. This leads to increased absorption of solar radiation, further increasing temperatures. Clouds and aerosols both contribute to the albedo, thereby reducing the solar flux reaching the Earth, and absorb infrared radiation causing temperatures to rise. The modeling of clouds and aerosols and their radiative properties is very difficult and is one of the largest sources of uncertainty in the climate models. Understanding the role that the ocean, with its giant heat capacity, plays in global warming and identifying and quantifying the various interactions occurring at the ocean–atmosphere interface are vital areas of research, which will affect the size of the predicted temperature increase. At present, there are few obvious opportunities for traditional atomic and molecular physics to play a significant part in global-warming research.

89.3.3 Upper Atmosphere Cooling

The buildup of CO₂ has an even greater effect on the temperature in the upper atmosphere than on that in the troposphere [24]. As discussed in Sect. 89.2.2, CO₂ is a coolant

in the stratosphere, mesosphere, and thermosphere, but as a greenhouse gas it is involved in heating the troposphere. The explanation for this revolves around the collision physics issue of quenching versus radiating.

In the troposphere, CO₂ absorbs infrared radiation coming from the Earth, exciting the ν_2 vibrational bending mode at 15 μm. The excited molecule can either reradiate or collisionally de-excite. In the lower atmosphere, where densities are large, the lifetime against collisions is very short, and the excited molecule is rapidly quenched. This transfer of energy from radiation through collisions into the kinetic energies of the colliding partners results in a net heating.

In the stratosphere and above, atomic oxygen collisions with CO₂ excite this same bending mode, but at these higher altitudes, densities are lower and quenching is greatly reduced. The excited molecule radiates, and the radiation escapes into space. A net cooling results because the opacity is low at these altitudes. The cooling of the stratosphere has also been linked with ozone trends [25].

Roble and coworkers [26, 27] investigated the doubling of CO₂ and CH₄ concentrations (as predicted for the twenty-first century) in the mesosphere and at the lower boundary of the thermosphere. Using sophisticated atmospheric general circulation models, they predict that the stratosphere, mesosphere, and thermosphere will show significant cooling – the largest cooling of 40–50 °C occurring in the thermosphere.

The extent of this cooling very much depends on the rate coefficient for the O + CO₂ excitation of the ν_2 bending mode. *Rishbeth* and *Roble* [26] assumed a value for this rate coefficient of 1×10^{-12} cm³/s, intermediate between the value of *Sharma* and *Wintersteiner* [28] (6×10^{-12} cm³/s) and an earlier value of 2×10^{-13} cm³/s used by *Dickinson* [29]. The *Sharma* and *Wintersteiner* value, based on observations of 15 μm emission in the atmosphere around 100–150 km, was recently confirmed by *Rodgers* et al. [30], but *Pollock* et al. [31] obtained a value of 1.2×10^{-12} cm³/s in laboratory experiments. Using the larger rate coefficient would result in even greater cooling [32].

The overall consequences of such a large temperature decrease in the upper atmosphere have not been fully explored – particularly the question as to how the dynamics of the atmosphere will be affected. Since many chemical reactions depend on temperature, there may be considerable readjustments in the vertical distribution of minor species in the atmosphere. Cooler temperatures cause the atmosphere to contract, reducing densities and, consequently, satellite drag. Cooler temperatures may also increase the occurrence of polar stratospheric clouds, thereby affecting ozone depletion (Sect. 89.4).

Most significantly, tropospheric warming and upper atmosphere cooling both result from a buildup of CO₂. The size of the predicted cooling is greater by an order of magnitude than the amount of the predicted heating. Thus, it may be

possible to monitor the global warming trend by observing the predicted cooling in the upper atmosphere.

There is evidence of this cooling in the stratosphere and mesosphere. *Keckhut* and coworkers [33] found cooling rates of 1.1 ± 0.6 K at 25 km, 1.7 ± 0.7 K between 35–50 km and 3.3 ± 0.9 K at 60 km per decade, while *Santer* and coworkers linked these changes in the thermal structure of the atmosphere with human activities [34]. *Gadsden* [35] also found that the frequency of occurrence of noctilucent clouds, the highest-lying clouds in the atmosphere, has more than doubled over the last 25 years. He calculated that this change could result from a decrease in the mean temperature at the mesopause of 6.4°C during this time period. However, increased concentrations of water produced by oxidation of increased amounts of methane may be responsible for the more frequent appearance of these clouds. This is an ongoing area of research.

89.4 Stratospheric Ozone

89.4.1 Production and Destruction

Ozone production takes place continually in the stratosphere during daylight hours, as molecular oxygen is photodissociated, and the resulting oxygen atoms undergo three-body recombination with O_2 :

Ozone can be destroyed through photodissociation:

but because an oxygen atom is produced, which immediately recombines with another O_2 to form O_3 , no net loss of O_3 results. The photodissociations of O_2 and O_3 are important heating processes in the stratosphere.

The amount of ozone in the stratosphere is quite variable, changing significantly with the seasons and with latitude. In the lower stratosphere, much of the ozone is created over the equatorial regions and then transported toward the poles.

In addition to being photodissociated, O_3 is destroyed by reactions with radicals that are involved in catalytic cycles. The shorthand notation for the major cycles, NO_x , HO_x , and ClO_x (BrO_x) refers to the catalytically active forms involved in the cycles. Our knowledge about the relative importance of these catalytic cycles in ozone destruction has increased dramatically over the last decades. A number of these cycles are given below, with the ozone-destroying step listed first, and the rate-limiting step closing the catalytic cycle and regenerating the ozone-destroying radical listed last. The net effect

in each of these cases is to convert ozone and atomic oxygen (otherwise known as odd-oxygen) into molecular oxygen:

and

and the halogen cycle, in which $Z = \text{Cl}$ or Br :

The following series of reactions couples the HO_x and halogen cycles:

Finally, the reaction set

is also important in the halogen destruction cycle. The coupling between these different cycles by reactions such as

turns out to be very important in understanding the details of ozone destruction, such as how much each mechanism contributes to the destruction as a function of altitude and in the presence of aerosols. *Wennberg* et al. [36] recently showed that catalytic destruction by NO_2 , which for two decades was considered to be the predominant loss process, accounted for

less than 20% of the O_3 removal in the lower stratosphere during May 1993. They further showed that the cycle involving the hydroxyl radical accounted for nearly 50% of the total O_3 removal, and the halogen-radical chemistry was responsible for the remaining 33%.

The NO_x and HO_x cycles occur naturally, whereas the ClO_x and BrO_x cycles are due mainly to manmade chemicals – CFCs and halons. The amplification that takes place through a catalytic cycle is the reason that these chemicals, which are only present at the level of parts per trillion, can have such a destructive effect.

It is useful to think in terms of a total chemical budget for a radical, such as Cl, that enters into a cycle. Chlorine is put into the stratosphere when chemicals such as CF_2Cl_2 are released into the atmosphere. Such compounds are chemically inert and insoluble in water, and therefore are not easily cleansed out of the lower atmosphere. In the stratosphere, however, the CF_2Cl_2 is subjected to solar UV radiation and is photodissociated, producing the Cl radical. Chlorine exists in the upper atmosphere in catalytically active forms, Cl and ClO, as well as in stable, reservoir species, HCl and ClONO₂. The total chlorine budget consists of both the catalytically active plus reservoir species. Reactions that reduce the formation of reservoir species, or convert reservoir species to catalytically active forms, contribute to the ozone destruction. Photolysis of stable reservoir species, such as ClONO₂, can produce catalytically active forms. Bromine has an identical cycle to that of chlorine but is 50 to 100 times more destructive than Cl because it does not react readily to go into its reservoir form, HBr. A knowledge of the photodestruction rates of all such species is important for an understanding of the overall ozone photochemical depletion problem.

Studies of the Antarctic ozone hole show that gas phase photochemical cycles, as given above, are not the whole story with respect to ozone depletion. Heterogeneous chemistries taking place on the surfaces of ice crystals and sulfate aerosols also play an important role. These are discussed briefly in Sects. 89.4.2 and 89.4.4.

89.4.2 The Antarctic Ozone Hole

The ozone depletion problem was largely theoretical until the discovery of the ozone hole over Antarctica. Following the 1985 announcement by *Farman et al.* [37] of ground-based observations of significant decline in O_3 concentrations during springtime in the Southern Hemisphere, it was possible to map this event using archived satellite data beginning in 1979. The data depict a worsening event throughout the early 1980s. In 1987, 70% of the total O_3 column over Antarctica was lost during September and early October, and the areal extent of the hole was $\approx 10\%$ of the Southern Hemisphere. The ozone hole continued to grow in depth and width dur-

ing the 1990s [38]. Recent data shows that this phenomenon continues, but due to the implementation of the Montreal protocol there are signs of decline in the Antarctic ozone depletion [39, 40].

The link between the release and buildup of manmade CFCs and the ozone hole over Antarctica was convincingly established by *Anderson et al.* [41] through in situ observations from high altitude aircraft flights into the polar vortex during the end of the polar night and the beginning of Antarctic spring in 1987.

The polar vortex is a stream of air circling Antarctica in the winter, creating an isolated region that becomes very cold during the polar night. Flights into the vortex were able to document a heightened, increasing level of ClO and a monotonically decreasing O_3 concentration over a 3–4 week time period during late September and early October.

The mechanism repartitioning the chlorine from its reservoir form into its catalytically active form is a heterogeneous process occurring on the surfaces of polar stratospheric clouds. At the cold temperatures during the polar night, polar stratospheric clouds form, consisting of ice and nitric acid trihydrate. Gaseous ClONO₂ collides with HCl that has been adsorbed onto the surface of the cloud crystals. Chlorine gas is liberated, and the nitric acid formed in the reaction remains in the ice [41]:

As solar radiation starts to penetrate the region at the beginning of spring, the Cl_2 molecules are rapidly photodissociated, producing Cl atoms, which initiate the catalytic destruction of O_3 . As there are few oxygen atoms available to complete the catalytic cycles, several mechanisms for regenerating the Cl and Br radicals that involve only the ClO and BrO molecules themselves have been proposed.

Mechanism I [42]

Mechanism II [43]

While Mechanism I accounts for 75% of the observed ozone loss, the sum of I and II yields a destruction rate in harmony with the observed O_3 loss rates [41].

89.4.3 Arctic Ozone Loss

The region around the North Pole does not appear to exhibit an ozone hole as severe as that found in the Antarctic. Several factors lessen the probability of a significant ozone hole developing in the Arctic. First, a stable polar vortex does not get well established due to increased atmospheric turbulence from the greater land surface area in the Northern Hemisphere. Second, temperatures during the Arctic winter do not get as cold as during the Antarctic winter, so that polar stratospheric clouds (PSCs) do not form as easily. As seen in the preceding section, the surfaces of PSCs play an essential role in the O₃ destruction mechanisms in the Antarctic.

However, ozone levels are showing 20–25% reductions during February and March [44] over a much larger area around the North Pole than in the South. Thus, ozone destruction is taking place during the transition from polar winter to spring in the Arctic, but the phenomenon is more widespread, diffuse, and not as well contained as in the Antarctic.

89.4.4 Global Ozone Depletion

Over the last four decades, satellite instruments have measured the total ozone column in the atmosphere. During this time ozone levels decreased globally. Only recently have they stabilized as a consequence of the policies introduced in Montreal protocol agreements. A recent analysis indicates the first evidence of recovery of stratospheric ozone levels, with diminished rates of ozone loss at altitudes of 35–45 km, coupled with a slowdown in the increase in stratospheric loading of chlorine [38].

Heterogeneous reactions on aerosol surfaces, as well as the homogeneous gas phase chemical cycles mentioned earlier, must be invoked to explain the global decline in ozone levels. A particularly important reaction appears to be the hydrolysis of N₂O₅ on sulfate aerosols. This occurs very rapidly, converting reactive nitrogen, NO₂, into its reservoir species HNO₃:

The N₂O₅ is formed at night by reaction of NO₂ and NO₃. Following the hydrolysis of N₂O₅, there is less reactive NO₂ available to convert ClO into its reservoir species, ClONO₂, and less NO₂ around to convert OH into the reservoir species, HNO₃. A heightened sensitivity of the ozone to increasing levels of CFCs develops. It has been shown that certain regions of significantly depleted ozone also show high concentrations of sulfate aerosols [45]. In addition, measurements of the ratio of catalytically active nitrogen to

total nitrogen can be reproduced using the above heterogeneous reaction, and not by using gas phase processes alone. The study of further mechanisms at varying altitudes and latitudes is an active area of research.

Record low global ozone measurements, 2 to 3% lower than any previous year, were reported beginning in 1992 [46] and continuing well into 1993. The increase in naturally occurring aerosols due to the eruption of Mount Pinatubo in June 1991 appears to explain this decline. During the winter of 1993–1994, the total ozone levels returned to levels slightly above normal [47], presumably because the excess aerosols had been removed from the stratosphere by natural sedimentation processes.

The continuing buildup of CO₂ is predicted to contribute to increase cooling of the stratosphere. Declining temperatures in the stratosphere may increase the frequency of formation of polar stratospheric clouds that drive the destructive heterogeneous chemistry creating the Antarctic ozone hole. An increased occurrence of these clouds outside of the polar regions could affect ozone levels globally. There are also indications that certain ozone depletion chemistries taking place on the surface of sulfate aerosols may also be enhanced by lower temperatures [45].

Ozone itself is the dominant heat source in the lower stratosphere. Decreasing the amount of ozone drives temperatures still lower [48]. It is unfortunate that the two most significant atmospheric global change effects – the buildup of CO₂ and the enhanced ozone destruction due to manmade CFCs – both cause decreasing temperatures in the stratosphere, which may further enhance the destructiveness of the ozone's photochemical cycles.

89.5 Atmospheric Measurements

Ground-based observations, as well as measurements made by instruments carried aloft in satellites, balloons, rockets, and high-flying aircraft, allow to explore the atmosphere.

Measurements may be made either in situ or by remote sensing techniques. The region of the atmosphere from ≈ 60 to 120 km, encompassing the mesosphere and lower thermosphere and ionosphere, is studied by in situ measurements using sounding rockets as it is too high for balloons and aircraft and too low (i.e., too much drag) for satellites. A comprehensive description of rocket measurements is provided by *Larsen* [49]. Remote sensing experiments are essential to observe the upper atmosphere. A comprehensive book on the subject is recommended [50].

Most of the instruments used to make atmospheric measurements were developed in molecular physics and spectroscopy laboratories. Even experiments utilizing sophisticated techniques, such as laser-induced fluorescence, and instruments, such as Fourier transform spectrometers, are be-

ing flown on payloads. An excellent compendium of satellite instruments for stratospheric research has been assembled by Grant [51]. A detailed description of past satellite instruments can be found in the *Encyclopedia of Atmospheric Science* [52–60].

A combination of good laboratory experiments, theoretical calculations, and ingenuity is necessary to extract accurate information from measurements made in the atmosphere. For instance, in order to understand the complicated interactions of the different photochemical cycles involved in ozone chemistry, spectroscopic emissions and absorptions of the many trace species are used to measure concentration profiles. An accurate knowledge of the emission spectroscopy of species such as OH, HO₂, H₂O₂, H₂O, O₃, HNO₃, NO₂, N₂O, N₂O₅, HNO₃, ClONO₂, BrO, HCl, HOCl, and ClO is essential. Such measurements provide a rigorous test of atmospheric models. The NASA EOS Aura satellite, launched in 2004, carries instruments making global measurements of a number of these species [61–63]. One year before, in August 2003, the Canadian Space Agency launched the ACE-FTS instrument [64]. Taking advantage of the high signal-to-noise measurements inherent to the solar occultation technique it was able to measure vertical profile distributions of more than 60 molecules and isotopologues globally.

In order to analyze the data and deconvolve some of the line profiles to give information on concentrations as a function of altitude, molecular data such as line strengths and pressure broadening coefficients are needed [11].

Until recently, it was impossible for remote sensing experiments to distinguish between ozone occurring in the stratosphere (where it is formed naturally) and ozone occurring in the troposphere (where it is a pollutant). Satellite instruments such as the ESA Global Ozone Monitoring Experiment (GOME), the Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY), and the Ozone Monitoring Instrument (OMI) have a broad enough spectral coverage and a high enough resolution that the temperature dependence of the ozone absorption features from 300–340 nm, known as the Huggins bands, can be used to separate out the ozone concentrations in the middle and lower atmospheres [65, 66].

The future of atmospheric remote sensing from space looks very promising. Projects around the world are increasing the number and quality of observations, allowing scientists to investigate the time and spatial scales previously out of reach. The Sentinel-5 Precursor satellite launched by the European Space Agency in 2017 carrying the TROPOMI instrument [67] is starting to show what future geostationary instruments, like the US Tropospheric Emissions: Monitoring of Pollutants (TEMPO) [68], the Korean Geostationary Environment Spectrometer (GEMS), and the European Space Agency's Sentinel-4 instrument, each having even higher spatial resolution, will be capable of. To keep track

of past and current satellite missions, as well as instrumental techniques for atmospheric observation, the NASA Earth Science site (<https://www.nasa.gov/topics/earth/index.html>) and the ESA Earth Observation site (https://www.esa.int/Our_Activities/Observing_the_Earth) are extremely useful.

Abstract

This chapter describes various applications of atomic and molecular physics to phenomena that occur at surfaces. Particular attention is placed on the application of electron- and photon-atom scattering processes to obtain surface specific structural and spectroscopic information.

The study of surfaces and interfaces touches on many fields of pure and applied science. In particular there are applications in the fields of semiconductor processing, thin film growth, catalysis, corrosion and fundamental physics in two-dimensions. A number of recent texts cover surface physics in general [1–4] as well as specific areas such as experimental techniques [5], surface electron spectroscopies [6, 7], and the application of synchrotron radiation to surface science [8]. Also a number

of book series that deal with areas of particular interest are published at regular intervals, such as surface chemistry [9], surface vibrations [10] and stimulated desorption processes [11].

90.1 Low Energy Electrons and Surface Science

To obtain information specific to the first few layers of atoms at the surface of a solid, techniques must be devised that discriminate between signals from the surface and from the bulk of the material. If a solid has dimensions of $\approx 1 \text{ cm}^3$, then only approximately one atom in 10^7 is located at the surface. This makes the application of bulk techniques to the study of surfaces (e.g. X-ray diffraction [12]) problematic.

There are several experimental approaches to achieving surface sensitivity. If the probe used is an atom or molecule that can be scattered from or desorbed from the surface, then these species can be analyzed by techniques such as mass spectrometry or resonant ionization. A more recent innovation has been the use of scanning probe microscopies [13] (e.g., the scanning tunneling microscope and its variants) which exploit a surface sensitivity such as the surface valence electron density. However the most common surface analytical techniques use the intrinsic surface sensitivity of low energy (10–2000 eV) electrons.

The surface specificity of low energy electrons arises from the very short inelastic mean free path (MFP) for these electrons in a solid. This property can be seen in Fig. 90.1 which

Fig. 90.1 The variation of the inelastic mean free path with electron kinetic energy (*universal curve*). Based on *Briggs and Seah* [14]

plots measured values of the inelastic MFP for a number of materials and electron energies between 1 and 2000 eV. The curve is called *universal* because the same general trend of short inelastic MFP is observed for nearly all materials [14]. The dominant energy loss mechanisms are valence band excitations (plasmons and electronic excitations), and since most materials have similar valence electron densities, the resultant inelastic scattering MFP is to a good approximation, material independent.

The very short inelastic MFPs for low energy electrons has the result that any that escape from the solid without having undergone inelastic scattering can only have originated very close to the surface, usually within a few atomic layer spacings. Many of the surface analysis techniques described in this chapter use this surface sensitivity to obtain surface structural and spectroscopic information. The same techniques are easily applicable to conducting and semiconducting materials, and can also be applied to insulating materials, if the charging effects are dealt with in some manner.

90.2 Electron–Atom Interactions

90.2.1 Elastic Scattering: Low Energy Electron Diffraction (LEED)

The elastic scattering of low energy (20–500 eV) electrons at surfaces is historically important in physics as the experiments of Davisson and Germer provided early experimental evidence of the wave nature of electrons. After these initial experiments, the technique was largely unused until the advent of cleaner ultra-high vacuum systems and surface preparation techniques in the 1960's. LEED is one of the most important and widely used surface characterization techniques due to its surface sensitivity and wide utility [5].

Diffraction from a two-dimensional net of scatterers results in a two-dimensional array of reciprocal lattice *rods* oriented normal to the surface. All kinematically allowed

rods intersect the Ewald sphere at all energies—unlike the case in bulk X-ray diffraction. The short inelastic MFP for scattering low energy electrons yields the surface sensitivity of LEED for a crystal surface. The kinematic theory used in X-ray diffraction is not directly applicable to LEED since the low energy electrons can undergo several elastic collisions in the surface region. The elastic MFPs for low energy electrons are comparable in magnitude to the inelastic mean free paths shown in Fig. 90.1. This *multiple scattering* does not affect the positions of the diffraction beams, but does alter their intensities due to interference effects.

Kinematic analysis is sufficient to determine the diffraction beam positions for a proposed structure, and this is the most common use for LEED. A diffraction pattern is often sufficient to determine the surface periodicity and unit mesh size. However determining the surface crystal basis from the intensities of the diffracted LEED beams requires moderately sophisticated calculations to be performed for proposed structures.

Quantitative LEED generally compares measured $I(V)$ curves (the intensity I of a particular diffraction beam as a function of electron energy measured in volts) with a calculated $I(V)$ profile for a proposed surface crystal structure. These calculations determine the propagating electron wave functions Ψ_{LEED} that take into account electron-ion core scattering cross sections and phase shifts, available multiple scattering pathways, inelastic scattering cross sections and Debye-Waller effects. The structural parameters are varied systematically until agreement can be reached with the experimental $I(V)$ curves [15, 16]. These calculations can yield surface atom positions to better than 0.1 Å vertically and 0.2 Å horizontally. Over 1000 surface structures have been determined using LEED and associated techniques [17].

Clean surfaces often have a different crystallography than simple termination of the bulk crystal structure. Due to the absence of neighbors above the surface, the surface atoms can undergo both relaxation (change in interlayer spacing) and reconstruction (changes in periodicity and bonding) [2]. While relaxation and reconstruction do occur on all types of surfaces, the reconstructions found on semiconductors are most striking. The strong covalent bonds that are broken when a semiconductor is cleaved give rise to high energy *dangling bonds*. The surface energy is minimized by having the surface reconstruct to reduce the total number of these bonds. The resultant structure is formed through a balance between eliminating as many dangling bonds as possible and the resultant stress caused in other bonds due to the displacements of the surface atoms. One example of this is the clean Si(111) surface, in which 49 surface atoms form a new periodic arrangement to make up the reconstructed Si(111)–(7×7) unit cell [2]. The number of dangling bonds is thereby reduced from 49 to 19.

90.2.2 Inelastic Scattering: Electron Energy Loss Spectroscopy

Low energy surface excitations such as phonons, plasmons and electron-hole pair excitations can be studied using inelastic electron scattering. High resolution electron energy loss spectroscopy (HREELS) [18] uses incident electron beam energies of 1–300 eV with energy resolutions of 1–10 meV. Inelastic scattering phenomenon are divided into three types: dipole, impact and resonant scattering. Surface vibrations are also studied using infra-red absorption spectroscopy and inelastic atomic beam scattering techniques [19].

Dipole Scattering

In dipole scattering HREELS, the incident electron ($1 < E_i < 20$ eV) undergoes a long range Coulomb interaction with dipole fields associated with a dynamic dipole moment. The main characteristic of dipole scattering is that the inelastically scattered electrons have an angular distribution that is strongly peaked (width $\Delta\theta \approx \hbar\omega/E_i$) close to the specular direction ($\theta_i = \theta_f$). In this limit there is no momentum exchange with the surface vibrational mode (i.e., $\mathbf{k}_{\parallel} = 0$ in the bandstructure), so dipole scattering HREELS is similar to infrared spectroscopy in that only ir active vibrational modes at the zone center can be studied. At the surface of a conductor, dielectric screening guarantees that only ir active modes having a component perpendicular to the surface are visible—modes having dipole moments parallel to the surface are screened by the surface and so cannot be excited by dipole scattering. This *quasi-selection rule* allows the site symmetry for some systems to be decided [18]. Dipole scattering is most commonly used in the study of vibrations of molecules on surfaces, which often have dipole-active vibrational modes that are both intrinsic and caused by adsorption (i.e., frustrated translations and rotations).

Impact Scattering

In impact scattering, the incident electron samples the short-range interatomic potential, and is not restricted to dipole-active vibrational modes [18]. Higher electron energies are used ($30 < E_i < 300$ eV) since the cross section for impact scattering generally increases with energy. The inelastically scattered electrons are distributed at all angles, and so there can be exchange of parallel momentum (\mathbf{k}_{\parallel}) with the surface, allowing the mapping of surface excitation bandstructure $\hbar\omega(\mathbf{k}_{\parallel})$. The cross sections for impact scattering HREELS can be calculated using an approach similar to LEED, but now considering the normal displacements of atoms from equilibrium positions. The scattering potential $V(\mathbf{r}, [\mathbf{R}])$ (where $[\mathbf{R}]$ is the set of position vectors of the N atoms in

the surface region) can be expanded in terms of the normal displacements μ_i from equilibrium according to

$$V(\mathbf{r}, [\mathbf{R}]) = V(\mathbf{r}, [\mathbf{R}_0]) + \sum_{i=1}^N \left(\nabla_{\mu_i} V(\mathbf{r}, [\mathbf{R}]) \right) \Big|_{[\mathbf{R}_0]} \cdot \mu_i + \dots \quad (90.1)$$

The first term is responsible for elastic scattering (LEED) and the second term is the dominant term for impact scattering. The inelastic cross section for mode i is then [20]

$$\frac{d\sigma}{d\Omega} = \left| \left\langle \Psi_{\text{LEED}}^*(\mathbf{k}_f) \left| \frac{\partial V}{\partial \mu_i} \right| \Psi_{\text{LEED}}(\mathbf{k}_i) \right\rangle \right|^2 \quad (90.2)$$

using electron wave functions calculated using the same formalism as LEED. The symmetry properties of this matrix element can be used to determine the polarization direction of surface vibrational modes by searching for systematic absences in the inelastic intensity in particular high symmetry direction of the surface [20]. Impact scattering studies are most commonly made in the study of surface phonon bandstructure and the vibrational modes of adsorbed molecules that are not dipole-active.

Resonant Scattering

Resonant electron scattering at surfaces [21, 22] is usually applied to the study of adsorbed molecules, and has much in common with resonant scattering from gas-phase atoms and molecules (see Chap. 49). In resonant scattering, the incident electron combines with a target molecule to form a short-lived molecular ion, which subsequently decays and can leave the molecule vibrationally or electronically excited. The cross sections for this process have a typical profile. For example, in a shape resonance the formation of the temporary negative ion intermediate corresponds to adding the incident electron to a particular unoccupied orbital of the target molecule. The study of the angular dependence of resonance scattering cross sections [22] can yield information on the orientation of molecules on surfaces, since the electron capture and emission cross sections are fixed by the molecular orientation and the resonance symmetry.

90.2.3 Auger Electron Spectroscopy

Auger electron spectroscopy (AES) is one of the most widely used surface science techniques due to its chemical and surface sensitivity [5, 14, 23]. Core holes are created in near surface atoms using a high energy electron beam (2–5 keV, 1–100 μA) or less commonly, an X-ray source. For these low

binding energy core holes, the Auger decay mode is highly probable (Sects. 26.1.1 and 66.3.1). Although the Auger energy and lineshape can give spectroscopic information, in surface science this is seldom used—rather it is the chemical fingerprint of the atoms which is of interest.

Auger electron spectroscopy is a surface sensitive technique by virtue of the low kinetic energy (50–1000 eV) of the emitted Auger electrons. Auger electrons from atoms more than a few Ångströms below the surface are inelastically scattered and so not detected by the energy selective detector. The kinetic energy of the Auger electrons is

$$\mathcal{T}_e = E_A - E_B - E_C - U \quad (90.3)$$

where E_A is the binding energy of the initial core electron and E_B , E_C are the binding energies of the other electrons (one or both are valence levels) involved in the Auger process. Energy shifts and relaxation are accounted in the term U which includes hole-hole interactions and atomic and solid state (dielectric) screening of the holes, and hence can be sensitive to the local chemical environment.

Auger spectra are typically obtained in derivative mode [i.e., $N'dN(E)/dE$] to separate the Auger transitions from the secondary electron background, and comparison is made to reference spectra [24]. The raw chemical sensitivity of AES is very high, and surface concentrations of $\approx 1\%$ of many common chemical species can be detected. Semiquantitative measurements may be made by comparison to these reference spectra, but such comparisons only give atomic concentrations within a factor of 2 (or worse) since the measured AES signal can be modified by a number of factors. More precise quantitative measurements can be made by calibration of the AES intensity for the atomic constituents at a surface [5]. The AES sensitivity to atoms A on a clean substrate (atoms B) can be determined if the absolute quantity of A can be established by some other means.

The chemical sensitivity of AES can also be exploited as a form of chemical microscopy (scanning Auger microscopy) since the exciting electron beam that is used may be focused to a very small size. The Auger signal from the small target volume can be analyzed for specific chemical components. By rastering the incident electron beam, a chemical map of the surface can be made.

90.3 Photon–Atom Interactions

90.3.1 Ultraviolet Photoelectron Spectroscopy (UPS)

Photoelectron spectroscopy (PES) (Sect. 65.1) has been historically divided into UV photoelectron spectroscopy for low photon energies (generally the study of valence electron

states) and X-ray photoelectron spectroscopy (study of core electron levels). The use of low energy photons ($5 < h\nu < 50$ eV) for PES of solids has the advantage that the photons have a negligible momentum ($\mathbf{k} \approx 0$). This allows straightforward mapping since the transitions are vertical in momentum space:

$$h\nu = E_f(\mathbf{k} + \mathbf{G}) - E_i(\mathbf{k}) \quad (90.4)$$

where \mathbf{k} is the electron state wavevector and \mathbf{G} is a reciprocal lattice vector.

Most UPS studies are done using angle-resolved photoelectron detection (also called angle resolved photoelectron spectroscopy or ARPES). The kinetic energy \mathcal{T}_e and emission angle θ of the photoelectrons are measured, allowing the initial state binding energy and momentum parallel to the surface (\mathbf{k}_{\parallel}) to be determined from

$$k_{\parallel} = \sqrt{\frac{2m\mathcal{T}_e}{\hbar^2}} \sin \theta. \quad (90.5)$$

The mean free path of the photoelectrons from valence levels allows both surface and bulk electron states to be studied. Separation of the surface from bulk bands can be accomplished in several ways [5]. Since a crystal surface has two-dimensional symmetry, only the \mathbf{k}_{\parallel} component of momentum is a good quantum number for the surface states. Also, in transporting the surface or bulk state photoelectron of momentum \mathbf{k} through the surface to the detector, only the \mathbf{k}_{\parallel} component is conserved. A bulk state disperses in three-dimensions, requiring knowledge of $\mathbf{k} = \mathbf{k}_{\parallel} + \mathbf{k}_{\perp}$. The magnitude of \mathbf{k}_{\perp} cannot be determined unless the inner potential (change in potential normal to the surface) is known by some other means. This property allows bulk and surface states to be distinguished since surface states remain fixed in energy for a constant \mathbf{k}_{\parallel} , while bulk states disperse if \mathbf{k}_{\perp} is changed while \mathbf{k}_{\parallel} is kept constant. This is done by measuring the photoelectron spectrum for a range of UV photon energies at a fixed value of \mathbf{k}_{\parallel} (often at $\theta = 0$ so $\mathbf{k}_{\parallel} = 0$). Bulk states disperse since \mathbf{k}_{\perp} varies as the photon energy is changed, but the surface states remain at a fixed binding energy in the photoelectron spectrum.

The photoelectron transition matrix element between initial and final states $|i\rangle$ and $|f\rangle$ due to the incident photon vector potential \mathbf{A} is

$$I \propto |\langle f | \mathbf{A} \cdot \mathbf{p} + \mathbf{p} \cdot \mathbf{A} | i \rangle|^2 \approx |\langle f | 2\mathbf{A} \cdot \mathbf{p} | i \rangle|^2. \quad (90.6)$$

The spatial variation of \mathbf{A} near the surface (the surface photoeffect) can be neglected, although this is not strictly valid at these low photon energies [25].

Due to the low photoelectron kinetic energies in most UPS work, precise calculation of photoelectron spectrum intensities is rather difficult due to multiple scattering and phase

Fig. 90.2 A set of UPS spectra for CO adsorbed on various surfaces, as well as gas phase and solid CO. The peak labeled *su* is a shake-up satellite peak. After [26]

shifts sensitive to valence electrons. However, the initial electron state symmetries can be determined using the symmetry properties of the matrix element Eq. (90.6). Selection rules allow the state symmetries to be determined by measuring the photoemission spectrum along high symmetry directions of the surface using polarized UV radiation [5].

The valence electron states of adsorbed molecules can also be studied using UPS. Peaks in the photoelectron spectrum due to valence levels of adsorbed molecules tend to have larger linewidths (≈ 1 eV typically) than in the gas phase due to solid state and instrumental effects, so vibrational structure is seldom resolved. The positions of the molecular valence states are shifted in energy due to the surface work function and solid state relaxation (dielectric screening) effects. In addition to these rigid shifts, chemical shifts are also observed due to bonding (chemisorption) interactions between the molecule and surface. The molecular character of the valence orbitals is often retained from the gas phase, so the shifted levels can be identified by using the symmetry properties of the photoemission matrix element. For example, photoemission from gas phase CO shows three valence states: 5σ , 1π and 4σ in order of increasing binding energy. A series of photoemission spectra [26] for gas phase CO, solid CO and CO chemisorbed on several transition metal surfaces (in order of increasing CO–surface binding energy) is shown in Fig. 90.2. For solid CO and

weakly chemisorbed CO/Ag(111) all three valence orbitals of molecular CO are well resolved, though the adsorbed CO spectrum is shifted rigidly in energy by relaxation effects. Since CO is chemisorbed more strongly on Cu(111) and Pd(111), the 1π and 5σ valence states shift relative to one another. The strongly overlapping 1π and 5σ states observed for chemisorbed CO can be individually resolved by using the photoemission selection rules and linearly polarized UV radiation [26]. The origin of the chemical shift between the 5σ and 1π levels has been ascribed to bond formation involving the CO 5σ level and σ -symmetry d-electron states on the transition metal surfaces [2].

90.3.2 Inverse Photoemission Spectroscopy (IPES)

Inverse photoemission spectroscopy is properly classified as an incident electron technique but is included here as a natural companion to UPS. IPES utilizes low energy electrons (5–50 eV) incident on a surface. Transitions from a high-lying initial electron state in the continuum to a lower unoccupied state cause a UV photon to be emitted. By detecting the emitted photon intensity as a function of energy, the joint density of states is measured [7]. IPES is used to study the unoccupied portion of surface and bulk band-structure, particularly the region between the Fermi level and the vacuum level, which is difficult to access by other means. This allows the study of unoccupied states of adsorbed molecules (e.g., antibonding molecular levels) as well as intrinsic surface states such as the Rydberg-like states of electrons trapped in the image potential at the surface [7].

90.3.3 X-Ray Photoelectron Spectroscopy (XPS)

X-ray photoelectron spectroscopy allows the study of the energy of atomic core levels via the Einstein photoelectric equation $\mathcal{T}_e = h\nu - E_b$, where \mathcal{T}_e is the kinetic energy of the photoemitted electron and E_b is the binding energy of the core level. Atoms bound in different chemical environments (e.g., at particular sites on a surface) experience different chemical shifts, and so are measured at slightly different binding energies. This sensitivity to chemical environment allows XPS to characterize the different types of binding sites for similar atoms, and measure their abundance by measuring the relative intensities of XPS emission from different species.

Shifts in \mathcal{T}_e arise from two sources: intra-atomic and inter-atomic relaxation shifts. The intra-atomic relaxation E_a is due to screening of the core hole by other electrons in the emitter atom. The inter-atomic relaxation E_r is important in solids (particularly for metals) and is due to screening of the core hole by the dielectric response of the surrounding

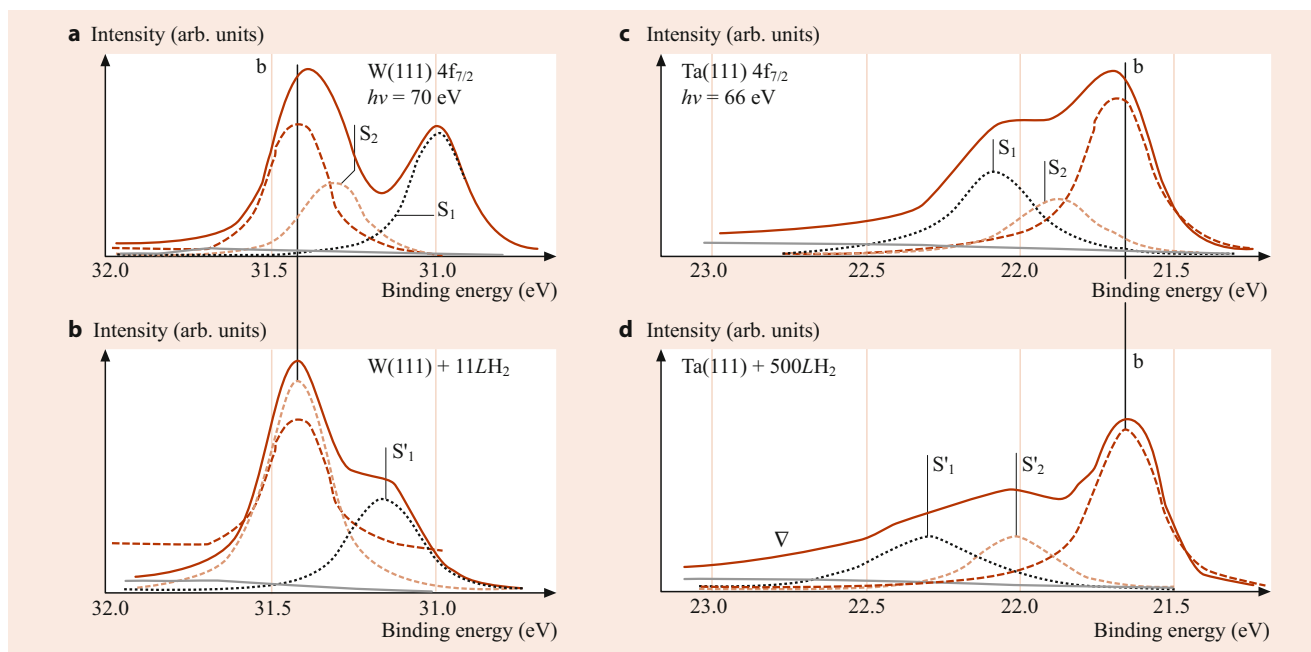

Fig. 90.3 XPS spectra of the $4f_{7/2}$ states of W(111) and Ta(111). Contributions from the bulk (b) and surface (S1,S2) atoms can be distinguished, and the surface atom peaks are shifted by the adsorption of hydrogen. After [27]

medium. These relaxation shifts (on the order of a few eV) tend to increase the kinetic energy of the emitted photoelectron, so the kinetic energy in the adiabatic limit is

$$\mathcal{T}_e = h\nu - E_b + E_a + E_r. \quad (90.7)$$

Since photoemission is a rapid process, nonadiabatic processes lead to shakeup and shakeoff features in which other electrons are excited to higher energy levels, causing the photoelectron to have lower kinetic energy [5] (see Sect. 65.1.2). It is also possible to excite discrete excitations of the solid, such as plasmons and a continuum of low energy electron-hole excitations, causing the XPS peak to have an asymmetric lineshape. The overall XPS distributions of \mathcal{T}_e thus contain contributions from the adiabatic channel, and lower energy photoelectrons in a series of discrete peaks or a continuum from nonadiabatic processes.

The chemical abundance of a species can be determined from the sum rule that the total XPS cross section is proportional to the sum of the adiabatic peak and all the shake-up and shake-off components. However it is usually only convenient to measure the intensity of the adiabatic peak. If comparisons are made between chemical species in different chemical environments, the shake-up and shake-off intensities may differ. Hence the adiabatic channel intensities might not reflect the true abundance. Very often this problem can be minimized by careful calibration, and chemical analyses can be made to an accuracy of a few percent.

The surface sensitivity of XPS is due to the short inelastic MFP for the photoelectrons, which can be made to have

energies in the range 10–1000 eV by appropriate choice of the X-ray wavelength. The XPS signal is proportional to $\exp[-z/(\lambda \cos \theta)]$, where z is the depth of the emitter, λ is the inelastic mean free path of the photoelectron and θ is the angle measured from the surface normal.

The popularity of XPS as a surface analysis technique is due to the availability of convenient and sufficiently intense monochromatic X-rays from lab sources (usually Al and Mg K_α X-ray lines at 1486.6 and 1253.6 eV). The increasing availability of continuously tunable X-rays from synchrotron radiation sources allows improved measurements due to the ability to tune the X-rays to slightly above threshold, where the XPS cross sections are maximized, the inelastic MFP is shorter (hence more surface specific) and electron monochromators can operate with higher resolution [5].

As an example of the chemical sensitivity of XPS, photoelectron spectra of the $4f_{7/2}$ core levels of W(111) and Ta(111) are shown in Fig. 90.3. The spectra show discrete peaks from both bulk and surface atoms. The binding energies of the surface atoms are affected by the adsorption of hydrogen.

XPS can also be used to give local structural information due to elastic scattering of the photoemitted electron in the region near the emitter [5]. One form of this is the use of forward scattering from a buried emitter. A high energy XPS photoelectron is focused in the direction of nearby atoms due to a lower effective potential close to the atomic core. Angular scanning of the XPS detector will then detect a more intense signal along the bond axis. This method has proved useful in studying the orientation of adsorbed molecules and the structure of hetero-epitaxial thin films [28].

90.3.4 X-Ray Absorption Methods

X-ray absorption methods [8] measure the decay of the core hole rather than the intensity of emitted photoelectrons, since that XPS process is complicated by a number of possible final state processes, as discussed above. To obtain surface sensitivity, the X-ray absorption is measured using a low energy electron emitting channel such as an Auger electron emission or the total electron yield, which are proportional to the overall X-ray absorption. These methods require an intense and tunable source of monochromatic x-radiation near the excitation edge for the core level of a particular atom, and so are usually performed using synchrotron radiation. Synchrotron sources have the additional benefit of linearly polarized light, which is crucial for NEXAFS and useful for SEXAFS discussed next.

SEXAFS: Measurement of Bond Lengths

The surface extended X-ray absorption fine structure (SEXAFS) technique is most commonly used to measure the bond lengths for atoms adsorbed on a surface. SEXAFS utilizes the elastic backscattering of the emitted XPS photoelectron from nearby atoms that surround the emitter. Elastically scattered waves arrive back at the emitter and add coherently (constructively and destructively) to the outgoing wave, thus modifying the matrix element for the transition to the final state [29]. Experimentally, the cross section $\sigma(h\nu)$ for X-ray absorption above the threshold photon energy is modified by an oscillatory structure. The *atomic* contribution to the absorption cross section can be removed using

$$\chi = \frac{\sigma - \sigma_0}{\sigma_0}, \quad (90.8)$$

where σ and σ_0 are the measured surface and free atom X-ray absorption cross sections. If only single scattering events are involved in backscattering to the emitter then the fine structure function χ is

$$\chi(k) = \sum_{i=1}^N A_i(k) \sin [2kR_i + \phi_i(k)], \quad (90.9)$$

where k is the magnitude of the photoelectron wavevector and the sum is done for N shells of atoms surrounding the emitter. The distance R_i is the radius of the i -th shell and $2kR_i$ is the associated phase factor for the backscattered photoelectron, with an amplitude $A_i(k)$. The phase shift $\phi_i(k)$ is required due to the backscattering path through the potential surrounding the emitter and scattering from the atom at R_i . If the ϕ_i could be ignored, then a simple Fourier transform of $\chi(k)$ would reveal the radial distribution function and the bond lengths R_i [29]. In practice, the phase shifts cannot be neglected, but very often these can be found by studying chemically similar systems in which the bond lengths

are known. The phase shifts for photoelectrons well above the absorption edge (having kinetic energies greater than ≈ 50 eV) are dominated by the atomic ion cores, and so are not sensitive to the valence electronic structure. The phase shifts can also be calculated in a straightforward way since this problem is essentially the same as done in LEED multiple scattering calculations.

The amplitudes $A_i(k)$ due to scattering from shell i at distance R_i from a point source emitter are [29]

$$A_i(k) = \frac{N_i^*}{kR_i^2} |f_i(\pi, k)| \exp(-2\langle u^2 \rangle_i k^2) \times \exp(-2R_i/\lambda), \quad (90.10)$$

where N_i^* is an effective number of atoms and $\langle u^2 \rangle_i$ is the mean-square displacement of the atoms in shell i . The backscattering amplitude $|f_i(\pi, k)|$ has been separated from its phase factor $\phi_i(k)$ in Eq. (90.9). The inelastic mean free path for the photoelectrons reduces the contribution from successive shells by a factor $\exp(-2R_i/\lambda)$, and it is this term that allows the kinematic single-scattering approach to be used. Multiple scattering paths involve longer trajectories and so are more strongly attenuated by this exponential factor. If the near-edge energy region of the absorption cross section is not included in the analysis, then the scheme outlined in Eqs. (90.9) and (90.10) is reasonable. The near-edge region (within ≈ 50 eV of the absorption edge) is troublesome, not only because of multiple scattering, but also because the phase shifts $\phi_i(k)$ for low energy photoelectrons are more sensitive to valence electron distributions, and so are more sensitive to the details of the local chemical environment.

The SEXAFS method is illustrated with the data of Fig. 90.4 for iodine adsorbed on Cu(111). Panel (a) shows the measured X-ray absorption $\sigma(h\nu)$ for both the surface system Cu(111)-I and bulk CuI. The extracted $\chi(k)$ and their Fourier transforms are shown in (b) and (c). The Cu-I nearest neighbor bondlength is clearly shown by the peak in (c), and is found to be 0.07 \AA longer than in bulk CuI. SEXAFS is most commonly applied to atomic adsorption systems since molecular systems are difficult to analyze, as they can contain several similar bond lengths, and the shells containing different atoms are difficult to model.

NEXAFS: Molecular Orientation at Surfaces

In SEXAFS, the X-ray absorption close to the excitation edge is avoided due to the problems of multiple scattering, and phase shifts that are chemically sensitive to valence electrons. The study of near-edge X-ray absorption fine structure (NEXAFS) can avoid these difficulties by using only the symmetry properties of the transition matrix element without concern for the absolute amplitudes [31]. For isolated molecules, unoccupied molecular states having σ or π symmetry are very commonly found close to or just below the

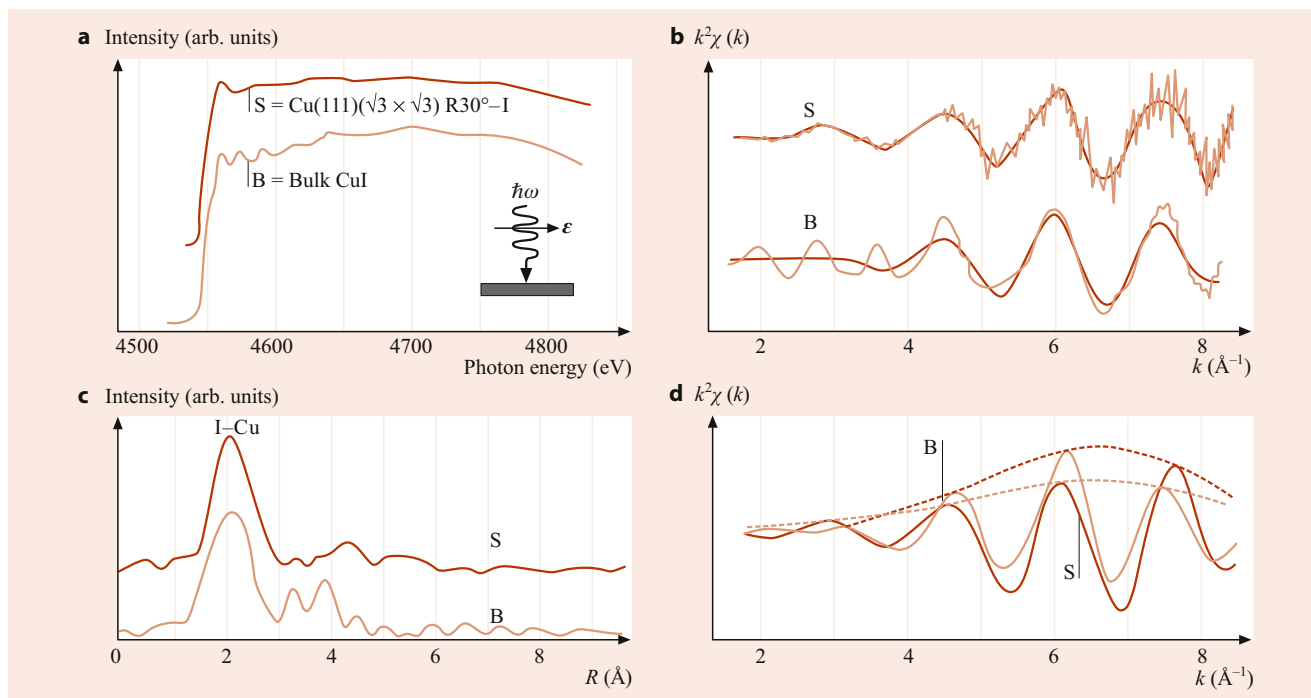

Fig. 90.4 (a) X-ray absorption data taken near the iodine edge for bulk CuI and Cu(111)-I. (b) The extracted fine structure function $\chi(k)$, shown multiplied by k^2 to enhance the high k structure. (c) The Fourier transform of $\chi(k)$ showing the location of the first shell of Cu atoms from the I emitters. threshold for photoemission. These *molecular resonances* often remain for adsorbed molecules, and the symmetry properties of the absorption intensity $I \propto |\langle f | \mathbf{A} \cdot \mathbf{p} | i \rangle|^2$ can be used to determine the molecular orientation.

For the overall matrix element to be nonzero, it must be totally symmetric. Using linearly polarized synchrotron radiation, the direction of polarization \mathbf{A} can be varied by rotating the crystal. For example, the K-edge X-ray absorption of CO on the Ni(100) surface in Fig. 90.5 shows final state resonances A (π -symmetry) and B (σ -symmetry). The intensity of these features depends of the direction of polarization of the incident X-rays. X-rays with a polarization vector parallel to the surface ($\theta = 90^\circ$) strongly excite the π -symmetry absorption while the σ -symmetry absorption is absent. For grazing incidence X-rays polarized normal to the surface, the σ -resonance is prominent. From dipole selection rules, this polarization dependence of the X-ray absorption is evidence that the CO molecule is adsorbed with its bond perpendicular to the plane of the Ni(100) surface.

The σ -resonance final state in NEXAFS corresponds to multiple scattering of the photoelectron along the bond axis. The overall phase shift for this final state is approximately

$$\int \sqrt{E - V(r)} dr \approx \sqrt{E - V(r)} R = \text{const.} \quad (90.11)$$

Fig. 90.5 Near-edge X-ray absorption data from the C K-edge from CO adsorbed on Ni(100) as function of incident photon angle θ . The molecular π (peak A) and σ (peak B) resonances are observed. The polarization dependence of the absorption allows the CO orientation to be determined. After [32]

where R is the bond length. This sensitivity of the final state phase shift to bond lengths allows the σ -resonance energy to be used as a measure the molecular bond length [33]. A plot of the σ -resonance energy versus $1/R^2$ shows a linear relationship, as is found in the case of simple hydrocarbons in the gas phase and adsorbed on a Cu(100) surface [31].

90.4 Atom–Surface Interactions

90.4.1 Physisorption

The binding interactions between atoms and surfaces can be classified as physisorption (long range attractive dispersion forces) and chemisorption, in which chemical bonds are formed. The long-range dispersion force between a polarizable atom and a conducting surface give rise to the leading term of the van der Waals potential $V(z) \propto -1/z^3$. At smaller atom-surface separations, the location of the reference image plane needs to be included, resulting in an attractive potential $V(z) = -C_v/|z - z_i|^3$ where z_i is the distance from the last atomic plane to the image plane, typically 2–3 Å. In principle, the constant C_v is calculable from the dielectric properties of the substrate and the atomic polarizability, but experiments have found values of C_v 40% less than expected [34]. The cause of this discrepancy has not been clarified, although contributions from surface roughness have been suggested.

At larger atom-surface separations, retardation effects must be taken into account in the dispersion interaction (the Casimir–Polder force, Sect. 83.3.4), and here theory predicts a $1/z^4$ interaction potential. This form for the potential has been confirmed experimentally [35].

As the atom approaches the surface, wave function overlap eventually causes repulsion. In the absence of chemical bond formation, the repulsive potential is simply proportional to the surface electron density $n(z)$, resulting in the overall physisorption potential

$$V(z) = Kn(z) - \frac{C_v}{|z - z_i|^3}. \quad (90.12)$$

The surface charge density $n(z)$ decreases exponentially above the surface [2], and the constant K can be determined to reasonable accuracy by an effective medium theoretical approach [36]. This shallow physisorption potential well has been studied experimentally in atomic beam (often He) scattering experiments. Under certain scattering conditions, it is possible for an incident atom to be *selectively adsorbed* on the surface by making transitions into and out of bound states of the potential well of Eq. (90.12). The incident atom with wavevector \mathbf{k} is diffracted by a surface reciprocal lattice vector \mathbf{G}_{hk} into a bound state E_n of the potential well [2]. The diffracted atomic beam intensities due to scattering via selective adsorption show strong variations which can be related to the quantum numbers (n, h, k) , and give information on the shape of the physisorption potential well.

90.4.2 Chemisorption

Many atoms and molecules will chemisorb when brought sufficiently close to a surface, forming chemical bonds (co-

valent or ionic) that are much stronger than the physisorption bond [3]. In chemisorption, there is charge transfer between the adsorbate and the surface, modifying the electronic structure of both. Valence electronic levels of the adsorbate are shifted in energy and also broadened by resonant interactions with the delocalized valence electrons at the surface (e.g., free electron-like s–p states). For many transition metal surfaces, interactions with the more localized d-states are also important.

The adsorbate-surface bond energies are most commonly studied by thermal desorption spectroscopy (TDS) [37, 38]. In this method, the adsorbate covered surface is heated using a linear temperature ramp, and the desorption rate of a particular species is measured using a mass spectrometer. By using a range of heating rates β , not only can the desorption energy be measured, but the kinetics governing the desorption process can be uncovered. For example, in the simplest case of a coverage-independent adsorption energy and first order kinetics, if the peak desorption rate occurs at a temperature T_0 then [39]

$$\frac{\nu}{\beta} = \frac{E_d}{k_B T_0^2} \exp\left(\frac{E_d}{k_B T_0}\right) \quad (90.13)$$

where E_d is the desorption energy and ν is the *attempt frequency* for desorption. Since both ν and E_d are unknown, values for both can be found by measuring TDS spectra using two different heating rates β or by estimating ν (often $\nu \approx 10^{13} \text{ s}^{-1}$). More complex desorption kinetics are studied by utilizing the full desorption profile, and a range of heating rates and initial adsorbate coverages. These kinetic data are also applicable to adsorption if the adsorption and desorption are reversible processes. For irreversible adsorption systems, it is possible to measure the adsorption energies directly [40] by monitoring the ir radiation emitted from a surface as a submonolayer quantity of atoms or molecules is adsorbed.

90.5 Recent Developments

Surface Physics has both rapidly matured and expanded its connections with other disciplines in the last eight years. A number of notable review works have been published recently [41–45]. The application of surface science techniques has expanded rapidly in a number of technological areas, such as semiconductor devices, catalysis, and magnetic materials. The emerging field of nanotechnology has drawn heavily from the techniques of surface science. Important advances have been made in a large number of areas, including biosurfaces [46, 47], cluster science [48], carbon fullerene materials [49, 50], electrochemistry [51], and surface photochemistry [52].

Continuing advances have been made in the application of light from synchrotron radiation sources—so much so that a complete catalog of applicable techniques would be difficult to compile. Many new facilities have been constructed, with higher brightness sources allowing the development of a large number of new techniques using synchrotron radiation from the ir through the soft and hard X-ray regimes [53, 54].

Abstract

For an atom with a small to moderately large atomic number Z , the typical length scale a_0/Z of the innermost core orbitals is so much larger than typical nuclear length scales that the corrections to the energy levels and wave functions arising from the nonzero electric charge radius of the nucleus can accurately be computed using first-order perturbation theory, as is described in Sect. 91.2.

Nonetheless, these relatively small shifts can sometimes have a profound effect on processes in atomic and/or nuclear physics, particularly if two or more energy levels are very close. For example, as is discussed in Sect. 91.3, the presence of the electron cloud makes energetically possible the β -decay of ^{187}Re to ^{187}Os and significantly modifies the energy distribution of products in the β -decay of tritium in various chemical environments. Also, electronic screening can greatly enhance the cross sections of low-energy nuclear reactions relative to what they would be for bare nuclei.

In isotopes of hydrogen, the replacement of an electron by a muon, with $m_\mu \approx 207m_e$, results in a tiny neutral *atom* that can closely approach another nucleus, thereby catalyzing nuclear fusion. For example, the rate of deuterium–tritium fusion is enhanced by 77 orders of magnitude if a single electron is replaced by a muon. A rich variety of bound-state properties and scattering processes for these exotic atoms and molecules has been extensively investigated, as is reviewed in Sect. 91.4.

91.1 Introduction

That nuclei are not infinitesimally small, structureless particles causes small but perceptible shifts in the electronic structure of atoms and molecules. Even for nuclei with a small atomic number Z , the effects are readily detectable through modern high-precision spectroscopy, and their magnitude grows as $Z^{14/3}$. Conversely, the presence of electrons tightly bound to atomic nuclei can alter the ordering of nuclear energy levels or make them unstable to β decay. Atomic effects can also influence nuclear branching ratios into the product

channels. Nominally small atomic effects have been shown to affect the complicated chain of nuclear reactions responsible for the generation of energy in the sun. Setting bounds to the rest mass of the neutrino from the endpoint of the β -decay spectrum of tritium requires a precise understanding of atomic and molecular structure and scattering processes.

The great disparity between nuclear scales of energy (several MeV) and distance (10^{-5} to 10^{-4} Å) and the corresponding atomic scales (several eV and 1 Å, respectively) usually allows the separate treatment of nuclear and atomic effects. However, since not absolute energies but energy differences determine the magnitudes of perturbative effects, near coincidences in energy differences can greatly enhance the interplay between the two regimes. Such comparable differences of energies account for the important role of nuclear structure in the Lamb shift splitting between the $2s_{1/2}$ and $2p_{1/2}$ states of the hydrogen atom (Chap. 28) and the influence of atomic structure on nuclear processes (Sects. 91.2 and 91.3).

For the case of muonic atoms and molecules, the interplay is enhanced by the much larger mass of a muon relative to an electron. This decreases the distance scale by a factor of m_e/m_μ and increases the energy scale by a factor of m_μ/m_e . Small corrections such as the vacuum polarization part of the Lamb shift are amplified even more ($\approx (m_\mu/m_e)^3$ for low Z).

Besides the areas where atomic physics effects play an important role in nuclear physics, or vice versa, it is worth remembering that atomic and molecular physicists and nuclear physicists can benefit from knowing the theoretical techniques that have been developed in each others' fields. For example, it is well known that group theoretical methods are widely employed in formulating and solving many-body problems in nuclear, atomic, and molecular physics. To take another case, the coupled-cluster method, which was first proposed in the late 1950s by *Coester* and *Kümmel* in the context of nuclear theory [1–3], was applied a decade later to electronic structure problems in atomic and molecular physics and quantum chemistry by *Cizek*, *Paldua*, and *Shavitt* [4–6], and in the 1980s was widely developed by Rod Bartlett and coworkers at the University of Florida and by John Pople and coworkers at Carnegie Mellon University. *Quantum halos*, which are very loosely bound states for which most of the probability density is spread diffusely over the classically forbidden region, have been treated in a unified manner for both nuclear and molecular systems [7].

91.2 Nuclear Size Effects in Atoms

91.2.1 Nuclear Size Effects on Nonrelativistic Energies

Interest in the influence of a finite nuclear charge distribution on the energy levels of the hydrogen atom goes back

to the measurement of the Lamb shift [8–11], and to even earlier indications that the fine structure of hydrogen did not quite agree with the predictions of the Dirac equation for a point nucleus [12–15]. The finite proton size does, in fact, raise the energy of the $2s_{1/2}$ state relative to $2p_{1/2}$, but the shift is only $\approx 0.012\%$ of the dominant electron self-energy contribution (Chap. 28). It must nevertheless be taken into account in high-precision tests of QED. A long-standing disagreement in the proton size between values obtained from electron-based measurements and muon-based measurements has now been resolved [16], resulting in the value $r_p = 0.833(10)$ fm, in excellent agreement with the muonic value $r_p = 0.84087(39)$ fm [17, 18].

Early derivations were given by several authors [19–22] and generalized by *Zemach* [23] (also [24]) to a form involving integrals over the nuclear electric and magnetic form factors. The basic result is illustrated by the following argument. Let $\rho(\mathbf{r})$ be the electron density, which may have no spatial symmetry properties in the particular case of a polyatomic molecule, and $\rho_n(\mathbf{r}_n)$ be the charge density of a nucleus, which obeys

$$\int d^3r_n \rho_n(\mathbf{r}_n) = Z. \quad (91.1)$$

Assume that $\rho_n(\mathbf{r}_n)$ has no permanent electric dipole moment, so that

$$\int d^3r_n \mathbf{r}_n \rho_n(\mathbf{r}_n) = \mathbf{0}. \quad (91.2)$$

By writing the Coulomb potential for a point-like nucleus as

$$-\frac{Z}{r} = -\int d^3r_n \frac{Z\delta^{(3)}(\mathbf{r}_n)}{|\mathbf{r} - \mathbf{r}_n|}, \quad (91.3)$$

the first-order shift of the electronic energy due to the replacement of the point-like nucleus by an extended nucleus is

$$\Delta E_{\text{nuc}} = \int d^3r \int d^3r_n \frac{Z\delta^{(3)}(\mathbf{r}_n) - \rho_n(\mathbf{r}_n)}{|\mathbf{r} - \mathbf{r}_n|} \rho(\mathbf{r}). \quad (91.4)$$

Since the Fourier transform, defined by

$$\hat{\rho}_n(\mathbf{k}) = \int d^3r_n e^{-i\mathbf{k}\cdot\mathbf{r}_n} \rho_n(\mathbf{r}_n), \quad (91.5)$$

preserves inner products within a factor of $(2\pi)^3$ and maps convolutions to simple products, the integral in Eq. (91.4) reduces to

$$(2\pi)^3 \int d^3k [Z - \hat{\rho}_n(\mathbf{k})] \frac{4\pi}{k^2} \hat{\rho}(\mathbf{k}), \quad (91.6)$$

where the hats denote the Fourier transforms of the densities, and $4\pi/k^2$ is the Fourier transform of the Coulomb potential $1/r$. Since $Z = \int d^3r_n \rho_n(\mathbf{r}_n)$, the energy shift can be

reexpressed as

$$(2\pi)^3 \int d^3k \int d^3r_n (1 - e^{-i\mathbf{k}\cdot\mathbf{r}_n}) \rho_n(\mathbf{r}_n) \frac{4\pi}{k^2} \hat{\rho}(\mathbf{k}), \quad (91.7)$$

which is still an exact first-order perturbation expression. Since typical nuclear length scales are much smaller than typical nonrelativistic atomic length scales, it is legitimate to expand the exponential in a Taylor series. The zeroth-order term, -1 , is canceled by the $+1$. The linear term, $i\mathbf{k}\cdot\mathbf{r}_n$, contributes nothing by the hypothesis that the nuclear charge distribution has no permanent electric dipole moment. The first nonvanishing term is

$$(2\pi)^3 \int d^3k \int d^3r_n \frac{1}{2}(\mathbf{k}\cdot\mathbf{r}_n)^2 \rho_n(\mathbf{r}_n) \frac{4\pi}{k^2} \hat{\rho}(\mathbf{k}). \quad (91.8)$$

If $\rho(\mathbf{r})$ is nonzero at the nucleus, then for large k , the leading behavior of $\hat{\rho}(\mathbf{k})$ is that of a spherically symmetric s -wave with a radial dependence proportional to k^{-4} . The angular integration in the variable \mathbf{k} leads to the replacement of $(\mathbf{k}\cdot\mathbf{r}_n)^2$ by its average value $(1/3)k^2r_n^2$, so the expression Eq. (91.8) reduces to

$$\frac{2\pi}{3} (2\pi)^3 \int d^3k \hat{\rho}(\mathbf{k}) \int d^3r_n r_n^2 \rho_n(\mathbf{r}_n), \quad (91.9)$$

which can be further simplified by observing that

$$(2\pi)^3 \int d^3k \hat{\rho}(\mathbf{k}) = (2\pi)^3 \int d^3k e^{i\mathbf{0}\cdot\mathbf{k}} \hat{\rho}(\mathbf{k}) = \rho(0), \quad (91.10)$$

and by definition

$$\int d^3r_n r_n^2 \rho_n(\mathbf{r}_n) = Z\langle r_n^2 \rangle, \quad (91.11)$$

thus yielding the final expression

$$\Delta E_{\text{nuc}} = \frac{2\pi}{3} Z e^2 \rho(0) \langle r_n^2 \rangle, \quad (91.12)$$

with

$$\rho(0) = \left(\frac{\mu}{m_e}\right)^3 \frac{Z^3}{\pi n^3} a_0^{-3} \quad (91.13)$$

for a hydrogenic ion with reduced mass μ . This derivation is independent of the specific nuclear model or the assumption of spherical symmetry of the electron density. Since $\langle r_n^2 \rangle$ scales as $Z^{2/3}$, ΔE_{nuc} then scales as $Z^{14/3}$. For a molecule with several nuclei, the contributions Eq. (91.12) from each nucleus should be summed.

For the helium atom, $\rho(0) = \langle \delta(\mathbf{r}_1) + \delta(\mathbf{r}_2) \rangle$ can be accurately calculated from high-precision variational wave functions (Chap. 12). For the $1s_2 \ ^1S_0$ ground state, $\rho(0) \simeq$

$(\mu/m_e)^3 [3.6208586 - 0.18237(\mu/M)] a_0^{-3}$, where M is the nuclear mass. Results for other states up to $n = 10$ are tabulated in [25]. Combined with high-precision isotope shift measurements, the results can be used to extract differences in nuclear radii for pairs such as $^3\text{He}/^4\text{He}$, $^6\text{Li}/^7\text{Li}$, and H/D [26–29]. The method has been applied to the short-lived, neutron-rich nuclei ^6He , ^8Li , and ^9Li [30, 31].

Equation (91.12) works well for atoms with small Z , since relativistic corrections to the electron density are small. However, it breaks down for heavier nuclei, for which relativistic wave functions are needed.

91.2.2 Nuclear Size Effects on Relativistic Energies

The preceding analysis breaks down for relativistic wave functions because they are singular at a point nucleus, making $\rho(\mathbf{0})$ infinite. In this case, the Dirac equations with Hamiltonians H_0 and H for the point nucleus and distributed nucleus cases, respectively, can be combined to obtain

$$(E - E_0)\Psi^\dagger\Psi_0 = \Psi^\dagger H\Psi_0 - \Psi^\dagger H_0\Psi_0. \quad (91.14)$$

If a finite radius r_s is now chosen such that $H = H_0$ outside the sphere $r = r_s$, then this equation can be integrated from r_s outward to yield [32]

$$\Delta E_{\text{nuc}} = \frac{\hbar c (gf_0 - fg_0)_{r=r_s}}{\int_{r_s}^{\infty} (gg_0 + ff_0) dr}, \quad (91.15)$$

where f_0 and f are the large radial components of Ψ_0 , and Ψ and g_0 and g are their small radial components (Chap. 9), and the numerator is the surface term that remains after integrating by parts the $c\boldsymbol{\alpha}\cdot\mathbf{p}$ term in H . The units are $\hbar c/a_0 = \alpha m_e c^2$. The solutions can be further expanded in terms of Bessel functions, or the Dirac equation can simply be integrated numerically.

For hydrogenic ions up to moderately large Z , the results are reasonably well represented by [33, 34]

$$\Delta E_{\text{nuc}} = \frac{2}{3n^3} (Z\alpha)^2 m_e c^2 \times [\delta_{\ell,0} + C_2(Z\alpha)^2] (Z^2 \langle r_n^2 \rangle / a_0^2)^\gamma, \quad (91.16)$$

with $\gamma = [1 - (Z\alpha)^2]^{1/2}$, and $C_2 \simeq 0.50, 1.38$, and 0.1875 for the $1S_{1/2}$, $2S_{1/2}$, and $2P_{1/2}$ states, respectively. Extensions to higher-order terms are discussed in [35]. The above formula was used in the tabulations of *Mohr* [34] for $10 \leq Z \leq 40$, while *Johnson* and *Soff* [36] used the numerical integration method for Z up to 110. The nuclear electric and magnetization density distributions are tabulated in [37], nuclear moments in [38], and nuclear masses in [39]. In the absence

of better data, the root-mean-square nuclear radius can be estimated from $\langle r_n^2 \rangle^{1/2} \approx 0.777A^{1/3} + 0.778 \pm 0.06$ fm, where A is the atomic mass number.

91.2.3 Nuclear Size Effects on QED Corrections

The progress in the experimental study of transition energies in heavy ions stripped of most of their electrons [40–42] has inspired theoretical work on modifications of QED corrections due to an extended nuclear charge distribution. Calculations based on propagators expanded in terms of basis splines [43–45] (Sect. 8.1.1) have led to relatively rapid convergence with the number of angular functions.

91.3 Electronic Structure Effects in Nuclear Physics

91.3.1 Electronic Effects on Closely Spaced Nuclear Energy Levels

The presence of a nearby cloud of electrons can significantly affect nuclear processes involving closely spaced nuclear energy levels. One of the most dramatic cases involves the β -decay process $^{187}\text{Re} \rightarrow ^{187}\text{Os} + e^- + \bar{\nu}_e$, which is energetically forbidden by about 12 keV for bare nuclei but becomes allowed for the neutral atoms when the difference in electronic binding energies is included. The nuclear charges are $Z = 75$ for ^{187}Re and $Z = 76$ for ^{187}Os . There is also the possibility of the electron being captured into a bound state of ^{187}Os , as opposed to the continuum β -decay process.

The total electronic binding energies of heavy neutral atoms can be roughly estimated using the large- Z expansion for $E(Z)$ given by Eq. (21.31) in Chap. 21. The difference between the energies of two neutral atoms with atomic numbers $Z + 1$ and Z , respectively, is then given approximately by

$$\begin{aligned} E(Z + 1) - E(Z) &\simeq \frac{dE}{dZ} \\ &\simeq (-48.83Z^{4/3} + 27.21Z^{3/3} \\ &\quad - 12.24Z^{2/3}) \text{ eV}, \end{aligned} \quad (91.17)$$

which amounts to about -13.6 keV at $Z = 75$. This is sufficient to overcome the 12 keV energy deficit in the otherwise energetically forbidden β -decay of ^{187}Re .

The general theory of bound state β -decay is discussed by *Bahcall* [46], who also calculated the ratio ρ of bound state β -decay to continuum β -decay for bare nuclei. In the case of $^{187}\text{Re} \rightarrow ^{187}\text{Os}$, ρ is of importance in estimating changes in the half-life for β -decay of ^{187}Re under various conditions of ionization, since the measured isotope ratios $^{187}\text{Re}/^{188}\text{Re}$

and $^{187}\text{Os}/^{188}\text{Os}$ from terrestrial rocks and meteorites can be used to determine not only the age of the solar system but also the age of our galaxy [47, 48]. Estimates based on a modified Thomas–Fermi (TF) model [49] indicate that $\rho \simeq 0.01$, and further multiconfiguration Dirac–Fock calculations give $\rho = 0.005$ to 0.007 [50–52]. See [50–52] for further details and references.

91.3.2 Electronic Effects on Tritium Beta Decay

The mass of the neutrino, normally taken to be zero in the Standard Model, can be determined in principle from analysis of the β -decay process $^3\text{T} \rightarrow ^3\text{He}^+ + e^- + \bar{\nu}_e$. An early measurement based on this method [53–55] yielded a neutrino mass of ≈ 25 eV. Several independent tests of this result were initiated soon thereafter. Since the experiments are performed not on bare tritons but on tritium gases and solids under various conditions, it is essential to understand quantitatively the atomic and molecular processes that affect the distribution of the highest-energy electrons produced from various initial states [56, 57].

Martin and *Cohen* [58] used a Stieltjes imaging technique to calculate shakeup and shakeoff probabilities for the β -decay of T_2 into $^3\text{HeT}^+$. Simultaneously, extensive calculations were carried out by *Kolos*, *Jeziorski*, *Szalewicz*, *Monkhorst*, et al. [59–63] using potential energy curves for the reactant T_2 and TH molecules and the product $^3\text{HeT}^+$ and $^3\text{HeH}^+$ molecules and accounting for the production of electronically and rovibrationally ground and excited final states, as well as resonant states. Nuclear motion was found to have a small but detectable effect on the results, and solid-state effects for frozen T_2 were also investigated and found to be small. These calculations played a crucial role in the interpretation of the experiments [64–68], which indicated that the neutrino mass is less than ≈ 10 eV. In 1998, there was published evidence from the super-Kamiokande experiment that the three flavors of neutrinos oscillate, as further confirmed by the Sudbury Neutrino Observatory. This implies that neutrinos have a nonzero rest mass [69]. Subsequently, upper bounds of the order of a few eV to the neutrino mass have been derived from measurements of tritium beta decay [70, 71] and from cosmological considerations [72]. As of 2018 the best upper bound from tritium beta decay experiments was about 2 eV [73].

91.3.3 Electronic Screening of Low-Energy Nuclear Reactions

The cross section $\sigma(E)$ for a nuclear reaction involving charged reactants drops very rapidly for collision energies E below the Coulomb barrier. A WKB treatment shows that

for low collision energies, the dependence of $\sigma(E)$ can be conveniently expressed as

$$\sigma(E) = S(E) E^{-1} e^{-2\pi\eta}, \quad (91.18)$$

where $S(E)$ is the astrophysical factor, and

$$\eta = Z_1 Z_2 \alpha c (\mu/2E)^{1/2} \quad (91.19)$$

is the Sommerfeld parameter, which depends on the charge numbers Z_1 and Z_2 of the projectile and target nuclides, their reduced mass μ , and the center-of-mass energy E . For nuclear reactions involving light nuclei, it is found that $S(E)$ typically varies slowly with E except close to resonances. Thus, an accurate determination of $S(E)$ at moderately low E can be used to extrapolate $\sigma(E)$ to much lower energies, which are beyond the reach of laboratory experiments but are of great relevance to the nuclear reactions that occur in stars.

However, electron screening effects can greatly enhance cross sections for nuclear reactions as measured in the laboratory at low energy [74], because at least the target nucleus is almost always surrounded by a cloud of electrons that screen the Coulomb repulsion between nuclei. The effect has been observed in various low-energy reactions such as ${}^3\text{He}(d, p){}^4\text{He}$, ${}^6\text{Li}(p, \alpha){}^3\text{He}$, ${}^6\text{Li}(d, \alpha){}^4\text{He}$, and ${}^6\text{Li}(p, \alpha){}^4\text{He}$ [75–78]. Since reactions in stars involve bare nuclei, the laboratory data must be carefully corrected for screening effects.

Analysis of the data for the ${}^3\text{He}(d, p){}^4\text{He}$ reaction indicates that the effect of screening is always greater than that predicted in the adiabatic limit [79–81]. A more general theoretical treatment of the $d + {}^2\text{H}$ and $d + {}^3\text{He}$ reactions [82], using a time-dependent Hartree–Fock method for the electrons screening and classical motion for the nuclei found less enhancement than that observed. An improved treatment taking account of electron correlation and quantum-mechanical effects on the nuclear motion will likely be needed. This remains an important area of development for the future.

For some work on the subject of electronic screening of low-energy nuclear reactions, see [83–88].

91.3.4 Atomic and Molecular Effects in Relativistic Ion–Atom Collisions

High-energy accelerators can now produce beams of atomic ions partly or completely stripped of their electrons, even for Z as high as 92. The collisions of such beams of highly charged ions with fixed targets involve a broad array of atomic and molecular processes, such as excitation, ionization, charge transfer, and, in the extreme relativistic case, pair production. A similarly broad array of theoretical techniques is required to study these topics. A thorough review of these,

including comparisons with experimental data where available, is given in [89, 90].

A topic of particular interest is the first experimental observation of the capture of electrons from electron–positron pair production in the extreme relativistic collision of a 0.96 GeV/nucleon U^{92+} beam with gold, silver, copper, and Mylar targets [91]. The energy and angular distributions of the positrons were also measured. For the gold target, the cross section for capture was nearly as large as that for pair production without capture, and it was found to vary with the nuclear charge Z_t of the target nucleus roughly as $Z_t^{2.8(\pm 0.25)}$. Neither the dependence on Z_t nor the relatively great probability for capture is in agreement with perturbation theory, which highlights the need for further exploration of this exotic system.

91.4 Muon-Catalyzed Fusion

Exotic muonic atoms and molecules are more suitable subjects than electronic atoms and molecules for probing some physical effects. The muon μ^- is a leptonic elementary particle like the electron, except that it is 206.768 times more massive and has a finite lifetime ($\tau_0 = 1/\lambda_0$, where λ_0 is the rate of decay) of 2.197 μs . This lifetime is amply long for most experiments. In normal atoms, the fine-structure splitting (due to $\mathbf{L} \cdot \mathbf{S}$ coupling) is much larger than the hyperfine splitting (due to $\mathbf{s}_{\text{nuc}} \cdot \mathbf{s}_e$ coupling); this relation is reversed in muonic atoms. Likewise, vacuum polarization, relativistic, finite-nuclear-size, and nonadiabatic effects are enhanced. (*Note:* the muonic Bohr radius $\hbar^2/m_\mu e^2 \approx (1/207) a_0$ is similar in size to the Compton wavelength $\hbar/m_e c \approx (1/137) a_0$.) Remarkably, muonic molecules make nuclear fusion possible at room temperature. In the phenomenon of muon-catalyzed fusion (μCF), there are both indirect and direct interactions between the atomic and molecular physics and the nuclear physics. Indirectly, the atomic and molecular densities and transition rates control the nuclear fusion rates, and, in turn, the kinetic energies of the fusion products affect the atomic and molecular kinetics. Directly, the nuclear structure affects some molecular energy levels that determine important resonant rates and the boundary condition on the muonic wave functions used to calculate the muon *sticking* loss.

The phenomenon of μCF was actually discussed theoretically [92–94] before it was experimentally observed [95]. Shortly after its observation, its possible use for energy production was discussed [96]. This was an attractive prospect, since hot fusion schemes are made difficult by the electrostatic (Coulomb) repulsion between nuclei. In the two conventional approaches to controlled fusion, magnetic and inertial confinement, this barrier is partially surmounted by energetic collisions. (*Note:* the particle densities N and con-

finement times τ in the hot plasmas ($T \gtrsim 10^8$ K) are typically more than ten orders of magnitude different for these two schemes, but the product of the two required for d-t fusion is $N\tau \gtrsim 10^{14}$ s/cm³ in either case. For muon-catalyzed fusion, effectively $N\tau \approx 10^{25}$ s/cm³, but this criterion does not tell the real story.) In contrast, in μ CF, the objective is for the nuclei to tunnel through the barrier without the benefit of kinetic energy. This feat is enabled by binding two hydrogenic nuclei (p, d, or t) in an exotic molecule like H_2^+ with the electron replaced by a negative muon.

Since the molecular size is inversely proportional to the mass of the binding particle, the average distance between nuclei in $pp\mu$ is $\approx 1/200$ Å (500 fm) instead of 1 Å as in ppe (i.e., H_2^+). This distance, which would be reached in a d + d collision at ≈ 3 keV ($\approx 3 \times 10^7$ K), is still large compared with the separation of a few fm where the nuclear strong forces cause fusion, but fusion occurs rapidly because of the increased vibrational frequency and, more importantly, the increased probability of tunneling per vibration. The vibrational frequency is $(m_\mu/m_e)^{3/2} \approx 3 \times 10^3$ times faster than for the corresponding electronic molecule. (Note: for comparison, the muonic/electronic energy scales as m_μ/m_e and the rotational energy scales as $(m_\mu/m_e)^2$. These relations [97] are based on the Born–Oppenheimer approximation, which is not very accurate for muonic molecules.) The effect on the tunneling probability depends on the nuclear masses; for $dt\mu$, which has the largest nuclear matrix element (astrophysical S factor, Sect. 91.3.3), the increase is by a factor of $\approx 10^{77}$ compared with DT, and the consequential fusion rate is $\lambda_{dt\mu}^f \approx 10^{12}$ s⁻¹.

Just on the basis of the fusion rate, one would expect a yield of $\lambda_{dt\mu}^f/\lambda_0 \approx 10^6$ muon-catalyzed d-t fusions for the average muon. While this number indeed provides an upper limit, the actual average number of fusions, ≈ 150 for $dt\mu$, is much smaller and is determined by the atomic and molecular physics of the catalysis cycle (although the energy released in the nuclear fusion does play an important role here). Some of the atomic and molecular processes in the μ CF cycle are quite ordinary, but others, like atomic capture and resonant molecular formation, have no counterpart with normal atoms.

Muon-catalyzed fusions of all pairs of hydrogen isotopes, except two protons, have been observed. Based on the experiments and theory, the dominant reaction products are [98–103]:

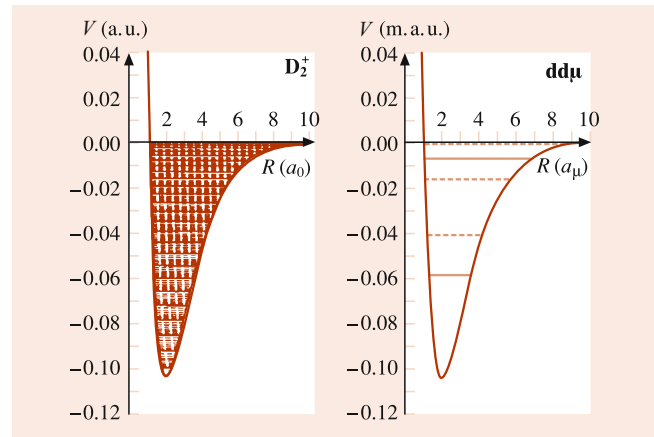

Fig. 91.1 Rovibrational energy levels for D_2^+ and $dd\mu$. The $J = 0$ levels are shown as solid lines, and the $J > 0$ levels are shown as dashed lines. For D_2^+ , all 28 vibrational levels are displayed, but the associated rotational levels are displayed only up to the next higher vibrational level. All levels of $dd\mu$ are displayed; the $(J = 1, v = 1)$ level is barely discernible below the $V = 0$ axis

(Note: A channel producing ${}^4\text{He}$ and a e^+e^- pair was theoretically predicted to be significant [104] but seems to be ruled out by experimental results published in 2012 [105].)

In these reactions, a μ without an energy designated is a spectator; i.e., it serves to bring the nuclei together but plays no significant role in the kinematics of the reaction – such a μ may actually be bound (stuck) to one of the product nuclei.

Each reaction is of special interest in its own right: $pd\mu$ and $pt\mu$ for the contribution of μ conversion, and $tt\mu$ for the correlation of the two final state neutrons. Only the $dd\mu$ and $dt\mu$ molecular formations are resonant; i.e., their formation can occur in a one-body state because they, and only they, possess a loosely bound state such that the muonic binding energy can go into rovibrational energy of the electronic molecule. That the existence of such a state really is fortuitous can be seen in Fig. 91.1 where the bound rovibrational states of $dd\mu$ (1 m.a.u. = 5626.5 eV) are compared with the rovibrational states of D_2^+ (1 a.u. = 27.2 eV). Although both $dd\mu$ and $dt\mu$ can be formed resonantly, $dt\mu$ is unique in having a rapid (as compared with muon decay) formation rate and also in having a small sticking loss. The sticking loss is due to the possibility that the negatively charged muon may form a bound state with the positively charged fusion product. The relatively low branching fraction ($< 1\%$) for $dt\mu \rightarrow {}^4\text{He}\mu + n$ is due simply to the high speed of the outgoing ${}^4\text{He}$ (α particle).

Fig. 91.3 Comparison of different capture cross sections for $\mu^- + \text{H}$ collisions: adiabatic ionization with straight-line trajectories (AI-slt), adiabatic ionization with curved trajectories (AI-ct), diabatic states with polarized orbital (DS), classical-trajectory Monte Carlo (CTMC), time-dependent Hartree–Fock (TDHF), classical-quantal coupling (CQC), quantum mechanical wavepacket (QM1), and Chew–Goldberger integral equation (QM2)

Early calculations were done using the Born or Coulomb–Born approximation [112]. These methods are not very accurate for μ^- at velocities below 1 a.u., but, more importantly, their implementation treated slowing down and capture inconsistently. The upshot was prediction of capture of muons at kinetic energies of hundreds of eV, whereas it turns out that most captures actually do not occur until the muon is slowed to energies below 100 eV.

The perturbative methods failed because of the great electron charge redistribution that occurs during the capture process. Other approaches have led to progressively more accurate treatment:

1. Adiabatic ionization with straight-line trajectories (AI-slt) [113]
2. Adiabatic ionization with curved trajectories (AI-ct) [114, 115]
3. Diabatic states (DS) [116, 117]
4. Classical-trajectory Monte Carlo (CTMC) [115]
5. Time-dependent Hartree–Fock (TDHF) [118]
6. Classical-quantal coupling (CQC) [119]
7. Quantum mechanical wavepacket (QM1) [120]
8. Chew–Goldberger integral equation (QM2) [121].

Results for the capture cross sections are shown in Fig. 91.3.

The early study by *Wightman* [113] shed a great deal of light on the capture process. His method, known as adiabatic ionization (AI), followed from the observation of *Fermi and Teller* [122] that there exists a critical value of the dipole moment eR_c , formed by the negative muon and positive proton at distance $R_c = 0.639 a_0$, for binding the electron. In colli-

sions where the μ^- approaches closer than this distance, the electron is assumed to escape adiabatically, and, if the electron carries off more energy than the muon’s initial kinetic energy, the $\mu\mu$ atom is formed. This cross section is thus

$$\sigma_{\text{AI-slt}} = \pi R_c^2, \quad (91.29)$$

and μ^- capture results if and only if $E < 0.5$ a.u., the target ionization energy.

The AI-slt model has three major shortcomings: (1) it does not take into account trajectory curvature, which is caused by the Coulomb attraction of the negative muon toward the positive nucleus and can be large at the low-trajectory velocities where capture usually occurs, (2) the adiabatically escaping electron takes off no kinetic energy, and (3) ionization occurs with unit probability if the approach is closer than R_c . The first failing is easy to remedy. The cross section with curved adiabatic trajectories (AI-ct) is just [115]

$$\sigma_{\text{AI-ct}} = \frac{\pi R_c^2}{E} \left(E + \frac{1}{R_c} - 0.5 \text{ a.u.} \right), \quad (91.30)$$

as long as the collision energy E in the center-of-mass system is greater than 0.03 a.u. (0.8 eV). Hence, trajectory curvature increases the capture cross section by a factor $1 + (1.06/E)$ (for E in a.u.), which is over a factor of 3 even at the highest collision energy (0.5 a.u.) where adiabatic capture can occur. For $E < 0.03$ a.u., the centrifugal barrier in the effective potential,

$$V_{\text{a(eff)}}(R, b) = V_{\text{a}}(R) + \frac{b^2}{R^2} E, \quad (91.31)$$

restricts penetration and reduces the cross section below the value given by Eq. (91.30) [114].

Cures for the second and third failings are less trivial. These two assumptions were first avoided by using the diabatic-states (DS) model [116, 117]. The adiabatic electronic potential energy no longer increases once it reaches the continuum ceiling; however, in view of the μ^- acceleration by the Coulomb attraction, the electron cloud actually does not have enough time to adjust adiabatically. In recognition of this situation, the diabatic treatment yields an electronic potential energy that crosses into the continuum at a distance larger than R_c and continues to rise smoothly. The concomitant probability of ionization is given by the ionization width, obtained from a Fermi-golden-rule-like formula. The next method applied was classical-trajectory Monte Carlo (CTMC) [115], discussed in Chap. 62. The CTMC method treats the dynamics of all particles exactly but classically. The classical approximation was later eliminated by using the time-dependent Hartree–Fock (TDHF) method discussed in Sect. 53.3 [118]. However, the improvement was open to question since it was achieved at the expense of

neglecting correlation, which turns out to be important in the present problem. This deficiency was remedied by the classical-quantal coupling (CQC) method, which makes only the seemingly well-justified approximation of treating the muon classically while retaining the quantum treatment of the electron [119]. Since then, there have been two rigorous quantum-mechanical calculations [120, 121] using time-dependent methods. These calculations have been limited to collision energies below 10 eV (0.37 a.u.). At very low energies, especially in view of the resonance behavior found [120], the time-dependent methods require quite time-consuming computations. Recently, the capture cross section was also calculated quantum mechanically by the time-independent R -matrix method, which was able to better characterize the resonances; this calculation was done only for very low energies (below 1 eV) [123]. Except for the adiabatic ionization and TDHF methods, the results of the various methods are generally in fairly good agreement, although calculations for $E_{\text{cm}} > 0.5$ a.u. are more challenging, and the classical results have yet to be confirmed by completely quantum mechanical calculations.

Real μ^- capture experiments (and μCF) are generally done with molecules (H_2 , DT , etc.). The naive notion, once accepted, that the H_2 cross section is simply twice that of H is quite unrealistic for slow ($v \ll 1$ a.u.) collisions. The capture by hydrogen molecules, which is the first step in μCF , is now theoretically much better understood [124]. The molecular cross section is greatly enhanced, primarily due to the molecular vibrational degree of freedom, which enables the molecule to capture μ^- at collision energies up to ≈ 40 eV in hydrogenic states with principal quantum number $n \gtrsim 9$, whereas atomic capture cuts off above ≈ 14 eV with $n \gtrsim 14$. There is a corresponding isotope effect in the molecule, which is absent in the atom.

91.4.3 Muonic Atom Deexcitation and Transfer

The muon is captured in a highly excited state but normally must reach the $1s$ configuration of the heavier isotope (in the case of mixtures like D/T) before the muonic molecule is formed. In the $1s$ configuration, there are two hyperfine levels – the ground state with the nuclear and μ^- spins antiparallel and an excited state with spins parallel. Resonant molecular formation rates in the two states can be quite different and also depend strongly on the atom's kinetic energy. Thus, there are several types of muonic atom collisions that must be taken into account: (1) elastic scattering in the ground and excited states, (2) isotopic transfer in excited states, (3) deexciting transitions (which may also occur radiatively), (4) isotopic transfer in the $1s$ state, and (5) hyperfine transitions. Cross sections for most of these processes have been calculated. The bulk of the calcula-

tions have been done by expanding in adiabatic (or modified adiabatic) eigenfunctions, but there also exist some calculations using the coupled-rearrangement-channel, Faddeev, hyperspherical, and variational approaches ([97, 107] for references).

The cascade of the initially formed muonic atom, especially in mixtures, is a complicated process [125]. It constitutes a crucial part of the d - t μCF cycle in that it determines the parameter q_{1s} in Eq. (91.26). This parameter is essential to experimental analysis, but it was evident that early calculations yielded values of q_{1s} too small to be consistent with experiments. Theoretical calculations suggest the explanation is that the excited muonic atoms are not thermalized [126–128]. Epithermal atoms have three effects here: (1) the normal transfer rates are smaller, (2) the transfer is reversible down to lower principal quantum numbers n where E still exceeds the threshold for excitation of the next-higher level, and (3) excited-state [from $(t\mu)^*$] resonant formation of $(d\mu)^*$ molecules that can predissociate back to $d\mu$ is enhanced [129]. (*Note:* the isotopic energy splittings are $134.7/n^2$ for $d\mu$ - $p\mu$, $182.8/n^2$ for $t\mu$ - $p\mu$, and $48.0/n^2$ for $t\mu$ - $d\mu$.) The parameter q_{1s} is determined by competition between transfer and deexcitation, which depend on the kinetic energies that result from further competition between superelastic deexcitation and thermalizing elastic collisions. It appears that the stage of the cascade most crucial for q_{1s} is $n \approx 4$ for normal muon transfer and $n = 2$ for the resonant sidepath.

In contrast with electrons, for muons the elastic cross sections are more difficult to calculate than the inelastic ones. The inelastic transitions occur at short range (a few a_μ) where the effects of electronic structure are negligible. However, electronic effects are not negligible for low-energy (< 1 eV) elastic scattering where $\lambda_{\text{dB}} \approx 1 a_0$. They have been taken into account for ground state but not yet excited-state scattering. In doing so, it is not necessary to solve the general problem directly because of the following simplifications: (1) this energy is below the vibrational threshold, so the molecular target can be taken as a rigid rotor, and (2) the relative smallness of the muonic atoms makes the sudden approximation adequate.

If the $1s$ state is reached without muon transfer to the heavier isotope already having occurred, the transfer takes significant time and plays an important role in determining the tritium fraction c_t that optimizes the fusion yield. All of the $1s$ isotopic-exchange cross sections display the characteristic $\approx 1/v$ velocity dependence at thermal energies, so that the corresponding rate $v\sigma$ is independent of temperature.

In muon-catalyzed d - d and d - t fusions, the resonant molecular formation rates in different hyperfine structure (HFS) states can differ by two or more orders of magnitude at low T due to their different energy levels. The HFS also has important effects on thermalization and diffusion

via the different elastic cross sections. Under usual μCF experimental conditions, the hyperfine quenching (or *spin flip*) is irreversible; the HFS splittings are 0.1820, 0.0485, and 0.2373 eV for $p\mu$, $d\mu$, and $t\mu$, respectively. Theoretically, it is expected that transitions between HFS levels mainly occur in symmetric collisions since muon exchange suffices in such collisions [130]; e.g.,

(the usual terminology here is *muon exchange*, although it might seem more logical to refer to the reaction as *triton exchange* since it is the identity of the tritons that enables the reaction). As in the case of the isotopic exchange cross sections, the behavior is $\approx 1/v$ at thermal energies, so the rates are nearly independent of temperature.

91.4.4 Muonic Molecule Formation

Until the prediction by *Vesman* [131] of a resonant formation for $dd\mu$, it was thought that all muonic molecules were formed by an Auger process of the type

Unlike the resonant process for $dd\mu$ and $dt\mu$, the nonresonant process generally depends weakly on the temperature of the target, the hyperfine state of the muonic atom, and the *spectator* atom X in the molecule DX , where X can be H, D, or T. The nonresonant rate at low (liquid hydrogen) temperature for $dd\mu$ formation is about $3 \times 10^4 \text{ s}^{-1}$, and for $dt\mu$ it is about $6 \times 10^5 \text{ s}^{-1}$. These rates are competitive with the resonant rates at low T for $d\mu(\uparrow\downarrow) + D_2$ and $t\mu(\uparrow\uparrow) + D_2$, but are two and three orders of magnitude smaller than the resonant rates for $d\mu(\uparrow\uparrow) + D_2$ and $t\mu(\uparrow\downarrow) + D_2$, respectively. The $(\uparrow\downarrow)$ state is the ground state; thus HFS quenching plays an important role in low-temperature experiments, especially for $dd\mu$. At room temperature, resonant formation is dominant for both the ground and excited hyperfine states of $d\mu$ and $t\mu$.

In the *Vesman* mechanism, the binding energy of the muonic molecule goes into rovibrational excitation of the electronic host molecule instead of into ionization of a molecular electron. The process is resonant since the collision energy must be tuned to match the energy of the final discrete state. For the compound molecule formed, two sets of rovibrational quantum numbers are needed, e.g.,

where (K_i, v_i) and (K_f, v_f) are the initial and final rovibrational quantum numbers of the electronic molecule, (J, v)

Fig. 91.4 Energy levels for the resonant reaction $t\mu + [D_2]_{K_i=0, v_i=0} \rightarrow [(dt\mu)_{J=1, v=1}^{F=0, S=1} \text{de}]_{K_f v_f}$. The rovibrational quantum numbers are designated by (J, v) for the muonic molecule and (K, v) for the electronic molecules

are the quantum numbers of the muonic molecule, F is the spin of the muonic atom, and S is the total spin of the muonic molecule. The energetics of this process is shown in Fig. 91.4.

The resonant condition is achieved at the collision energy

$$\epsilon_{\text{res}}(t\mu + D_2) = \epsilon_{11}^{FS} [dt\mu] + E_{K_f v_f} [(dt\mu)\text{de}] - E_{K_i 0} [D_2] , \quad (91.35)$$

where it is explicitly recognized that $(J, v) = (1, 1)$ is the only muonic level that can satisfy the resonant energy condition and that only $v_i = 0$ is populated at ordinary temperatures. Accurate calculations require values of ϵ_{res} to within about 0.1 meV. The rovibrational energies $E_{K v}$ of the electronic molecule, as well as the Coulomb contributions to the binding energy of the muonic molecule, ϵ_{11}^{FS} , are now known to this high accuracy. However, ϵ_{11}^{FS} is subject to corrections due to relativity, vacuum polarization, nuclear charge distributions and polarizabilities, the hyperfine interaction, and the finite size and shape of the muonic molecule in the complex. The present overall accuracy is ≈ 1 meV. Some of the resulting values of ϵ_{res} are given in Table 91.1. The calculated cross section for reaction Eq. (91.34) is sharply peaked at E_{res} but must be averaged over a kinetic energy distribution (e.g., Maxwellian) to obtain the observable rate. Still, the rate will display a characteristic resonant dependence on T .

Because the E_{res} are different for each target molecule (D_2, DT, T_2, \dots), the effective molecular formation rate in a mixture depends on the molecular composition in addition to the isotopic fractions (c_d, c_t, \dots) if the target is not in chemical equilibrium.

Table 91.1 Resonant (quasiresonant if negative) collision energies ϵ_{res} (in meV) calculated using Eq. (91.35)^a

$d\mu + D_2$		$t\mu + D_2$		$t\mu + DT$

$\frac{1}{2}, \frac{3}{2}, 1, 2$	78.3				

^a Note: $kT = 1$ meV for $T = 11.6$ K

The rate of resonant molecular formation is given by

$$\lambda^{mf}(T) = N \sum_f \int \left\{ d\epsilon 2\pi |\langle i | \hat{V} | f \rangle|^2 \times f(\epsilon, T) I(\epsilon - \epsilon_{if}, T) \right\}, \quad (91.36)$$

where N is the target density, $f(\epsilon, T)$ is the collisional energy distribution, ϵ_{if} is the energy of the unperturbed resonance, $I(\Delta\epsilon, T)$ is the intensity at energy $\Delta\epsilon$ relative to the unperturbed energy, and $\langle i | \hat{V} | f \rangle$ is the transition matrix element, with \hat{V} the Coulomb perturbation operator in the *post* form of the rearrangement-collision Hamiltonian using the $dt\mu$ bound state as the zeroth-order Hamiltonian; \hat{V} can be expressed as a multipolar expansion beginning with

$$\hat{V} = e^2 \mathbf{d} \cdot \mathbf{E} + \dots, \quad (91.37)$$

where \mathbf{d} is the dipole operator of the $dt\mu$ (or $dd\mu$) system, and \mathbf{E} is the electric field at the $dt\mu$ (or $dd\mu$) center of mass due to the *spectator* nucleus and electrons [132]. A calculation has been done including the quadrupole term [133], but the dipole term is dominant. In the dipole approximation [134] conservation of angular momentum requires [135]

$$\mathbf{L} + \mathbf{K}_i = \mathbf{J} + \mathbf{K}_f, \quad (91.38)$$

where \mathbf{L} is the orbital angular momentum of relative motion for $t\mu + D_2$ in reaction Eq. (91.34). At low T , $L = 0$ is predominant, so that $K_f = K_i \pm 1$. This is simply the case for $d\mu + D_2 \rightarrow (dd\mu)dee$, where the most probable transition is $(K, v) = (0, 0) \rightarrow (1, 7)$. For $dt\mu$, the vibrational state of the electronic molecule changes by only $\Delta v_i = 2$ or 3 instead of 7, so the matrix element of Eq. (91.37) and the resulting rate are considerably larger than for $dd\mu$. However, it can be seen in Fig. 91.4 that if D_2 is in its ground state ($K_i = 0$), the first level energetically accessible for $(dt\mu)dee$ has $K_f = 3$. If, as proves to be adequate in the case of $dd\mu$, the intensity

distribution I is taken to be a δ function, the lower levels are eliminated from Eq. (91.36). There are two possible solutions to this problem, whose relative importance has not been fully determined: (1) the less likely $L > 0$ collisions contribute, or (2) the levels with smaller K_f play a role even though they lie *below threshold*.

The latter case is termed *quasi resonant*. Theoretically, the levels below threshold can contribute (1) directly if they are broadened so that they extend to positive energy [136–138], or (2) indirectly if configurations with different K_f are mixed [139]. Broadening can occur either inhomogeneously due to the finite lifetime (mainly with respect to Auger emission of an electron in the complex) or homogeneously due to collisions with neighboring molecules. Interactions with neighboring molecules can also mix the different K_f states, so the $K_f = 3$ state may *borrow* some intensity from the lower K_f states. Three-body molecular formation facilitated by neighboring molecules leads to a density dependence of the formation rate (normalized to LHD) that has been observed in experiments.

There have been a number of measurements of the $dd\mu$ molecular-formation rate for various target densities and temperatures. However, the epithermal effect due to nonthermalized $d\mu$ may be significant and makes a full understanding of the temperature dependence a little difficult, especially at low temperatures. Further measurements have been carried out [140, 141] by controlling the initial molecular state (K_i) with the use of ortho- D_2 ($K_i = 0, 2, \dots$) and normal or even para-rich ($K_i = 1, 3, \dots$) D_2 . These measurements have clarified the dependence on the molecular state and the density. The resonant formation rate with ortho- D_2 was found to be much larger than with normal D_2 in the gas around 35 K, while its rate is reduced by nearly half at liquid density, even smaller than for normal- D_2 . This finding indicates that the resonance with ortho- D_2 must be very close to the threshold, and that the target density could be affecting its shift or broadening.

The resonant $dd\mu$ formation has now been observed directly [142]. Previously, the experimental evidence for this

in the zero-density limit since R is still finite in this limit.) The net sticking is then

$$\omega_s = \omega_s^0(1 - R). \quad (91.43)$$

Since the nuclear reaction is very rapid compared with the atomic and molecular dynamics, the probability of sticking in a given state ν is given adequately by the sudden approximation,

$$P_\nu = |\langle \psi_\nu^{(f)} | \psi^{(i)} \rangle|^2, \quad (91.44)$$

where the initial wave function $\psi^{(i)}$ is the normalized molecular wave function in the limit $r_{\text{dt}} \rightarrow 0$, and the final wave function $\psi_\nu^{(f)}$ is given by

$$\psi_\nu^{(f)} = \phi_{n\ell m}(\mathbf{r}) e^{i\mathbf{q}\cdot\mathbf{r}}, \quad (91.45)$$

in which $\phi_{n\ell m}$ is an atomic wave function of $({}^4\text{He}\mu)^+$, and the plane wave with momentum \mathbf{q} represents its motion with respect to the initial molecule (recoil determined by conservation of energy and momentum). The total sticking is then

$$\omega_s^0 = \sum_\nu P_\nu. \quad (91.46)$$

The $({}^4\text{He}\mu)^+$ wave function is known analytically since it is hydrogenic. Most of the labor goes into determination of the muonic molecule wave function. In the Born–Oppenheimer approximation this is simply $({}^5\text{He}\mu)^+$ and results in $(\omega_s^0)_{\text{BO}} = 1.20\%$ for $\text{dt}\mu$ [151]. More accurate nonadiabatic calculations show that the muonic motion lags behind that of the nuclei and reduces ω_s^0 to 0.886% [152, 153]. After inclusion of nuclear effects, the best current theoretical value of ω_s^0 is 0.912% [149, 154].

Since the ground-state $(\text{He}\mu)^+$ ion is bound by 11 keV, it takes a quite energetic collision to strip off the muon. The reactivation fraction R is determined basically by competition between collisional processes that slow down the muonic ion and those that lead to stripping. Calculation of R requires a full kinetic treatment of the fast $(\text{He}\mu)^+$ ion, starting with its distribution among various states (1s, 2s, 2p, \dots , $n \approx 10$). The most important processes are stopping power (due mainly to ionization of the medium) and muon ionization or transfer in collisions of the $(\text{He}\mu)^+$ ion with an isotope of H, but inelastic (excitation and deexcitation), Auger deexcitation, and ℓ -changing collisions, as well as radiative deexcitation are also involved. The initial sticking occurs mostly in the 1s state (77% of the $\alpha\mu$'s from $\text{dt}\mu$ fusion), but the excited states have larger ionization cross sections. Most of the muons stripped from $\alpha\mu$ originally stuck in the 1s state, but a significant number is promoted to excited states before being ionized (so-called *ladder ionization*). The

Fig. 91.5 Theoretical sticking fraction (solid curve) and reactivation probability (dashed curve) for d-t μCF

metastable 2s state is significant for its role in prolonging the excited-state populations. The resulting values of R and ω_s are shown as a function of density in Fig. 91.5.

Most experiments on d-t μCF have been done with neutron detection [155–157], where λ_c and the muon loss probability per cycle W can be deduced from the time structure of the neutron emissions. The analysis is indirect and requires a theoretical model. What is actually measured is the product $W\phi\lambda_c$; the extraction of ω_s requires corrections for other loss mechanisms and separate determination of λ_c . Thus, it is desirable to have other experimental diagnostics. Two types of corroborating experiments detect either X-rays from the $\alpha\mu$ formed by sticking or detect the species $(\alpha)^{2+}$ and $(\alpha\mu)^+$ by the different effects of their double and single electrical charges.

The theoretical sticking is compared in Table 91.2 with that from all three types of experiments. For a more meaningful comparison of measurements at different densities ϕ , the theoretical R has been used to convert all values to ω_s^0 . The theoretical values are slightly, but significantly, higher than the observations. This discrepancy has not yet been resolved.

One suggested explanation for the lower-than-predicted value of ω_s may be that a significant fraction of the fusions might occur in muonically excited bound or resonant states for which the initial sticking is lower than in the ground state [158].

A 2003 experiment systematically studied muon-catalyzed fusion in solid deuterium and tritium mixtures as a function of temperature and tritium concentration [159]. An unexpected decrease in the muon cycling rate (λ_c) and an increase in the muon loss (W) were observed. The former is likely due to the freezing out of phonons contributing to the resonance energy. The latter is especially intriguing. It is inconceivable that ω_s^0 for fusion in a given state of $\text{dt}\mu$ could depend on temperature, but this observation could imply either an unexpected effect of temperature on the muonic state in which fusion occurs or an unpredicted temperature

Table 91.2 Comparison of sticking values^a

Source	ϕ	ω_s (%)	ω_s^0 (%)
Theory			
[149, 154]	1.2	0.59	0.91
Neutron experiments

RAL [170]	0.001	–	$0.80 \pm 0.15 \pm 0.12$
PSI [171]	0.17	0.56 ± 0.04	0.80

^a Experimental values of ω_s^0 without error bars were obtained assuming the theoretical stripping [172, 173].

In cases of two error estimates, the first is statistical and the second is systematic.

The extraction of ω_s^0 from the X-ray experiments requires theoretical scaling

dependence of the thermalization kinetics (e.g., due to ion channeling). It should be noted that the experimental analysis does not reject the possibility of some correlation between the extracted values of λ_c and W [158].

91.4.7 Prospectus

Muon-catalyzed d-d fusion in D₂ and HD gases has now been investigated in a wide temperature range, with all the main observables in the reaction chain accurately measured [101, 160]. The energy of the loosely bound dd μ was extracted with high precision [101], and it is in impressive agreement with the latest theoretical results. The experimental knowledge of parameters for p-t μ CF [105] and t-t μ CF [103] have also been advanced.

The d-t μ CF is now fairly well understood [102], but investigations under broader conditions of temperature and density are still desirable; in particular, three-body effects on molecular formation at high densities, the excited-state cross sections and kinetics that go into the determination of the cascade factor q_{1s} , and the remaining discrepancy in the sticking factor ω_s , which might have a theoretical or experimental resolution. Experimentally it is of interest to push on to higher temperatures and densities to see whether more surprises lurk there. There have been a few schemes proposed to enhance stripping of stuck muons artificially, but none has been subjected to experiments yet.

The currently observed yield of about 150 d-t fusions (releasing 17.6 MeV each) per muon produces an energy return 25 times the rest-mass energy of the muon but is only about

one-third of that required for breakeven in a pure-fusion reactor. This conclusion is based on the estimated energy cost of producing a muon, ≈ 8 GeV [161, 162]. Other possible practical uses of μ CF include a hybrid (fusion–fission) reactor [161, 162] or an intense 14 MeV neutron source [163, 164].

Apart from such technological applications, the study of μ CF is fruitful for a number of reasons, including (1) bridging the gap between atomic and nuclear physics, (2) enabling nuclear reactions *including* p-waves at room temperature, (3) allowing precise studies under unusual physical conditions, (4) observing a compound electronic-muonic molecular environment, and (5) exhibiting phenomena spanning nine orders of magnitude in distance and energy. The experimental possibilities are far from exhausted even though the holy grail of pure fusion energy now appears just beyond reach.

James S. Cohen Dr Cohen is Group Leader of the Atomic and Optical Theory Group in the Theoretical Division of Los Alamos National Laboratory and a Fellow of the American Physical Society. He received a PhD in Physics from Rice University in 1973. His general area of research is theoretical atomic and molecular physics, with a special interest in exotic muonic and antiprotonic species.

John D. Morgan III Dr Morgan, Associate Professor, obtained his BS from The George Washington University, his MSc in Theoretical Chemistry from Oxford University, and his PhD in Chemistry from Berkeley. He has served on the editorial boards of the *Journal of Mathematical Physics* and the *International Journal of Quantum Chemistry*. His interests include the application of sophisticated mathematical techniques to assist the accurate calculation of properties of atoms and molecules.
