Preface to the Second Edition

We are delighted to present the second edition of the *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition* to you all. We were overwhelmed by the interest shown by the readers in the first edition, reflected in many thousand downloads of the chapters.

In the meantime, during the past 5 years or so, a huge amount of research has been published in the field of gastroenterology, hepatology, and nutrition, resulting in a new understanding of the pathophysiological mechanisms of childhood gastrointestinal and liver disorders that has helped to develop newer diagnostics, therapies, and guidelines. It was time to compile the new relevant information in an updated second edition.

Thus, our authors and the editors have worked hard to put together the most useful and up-to-date practical information and present it in the revised chapters.

Furthermore, new authors have been included who are the opinion leaders in their subjects, maintaining and enhancing the international inclusive approach that uniquely keeps characterizing our book.

This edition, like the first one, maintains the practical and ready reference approach for all our readers: trainees, allied healthcare professionals, and established senior practitioners in the field of pediatric gastroenterology, hepatology, nutrition, and transplantation, maintaining the very vision that the late Dr. Branski originally had and that inspired us.

We are humbly confident that we have succeeded in delivering that in this edition as well.

Lastly, we would like to thank the publisher for the enthusiasm and trust in our leadership to help deliver the second edition despite the disruption caused by the Covid-19 pandemic.

We, as editors, are grateful to all the authors for their work and their trust in our role. All of them have carefully and thoroughly reviewed and updated the information by including latest published evidence to enrich the learning experience of the readers and allow them to deliver the best care to all our patients, from babies to young adults.

Chicago, IL, USA — Stefano Guandalini
London, UK — Anil Dhawan

Acknowledgments

I take this opportunity to thank my colleagues who contributed to the second edition of this book for their attention to detail and punctuality.

I would like to thank my wife Anita, who has been behind everything that I have done well in life, and our two boys, Atin and Ashish, for their love and support.

– Anil Dhawan

It's hard to believe 5 years have already gone by since the first edition of this textbook appeared. Besides the original inspiration by the late David Branski, without whose input this book would have never seen the light, I want to acknowledge here not only again all those whom I thanked for the first edition, from my illustrious mentors to the colleagues in ESPGHAN and NASPGHAN and the broader world of my beloved creature FISPGHAN, but also my partners and friends – new and old – at the University of Chicago, who praised this enterprise.

Last but not least, I am sincerely thankful to the unwavering love and support from my wife Greta both during the long years of work and now on my retirement, even more demanding!

– Stefano Guandalini

Part I

GI-Nutrition

Microvillus Inclusion Disease and Tufting Enteropathy

1

Agostino Nocerino and Stefano Guandalini

Introduction

The Larger Group of "Intractable Diarrheas of Infancy"

Before focusing on microvillus inclusion disease and tufting enteropathy, we will briefly review similar cases in the literature. In 1968, Avery, Villavicencio, and Lilly were the first to describe severe chronic diarrhea in 20 infants and named it "infantile intractable diarrhea"; according to their description, this was prolonged and intractable despite extensive hospital therapy [1].

This syndrome was defined on the basis of some clinical characteristics, namely: (1) Diarrhea of more than 2 weeks duration; (2) Age, less than 3 months; (3) Three or more stool cultures negative for bacterial pathogens; (4) Necessity of intravenous rehydration; and (5) Prolonged and intractable diarrhea despite hospital therapy.

The death rate was very high: 9 out of the 20 babies (45%) in Avery et al.'s report had died, and at 70% it was even higher in Hyman et al [2].

Heterogeneity and lack of specificity are evident in Avery's original report: different pathologies were grouped in it, some of which with a diagnosis which was well defined even at that time. Only autopsy data were available for the first cases, and only after the introduction of total parenteral nutrition at the beginning of the 1970s [3] was it possible to study the matter in greater depth, thanks to proximal small intestinal biopsy [4] and later on to the development of endoscopic techniques which were safe and adequate for the infant as well. It became consequently possible to discriminate different causes for the so-called intractable diarrhea of infancy [5], but its definition superimposes on the definition of "protracted diarrhea of infancy": the latter lasts for a similar length of time but a failure to gain weight is enough to define the clinical picture [6].

In 1995 the Pediatric Gastroenterologists of the Federico II School of Medicine of Naples (Italy) observed that in most cases of severe and protracted diarrhea (SPD) an etiological diagnosis was possible and that consequently the term "intractable childhood diarrhea" was now frequently inappropriate. They proposed to limit it to the group that needed total parenteral feeding, defining the clinical picture as "severe diarrhea requiring parenteral nutrition" [7]. In view of the changes in the spectrum of known causes of SPD over the past few decades, the Italian Society of Pediatric Gastroenterology, Hepatology and Nutrition (SIGENP) proposed in 1999 [8] to include in this definition autoimmune enteropathy (severe or partial villus atrophy with crypt hyperplasia and presence of anti-enterocyte antibodies and/or associated autoimmune disorders), congenital microvillus atrophy, tufting enteropathy, epithelial dysplasia, and intestinal microvillus dystrophy (the latter later unified with microvillus inclusion disease).

However, the definition of "protracted diarrhea of infancy" has remained prevalent in clinical practice and in the literature, even compared to the broader definition of "pediatric intestinal failure" [9], an entity resulting from various causes including trichohepatoenteric syndrome, tufting enteropathy, microvillus inclusion disease, and autoimmune enteropathy [10].

Many cases of "protracted diarrhea of infancy" are diet-associated, as a consequence of cow's milk or lactose intolerance or malnutrition. Malnutrition causes intestinal atrophy and consequently a malabsorption syndrome with diarrhea, apparently improving with fasting. These features have almost disappeared in developed countries.

Table 1.1 Main causes of protracted diarrhea in infancy

Small intestinal enteropathy of unknown origin
Intractable ulcerating enterocolitis of infancy
Congenital enterocyte heparan sulfate deficiency
Congenital intestinal integrin deficiency
Congenital secretory diarrheas
Congenital chloridorrhea
Congenital Na-losing diarrhea
Autoimmune enteropathy
Diseases of the intestinal epithelium
Microvillus inclusion disease
Tufting enteropathy

The main causes of "intractable diarrhea of infancy," including more severe and longer-lasting forms, can be summed up as follows (Table 1.1):

Autoimmune Enteropathy

The term "autoimmune enteropathy" (AIE) was introduced to describe persistent diarrhea associated with autoimmune diseases with the production of antibodies directed against epithelial cells of the small and large intestine.

This rare disorder (a recent review of the literature found a total of 98 reports published in the form of case reports and case series) [11] is frequently associated with primary immunodeficiencies and mostly occurs in young infants and children (6–18 months old). It is characterized by severe diarrhea and small intestinal mucosal atrophy resulting from immune-mediated injury. A retrospective study on clinical and histological findings from 40 AIE patients showed a prevalent celiac disease pattern (50%), mainly in patients with primary immunodeficiencies, followed by the mixed pattern (35%), chronic active duodenitis (10%), and GVHD-like pattern (5%) [12]. It remains a challenging diagnosis because of its clinical-pathological variability. This entity is dealt with in Chap. 2.

Small Intestinal Enteropathy of Unknown Origin

This entity could be a variation of autoimmune enteropathy, as the increase in inflammatory cells in the lamina propria shows. It appears in infants less than 12 months, with a lower death rate compared to those with autoimmune enteropathy, but it can be very severe. Infants can become TPN-dependent [5].

Intractable Ulcerating Enterocolitis of Infancy

A rare disease initially described in 1991 in five children presenting in the first year of life with intractable diarrhea, ulcerating stomatitis, and large ulcers with overhanging edges throughout the colon within the first year of life [13]. The affected infants can show a colitis whose severity may require a subtotal colectomy, even if the long-term prognosis is good. It has been suggested that affected children have a genetically determined primary immune dysregulation [14].

Congenital Enterocyte Heparan Sulfate Deficiency

Described in 1995 in three infants who within the first weeks of life presented with secretory diarrhea and massive enteric protein loss [15]. The small intestinal mucosa is normal on light microscopy, but histochemical exams show a complete absence of enterocyte heparan sulfate. The sulfated glycosaminoglycans of the basocellular membrane are mostly deficient, particularly heparan sulfate, while the distribution of vascular and lamina propria glycosaminoglycans is normal [15]. Diarrhea is so severe as to make total parenteral nutrition (TPN) necessary, together with repeated albumin infusions because of severe protein-losing enteropathy. Studies in men and mice show that heparan sulfate is essential in maintaining intestinal epithelial barrier function [16], and that the specific loss of heparan sulfate proteoglycans from the basolateral surface of intestinal epithelial cells is common to many forms of protein-losing enteropathy [17].

Congenital Intestinal Integrin Deficiency

In 1999, Lachaux et al. described a case of intractable diarrhea starting 9 days after birth, associated with pyloric atresia and total epithelial detachment of gastric and intestinal mucosa. Immunofluorescence analysis showed α6β4 integrin deficiency at the intestinal epithelium–lamina propria junction [18].

Mutations in α6 or β4 integrins cause junctional epidermolysis bullosa with pyloric atresia. In 2008, two Kuwaiti brothers with pyloric atresia were described, respectively affected by intractable diarrhea and episodes of protein-losing enteropathy, with a novel mutation in β4 integrin that induced a desquamative enteropathy in infancy without significant skin disease [19].

Congenital Secretory Diarrheas

Includes congenital chloridorrhea and congenital sodium diarrhea, dealt with in Chap. 36.

Diseases of the Intestinal Epithelium

Microvillus inclusion disease and tufting enteropathy are the best-known diseases of the intestinal epithelium causing intractable diarrhea of infancy.

In 1994, Girault et al. described eight infants with early-onset severe watery diarrhea associated to facial deformities and unusual tufts of woolly hair with trichorrhexis nodosa. Duodenal biopsies showed moderate to severe villus atrophy, with normal or hypoplastic crypts; colon biopsies were basically normal. As a consequence, severe malabsorption was present. All patients had no antibody response to immunization antigens; the immunological response to vaccinations was poor. Five children died despite TPN [20]. Two children from the series of Girault et al. had hepatic cirrhosis; six additional patients had signs and symptoms compatible with this new "syndromic diarrhea," associated to hepatic involvement (Trichohepatoenteric syndrome, THES) characterized by fibrotic livers with marked hemosiderosis [21–23].

Nine different mutations in *TTC37* gene (5q14.3–5q21.2) were found in 12 children from 11 families with classical features of THES. *TTC37 codes for a protein that has been named* "thespin" (THES ProteIN) [24].

Enlarged platelets with abnormal α-granule secretion can be observed in some patients. The estimated incidence of the syndrome is 1 in 400,000 to 1 in 500,000 live births.

A review of the literature conducted in May 2017 included 80 patients, 40 with mutations of TTC37 and 14 with mutations of SKIV2. This showed that parenteral nutrition was used in the management of 83% of the patients and that it was possible to wean 44% off parenteral nutrition. The mean duration was 14.97 months. Data on the efficacy of immunoglobulins were reported for only six patients, with a diminution of infection or reduced diarrhea. Antibiotics, steroids, and immunosuppressant drugs were used with little efficacy. Hematopoietic stem cell transplantation (HSCT) was performed in four patients, two of whom died [25].

Microvillus Inclusion Disease

In 1978, Davidson et al. described five infants presenting with intractable diarrhea of infancy characterized by secretive diarrhea and malabsorption, starting in the first hours after birth with hypoplastic villus atrophy in the small intestinal biopsy. Four of these infants had a deceased brother who had shown similar symptoms.

In one of these infants, electron microscopy identified the presence of a peculiar abnormality of the microvilli of the enterocytes [26] (Fig. 1.1).

Three new cases with the same clinical and histological characteristics as this infant were described in France in 1982, and the four of them were grouped into a new disease called congenital microvillus atrophy [27, 28]. Two new cases were described in Great Britain in 1985 [29], and one in Italy in 1986; a brother of the Italian child, who was born subsequently, was similarly affected [30]. A survey completed in 1987 among centers known for their involvement in pediatric gastroenterology identified more than 30 cases worldwide. Additional cases were later published.

In 1989, Cutz et al. proposed the use of the term "microvillus inclusion disease" to highlight the characteristic ultrastructural lesions of the disease [31].

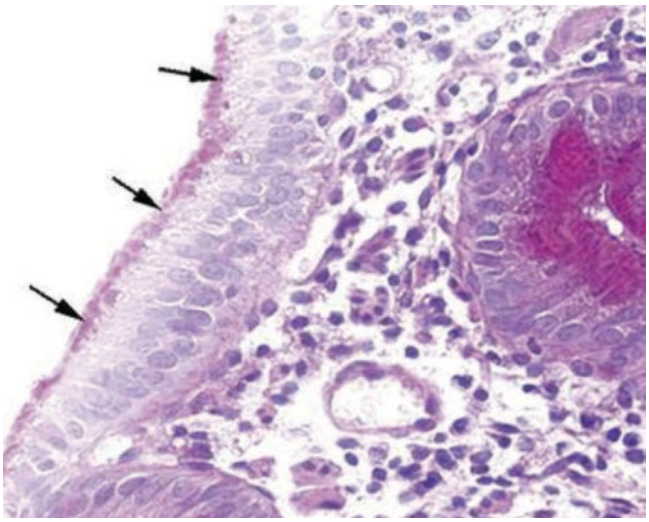

Fig. 1.1 Microvillus inclusion disease. PAS staining highlights abundant PAS-positive material (*arrows*) in the apical part of the enterocyte cytoplasm. PAS × 260 [20] (Reprinted from Springer and Virchows Archive: Official Journal of the European Society of Pathology, Morroni et al. [99], Fig. 1, with kind permission from Springer Science and Business Media)

Clinical Presentation

First child of parents with no blood relation, A.G. was born after 37 weeks of gestation, the pregnancy having been complicated by a risk of miscarriage in the fifth month. His weight at birth was 3500 grams.

The infant was hospitalized when he was 40 days old because of abundant diarrhea (15–20 evacuations a day of liquid stools), which started on the sixth day of life and was resistant to numerous dietary and pharmacological therapies.

On admission to hospital, the patient weighed 2800 grams, and was suffering from dystrophia and dehydration; total parenteral nutrition (TPN) was therefore immediately started. The acid-basic balance showed hyponatremic acidosis (pH 7,2; EB –8,3; Na 128 mEq/1). The secretive nature of diarrhea was confirmed by its entity (about 100 ml/kg/die) with a total absence of oral nutrition and with the persistence of TPN in progress.

Moreover, the typical absence of ionic gap in the stools was present: osmolality 226 mOsm/l, Na 86 mEq/1, K 23.5 mEq/1 (gap 7 mOsm/l).

Loperamide and chlorpromazine increased intestinal absorption but did not change the clinical picture.

Microbiological tests including electron microscopic analysis of the feces for the identification of viruses and the search for enterotoxigenic bacteria and parasites with specific methods were repeatedly negative.

The abdominal ultrasound showed adrenal hyperplasia associated with hyperaldosteronism (1160 ng/ml, v. n. <125 ng/ml).

Jejunal biopsy showed a picture of villus atrophy with no hyperplastic crypts and periodic acid-Schiff (PAS)-positive material stored in the apical cytoplasm of enterocytes. Electron microscopy was diagnostic for microvillus inclusion disease.

Microvillus Inclusion Disease: A Congenital Secretory Diarrhea Starting in Neonatal Age

In most cases, severe diarrhea appears in the first days of life, usually within the first 72 h, and is immediately life threatening. The stools are watery, and the stool output is 100–500 mL/kg/d when the infant is fed, a volume comparable to or higher than that observed in cholera. The diarrhea is of secretory type; therefore, it persists at a stable rate of 50–300 mL/kg/day despite fasting, and the electrolyte content of the stools is increased, without an osmotic gap. However, the mucosal atrophy causes additionally osmotic diarrhea in presence of luminal nutrients. For this reason, feeding increases the fecal output, and oral feeding in nutritionally significant amounts is impossible. Due to the high output, patients can lose up to 30% of their body weight within 24 h, resulting in profound metabolic acidosis and severe dehydration, unless vigorous intravenous rehydration is started.

Microvillus inclusion disease is the leading cause of secretory diarrhea in neonates with onset in most cases within the first few hours after birth [32]. However, in a small percentage of cases (currently considered around 5% of total) [33], diarrhea starts later in life: between 1 and 3 months, and more commonly at 6–8 weeks of age. This less severe form has been denominated late-onset microvillus inclusion disease, while the classical form beginning at neonatal age has been denominated early-onset microvillus inclusion disease [34].

A few cases have been termed atypical microvillus inclusion disease, in which the onset can be early or late, but the histological picture is different, particularly for the absence of detectable microvillus inclusions. The first case was a 5-month-old Navajo with profuse diarrhea beginning on the sixth day of life, who did not have microvillus inclusions in the duodenal tissue; a second biopsy confirmed the absence of classic microvillus inclusions despite the lack of surface microvilli and the presence of cytoplasmic vesicular bodies. However, a few microvilli associated with cytoplasmic inclusions were observed in a third biopsy [35]. In consideration of the typical clinical presentation, a diagnosis of microvillus inclusion disease was made, instead of intestinal microvillus dystrophy proposed for other cases with similar ultrastructural findings but slightly atypical clinical presentation [36]. Other similar cases were observed later.

Therefore, three variants of the disease have been identified: early-onset microvillus inclusion disease, late-onset microvillus inclusion disease, and atypical microvillus inclusion disease.

1. Early-onset MVID presents a complete loss of intestinal proteins, both in the villi and in the crypts.
2. In the late-onset MVID, there are normal microvilli at the base of the villi and in the crypts. The clinical picture is less severe and occurs later, usually from the second month of life.
3. In the atypical MVID, the microvillus proteins are absent or defective only at the crypts, while in the villi there are normal microvilli at the villus surface.

However, because of the sparse distribution of microvillus inclusions, it is not certain that their absence could not be limited to the sample.

The disease is characterized by defective transport of plasma membrane proteins to the apical brush border, due to mutations of the MYO5B gene on chromosome 18q21 [37, 38], encoding myosin Vb motor protein and two small GTP binding proteins, Rab8 and Rab11 [39].

Several mechanisms responsible for the pathological picture of MVID have been suggested, and in particular the presence of defects in vesicle trafficking or delivery (*Trafficking model*), in the recycling and delivery of apical recycling endosomes (*Recycling model*) or in the colocalization of ezrin and ezrin kinase in apical recycling endosomes (AREs), while ezrin kinases are normally transported to the apical membrane where they activate ezrin (*Local induction model*). It is possible that these mechanisms coexist, and so a hybrid model that combines all three models has been proposed [40].

The hallmark of the disease is the electron microscopic finding of disrupted enterocytic microvilli (i.e., digitations of the apical membrane of the intestinal epithelial cell protruding into the lumen) without inflammatory changes and the appearance of characteristic inclusion vacuoles, whose inner surfaces are lined by typical microvilli. Both lesions are seen only with the electronic microscopy.

The main histological features of the disease include diffuse villus atrophy without inflammatory changes and accumulation of periodic acid-Schiff (PAS)-positive material within the apical cytoplasm of enterocytes. The definitive diagnosis of MID rests on distinctive ultrastructural findings: microvillus inclusions (more frequently in villus enterocytes), increased electron-dense secretory granules (preferentially in crypt epithelial cells), and poorly developed brush border microvilli on the intestinal surface epithelium.

Microvillus inclusion disease is usually characterized by growth retardation and some developmental delay later in infancy. While no other specific findings can be detected, the disease can be associated with other abnormalities, indicated in Table 1.2.

Some cases of microvillus inclusion disease associated with other clinical pictures (for example, cardiac malformations, facial dysmorphia, transient neuronal dysplasia, aganglionic megacolon, Down syndrome, intrahepatic cholestasis, and hypochondroplasia) have been described. In a series of 24 patients with MVID followed up from birth to 23.5 years, liver disease was recorded in 22 patients, kidney disease in 9, and pulmonary disease in 2 cases [41].

Table 1.2 Anomalies described in association to microvillus inclusion disease

Meckel diverticula	Abdominal adhesions
Inguinal hernias	Renal dysplasia
Absent corpus callosum	Hydronephrosis
Mesenteric duct remnants	Craniosynostosis
Abnormal vertebrae	Down syndrome
Aganglionic megacolon	Hematuria
Pneumocystis jiroveci pneumonia	Dihydropyrimidinase deficiency
Autosomal dominant hypochondroplasia	Microcephaly
Renal Fanconi syndrome	Other renal problems
Hypophosphatemic rickets	Diabetes
Cardiac problems	Pulmonary problems
Liver dysfunction	Multiple hepatic adenomas

An infant who had presented on the second day of life with the first symptoms of necrotizing enterocolitis was diagnosed with congenital microvillus atrophy at the age of 2.5 weeks. The clinical picture of necrotizing enterocolitis was repeated at the age of 4, 7, and 11 weeks of life and was treated with antibiotics on a monthly basis. The authors suggested that the picture of necrotizing enterocolitis was caused by damage to the barrier function of intestinal epithelial cells [42].

A series of eight children aged between 2 days and 14 months at onset, six of whom were homozygotes or compound heterozygotes for MYO5B mutations, were observed with minor microscopy histological abnormalities, sometimes focal or delayed but consistent with MVID. Malformations and severe mental retardation were observed in three cases, and hydrocephaly in one [43].

An infant with microvillus atrophy presented with liver dysfunction, hematuria, and *Pneumocystis jiroveci* pneumonia during the course of the disease; the child succumbed after massive pulmonary hemorrhage. The authors hypothesized that the coinfections could have been facilitated by an altered MYO5B function [44].

MVID-associated liver dysfunction similar to progressive familial and benign recurrent intrahepatic cholestasis has been described in other cases, to suggest that MVID is not exclusive to the intestine.

Histologic Findings

Findings from duodenal biopsy must not be considered diagnostic. Histologic results of duodenal biopsy samples can range from essentially normal to mildly abnormal, showing the following:

- Thin mucosa caused by hypoplastic villus atrophy
- Diffuse villus atrophy (loss of villus height)
- Crypt hypoplasia

Periodic acid-Schiff (PAS) staining of the intestinal biopsy sample does not show the usual linear staining along the brush border but reveals PAS-positive material in the apical cytoplasm. The PAS staining material corresponds to the increased number of electron-dense secretory granules in the epithelium. The abnormal pattern of staining appears in the upper crypt region and continues over the villus [45] (Fig. 1.2).

PAS accumulates in low crypts in atypical microvillus atrophy, in upper crypts in congenital microvillus atrophy, and in low villi in late-onset microvillus atrophy.

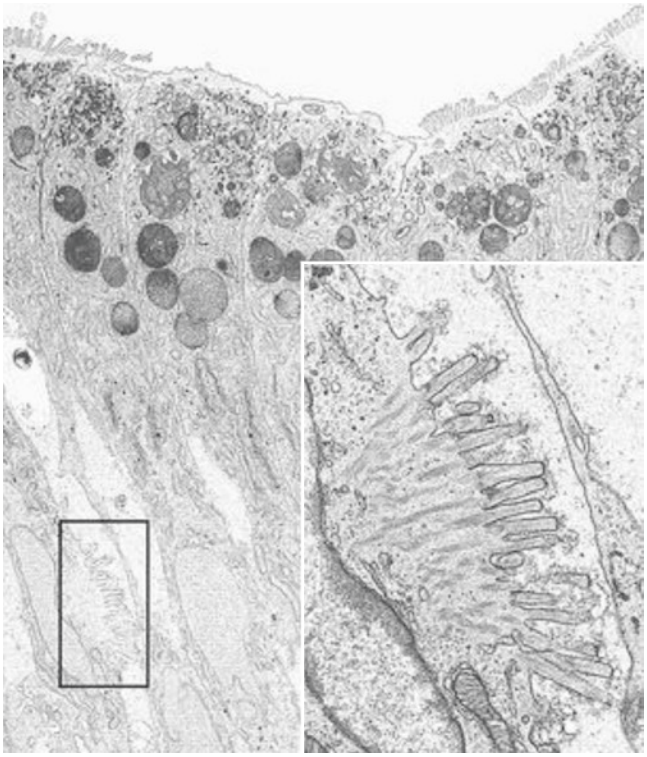

Fig. 1.2 Microvillus inclusion disease. [99], Fig. 5, with kind permission from Springer Science and Business Media)

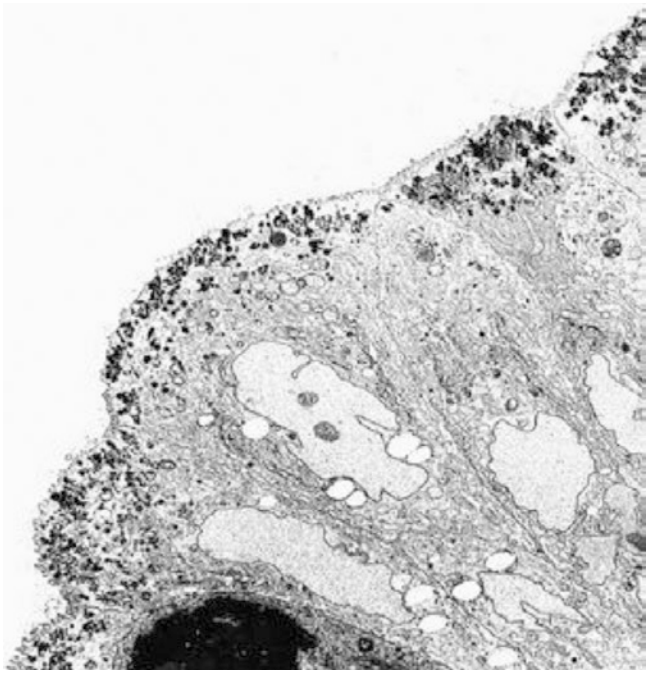

Fig. 1.3 Microvillus inclusion disease. The apical cytoplasm of villus epithelium shows an increased number of secretory granules associated with microvillus alterations. ×2400 [20] (Reprinted from Springer and Virchows Archive: Official Journal of the European Society of Pathology, Morroni et al. [99], Fig. 4, with kind permission from Springer Science and Business Media)

Similar results were obtained with anti-CD10 immunohistochemistry: in affected children the normal linear staining in surface enterocytes is absent, while prominent cytoplasmic reactivity is seen. CD10 is a neutral membrane-associated peptidase; thus, abnormal stain findings with PAS or anti-CD10 immunohistochemistry are expressions of the abnormalities in microvillar structure.

Rectal biopsy findings demonstrate microvillus involutions and an increased number of secretory granules. This test has been proposed as a relatively easy method for making an early diagnosis. Anti-CD10 immunohistochemistry can aid in the diagnosis, because abnormal cytoplasmic CD10 staining of absorptive colonocytes has been observed in microvillus inclusion disease [46], although while CD10 immunostaining identifies normal enteric mucosa with 100% specificity, negative staining does not definitively exclude small intestinal mucosa in the setting of active enteritis, a common condition in ileal pouch mucosa.

The diagnosis rests on findings demonstrated by application of immunohistochemical stains for microvilli antigens, such as villin or CD10, and electron microscopy (EM) [47] (see Figs. 1.3 and 1.4).

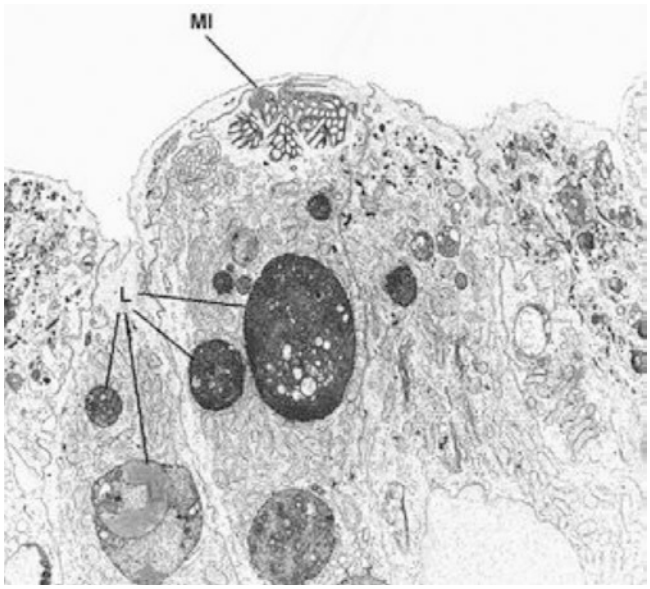

Fig. 1.4 Microvillus inclusion disease. The villus enterocytes lack brush border microvilli, whereas their apical cytoplasm contains a microvillus inclusion (MI) and numerous lysosomes (L) ×5.500 [20] (Reprinted from Springer and Virchows Archive: Official Journal of the European Society of Pathology, Morroni et al. [99], Fig. 2, with kind permission from Springer Science and Business Media)

Electron microscopy shows well-preserved crypt epithelium with abundant microvilli. Villus enterocytes are severely abnormal, particularly toward the apices of the short villi. The microvilli are depleted in number, short, and irregularly arranged. Some of the enterocytes contain the typical microvillus involutions, which are intracellular vacuoles where microvilli are observed lining the inner surface. Transmission electron microscopy (TEM) can efficiently demonstrate both the absence of surface microvilli, microvillus disorganization, and intracytoplasmic microvillus inclusions in enterocyte cytoplasm containing cryptic microvilli [48].

A striking feature is the finding of several small, membrane-bound vesicles containing electron-dense material (see Figs. 1.3 and 1.4). A few cases have been described in which the classic microvillus inclusions are shadowed by other features, such as large aggregates of electron lucent, vermiform membranous vesicles in enterocyte cytoplasm, corresponding to the PAS-positive material [49].

Epidemiology

Congenital microvillus atrophy is a rare disease. By 2014 only 137 cases had been published or gathered in an online registry [33]; to date around 200 cases of MVID have been reported, with a prevalence <1/1000.000, apparently more numerous in countries where marriages between blood relatives are more frequent [33].

A female preponderance had been observed among the published cases, with a female-to-male ratio of 2:1, but in the total reported 137 cases, there is instead a 1.54 male/female ratio. Consanguinity is present in 41% of the assessable cases with a gender preference for males. A cluster of cases from the Navajo reservation in northern Arizona suggests an incidence as high as 1 case per 12,000 live births [50].

Pathophysiology

Due to their alterations, mature enterocytes inefficiently absorb ions and nutrients, causing a malabsorption syndrome; however, the diarrhea is caused mainly by active secretion of water and electrolytes in the intestinal lumen (secretory diarrhea). The pathogenesis of the secretory diarrhea is unknown; it is believed to result from an unbalance between decreased absorption and unaltered secretion.

Measurement of stool electrolytes and osmolality enables rapid and accurate assessment of the pathogenesis of this chronic diarrhea (osmolar vs secretory) and greatly narrows the differential diagnosis.

Fecal electrolytes demonstrate a typical pattern of secretory diarrhea. Fecal sodium levels are high (approximately 60–120 mEq/L), and no osmotic gap is found. In patients with secretory diarrhea, the following formula applies: 2 × (Na concentration + K concentration) = stool osmolarity± 50. In osmotic diarrhea, stool osmolarity exceeds 2 × (Na concentration + K concentration) by 100 or more.

Secretory diarrhea occurs in the fasting state and is associated with large output losses that cause dehydration and metabolic acidosis.

In osmotic diarrhea, findings on stool microscopy are negative for white blood cells (WBCs), blood (exudative diarrhea), and fat (steatorrhea).

Even if there are data about the anomalies in water and electrolytes transport in the small intestine, it is not known whether and how the colonic mucosa participates in the absorption alterations in the disease.

In one of the Italian cases, we used the technique of rectal perfusion that showed a decrease in sodium absorption, only partially corrected by chlorpromazine administration [51].

Pathogenesis

Severe perturbation of the microvillar cytoskeleton may disrupt the transport of brush border components that have to be assembled at the apical membrane. The postulated abnormality in the cytoskeleton causes a block in exocytosis, mainly of periodic acid-Schiff (PAS)-positive material (e.g., polysaccharides, glycoproteins, glycolipids, neutral mucopolysaccharides). Consequently, small secretory granules that contain a PAS-positive material accumulate in the apical cytoplasm of epithelial cells.

Genetic evidence of the link between MVID and apical vesicle trafficking was initially obtained in Rab8 knock-out (KO) mice [52].

In 2008, the presence of mutations in the Myosine Vb (MYO5B) gene was described in seven patients (out of ten tested), predominantly of Turkish origin [37]. Homozygous mutations in the same gene were subsequently found in seven cases of Navajo origin; five parents were heterozygote [38]. A total of 41 unique MYO5B mutations had been identified [33]. Most patients with early-onset MVID display inactivating mutations in the MYO5B gene, one of the three myosin-5 genes (MYO5A, MYO5B, MYO5C) present in mammals, which are implicated in the spatiotemporal segregation and the transportation of organelles.

The MYO5B gene codifies Myosine Vb, an actin-based motor protein which carries the recycling endosomes to the apical plasma membrane along the actin filaments of the microtubules after having bound to a specific small guanosine-5'triphosphatase (GTPase) rab protein, such as Rab 11A, Rab8A, and RAB8A, located on the surface of recycling endosomes [53]. Myosine Vb mediates the tethering of Rab guanosine triphosphates, which determines apical vesicle transport and membrane recycling [54].

Studies in neonatal mouse models have shown that loss of active MYO5B causes early diarrhea, failure to thrive, evident microvillus inclusions, and loss of apical transporters in the duodenum. By contrast, induction of MYO5B loss in adult mice led to the rapid onset of diarrhea, but did not induce the formation of significant numbers of microvillus inclusions, to suggest that the formation of microvillus inclusions in duodenal enterocytes is far more pronounced in neonates, in whom we see a loss of proper trafficking and recycling of transporters to the apical brush border in enterocytes [55].

Thanks to this link the recycling endosomes move along the actine filaments [56] (*See* Fig. 1.5). The functional deficiency of Myosine Vb causes impaired microvillus formation and defective epithelial polarization [48]. The MYO5B mutant proteins are unable to bind to either RAB8A or RAB11A, with consequent microvillus structural defects, and the recycling endosomes are not carried in a normal way: in the enterocytes of the subjects with microvillus inclusion disease, no regular accumulation of myosine Vb and of the recycling endosome-associated proteins (one of these is Rab 11) can be observed close to the apical membrane, and no specific staining pattern is present [57]. Consequently, liquids and foods are not absorbed sufficiently, resulting in diarrhea, hypo-nutrition, and dehydration.

Therefore, Rab 11 distribution in the enterocytes can be a helpful diagnostic tool [58]. However, the spectrum of cellular defects in MVID is heterogeneous, and the severity of villus blunting, the ectopic formation of basolateral microvilli, the presence of ultrastructural features of microvillus inclusions (MVIs) may vary significantly. The cellular basis of this variability is still under study. In vitro cell-based mod-

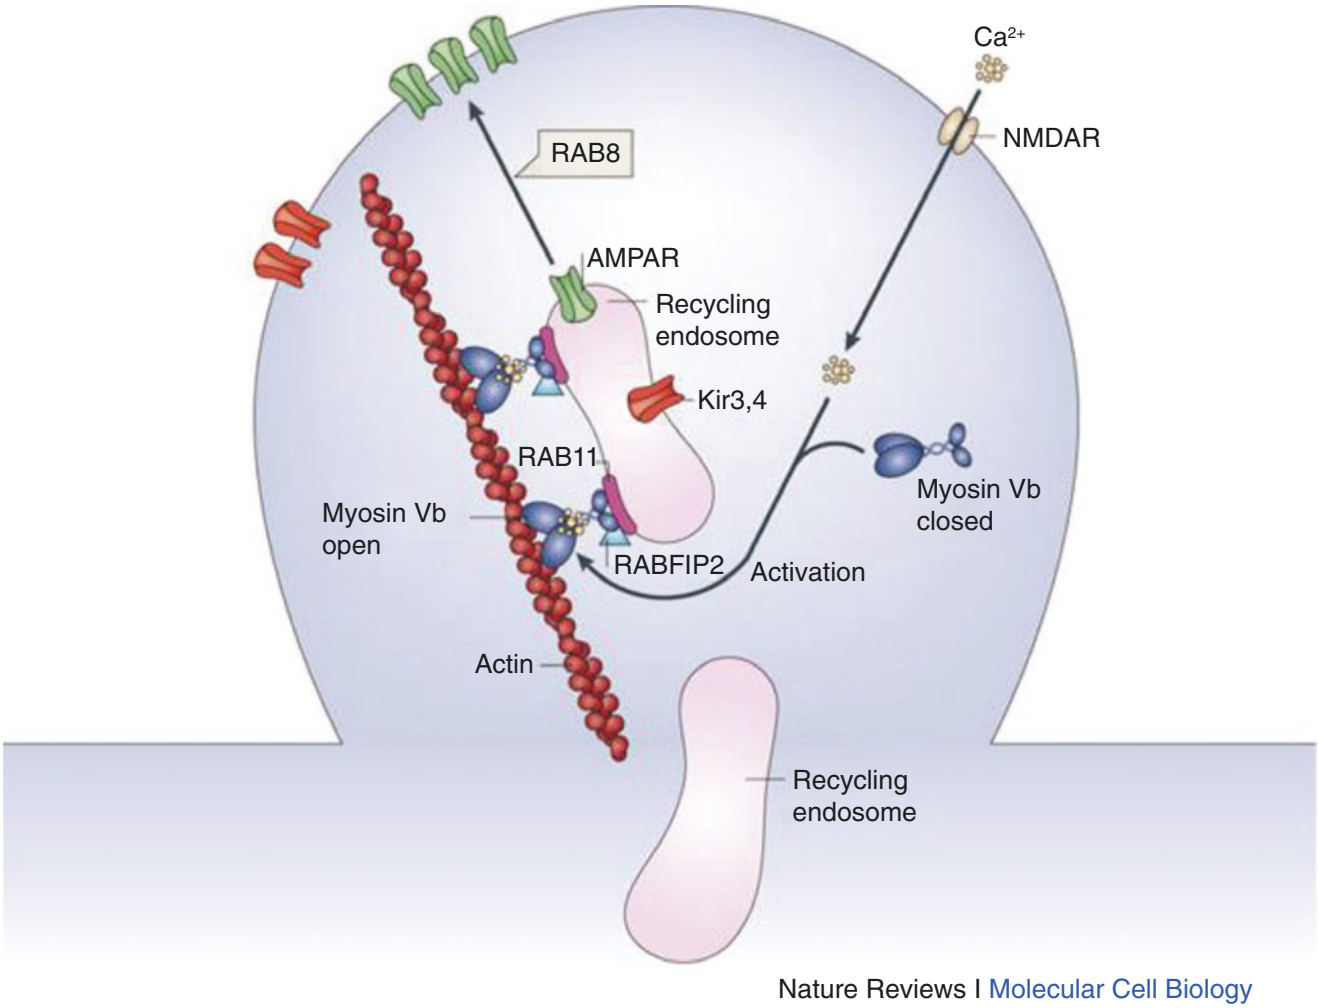

Fig. 1.5 Endocytic recycling. Myosin Vb is a conformation-dependent binding partner of Rab11-FIP2. Activation of myosin Vb induces translocation of recycling endosomes and their cargo. Final transport from the recycling endosome to the cell surface is mediated by Rab8 [37] (Reprinted by permission from Macmillan Publishers Ltd. and Nature Publishing Group: Nature Reviews Molecular Cell Biology, Grant and Donaldson [56])

els proved useful for greater understanding and showed that the MVID phenotype is correlated with the degree of enterocyte differentiation [59].

Molecular analysis strongly contributes to the unequivocal diagnosis of MVID and even prenatal diagnosis. So far about 60 different mutations have been identified, indicating the strong genetic heterogeneity of the disease.

Other biochemical mechanisms depending on myosin Vb which can produce alterations in the structure of the microvilli are presently being studied [60].

Myosin Vb is expressed in all the epithelial tissues and, as a matter of fact, microvillus inclusions in the stomach and colon, in addition to less well-defined inclusions in gallbladder epithelium and in renal tubular epithelial cells, have been reported in some patients with microvillus inclusion disease (MVID). Nevertheless, no extraintestinal symptoms are generally reported. Two children with renal Fanconi syndrome who carried mutation MYO5B did not show alterations in the apical brush border morphology and the PAS staining pattern in renal tubular epithelial cells, which makes it unlikely for it to be the cause of proximal tubular renal dysfunction [61].

At present it is not possible, from molecular analysis, to predict the outcome of the disease, since the prognosis depends mainly on early treatment, including intestinal transplantation.

Recent evidence shows that the effects of mutations in MYO5B are not limited to the small intestine but extend to other organs such as the liver, colon, pancreas, stomach [62], and bile salt export pump (BSEP) in the canalicular membrane, contributing to cholestasis [63].

In 2014, Dutch investigators found that the mild variant of MVID appears to be caused by loss of function of syntaxin 3 (STX3), an apical receptor involved in membrane fusion of apical vesicles in enterocytes [64]. STX3 mutations were identified by whole exome sequencing in two patients diagnosed with MVID based on clinical symptoms but without MYO5B mutations. In fact, whole exome sequencing of DNA from patients with variant MVID revealed homozygous truncating mutations in STX3, and in addition, patient-derived organoid cultures and overexpression of truncated STX3 in CaCo2 cells recapitulated most characteristics of variant MVID.

Mutations in STXBP2, a gene that encodes the syntaxin-binding protein-2 (also called mammalian uncoupled munc18–2 protein) which as STX3 may have a role in membrane fusion, have also been identified in patients with severe chronic diarrhea starting shortly after birth without signs of infection [65], as well as in patients with familial hemophagocytic lymphohistiocytosis type 5 (FHL5, OMIM 613101), a hyperinflammatory immune disorder which in 40% of cases is associated with severe chronic diarrhea starting shortly after birth.

It has been suggested that MYO5B, STX3, and STXBP2 are part of a common disease mechanism that unifies a subset of phenotypically linked congenital diarrheal disorders, regulating protein trafficking to the apical brush border [66].

Prenatal Diagnosis

Pregnancy and birth are usually normal in individuals with microvillus atrophy. However, cases with severe prognosis have been reported [67]. Polyhydramnios has been reported very rarely [33], in contrast to the clinical picture of patients with other causes of congenital secretory diarrhea, and antenatal and natal periods are usually uneventful.

Nevertheless, in some cases, polyhydramnios and bowel dilation in the third trimester have been described. In one case, a high fetal alpha-fetoprotein in the second trimester was observed [68]. Authors have speculated that the fetal alpha-fetoprotein elevation might possibly be caused by in utero body fluid leakage into the amniotic fluid through fetal enteropathy.

Identification of the gene responsible for the disease allows its prenatal diagnosis [69].

Treatment

The prognosis of early-onset microvillus inclusion disease is poor. If patients are untreated, the disease is rapidly fatal because of dehydration and malnutrition.

In late-onset microvillus inclusion disease diarrhea tends to be less severe, and some alimentation is possible.

Medical Care

Agents tentatively given to induce a better growth of the intestinal mucosa (e.g., epithelial growth factor, colostrum) are ineffective. Several drugs (e.g., corticosteroids, cromoglycate disodium, cimetidine, somatostatin, octreotide, loperamide, chlorpromazine, urogastrone/epidermal growth factor) have been tried to counteract the massive secretory diarrhea in patients with microvillus atrophy; however, none has proven effective.

In a 4-year-old boy diagnosed with congenital atrophy of the microvilli, after unsuccessful treatment with loperamide (0.2 mg/kg 4 times a day), racecadotril therapy proved to be effective [70]. The drug reduces the degradation of the enkephalins, abundant in the intestinal villi, and has an antisecretory effect through the inhibition of the cyclic adenosine monophosphate (cAMP) [71].

At present, the only available therapy is total parenteral nutrition (TPN). Children with late-onset microvillus inclusion disease usually have less severe diarrhea; as they get older, TPN can be reduced to once or twice per week.

If patients are treated with TPN, their prognosis entirely depends on the complications of this approach. These complications include cholestasis with subsequent liver damage leading to cirrhosis, catheter-related sepsis due to infection with bacterial or fungal agents, and progressive lack of vascular access.

In the observed cases, cholestasis appears to be worsened by transplantation.

The study of eight patients who developed cholestatic liver disease suggests that cholestasis is enhanced by the impairment of the MYO5B/RAB11A apical recycling endosome pathway in hepatocytes [72].

Surgical Care

Successful outcomes of small intestinal transplantation have been reported, and evidence suggests that an early transplant might be beneficial. The limited experience accumulated in a few centers worldwide reflects an overall survival rate of approximately 50% at 5 years after small-bowel transplantation; this is a much better outcome than is seen with other indications for intestinal transplantation [73]. Patients who did not receive colonic transplant weaned later from parenteral nutrition.

The analysis of 16 patients who underwent a small-bowel transplantation shows a lower death rate compared to those who did not (23% versus 37%) after an average 3.5-year observation period (but variable between 3 months and 14 years). In all the cases, apart from the first two, the colon had been transplanted too [74].

Although only small series have been reported, evidence suggests that early small-bowel transplantation should be performed, at least in children with early-onset microvillus inclusion disease. Patients with late-onset microvillus atrophy appear to have an improved prognosis.

Transplantation appears to be the only option for patients who do not fare well with long-term TPN (e.g., because of sepsis, liver damage, lack of vascular access). For patients in whom transplantation is successful, a gradual return to a normal diet is considered possible.

In the observed cases, TPN-related cholestasis appears to be made worse by transplant. Therefore, in children with cholestasis, the worsening of this picture after the transplant points to a combined liver-intestinal transplantation.

Tufting Enteropathy (or Intestinal Epithelial Dysplasia)

In 1994, Reifen et al. described two infants less than a month old with protracted diarrhea. The diarrhea was so profuse to make total parenteral nutrition (TPN) necessary but it improved when enteral nutrition was interrupted. The jejunal biopsies showed a peculiar picture characterized by the presence of focal aggregations of packed enterocytes in the shape of a teardrop, as a consequence of an apical rounding of the plasma membrane. These focal areas looked like tufts and that is why the term "tufting enteropathy" was coined [75]. Curiously, a case with the same characteristics was identified among those presented by Davidson et al. in the same paper where the first case of microvillus inclusion disease had been described [26].

According to current criteria, diagnosis is based on the presence of total or partial villus atrophy associated with crypt hyperplasia, in the absence of signs of inflammation, associated with the characteristic focal localized epithelial tufts, whose presence is an element of distinction from two other enteropathies that directly affect enterocytes, the microvillus inclusion disease, and the trichohepatoenteric syndrome. The tufts are formed by enterocytes enclosed in a plasma membrane, located in the duodenum and jejunum.

Clinical Expression

The incidence of the disease has been estimated to be rare, with a prevalence of 1:50.000–1:100,000 live births in Western Europe [76], but it seems higher in people of Arab origin.

The vast majority of the mutations in the EpCAM gene that cause the disease have been identified in patients originating from Europe, North West Africa, and the Mediterranean area and from Saudi Arabia in particular. The incidence rate is higher in areas with high proportion of close relatives and in the Arab region than in other regions [77]. However, reports from Asia are very scarce, and the incidence of tufting enteropathy in this area is unknown; the cases published so far include only two patients from South Korea and one from China [78].

The clinical picture is characterized by a severe secretory diarrhea, generally with loose stools, starting in the first weeks of life. During pregnancy, there is no polyhydramnios, as in the microvillus inclusion disease and differently from congenital sodium diarrhea and congenital chloridorrhea.

The alterations in the enterocytes in any case cause an accentuation of the diarrhea with nutrition, including total enteral nutrition, as had already been observed from the very first cases described. The histological analysis of the intestine shows anomalies of the basement membrane, disorganization of the enterocytes, and a "crowding" at the apex of the villi which are arranged like tufts.

There are two different clinical forms: one is isolated and the other is syndromic, associated with various anomalies, particularly facial dysmorphism with choanal atresia and superficial punctuated keratitis [79, 80], together with reduced body size and immunodeficiencies.

However, the clinical picture can be confusing. Three cases of tufting enteropathy associated with chronic arthritis and one diagnosed with juvenile rheumatoid arthritis, treated with prednisolone, have been described [81, 82].

Pathophysiology

The clinical picture is mainly caused by an abnormal development of intestinal epithelial cells, which are destroyed and grouped into clusters.

In 2008, a biallelic mutation of the gene for the epithelial cell adhesion molecule (EpCAM gene) was identified in five affected children, two of whom belonged to the same family [83].

Subsequently, other mutations were identified, the main ones of which are located in exons 3, 4, and 5, and cause a deletion of the extracellular and transmembrane regions of the EpCAM protein [84]. The EpCAM is a Type I superficial glycoprotein that is expressed on the surface of the basolateral membrane of many epithelial cells, with a fundamental role in the structural integrity and adhesion of epithelial tissues [85]. The mutant EpCAM accumulated in the endoplasmic reticulum is co-localized with GRP78/BiP, a reticulum chaperon. It has therefore been hypothesized that a response through a protein pathway may be induced in the endoplasmic reticulum [86].

In 2010, a mutation in the SPINT2 gene was found in a case affected by a syndromic form of tufted enteropathy. SPINT2 is a transmembrane protein which seems to be involved in epithelial regeneration [87], whose mutations may result in an indirect loss of EpCAM protein, due to activation of matriptase, a type II transmembrane serine protease expressed in most human epithelia, which causes its proteolysis [88]. Mutations in SPINT2 (MIM# 605124) have been implicated in a syndromic form of the disease, which may cause an indirect loss of EpCAM protein due to proteolysis by the activation of matriptase [89].

It is interesting to note how mutations in the SPINT 2 gene are also present in the syndromic congenital sodium diarrhea, where choanal atresia, hypertelorism, and corneal erosions are particularly frequent and anal atresia can be found in certain cases [90].

The analysis of 57 patients revealed mutations in the gene for EpCAM in 73% of the cases, all of them presenting with an isolated intestinal disease, but in 21% of cases, all with a syndromic form of the disease, mutations of the SPINT2 gene were present [90].

According to this study, tufting enteropathy could be separated into at least three genetic classes, each with specific phenotypes.

However, it seems impossible at present to distinguish between tufting enteropathy and syndromic enteropathy, even from a genetic point of view.

Histological Features

Jejunal biopsy shows a picture of partial villus atrophy together with crypt hyperplasia. The most characteristic feature, the one which gave the name to the disease, is the presence of "tufts," small focal aggregates of teardrop-shaped enterocytes with apical rounding (*see* Fig. 1.6a, b) [91], in addition to characteristic focal epithelial tufts composed of enterocytes with plasma membrane rounding found in the duodenum and jejunum.

The "tufts" are not a characteristic exclusive to intestinal epithelial dysplasia, because they have been observed in other mucosal enteropathies and in normal jejunum. In the latter cases anyway, they were present in <10% of the epithelial surface, while in "tufting enteropathy," they are present in more than 80% of the jejunal surface. But the picture is not always so evident in the earliest period of the disease. Attempts at immunohistochemical analysis (including beta-catenin, E-cadherin, desmoglein, and laminins) have not been easy applicable [92]. On the contrary, staining with EpCAM/MOC31 antibody, an EpCAM antibody clone, showed a sensitivity and specificity of 100% for loss of staining in 15 studied patients [93].

Electronic microscopy shows relatively normal microvilli, and it may be useful as a diagnostic tool only to exclude microvillus inclusion disease.

Mild inflammation of the lamina propria is also present. Infiltration of T lymphocytes within the lamina propria had always been observed since the original description, even if inferior to celiac disease, but it sometimes gives rise to a suspicion of autoimmune enteropathy [75].

Treatment

Tuft enteropathy is associated with severe secretory diarrhea, which worsens with nutrition. That is why affected children have to be treated with total parenteral nutrition (TPN).

Some cases seem to have a less severe course and they can be given a partial parenteral nutrition [94].

There is currently no specific treatment for tufting enteropathy. Many cases are treated with long-term parenteral nutrition, which it may be possible to reduce or suspend with increasing age [95]. Twelve patients survived for 8–30 years under long-term parenteral nutrition therapy. In those cases where it is impossible to continue parenteral nutrition, or when there were other serious issues, bowel transplantation was attempted [96].

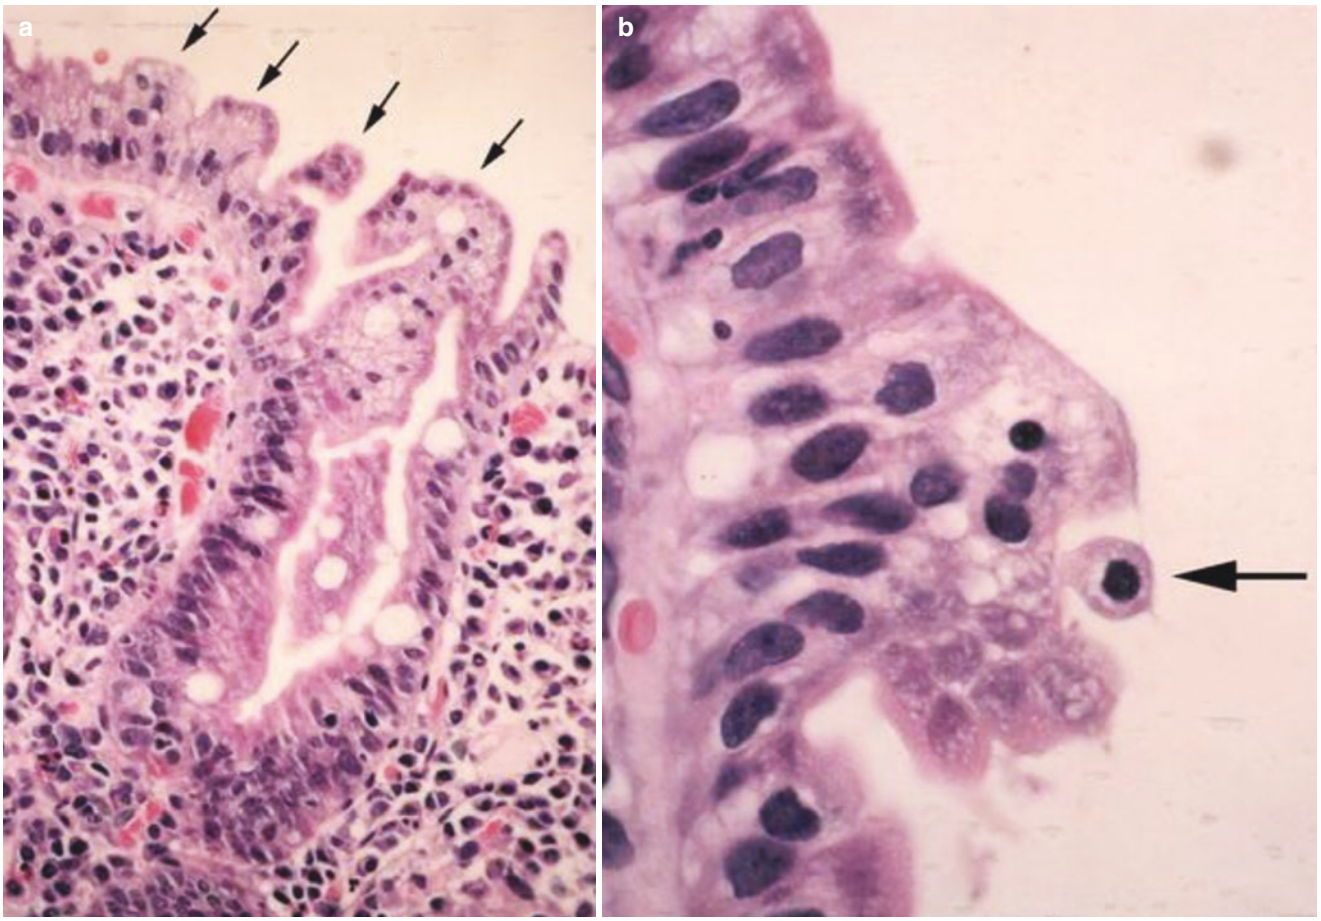

Fig. 1.6 (**a**) Numerous tufts of enterocytes (*) on the mucosal surface of the duodenum. (**b**) A characteristic tear-drop-shaped structure (*arrow*) in an epithelial tuft (H&E stain; original magnification: a – ×80; b – ×400) [58] (Reprinted from Springer and European Journal of Pediatrics, El-Matary et al. [91], Fig. 1, with kind permission from Springer Science and Business Media)

Cases totally dependent on total parenteral nutrition are candidates for intestinal transplantation.

Tufting enteropathy is often associated with other pathologies related to epithelial cells or malformations. More than 60% of patients have punctate keratitis [97] or other eye diseases [98], associated with other changes, such as nostril atresia, esophageal atresia, or absence of the anus [79].

In some cases where there was a risk of liver failure as a result of TPN, an intestinal or combined liver / intestinal transplant was performed, with satisfactory results in a case where the transplant was performed before aggravation. Repeated biopsies are sometimes required for diagnosis.

The Spectrum of Autoimmune Enteropathy

2

Natalia Nedelkopoulou, Huey Miin Lee, Maesha Deheragoda, and Babu Vadamalayan

Introduction

Chronic, unexplained diarrhea in children younger than 3 months old was first characterized as "intractable diarrhea" [1]. The term "protracted diarrhea" was later used to describe infants with frequent and loose stools severe enough to often require parenteral alimentation as nutritional support [2]. The differential diagnosis of enteropathies in infancy and childhood includes inherited epithelial and congenital transport defects, enzymatic deficiencies, and allergic enteropathy (Table 2.1).

The most frequent diagnosis in children with protracted diarrhea is autoimmune enteropathy [3, 4]. It is a rare, immune-mediated disorder starting usually within the first months of life. The age of onset is between 1 month and 5 years (median age 17 months) [5], but late-onset adult forms have been also reported [6–9]. The disease was first described by Walker-Smith et al. in 1982 in a male child with clinical features of celiac disease and villus blunting unresponsive to gluten-free diet [10] and represents a heterogeneous group of disorders rather than a discrete entity. The incidence is estimated at less than 1 in 100000 infants. The diagnostic criteria are debatable, but the presence of circulating anti-enterocyte antibodies and the lack of immunodeficiency have been proposed as the hallmark features of autoimmune enteropathy [5, 11]. The latter criterion has been challenged by clinical experience and better understanding of the immunology of autoimmunity and self-tolerance [12].

Table 2.1 Differential diagnosis of diarrhea in infancy and childhood

Transport defects and enzymatic deficiencies
Disaccharidase deficiency
Sodium–hydrogen exchanger (congenital sodium diarrhea)
Chloride–bicarbonate exchanger (chloride-losing diarrhea)
Sodium-glucose cotransporter (glucose–galactose malabsorption)
Lysinuric protein intolerance
Chylomicron retention disease
Abetalipoproteinemia
Ileal bile acid receptor defect
Enterokinase deficiency
Inherited epithelial defects and villous atrophy
Enterocrine cell dysgenesis
Microvillus inclusion disease
Autoimmune enteropahty
IPEX syndrome
Tufting enteropathy
Lymphangectasia
Celiac disease
Allergic enteropathy/eosinophilic enteritis
Infectious/post-infectious enteropathy
Other
Idiopathic
Acrodermatitis enteropathica
Metabolic diseases
Tumors

Autoimmune enteropathy is characterized by variable clinical expression, ranging from isolated gastrointestinal involvement to severe systemic disease [13, 14]. Patients diagnosed with the disease often exhibit extra-intestinal manifestations of autoimmunity, in contrast to those with tufting enteropathy and microvillus inclusion disease [15]. Based on a genetic approach combined with immunological evaluation three different forms of autoimmune enteropathy have been proposed:

1. A predominately or isolated gastrointestinal form of autoimmune enteropathy with typical anti-enterocyte antibodies in both sexes
2. A systemic X-linked form of autoimmune enteropathy associated with different endocrinopathies, hematologi-

cal symptoms, and severe eczematic skin disease, known as immune dysregulation, polyendocrinopathy, and autoimmune enteropathy X-linked syndrome (IPEX) occurring only in males
3. An IPEX-like form, a priori FOXP3-independent occurring in both sexes

IPEX and APECED syndromes (APR-1/autoimmune phenomena, polyendocrinopathy, candidiasis, and ectodermal dystrophy) are systemic forms of autoimmune enteropathy [16].

Diagnosis

The diagnostic criteria for autoimmune enteropathy were originally proposed by Unsworth and Walker-Smith et al. and included (a) protracted diarrhea and severe enteropathy with small-intestinal villous atrophy, (b) no response to exclusion diets, (c) evidence of predisposition to autoimmune disease (presence of circulating enterocyte antibodies or associated autoimmune disease), and (d) no severe immunodeficiency [17]. A more recent adult study proposed the updated criteria and now the diagnosis is established when all of the criteria are present (Table 2.2). The disease should be considered in the differential diagnosis in all patients presenting with severe, unexplained diarrhea requiring parenteral nutritional support particularly in infants, since autoimmune enteropathy is the most common cause of protracted diarrhea in infancy [3]. The endoscopic examination with small bowel biopsy is the cornerstone of investigation.

The diagnostic work-up should also include information regarding the birth and family history and the time of onset of diarrhea. The disease is characterized by secretory diarrhea, nonresponsive to bowel rest. Most of the affected infants have no history of gluten ingestion at the time of presentation. Furthermore, the lack of response to a gluten-free diet points toward autoimmune enteropathy [5, 11, 18].

Serum immunoglobulin assays show normal IgM and decreased IgG attributed to protein-losing enteropathy. IgA is often within normal range, but IgA deficiency associated with villous atrophy has been also reported in autoimmune enteropathy. T- and B-cell function tests, the lymphocytic subsets, and polymorphonuclear cell counts are generally normal. Anti-smooth muscle, anti-nuclear, and anti-thyroid microsomal autoantibodies have been identified during the disease [5, 8, 19, 20].

Determination of fecal inflammatory markers, like fecal calprotectin, is a simple method that is helpful in distinguishing constitutive intestinal epithelial disorders, such as microvillus atrophy and epithelial dysplasia from immune-inflammatory etiologies such as autoimmune enteropathy and inflammatory colitis. It has been proposed that the dramatically increased levels of fecal calprotectin in neonates and infants with immune-inflammatory disorder can distinguish these disorders from constitutive epithelial disorders with 100% specificity [21].

Table 2.2 Diagnostic criteria for AIE

Diagnostic criteria for AIE by Unsworth and Walker-Smith [17]	Updated diagnostic criteria for AIE by Akram et al. [14]
1. Protracted diarrhea and severe enteropathy with small-intestinal villous atrophy 2. No response to exclusion diets 3. Evidence of predisposition to autoimmune disease (presence of circulating enterocyte antibodies or associated autoimmune disease) 4. No severe immunodeficiency	1. Chronic diarrhea (>6 weeks) 2. Malabsorption 3. Small bowel histology showing partial or complete villous blunting, deep crypt lymphocytosis, increased apoptotic bodies, minimal intraepithelial lymphocytosis 4. Exclusion of other causes of villous atrophy, including celiac disease, refractory sprue, and intestinal lymphoma 5. Presence of anti-enterocyte and/or anti-goblet cell antibody supports the diagnosis and sometimes correlates with disease improvement, but is not required to make the diagnosis

Clinical Presentation

Chronic, secretory diarrhea refractory to bowel rest that leads to dehydration, electrolyte abnormalities, malabsorption, and severe weight loss is the typical clinical presentation of autoimmune enteropathy. Diarrhea usually begins between 2 and 4 weeks of age, and the secretory component can be delayed for a few months [3, 11, 22]. The symptoms can be debilitating, unresponsive to restriction of diet, and the disease is potentially life-threatening. The establishment of the diagnosis is crucial in order to ensure optimal treatment. Patients typically require immunosuppressive therapies and total parenteral nutrition for electrolyte balance and nutritional support [17, 23].

Even though the mucosal abnormality is primarily confined to the small intestine, the term "generalized autoimmune gut disorder" has been used to describe the association between autoimmune enteropathy and autoimmune colitis [8]. Emerging evidence suggests that autoimmune enteropathy can be a manifestation of a more diffuse autoimmune disorder of the gastrointestinal system, comprising gastritis, colitis, hepatitis, and pancreatitis with positivity of a variety of autoantibodies, including anti-parietal, anti-goblet cell, and anti-smooth muscle antibodies [6, 19, 24, 25].

Furthermore, the involvement of extraintestinal organs can be present during the course of the disease. Multisystem extra-intestinal manifestations include endocrine, renal,

pulmonary, hematologic, and musculoskeletal. Hypothyroidism with interstitial fibrosis and lymphocytic infiltration of the thyroid gland, membranous glomerulonephritis and nephrotic syndrome, interstitial pneumopathy, periportal fibrosis and bronchitis, hemolytic anemia, rheumatoid arthritis, thymoma, and dermatitis/atopic eczema have all been reported [5, 11, 19, 26, 27, 28]. Severe forms of AIE can be associated with identified syndromes, namely IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) and APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy) syndrome [11].

Thymus plays a key role in the deletion of potentially self-reactive clones of T cells. The association between autoimmune enteropathy and thymoma has been described in both pediatric and adult patients and provides further evidence about the role of thymoma and the development of autoimmunity [27, 28].

Pathogenesis

The underlying immunologic and molecular mechanisms in autoimmune enteropathy have not yet been fully elucidated and are widely debatable. However, it has been established that an autoimmune response is involved in the pathogenesis of the disease. Thymus plays a key role and orchestrates a healthy immune system. The intrathymic maturation of T lymphocytes is crucial for the deletion of potentially self-reactive clones of T cells. The dysfunction of the thymus results in the nondeletion and presence of self-reactive T cells that can induce the expansion of anti-self B cells [11, 29, 30].

In autoimmune enteropathy, the gut is the site where the autoimmune reaction takes place and is mediated by the activation of self-reactive T cells locally, resulting in the typical histological lesions. In normal states, the expression of human leukocyte antigen (HLA) class II molecules on the enterocyte surface is crucial in establishing and maintaining the oral tolerance as the epithelial cells present exogenous peptides to the clonotypic T-cell receptors. The overexpression of HLA-DR antigens in enterocytes and the inappropriate expression of HLA class II molecules in the crypt epithelium of the proximal small intestine in children with autoimmune enteropathy have been reported [15, 31]. The overexpression of HLA class II molecules results in the proliferation of CD4+ and CD8+ T lymphocytes [8, 15, 32].

An increase in the levels of CD4+ and CD8+ T lymphocytes in the lamina propria in subjects affected by autoimmune enteropathy provides further evidence that the T cells are involved in the pathogenesis of the disease [33, 34]. The intestinal T lymphocytes cause damage to the enterocytes by exerting direct cytotoxicity, via the production of lymphokines or through an antibody-dependent cytotoxicity resulting in cellular apoptosis [32, 35, 36].

A variety of circulating auto-antibodies such as antibodies against gastric parietal cells, pancreatic islets, glutamic acid decarboxylase, insulin, smooth-muscle, endoplasmic reticulum, reticulin, gliadin, adrenal cells, nuclear antigens, DNA, thyroglobulin, and thyroid microsomes has been detected in patients with autoimmune enteropathy [7, 17]. The presence of antibodies against goblet cells, enterocytes, and colonocytes is supportive of the diagnosis. These antibodies are directed against components of the intestinal brush border membrane, with an increasing intensity from the crypts toward villus tip [5, 13]. However, they are neither diagnostic nor specific for the disease and have been also identified in other disorders such as the cow's milk allergy, inflammatory bowel disease and in adults with HIV infection. Moreover, the appearance of the autoantibodies after the onset of the mucosal damage, the lack of correlation between the titer and the histological severity, and their disappearance after treatment, but before the complete mucosal restoration support the hypothesis that these antibodies are most likely a secondary event in the pathogenesis of the disease in response to bowel injury [10, 37–39].

The nature of the gut antigen that elicits the immune response and results in the alteration of the intestinal permeability has been extensively investigated. A 55kD protein located in both the gut and renal epithelial cells that reacted with serum autoantibodies was first identified by Colletti et al. in 1991 in a patient with complicated presentation of autoimmune enteropathy with small bowel and glomerular involvement [40]. A few years later, a 75kD autoantigen that is distributed through the whole intestine and the kidney was recognized in patients with X-linked autoimmune enteropathy associated with nephropathy, as reported by Kobayashi et al. [41]. Autoantibodies against this 75kD autoantigen, known as harmonin, are specific to IPEX patients [42, 43, 44]. Kobayashi et al. also identified in a proportion of patients with IPEX the autoantibodies against villin; the actin-binding 95 kDa protein involved in the organization of actin cytoskeleton in the brush border of epithelial cells was described as an additional target of autoantibodies in a proportion of patients with IPEX [43, 45]. The intestinal auto-antigen in autoimmune polyendocrine syndrome type 1 (APECED) is tryptophan hydroxylase, which is mainly present in the enterochromaffin cells of the mucosa [46].

Emerging evidence has pointed toward an uncontrolled inflammatory reaction caused by the disturbance of the effector–regulatory T-cell interaction and leading to the production of autoantibodies, such as anti-enterocyte antibodies [47]. The understanding of the underlying molecular mechanism and the identification of the genetic defect in IPEX was achieved due to the clinical similarities between

scurfy mice and boys with the disease. Scurfy mice are naturally occurring X-linked mutants that present with massive lymphoproliferation, diarrhea, intestinal bleeding, scaly skin, anemia, thrombocytopenia, and hypogonadism [48]. Based on the observation that the disease-causing mutation in scurfy mice was on the X chromosome, the human IPEX locus was identified on chromosome Xp11.23-q13.3 and the gene was named FOXP3. It comprises of 11 exons which encode the FOXP3 protein or scurfin, a 48 kDa protein of the forkhead (FKH)/winged helix transcription factor family that is predominantly expressed in CD4+CD25+ T cell with regulatory function, at significantly lower levels in CD4+CD25– T cells and not at all in CD8+ or B220+ cells [49–52].

Increasing experimental evidence has shown that scurfin is implicated in the thymic maturation of T cells that are designated to acquire regulatory function. CD4+CD25+ Tregs represent a small subset (5–10%) of CD4+ T helper cells in humans and mice. Studies on CD4+CD25+ T cells from IPEX patients with the use of anti-CD127 have shown that FOXP3 plays a crucial role in the generation of functional T regulatory cells (Tregs) and intact FOXP3 is indispensable for the development of fully functional Tregs, whereas FOXP3 with amino acid substitutions in the FKH domain is sufficient for the generation of functionally immature Tregs [53]. Tregs are potent immunosuppressive cells of the adaptive immune system. The suppressive mechanisms for Treg cells include CTLA4 engagement of B7 molecules on target cells; expression of immunosuppressive cytokines such as IL-10, TGF-β, and IL-35; cytotoxicity of target cells through the perforin/granzyme pathway; induction of indoleamine 2,3-dioxygenase (IDO); and the catabolism of tryptophan in target cells, as well as consumption of adenosine by expression of CD73 and competition with effector T cells for IL-2 since Treg cells constitutively express the high affinity IL-2 receptor CD25 [54]. The loss of the regulatory function of T lymphocytes with subsequent uncontrolled inflammatory reaction is also implicated in the pathogenesis of IPEX syndrome.

FOXP3 has deoxyribonucleic acid (DNA) binding activity, and due to its structure may serve as nuclear transcription factor and act as a repressor of transcription and regulator of T-cell activation [55, 56]. The transcription of a reporter containing a multimeric FKH binding site is repressed by intact FOXP3. Such FKH binding sites are located adjacent to nuclear factor of activated T cells (NFAT), regulatory sites in various cytokine promoters such as IL-2, or granulocyte-macrophage colony-stimulating factor enhancer. Therefore, intact scurfin protein appears to be capable to directly repress NFAT-mediated transcription of the IL-2 gene in CD4+ cells upon activation [57].

Data from animal models with transgenic induction of FOXP3 have shown that the overexpression of scurfin in normal mice leads to a tremendous suppression of immune functions, whereas the depletion of Tregs in healthy mice results rapidly in the development of different T-cell-mediated autoimmune disorders, similar to scurfy in mice or IPEX in humans that go in complete remission upon reconstitution with Treg cells [58, 59].

The three domains that are crucial for the function of FOXP3 are the C-terminal region, which contains the forkhead domain that directly binds DNA regions, the central domain with a zinc finger and leukine zipper that promotes the oligomerization of the FOXP3 molecule, and the repressor domain located in the N-terminal region that binds the NAFT [60, 61]. Genetic screening on X chromosome in patients with IPEX revealed that the majority of mutations cluster primarily within the FKH domain and the leukine zipper within the coding region of the FOXP3 gene causing potentially absent FOXP3 protein expression or a protein product with loss of function [13, 60].

Histopathology

Histologic evaluation of the small bowel in typical autoimmune enteropathy reveals partial or total villous blunting/atrophy and crypt hyperplasia. In addition, there is a marked infiltration of the lamina propria by mixed inflammatory cells with a prominence of mononuclear cells, including T lymphocytes [15]. Apoptotic bodies and intraepithelial lymphocytes are present in the crypt epithelia. Most cases show a relative paucity of surface lymphocytosis in contrast to celiac disease. The lymphocytic infiltration of the intestinal mucosa is constituted by CD4-CD8 T lymphocytes and macrophages. Goblet, Paneth, and/or enterochromaffin cells may be reduced in number or absent. Cryptitis and crypt abscesses have been reported in severe autoimmune enteropathy. Crypt enterocytes commonly show an increased expression of HLA-A, -B, -C molecules [8, 62, 63] (Table 2.3) (Fig. 2.1).

Autoimmune enteropathy primarily involves the small bowel with the histologic lesions being most prominent in the proximal small intestine. However, changes have been

Table 2.3 Histological findings in autoimmune enteropathy

1. Partial or total villous blunting/atrophy and crypt hyperplasia.
2. Marked infiltration of mononuclear cells, including activated T lymphocytes in the lamina propria.
3. Apoptotic bodies and intraepithelial lymphocytes present in the crypt/gland epithelia, but relatively paucity of surface lymphocytosis.
4. Crypt abscesses in severe autoimmune enteropathy.
5. Increased expression of HLA-A, -B, -C molecules in crypt enterocytes.

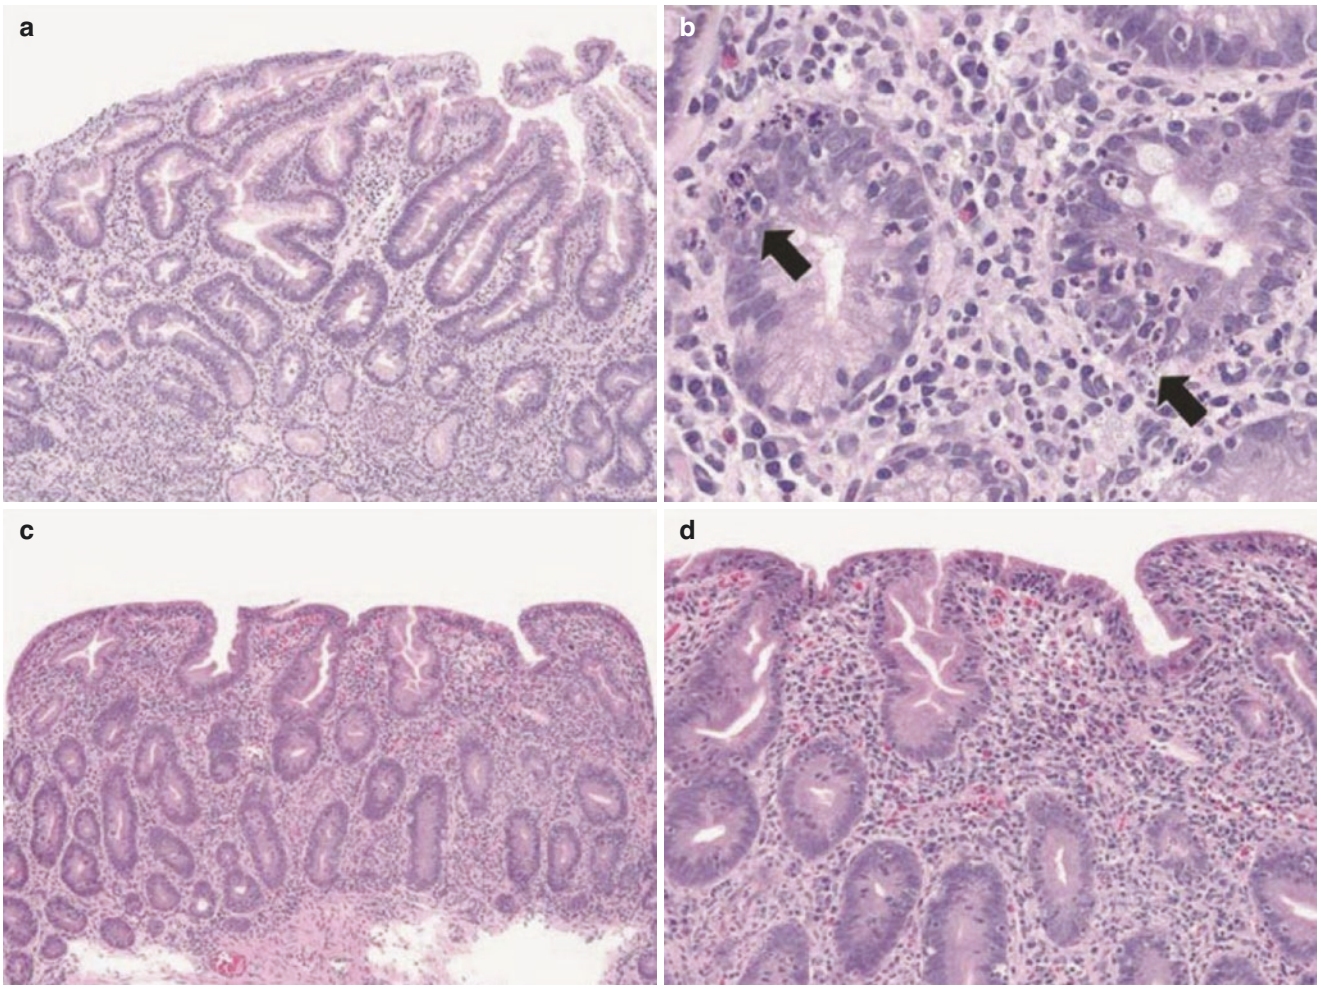

Fig. 2.1 (**a**, **b**, low and high magnifications, respectively) In some cases of pediatric autoimmune enteropathy, the small intestinal biopsies show cryptitis and crypt abscesses that may obscure the salient finding of autoimmune enteropathy, crypt apoptosis (arrows). There is also an absence of Paneth cells. (**c**, **d**) As described in adult patients, small intestinal biopsies can demonstrate a combination of both autoimmune enteropathy and sprue-like histologic findings, characterized by severe villous blunting, marked intraepithelial lymphocytosis, diffuse mononuclear inflammatory infiltrate, and prominent crypt apoptosis. Of note, goblet cells are lacking within this specimen

also described in the esophagus, stomach, and colon in both pediatric and adult patients supporting the hypothesis for a diffuse disease process involving the entire gastrointestinal tract.

Recent reports describe the infiltration of the squamous epithelium by lymphocytes or eosinophils in the esophagus. Gastric biopsies can show features of chronic nonspecific gastritis with or without reactivity. Atrophic gastritis, intestinal metaplasia, and glandular destruction have been also described. There may be increased apoptosis of glandular epithelium [6, 64]. The colonic morphological lesions vary from mild active colitis with inflammatory cell infiltration to severe, diffuse, chronic colitis with goblet cell depletion, Paneth cell metaplasia, distortion of crypt architecture, and crypt abscess formation. An increase in intraepithelial lymphocytes has been also described [25, 64].

Treatment

Early recognition and accurate diagnosis of autoimmune enteropathy is mandatory to ensure the optimal treatment. The disease is characterized by life-threatening diarrhea often nonresponsive to bowel rest. Total parenteral nutrition (TPN) represents an important step in the management of autoimmune enteropathy for nutritional support, adequate rehydration, and optimal growth [11, 14, 65]. However, the pediatric patients are not always TPN-dependent during the course of the disease [66]. When the gastrointestinal involvement is less severe, elemental or low carbohydrate containing formula is recommended to promote enteral delivery of nutrients and calories. The potential tolerance to enteral feeds and the concomitant inflammatory changes affecting the colon make small bowel transplantation not an ideal treatment option for autoimmune enteropathy [17, 67].

Long-term immunosuppression is the mainstay of treatment for the disease. Standard immunosuppressive therapies include corticosteroids, cyclosporine, azathioprine, and 6-mercaptopurine. Steroids in the form of prednisolone or budesonide are often needed to induce remission. However, the disease can be refractory to steroids or diarrhea recurs when they are tapered [68].

Since the early 1990s pediatric patients with autoimmune enteropathy have been successfully treated with oral cyclosporine A. Studies have shown that a relatively low drug level (50 ng/mL) led to improvement in growth, intestinal carbohydrate absorption, and small bowel histology. However, a number of patients do not respond to the medication and a possible reason is the inefficient absorption of the oral compound due to the underlying chronic enteropathy [69, 70].

Tacrolimus has been used as a therapeutic treatment option with beneficial effects in a variety of autoimmune diseases, including autoimmune hepatitis, primary sclerosing cholangitis, and steroid-refractory nephrotic syndrome. Its mechanism of action is similar to cyclosporine. Both drugs block the gene activation for cytokine production by inhibiting the antigenic response of helper T lymphocytes, suppressing interleukin and interferon-γ [22]. Bousvaros et al. first used tacrolimus as an alternative therapy for autoimmune enteropathy and concluded that it can be efficacious if other immunosuppressive regimens fail. Clinical improvement occurred between 1 and 4 months once therapeutic levels were achieved, and serum drug levels were obtained between 5 and 15 ng/mL. Tacrolimus' absorption is less dependent on mucosal integrity compared to cyclosporine; however, mucosal healing improves its absorption, and the dosage should be adjusted to achieve the desired blood levels of the drug. The need for long-term or lifelong treatment with tacrolimus in autoimmune enteropathy necessitates baseline and frequent monitoring in order to prevent potential complications including nephrotoxicity, neurotoxicity, increased predisposition to infections, and lymphoproliferative disease [71].

The combination of tacrolimus and infliximab has been proven successful in controlling the inflammation in severe autoimmune enteropathy in both pediatric and adult patients. The synergistic effect of these agents is based on the different aspects of the immune system on which they act. Emerging evidence support that infliximab itself is a highly effective tool for achieving clinical remission and restoring small bowel villous architecture in autoimmune enteropathy. The drug has been introduced because of its TNF-α antagonistic effect since high levels of this cytokine are being produced by intestinal intraepithelial T lymphocytes of patients with autoimmune enteropathy. The response to infliximab is usually rapid and the quality of life of the patients improves dramatically. However, it has been recognized that aggressive immunosuppressive treatment carries a potential risk of life-threatening hypersensitivity reactions and malignancies that should be also considered [17, 72, 73].

Additional immunosuppressive therapies have been used in autoimmune enteropathy. Cyclophosphamide is an alkylating agent related to nitrogen mustard and is a potent immunosuppressive agent used in bone marrow transplantation (BMT) conditioning regimens [74]. Low dose oral cyclophosphamide led to resolution of the intestinal symptoms in a teenage boy with total villous atrophy, selective immunoglobulin A deficiency, and anti-epithelial cell antibodies [75]. However, the use of cyclophosphamide in doses up to 3 mg/kg/d has not always been successful in the management of the disease [40, 76]. Remission of symptoms and improvement of intestinal histopathology was reported in an infant with severe autoimmune enteropathy with a single course of high-dose intravenous cyclophosphamide, approximately 20 times greater than those previously used [77].

Myco-phenolate mofetil (MMF) has been proposed as an alternative therapeutic option after the successful induction of remission and the improvement of the intestinal absorption and linear growth in an infant with autoimmune enteropathy and concomitant factor V Leiden defect [78].

Rapamycin is a macrolide compound and has immunosuppressive and antiproliferative properties due to its ability to inhibit mTOR (mammalian target of rapamycin) [79]. Rapamycin was found to be beneficial and appeared to be superior to calcineurin inhibitors when used as an immunosuppressive therapy in IPEX patients [80].

The successful use of adalimumab, an *antitumor necrosis factor*-alpha monoclonal antibody administered subcutaneously, has been reported in adult cases of autoimmune enteropathy [81, 82]. Other biologics, including vedolizumab (an anti-α4β7 integrin) and abatacept, have also been used in adult cases of autoimmune enteropathy [83, 84, 85].

IPEX Syndrome

IPEX is a rare disease and represents a systemic form of autoimmune enteropathy characterized by immune dysfunction, polyendocrinopathy, enteropathy, and X-linked inheritance. The prevalence of the syndrome remains unknown.

IPEX is inherited in males via an x-linked recessive manner and results from mutations in the *FOXP3* gene located at the Xp11.23-q13.3 locus [51]. At least 70 distinct *FOXP3* mutations have been reported, although identical *FOXP3* mutations can cause different phenotypes in patients [42].

Even though the severity of symptoms is variable, the most common feature of IPEX is the involvement of pancreas

and thyroid with an early onset. Glucose intolerance can be present at birth and insulin-dependent diabetes mellitus begins often during the first year of life as a result of the complete inflammatory destruction of the pancreatic islet cells prior to the intestinal symptoms [86]. Thyroiditis presents most commonly as hypothyroidism requiring substitutive therapy but may also present in the form as hyperthyroidism [13, 65].

The gastrointestinal involvement in children with IPEX syndrome includes severe, secretory diarrhea that can be bloody or mucousy and generally worsens after the breastfeeding is changed to formula [87, 88]. Protein-losing enteropathy with hypoalbuminemia and a markedly increased clearance of a-1 antitrypsin are indicators of a poor prognosis [47]. Diarrhea often persists despite bowel rest, and total parenteral nutrition is required for nutritional support.

In addition to the endocrinopathies and the gastrointestinal involvement, the basic triad of IPEX syndrome includes chronic dermatitis, most commonly in the form of eczema. In addition, other immune-mediated dermatological disorders like alopecia, pemphigoid nodularis, psoriasiform dermatitis, or onychomycosis-like lesions have been described [87, 89, 90]. The majority of boys with classical IPEX syndrome develop autoimmune hematologic disorders, such as Coombs-positive hemolytic anemia, neutropenia, or thrombocytopenia with anti-platelet antibodies. Renal involvement affects approximately 30% of the cases and presents as tubulopathy, nephrotic syndrome, or glomerulonephritis. Autoimmune hepatitis is also common. The clinical spectrum of the syndrome includes neurological manifestations, such as seizures and developmental delay. The majority of patients do not experience recurrent infections, as the disease itself does not impair the body's response to pathogens. However, IPEX syndrome carries a higher risk of infections due to the disruption of skin or gut barrier, as well as the need for immunosuppressive regimen [42] (Table 2.4).

The small bowel histopathology of pediatric subjects with IPEX syndrome can range from a graft-versus-host disease-like pattern with complete villous atrophy, mild inflammation of the lamina propria, apoptotic bodies, crypt abscesses, and loss of goblet cells (as described above) to a more celiac-disease-like pattern with partial villous atrophy, moderate inflammation of the lamina propria, an increase in intraepithelial lymphocytes, and crypt hyperplasia. Moreover, a patient with anti-goblet cell antibodies demonstrated partial villous atrophy, moderate inflammation of the lamina propria, an increase in intraepithelial lymphocytosis, and complete lack of goblet cells [91]. Depending on the organs involved in IPEX syndrome, the typical lymphocytic infiltration can also be present in thyroid, liver, skin, brain, or pancreas with complete destruction of islet cells [65, 92].

Table 2.4 Multisystemic disorders in IPEX syndrome

IPEX syndrome
Endocrine: glucose intolerance, insulin-dependent diabetes mellitus, hypo/hyperthyroidism
Gastrointestinal: secretory diarrhea, protein-losing enteropathy, autoimmune hepatitis
Skin: eczema, alopecia, pemphigoid nodularis, psoriasiform dermatitis
Hematologic disorders: autoimmune hemolytic anemia, neutropenia, thrombocytopenia
Renal: glomerulonephritis, tubulopathy, nephrotic syndrome
Neurological manifestations: seizures, developmental delay
Other: susceptibility to infections, reactions to vaccines

The syndrome should be considered in young males presenting with protracted diarrhea with villous atrophy and failure to thrive combined with diabetes mellitus and/or hypothyroidism and skin manifestations. Anti-harmonin autoantibodies (HAA) and anti-villin autoantibodies (VAA) are useful for the preliminary screening of patients for IPEX syndrome. HAA has a high specificity for IPEX syndrome. As villin is highly immunogenic, VAA can be negative in IPEX patients with enteropathy and positive in other autoimmune diseases [42, 43]. The definite diagnosis of IPEX is based on genetic studies and mutation analysis of the FOXP3 gene [93]. Immunocytochemical staining of FOXP3 molecule in bowel biopsies has been proposed as a potential screening test [94].

Given the potential serious side effects and the limited efficacy for long-term remission of immunosuppressive medication, there is a need for new therapeutic approaches for IPEX and autoimmune enteropathy. The most promising is in the form of hematopoietic stem cell transplantation (HSCT). A recent literature review of case reports and case series for HSCT in IPEX patients found 28 cases of pediatric patients who had HSCT between 4 months and 16 years of age. The source of hematopoietic cells was bone marrow for 20 patients and peripheral blood for 8 patients, with successful results in 23 of the 28 patients. Of the five unsuccessful cases, one required re-transplantation. Death was reported in 5 out of 28 patients (21%). Complications included infections, autoimmune cytopenia, pancreatitis, and GVHD [95].

A recent retrospective multicenter study by the group Barzaghi et al. evaluated the disease onset, progression, and long-term outcome of IPEX patients receiving HSCT or prolonged immune suppression. Out of 96 patients in the study, 34 received immunosuppression, 58 underwent HSCT, and 4 did not require immunosuppression or HSCT. HSC sources included bone marrow (35/58), peripheral blood stem cells (12/58), and cord blood (13/58). Survival rates at 15 years among patients undergoing HSCT were lower, but not significantly, compared to patients who only received long-term immunosuppression (73.2% vs 86.8%; $p = 0.055$). This was due to the high mortality rate within 2.5 years

following transplantation, with no additional mortality rate for patients who survive over 2.5 years after transplant up to 15 years later. IPEX patients with higher organ involvement score (severe organ impairment) at HSCT had the lowest chance of survival. Non-transplanted patients had persistent disease progression that contributed to increased mortality over time [80].

Interestingly, the conditioning regimen was itself effective in controlling symptoms in some patients [55, 97] and a reduced-intensity conditioning regimen prior to engraftment resulted in more FOXP3 T regulatory cells than more aggressive conditioning [96, 98]. Beneficial effect on the pancreatic function and recovery of diabetes mellitus was achieved in some cases; however, the islet damage is often permanent at the time of bone marrow transplantation [86]. Insulin for diabetes and hematic transfusions are often needed for the symptomatic management of IPEX syndrome.

IPEX-Like Syndromes

A number of other gene defects that give rise to an IPEX-like phenotype have been discovered, including loss of function mutations in CD25 (IL2RA), STAT5b, ITCH, gain of function mutations in STAT1, gain of function mutations in STAT 3, CTLA4, and LRBA (54, 99). *CD25* is the α-chain of the interleukin 2 (IL-2) receptor. Deficiency of CD25 leads to defects in responsiveness to IL-2 which results in widespread immune dysregulation. Patients with CD25 deficiency have clinical similarities to IPEX patients, with symptoms including severe diarrhea, insulin-dependent diabetes mellitus, autoimmune thyroiditis, early onset eczema, alopecia universalis, and autoimmune enteropathy. However, CD25 deficiency is distinguished by a profound susceptibility to viral, fungal, and bacterial infections. CMV pneumonitis, enteritis, and EBV lymphoproliferative disease, oro-esophageal candidiasis, and adenoviral gastroenteritis have been reported in patients with CD25 deficiency [54].

Signal transducer and activator of transcription 5 (STAT5) consists of two highly related proteins, STAT5A and STAT5B, which are encoded by two separate genes but are 90% identical at the amino acid level. STAT5 proteins are involved in cytosolic signaling and in mediating the expression of specific genes. Defects in STAT5b are inherited in an autosomal recessive manner. Many of the features of STAT5b deficiency, including eczema, chronic diarrhea, thyroiditis, and increased susceptibility to infections, are similar to findings in CD25 deficiency. This is likely due to the fact that IL-2 signals are transmitted via STAT5 [54, 99]. The severity of disease in STAT5b deficiency is less severe compared to CD25 deficiency, probably because STAT5a may substitute some of the functions of STAT5b deficiency [54].

Autosomal dominant heterozygous gain-of-function (GOF) mutations in STAT1, which is associated with chronic mucocutaneous candidiasis, have been found by Uzel et al. in five patients with IPEX-like symptoms. All five patients presented with eczema and enteropathy. Endocrinological manifestations in these patients include type 1 diabetes, hypothyroidism, and growth hormone insufficiency. Four patients had mucocutaneous candidiasis. All five patients suffered from recurrent infections including respiratory infections, herpes virus infections, and blood-borne infections. The patients also suffered from cardiovascular problems, including vascular aneurysms, calcification, and hypertension [100].

Children within an extended Old Order Amish kindred presented with developmental delay, dysmorphic features, failure to thrive organomegaly, and multisystem autoimmune diseases, including autoimmune enteropathy, with autosomal recessive inheritance being apparent in this extended family in which prominent consanguinity was noted. Human ITCH E3 ubiquitin ligase deficiency was recognized as the underlying cause of this syndromic multisystem autoimmune disease. ITCH deficiency results in abnormal T helper cell differentiation and failure of T cell anergy induction. Genetic mapping in patients revealed a truncating mutation in the ITCH gene [101, 102].

Heterozygous germline GOF mutations in STAT3 have been associated to multiorgan autoimmune manifestations (i.e., type 1 diabetes, enteropathy, interstitial lung disease, cytopenia, and hypothyroidism), lymphoproliferation, short stature, and recurrent infections [103].

CTLA4 or CTLA-4 (cytotoxic T-lymphocyte-associated protein 4), also known as CD152, is expressed by activated T cells and transmits an inhibitory signal to T cells. CD28, on the other hand, is expressed on T cells that provide co-stimulatory signals required for T-cell activation and survival. Both molecules compete for ligands CD80 and CD86 on antigen-presenting cells. CTLA-4 binds CD80 and CD86 with greater affinity and avidity than CD28 thus enabling it to outcompete CD28 for ligand binding [104]. Lipopolysaccharide-responsive beige-like anchor protein (LRBA) is a cytosolic protein which blocks the transport of CTLA-4 (that are constitutively internalized from the surface of Treg cells) to lysosomes for removal, thereby maintaining the amount of CTLA-4 trafficked back to the cell surface [105]. This is important as CTLA-4 plays a role in the inhibition of self-reacting T cells after antigen recognition. Patients with CTLA4 mutations suffer from recurrent respiratory tract infections, hypogammaglobulinemia, autoimmune cytopenia, autoimmune enteropathy, and granulomatous infiltrative lung disease [104]. LRBA deficiency presents as a syndrome of autoimmunity, lymphoproliferation, and humoral immune deficiency, with clinical manifestations including immune dysregulation, organomegaly, recurrent infections, hypo-

gammaglobulinemia, idiopathic thrombocytopenic purpura (ITP), autoimmune hemolytic anemia (AIHA), autoimmune enteropathy, granulomatous-lymphocytic interstitial lung disease, and type I diabetes [50].

APECED Syndrome

Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED), also known as autoimmune polyendocrine syndrome type 1 (APS-1), is a rare, autosomal recessive disease. APECED is caused by biallelic mutations in the autoimmune regulatory or AIRE gene in chromosome 21q22.3 [106, 107]. AIRE is expressed in medullary thymic epithelial cells and promotes expression of tissue specific antigens to be displayed to developing T cells. With this unique antigen presentation to developing T cells, autoreactive T cells with affinity for self-proteins either die by apoptosis or become forkhead box P3 (FoxP3) expressing T regulatory cells (Tregs). When AIRE is nonfunctional or absent, autoreactive T cells escape to the general circulation and peripheral lymphoid organs where they can cause autoimmune reactions and the disease APS-1 [108, 109]. The understanding of the underlying pathophysiology of this monogenic disease has provided important information on the pathogenesis of organ-specific autoimmunity and T cell selection.

APECED has been reported at a relatively higher prevalence in genetically isolated populations like Finns, Sardinians, and Iranian Jews [110–113]. The classical triad of APECED consists of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiasis, and two of them are required for the diagnosis. However, several other endocrine and non-endocrine manifestations accompany the pathognomonic triad.

The onset of APECED is usually in childhood with chronic mucocutaneous candidiasis occurring as early as infancy the first symptoms occurring on average at the age of five [114]. The wide spectrum of the clinical manifestations is attributed to a variable pattern of destructive autoimmune reaction mediated by specific antibodies that can attack any tissue or organ [115, 116]. Tryptophan hydroxylase (TPH) is an enzyme involved in the synthesis of neurotransmitters in the nervous system and in the gastrointestinal endocrine cells. The presence of autoantibodies against this enzyme is associated with autoimmune enteropathy in APECED [117–120]. The gastrointestinal involvement also includes diarrhea, constipation, autoimmune hepatitis, chronic atrophic gastritis, or autoimmune gastritis with pernicious anemia [121]. Exocrine pancreatic failure results in malabsorption and steatorrhea in a small subgroup of patients [114].

Patients affected by at least two of the triad of chronic mucocutaneous candidiasis, autoimmune hypoparathyroidism, and Addison's disease, especially from populations such as Finns, Sardinians, and Iranian Jews should be investigated for APECED syndrome. The identification of mutations on AIRE gene is recommended to confirm the diagnosis [114].

The treatment of APECED syndrome is challenging and is mainly based on parenteral nutritional support. Immunosuppressive treatment includes high doses of intravenous steroids and methotrexate, which is well tolerated in children. Systemic chemotherapy against *Candida* infection and hormone replacement therapy are also required. Patients with APECED should be closely monitored for new components of the syndrome [122].

Prognosis

Autoimmune enteropathy is a potentially life-threatening disease. Both intestinal and extra-intestinal manifestations can lead to debilitating symptoms requiring a complex therapeutic approach. The disease itself has not been linked to the development of intestinal malignancies; however, the intensity of immunosuppressive therapy and the increasing longevity of patients potentially increase the risk of malignancy [22]. Autoimmune enteropathy is now considered as a systemic disease, and its most severe form, IPEX syndrome is often characterized by unresponsiveness to treatment with a high mortality rate [71]. Malnutrition in infants and infections in later ages are the most frequent causes of death. Given the immunologic nature of IPEX syndrome, HSCT currently seems the most promising treatment of choice. However, more experience is needed to ensure that this therapeutic approach leads to permanent remission [55, 97]. Finally, the great variability of the clinical expression and the absence of a clear genotype-phenotype correlation in APECED syndrome create the need for the identification of potential disease-modifying genes that are involved in the clinical expressivity of organ-specific autoimmunity.

Congenital Problems of the Gastrointestinal Tract

3

Nigel J. Hall

Introduction

Congenital abnormalities of the gastrointestinal tract (GIT) are relatively common. Owing to their nature, they frequently require surgical correction, and on occasion this must be undertaken as a matter of emergency in order to avoid catastrophic intestinal ischemia and necrosis resulting in loss of bowel or damage to a secondary organ system. This chapter provides an overview of the most common conditions encountered and those which require intervention as a matter of urgency. It is not possible within the space available to describe in detail all of the variants of congenital GIT abnormalities that may be encountered and the precise nature of the treatment options available. For ease of understanding, we commence with the upper GIT and continue in a caudal direction.

Conditions Affecting the Upper Gastrointestinal Tract

Esophageal Atresia (EA) and Tracheoesophageal Fistula (TEF)

This complex group of anomalies with an incidence of 1 in 2440–4500 live births [1, 2] results from failure of correct division of the tracheal primordium from the esophagus during early embryonic development. The precise etiology is unknown with a number of embryological theories proposed to explain the different variants of this anomaly. There is a high incidence of coexisting abnormalities including the VACTERL (Vertebral column, Anorectal, Cardiac, Tracheal, Esophageal, Renal, and Limbs) syndrome, CHARGE (Coloboma of the eye, Heart defects, Atresia of the nasal choanae, Retardation of growth and/or development, Genital and/or urinary abnormalities, and Ear abnormalities and deafness) association, and isolated cardiovascular anomalies [3].

Classification

A number of classification systems have been proposed over the years. Table 3.1 describes the most commonly encountered anatomical variants (Fig. 3.1), and the Spitz classification (Table 3.2) [3] incorporating birth weight and presence of major congenital heart disease status may be useful in predicting survival.

Clinical Features

EA is commonly associated with maternal polyhydramnios, and with increasing frequency, the diagnosis is being made antenatally particularly if there is no TEF. In the postnatal period, symptoms associated with the condition include excessive salivation, feeding difficulties, respiratory distress, and cyanotic episodes. Cases of EA (vwith the exception of the rare EA with double fistula) can be confirmed by failure of passage of a nasogastric tube into the stomach. Cases of TEF in the absence of EA (i.e., H-type fistula) may present

Table 3.1 Classification of EA/TEF anomalies and frequency

Type of lesion	Frequency (%)
EA and distal TEF	88.8
Isolated EA	7.3
H-type fistula	4.2
Distal and proximal TEF	2.8
Proximal TEF	1.1

later, usually with recurrent episodes of respiratory distress or pneumonia.

Treatment

The overall aim of surgical correction is early division of any fistula with the respiratory tract to protect the lungs and airway, and restoration and maintenance of esophageal continuity to allow normal feeding. Following diagnosis, a Replogle tube is placed in the upper esophageal pouch which allows suction of secretions and minimizes the risk of pulmonary aspiration. Surgical repair involves ligation and division of any fistula and primary anastomosis of the two ends of the esophagus where possible. Infants who are too unstable to

tolerate primary esophageal repair, typically preterm infants with respiratory distress, may be treated with ligation of the fistula only followed by delayed esophageal anastomosis once a period of cardiorespiratory stability can be achieved. Most infants with "pure EA," that is, EA without TEF, and some infants with EA with TEF have a gap between the two ends of the esophagus that is too wide for primary anastomosis to be achieved. This group poses a particular surgical challenge. These infants are typically fed by gastrostomy initially, and the esophageal anastomosis is re-attempted after a period of growth (typically at least 6 weeks) during which the esophageal ends often grow closer together permitting anastomosis. If attempts at anastomosis remain unsuccessful, esophageal replacement such as by gastric transposition is considered.

Outcome

The majority of patients do well following anastomosis, but a number of complications may occur, and they require recurrent procedures. The most common surgical complication is anastomotic stricture. Strictures frequently require dilatation, and balloon dilatation is the preferred technique. Other complications include anastomotic leakage, recurrent TEF, gastroesophageal reflux, and disordered peristalsis. The combination of poor esophageal motility and gastroesophageal reflux with or without anastomotic stricture may lead to long-term feeding difficulties.

The Stomach

The most common abnormality of the stomach in the neonatal period is hypertrophic pyloric stenosis. Whether this is truly a congenital abnormality or an acquired disorder is questionable. It is further discussed in Chap. 4.

Other congenital conditions affecting the stomach including congenital microgastria, gastric volvulus, and congenital gastric outlet obstruction due to a pyloric web or atresia are all extremely rare and are mentioned only for completeness.

Obstructive Lesions of the Duodenum, Jejunum, and Ileum

The most common congenital conditions affecting the duodenum, jejunum, and ileum all result in partial or complete gastrointestinal obstruction. The presenting features and investigations recommended to diagnose the underlying abnormality are similar for all conditions. The clinical features and investigations of these conditions are therefore presented first followed by a description of each type of abnormality and the recommended treatment options.

Clinical Features

Obstructive lesions of the small intestine from the pylorus down to the ileocecal valve may give rise to polyhydramnios in the antenatal period which is detectable by antenatal ultrasonography. As a general rule, the more proximal the lesion, the more severe the degree of polyhydramnios, and distal ileal lesions may be present in the absence of polyhydramnios [5]. The list of differential diagnoses giving rise to polyhydramnios is however extensive. Another feature that may be seen on antenatal ultrasonography is the presence of dilated loops of intestine with or without echogenic bowel. While the combination of echogenic and dilated loops of bowel is often a sign of some form of intestinal abnormality, the precise nature of any problem is rarely identified before birth. One exception to this is a diagnosis of congenital duodenal obstruction in which case the appearance of a double bubble on antenatal ultrasonography has high sensitivity and specificity.

Following birth, the most common and important clinical manifestation of obstructive lesions of the GIT is bile-stained vomiting. Vomiting with truly bilious staining is always abnormal in the neonatal period and always requires investigation. Lesions in the duodenum and jejunum usually result in bilious vomiting within hours. In addition, the abdomen may appear empty or even scaphoid, and visible gastric peristalsis may be observed. Lesions lower in the ileum result in a distended abdomen if the obstruction is complete, and there may be failure to pass meconium. Obstructive lesions may also give rise to intestinal perforation in the neonatal period and occasionally antenatally. In all cases of neonatal intestinal obstruction, infants become progressively hypovolemic and are prone to circulatory and respiratory collapse. They require fluid resuscitation and may require ventilatory support. GIT obstruction should therefore be considered in any infant who is dehydrated especially if there is a history of vomiting.

Stenotic lesions of the small bowel in which the obstruction is incomplete may give rise to increased diagnostic difficulty. Affected infants may present with intermittent vomiting and episodes of partial obstruction. They eventually fail to thrive or develop complete obstruction at which stage they are fully investigated and the diagnosis becomes apparent.

Intestinal malrotation is considered separately as it may present with a spectrum of clinical scenarios depending on the degree of intestinal obstruction or midgut volvulus or both. The clinical pictures of all types of abnormal rotation are those of acute or chronic intestinal obstruction and/or acute or chronic abdominal pain suggestive of intestinal ischemia. True malrotation typically presents in the first year

of life with symptoms of upper GIT obstruction including vomiting which is usually bile-stained. A coexisting volvulus may be suspected by abdominal pain, peritonitis, and hypovolemic shock associated with intestinal ischemia. However, these signs may be relatively nonspecific in the young infant. Malrotation may also present later in life.

Investigations

The aim of investigating cases of suspected obstruction of the small intestine is twofold. First to identify the nature and anatomical location of the lesion to allow for planning of correct treatment and second to identify cases of malrotation in whom there is a risk of midgut volvulus and intestinal ischemia. These cases require urgent surgical intervention to reduce the risk of potentially catastrophic intestinal necrosis. The history and examination may give clues as to the location of the lesion as described above. An abdominal X-ray may simply confirm the presence of dilated intestinal loops but may also give further clues in some cases. A double bubble appearance on abdominal X-ray with a lack of air in the distal intestine (Fig. 3.2) is characteristic of duodenal obstruction. Multiple air-filled loops of proximal bowel often with air-fluid levels along with a paucity or complete absence of gas in the distal bowel is highly suggestive of obstruction of the ileum. Intestinal perforation if present will usually be apparent on abdominal X-ray, and in the rare cases of antenatal perforation, there may be widespread or localized flecks of calcification representing calcified meconium within the peritoneum.

In cases in which the diagnosis is not clear on abdominal X-ray or in which midgut malrotation or volvulus is suspected, a limited upper gastrointestinal contrast study is indicated. The classical finding in cases of malrotation is that the duodenojejunal flexure lies to the right side of the spine instead of its normal left-sided position (Fig. 3.3). This finding should prompt urgent surgical treatment due to the risk of coexisting midgut volvulus. The contrast study may also identify the presence of a stenotic segment or complete obstruction.

Cases of lower ileal stenosis or atresia are often more difficult to diagnose, and a contrast enema is invaluable in distinguishing between ileal and colonic obstruction and could be therapeutic in cases of meconium ileus (see below).

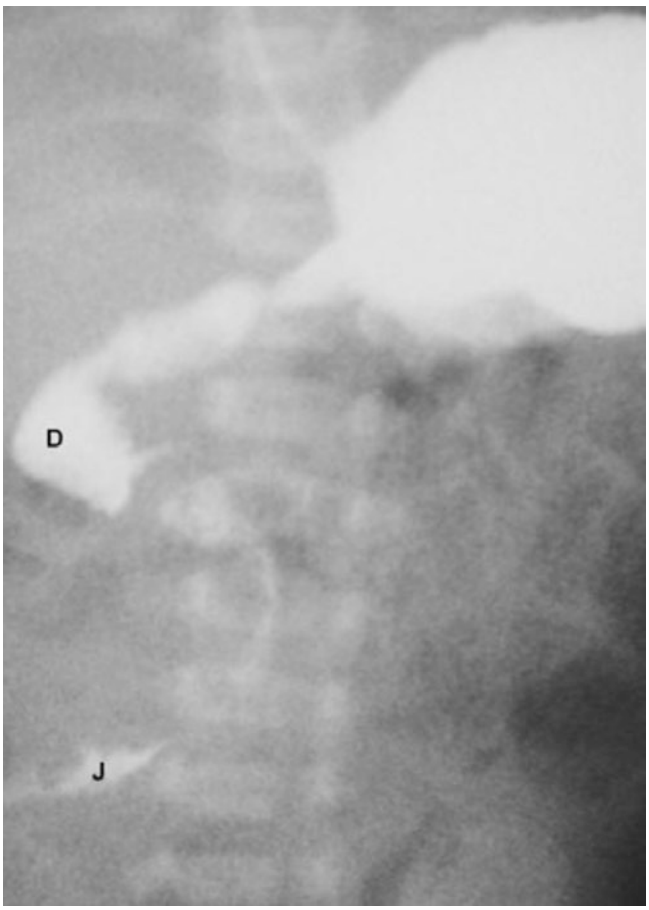

Fig. 3.3 Upper gastrointestinal contrast study of a case of malrotation. The contrast is seen within the duodenum (*D*) and flowing into the upper jejunum (*J*) both of which lie completely to the *right* of the midline (Reprinted with permission from Hall and Pierro [4], Fig. 2.3)

Conditions Affecting the Duodenum

Duodenal atresia and duodenal stenosis both of which may be associated with an annular pancreas are the commonest congenital conditions to affect the duodenum. Both are capable of giving rise to duodenal obstruction. The incidence is reported to be between 1 in 5000 and 10,000 live births [6].

Explanations of the etiology of duodenal atresias are not universally accepted. Unlike atresias of the ileum, they are not thought to be due to vascular accidents, and the most widely accepted explanation is that of failure of recanalization of the intestinal lumen during early embryonic development.

Classification

There are four basic types of duodenal obstruction (Fig. 3.4). In type 1, there is a stenosis of the duodenum resulting from a diaphragm or web partially or totally occluding the lumen. Due to the incomplete nature of the obstruction, cases may present in childhood rather than in the neonatal period. In type 2 duodenal atresia, the proximal and distal segments end blindly but remain connected by a fibrous cord. There is complete separation of the bowel segments in type 3, and type 4 comprises an atretic segment with an annular pancreas. Multiple atresias are said to occur in up to 15% of cases [7].

Treatment

The principles of treatment are to restore intestinal continuity while avoiding interference with the ductal system draining the pancreas and biliary tree. This is best achieved using a duodenostomy in which the obstructed segment is bypassed by joining the proximal segment directly to the distal segment. Following surgery, the long-term gastrointestinal results are good [8].

Conditions Affecting the Ileum and Jejunum

The main congenital problems directly affecting the small intestine from the duodenojejunal flexure down to the cecum are atresia and stenosis. Jejunoileal atresia occurs more commonly than its duodenal counterpart with an incidence of varying from 1 in 330 to 3000 live births [9]. Such lesions are one of the most common causes of neonatal intestinal obstruction. The major difference between atresias of the ileojejunum and those of the duodenum is in their etiology. It is postulated that atresia or stenosis of the jejunum and ileum is the result of a localized vascular accident during intrauterine life. Subsequent ischemic necrosis and reabsorption of the affected segment or segments result in a contracted scarred bowel wall leading to stenosis at one end of the spectrum to a complete intestinal and mesenteric defect at the other. Fetal animal experiments have confirmed at least in part this hypothesis [10], and the absence of other congenital abnormalities found in association with jejunoileal stenoses and atresias supports the localized vascular accident theory.

Classification

Morphological classification of these lesions allows different surgeons and centers to compare outcomes, and it is also of therapeutic and prognostic value. The most commonly accepted system is that proposed by Louw [11] and modified by Grosfeld [12]. Whether the lesion is classified as ileal or jejunal is determined by the most proximal affected segment (Fig. 3.5).

Stenosis is a localized narrowing of the lumen without any break in the continuity or mesenteric defect. The intestinal wall may be thickened and rigid at the stenotic site, and there is a small, often minute lumen. The overall intestinal length is not shortened. Type I atresia is the result of a membranous web occluding the lumen with no mesenteric defect and no intestinal shortening. The lumen is usually completely occluded, and the proximal bowel therefore dilated but remaining in continuity with the collapsed distal segment. Type II atresia arises from a complete obliteration of the intestinal segment into a fibrous cord which joins two blind ends and runs in the free edge of the mesentery. There is no mesenteric defect, and once again, the total bowel length is usually normal. In both type III(a) and III(b) atresia, the intestine is likely to be shortened, and this may have significant clinical consequences. Type III(a) atresia consists of blind-ending proximal and distal bowel with no connection and an often large mesenteric defect. The blind ends are often physiologically abnormal with decreased or absent peristaltic activity which may give rise to torsion, distension, or perforation. Type III(b) atresia, also known as apple-peel atresia because of its gross morphology, may involve massive intestinal loss. It consists of intestinal atresia near the ligament of Treitz, obliteration of the superior mesenteric artery (SMA) beyond the origin of the middle colic branch, and the absence of the dorsal mesentery. The remaining intestine is coiled helically (like an apple peel) around a single perfusing vessel, often has impaired vascularity, and is almost inevitably short. Furthermore, there may be additional segments of type I or II atresia within the apple-peel segment. Such a configuration most likely arises from occlusion of the SMA due to thrombus,

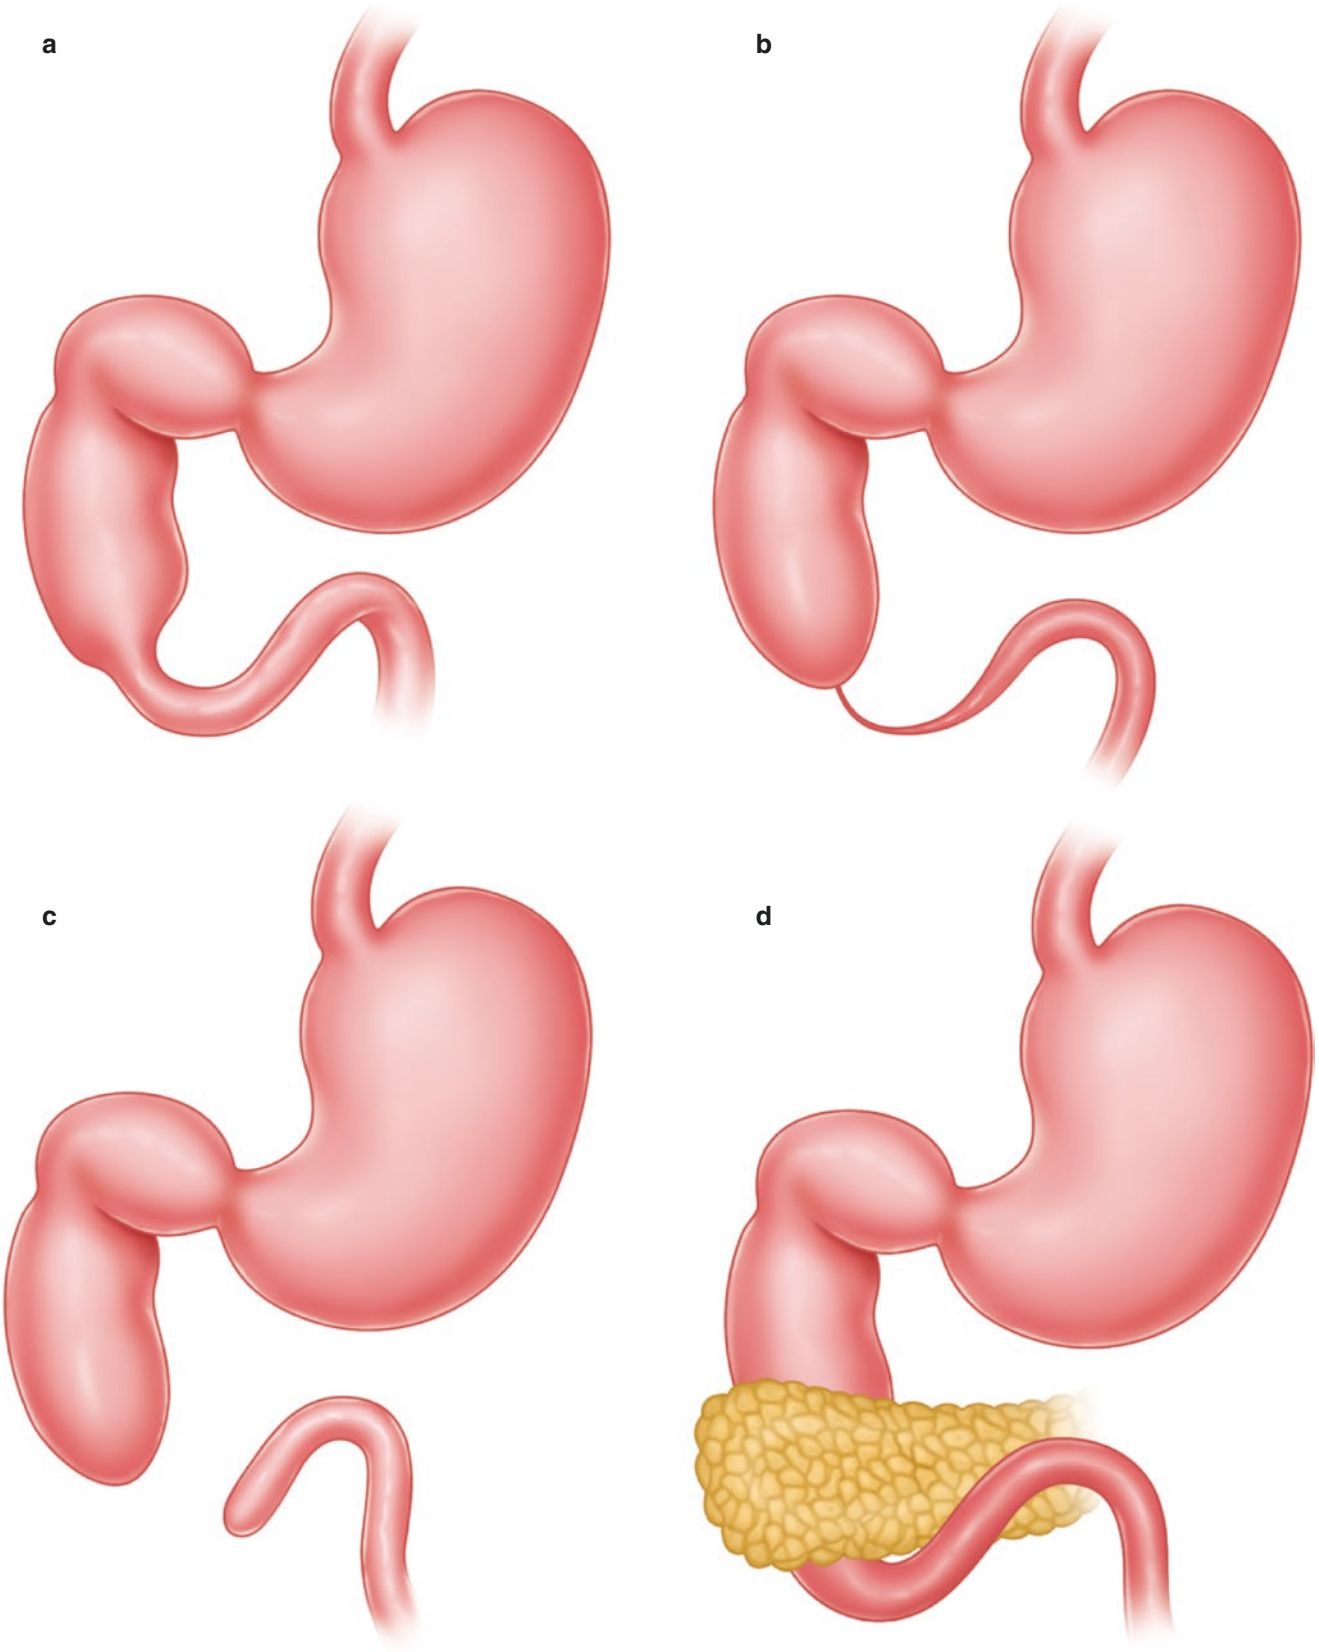

Fig. 3.4 Variants of duodenal atresia. (**a**) Type 1 atresia due to an internal diaphragm, (**b**) type 2 atresia with blind-ending loops remaining connected by a fibrous cord, (**c**) type 3 atresia with blind ends completely separated, (**d**) type 4 duodenal obstruction with an annular pancreas (Reprinted with permission from Hall and Pierro [4], Fig. 2.4)

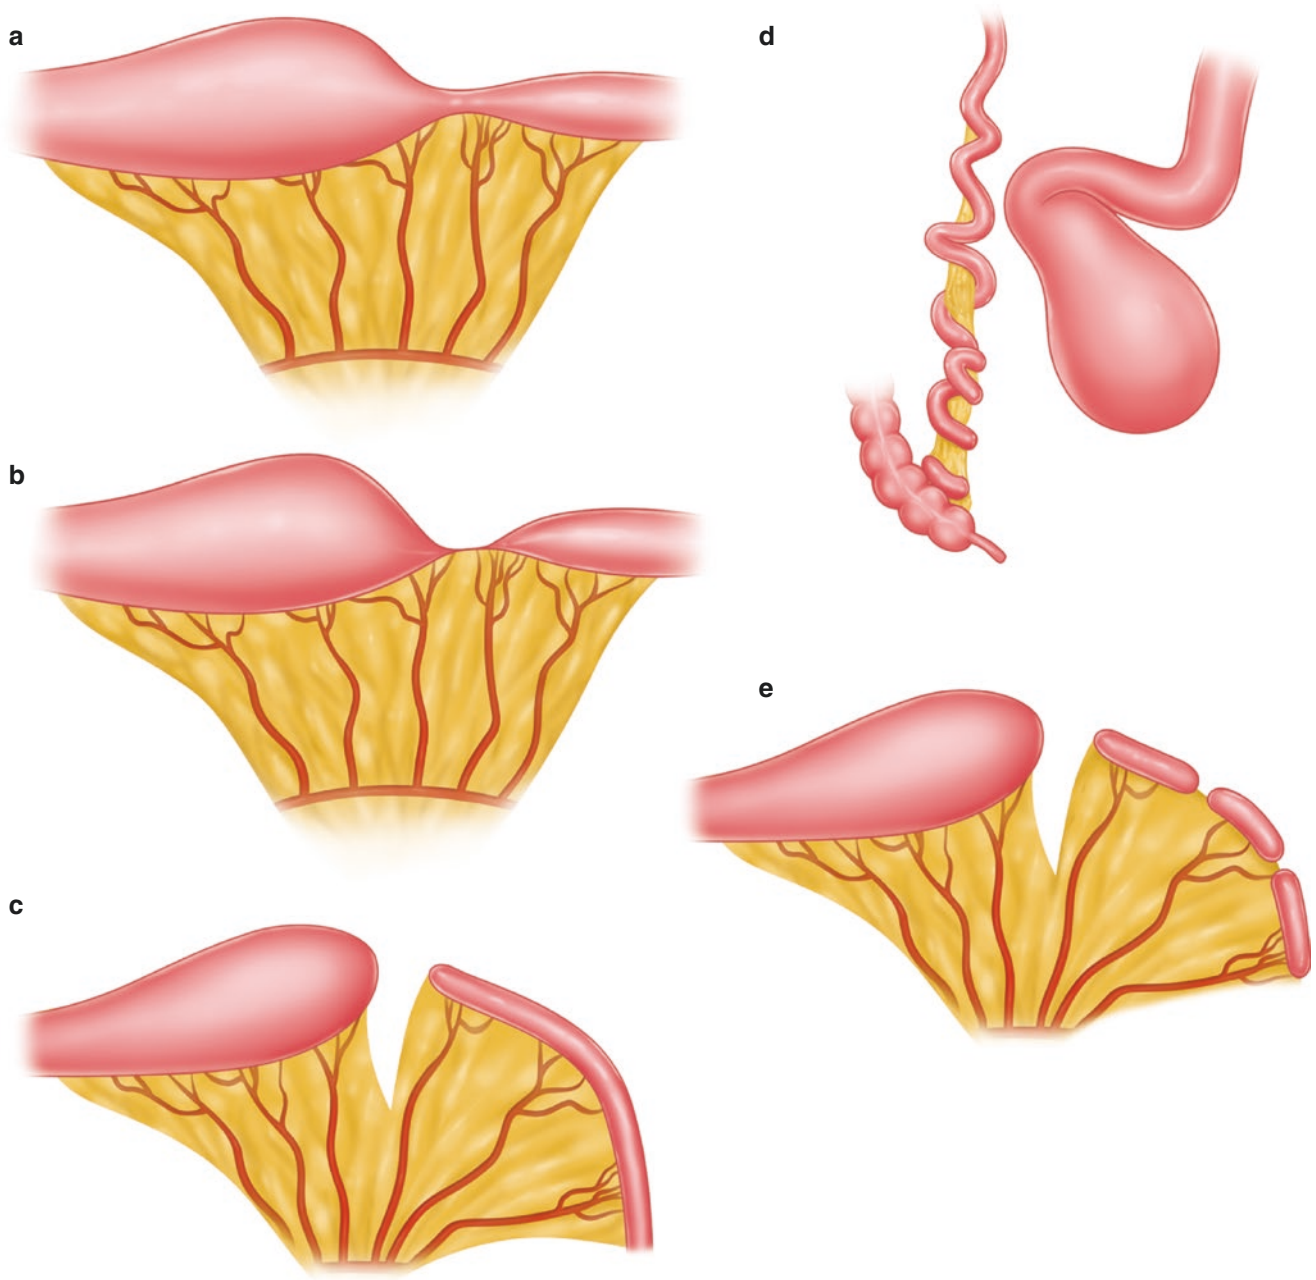

Fig. 3.5 Variants of ileal atresia. (**a**) Type I due to an internal web (not shown) with no mesenteric defect, (**b**) type II atresia with blind ends joined by a fibrous cord, (**c**) type III(a)—blind ends separated with a mesenteric defect, (**d**) type III(b) in which the ileum is coiled like an "apple peel" around a single vessel and completely separated from the proximal dilated jejunum, (**e**) type IV or multiple atresias (Reprinted with permission from Hall and Pierro [4], Fig. 2.5)

embolus, or strangulation as part of a midgut volvulus. In type IV atresia, there are multiple atretic segments, and the intestine may resemble a string of sausages. Overall, bowel length is usually shortened, and the intestine grossly dilated. It has been proposed that the etiology of type IV atresia may be due to failure of recanalization of solid epithelialization throughout the length of the intestine rather than from multiple single vascular events.

While it is generally accepted that stenosis and atresia of types I, II, and III(b) are the result of intrauterine vascular accidents, a genetic component has been suggested in type III(b) and IV.

Treatment

The mainstay of surgical treatment for this type of lesion is resection of the atretic or stenotic segment and primary anastomosis with closure of the mesenteric defect. The proximal intestinal segment is usually dilated and functionally abnormal with absent or ineffective peristalsis. This dilated proximal segment is excised along with a short segment distal to the stenosis or atresia. It is essential to establish patency of the distal bowel by irrigation or wash out intestine, and subsequently, a primary anastomosis is performed. There is a balance to be struck between the length of dilated proximal segment resected and the risk of leaving the infant with a short length of small bowel. As such, it is almost inevitable that the caliber of proximal bowel will be greater than that of the distal intestine, and a number of techniques exist to assist construction of the anastomosis in such circumstances.

Outcome following intestinal atresia is dependent primarily on the length of remaining intestine and the presence of the ileocecal valve. Short bowel syndrome has been defined as the presence of less than 75 cm of the small intestine or 30% of the predicted intestinal length in a premature infant [13, 14]. Outcomes following short bowel syndrome vary, and there is a high level of dependence on parenteral nutrition. However, intestinal adaptation can occur such that more than 80% of babies with short bowel syndrome do eventually become entirely enterally nourished [15].

Intestinal Malrotation

The incidence of intestinal malrotation is difficult to truly establish as not all affected patients develop symptoms, but autopsy studies estimate the incidence at approximately 1 in 500.

The traditional embryological basis for disorders of intestinal rotation is that of abnormal positioning of the intestinal loops in relation to one another as they return to the abdominal cavity from the yolk sac. During normal development, the midgut rotates through 270° so that the duodenum lies posterior to the colon, and the duodenojejunal flexure is to the left of the midline. A consistent finding in cases of malrotation is abnormal positioning of the duodenojejunal flexure. However, an alternative hypothesis has been proposed based on animal studies [16]. Kluth proposes that malrotation is the result of failure of localized growth of the duodenal loop rather than a disorder of rotation.

The term "malrotation" covers a spectrum of anatomical abnormalities. In non-rotation, the duodenojejunal flexure lies to the right of the spine along with most of the small intestine. The cecum and colon are typically on the left side of the abdominal cavity. Adhesions formed between loops of bowel or the intestine and abdominal wall are usually responsible for obstructive symptoms at presentation. In malrotation, the distribution of intestinal contents within the abdominal cavity is such that the duodenum again lies to the right of the spine with the cecum anterior to it. Adhesions between these two structures (Ladd's bands) are often present and may result in partial or total occlusion of the second part of the duodenum. In addition, the mesenteric attachment to the posterior aspect of the abdominal cavity is typically very short, and there is a risk of volvulus with ensuing intestinal ischemia. Other forms of abnormal intestinal rotation (inversed rotation, malrotation with mesocolic hernia, and malposition of the cecum) are all rare.

Treatment

There are two aspects to this disorder which require surgical intervention. The first and most important aspect is that of midgut volvulus. Any infant in whom malrotation is suspected based on clinical findings and radiological investigations should undergo laparotomy as a matter of urgency in order to minimize the risk of intestinal ischemia due to a volvulus. At laparotomy, blood-stained peritoneal fluid may indicate the presence of ischemic intestine. Any volvulus should be derotated (usually in clockwise direction), and the intestine examined for viability. Nonviable bowel is resected, and a primary anastomosis performed. If there is doubt about the viability of remaining intestine, a second-look laparotomy can be performed after 24 h.

In cases of malrotation not complicated by volvulus, the procedure of choice for most surgeons is the Ladd's procedure. This involves division of all adhesions or adhesive bands between the cecum, duodenum, and parietal peritoneum, broadening of the mesenteric base around the SMA and repositioning of the intestine within the abdominal cavity such that the duodenum is on the right and the cecum lies in the left upper quadrant. Some surgeons recommend performing an appendicectomy due to the difficulties of diagnosis should appendicitis develop later in life.

Meconium Ileus

Meconium ileus is a common cause of neonatal intestinal obstruction and the commonest cause of antenatal intestinal perforation [17]. It should be included in the differential diagnosis of infants presenting with GIT obstruction. In approximately 80% of cases, it is associated with cystic fibrosis [18–20], an autosomal recessive disease affecting predominantly the lungs and pancreas. The underlying defect in cystic fibrosis, an abnormality in a transmembrane chlo-

ride channel, results in the production of abnormally viscid and sticky meconium. This meconium sticks to the intestinal mucosa causing intestinal obstruction usually occurring late in gestation. Why some infants with cystic fibrosis do not develop meconium ileus is unclear. Meconium ileus can be classified as: (1) "uncomplicated" when is limited to intraluminal obstruction caused by the abnormal meconium or (2) "complicated" when is associated with intestinal atresia, volvulus, or meconium peritonitis.

Clinical Features

In cases of uncomplicated meconium ileus, the infant usually presents shortly after birth with symptoms of lower gastrointestinal obstruction, including abdominal distension and vomiting which may or may not be bile stained. The rectum may appear empty and narrow on plain radiograph, and the infant does not pass meconium. If meconium ileus is complicated by volvulus, intestinal ischemia, or perforation, the infant can be systemically unwell with acidosis and hypovolemic shock and may require ventilatory support. Abdominal X-ray showing dilated intestinal loops and occasionally abundance of meconium in the right lower quadrant are supportive of the diagnosis as is a gastrografin contrast enema revealing a small collapsed colon (microcolon) and often inspissated pellets of meconium in the right lower quadrant.

Treatment

In some cases, the gastrografin enema mentioned above may relieve the obstruction sufficiently to be curative. However, a number of uncomplicated cases and all complicated cases require surgery. The procedure performed depends on the findings during laparotomy. Atretic or grossly dilated segments of bowel may be resected, the inspissated meconium removed from the intestinal lumen, and the distal bowel flushed through. Occasionally, a stoma is formed to allow intestinal decompression. Outcome of surgical treatment is generally good, and gastrointestinal complications are of lesser significance than the pulmonary disease caused by the underlying cystic fibrosis.

Meckel's Diverticulum

Meckel's diverticulum is the commonest omphalomesenteric remnant with a reported incidence of approximately 2%. Of these, only a small proportion become clinically significant. The diverticulum originates from incomplete obliteration of the omphalomesenteric duct and exists as a free-lying diverticulum on the anti-mesenteric border of the ileum.

Clinical Features

There are a variety of disease entities attributed to a Meckel's diverticulum including gastrointestinal hemorrhage, intussusception, diverticulitis, and perforation. The commonest presenting symptom is that of gastrointestinal bleeding due to excessive acid and pepsin production from ectopic gastric mucosa which may be present within the diverticulum. Bloody diarrhea in the absence of abdominal pain is the classical presenting picture. Other complications of Meckel's diverticulum are intussusception in which the diverticulum acts as a lead point, diverticulitis with symptoms similar to those of appendicitis, and perforation.

Treatment

Management of all clinically significant cases of Meckel's diverticulum is resection of the diverticulum after adequate preoperative resuscitation. At operation, the diverticulum and a wedge of ileum are resected. The ileal wedge is included as ectopic tissue may not be entirely confined to the diverticulum. Following surgical excision outcome is good.

Congenital Hepatic, Pancreatic, and Biliary Abnormalities

Abnormalities of the hepato-pancreato-biliary system are all quite rare. They are included here as knowledge of their existence is important as they form part of the differential diagnosis for infants with jaundice, malabsorption, and hypoglycemia.

The commonest lesions of the biliary tree are biliary atresia and congenital biliary dilatation. In biliary atresia, the biliary tree is obliterated either completely or partially. Congenital biliary dilatation describes a variety of abnormalities of the biliary tree in which the dilated segment may be either intrahepatic or extrahepatic and either fusiform or cystic in nature. Dilatations of the extrahepatic biliary ducts are commonly known as choledochal cysts. The dilated bile duct is both anatomically and functionally abnormal resulting in cholestasis. Infants with biliary atresia and severe cholestasis associated with biliary dilatation present in the neonatal period with prolonged jaundice due to accumulation of conjugated bilirubin. When the degree of obstruction to the biliary tree is not so severe, congenital biliary dilatation may present later in life with malabsorption, intermittent jaundice, abdominal pain, or even pancreatitis. In addition, a choledochal cyst may present as an upper abdominal mass. Treatment of these lesions is based on allowing drainage of the biliary tree into the intestine, and the surgery involved is often complex. The operation of choice for biliary atresia is

the Kasai porto-enterostomy [21]. The atretic remnants of the extrahepatic biliary ducts are removed, and the porta hepatis is anastomosed to a defunctioned loop of jejunum. The timing of surgery is of paramount importance to avoid hepatocellular damage, but even with prompt diagnosis and early surgical intervention, infants with biliary atresia often have residual hepatic impairment due to intrauterine cholestasis. In cases of choledochal cysts, the dilated portion of the extrahepatic ducts is removed together with the gallbladder, and the common hepatic duct is anastomosed to the duodenum or a defunctioned loop of jejunum.

There are a number of congenital hepatic anomalies which give rise to structural and/or functional abnormalities of the liver parenchyma or the intrahepatic biliary tree. These include infantile and adult-type polycystic disease, congenital hepatic fibrosis, biliary hypoplasia, and congenital tumors of the liver such as hamartomas and hemangiomas. Presentation is usually with one of hepatomegaly, portal hypertension, or cholangitis. Treatment is that of resection of suitable lesions and prevention or treatment of hepatic disease.

Congenital lesions involving the pancreas are rare, the commonest being annular pancreas (see section on the duodenum). Other anatomical anomalies are seen including pancreatic ductal anomalies, pancreatic cysts, and very rarely pancreatic agenesis. There are a group of infants who present in the neonatal period with hypoglycemia who are found to have inappropriately high levels of circulating insulin. The condition hyperinsulinemic hypoglycemia (previously commonly referred to as "nesidioblastosis") is characterized by inappropriate endogenous insulin secretion in the presence of low blood glucose. It may result from an insulin-secreting tumor in the pancreas (a so-called insulinoma), but more commonly, no tumor is identified and the disease is a result of a genetic defect in a membrane channel controlling insulin secretion. Infants require high glucose intake to maintain normoglycemia while investigated for the presence of an isolated secretory tumor. Treatment is by surgical excision of the tumor if present; otherwise, a 90–95% subtotal pancreatectomy is performed.

Conditions Affecting the Lower Gastrointestinal Tract

Hirschsprung Disease

Hirschsprung disease is the commonest congenital malformation of the enteric nervous system with an incidence of approximately 1 in 5000 live births [22–24]. While most cases are sporadic, a positive familial occurrence exists in 3.6–7.8% of cases [25], and the presence of coexisting abnormalities including trisomy 21 suggests a genetic involvement. The condition is fully addressed elsewhere (see Chap. 22).

Anorectal Anomalies

Congenital abnormalities of the anorectal region occur with an incidence of 1 in 4000–5000 live births [26–28]. A very small minority may be familial with the majority being isolated findings or part of a congenital syndrome such as the VACTERL syndrome. There are a number of different types of anorectal anomalies resulting from the complex embryological development of the anorectal region involving differentiation of the cloaca. The Wingspread classification [29] divides them into high, intermediate, or low based on the relationship of the terminal bowel or any fistula arising from the bowel to the pelvic diaphragm. Precise definition of the abnormal anatomy is of paramount importance when planning corrective surgical treatment.

Clinical Features

Abnormalities of the anorectal region are usually diagnosed on inspection during the newborn period, but surprisingly, this is not always the case. In many cases, the anus will be absent, and meconium may be seen to originate from an abnormal site including a mucocutaneous fistula, the urethra in males, or the vaginal vestibule in females. Anomalies in which the anus is present but abnormally sited or stenosed may be more difficult to diagnose in the absence of adequate experience. The most complex abnormality in females is represented by the cloaca which is represented by a single opening in the perineum with rectum, vagina, and urethra joining a single channel.

Treatment

Treatment is aimed at preventing complications associated with the anomaly including urinary tract infection and lower gastrointestinal obstruction and subsequently restoring the anatomy to as near to normal functional and cosmetic state as possible. In the majority of cases, the initial surgery involves forming a colostomy in the descending or sigmoid colon to allow intestinal drainage and avoid dilatation of the lower bowel [30]. Following assessment, planning of surgery and growth of the infant reconstructive surgery is undertaken most commonly by the posterior sagittal approach [31]. Some anomalies also require a laparotomy to divide a high recto-vesical fistula. Surgery of these cases and particularly

of cloaca is complex and should be performed by an experienced surgeon.

Outcome

In similarity to patients with Hirschsprung disease, incontinence and constipation are the most significant long-term complications of anorectal anomalies and often have a significant impact on quality of life. In one large series, soiling occurred in 57% of 387 cases. The incidence of fecal incontinence was 25% and constipation 43% [31]. Ongoing medical and on occasion surgical treatment is necessary to minimize disruption to a normal lifestyle.

Conditions Which May Occur at Any Point in the Gastrointestinal Tract

Gastrointestinal Duplications

Duplication cysts of the GIT are rare congenital abnormalities. They can occur at any point in the GIT from mouth to anus, although they are most commonly found around the ileocecal region. Duplication cysts are defined according to strict criteria as devised by Ladd and Gross; they are closely attached to some part of the GIT, have a smooth muscle coat, and have an epithelial lining which resembles some part of the alimentary canal [32]. Duplications may be spherical or tubular in macroscopic appearance, those that are tubular accounting for 10–20% and often having a communication with the bowel.

Clinical Features

Between 25% and 30% present in the neonatal period and most have presented by the age of 10 years. Clinical features at presentation depend on anatomical site, size, and secondary effects and include an oropharyngeal, abdominal or rectal mass, respiratory distress, gastrointestinal bleeding, obstruction, and intussusception. Duplication cysts may also be found as incidental findings at laparotomy, and some lesions have been detected on antenatal ultrasound [33, 34].

Treatment

The recommended management of duplication cysts is complete surgical excision wherever possible in order to prevent recurrence and complications secondary to ectopic gastric mucosa. When complete excision is not possible, it is essential to remove the mucosal lining.

Conditions Affecting the Walls of the Abdominal Cavity

While not truly conditions of the GIT, there are a number of conditions which cause the abdominal contents to develop outside the abdominal cavity. These conditions are included as they have secondary effects which may significantly affect the GIT and be a cause of gastrointestinal dysfunction.

Congenital Diaphragmatic Hernia

The incidence of congenital diaphragmatic hernia (CDH) varies from 1 in 3500 to 1 in 5000 live births [35]. Its etiology is unknown although is probably multifactorial. The essential anatomical defect is a breach in the continuity of the diaphragm which allows herniation of the abdominal viscera into the thoracic cavity. This has a secondary effect of impeding development of the lungs during intrauterine life. The resulting hypoplastic lungs are a cause of significant morbidity and mortality in this condition. Compression by misplaced abdominal contents does not explain the severity of lung disease seen, and it is well recognized that lung development is markedly abnormal in infants with CDH.

Classification

A number of different defects can occur owing to the complex development of the diaphragm. The majority of cases are of the Bochdalek type in which the defect is posterolateral and most commonly on the left side. The defect can range in size from a small slit to involve almost the entire hemidiaphragm. Defects in the central tendon of the diaphragm result in Morgagni hernias which are retrosternal in nature and most commonly on the right side. Finally, agenesis of the diaphragm may occur which is usually left sided and extremely rare.

Clinical Features

In the current era, diaphragmatic hernia is often diagnosed during prenatal ultrasound scanning. The advantage of prenatal diagnosis is that delivery can be planned to take place in a unit with appropriate pediatric surgical and intensive care facilities. For those infants who avoid prenatal diagnosis for whatever reason, the clinical features depend on the volume of abdominal contents within the thoracic cavity and the degree of lung hypoplasia. In the most severe cases, there will be severe respiratory distress and cyanosis from shortly after birth. At the other end of the spectrum are infants who

have minimal if any respiratory symptoms or signs and in whom intestinal loops are noted to be in the abdomen on chest X-ray (Fig. 3.6).

Treatment

While the definitive treatment of diaphragmatic hernia is surgical closure, the timing of this is not of paramount importance and should be undertaken once the infant is stable from a cardiovascular and respiratory point of view. The respiratory management of these infants can be problematic due to the severe lung hypoplasia and associated pulmonary hypertension. Most require conventional ventilatory support as a minimum, and many require high-frequency oscillatory ventilation (HFOV) to ensure adequate oxygenation. Other measures to reduce pulmonary hypertension including inhaled nitric oxide, adenosine, or sildenafil may be effective. Resistant cases may be candidates for extracorporeal membrane oxygenation (ECMO), during which the infant is placed on a life support system in the hope that the lungs and in particular the pulmonary vasculature will mature. Various criteria for ECMO exist [36] with the aim of reserving it for those who have the most severe respiratory failure and those who are most likely to benefit. There remain unfortunately a number of infants with CDH whose lung disease presents too great a challenge, and they do not survive.

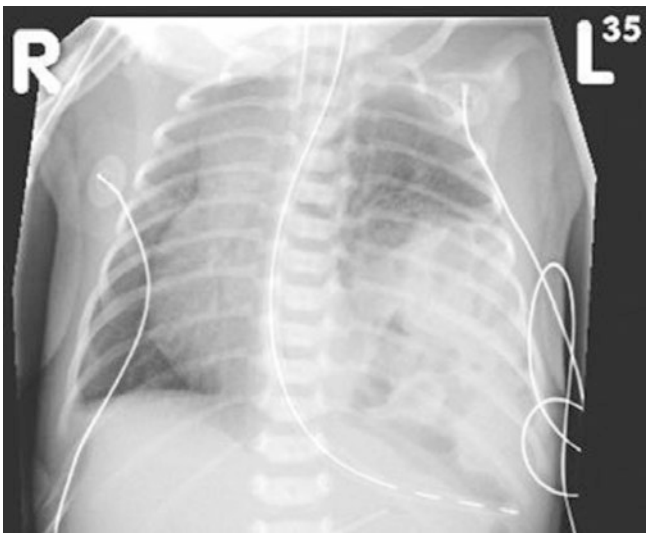

Fig. 3.6 Chest radiograph of an infant with congenital diaphragmatic hernia. Loops of intestine are clearly seen within the *left* hemithorax, and there is mediastinal shift to the *right* (Reprinted with permission from Hall and Pierro [4], Fig. 2.7)

Surgery

The principles of surgical repair are to return the abdominal contents to the abdominal cavity and repair the diaphragmatic defect. It may be possible to repair the defect by simply suturing the edges together. However, if the defect is large, a patch repair may be undertaken using prosthetic material. The long-term outcome of CDH is dependent primarily on the degree of pulmonary hypoplasia. The main gastrointestinal consequence appears to be gastroesophageal reflux seen in up to 62% of cases [37].

Anterior Abdominal Wall Defects

Although separate clinical entities, the two conditions exomphalos and gastroschisis which comprise anterior abdominal wall, defects are grouped together due to similarity in their clinical appearance and the recommended course of management. In both conditions, some portion of the viscera lies outside the abdominal cavity extruding through a defect in the anterior abdominal wall.

Exomphalos

The defect on the anterior abdominal wall in cases of exomphalos lies in the midline. Viscera herniate through this defect but remain contained within an avascular hernial sac consisted of peritoneum and amniotic membrane (Fig. 3.7).

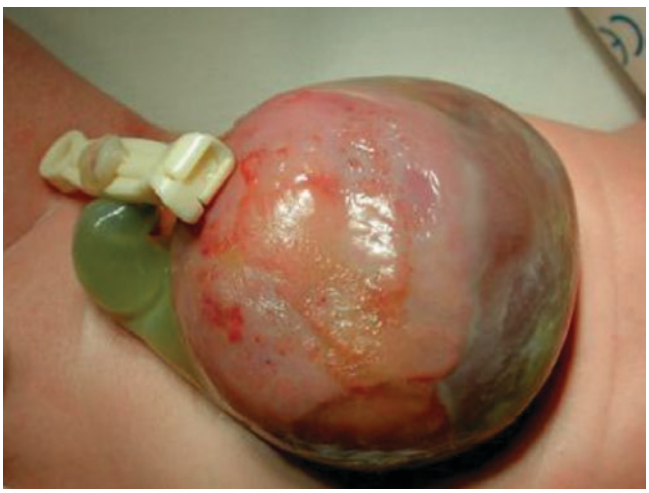

Fig. 3.7 Clinical appearance of an infant with exomphalos. The abdominal contents are enclosed within an avascular hernial sac (Reprinted with permission from Hall and Pierro [4], Fig. 2.8)

The size of the defect and hence the size of the sac may vary in size from a small swelling at the base of the umbilical cord (exomphalos minor) to a much larger sac containing liver and a large proportion of the small intestine (exomphalos major). The embryological origins of exomphalos are believed to be failure of complete closure of the anterior abdominal wall around a persistent body stalk. Visceral contents continue to develop within this body stalk and thus remain outside the abdominal cavity. While the precise etiology of exomphalos is not clear, it is well recognized that exomphalos often coexists with a number of other congenital abnormalities, and this may suggest at least in part a genetic component. Associated abnormalities include Beckwith–Wiedemann syndrome; the trisomies 13, 18, and 21; and the upper and lower midline associations.

Gastroschisis

The anterior abdominal wall defect in cases of gastroschisis is full thickness and typically to the right of the umbilical cord. Unlike exomphalos, there is no sac covering the eviscerated intestine which is usually dilated and inflamed (Fig. 3.8). The liver is not herniated. The precise embryological basis of gastroschisis is unclear, and a number of hypotheses have been proposed. The fact that gastroschisis is rarely associated with any other congenital abnormalities—with the exception of intestinal atresias and malrotation—suggests that the events resulting in exomphalos are likely to have a separate embryological basis.

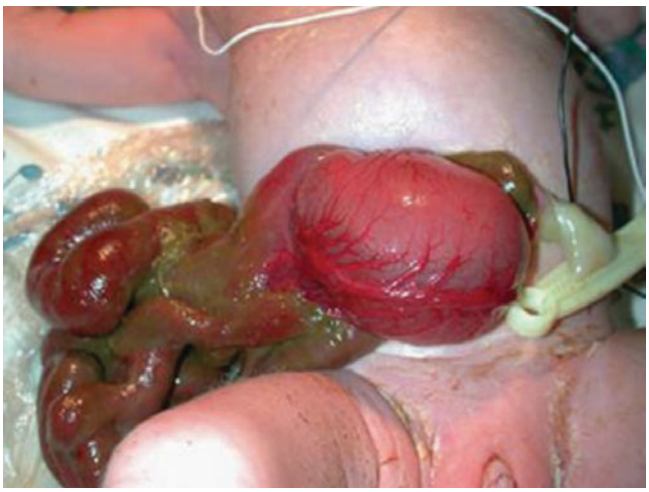

Fig. 3.8 Clinical appearance of an infant with gastroschisis. There is no sac enclosing the herniated intestine which is thickened and inflamed (Reprinted with permission from Hall and Pierro [4], Fig. 2.9)

Treatment

It is now usual for these two abnormalities to be detected in the antenatal period, and delivery in a specialist center with pediatric surgical facilities is recommended. In gastroschisis, there is no convincing evidence to suggest that preterm or caesarean section delivery confers any distinct advantage [38–40], but delivery is commonly induced at around 37 weeks gestation to avoid late gestation fetal death [41]. What is of paramount importance is protection of the intestine and prevention of fluid loss in cases of gastroschisis from the moment of delivery. The eviscerated intestine is wrapped in clingfilm and adequate support provided to prevent fluid loss and ischemic damage to the bowel. For exompahalos vaginal delivery is possible except in cases of exomphalos major. The hernial sac in exomphalos provides protection to the underlying bowel and surgical intervention is usually not emergent. However, cases of exomphalos in which the hernial sac ruptures during delivery should subsequently be treated as for gastroschisis.

Surgical Closure

The aim of surgery in both conditions is the return of abdominal contents to the abdominal cavity and closure of the overlying skin. In some cases, this can be achieved in one surgical procedure (primary closure), but in many instances, the abdominal cavity is not of sufficient volume to accommodate the eviscerated organs. In these cases, a staged closure is performed in which a "silo" is attached under the fascia around the base of the defect and completely encloses the eviscerated abdominal contents. This gives the intestine protection from dehydration and contains the bowel within a manageable sac reducing the risk of intestinal damage. Recently some surgeons have been preferentially using a silo for all cases of gastroschisis at least in part due to the belief that a more gradual return of the bowel to the abdomen may result in favorable outcomes [41–44]. The silo is gradually reduced in size as the abdominal cavity allows and the skin closed either in a final operation or using a technique of non-operative closure. In cases of exomphalos major, some surgeons elect not to reduce the viscera to the abdominal cavity in the newborn period but to allow the sac to epitheliase and perform fascial repair during childhood. Following abdominal wall closure, there is a period of intestinal dysmotility which is much more pronounced in infants with gastroschisis. During this period nutrition is maintained using parenteral nutrition. The overall prognosis for infants with both these conditions in the absence of coexisting abnormalities is good [45].

Pyloric Stenosis

4

Indre Zaparackaite, Shailee Sheth, and Ashish P. Desai

Introduction

Pyloric stenosis is a common pediatric surgical condition. It involves both narrowing and lengthening of the pylorus due to hypertrophy of the pylorus muscle. As this diagnosis is most often found in the first few months of life, it is often referred to as infantile hypertrophic pyloric stenosis (IHPS).

Hirschsprung first clinically described IHPS in 1888; however, it was much earlier, in 1717, that Blair actually reported findings of pyloric stenosis following an autopsy of a 5-month-old infant [1]. In 1911, Conrad Ramstedt incidentally developed pyloromyotomy, which has remained the standard procedure for the treatment for more than a century. For long time it was known as Fredet-Ramsted pyloromyotomy, Pierre Fredet being credited for extramucosal pyloroplasty, which was later modified by Ramsted.

Incidence

Incidence of IHPS is approximately 4 in 1000 live births, with a higher prevalence among the Caucasian population. Males appear to be affected much more commonly than females, at a 4:1 ratio. Child presents between age of 3 and 12 weeks [2] and is rarely seen in babies over 6 months of age. Several recent European studies and a nested case-control study from Israel have suggested a consistent decrease in IHSP incidence, which is most likely attributed to changes in environmental factors [3]. Condition is more commonly seen in children whose mother had pyloric stenosis compared to the one whose father has PS.

Anatomy

The pylorus is a muscle, which forms an anatomical connection between the stomach and the duodenum. It consists of two parts: the pyloric antrum and the pyloric canal, which connect to the body of the stomach and the initial part of the duodenum, respectively, allowing the passage of nutrients from the stomach to the small intestine, aiding the digestive process. Before the pyloric antrum, a prepyloric sphincter is positioned, which can constrict allowing the stomach to be shut as a separate entity from the small intestine for brief seconds during peristaltic waves. Additionally, at the end of the distalpyloric canal, a pyloric sphincter is located, which is fundamental to allow food passage from the stomach to the small intestine. Pylorus hence acts as a muscular valve preventing food from re-entering the stomach once it has passed into the small intestine.

The pyloric sphincter consists of circular smooth muscle, allowing the sphincters to contract and relax as required. As the content of the duodenum increases, this causes an increase in pressure, closing the pyloric sphincter, thus controlling the amount of food that is digested at any one time. A mucosal membrane underlines this sphincter, allowing gastric secretions to enter the pylorus further aiding digestion. As a general rule, the pylorus mainly refers to the pyloric sphincter, and therefore IHPS refers to a narrowing of the sphincter due to hypertrophy of the circular muscle. As hypertrophy occurs, this also causes the pyloric canal to lengthen and leads to a gastric outlet obstruction.

Histology

Under normal conditions, the pylorus, when viewed under a microscope, contains a number of features that allow for successful digestion. These include gastric pits and parietal cells, secreting gastric acid, as well as neuroendocrine cells to allow communication between the brain and gastrointestinal tract, enabling efficient contraction and secretion. Furthermore, Auerbach's plexus is implicated to play an important role in gut motility, by providing sympathetic and parasympathetic innervation to the muscular layers of the gut. However, during IHPS, it has been found that there is a degeneration of intramuscular ganglion cells in Auerbach's plexus, along with the accretion of lysosomes and cytoplasmic bodies in many of the axons [2]. Additionally, the ganglion cells appear smaller and reduced in number [4]. Cameron [5] has suggested that due to both the degeneration and consequent reduction in ganglia cells, Auerbach's plexus is ineffective, causing a reduction in neural activity, leading to asynchronous contraction of the pyloric muscle. As contractions are asynchronous, they increase in an attempt to produce a successful contraction, which is thought to lead to hypertrophy of the circular muscle, and hence IHPS.

Etiology and Risk Factors

Etiopathogenesis of pyloric stenosis is still not clearly understood. It is thought to be multifactorial with both environmental and genetic factors contributing toward the disease manifestation.

Genetic Factors

There appears to be a familial link for pyloric stenosis, but the specific genetic factors involved have not yet been identified. In a study conducted in Denmark in 2010, 1,999,738 children were studied in their first year of life, with findings of 3362 having IHPS. From the study, it was identified that, for a singleton, the incidence rate for IHPS was 1.8/1000, compared to 3.1/1000 live births in twins. Additionally, the rate ratio was 182 for monozygotic twins, compared to only 29.4 for dizygotic twins, illustrating a strong genetic link for IHPS. Overall, a heritability of 87% for IHPS was found [6].

Nitric oxide synthase gene (NOS1) could be a susceptibility locus for IHPS [7]. As nitric oxide (NO) is involved in smooth muscle relaxation, NOS must catalyze the production of NO, to allow the pylorus muscle to relax. It is suggested that reduced levels of NOS lead to a reduction in NO and hence diminish smooth muscle relaxation. As a result, increased muscular contraction occurs, leading to hypertrophy. In further support of this theory, Huang et al. [8] generated mice lacking NOS. These mice were found to have enlarged stomachs and hypertrophy of the pyloric sphincter. These findings could have great implications for future non-surgical treatment of IHPS, as early interventions to increase NO production could lead to management, if not prevention, of the disease.

Other factors implying genetic component are male preponderance as well as four times increased risk of a child of a mother who had IHPS to be diagnosed with the condition, compared to the child of a father who had IHPS.

Environmental Factors

In addition to genetic factors, a number of environmental factors have been implicated as risk factors for IHPS. Despite the higher incidence in males and the familial heritability pointing to a genetic cause, the decreasing prevalence in some countries such as Denmark points to environmental factors also playing a role in the development of IHPS [4]. Maternal smoking leads to infants having an increased likelihood of developing pyloric stenosis, probably due to interference with mitochondrial oxidative phosphorylation and increase in the concentration of calcium in pylorus muscle, via an unknown mechanism, leading to increased contraction [9]. Nonetheless, more research into the causal mechanisms is still needed. Furthermore, it could be argued that the decrease in incidence of pyloric stenosis in Denmark (from 1.4/1000 to 1.1/1000 live births) may be related to a possible decrease in consumption of cigarettes in Denmark due to increased health warnings in the media.

A further environmental factor that has received plenty of research and promising results is that of feeding methods for babies [10]. It has been implied that babies who are bottle-fed (with formula) are more likely to develop IHPS compared to those that are breast-fed.

Interestingly, Krogh et al. [11] conducted a study to compare feeding practices and identify their relationships, if any, with IHPS; 70,148 infants were involved in the study, and of that 65 had IHPS, 29 of which were bottle-fed for the first 4 months of life. When looking at the odds ratio, for those who were bottle-fed compared to breast-fed, it was 4.62, indicating that babies who were bottle-fed were 4.62 times more likely to suffer from IHPS compared to those who were breast-fed. Furthermore, when comparing babies who were both breast- and bottle-fed to those who were never breast-fed, latter group had a higher risk of developing IHPS. Additionally, McAteer et al. [12] found that, in a state in Washington, the incidence of pyloric stenosis had decreased from 14/10,000 to 9/10,000 while the likelihood of breast feeding had increased from 80% to 94%, therefore, supporting the findings of Krogh et al. [13]. The exact reasons for this are unknown; however, it has been argued that breast milk contains a number of peptide hormones that relax the pylorus, such as vasoactive intesti-

nal peptide (VIP), whereas formula milk has a higher gastrin content, which is thought to be involved in promoting smooth muscle contractions and could therefore be involved in pyloric muscle hypertrophy. However, these theories are still very tentative.

Other risk factors for pyloric stenosis are the first-born children (76.3% risk if first child, 19.6% if second), older maternal age, preterm delivery, caesarean section [13], and macrolide antibiotics among others. Interestingly, it was also found that if these risk factors were reduced, it also reduced the incidence of pyloric stenosis occurring in males and made the prevalence between males and females much more similar.

Metabolic Changes in Pyloric Stenosis

A fluid electrolyte imbalance is usually present in individuals with IHPS. Classically, child presents with hypochloremic, hyponatremic metabolic alkalosis. Hydrochloric acid is lost, resulting in metabolic alkalosis due to the loss of hydrogen and chloride ions via vomiting (chloride-responsive metabolic alkalosis). Usually, the parietal cells of the stomach secrete H^+ ions via carbonic acid, which cross the lumen membrane to enter the stomach. These are then transported to the duodenum via the spasmodic contraction of the pyloric muscle. However, in pyloric stenosis, this passage of ions from the stomach to the duodenum is not possible due to the anatomical changes, consequently preventing the duodenum from secreting pancreatic bicarbonate that is usually stimulated by the hydrogen ions. This lack of hydrogen ions further adds to the metabolic alkalosis [14]. Selective absorption of H^+ ions in the renal tubules due to metabolic alkalosis leads to loss of Na^+ and HCO3− further increasing hypokalemia and hyponatremia.

In children with prolonged fluid loss and vomiting due to delayed diagnosis, kidneys try to compensate for the fluid loss by reducing urine output. However, the kidneys also prevent the loss of potassium ions at the expense of hydrogen ions, due to a cation exchange. This causes a paradoxical aciduria. Hence, paradoxical aciduria is a sign of prolonged and severe dehydration.

Clinical Features and Differential Diagnosis

The main symptom of this condition, distinguishing it from other gastrointestinal conditions, is that of non-bilious, projectile vomiting after feeding which progressively worsens. Milk often changes from being white to becoming an off-white, pale yellow color, as it becomes curdled due to mixing with stomach acids whilst it remains stagnant in the stomach. The vomiting causes the metabolic changes of pyloric stenosis to manifest.

Additionally, infants with pyloric stenosis remain hungry after vomiting. Further symptoms relating to the inefficient digestion include a change in stools, with very small, "starvation stools" being produced. The reduced intake of food and nutrients inevitably leads to severe weight loss.

The longer the condition progresses, the more severe the symptoms become. If not treated in time, infant is severely dehydrated and has decreased urine output.

Differential diagnosis of pyloric stenosis should include vomiting due to over feeding and medical conditions like gastroesophageal reflux, sepsis, raised intracranial pressure, gastroenteritis, and other metabolic conditions. Surgical conditions mimicking symptoms of pyloric stenosis are rare and include pyloric web and pyloric atresia, which are usually diagnosed at the earlier age.

Investigations and Diagnosis

A diagnosis of pyloric stenosis is made clinically based on the symptoms and metabolic changes at presentation. A test feed is the common term used for the process of finalizing the diagnosis but currently it is becoming a vanishing clinical skill while sensitivity and specificity of ultrasound is approaching 100%. This involves examination of the abdomen while child is being fed, whereby a small "olive-sized" mass may be palpable in the epigastric region. This mass is the hypertrophic pyloric muscle, indicative of IHPS. Additionally, visible peristalsis in epigastrium might be present due to increased muscular contraction of the stomach and duodenum in an attempt to push food from the stomach downwards.

Imaging studies to confirm pyloric stenosis will most often include an ultrasound to assess the level of thickening of the pylorus. On most occasions, a muscle wall thickness of more than 3 mm (usually between 3 and 8 mm) on ultrasound investigation is diagnostic of pyloric stenosis with an average of 5 mm thickness in most cases [15]. Furthermore, a pyloric canal length of more than 14 mm and pyloric diameter of more than 12 mm are set as the parameters for diagnosing IHPS [16] (Figs. 4.1 and 4.2).

However, in an article published in the *Permanente Journal,* it was inferred that these parameters can be misleading as both the height and weight of infants can alter the pyloric thickness, although the thickness may be less than 3 mm for an infant of lower than average weight pyloric stenosis may still be present. This study clearly illustrates the importance of taking all factors into account when making a diagnosis, rather than relying solely on imaging techniques. A positive correlation can be seen between both age and weight of the infant with thickness of pyloric muscle [17].

Occasionally, a barium swallow is done, in which a characteristic "string sign" is found, illustrating the narrowing of the pylorus allowing very limited barium to travel from the

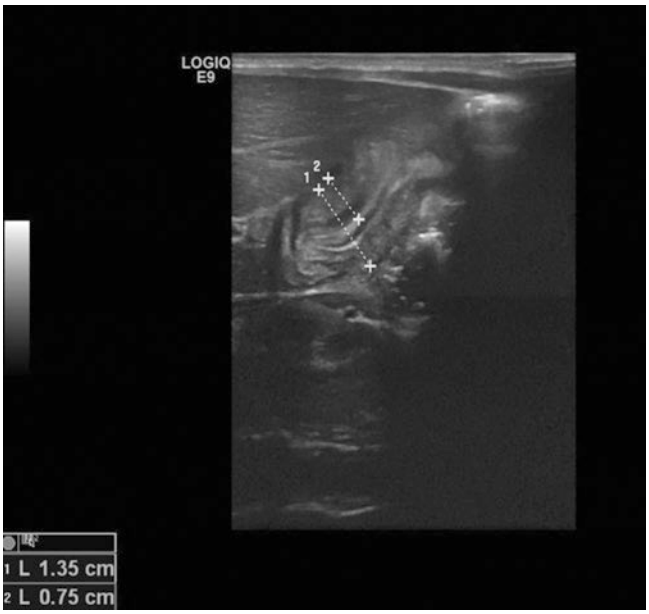

Fig. 4.1 Pyloric stenosis ultrasound transverse view

Fig. 4.2 Pyloric stenosis ultrasound longitudinal view

stomach to the duodenum. Other signs present on a barium swallow include the "shoulder sign" which occurs when the hypertrophied pyloric muscle indents into the pyloric antrum and the "mushroom sign" in which the hypertrophied pyloric muscle indents into the initial part of the duodenum.

Treatment

Preoperative Management

On suspicion of pyloric stenosis, the child should be kept nil by mouth. A nasogastric tube should be inserted and kept on free drainage. All fluid losses should be replaced using normal saline with 10 mmol/l of potassium.

Fluid resuscitation usually using 5% dextrose with 0.45% saline should be started. The amount should be adjusted after assessing the amount of dehydration. Once urine output is established, potassium should be added to IV fluid.

Surgical Treatment

Once the child is fully resuscitated, pyloromyotomy is the treatment of choice.

A pyloromyotomy is a simple procedure during which the hypertrophied pyloric muscle is cut longitudinally and then split. This releases the tension in the thick hypertrophied muscle and consequently allows the muscle to relax. This procedure is known as the Ramstedt's pyloromyotomy, as he initiated this technique of just spreading the muscle rather than doing pyloroplasty.

Surgery could be done either by right upper transverse abdominal incision or as the transumbilical pyloromyotomy (Bianchi approach) [18], which is performed via supraumbilical skinfold incision. Laparoscopic approach is also increasingly utilized. A number of studies have been conducted to establish the differences, if any, between the two. Nonetheless, most studies have suggested that both are effective, with different studies giving contradicting evidence on what form of procedure is more superior. In one study, it was suggested, however, that laparoscopic surgery is slightly superior in that babies are able to have a full feed in a slightly shorter duration of time compared to open pyloromyotomy (18.5 h versus 23.9 h), as well as having a shorter duration of stay in hospital (33.6 h versus 43.8 h) [19]. In a study by Lemoine et al. in 2011 [20], it has been suggested that a transumbilical pyloromyotomy is associated with increased postoperative pain compared to the laparoscopic approach.

In recent years the reports started emerging describing successful endoscopic treatment of IHSP, this novel procedure was adopted from gastroparesis treatment in adults. Gastric peroral endoscopic myotomy, known as G-POEM, totally defies the original principles of pyloromyotomy—the thickened pyloric muscle is accessed from the mucosa and at the end the mucosal entry is closed by clips. The advocates of this procedure suggest that patients may benefit from quicker recovery [21, 22] and it also can be applied treating older patients with atypical presentation [23].

Conservative Treatment

Medical treatment of IHSP with atropine sulfate was proposed a while ago and several meta-analyses were performed with a purpose to evaluate its efficacy [24–27]. The atrophine action on IHSP is based on its potent antimuscarinic activity and it leads to relaxation of smooth pyloric muscle.

Intravenous atropine is more effective than oral and produces a faster response but it also may be associated with adverse effects such as transient tachycardia and flushing. The latest comprehensive meta-analysis by Lauriti et al. detected five studies comparing atropine treatment with pyloromyotomy. Pyloromyotomy had higher success rate than atropine (100% versus 80.8%) and shorter hospital stay (5.6 days versus 10.3 days) [28]. Based on the findings, current recommendation in the UK is to reserve atropine treatment for patients unfit for general anesthesia or surgery.

Complications

Most common complications of surgery include inadvertent opening of the mucosa and incomplete myotomy. Other complications involve bleeding, wound infection, wound dehiscence, postoperative incisional hernia, and about 1% may undergo a negative laparotomy [29]. Self-limiting postoperative vomiting is considered a complication by some authors if hospital stay is extended beyond 48 h. Commonly postoperative vomiting is attributed to the degree of preoperative metabolic and electrolyte derangement and to a lower weight on admission [30]. In case of prolonged vomiting an incomplete pyloromyotomy should be suspected. As with many surgeries, wound infection is a further possible complication, more often seen at open surgery than at laparoscopy.

The in-hospital complication rate is reported between 2.7% and 5.16%. Complications of surgery are minimal, and in most cases, a pyloromyotomy is said to be very effective. A recent meta-analysis by Kelay et al. revealed a 4% higher rate of incomplete pyloromyotomy with the laparoscopic technique in comparison to open surgery. The incidence of mucosal perforation is calculated just about 1% and there was no significant difference between laparoscopic and open groups [31]. Nevertheless in the most recent papers laparoscopic surgery is being advocated as a superior method, it is supported by clinical evidence and excellent results reported in high volume centers [32, 33].

Outcome

Mortality in patients with pyloric stenosis may result from delays in diagnosis, followed by eventual dehydration and shock. The death rate for pyloromyotomy per se is extremely low, at about 0.1–0.5% but unnoticed intraoperative duodenal perforation may carry catastrophic consequences for a malnourished baby. The other cause of mortality can be perioperative apnea followed by cardiac arrest, which may occur as a sequence of profound or not sufficiently corrected metabolic alkalosis [31]. Therefore these patients should be placed on apnea monitor after surgery. IHPS is not considered as surgical emergency and metabolic correction should be performed before contemplating surgery.

The late outcomes of children who had pyloric stenosis remain unclear indicating that a long-term pediatric follow-up might be beneficial. Two studies suggested that neurological development of patients who had IHSP may be poorer in comparison to controls and the former IHSP patients might be more susceptible to functional abdominal problems later in life [34].

GI Problems of Term Babies

Normal feeding is essential to growth and development of newborns: they are able to eat, to digest food, and to absorb nutrients, with normal bowel movements after being fed. Difficulties may occur, meaning a temporary adjustment or suggesting a more serious problem. Symptoms indicating gastrointestinal problems need to be recognized.

Difficult Feeding

The clinical evaluation of a neonate with complex issues related to feeding and swallowing includes a physical examination and feeding observation. Instrumental assessments of swallowing may be needed when concerns are noted regarding pharyngeal phase physiology and risks for aspiration with oral feeding. An interdisciplinary approach is often needed. Feeding difficulties may herald more severe and general disorders, listed in Table 5.1 [1].

Some diseases need urgent treatment. Hypothyroidism is diagnosed through a blood sample (low T3 and T4 and high TSH). Prader-Willi syndrome is characterized by hypotonia in an otherwise normal child and may require tube feeding at the beginning. Among a variety of craniofacial syndromes, Pierre Robin syndrome is characterized by retrognatism,

Table 5.1 Disorders that affect hunger/appetite, food-seeking behavior, and ingestion in newborns

Anatomic abnormalities of the oropharynx
Anatomic/congenital abnormalities of the larynx and trachea
Anatomic abnormalities of the esophagus
Disorders affecting suck-swallow-breathing coordination
Disorders affecting neuromuscular coordination of swallowing
Disorders affecting esophageal peristalsis
Mucosal infections and inflammatory disorders causing dysphagia
Other miscellaneous disorders associated with feeding and swallowing difficulties, such as xerostomia, hypothyroidism, trisomy 18 or 21, Prader-Willi syndrome, allergies, lipid and lipoprotein metabolism disorders, and a variety of craniofacial syndromes.

https://doi.org/10.1007/978-3-030-80068-0_5

glossoptosis, and sometimes cleft palate, with difficulties in breathing and swallowing which need immediate prevention measures, such as lying in prone position and tube feeding [1].

Gastroesophageal Reflux

Gastroesophageal reflux (GER) occurs when stomach contents backs up into the esophagus.

GER is most of the times benign, due to a high of volume inside the stomach, and/or temporary cardial insufficiency, and manifested only by regurgitations, spitting up and dribbling milk with burps or after feedings, without any other symptoms, especially pain. This situation characterizes the "happy spitters." These babies may be helped with feeding of smaller amounts and more frequent, burping the baby often during the feedings, holding the baby in an upright position for about 30 min after feeding and making sure that the baby's diaper is not too tight. When the child is not breastfed, using an infant formula enriched with food thickeners may also help [2].

GER may also be more severe. Several symptoms can be related to neonatal gastroesophageal reflux disease (GERD), Table 5.2. Feeding may be followed by forceful or projectile vomiting or spitting up of large amounts of milk. Reflux may also lead to esophageal irritation by the stomach contents, that is, esophagitis. When the stomach content reaches the pharyngeal regions, it can be aspirated into the lungs, a phenomenon recognized by "rattling," heard, and felt in the baby's chest and back. Babies may also gag and choke during feedings.

GERD may be primary, related to several mechanisms mainly of motor origin [2]. Variations during sleep and wakefulness suggest the involvement of autonomic nervous activity changes [3]. Signs and symptoms of GERD traditionally attributed to acidic reflux in neonates do not seem to be significantly altered by proton pump inhibitors (PPI) treatment in clinical trials [4] in contrast with their large use in clinical practice.

GERD may also be secondary, related to either medical of surgical disorders, Table 5.3. Food allergy dominates, especially for milk, to which the child may react either in infant formulas or in breast milk [5, 6], Diagnosis is based on elimination diets using milk free infant formulas or cow's milk elimination in mother's diet, since allergy testing is rarely positive at this age [5, 6]. The neonatal period remains a critical period for diagnosing conditions leading to vomiting, such as neonatal medical or surgical conditions. The latter must be kept in mind despite the wide use of prenatal diagnosis.

Table 5.2 Symptoms of neonatal gastroesophageal reflux disease (GERD)

Typical or atypical crying and/or irritability
Sleep disturbances
Apnea and/or bradycardia
Poor appetite; weight loss or poor growth (failure to thrive)
Apparent life-threatening event
Vomiting
Hematemesis and/or melena
Recurrent pneumonitis and/or pulmonary atelectasis.
Severe laryngomalacia

Diarrhea

In a newborn, the first bowel movements expel meconium, a sticky, greenish-black substance that forms in the intestines during fetal life. Yellow stools appear after the first few days. In breastfed babies, stools tend to be soft, seedy, yellow green, often as every few hours with feedings and at least several times a day. In formula-fed babies, stools are yellow and formed and occur once or twice a day.

In a baby with diarrhea, stools are watery, very loose, and occur very frequently. Signs of cramping are absent or difficult to perceive. Different causes may be considered, as indicated in Table 5.4 [7]. Diarrhea may reveal neonatal-onset Crohn's disease and intractable ulcerating enterocolitis [8] or neonatal enteropathies [9]. Several viral infections may be responsible, such as cytomegalovirus even in immunocompetent babies [10]. Other viruses may be involved [11], such as adenoviruses [12], parechoviruses [13], rotavirus, norovi-

Table 5.3 Secondary neonatal gastroesophageal reflux disease (GERD)

Medical disorders:
Milk allergy, in formula-fed infants or—in breast-fed children—to milk ingested by mothers
Other food allergies
Surgical conditions:
Esophageal atresia
Hiatal hernia
Diaphragmatic hernia
Omphalocele
Gastroschisis
Other rare causes of neonatal intestinal obstructions

Table 5.4 Frequency, etiology, and current management strategies for diarrhea in newborn infants [7]

Food allergy (20.5%)
Gastrointestinal infections (17.9%)
Antibiotic-associated diarrhea (12.8%)
Congenital defects of ion transport (5.1%)
Withdrawal syndrome (5.1%)
Hirschsprung's disease (2.5%), parenteral diarrhea (2.5%)
Cystic fibrosis (2.5%)
Metabolic disorders (2.5%)

Incidence 6.72 per 1000 hospitalized child, 39 cases of diarrhea (36 acute, 3 chronic); 3 patients died

rus, astrovirus, and some infections being potentially associated with necrotizing enterocolitis (NEC) [11].

Diarrhea in a newborn can quickly lead to severe dehydration and thus needs immediate oral rehydration. The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) solution contains 60 mOsm/L of Na and is recommended for children of Europe, but it seems to be effective in children living in developing countries [14]. Maintenance of breast feeding in breastfed infants is always recommended.

Constipation

Constipation is characterized by rare bowel movements, less than once a day, sometimes less than once every 3 or more days. Generally, stools are very compact and free from moisture, appearing as hard balls or pebbles. Signs of discomfort or pain are frequent, quick drawing-up of the legs, accompanied by a red-faced grunting as baby attempts to have a bowel movement. Examination of a constipated newborn needs checking the quality of feeding, the presence of abdominal distension, and gently analyzing the anal region.

Delay in passing meconium, abdominal distension, and low weight gain suggest or are associated with organic disturbances, such as Hirschprung's disease, often requiring a specific surgical procedure (see corresponding Chapters). Other severe presentation may need medical treatment such as meconium ileus (see below). The list of conditions potentially associated with constipation is depicted in Table 5.5 [15].

Functional constipation is the more likely. Breastfeeding newborn babies may pass three to four bowel movements per day within the first 2 weeks. The bowel movements of bottle-fed babies may be a bit less frequent. Apply a small dab of lubricating gel on baby's anus to protect the sensitive area and allow stool to pass a bit easier. Avoid using mineral oil as a lubricant.

Anal fissures are possible even in neonates, in the form a small tear in the anus. When limited, anal fissures may occur from baby forcing the passage of hard stool, usually with recurrent straining. Anal fissures may be associated with milk allergy [16]. What appears as a larger anal fissure may be an anomaly of the anal regions participating in the process of anorectal malformations, and requiring a surgical procedure.

Table 5.5 Key points of history and physical examination to guide in the evaluation of constipation in newborn [15]

Functional constipation
History
Starting during the first days of life
Obvious precipitating factors coinciding with the start of symptoms: fissure, change of diet, infections
Examination
Generally well, weight and height within normal limits
Soft abdomen
Normal appearance of anus and surrounding area
Organic constipation
Cystic fibrosis
Respiratory problems
Failure to thrive
Cow's milk allergy
Personal and family history (allergy)
Eczema
Hirschsprung disease
Onset of symptoms <1 month
Reported from birth or first few weeks of life
Passage of meconium >48 h
Bloody diarrhea, bilious vomiting
Growth delay or failure to thrive, bilious vomiting
Abdominal distension (sometimes massive)
Tight empty rectum in presence of palpable abdominal fecal mass
Explosive stool and air from rectum upon withdrawal of examining finger
Anatomic malformations
Anal stenosis: ribbons stools, tight anal canal on rectal examination
Abnormal anal position

Colic

Colic is a problem that affects many babies during the first 3 to 4 months of life, starting typically by 3 weeks of age but sometimes much earlier. It is defined as prolonged or excessive crying in an infant whose examination is normal, often associated with gas, irritability, and sleeping disorders. The crying can be very loud, can last for several hours a day, and predisposes to the shaken baby syndrome [17], hence the necessity for appropriate handling. What causes colic is still unclear. Studies show an increased fecal content of calprotectin [18], a marker of intestinal inflammation, thereby suggesting a physiological inflammation during the first months of life. Another possible reason for excessive crying in babies might be that they are oversensitive to gas in the intestine, similarly to what is observed in older children during irritable bowel syndrome, although this disorder is lacking evidenced-based approaches [19]. Milk allergy is also possible, thus leading to a trial elimination diet using cow's milk protein hydrolysates [6].

GI Problems of Preterm Infants

Feeding Difficulties

Digestive tolerance of preterm infants is one of the major problems of neonatal wards. Preterm infants have the paradoxical situation of a considerable demand in nutrients contrasting with a low digestive tolerance, owing to immaturity of the digestive tract, low oral sucking, and swallowing

maturity and with the need to interrupt as soon as possible parenteral feeding to reduce the infectious and metabolic risks and to introduce progressively enteral feeding to enhance the digestive tube maturity [20]. Although incompletely understood, difficulties in preterm infants in the neonatal intensive care unit (NICU) may be related to the potential consequences of an immature intestinal barrier defense and bacterial colonization disturbances, Table 5.6 [21]. What is at stake in this age range is the need to increase as far and as rapidly as possible the rate of enteral feeding with the constant need to avoid gastrointestinal signs of bad tolerance, especially trying to avoid NEC.

Table 5.6 NICU exposures and potential consequences on intestinal barrier defense and bacterial colonization in preterm infants [21]

	Exposure	Potential consequences
Non-specific barrier defense	*Prematurity*	Decreased immunoglobulin levels
		Decreased production of digestive enzymes
		Decreased production of mucus
		Dysfunctional peristalsis
	Delayed feeding	Villous atrophy
		Decreased production of digestive enzymes
		Decreased production of mucus
		Decreased peristalsis
	Medications	
	Histamine H2 blockers or proton pump inhibitors (PPI) Vasopressors and Indocin	Decreased gastric acidity
		Increased risk for intestinal ischemia and enterocyte injury
	Sedatives and paralytic agents	Decreased peristalsis
Bacterial colonization	*Prematurity*	Accentuated inflammatory response
		Abnormal glycosylation pattern
	Delayed feeding	Delay in bacterial colonization
	Broad-spectrum antibiotics	Prolonged sterilization of gut
		Delayed colonization of beneficial, commensal bacteria
		Preferred bacterial colonization of pathogenic bacteria
	Formula feeding and hospitalization	Preferred bacterial colonization of pathogenic bacteria

Progressive Increment of Oral Feeding in Premature Infants

Premature infants of gestational age (GA) >34 weeks are generally able to coordinate sucking, swallowing, and breathing, and so establish breast or bottle feeding. In less mature infants, oral feeding may not be safe or possible because of neurological immaturity or respiratory compromise [20]. In these infants, milk can be given as a continuous infusion or as an intermittent bolus through a fine feeding catheter passed via the nose or the mouth to the stomach [22]. In older babies, around 34 weeks of GA, the infant begins to suckle, and the bottle progressively replaces the tube feeding.

Several Cochrane reviews [23–26] confirm that the introduction of enteral feeding for very preterm infants, that is, less than 32 weeks of GA or very low birth weight (VLBW) <1500 g infants, is often delayed due to the bad clinical tolerance of early enteral introduction and may increase the risk of developing NEC. However, the available trial data suggest that introducing progressive enteral feeding before 4 days after birth and advancing the rate of feed quantities at more than 24 ml/kg/day does not increase the risk of NEC in very preterm infants and VLBW infants [23–26]. In contrast, prolonged enteral fasting may diminish the functional adaptation of the immature GI tract and extend the need for parenteral nutrition with its attendant infectious and metabolic risks [26]. Also, delayed introduction or slow advancement of enteral feeding results in several days of delay in the time taken to regain birth weight and establish full enteral feeds [26]. Trophic feeding, giving preterm infants small quantities of adapted preterm milk formulas to promote intestinal maturation, may enhance feeding tolerance and decrease the time taken to reach full enteral feeding independently of parenteral nutrition [23–26]. Although it is well agreed on that oral feeding should be initiated slowly first by the help of nasogastric tube and then progressively followed by oral feeding, the way in which the preterm infants are introduced and advanced varies widely. The use of dilute formula in preterm or VLBW infants might lead to an important reduction in the time taken for those infants to achieve an adequate daily energy intake [27]. Uncertainty also exists about the risk-benefit balance of different enteral feeding strategies in human milk-fed versus formula-fed very preterm or VLBW infants as the trials and reviews did not contain sufficient data for subgroup analyses [26].

Gastroesophageal Reflux (GER)

GER is common among preterm infants, due to several physiological mechanisms. Its real frequency in preterm and VLBW infants is not well established. The responsibility of

GER is suspected in the occurrence of apnea, bradycardia, pallor, cyanosis with or without oxygen desaturation, severe malaise, feeding difficulties with weight loss or poor growth (failure to thrive), crying, hematemesis, melena, and finally sudden infant deaths (SIDs) [2]. GER could be diagnosed for extra-digestive manifestations by 24 h pH-metry monitoring and for digestive manifestations by upper GI endoscopy with specific neonatal endoscopes [28].

The therapeutic management of GER still represents a controversial issue among neonatologists. Overtreatment, often useless and potentially harmful, is increasingly widespread. Hence, a stepwise approach, firstly promoting conservative strategies such as body positioning (the best position is the ventral decubitus associated with a 30° of orthostatism position under continuous monitoring in the NICU) or changes of feeding modalities should be considered the most advisable choice in preterm infants with GER [2]. Non-pharmacological management of GER might represent a useful tool for neonatologists to reduce the use of anti-reflux medications, that is, prokinetics and anti-H2 blockers or PPI, which should be limited, due to their side effects, to selected cases of severe symptomatic infants [29]. ESPGHAN Guidelines and summary of recommendations for GER diagnosis and treatment in infants are summarized in Table 5.7 [2].

Enteropathy

In neonatal units, there is a tendency to assume that any acutely sick infant with gastrointestinal symptoms has NEC, even though all digestive issues are not related to it. However, a better definition of neonatal enteropathy and of its risk factors in preterm neonates is needed. Neonatal enteropathy is the presence of feeding difficulties, with increased gastric residual, abdominal distension associated with sensitive and/or surgical abdominal examination, and rectal bleeding with bloody stool. Sometimes, preterm infants present with subocclusion (transient) or complete occlusion.

In a prospective study Suc et al. [30], 351 preterm infants admitted to a neonatal ward were fed similarly, depending their maturation, gestational age, and GI status. GI symptoms were seen in 53: 23 transient obstructions, 6 NEC, and 24 hemorrhagic colitis. Ten risk factors were found to be sig-

Table 5.7 ESPGHAN Guidelines; summary of recommendations for GER diagnosis and treatment in infants [2]

Recommendations	Quality of evidence
1. In infants, there is no symptom or group of symptoms that can reliably diagnose GERD or predict treatment response	B
2. Esophageal pH monitoring is a valid and reliable measure of esophageal acid exposure only	B
3. Combined multiple esophageal impedance-pH recording *is* superior to pH monitoring alone for evaluation of GER-related symptom association	B
4. Reflux-induced esophageal damage is defined endoscopically as visible breaks of the distal esophageal mucosa	C
5. There is no evidence to support an empiric trial of pharmacologic treatment in infants with symptoms suggestive of GERD	B
6. There is evidence to support a trial of an extensively hydrolyzed protein formula for a 2- to 4-week trial in formula fed infants with vomiting.	B
Thickening of formula results in decreased visible reflux (regurgitation)	A
7. Prone and lateral positioning is associated with a higher rate of sudden infant death syndrome. In infants from birth to 12 months of age, the risk of sudden infant death syndrome outweighs the potential benefits of prone sleeping. Therefore, supine positioning during sleep is generally recommended	A
8. In the infant with recurrent regurgitation, a thorough history and physical examination with attention to warning signs is generally sufficient To allow the clinician to establish a diagnosis of uncomplicated GER	C
9. In the infant with uncomplicated regurgitation, parental education, reassurance, and anticipatory guidance are recommended	C
10. In otherwise healthy infants with unexplained crying, notability *or* distressed behavior there is no evidence to support acid suppression	A
11. In the infant with reflux esophagitis, initial treatment consults of lifestyle changes and PPI therapy. In most cases, efficacy of therapy can be monitored by the degree of symptom relief.	A
12. In the infant with feeding refusal, acid suppression without earlier diagnostic evaluation is not recommended	D
13. In the vast majority of infants, reflux LS not related to pathologic apnea or to apparent life-threatening event, although a clear temporal relation exists in individual infants. In infant in whom this relation is suspected or if symptoms recur, impedance-pH recording in combination with polysomnographic recording may aid in establishing cause and effect	B

Level A: Consistent randomized controlled clinical trial, cohort study, all or none, clinical decision rule validated in different populations
Level B: Consistent retrospective cohort, exploratory cohort, ecological study, outcomes research, case-control study; or extrapolations from level A studies
Level C: Case-series study or extrapolations from level B studies
Level D: Expert opinion without explicit critical appraisal, or based on physiology, bench research or first principles

nificantly correlated with GI disturbances: umbilical venous catheter, benzodiazepines, birth weight <1,500 g, patent ductus arteriosus, ventilatory assistance, abnormal amniotic fluid, gestational age <32 weeks, early antibiotic treatment, passage of meconium >48 h, episodes of apnea, and/or bradycardia. GI problems might thus be separated into three groups: (1) isolated intestinal obstruction, seen in the most immature babies during the first week of life with the risk of developing NEC; (2) frank blood in the stool, indicating colitis and possibly minor forms of NEC; (3) combined obstructive and hemorrhagic symptoms, typical of NEC.

The diagnosis of enteropathy relies on clinical examination associated with biological parameters (complete blood count, C-reactive protein, and bacteriological cultures) and radiological exploration (abdominal X-ray and/or ultrasonography).

Specific treatment is offered according to diagnostic work up, that is, enteral and/or parenteral nutritional assistance, antibiotics, and sometimes support during acute life-threatening events.

Necrotizing Enterocolitis (NEC)

Background of Prematurity and NEC

NEC is a devastating gastrointestinal disease dominating in preterm infants. The pathogenesis, likely multifactorial, is incompletely understood. At this age, infants experience multiple perturbations to normal postnatal intestinal and immune development, all of which increase their vulnerability to NEC. The prevalence is increased in formula-fed infants, suggesting protection by the bioactive compounds of breast milk. The intestinal microbiota profiles observed during NEC as compared to control infants suggest a lack of benefits from commensal bacteria and an increased risk of intestinal inflammation and bacterial translocation by pathogenic bacteria [31]. NEC incidence seems also reduced by prebiotics and probiotics and increased after prolonged antibiotics exposure use leading to delayed bacterial colonization, with preference for pathogenic microorganisms. H2-blocker or PPI, decreasing gastric acidity, might dampen one component of the first-line defense against pathogenic antigens provided by intestinal tract [32].

The role of Toll-like receptor-4 (TLR4) is likely to be critical in the postnatal susceptibility to NEC of preterm infants [33]. In animal models, the absence of TLR4, such as in TLR4 knockout mouse, prevented the development of NEC [34]. Downregulation of TLR4 suppresses downstream pro-inflammatory signaling, such as observed with postnatal intestinal bacterial colonization by commensal organisms, whereas TLR4 activation increases pro-inflammatory signaling.

Signs and Symptoms

NEC affects typically premature infants, with a timing of onset generally inversely proportional to the GA of the child. Initial symptoms include feeding intolerance, increased gastric residuals, abdominal distension, and bloody stools. Symptoms may progress rapidly to abdominal discoloration with intestinal perforation and peritonitis and systemic hypotension requiring intensive medical support [35].

Spontaneous ileal perforation (SIP) is a clinical entity distinct from NEC, consisting of a perforation in the gastrointestinal tract of a newborn with no demonstrable cause, typically found in the terminal ileum, with abdominal distention and vomiting for 3 to 4 days as presenting symptoms. SIP is frequently seen in preterm newborns, especially with very low birth weight, and rarely in full-term newborns. The potential protective effects for SIP are the use of caffeine, inhaled nitric oxide, and early transfusion [36].

Diagnosis

The diagnosis is usually suspected clinically but often requires the aid of diagnostic imaging modalities. Radiographic signs of NEC include dilated bowel loops, paucity of gas, a "fixed loop" (unaltered gas-filled loop of bowel), pneumatosis intestinalis, portal venous gas, and pneumoperitoneum (extraluminal or "free air" outside the bowel within the abdomen). More recently ultrasonography has proven to be useful as it may detect signs and complications of NEC before they are evident on radiographs [37]. Recently, fecal biomarkers, such as fecal calprotectin, have been tested as noninvasive markers, for diagnosis and follow-up but current results show fecal calprotectin levels in at-risk infants highly variable [38, 39].

Three stages of NEC exist:

Stage 1: Apnea, bradycardia, lethargy, abdominal distension, and vomiting
Stage 2: Pneumatosis intestinalis and the above features
Stage 3: Low blood pressure, bradycardia, acidosis, disseminated intravascular coagulation (DIC), and anuria

Treatment

Primary treatment consists of supportive care. Bowel rest is obtained by stopping enteral feeds, intermittent suction to obtain gastric decompression, fluid repletion to correct electrolyte abnormalities and third space losses, adapted support for blood pressure, parenteral nutrition, and prompt antibiotic therapy. Monitoring is clinical, although serial supine and left lateral decubitus abdominal roentgenograms should be performed every 6 h. Where the disease is not halted through medical treatment alone, or when the bowel perforates, immediate emergency surgery to remove the dead

bowel is generally required. Surgery may require a colostomy, which may be able to be reversed at a later time. Some children may suffer later as a result of short bowel syndrome (SBS) if extensive portions of the bowel had to be removed.

Prevention

The American Academy of Pediatrics, in a 2012 policy statement, recommended feeding preterm infants human milk, finding "significant short- and long-term beneficial effects," including lower rates of NEC. Meta-analyses of four randomized clinical trials performed over the period 1983 to 2005 supports the conclusion that feeding preterms human milk is associated with a significant reduction (58%) in the incidence of NEC. A more recent study of preterm infants fed an exclusive human milk diet compared with those fed human milk supplemented with cow-milk-based infant formula products noted a 77% reduction in NEC [40].

Parenteral nutrition (PN) provides a relatively safe means of meeting nutrient intakes, and while sparing the intestine and is widely used in preterm infants in the initial period after birth, especially in infants who do not tolerate enteral feeds. In most preterm infants, authorities recommend amino acid intakes approximating to 3.5–4 g/kg/day of protein, lipid intakes of 3–4 g/kg/day, and sufficient carbohydrate to meet a total energy intake of 90–110 kcal/kg/day [41]. However, in the prevention of NEC, the short-term benefits of parenteral nutrition itself or of variation in its composition lack evidence.

Neonatologists from NICU reported on the importance of providing small amounts of trophic oral feeds of human milk starting, while the infant is being primarily fed intravenously, in order to prime the immature gut to mature and become ready to receive greater oral intake [40]. Human milk from a milk bank or donor can be used if mother's milk is unavailable [40]. Finally, probiotic and prebiotic supplementation is a promising approach for the prevention of NEC in preterm and VLBW infants [42].

Typical recovery from NEC if medical, nonsurgical treatment succeeds includes 10–14 days or more without oral intake and then demonstrated ability to resume feedings and gain weight. Recovery from NEC alone may be compromised by comorbid conditions that frequently accompany prematurity. Long-term complications of medical NEC include bowel obstruction, anemia, and SBS.

Meconium Ileus (MI)

Definition and Etiology

Meconium ileus (MI) results from an intraluminal intestinal obstruction produced by thick inspissated meconium. Most patients have cystic fibrosis (CF) disease (90% of cases), others having a history of isolated simple MI. The abnormal meconium is very dry, contains higher-than-usual concentrations of protein, and adheres firmly to the mucosal surface of the distal small bowel, creating an intraluminal obstruction [43]. This leads to poor intestinal motility, low grade obstruction, and distended loops without air fluid levels. Associated risk factors are severe prematurity and low birth weight, caesarean delivery, maternal $MgSO_4$ therapy, and maternal diabetes. The incidence of MI has shown to increase while its management continues to be challenging and controversial for the risk of complicated obstruction and perforation [44].

Diagnosis

MI is usually manifested by intestinal obstruction. This situation is more common in the very preterm and VLBW infants than preterm infants more than 32 weeks GA. Clinically, in an otherwise healthy-appearing infant, abdominal distension is visible in the first 12–24 h of life, without meconium elimination in the first 48 h. Physical examination reveals firm palpable masses throughout the abdomen without real surgical signs. There may be feeding difficulties with increased gastric residuals but without vomiting.

MI may be complicated in utero by volvulus, atresia, perforation, and meconium peritonitis, in 30% to 50% of the cases. When born with those complications, infants appear sicker, with often vomiting and signs of neonatal sepsis and more marked abdominal distension causing respiratory distress.

Radiological examination shows dilated bowel loops and the viscous nature of meconium produces a "ground-glass" appearance. Perforation after birth results in free intraperitoneal air. Newborns suspected of MI or any other distal bowel obstruction are diagnosed with a contrast enema study.

All newborns with MI need to be assessed for CF with the sweat chloride test and the genetic assessment of the several mutations of CFTR CF [43].

Treatment

In case of simple MI, approximately 60% of infants have their obstruction successfully relieved by diagnostic contrast enema, ideally using a water-soluble contrast agent [43]. Failure of the contrast to dislodge the inspissated meconium after two attempts is an indication for surgical intervention, for enterotomy with acetylcysteine irrigation and immediate closure. When the enema fails, acetylcysteine, 5 ml every 6 h, may be given via a nasogastric tube to help complete the clean-out. Complicated MI always requires surgical interventions, and the choice of operations depends on the pathologic findings [43].

Congenital Anomalies

Esophageal Atresia (EA)

Definition

Esophageal atresia (EA) (also dealt with in Chap. 3) is a congenital anomaly of the tracheoesophageal separation where the development of the midst esophagus is lacking and that occurs either rarely isolated or frequently associated with trachea-esophageal fistula (TEF). In the most frequent case (85%) the trachea-esophageal fistula is located in the distal esophagus, Fig. 5.1, Table 5.8 [45–47]. The incidence of EA varies from 1 in 3000 to 1 in 4000 live births, with a slight predominance in male and in preterm infants. The role of genetic remains unclear.

Diagnosis

In approximately one-third of pregnancies with EA, the presence of polyhydramnios, due to the inability of the fetus to swallow amniotic fluids, may suggest the disease. Antenatal ultrasound then may show, after about 26 weeks of gestation, an absent or small stomach, which in the setting of polyhydramnios strongly suggests EA. The upper neck pouch sign is another sign that may help antenatal diagnosis.

In almost all types of EA, a feeding tube will not pass through the esophagus at the first neonatal exam in the delivery room. Within first hours the newborn will present oral secretion followed by severe cough and choking episodes. The infant may become cyanotic and may even stop breathing as the overflow of fluid from the blind pouch is aspirated the trachea. If cyanosis results in laryngospasm (basically a protective mechanism to prevent aspiration into the trachea), a severe respiratory distress will rapidly develop.

Digestive symptoms occur immediately. Infants vomit when they are fed, and, owing to the passage of air through the distal trachea-esophageal fistula, abdominal distension develops. A flat or a gasless abdomen suggests an EA without fistula. The most dramatic presentation of the trachea-esophageal fistula occurs with a proximal fistula. Affected infants develop life-threatening respiratory failure from aspiration almost immediately after birth. In contrast, with the so-called H-type, infants usually do not develop any symptom in the neonatal period, but present later on with a history of recurrent mild respiratory distress related to feeding or pneumonia.

Other birth defects may coexist in other organs, such as in the VACTERL association involving other organs (Vertebral column, Anorectal, Cardiac, Tracheal, Esophageal, Renal, and Limbs).

If any of the above signs/symptoms or malformation is noticed, it is mandatory to pass a catheter into the esophagus to check, prompting other tests to confirm the diagnosis if a resistance is noted. This can be done with a catheter visible on a regular X-ray film, demonstrating the blind pouch ending. A small amount of barium placed through the mouth may help.

Treatment

If EA or trachea-esophageal fistula is suspected, all oral feedings are stopped and replaced by intravenous fluids. Appropriate positioning will help the infant draining the secretions and decrease the risk of aspiration. A tube with a continuous aspiration placed into the proximal esophagus

Table 5.8 Classification of esophageal atresia [45–47]

Gross et al. [45]	Vogt et al. [46]	Ladd et al. [47]	Name	Description	Frequency
	Type 1		Esophageal agenesis	Very rare complete absence of the esophagus, not included in classification by Gross or Ladd	N/A
Type A	Type 2	I	"Long Gap," "Pure," or "Isolated" esophageal atresia	Characterized by the presence of a "gap" between the two esophageal blind pouches with no fistula present.	7%
Type B	Type 3A	II	Esophageal atresia with proximal TEF (tracheoesophageal fistula)	The upper esophageal pouch connects abnormally to the trachea. The lower esophageal pouch ends blindly.	1%
Type C	Type 3B	III, IV	Esophageal atresia with distal TEF (tracheoesophageal fistula)	The lower esophageal pouch connects abnormally to the trachea. The upper esophageal pouch ends blindly.	86%
Type D	Type 3C	V	Esophageal atresia with both proximal and distal TEFs (two tracheoesophageal fistulas) TEF (tracheoesophageal fistula) only with no esophageal atresia	The upper and lower esophageal pouches make and abnormal connection with the trachea in two separate, isolated places.	2%
Type E	Type 4		H-type	Esophagus fully intact and capable of its normal functions, however	4%
Type F			Congenital esophageal stenosis	A congenital form of esophageal stricture Esophagus is fully intact and connected to the stomach, however, the esophagus gradually narrows, causing food and saliva to become "caught" in the esophagus On occasion, this type can go undiagnosed until adulthood Not included in classification by Vogt or Ladd	N/A

N/A Not known

pouch can minimize the aspiration of saliva. Also, minimizing positive pressure ventilation can minimize gastric distension and reflux. The use of systemic anti-H2 or PPI can reduce the toxicity of acid secretion on the lung and the distal esophagus pouch, but reflux in itself might help the development of the lower pouch. If gastric distension occurs progressively, surgery becomes an emergency.

Surgery to fix EA is a semi-emergency. Once the baby is in condition, surgery is made by thoracotomy, thoracoscopy, and robot surgery. The esophagus can usually be sewn together. Following surgery, the baby may be hospitalized for a variable length of time depending mainly on associated malformations. Care for each infant is individualized [47]. Long-term follow-up is mandatory, owing to the risk of chronic reflux, Table 5.3.

Imperforate Anus

Definition

Anorectal anomalies occur in 1 out of 2500–5000 births, slightly more commonly in males and with associated anomalies in more than half of affected infants. These are vertebral, genitourinary tract, and GI malformations. Imperforate anus may occur in the setting of the VACTERL association (see Chap. 11, EA). The anatomical variability of these anomalies renders genetic analysis complex, so that genetic factors are clearly associated with anorectal anomalies in only 8% of patients. In infants with trisomy 21% and 18%, 95% of those with anorectal malformations have imperforate anus without fistula, as opposed to only 5% of all patients with anorectal anomalies.

Imperforate anus is the most common anomaly, but other forms of anorectal malformations may occur, such as anterior ectopic anus [48]. This form is more commonly seen in females and presents with constipation [49].

Diagnosis

Anorectal malformations have been classified according to the level of the rectal pouch, that is, "high," above the elevator sling, "low," below the elevator sling, or "intermediate" and to the presence or the absence of an associated fistula. The latter is present in 95% of cases, either externally as an ano-cutaneous fistula or internally as a recto-urinary tract fistula [50].

Diagnosis relies on clinical examination of the perineal region at birth, completed with X-ray studies in cases of diagnostic uncertainty and for the assessment of the associated malformations.

Females may pass meconium through a perineal, vestibular, or vaginal fistula. Infants with a "low" defect may have cutaneous fistulas, meconium present at the perineum, a bulging anal membrane, and well-formed buttocks. Males with a "low" defect may have a bucket-handle malformation or cutaneous fistulas along the midline raphe toward the penis, discharging meconium drops. Finding meconium in the urine or air in the bladder may identify the presence of an internal fistula [50].

Plain abdominal X-ray may show progressive distal bowel obstruction. To identify the distance between the rectal pouch and the skin, a cross-table prone film is obtained with the pelvis elevated, after the first 24 h of life, during which the gap may appear falsely increased. Perineal ultrasound examination may prove to be more accurate than plain films. Abdominal ultrasound, cardiac echography, and skeletal films may be required to rule out other associated anomalies.

Treatment

Several procedures aim at restoring the anorectal canal in "low" defects, by cut-back of a cutaneous fistula, anal transposition, or limited posterior sagittal ano-rectoplasty.

"High" and so-called intermediate defects require an immediate colostomy, followed by elective repair of the localized fistula. Several approaches to the definitive correction of the anorectal anomalies have been described; the aim is always to close all fistulas and then tunnel the rectal pouch through the anatomic sphincter muscle to the anoderm. A posterior sagittal ano-rectoplasty is often the choice.

Children born with "low" defects often will be constipated, whereas incontinence may occur in one-third of patients with "high" defects. Quality of life correlates closely with whether continence can be established. Nevertheless, most of those infants can be rendered functionally continent through a bowel management program with medical laxative treatment, anal enema, and anorectal biofeedback rehabilitation program.

Abdominal Wall Problems

Umbilical Hernia

Umbilical hernia is in infants and is manifested by the intestine protruding through an opening in the abdominal muscles in the navel region. In an infant, it may be hernia may be especially evident when the infant cries, causing the baby's bellybutton to protrude. Many umbilical hernias close on their own by age 1, though some take longer to heal. Surgical repair to prevent complications is needed only when umbilical hernias do not disappear by age 3.

Omphalocele

An omphalocele is an abdominal wall defect where the intestines, liver, and other organs remain in a sac outside of the abdomen because of a defect in the development of the muscles of the abdominal wall. Omphalocele occurs in 2.5/10,000 births and has a high rate of mortality (25%) and of association with other severe malformations, cardiac anomalies (50%), and neural tube defect (40%) and may be associated with pulmonary hypoplasia. The digestive omphalocele can be associated with Beckwith-Wiedemann syndrome. Chromosomal abnormalities are seen in approximately 15% of live-born affected infants, such as trisomy 13 or 18. Long-term complications include parenteral nutrition dependence, GER, parenteral nutrition–related liver disease, feeding intolerance, and neurodevelopmental delay, owing to the difficulties encountered during intensive care and long-lasting stay in the hospital [51]. Omphlocele is usually detected during routine ultrasonographic surveillance, during an investigation of a disparity of uterine size with time from conception or during an evaluation of an increased maternal serum alpha-fetoprotein level. Death rate amounts to 15% of cases and in giant malformations including liver.

Gastroschisis

Gastroschisis is a congenital defect of the anterior abdominal wall, usually less than 4 cm, almost always to the right of the umbilicus, through which the abdominal contents freely, protrude. There is no overlying sac as opposed to omphalocele (which involves the umbilical cord itself and where the organs remain enclosed in visceral peritoneum). The defect may be due to a disruption of the blood supply of the abdominal wall in the first weeks after conception. Antenatal ultrasound examination has made the detection of gastroschisis possible in the first trimester of pregnancy. Surgical management at the birth is an emergency and depends on the presence of perivisceritis. It may require numerous surgical procedures. The neonatal management needs to be careful and done by trained specialists early minimal enteral feeding and gradual enteral nutrition increment and progressive refeeding considerably improve the prognosis [52].

Prune-Belly Syndrome

Prune-belly syndrome is a group of birth defects that involve three main problems, a poor development of the abdominal muscles, causing the skin of the belly area to wrinkle like a prune, cryptorchidism, and urinary tract problems. The latter are the most common issue in the long-term outcome of affected patients.

Inguinal Hernia

Inguinal hernia occurs when the contents of abdominal cavity protrudes through the inguinal canal. Inguinal hernia is very frequent, affecting predominantly male infants, especially premature infants. Inguinal hernia repair in infants is a routine surgical procedure. However, numerous issues, including timing of the repair, the need to explore the contralateral groin, use of laparoscopy, and anesthetic approach, remain unsettled [53].

Omphalomesentéric Band

The omphalomesenteric cord (band) represents the distal residual of the omphalomesenteric duct and may be an origin of obstruction in early infancy with various radiographic pre-

sentations, including intermittent obstruction [54]. The treatment requires surgery.

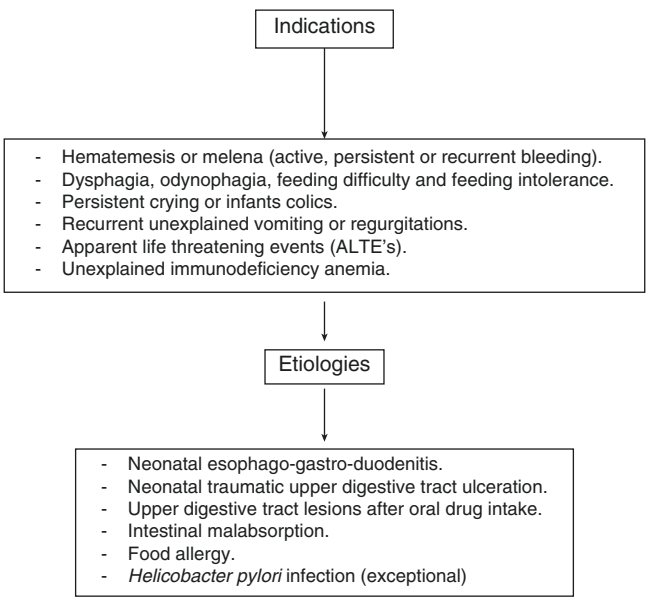
Upper and Lower Endoscopy

Upper Digestive Neonatal Endoscopy

Endoscopy is usually performed at the practitioner's request, upon clinical symptoms that may be considered symptomatic of endoscopic lesions, affecting the sole esophagus or also the stomach, Table 5.9. These are mainly hematemesis, of course, but also retching, regurgitation, increased crying, anorexia, difficult feeding and/or failure to thrive, and malaise. In a multicentric study [55], a large range of symptoms led to endoscopy, hematemesis (55.5%), malaise-like sudden pallor, bradycardia, or cyanosis with or without hypotonia (39.4%), feeding problems and vomiting (53.3%).

Upper bleeding is considered to usually affect sick premature infants and to be unusual in term healthy newborns. In 100 infants treated in an NICU [56], 20% showed gastrointestinal bleeding and mechanical ventilation was the only risk factor. Several studies described healthy full-term neonates who, after an uneventful delivery, had more or less profuse bleeding in the first 48 h of life. In a case-control study comprising 5180 newborn babies, 64 (1.23%) suffered from upper gastrointestinal bleeding [57]. In the case-control study recently published in neonates with upper gastrointestinal bleeding [57], esophageal damage was observed in 24/53 patients. Esophageal lesions were isolated in nine cases and occurred jointly with gastric or duodenal damage respectively in 14 and 1 cases. Gastric lesions were seen in 43/52 patients and duodenal ones in 1/52. There were 17 gastric ulcers and 1 duodenal ulcer [57]. Massive bleeding with life-threatening proportions in the first 24 h of life may allow discovering hemorrhagic gastritis, profuse upper gastrointestinal bleeding, and duodenal ulcers. Antenatal bleeding seems also possible, with esophagitis and gastritis revealed by a bloody amniotic fluid [58]. Fatalities during the first days of life resulting from bleeding due to gastric ulceration have also been described [59]. However, the exact incidence of endoscopic lesions in newborns remains debatable. Endoscopic examination of newborns is rarely readily available, and even severe lesions in the upper GI tract probably often remain undiagnosed or are not detected until the condition of the patient deteriorates because of perforation or hemodynamically significant bleeding. Also, owing to the abovementioned lesions, already well known by neonatologist, the use of PPI or anti-H2 drugs in neonates at risk may have considerably reduced the actual occurrence of these lesions.

Table 5.9 Indications and etiologies of upper digestive endoscopy in the neonate



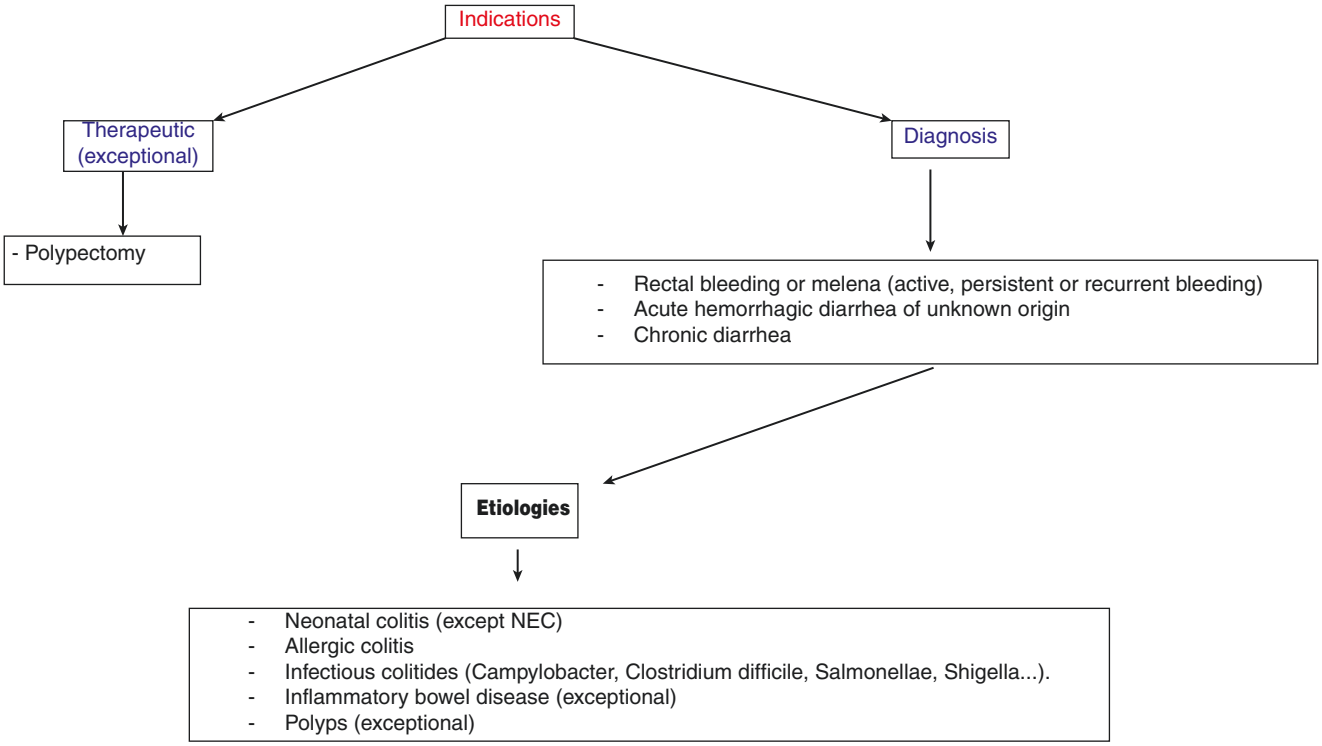
Endoscopy may also be prompted by severe general symptoms, in the form of apparent life-threatening events (ALTEs) led to discovery of severe lesions of esophagus and stomach in two different neonatal cases [60, 61]. If severe esophago-gastritis lesions are shown, an antacid treatment can control the symptoms and be perhaps lifesaving. In addition, the disease has a spontaneously favorable outcome ruling out the need for home monitoring and alleviating considerably the strain on the family. In the presence of neonatal ALTEs, upper digestive endoscopy might be proposed as part of the initial work-up, along with other mandatory investigations, such as diagnosis of long QT syndrome. This does not preclude the use of other means of investigation of GER, such as pH-metric esophageal recording.

Mucosal lesions seen at endoscopy may affect the esophagus, in the form of severe esophagitis appearing as ulcers covered with fibrinous material, occupying the whole perimeter of the esophagus and up to one-third or two-thirds of its distal part. The cardial orifice is usually constantly open with a frequent local inflammation. Gastric lesions usually appear in the form of petechiae or aphteous ulcers, associated or not to blood in the lumen. Duodenal lesions are limited to erythema, mucosal ulcers being rare. In the group with esophagitis and gastritis, severe mucosal lesions could be found following minor symptoms.

Lower Digestive Neonatal Endoscopy Findings (Colonoscopy)

In infants, rectal bleeding may be confusing when it is due to swallowed maternal blood during delivery or during breastfeeding, Table 5.10. The stool may be black or bright red and

Table 5.10 Indications and etiologies of lower digestive endoscopy in the neonate



the infant without symptoms. The Apt-Downey test distinguishes fetal from maternal hemoglobin and helps distinguishing the source of bleeding. Hemorrhagic disease of the neonate is now uncommon after prophylactic administration of vitamin K at delivery. Finally, maternal drug such aspirin, phenytoin, cephalotin, and phenobarbital may interfere with clothing function and cause hemorrhage [62]. Anal fissures are regarded as the most common cause. Giacoia and Williams [63] report two cases in which the presence of an anal fissure delayed the diagnosis of nonspecific colitis in premature infants. It is the authors' experience that the aspect of anal fissure in the term or preterm neonate is often the exteriorization of a rectal inflamed mucosa and that such a diagnosis should probably prompt the systematic search for an underlying condition, such as colitis [28], and, as mentioned above, cow's milk allergy [16].

Rectal bleeding in the neonatal period is nonetheless an alarming event that suggests possible NEC, the latter being associated with a string of other clinical features which may render the diagnosis likely and the need for urgent hospital care and investigation. Early reports, which lack reliability in the absence of endoscopy, had already addressed the issue of rectal bleeding and NEC. In a 1979 survey of 69 infants referred to hospital for rectal bleeding in the first month of life, in which NEC accounted for only 3% of cases [64]. Six infants born at term and had normal perinatal courses developed an inflammatory proctocolitis in the first month of life while being exclusively breast fed and had sigmoidoscopy showing focal ulcerations, edema, and increased friability [65]. A personal study [66] aimed at a better appraisal of unexplained neonatal rectal bleeding using rectosigmoidoscopy. Mucosal alterations were ecchymotic patches, either in the form of one or several longitudinally stretched ecchymotic stripes on an otherwise normal mucosa or in the form of shapeless ecchymosis irregularly dispersed on a friable and congestive mucosa. In 18 neonates with rectal bleeding, colonoscopy revealed a colitis characterized endoscopically by ecchymotic mucosal lesions, the so-called ecchymotic colitis [67].

Colonoscopic changes during the neonatal period may involve NEC, *Campylobacter* infection, *Clostridium difficile*, and dietary protein intolerance [28]. Rectal bleeding and/or colonoscopic changes have also largely been associated with blood transfusion or exchange transfusion [28]. Ulcerative colitis, a rare condition during infancy [28], may be recognized on the association to rectal bleeding and colonoscopic lesions of a severe and progressively worsening alteration of the general condition, Table 5.10.

Enteral Nutrition in Preterm Neonates

6

Gianluca Terrin, Maria Di Chiara, Giulia Sabatini, Thibault Senterre, and Mario De Curtis

Introduction

Over one million children die from preterm birth-related complications every year. According to the World Health Organization, there has been an increase in the incidence of preterm births over the past 20 years [1]. Preterm births are the leading cause of newborn deaths and the second leading cause of death in children under the age of 5 years. Preterms have higher rates of adverse health outcomes in early adulthood compared with their term counterparts [1, 2]. Malnutrition of preterm newborns, especially those very low birth weight (VLBW), is associated with poorer head growth, persistent smaller head size resulting in poor psychomotor and mental skills, higher rates of cerebral palsy, and autism [3]. Despite significant improvement in neonatal intensive care, nutrition of preterm infants remains a challenging issue. Enteral nutrition (EN) should be attempted in each preterm neonate as soon as possible [4, 5]. However, the gastrointestinal tract of preterm infants and especially of VLBW infants is immature at birth and initially incapable of receiving full enteral feeding [5–7]. The inability of receiving EN is defined feeding intolerance (FI), which is variously characterized by signs such as increased volume gastric residual, bilious- or blood-stained stomach residuals, abdominal distension, and/or emesis [8–10].

In most cases, FI represents a benign condition related to the immaturity of gut function; however, its presentation largely overlaps with that of an impending necrotizing enterocolitis (NEC) [11–16]. NEC is a major gastrointestinal emergency in preterm newborns and affects about 3–10% of VLBW infants [16]. Early enteral feeding practices are potentially modifiable risk factors for NEC in very preterm infants. In order to limit the occurrence of NEC, EN is often delayed or withheld over long periods, leading to a delay establishment of full enteral feeding. This practice may prolong the time to regain birth weight and duration of hospital stay. Human milk (HM) and preterm formula represent the two available options for enteral nutrition in preterm newborns. Even if HM is the most physiologic choice, it does not address nutritional requirement of preterm infants. On the other hand, the use of formula is associated with an increased risk of NEC. For all these reasons, optimal use of EN in preterm newborns is still a challenging issue.

In this chapter, we focused on the peculiarities of the nutritional care of preterm neonates, during hospitalization and after discharge from neonatal intensive care unit (NICU).

Nutrition Objectives in Premature Neonates

The vast majority of infants born at a gestational age lower than 29 weeks do not achieve the median birth weight of the reference fetus at theoretical term or 40 weeks postmenstrual age (PMA) [17]. At discharge, the estimates of growth failure range from 30% to 67%. EN should be introduced appropriately to reduce the risk of cumulative nutritional deficit and malnutrition. However, it remains unclear which postnatal artificial feeding regimens are appropriate to support postnatal growth adequately [5–8].

Age of life and clinical conditions influence modalities of enteral nutrition administration. Two different phases could be identified: (I) the early adaptive period of clinical instability (from birth to approximately day 7 of life) and (II) the intermediate-stable growing period. Recommended intakes and modalities of enteral feeding during these two different phases are reported below.

Enteral Nutrition During the Early Adaptive Period

The main goal of neonatal nutrition during this phase is to provide immediately the recommended intakes in order to limit the cumulative deficit and to reach a positive nitrogen balance since the first days of life [7, 9, 18]. Despite of many studies enrolling VLBW infants demonstrated that early optimized nutritional support significantly reduces growth restriction during the first days after birth, it might be difficult to satisfy all nutritional needs in this period of life. FI is frequently observed, in the first days of life; thus, PN must be started immediately after birth in all VLBW neonates to maintain adequate fluid, electrolytes, and nutrients intake, until full enteral feeding (120 kcal/kg/d) is reached. In this phase, small amounts of enteral feeding (also called "minimal enteral feeding," "gastrointestinal priming," "trophic feeding," and "hypocaloric feeding") could improve the maturation of the gastrointestinal tract, digestive hormone release, and gut motility. In addition, withholding EN predisposes neonates to the consequences of starvation such as gastrointestinal atrophy, malnutrition, and infections. Minimal enteral feeding (MEF) should be started as soon as possible, when the patient is stable, at a minimal volume of 10–30 ml/kg of body weight, and it could be increased by 20–30 ml/kg of body weight per day if clinical conditions are stable and feeding intolerance does not occur (Fig. 6.1). In the VLBW infant with prenatal history of blood uteroplacental flow alterations, a delayed onset of MEF could be considered [10]. Measurement of flow in mesenteric vessels, by ultrasonography, could be useful in deciding if starting MEF is safe for a neonate [11, 12]. Results of clinical trials in premature infants support the opinion that MEF, preferentially by human milk, has some clinical benefits such as reducing the time to reach full enteral feeding and length of hospitalization without increasing the risk of NEC [11, 12, 19–21]. When signs of FI are not specific nor systemic (Fig. 6.1), MEF could be continued in order to reduce the duration of parenteral nutrition and to limit the risk of infections [12]. MEF should not be considered in the total energy intakes during parenteral nutrition [19].

Table 6.1 Benefits and limits of human milk and formula for preterm neonates

	Nutritional powder	Effects on infectious diseases	Effects on the risk of necrotizing enterocolitis (NEC)
Human milk			
Fresh	Risk of nutrient deficiencies and slower neonatal growth compared to fortified human milk and preterm formula	Reduced risk of infection (sepsis and urinary tract infection) compared to preterm formula feeding Risk of transmission of CMV infection	Reduced risk of NEC compared to preterm formula feeding
Holder pasteurization	Minimal reduction in fat and energy content compared to fresh human milk Partial reduction in nutritional and biological quality compared to fresh human milk	Reduced risk of infection compared to preterm formula feeding. Similar rate of sepsis compared to fresh human milk No risk of transmission of CMV infection compared to fresh human milk	Reduced risk of NEC compared to preterm formula feeding
Short-term heat pasteurization (5 s at 72 °C)	No evidence available	No risk of transmission of CMV infection compared to fresh human milk	No evidence available
Freezing (−20 °C)	Preserve nutritional and biological quality of human milk	Higher risk of transmission of CMV infection compared to holder pasteurized human milk, but reduced compared to fresh human milk	No evidence available
Human fortified milk			
Fortified with bovine-milk based fortifiers	Improvements in growth (weight, length, and head circumference) during hospital stay compared to not-fortified human milk Nutrient availability and properties of human milk may be changed by fortification Lower growth compared to preterm formula feeding Improved growth using target fortification	Lower risk of sepsis compared to preterm formula feeding	Lower risk of NEC compared to preterm formula feeding No significantly increased risk of NEC compared to not-fortified human milk
Fortified with human milk-based fortifiers	Similar rate of growth compared to human milk fortified with bovine-based products	Similar rate of sepsis compared to human milk fortified with bovine-based product	Reduced risk of NEC compared to feeding with preterm formula or human milk fortified with bovine-based product
Preterm formula			
Powdered	Improvement of fat absorption, nitrogen retention, bone mineralization, and growth compared to pooled human milk	Higher risk of sepsis compared to human milk feeding Risk of *Enterobacter sakazakii* infection	Higher risk of NEC compared to human milk feeding
Liquid	Improvement of fat absorption, nitrogen retention, bone mineralization, and growth compared to pooled human milk Reduced bioavailability of various nutrients (proteins, calcium, or copper) compared to powdered formulation due to precipitation or heat treatment	Higher risk of sepsis compared to human milk feeding	Higher risk of NEC compared to human milk feeding

Nutrition During the Intermediate and Stable Growing Period

During this period, parenteral fluid is progressively weaned and stopped when 120 ml/kg/d (100 kcal/kg/d) of EN is well tolerated. EN can be increased up to 140–180 ml/kg per day (115–135 kcal/kg/d), according with the type of formula used and nutritional requirements.

Human milk is the preferred feed for preterm infants in this phase (Table 6.1). Due to the variability of expressed human milk composition, particularly in protein and fat contents, this weaning period from parenteral nutrition is at high risk of relative malnutrition, contributing to cumulative nutritional deficit and postnatal growth restriction [17]. Therefore, it is commonly accepted that human milk (HM) needs to be fortified to meet the nutrient needs of the preterm infant.

It is worth mentioning that transition phase from parenteral to enteral nutrition still remains a critical period for the achievement of adequate growth [19]. It has been demonstrated that the optimization of nutrition during the transition phase, as well as maintaining appropriate nutrient intakes, improves growth rates in preterm infants [19]. However, the lack of nutritional recommendations during weaning from PN complicates the nutritional management of preterm newborns and may contribute to the accretion of nutrients deficit. Thus, it should be paid attention in this phase to limit nutrients deficit, which in turn may result in poor growth rate and altered body composition.

Feeding Modality

Frequency of Feeding: Bolus or (Semi-) Continuous Feeding

Continuous versus intermittent bolus milk feeding in preterm infants has long been a topic of debate. Bolus feeding results in a significant increase in blood flow to the portal-drained viscera (i.e., stomach, spleen, intestine, and pancreas). There is a surge in gastrointestinal hormones, which is higher than when neonates are fed continuously. On the other hand, clinical trials have demonstrated better tolerance with continuous milk feeding in preterm neonates [22]. A significant increase in pulmonary resistance, airflow, and respiratory instability and a decrease in cerebral perfusion have been noted with the bolus feeding method [23]. Several studies have shown that intermittent bolus feedings reduce the time to achieve full enteral feeds, decrease feeding intolerance, and increase weight gain [24]. However, to date literature review is contradicting. A Cochrane review, comparing clinical effects of continuous versus intermittent bolus nasogastric milk feeding in preterm infants, concluded that the present evidence is inadequate for determining an optimal feeding strategy because of the small sample sizes and methodological limitations [25]. Therefore, there is still not enough evidence to recommend either bolus or (semi-) continuous feeding as the preferred method, but the change from one to another can be justified when feeding intolerance persists in smaller neonates.

Oral Feeding

Oral feeding is possible only when the newborn is capable of an adequate suck-swallow reflex. In the term infant, the full, complex, integrated mechanism of swallowing, with the movement of the bolus of milk into the stomach, protection of the airway, inhibition of respiration, and appropriate relaxation of the esophageal sphincter and gastric fundus is achieved within 2 days of life. The swallow function is present from 16 weeks of gestational age, and gastrointestinal motor activity, in small bursts, from 24 weeks onward [26]. Organized motility is present from around 30 weeks of gestation and nutritive and swallowing function from nearly 32 weeks. The very preterm infant (<32 weeks) may be put on the breast but the likelihood that the infant will ingest a significant volume of milk is very small. However, it may offer the mother a considerable psychological benefit and should therefore be strongly encouraged.

Intragastric Feeding

As oral feeding is not possible in VLBW infants, EN is administered through gastric tubes [27]. Either nasogastric or orogastric tubes can be placed; their correct position can be checked (i.e., gastric fundus) by measuring external distance (i.e., distance from nose or mouth to ear plus distance from umbilicus and xiphoid process) or by measuring the pH of aspirate using pH indicator strips/paper. The correct tube placement could be confirmed on a chest x-ray. The nasogastric tube has the advantage of easier fixation but has been noted to increase airway resistance in preterm infants by 30–50%. With the use of some respiratory devices, a permanent nasogastric tube is not possible. An increased incidence of periodic breathing and central apnea has also been noted in association with permanent nasogastric tubes, in preterm infants [27]. Furthermore, persistent tubes may lead to loss of nutrients such as lipids and calcium that may not reach the infant [27]. Hence, the routine use of nasogastric tubes is not advisable for many preterm infants; in this case, intermittent orogastric tube that could be useful for 2–3 consecutive feeds seems to be a more appropriate modality of EN administration.

Transpyloric Feeding

Although transpyloric feeding is frequently used in pediatric intensive care, no proven benefits in tolerance, growth, or in aspiration rates have been reported in neonates. In addition, there is rising evidence suggesting an increase in NEC and in mortality rate in neonates receiving transpyloric feeding [27].

Feeding Tolerance Evaluation and Feeding Advancement

FI may sometimes be obvious when severe gastrointestinal manifestations are identified (emesis, vomiting, severe abdominal distension, ileus with visible intestinal loops, and

blood in the stools) or when gastrointestinal symptoms are associated with systemic disorders like apnea, bradycardia, poor perfusion, and/or hemodynamic instabilities. However, intermediate scenarios are frequent in preterm infants. Routine monitoring of gastric residual in preterm infants on gavage feeds is a common practice, which is used to guide initiation and advancement of feeds [20]. Gastric residual volume measurement is the practice by which nurses try to aspirate (suck out) the whole of the child or infant's stomach contents every few hours to assess the volume and appearance of the stomach contents [20]. The aspiration of gastric residuals is a common practice while tube feeding infants and aspirate usually need to be reinfused to reduce the loss of enzymes and electrolytes. Routine monitoring of gastric residual as a guide, in the absence of uniform standards, may lead to unnecessary delay in initiation and advancement of feeds and delay in reaching full enteral feeds. This in turn may increase the delay in achieving full enteral feeds, the risk of extrauterine growth restriction, and neurodevelopmental impairment. However, a number of literature suggests that an increase in/or an altered gastric residual may be predictive of NEC [15, 16, 21]. Withholding monitoring of gastric residual may take away the early indicator and thus may increase the risk of NEC.

Thus, the strategy of not checking routinely gastric residual volumes should be adopted only after an appropriate training of the caregivers. When stomach residual volumes are used as markers of FI, it should be appropriate to establish reference values. Gastric residuals >4 ml/kg or >50% of 3 h previous feed could be considered as a valid criterion to interrupt or reduce enteral feeding [20, 21, 28]. In the absence of signs of FI, the volume of enteral nutrition could be daily increased. The ideal rate of progression of milk volume given to VLBW infants is controversial. Cochrane Review has concluded that a rapid rate of advancing feeds was not associated with a higher risk of NEC [20]. Although additional studies are needed, a small progressive increment of 20 ml/kg per day after a few days of stabilization can be recommended (Fig. 6.1). In the presence of erythematic abdominal wall, absence of bowel sounds, blood in the stools or in aspirates, enteral nutrition should be discontinued and serial abdominal ultrasounds and radiological examinations should be started in order to early identify NEC [15, 16, 20, 21, 28].

Nutrient Needs During Enteral Feeding

Protein

Protein Requirements

The ideal amount of dietary protein for preterm infant is still a matter of debate. Dietary protein needs for preterm infants are calculated through two different methods [18, 29]. The first one, the empirical approach, measures biochemical or physiological responses to graded intakes. The second method, the factorial approach, considers the requirements as the sum of the essential losses (e.g., urine, feces, skin), plus the amount incorporated into newly formed tissues, accounting theoretical fetal accretion at the same PMA. The empirical approach evaluates physiological and biochemical variables to determine minimum and maximum protein needs in the growing preterm infant.

In the factorial approach, compositional analysis of fetal tissues has been a valuable source of data for our understanding of the nutrient needs of the fetus and, by extension, those of the growing preterm infant. Fetal accretion rates have been obtained from compositional analyses of aborted fetuses or stillborn infants. From these data, the protein increment for growth has been estimated as approximately 2.5 g/kg/d [29]. Protein requirement is thus calculated by adding to this value the obligatory losses, and the amount needed for the additional catch-up growth. In a large population of preterm infants receiving a controlled energy intake, the minimal protein supply necessary to obtain a zero nitrogen balance (to cover all nitrogen losses) was calculated to be 2 g/kg/d. A similar value was estimated to cover the need for catch-up growth. Thus, the protein requirements of premature infants are between 3.5 and 4.5 g/kg/d (Fig. 6.2) [29].

Protein intake must be sufficient to achieve normal growth without negative effects such as acidosis, uremia, and elevated levels of circulating amino acids [18, 31]. A recent Cochrane analysis aimed to determine whether higher (≥3.0 g/kg/d) versus lower (<3.0 g/kg/d) protein intake during the initial hospital stay of formula-fed preterm infants or low birth weight infants (<2500 g) results in improved growth and neurodevelopmental outcomes without evidence of short- and long-term morbidity [32]. Five studies compar-

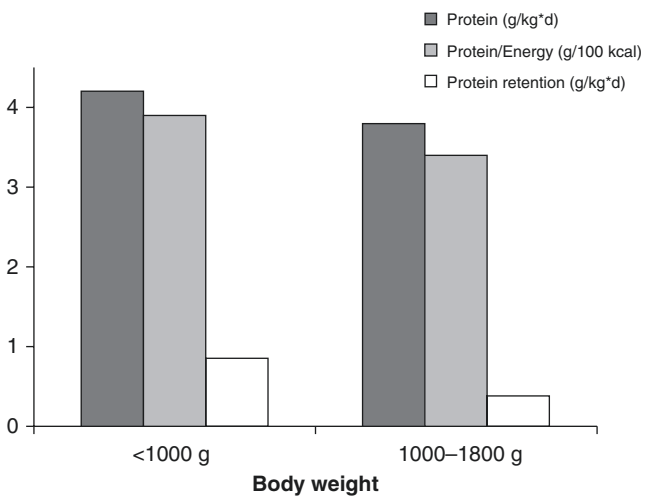

Fig. 6.2 Recommended protein intake and protein to energy ratio for preterm infants to obtain optimal protein retention [9, 30]

ing low versus high protein intake were included. Improved weight gain and higher nitrogen accretion were demonstrated in infants receiving formula with higher protein content while other nutrients were kept constant. No significant differences were seen in rates of NEC, sepsis, or diarrhea. One study compared high (3 g/kg/d) versus very high (>4 g/kg/d) protein intake during and after an initial hospital stay [33, 34]. Very high protein intake improved gain in length at term, but differences did not remain significant at 12 weeks corrected age. Three of the 24 infants receiving very high protein intake developed uremia, defined as serum urea nitrogen level greater than 6. Formula with higher protein content improves all growth parameters and neurodevelopment [35, 36]. However, available evidence is not adequate to permit specific recommendations regarding the provision of very high protein intake (>4.5 g/kg/d) from formula during the initial hospital stay or after discharge.

Enteral Nutrition Protein Composition

Nitrogen absorption rate (absorbed/intake) differs significantly according to the feeding regimen (Fig. 6.3). It is higher with powder whey-predominant protein preterm formulas than with human milk supplemented with fortifiers, powder protein-hydrolyzed formulas, or ready-to-use liquid whey-predominant preterm formulas. These differences result from the nature of the various types of protein supply. Also net protein utilization is higher for preterm formulas compared with human milk, with or without protein supplementation. Technical processes (i.e., hydrolysis) may alter macronutrient concentrations of formula, and the pasteurization of human milk before delivery to newborn also cause a reduction in the protein concentration of about 4% [37, 38].

The whey/casein ratio significantly influences individual amino acid intakes and plasma amino acid concentrations. Plasma threonine is increased and tryptophan relatively decreased in infants fed a whey-predominant formula, whereas methionine and aromatic amino acids are increased in those fed a casein-predominant formula [38]. The high plasma threonine concentration observed in preterm infants fed whey-predominant formulas is related to the glycomacropeptide obtained from casein by enzymatic casein precipitation of cow's milk proteins. Acidic precipitation, by contrast, removes the glycomacropeptide rich in threonine from the soluble phase [38]. In preterm infants receiving either an enzymatic or an acidic whey-predominant formula, a significant reduction in plasma threonine concentration was observed in acidic whey protein formula-fed infants, compared to those receiving conventional enzymatic whey protein formulas. All other plasma amino acid concentrations were similar, with the exception of valine, which was slightly reduced in acidic whey protein formula-fed infants [30].

The relative percentage of α-lactalbumin depends on the ratio between different cow's milk protein contents [30]. Indeed, this protein fraction is naturally rich in tryptophan and helps normalize the low levels of this amino acid frequently observed in whey-predominant formula-fed infants. Formulas based on hydrolyzed proteins have been recently proposed for the feeding of preterm infants to reduce gastrointestinal problems such as delayed gastric emptying, abdominal distension, hard stools, and feeding intolerance [39]. The technological processes necessary to perform hydrolysis and reduce protein antigenicity may, however, modify the amino acid content and/or amino acid bioavailability [39]. The use of a higher percentage of whey in protein-hydrolyzed formulas may worsen the plasma amino

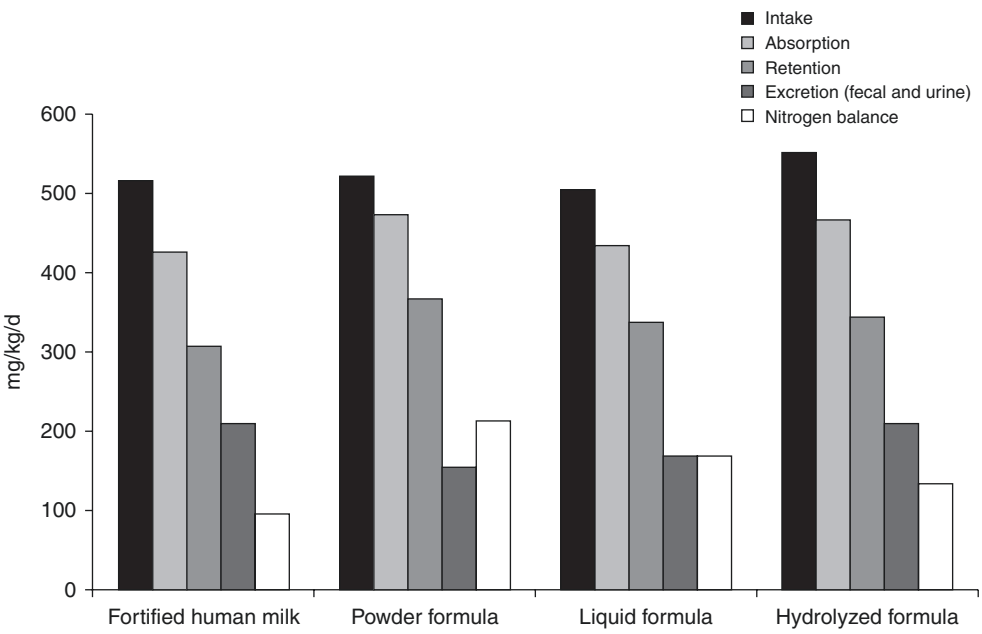

Fig. 6.3 Nitrogen balance according to feeding regimens in preterm infants [27]

acid pattern by increasing threonine and decreasing aromatic amino acid concentrations [38]. Moreover, a significant decrease in plasma histidine and tryptophan concentrations, probably due to a relative reduction in amino acid bioavailability, could also be observed. Using a more appropriate technology, these formulas have been corrected for the threonine content and supplemented with histidine and tryptophan [40, 41].

An interesting observation is the relatively lower absorption rate of ready-to-use liquid preterm formulas or protein-hydrolyzed preterm formulas, where the technical process seems to impair nitrogen absorption in relation to heat treatment—inducing some Maillard reaction—or to preliminary hydrolysis, altering the physiological absorption process in the lumen or at the border of the gastrointestinal tract. The efficiency of protein gain, estimated by the ratio between retained and metabolizable nitrogen (absorbed), differs also according to the feeding regimen. The highest values were obtained in preterm infants fed powder and liquid preterm formulas. It was significantly lower in those fed protein-hydrolyzed formulas and fortified human milk. The lower value obtained with fortified human milk may be related to non-protein nitrogen content, which represents 20–25% of total nitrogen content of human milk, but still 13.5–17% of total nitrogen content of fortified human milk. The contribution of non-protein nitrogen fraction of fortified human milk to protein gain is lower than that of the α-lactalbumin or the casein content of human milk [30, 36, 38, 41]. Due to its biological activities, the non-protein nitrogen of human milk (HM) may not be included in protein intakes when HM is compared to formulas. This may explain why we still frequently observe differences in growth rate of infants fed HM or PTF with theoretical similar nitrogen content. On the other hand, formulas do not contain any of the biologically active immune substances, nor enzymes, hormones, or growth factors found in HM [31–33]. The long-term implications of this deficiency have not been completely determined. Further long-term randomized studies with higher number of patients and standardized supplemental amounts and experimental conditions are needed to establish the efficacy of non-nutritional compounds, such as nucleotides, polyamines, and growth factors supplementation in preterm formula [18].

Energy

The energy demands for preterm infants depend on many factors including PMA, genetically determined metabolic rate, thermal environment, activity, sleep status, nutritional status, nutrient intake, body composition, and occurrence of illness [41, 42]. Energy expenditure, measured by indirect calorimetry, increases with postnatal age and varies from 45 to 55 kcal/kg/d. The energy cost for a postnatal weight gain of 17–20 g/kg/d with adequate LBM accretion varies from 50 to 70 kcal/kg/d in premature infants [41–43]. Energy absorption from enteral nutrition, in healthy growing premature neonates after the first 2–3 days of life, is about 80–90% of energy intake. The remainder is lost in stool and a small quantity as urea in the urine. Energy absorbed is in part stored in tissues, mainly as fat but also as protein, and in part spent by the metabolism (energy expenditure). Energy intakes less than or equal to 100 kcal/kg/d will not meet the needs of some preterm infants before discharge. Where PER are adequate (3.2–3.6 g/100 kcal) in a formula providing well-absorbed nutrients, an energy intake around 120 kcal/kg/d is generally appropriate and may result in a fat mass deposition close to intrauterine references. Small-for-gestational-age infants, in particular if they experienced intrauterine malnutrition, may need higher energy intake than appropriate-for-gestational-age infants [8, 17, 41–43]. Energy intake recommended for preterm infants is 115–135 kcal/kg/d [8, 42, 43]. All recommendations are related to preterm formula, but energy requirement could differ in preterm receiving HM by contrast to those fed with preterm formula [8, 41–44].

Protein to Energy Ratio

Protein intake and PER are the main determinants of weight gain [33]. Protein intake is the only determinant of lean body mass gain in contrast to fat mass gain, which is positively related to energy intake and negatively to PER. Protein and energy needs are reciprocally limiting, the intake of one affecting the ability of the infant to assimilate the other [33, 43, 45]. A suboptimal range of the PER leads to untoward consequences. If energy intake is inadequate, proteins are used as an energy source and the nitrogen balance becomes less positive. Increasing the caloric intake will spare protein loss and improve nitrogen retention. If there is a surfeit of energy with limited protein intake, the protein retention reaches a plateau and the energy excess is used for excessive fat deposition. Thus, an adequate PER should be respected at all PMA, with adequate partition of energy intake between fat and carbohydrates. This crucial point should be respected particularly in the period of clinical instability, when nutritional regimens in a significant part depend on parenteral nutrition [45]. Recommended intakes for preterm infants at 26–30 weeks' PMA should be 3.8–4.5 g of protein/kg per day with a high PER above 3.2 g/100 kcal and ideally around 3.6 g/100 kcal [8]. A recent experts panel has recommended 3.6–4.1 g/100 kcal in VLBW infants, while the ESPGHAN have recommended 3.6–4.1 g/100 kcal in ELBW infants and 3.2–3.6 g/100 kcal for other preterm infants <1800 g [8, 45].

Fat

Fat Requirements

Fat provides the major source of energy in growing preterm infants. Recommended fat intake is 4.8–6.6 g/kg/d [8]. Although some infants with restricted fluid may need high fat content in their feeds to meet energy needs, 4.4–6.0 g/100 kcal is a reasonable range for most preterm infants [45]. Lipid availability by enteral route depends more on digestion and absorption capability than on enteral nutrition content and composition. Digestion of lipids is not fully developed in premature infants [5]. Lipid malabsorption is the result of low levels of pancreatic lipase and bile salts. The bile acid pool is only half the size of that of a full-term infant. HM provides additional lipases: lipoprotein lipase, bile salt-stimulated lipase, which improves intestinal lipolysis. However, additional fat should also be provided to HM because of the variability of fat content in expressed HM, especially when various processes are applied to HM prior to delivery to neonates [45, 46].

Enteral Nutrition Fat Composition

Fats represent approximately 50% of the non-protein energy content of human or formula milk. Fat could be provided in different forms with different nutritional power.

Medium-chain triglycerides (MCT) MCTs are hydrolyzed more readily than long-chain triglycerides (LCT), and fatty acids with more double bonds are absorbed more efficiently [45, 47, 48]. In order to improve fat absorption, commercial formulas contain a significant quantity of MCTs that are more easily absorbed than LCTs and transported directly to the liver via the portal vein as nonesterified fatty acids. The use of MCTs instead of LCTs in preterm infant formulas can reduce the formation of calcium and magnesium soaps with unabsorbed long-chain saturated fatty acids and, thereby, increase calcium and magnesium absorption. However, it needs to be stressed that the energy content of MCTs corresponds only to 85% of that of LCTs. The use of MCTs in formulas induces an increase in plasma ketones as well as in urinary excretion of dicarboxylic acids, suggesting that MCT metabolism could be slightly limited [45, 47]. Moreover, since MCTs do not contain essential fatty acids, a high MCT intake can reduce the availability of the essential long-chain fatty acids. For these reasons, it is recommended that the maximum MCT intake in preterm formula be limited to 40% of total fat content [8, 45].

Long-chain Triglycerides (LCT) Because humans cannot insert double bonds at the n-3 and n-6 positions, fatty acids with double bonds in these positions cannot be synthesized endogenously. Therefore, either specific n-3 and n-6 fatty acids or the precursor of each series such as linoleic acid (LA) (18:3n-3) and α-linolenic acid (ALA) (18:2n-6) must be provided as a component of the diet. In preterm infants, LA intakes of 3.2–12.8% of energy intake have been recommended [8, 48, 49]. Both LA and ALA are metabolized by a series of desaturation and elongation reactions to more unsaturated longer-chain fatty acids. Important metabolites of these two fatty acids include 20:5n-3 eicosapentaenoic acid (EPA), 22:6n-3 docosahexaenoic acid (DHA), and 20:4n-6 arachidonic acid (AA) [47, 48].

Recent studies have reported outcome data in preterm infants fed milk with a DHA content 2–3 times higher than the current concentration in infant formulas. Overall, these studies show that providing larger amounts of DHA supplements, especially to the smallest infants, is associated with better neurologic outcomes in early life [47]. DHA intakes of 55–60 mg/kg/d from the time of preterm birth to expected term have been tested and appear to be safe, to promote normal DHA status, and to improve visual and neurocognitive functions. These values are likely to represent an adequate intake for very preterm infants, but further research is needed to confirm that they represent adequate intake for all infant groups (i.e., extremely, very, and moderately preterm infants, with or without intrauterine growth restriction, and males and females). Because the maximum DHA content of HM is >1.5% of fatty acids (equivalent to 84 mg/kg/d), and because no studies with such a high intake in preterm infants have been reported, no upper limit can be set with certainty.

Considering that endogenous synthesis of long-chain polyunsaturated fatty acids (LCPUFAs) is limited in preterm infants, these molecules are considered as semi-essential or essential. Several studies have suggested that the LCPUFAs supply in preterm infants has a beneficial effect on growth, visual, and cognitive function, as well as on the immune system. Although some methodological issues in these studies do not allow definitive conclusions to be drawn, most of the formulas in Europe and the USA are currently supplemented with LCPUFAs [45, 48, 49].

Recommended intakes are 12–30 mg/kg/d or 11–27 mg/100 kcal for DHA and 18–42 mg/kg/d or 16–39 mg/100 kcal for AA [8]. The ratio of AA to DHA should be in the range of 1.0–2.0 to 1 (wt/wt), and EPA supply should not exceed 30% of DHA supply [8].

Fat composition of HM While the amount and composition of carbohydrate and protein remain relatively constant in mature HM, the composition of fat is highly variable and is affected within hours and to a large extent by maternal nutrition intake. Gestation, lactation, parity, milk volume, caloric and carbohydrate intake, and weight changes are among the maternal factors that can alter the fat content and composition of breast milk. Specifically, phospholipid and cholesterol content are higher in colostrum preterm than term breast milk. In addition, LCPUFA are higher in preterm

and transitional milk and remain high for the first 6 months in women who deliver preterm. In term milk, on the other hand, LCPUFA declines throughout the first 6 to 12 months of lactation. Fatty acids rise with a high-carbohydrate maternal diet. Palmitic acid content of breast milk increases in a low-calorie diet. Weight gain during pregnancy is positively associated with higher milk fat content. During infant feedings, foremilk has less fat content than hindmilk. Moreover, the higher the volume of breast milk, the lower the milk fat concentration. The lengths of both gestation and lactation affect the lipids that constitute the milk fat globule membrane. Total phospholipid and cholesterol level is higher in colostrum and transitional milk than in mature milk. The period of colostrum lasts less than 10 days, but during this short time the higher lipid levels are beneficial in such processes as neonatal cell membrane production needed for growth, brain development, and bile salt synthesis. LCPUFA levels normally decrease in breast milk during lactation, but in women who have delivered infants before term, the levels remain constant in preterm milk for at least 6 months. Milk fat content changes during each feeding. There is a strong positive relationship between weight gain during pregnancy and milk fat content. Preterm milk may contain a slightly higher proportion of medium- and intermediate-chain fatty acids than term milk, which may be advantageous for fat and calcium absorption in preterm infants. The estimated mean fat content in banked HM is around 3.2 g/100 ml, somewhat lower than the generally accepted value for mature HM [46, 50, 51]. This may be related to inadequate emptying of the breast during pumping or to processes applied before delivery DHM to neonates.

Pasteurization and storage of DHM induces lipolysis, inactivates bile salt-stimulated lipase and lipoprotein lipase, reduces fats, and increases the absolute amount of free fatty acids in pooled samples. Holder pasteurization involves a modification of the biological activity of a large number of enzymes, including lipases. These effects alter the integrity of HM and may contribute to slower growth in preterm infants fed banked milk versus their mothers' own milk. Based on this amount of evidence, a further supplementation with specific fatty acids could be considered for these infants [45, 50, 51].

Carbohydrates

Carbohydrate Requirements

Carbohydrates are essential to provide adequate energy supply and they represent a major source of dietary energy. Based on carbohydrate equivalents of total energy expenditure, the experts have recommended a minimum of 10.5 g/100 kcal and a maximum of 12.0 g/100 kcal [8, 45]. Carbohydrates are essential to provide adequate energy supply. Additionally, carbohydrates promote epithelial cell proliferation, insulin secretion, and calcium absorption [8, 45]. Thus, they are also essential to the overall health of the gastrointestinal tract other than the fulfillment of energy requirements.

Enteral Nutrition Carbohydrate Composition

The predominant carbohydrate in mammalian milk and in term infant formula is lactose. After digestion by lactase, lactose is absorbed as glucose and galactose, which utilize the same carrier mechanism. In the human fetus, intestinal lactase activity is measurable by 10–12 weeks of gestation [52]. There is a gradual increase in lactase activity with advancing gestation, although the activity remains low until about 36 weeks of gestation, when it reaches the levels seen in full-term neonates [52]. Based on the low lactase activity in early gestation and the estimated length of the bowel, it was calculated that a preterm infant weighing 1300–1400 g might be expected to absorb only 30–50% of the ingested lactose. The lactose that is not fully digested serves as a source of nutrition for bacterial flora in the colon, where it is transformed into short fatty acids and then absorbed [5]. Through the process of fermentation, this not only facilitates colonic water and electrolytes absorption but also stimulates cell turnover of both the colon and the small intestine. In addition to lactose, which serves as an energy source, human breast milk contains 7–25 grams of complex sugar molecules (oligosaccharides) per liter. These various sugars are only found at significant concentrations in HM, and they are collectively known as HM oligosaccharides (HMOs). Oligosaccharides represent the third largest solute load of the diet after lactose and fat [52]. Oligosaccharides are hydrolyzed by salivary, pancreatic, and intestinal amylase and maltase to free glucose, which is rapidly absorbed. Many of the protective effects of HM (i.e., against diarrheal diseases, respiratory, and ear infections) have been attributed to oligosaccharides. A further advantage of oligosaccharides for preterm infant formulas includes the improved gastric emptying [52, 53]. Oligosaccharides may be considered as prebiotics. There are some reports that such prebiotics have beneficial effects on various markers of health. For example, primary prevention trials in infants have provided promising data on prevention of infections and atopic dermatitis. However, additional well-designed prospective clinical trials and mechanistic studies are needed to advance knowledge further in this promising field.

Fluids and Electrolytes

The goal of fluid administration is to replace water loss, maintain water and electrolyte homeostasis to provide extra water and electrolytes to build up new tissues. Total fluid

intake is related to ingested caloric and protein intake as well as to the renal solute load [54, 55]. Randomized controlled trials on enteral fluid intake of preterm infants are lacking as are studies comparing different fluid volumes providing identical nutrient intakes. From data of combined parenteral/enteral regimens, and assuming full enteral absorption, it follows that fluid volumes between 96 and 200 ml/kg/d are tolerated, and that these values may serve as lower and upper limits [8]. When exclusively enteral feeding is reached, a rate of 150–180 ml/kg/d by standard formula or fortified breast milk should be provided to meet nutrient requirements. Some infants may need higher volumes to meet higher requirements of substrates other than fluid. Preterm infants of less than 35 weeks gestation have obligate high renal and intestinal sodium losses during the first 2 weeks of life, leading to cumulative negative sodium balance in most and hyponatremia in many. It has been demonstrated that increasing dietary sodium intake to 4 mmol/kg/d for infants born at 31–34 weeks, and to 5 mmol/kg/d for those born before 31 completed weeks, prevents the negative sodium balance and hyponatremia and leads to more rapid weight gain and earlier discharge from hospital [54–56]. Premature infants require a higher sodium intake in the first 2 weeks of postnatal life than those born at or near term, and failure to provide such an intake may predispose to poor neurodevelopmental outcome in the second decade of life [57]. Potassium intakes are estimated around 2–3 mmol/kg [8, 58].

Calcium and Phosphorus

Calcium and Phosphorus Requirements

After birth, the use of the gastrointestinal tract to provide all nutrients for growth causes a large reduction in calcium bioavailability [59–61]. Various factors affect calcium absorption: vitamin D status, solubility of calcium salts, and the quality and quantity of fat intake. In preterm infants, the vitamin D body stores at birth depend mainly on maternal vitamin D status. In the USA, where dairy products are routinely supplemented with vitamin D, a daily additional intake of 400 IU in the formula may sometimes be sufficient to maintain an adequate plasma concentration of 25-OH and 1–25(OH)2 vitamin D. By contrast, in most parts of Europe, cord blood concentration of 25-OH vitamin D of premature infants is frequently less than 10 μg/ml; in this case, up to 1000 IU/d of vitamin D are recommended [8, 60]. The increased needs of premature infants could be partly due to a relative malabsorption of vitamin D, resulting from a low secretion of bile acids [62]. A calcium retention close to 90 mg/kg per day could currently be expected in preterm infants fed preterm formula with a highly soluble calcium content. These values are still lower than the estimated fetal accretion during the last trimester of gestation (100–120 mg/kg per day). However, there are dramatic physiological changes in bone metabolism resulting from various factors after birth: disruption in maternal mineral supply, stimulation of calciotropic hormone secretion, change in hormonal environment, and relative reduction in mechanical stress. These events stimulate the remodeling process leading to an increase in endosteal bone resorption and a decrease in bone density. In preterm infants, these adaptation processes modify the mineral requirement, since, by itself, the increased remodeling and bone turnover provides a part of the mineral requirement necessary for postnatal bone growth [55, 60].

Phosphate is one of the main intracellular ions present in the cytoplasm. The provision of adequate amounts of nitrogen, potassium, and phosphorus is the condition required to obtain adequate lean body mass accretion and rapid cell growth. The phosphorus to nitrogen ratio in the cells is not stable, and it is increased in the rapidly growing tissues. A large amount of phosphorus is also deposited in the bone in a fixed proportion with calcium and can act as mineral reservoir. In fact, regardless of the proper bone metabolic status, phosphorus consumption by the cell metabolism is privileged in the growing newborn, and phosphorus may be released into circulation from the bone if necessary for cellular requirements. In case of insufficient phosphorus intakes, hypophosphatemia occurs due to cell metabolism requirements. Afterward, and due to bone phosphorus mobilization from the bone, bone calcium release induces hypercalcemia and hypercalciuria [60]. The strict relationship among amino acid, calcium, and phosphorus intakes is not specific to the first days of life of parenterally fed neonates. This phenomenon of phosphorus deprivation may also be observed in preterm infants enterally fed when a supplementation of protein was not accompanied by a modification of the Ca/P ratio. Calcium retention level ranging from 60 to 90 mg/kg/d assures appropriate mineralization, it decreases the risk of fracture, and it diminishes the clinical symptoms of osteopenia. An intake of 100–160 mg/kg/d of highly bioavailable calcium salts, 60–90 mg/kg/d of phosphorus, and 800–1000 IU of vitamin D per day is recommended [8].

Calcium and Phosphorus Composition in Enteral Nutrition

In preterm infants fed HM, calcium absorption range from 60% to 70% depending on the calcium salts and intake. Calcium retention is mainly related to phosphorus supply, which is frequently the limiting factor of bone mineralization. Supplementation of HM with phosphorus alone improves calcium retention from 25 to 35 mg/kg/d. When calcium and phosphorus are provided together or as HM fortifiers, calcium retention may reach 60 mg/kg/d. Recent use of HM fortifiers containing highly soluble calcium glycerophosphate has improved calcium retention up to 90 mg/kg per day at intake of 140 mg/kg/d [8, 60]. In formula-fed

infants, calcium absorption is usually less than with HM, ranging from 35% to 60% of intake. Calcium absorption is related to calcium, fat intakes, and techniques of milk preparation [8]. With ready-to-use liquid formulas, calcium absorption is usually lower than with powder formulas. With the use of formulas with a well-absorbed fat blend of about 85%, the formation of calcium soap is of minimal interest in clinical practice. Finally, owing to the poor solubility of calcium salts, especially calcium phosphate, the calcium content measured in the formula could be significantly lower than the claimed value, and additional loss due to precipitation may occur before feeding.

Iron

Preterm infants require iron for erythropoiesis, brain development, muscle function, and cardiac function. The symptoms of iron deficiency are not due to anemia only but are also due to tissue losses of iron-containing enzymes and iron–sulfur proteins. It has been estimated that, in the absence of iron supplementation, a VLBW preterm infant has enough iron stores to last 2 months [63]. However, due to their growth requirements and blood samples, preterm infants need supplemental iron after 2 weeks of age. Enteral dose of iron for the preterm infant ranges from 2 to 4 mg/kg/d, depending on the degree of prematurity and the amount of phlebotomy. The introduction of erythropoietin puts a greater stress on iron balance, forcing the infant to mobilize endogenous iron stores at a faster rate. For infants receiving this medication, an enteral dose of 6 mg/kg/d is recommended. No study has demonstrated oxidative toxicity from enteral iron given at conventional doses in preterm infants. Iron needs of preterm infants remain greater than those of term infants because of their more rapid relative rate of growth and therefore blood volume expansion. Given their lower endogenous iron stores, it would be prudent in preterm to monitor the presence of anemia earlier than in term infants.

Trace Elements

Trace elements contribute less than 0.01% of total body weight. Functionally, they participate as constituents of metalloenzymes, cofactors for metal ion-activated enzymes, or components of vitamins, hormones, and proteins. Preterm neonates are at particular risk to develop trace elements deficiency due to low body stores because of reduced time for their placental transfer, which normally occurs during the third trimester of pregnancy [64, 65]. Trace minerals with established physiological importance in humans include zinc, copper, selenium, manganese, chromium, molybdenum, and iodine. In particular, zinc has been shown to be crucial for ensuring adequate growth. Zinc is, indeed, a key element for protein synthesis in preterm newborns. Zinc requirements for term infants are estimated to be 0.8 mg/d, whereas preterm neonates may require up to 3 mg/kg/d to achieve adequate zinc retention [64]. Zinc content in HM varies considerably (0.7–1.6 mg/L) and declines with time; while colostrum contains 8–12 mg/L, HM at 7 days of neonatal life contains 3–6 mg/L of zinc. These values rapidly decrease at 1–3 mg/L at 1 month of life [64, 65]. Recently, it has been showed that doses of zinc higher than those recommended by the ESPGHAN may reduce morbidity and mortality in preterm neonates [66]. Furthermore, it has been suggested that early aggressive nutrition in preterm newborns, promoting protein synthesis, may cause electrolyte imbalances, especially it may increase zinc consumption [67]. The current nutritional practices for preterm neonates consist of administering high doses of protein and calories as soon as possible after birth. Zinc is required for the activity of a number of proteins (i.e., enzymes, membrane proteins, gene-regulatory proteins, and hormonal receptors), it has a crucial role in maintaining quaternary structure stability of proteins, and it participates in the regulation of gene expression, cell division, and growth [8, 64, 65]. Consequently, during anabolic processes which result in higher protein synthesis, particularly after birth, the requirements of zinc increase. The recommended enteral intake ranges between 0.8 and 3 mg/kg/d [64, 65, 67]. For these reasons, an increased protein and energy intake should be associated with an increased zinc intake.

Oral Vitamin Requirements

Vitamins are organic compounds that are essential for metabolic reactions but are not synthesized by the body [8, 45]. Vitamins are classified as water soluble or fat soluble, based on the biochemical structure and function of the compound. Water-soluble vitamins cannot be formed by precursors (with the exception of niacin from tryptophan) and do not accumulate in the body (with the exception of vitamin B12). They include B complex vitamins and vitamin C. They serve as prosthetic groups for enzymes involved in amino acid metabolism, energy production, and nucleic acid synthesis. A daily intake is required to prevent deficiency. Excretion occurs in the urine and bile. Altered urinary losses due to renal immaturity during the first week of life predispose a preterm infant to vitamin deficiency or excess [8]. Fat-soluble vitamins include vitamins A, D, E, and K. Fat-soluble vitamins require carrier systems, usually lipoproteins, for solubility in blood, and intestinal absorption depends on fat absorption capability [8]. Vitamins are not required daily and deficient states develop slowly. On the other hand, excess of vitamins may produce toxicity.

Human Milk

Benefits of Human Milk

Since 20 years, the American Academy of Pediatrics (AAP) has acknowledged the advantages of HM feeding with the statement that it is the preferred feeding for all infants, including those born preterm [68]. However, not all mothers can provide sufficient milk to meet requirements; thus, supplementation with either preterm formula (PTF) or donor human milk (DHM) is a common practice. Current recommendations are for the use of mother's own milk (MOM), when available, with appropriately screened and pasteurized DHM the next best choice if there is insufficient MOM [68, 69]. Randomized trials (RT) and meta-analyses provide evidence of the relative advantages of HM feeding compared with formula feeding [68, 69]. Advantages of HM feeding, with either pasteurized DHM or MOM, include protection from NEC, infection, retinopathy of prematurity (ROP), and improved cognitive outcomes [68, 69].

Cohort studies, comparing infants fed any HM with infants fed EPTF, demonstrated a clear effect of any HM in reducing NEC. However, the evidence of positive effect of HM was inconclusive for severe NEC. Preterm infants fed HM have fewer infections than those fed on formula. This advantage has been observed with both fresh and pasteurized HM [68]. Recent meta-analysis on the effect of HM on ROP showed a protective effect of HM on ROP and severe ROP for both MOM and DHM in comparison with preterm formula. The protective effect of HM has been attributed to several factors, such as macrophages, lymphocytes, sIgA, lysozyme, lactoferrin, oligosaccharides, nucleotides, cytokines, growth factors, and enzymes present in breast milk. Immune defense can be provided by an interaction between these factors. Breast milk enhances the growth, motility, and maturity of the gastrointestinal tract, compared to formulas. It also induces faster gastric emptying. The mother's presence in the neonatal nursery combined with breast milk expression, particularly the premature infant's skin-to-skin contact with the mother, may reduce the risk of infections by nosocomial pathogens by passive immunization [68, 69]. Preterm infants fed HM during hospitalization showed better neurological development and a higher intelligence quotient compared to those fed formula, even after controlling for the mother's education and social class [68, 69]. Higher mental developmental index scores were reported in VLBW infants at 18 months of age who received HM, compared to those who never received HM in hospital [69]. At 16 years follow-up, the percentage of expressed breast milk in the neonatal diet correlated significantly with verbal IQ and white-matter volume in males. Potential factors of HM that might contribute to neurodevelopment are net protein utilization, amino acid and fat composition, other than hormone, growth factor, and micronutrients [8].

Limits of Human Milk in Preterm Newborns

Despite many benefits, HM and its nutrients content are not sufficient to cover the greater needs of VLBW infants. Breast milk composition depends on the gestational age at delivery, collection methods (e.g., drip method versus expression with a pump), and whether pooled milk or the infant's own mother's milk is used [69]. Greater concentrations of nitrogen, immune proteins, total lipids, medium-chain fatty acids, energy, vitamins, some minerals (calcium and phosphorus), and trace elements in milk from mothers who give birth prematurely (preterm milk) compared with milk of mothers giving birth at term (term milk) have been observed [68]. The higher concentrations of these nutrients tend to decline as lactation progresses, so exclusive feeding of mature preterm milk from 2 weeks postnatally may lead to nutrient deficiencies in the rapidly growing preterm infant [50]. The reason for the difference in nutrient density between preterm and term milk is not well known. Early interruption of pregnancy might induce an incomplete maturation of mammary glands leading to paracellular leakage of serum proteins and ions through junctions that have not completely closed. In addition, a different hormonal profile in women who deliver prematurely compared with those who deliver at term could be responsible for a different milk composition. The greater nutrient density in preterm milk could also be related to the higher concentration of nutrients in a lower volume of milk. One of the main limits of HM for preterm infants is its production. Mothers of preterm infants, for several reasons (stress, poor maternal health, delayed initiation of lactation), frequently produce an insufficient quantity of milk. The difficulties faced by mothers trying to provide milk for their preterm infant must not be underestimated. They may need to express milk for a period of weeks or months in the absence of significant suckling stimulus and in the presence of a great deal stress. Increasing the frequency of expression, kangaroo care, or skin-to-skin contact, relaxation tapes may improve milk volume produced by mothers. Moreover, a restriction of fluid intake in VLBW infants could reduce the volume of HM given, and thus not offer a sufficient quantity of nutrients.

Human Milk Fortification

HM does not provide sufficient nutrition for VLBW infant when fed at the usual feeding volumes leading to slow growth with the risk of neurocognitive impairment and other poor

health outcomes such as retinopathy and bronchopulmonary dysplasia. HM should be supplemented (fortified) with the nutrients in short supply, particularly with protein, calcium, and phosphate, to meet the high requirements of this group of babies.

The protein content of HM is too low to permit a weight gain similar to the intrauterine fetus. The low sodium level may lead to hyponatremia. The amounts of calcium and phosphorus is widely below the intake needed to achieve adequate bone mineral accretion and to avoid severe osteopenia.

Fortified human milk feeding regime significantly improves growth and may provide adequate intakes assuming a composition of HM plus fortifier of 2.5 g protein/100 ml with a protein: energy ratio (PER) above 3.2 g/100 kcal [8]. There are a number of products available for fortifying HM for preterm babies which differ by the origin of milk used (bovine, human, or donkey), and by nutrient composition (multinutrient fortifiers or supplements of protein, lipids, carbohydrates). HM fortifiers have been produced to increase the nutritional content of HMH in order to meet the nutritional requirements of VLBW infants and to preserve the benefits HM [69, 70]. Through a process of lacto-engineering, HM can be fortified with skim and cream components derived from heat-treated, lyophilized mature DHM to produce a "human milk fortifier." This method of fortification avoids cow's milk proteins, but it is impractical, since it involves a complex process and requires a large supply of donor milk. When compared with premature infants fed preterm formula, infants fed exclusively fortified human milk had a significantly lower incidence of NEC and/or sepsis, had fewer positive blood cultures, and required less antibiotic administration [70–72]. Some for-profit companies have been set up to collect and buy HM, to manufacture, and to sell HM-based products. To treat huge volumes of HM (1200 L from 250 donors), they use Vat pasteurization (63 °C, ≥30 min). Vat differs from holder pasteurization, which is the commonly used method in non-profit HM banks. Vat pasteurization significantly reduced lactoferrin and total HM oligosaccharide concentrations when compared to Holder pasteurization. Human milk-based fortifier is obtained by concentrating heat-treated donor HM and then adding vitamins and minerals. Many studies suggested a benefit in terms of morbidity and mortality when babies are fed an exclusively human milk-based diet including HM-based fortifier, leading to a reduction of costs [68]. The OptiMoM study, recently published by O'Connor et al. [73], is the first trial comparing the efficacy of HM-based fortifier to bovine-based fortifier in the absence of formula. It is essential to evaluate the benefit-risk ratio, particularly as these products are very expensive and use large amounts of donated milk to make the fortifier which could be used more directly to feed preterm babies.

Preterm human milk, fortified with protein of bovine origin, has become the standard practice in most neonatal units. The composition of several fortifiers expressed per gram of protein varies both qualitatively and quantitatively [73]. In general, they contain bovine whey protein (intact or hydrolyzed), carbohydrates (mainly or exclusively glucose polymers or maltodextrins), minerals, and electrolytes such as sodium, calcium, phosphorus, and magnesium and some also contain micronutrients and vitamins.

The properties of human milk may be changed by nutrient fortification. Fortification may influence nutrient availability and may alter some biological properties of human milk. This is the result of the osmotic content of the fortifier but also of the rapid and continuous activity of human milk amylase on the dextrin content of fortifiers. High osmolality may induce abdominal discomfort and delayed gastric emptying. Recently, in order to avoid these problems, fortifiers with whole proteins, reduced carbohydrate content, and increased fat supplementation have been proposed [69, 70]. The presence of fat in fortifiers has the advantage of increasing the energy intake of human milk without increasing osmolality values.

The use of multinutrient fortifiers is associated with short-term improvements in weight gain and increments in both length and head circumference growth during hospital stay [70]. Although the fortification of human milk improves the general growth of preterm infants, growth of specific parameters such as lean body mass, fat mass, and bone mineral content is significantly lower in fortified human milk-fed infants than in those fed preterm formula [69, 70]. These differences could be related to the lower protein content of human milk compared with hypothetic values used to establish fortification. Indeed, the variability in expressed human milk with respect to its protein and energy content is high. This variability may result in undernutrition after standard fortification method. It has been demonstrated that individualized fortification may optimize protein and energy intake [69, 70]. Compared with standard fortification, individual fortification significantly reduces the variability in nutritional intakes, allowing the maintenance of protein intake and the PER in the range of the current recommendations. Further studies are advocated to verify the long-term effects of individualized fortification method.

In conclusion, early use of a human milk fortifier up to 1.3 g of protein per 100 ml may be recommended for more immature or smaller preterm infants, beginning from the time when they are able to tolerate 40–50 ml/kg/d of milk [8, 69].

Expressed Donor Human Milk

Expressed donor milk can be foremilk or hindmilk. These two types of milk respectively have lower or higher fat and

energy contents than milk received by the breastfed infant [68]. Mature donor milk will have a lower protein sodium, zinc, and copper content than that of milk produced in early lactation. Feeding donor breast milk is classically associated with poor weight gain and growth restriction. However, analysis of available evidences revealed that most of the studies considered were 20–30 years old and from an era when donor breast milk was fed without fortification or mineral supplements, often as the sole diet. It is not clear whether similar effects would be seen when supplementation with fortifiers is adopted. Additionally, infant fed donor breast milk had a significantly reduced risk of NEC [71, 74]. Treatment of donor breast milk (i.e., collection, store, froze, pasteurization, exposition to light) may induce qualitative alteration [74]. Breast milk in human milk banks is stored at low temperatures and subjected to thermal processing to guarantee its microbiological safety. Holder pasteurization (heating at 62.5 °C for 30 min and subsequent fast cooling) is the most frequent. Such pasteurization has been mainly assessed in terms of reduction in the activity of proteins of major biological relevance, such as immunoglobulins, lactoferrin, lysozyme, and gastrointestinal enzymes such as lipase. It decreases fat and energy content of human milk [74]. Frozen storage at −20 °C of pasteurized milk reduces fat, lactose, and energy content of human milk. These aspects may influence macronutrients and energy intake. Breast milk transmission of human immunodeficiency virus (HIV) is considered an important mode of neonatal infection [75]. Despite this fact, many researchers have observed that corresponding to the volume of milk consumed by the infant, maternal transmission via breast milk is still comparatively low. Some have noted the long latency period of breast milk HIV transmission with evidence of numerous anti-HIV factors in breast milk [75, 76]. The presence of HIV or of other viruses in maternal milk seem to be a requisite to spur immunological defenses to optimize necessary protection to the infant. Because the only intervention to prevent HIV transmission via human milk is not to breastfeed, the AAP recommends that HIV-infected mothers not breastfeed their infants regardless of maternal viral load and antiretroviral therapy. Although the use of human breast milk from HIV-infected mother is not recommended in industrialized countries, an HIV-infected woman receiving effective antiretroviral therapy with repeatedly undetectable HIV viral loads may choose to breastfeed in particular circumstances. This rare condition generally does not constitute grounds for an automatic referral to child protective services agencies. Infant HIV infection status should be monitored by nucleic acid amplification testing throughout lactation and at 1, 3, and 6 months after weaning. Some concerns about CMV infection in preterm infants receiving breast milk from seropositive mothers exist because CMV is excreted in breast milk in most lactating mother after a few weeks [72]. Differences in CMV acquisition from fresh or frozen milk have been suggested, and short-term high temperature pasteurization techniques were found to prevent CMV transmission more effectively than freezing [72]. Cryotreatment preserves the nutritional quality of human milk, but unfortunately not cancel the risk of CMV transmission. In contrast, compared with freezing, holder pasteurization and short-term heat inactivation for 5 s at 72 °C partially destroy the activity of some digestive enzymes, contemporarily eliminates viral infectivity in milk in each stage of lactation [74–76]. Decisions about breastfeeding of VLBW infants by mothers known to be CMV-seropositive should be made with consideration of the potential benefits of human milk versus the risk of CMV transmission.

Infant Formulas

Preterm Formula

When human milk is not available or extremely limited, cow's milk-based formulas for preterm infants must be used. Over the past 20 years, there has been a significant improvement in the nutrient composition of preterm formulas in order to meet the high nutritional needs of growing preterm infants. VLBW infants fed with these formulas showed an improvement of fat absorption, nitrogen retention, bone mineralization, and weight gain, when compared to VLBW infants fed standard term formulas or pooled human milk [8]. Although numerous consensus conferences have been organized, the optimal formula for VLBW infants has not yet been designed. European preterm formulas present several differences in the nutrient composition when compared to American formulas [8]. The latter have a higher MCT and a lower LCPUFA content, provide less lactose, and have a higher mineral intake. Nevertheless, according to more recent data, a general profile in macronutrients could probably be suggested. Energy content could be slightly higher than at present. Current recommendation for energy intakes is 110–135 kcal/kg/d for the ESPGHAN 2010 and 110–130 kcal/kg/d for experts' panel. According to the protein requirements, the protein content would represent 3.2–3.6 g/100 kcal, i.e., 2.4–3.2 g/100 ml [8, 15]. Whey-predominant protein with reduced glycomacropeptide and α-lactalbumin enrichment could be used to optimize the amino acid profile [30, 37]. Up to now, the use of protein-hydrolyzed formulas have not been recommended [38, 68]. The partition of the non-protein energy supply would favor the carbohydrate content up to 50–60% in view of its suggested benefits in sparing protein oxidation, enhancing growth and protein accretion, as well as improving quiet sleep and influencing the distribution of behavioral activity states in VLBW infants. The remaining energy supply would

be covered by fat with a fat blend carefully designed to reduce the long-chain saturated fatty acids content, and provide the essential fatty acids (LA and ALA) in an appropriate ratio as well as the LCPUFAs such as DHA and AA [8, 15]. MCT could be used with a maximum of 30–40% of lipids content [9]. Highly metabolizable (50–60% absorption rate) calcium content would be limited to 100–120 mg/100 ml. According to the expected nitrogen and calcium retention, the phosphorus content of this formula would represent 55–65 mg/100 ml, considering phosphorus absorption close to 90%.

Preterm formulas are available as powder or liquid in glass bottles or cans. Liquid formulas have the advantage that they provide sterile feeding thereby reducing possible infections reported in preterm infants fed powder formulas, such as by *Enterobacter sakazakii* [77]. Nevertheless, it is worth remembering that with liquid formulas, there is frequent discordance between claimed and available content of several nutrients. For instance, part of the calcium content of liquid formula may precipitate on the wall of the receptacle reducing the calcium actually available to the preterm infants. In addition, the heat treatment necessary to sterilize the liquid formulas reduces the bioavailability of various nutrients such as proteins, calcium, or copper. In consequence, when human milk is not available, powder formulas allowing adaptation of nutrient density and being of higher nutritional value remain the formulas of choice for the feeding of VLBW infants.

Hydrolyzed Formula

When human milk is not available for preterm infants, hydrolyzed formula is increasingly used as an alternative to standard cow's milk formula. Hydrolyzed formula is perceived as better tolerated and less likely to lead to serious complications such as necrotizing enterocolitis [78, 79]. However, hydrolyzed formulas are more expensive than standard formulas, and concern exists that their use in practice is not supported by high-quality evidence. Recent meta-analysis demonstrated that feeding hydrolyzed formulas to preterm infants was not associated with a lower risk of feeding intolerance defined as [20, 21, 28] a high mean prefeeding gastric residual volume necessitating enteral feeding discontinuation or [20, 21, 28] abdominal distention or other concerning gastrointestinal signs. There was no advantage of hydrolyzed formula use on NEC occurrence. Contemporarily, hydrolyzed formula was associated with slower weight gain. There were no associations of formula type with bone mineralization. No trials reported mortality rates, growth and neurodevelopmental outcomes, or risk of allergy or atopy beyond the initial hospital admission.

Post-Discharge Enteral Nutrition

Although there is no clear evidence on the added benefit of administering a nutrient-enriched diet to preterm infants after discharge, a few reviews suggest an improvement in growth parameters with no effect on neurodevelopmental outcomes [76]. Studies indicate that variations in dietary nutrient intake can contribute significantly to growth deficits in preterm infants, thus highlighting the choice of appropriate nutrition in this cohort [76]. In most neonatal units, the discharge of VLBW infants usually occurs when premature infants reach 35–36 weeks PMA and/or a weight of about 1800–2100 g. By that time, they have frequently accumulated energy, protein, and mineral deficits and develop a growth restriction. Additionally, they still present higher nutrient requirements than healthy term infants and premature infants born at the same PMA [78–81]. Protein- and mineral-enriched formulas have been proposed to feed preterm infants after discharge with the aim of minimizing as much as possible, postnatal growth restriction during the early weeks of life, inducing early catch-up growth, and reducing the adverse effects of early malnutrition [78–81]. Energy intakes are the main determinant of milk volume intakes. Compared to regular (standard) formula, a simple increase in energy density without changes in nutrients proportion had no influence on nutrients supply except in infants with limiting feeding self-sufficiency, not able to drink their quantity for several reason (bronchopulmonary dysplasia, cardiac insufficiency, neurologic insufficiency, "quickly tired" infants) [82]. In contrast, an increase in protein density with high PER influences protein intake and protein metabolism, and a positive effect of growth parameters was not observed in all studies [78–81]. The benefit of the nutrient-enriched formula on VLBW infants' growth was mainly seen during the early post-discharge period, between discharge and theoretical term (40 weeks PMA). This increased growth rate is observed in all preterm infants, even in those without postnatal growth deficit at the time of discharge. Additionally, there is a strong gender influence on the result of diet manipulation during the post-discharge period and the main positive results are more obvious in boys [68–70].

Considerable attention should also be focused on other specific nutrients, particularly calcium, phosphorus, iron, LCPUFAs, and vitamin A. Feeding post-discharge preterm infants formulas or HM with greater concentrations of calcium and phosphorus than those contained in term formula improves bone mineralization, particularly if the special formulas used during hospitalization are continued after hospital discharge [78–81]. However, the relative osteopenia of VLBW infants observed at the time of hospital discharge usually improves spontaneously in most VLBW infants after discharge, in a manner similar to that induced by the accel-

eration of growth at the first stage of adolescence. Therefore, provision of large amounts of calcium and phosphorous for long periods may not be necessary. With regard to vitamin D intake, there is no evidence that preterm infants should receive greater doses that term infants to maintain a normal plasma vitamin D concentration after discharge [82, 83]. Body iron stores are highly variable at discharge, so it is important to screen for iron deficiency at discharge and during the first year of life [63, 64]. Scientific societies recommend that preterm infants receive iron supplements for up to 1 year after discharge [63, 64]. Preterm infants fed HM should receive an iron supplement of 2 mg/kg/d by 1 month of age, and this should be continued at least until the infant is weaned to iron-fortified formula or begins eating complementary foods that supply 2 mg/kg/d of iron. Infants who have received iron loads from multiple transfusions of packed red blood cells may not require supplements. LCPUFAs need to be added in higher concentration in VLBW infants' feeds to improve brain development and the retina in particular [81–83]. Vitamin A status may be suboptimal in formula-fed VLBW infants for many months after discharge. Contrasting data exist regarding the utility of aggressive enteral supplementation with vitamin A (3000 IU per day) after discharge. At the moment, additional studies are needed to determine the dose and duration of vitamin A supplementation that allows infants to reach full repletion values [81–83].

Growth at 4 and 12 months and mineralization at 4 months after discharge are better in VLBW infants fed preterm formula during the first 2 months after discharge than in those fed term formula [81–83]. Protein and nutrient-enriched formula provided after term seems to improve the quality of growth in preterm infants. Infants fed nutrient-enriched formula have lower fat mass, corrected for body size at 6 months' corrected age, than infants fed standard formula or HM. Preterm infants fed nutrient-enriched formula after discharge exhibit an increase in lean body mass and peripheral fat mass but not central adiposity compared with infants fed term formula. These data indicate that nutrient-enriched formulas do not promote central adiposity in preterm infants, a feature that is associated with metabolic syndrome later in life.

On another side, high protein intake in early infancy in term infants could enhance the development of several diseases, such as obesity and hypertension later in life [2, 3]. Even if low protein intakes and poor growth during initial hospitalization in VLBW infants have been associated with poor adverse developmental outcomes, the safety of prolonged high protein intake in preterm infants after discharge has not been completely established. Thus, further studies are necessary to address this crucial safety aspect. Since early nutrition should not be considered simply in terms of weight gain but also for the biological effects with possibly lasting or lifelong significance, it seems prudent to suggest an enriched formula only in infants at risk of future growth failure.

Among the preterm infants, not all are at similar risk of later growth failure and adverse developmental outcomes after discharge. SGA infants and preterm infants that have developed a postnatal growth restriction seem to be the population at higher risk, boys in particular. In these infants, breastfeeding should always be promoted with or without a transient fortification of expressed HM up to 40 to 52 weeks PMA. If breastfeeding is not possible, a preterm formula or a special post-discharge formula that contains more protein, minerals, trace elements, and LCPUFAs should be preferred to a standard term formula until the preterm infant reaches between 40 and 52 weeks PMA to improve catch-up growth. AGA infants without growth restriction at the time of discharge from the hospital usually continue to maintain appropriate growth. In these infants, exclusive breastfeeding should be encouraged at discharge, and if not possible, a term infant formula with relatively low protein density (2.2 g/100 kcal) should be provided with particular attention to its LCPUFAs, mineral, and trace element content.

In conclusion, breastfeeding should always be encouraged in all preterm infants after discharge. In those with high risk of longitudinal growth restriction, fortified human milk or enriched formula (protein, energy, LCPUFA, micronutrients) may also be added to breastfeeding in order to improve the nutrient supply and to promote catch-up growth [79–83]. After discharge, growth should be monitored weekly to adapt feeding and to avoid growth failure, especially in VLBW infants.

Monitoring the Effects of Artificial Nutrition on Growth

Anthropometric Measurements

Monitoring nutritional status is required to detect nutritional deficits early and to guide nutritional supply in preterm infants under intensive care. Thus, nutritional assessment should be an essential skill of neonatal status caring for preterm infants [84]. Overall growth is monitored by anthropometry, as a proxy for body composition: measurement of body weight, length, head circumference, and, to a lesser extent, skin fold and arm circumference [84]. Anthropometric method to monitor growth and assess nutritional status in infants is rapid, inexpensive, suitable for bedside evaluation, and noninvasive despite limitations in the validity of several measurements in small infants [84].

Body weight, though largely used, does not inform on body compartment sizes. Weight gain or loss, reflects also

changes in body composition. In utero, the fetus experiences a decrease in extracellular fluid volume and an increase in lean tissue and fat mass as gestational age increases. The initial postnatal weight loss is attributed to contraction of body water compartments and catabolism of endogenous glycogen, fat stores, and lean tissue in the absence of adequate energy and nutrients supply. Physiologic postnatal weight loss is 5–10% of total body weight. Maximum initial weight loss usually reaches its nadir by 3–6 days of life and birth weight is usually regained by 7–14 days of age. Body weight should be measured daily to assess growth and fluid and electrolytes status in order to define optimal management. Once birth weight is regained, subsequent weight gain of 17–20 g/kg/d is desirable for infants up to 32 weeks PMA. Weight gain should be evaluated weekly to identify infants with average weight gains of <15 or >25 g/kg/d. Unfortunately, poor weight gain is common in infants with extreme prematurity or pathological conditions (chronic lung disease, severe intraventricular hemorrhage, necrotizing enterocolitis, and late-onset sepsis). Postnatal growth restriction is mainly due to insufficient nutritional support and can be avoided in most VLBW infants receiving adequate nutritional intakes [84, 85].

Anthropometric measurements should be plotted on percentile growth curves for comparison with established reference data. Plotting weight on classic intrauterine growth charts can determine whether an infant is small for gestational age (SGA, weight <10th percentile or <2 standard deviation score), appropriate for gestational age (AGA), or large for gestational age (LGA weight >90th percentile or >2 standard deviation score). Growth restriction is usually defined for infants who cross (decrease) the percentile curves, when their standard deviation score decrease of more than 0.6 or 1.0, or when AGA body weight become SGA. Using the growth chart, optimal weight for length is identified by finding the weight, which is approximately on the same percentile as the infant's length measurement. Current weight expressed as a percentage of optimal weight for length can be used to identify infants at risk for under- or overnutrition [85]. Term neonates use to accumulate significant fat mass during the first months of life, and it is not known whether preterm neonates need to accumulate the same amount of fat mass during their first months of life, which would be significantly different than fetuses of the same PMA. Although most experts agree with the statement that low weight-for-length status correspond to growth restriction, it is not known what is the optimal weight-for-length status for preterm infant when they are plotted on intrauterine growth charts.

Neonates with a history of intrauterine growth restriction may have growth delays in weight, length, or head circumference. When intrauterine growth retardation (IUGR) occurs early in pregnancy, frequently symmetric or proportionate growth restriction is observed. In this case, all growth parameters are affected, resulting in a greater risk of neonatal morbidity, future growth problems, and neurodevelopmental delay. In the late IUGR, more often only one parameter displays impaired growth. If weight is low compared with length and head circumference, catch-up growth may be expected. When head circumference is low compared with weight and length, neurological or developmental impairment may occur.

Fenton's charts were designed to commence monitoring infants at 22 weeks' PMA and continue for 10 weeks post term according to the gender [85, 86]. Nevertheless, charts that do not take into account the initial physiological weight loss, such as the Fenton 2013 charts, are not appropriate to monitor short-term postnatal growth [84]. A large international longitudinal observational study showed that preterm infants with uncomplicated postnatal adaptation have transitioned to a weight gain trajectory of 0.8 standard deviations below birth weight at the 21st postnatal day [84]. Based on these data, it seems more useful for monitoring intrahospital growth a free-access online growth calculator (https://www.growthcalculator.org/) that graphically shows current percentiles, target weight, and deviation of the current weight in grams.

It is not easy to assess lean body mass in preterm newborns, especially in the presence of edema or dehydration. Many tools have been tested to better define body composition. Regional anthropometry, triceps skinfold, and mid-upper arm circumference which estimates body adiposity have been proposed as predictors of infant body composition. Standards are available for infants between 24 and 41 weeks of gestation, and they can be used to compare those of an individual infant with reference values or to assess individual changes over time [87]. However, intra- and inter-examiner measurement technique variability and positioning of infants can contribute to measurement of errors. In addition, the use of calipers to measure triceps skinfold may not be feasible in extremely immature infants who have delicate, easily punctured skin. For these reasons, regional anthropometry is not routinely assessed in preterm infants.

Laboratory and Biomedical Tools

Serum nutrient levels can be used as markers of nutritional status in VLBW infants, but many factors not related to nutrition can alter laboratory results and must be considered when interpreting biological data. Technical factors, such as storage and processing of the specimen, type of laboratory method used, and technician accuracy, may affect the validity of laboratory tests. Blood urea nitrogen (BUN), a by-product of protein degradation, is frequently used to monitor protein intake in premature infant feds with human milk,

after the first month of life [84]. However, BUN does not measure protein nutritional status but reflects dietary intakes, hydration status, renal function, and the presence of catabolism. Serum concentrations of transport proteins albumin, transferrin, prealbumin (transthyretin), and retinol-binding protein (RBP) have also been proposed as indicators of protein nutritional status [84]. Both albumin and transferrin have a longer half-life than prealbumin or RBP; thus, serum concentrations of different transport proteins reflect different nutritional intake at different time periods. Prealbumin and RBP concentrations appear to correlate better with nitrogen balance during artificial nutritional therapy. Serum transferrin and RBP levels may be influenced by suboptimal iron, zinc, or vitamin A status. Low values of these proteins are usually described in premature infants during the first 3 months of life when compared to term infants suggesting insufficient nutritional support in premature infants. However, if transport protein concentrations are normal but growth is poor, nutritional supply need to be increased to meet the nutritional demands of VLBW infants.

Alkaline phosphatase (ALP) is an enzyme predominantly produced in liver and bone. It may be elevated during normal growth conditions, liver diseases, or bone diseases. In preterm neonates, an increase of ALP may suggest the presence of an osteopenia of prematurity secondary to calcium, phosphorous, magnesium, or vitamin D deficiencies [84]. As previously discussed, hypophosphatemia and hypercalciuria should also be regularly ruled out to avoid severe osteopenia.

Iron deficiency is frequent in premature infants and typically occurs after 4–8 weeks. Serum ferritin may be used as a good marker of iron store and values above 116 μg/l are advised. Indeed, iron deficiency anemia and low ferritin stores below 75 μg/l have been associated with nonoptimal developmental outcomes. Classical prevention strategy of iron deficiency in preterm infants are delayed (30–120 s) cord clamping at birth and systematic 2–3 mg/kg/d supplementation from the third week of life. On another side, excessive iron intakes may be toxic leading to some oxidative stress, increased risk of infection and retinopathy, and poor growth without any advantages on developmental outcomes. High ferritin concentration above 400 μg/l might be considered as iron overload and iron intakes should be decreased [84].

Despite premature infants are at high risk for developing complications from deficiencies of zinc, vitamin B12, folate, vitamin E, and copper, laboratory tests used for diagnosis of vitamin deficiency are expensive and should be reserved to the infants at high risk of deficiencies: malabsorptive diseases and long-term (>3 weeks) parenteral nutrition [84].

Tracking body composition rather than just body weight is more accurate for monitoring nutritional status and improving nutritional outcomes [84, 88]. Dual-energy X-ray absorptiometry (DXA) and air displacement plethysmography (ADP) are validated and convenient methods for body composition assessment in small infants, since they are noninvasive, rapid to perform, and not affected by movements. However, these methods are expensive and not accessible for the majority of clinical settings.

Advances in imaging techniques have allowed more direct in vivo measurement of body composition. Dual-energy x-ray absorptiometry (DEXA), requiring minimum radiation exposure (<0.3 mrem), has been successfully used for measurement of lean mass, fat mass, and bone mineral content in newborns. DEXA remains the most widely used method for the in vivo measurement of whole-body composition in humans. However, there are concerns on the accuracy in VLBW infants, especially in regard to determination of fat mass. In particular, the diagnostic power of this method for body composition determination depends on model of device, software, and scanning mode. These aspects limit the possibility to use DEXA reference ranges for preterm neonates. Nowadays, air displacement plethysmography has recently emerged as a noninvasive technique to determine body fat mass and fat free mass in preterm infants [84, 88]. It is based on the measurement of body volume using gas laws, and several studies have confirmed the reliability and accuracy of air displacement plethysmography in animals, infants, and neonates [84, 88]. Further validation of these techniques is advocated for routine use.

Conclusions

Enteral nutrition is crucial to meet nutritional requirements of preterm neonates. HM is considered the first choice in preterm infants feeding. Each NICU should make strong efforts to promote lactation. Nutritional support relies on both PN and EN, bearing in mind that the parenteral route functions as a support not necessitating the cover of full requirements in the early adaptive period.

Concerns regarding FI and the perceived risk of NEC are the main obstacles for initiation and advancement of enteral feeds in VLBW infants in NICU. The appropriate management of feeding intolerance is advocated in order to reduce the risk of complications, such as NEC, a delay establishment of full enteral feeding, and the length of hospitalization.

Parenteral Nutrition in Premature Infants

7

Sissel J. Moltu, Alexandre Lapillonne, and Silvia Iacobelli

Introduction

This chapter on parenteral nutrition (PN) in premature infants is an update of the previous chapter [1] based on current body of evidence. The work of the authors of the first version is gratefully acknowledged.

Very premature infants (<32 weeks gestational age) have an immature gastrointestinal tract, and the combined use of enteral and parenteral nutrition (PN) is frequently required to cover nutrient needs during the early days or weeks of life. Studies on PN practices show that nutritional management varies widely and is often nonoptimal [2–8]. The impact of perinatal undernutrition on growth and brain development has been well known for years from both human and animal studies [9–12]. In premature infants, observational cohort studies and randomized controlled trials suggest that postnatal protein and energy malnutrition increase the severity of postnatal diseases and induce postnatal growth restriction, inadequate brain development, and poor neurodevelopmental outcomes [10, 13–24]. Several of these studies have evaluated how to optimize PN support in premature infants and thereby improve early energy and protein supplies. They confirm that preterm infants have a high risk of cumulative energy and protein deficits during the first days of life [10], but also that the parenteral weaning phase requires special attention [6, 7]. Optimal parenteral nutrient intakes may further be compromised by degradation/oxidation of the intravenous lipid emulsion (IVLE) or the fat-soluble vitamins given, destabilization of the emulsions used, precipitations, or by metabolic disturbances including electrolyte imbalances, osteopenia of prematurity, and hyperglycemia [25]. Other challenges of PN are prescription, transcription, or validation errors, the mix up of single products, errors at the infusion site, catheter misplacement or extravasation of the PN solution, and catheter-related septicemia [26–30].

To help harmonize nutritional practices and optimize clinical outcomes, both in the short and the long run, international guidelines on the provision of PN in children, including preterm infants, have been published [31] and revised [32]. The guidelines cover macro- and micronutrient requirements, common complications, and important organizational points [28–30, 33–43]. This chapter discusses the most important features regarding PN in premature infants, summarizing practical aspects and best practice recommendations.

The Standard for Premature Infants Growth

Growth Rates

Fetal growth rate is extremely high during the third trimester of gestation and much greater than during any other periods of life (Fig. 7.1). If the mean fetal weight gain during the last trimester of gestation is 15–17 g/kg/day, it must be emphasized that fetal weight gain usually decreases from ~20 g/kg/day at 24–28 weeks of gestation to ~10 g/kg/day at 39–40 weeks [44]. The optimal growth pattern for premature infants has not been defined, but generally a target growth similar to that of the fetus of similar gestational age (GA) up to term equivalent age (TEA) is recommended [45, 46], followed by growth similar to that of the breast-fed term infant afterwards [47]. However, fetal growth charts do not incorporate the physiological postnatal weight loss and are thus not optimal for

monitoring growth [44, 48]. Since healthy preterm infants usually adapt to their new trajectories (on average 0.8 SD below their birth weight percentile) within the first 3 weeks of life, Rochow et al. created individual based postnatal growth trajectories [49, 50] (Fig. 7.2). These are based on the respective day-specific median growth velocities obtained from day 21 of life from the Fenton growth chart adjusted with a correction factor so that the preterm and the term growth trajectories gradually merge around TEA (42 + 0/7 days). This concept may be a promising approach to monitor growth and adapt nutritional care, but needs validation [50]. At present the growth trajectory calculator is available online at http://www.growthcalculator.org/ (Rochow N et al., Rochow N, Landau-Crangle E, Thommandram A, Fusch C. Individualized postnatal growth trajectory for preterm infants – online calculator. 2016; Accessed August 2020).

Body Weight Composition

The body weight composition changes during the last trimester of pregnancy. Both intrauterine and extrauterine growth is physiologically associated with an increase in fat-mass deposition (Fig. 7.1). Advanced methods for body composition assessments such as dual energy X-ray absorptiometry (DXA) and air displacement plethysmography (ADP) are not available in most neonatal intensive care units. However, if performed with appropriate techniques and instrumentation, direct anthropometric measurement such as body weight, length, head circumference (HC), mid-upper arm circumference (MUAC), and skinfolds may be used with derived measurements (e.g., MUAC:HC, weight to length ratio) to estimate body composition [51]: skinfolds reasonably estimate body fat, whereas body length reflects skeletal growth and fat-free mass.

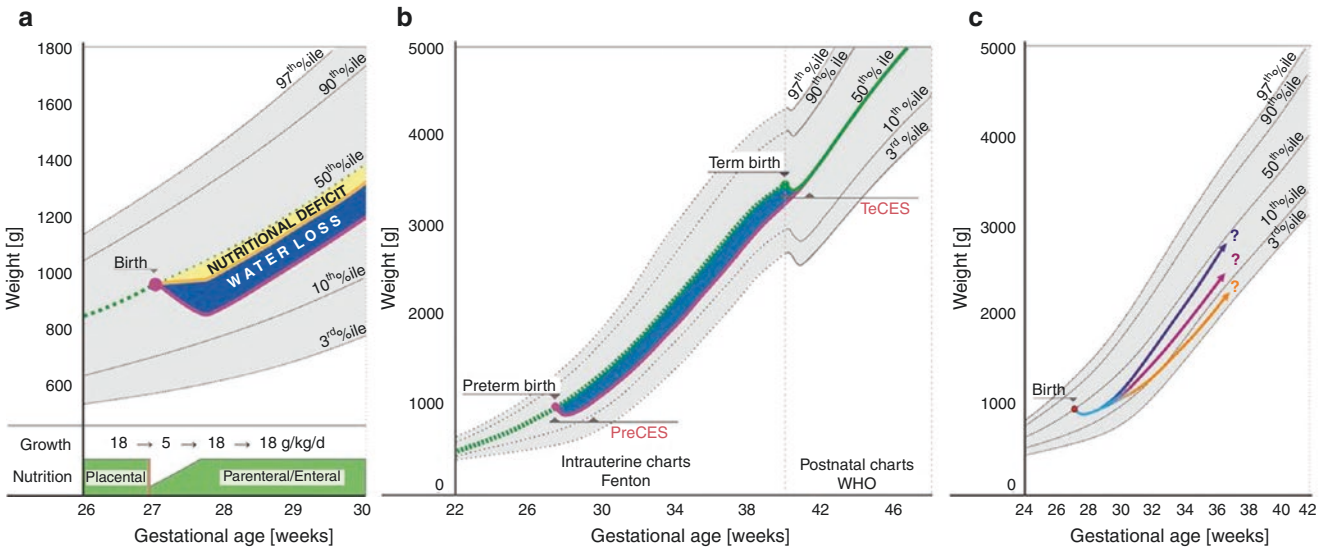

Fig. 7.2 Reproduced from Ref. [50] Use of common growth charts. (**a**) Physiologic weight loss during postnatal adaptation. Minor contribution from temporarily decreased nutrient intake (yellow area), major contribution from contraction of extracellular space with water loss (blue). (**b**) Postnatal offset of growth trajectories of preterm infants and convergence of preterm with term trajectories at 42 + 0/7 weeks; dotted curves of intrauterine trajectories obtained from a meta-analysis of birth weight percentiles, and solid-line postnatal trajectories represent preterm (purple) merging with term (green). One-time postnatal contraction of extracellular water spaces can either occur at term (TeCES) or after preterm birth (PreCES), leading to a temporary separation of growth curves by the equivalent of approximately −0.8 z-scores and remerging after 42 + 0/7 weeks. (**c**) Current growth charts with lack of target trajectories

Nutritional Support in Premature Infants

Nutrition of preterm infants may be divided into two distinct periods: the immediate adaptive or "transitional" period during the first 3–7 days of life and a stable "growing" period up to discharge from the neonatal intensive care unit (NICU). The transitional period, including the immediate postnatal adaptation of the premature newborn to the extrauterine environment, may be prolonged in very immature infants or in infants with major clinical disorders. Immature organs and accompanying morbidities influence nutrient intakes as well as the metabolism of the nutrients provided [2, 3, 8, 52]. During the adaptive and transitional period, most of these infants require PN support, but recent studies show that very and extremely preterm infants may reach full enteral feeds by 7–14 days [21, 53, 54]. Moreover, these studies highlight the importance of reducing the transitional period by more rapidly providing sufficient intakes to promote anabolism and to reach stable-growing requirements [6, 21, 54–56].

Energy

Postnatal Energy Metabolism

The Atwater's factors are usually used to calculate the metabolizable energy contents and intakes both in PN and enteral nutrition. However, the gross energy available after complete combustion of the respective macronutrients varies somewhat. For instance, the gross energy content of 1 g of amino acid (AA, ~4.75 kcal/g) is about 10% lower than that of 1 g of protein (~5.25 kcal/g), the gross and metabolizable energy content of glucose (~3.75 kcal/g) is less than that of more complex carbohydrates (~4 kcal/g), whereas for intravenous lipid emulsions (IVLE), metabolizable energy content is similar to gross energy (~10 kcal/g including glycerol energy content) but could be lower in IVLE containing medium-chain triglycerides (MCT) [1, 57, 58]. These differences are not easy to incorporate into practice.

The energy requirements for premature infants correspond to the sum of energy needed to support all basal functions, including thermoregulation and resting muscular activity (resting energy expenditure, REE), plus the energy needed for growth. The proportion of energy needed for physical activity is often negligible in extremely preterm infants because they usually sleep or lay comfortably wrapped. Energy expenditure measured by indirect calorimetry increases slightly with postnatal age and varies from 45 to 55 kcal/kg/day. The energy cost of growth includes the cost of tissue synthesis and the energy stored in the new accreted tissues such as fat mass and lean body mass (LBM). Estimating a postnatal weight gain of 17–20 g/kg/day accompanied by adequate LBM accretion, the extra energy needed for growth would be 50–70 kcal/kg/day in premature infants. Therefore, metabolizable energy requirements for premature infants on PN are calcu-

lated to be between 90 and 120 kcal/kg/day [33]. Taking into account the commonly encountered cumulative energy deficits and a potential need for catch-up growth, energy intakes higher than the upper recommendation may be needed.

Recommendations for Energy Supply During Total PN

Current PN recommendations for preterm infants suggest providing a minimum of 45–55 kcal/kg/day on the first day of life followed by a gradual increase to 90–120 kcal/kg/day within the first week of life [33]. The energy intakes need to be adjusted according to growth and metabolism during the stable growing period (Table 7.1).

Recommendations for Energy Supply During Partial PN

Nutritional recommendations promote early initiation of enteral feeding in premature infants [59]. However, since absorption may vary and feeding volumes below 25 mL/kg/day mainly serve as trophic gut feeding, these volumes are usually not included in the calculation of total energy intakes. Thereafter, when feeding increases total energy intakes need to consider the sum of both parenteral and enteral intakes. Due to lower absorption rates with enteral nutrition (80–90%) [58], recommended enteral energy intakes are generally 10–20% higher [45].

Table 7.1 Recommended nutrient intakes for premature infants requiring parenteral nutrition

	Early phase	Transition	Growing phase
Water (mL/kg/day)	60–100	120–180	140–160
Energy (kcal/kg/day)	45–55	75–100	90–120
Amino acids (g/kg/day)	1.5–2.5	2.5–3.5	2.5–3.5
Glucose (g/kg/day)	6–8	6–10	11.5–14.5 (17)
Lipids (g/kg/day)	1–2	2–3	3–4
Sodium (mmol/kg/day)	0–2 (3)	2–5 (7)	3–5 (7)
Potassium (mmol/kg/day)	(0)1–3	1–3	1–3 (5)
Chloride (mmol/kg/day)	0–3	2–5	3–5
Calcium (mmol/kg/day)	0.8–2.0	1.5–2.5	1.6–3.5
Phosphorus (mmol/kg/day)	1.0–2.0	1.5–2.5	1.6–3.5
Magnesium (mmol/kg/day)	0.1–0.2	0.1–0.3	0.2–0. 3

Adapted from the ESPGHAN 2018 guidelines. PN should always be accompanied by provision of vitamins and trace elements

Amino Acids

Intravenous AA Solutions

Considerable improvements in intravenous AA solutions have been achieved since the 1960s. Specific pediatric AA solutions were designed in the early 1990s with high essential and conditionally essential AA content for use in premature infants [60, 61]. Three different standards of AA profile have been suggested for premature infants: umbilical fetal cord blood AA during last trimester of gestation, healthy breast-fed term infant's plasma AA, and human milk AA composition [34]. Due to the poor solubility of tyrosine and cystine, current AA solutions have some relative AA imbalance compared to enteral nutrition [61]. The ideal intravenous AA mixture for PN in premature infants is still a matter of debate. Nevertheless, biochemical tolerance and nitrogen utilization in infants do not change significantly despite the different compositions of current pediatric intravenous AA solutions [1, 60]. There is also no evidence to show that one solution has better growth or long-term outcomes as compared to another [61].

Postnatal AA Requirements

Fetal protein accretion is estimated around 2–2.5 g/kg/day during the last trimester of gestation [62]. Isotope studies in animals and in human fetuses have demonstrated that fetal AAs are not exclusively used for protein synthesis but also serve as an energy source by oxidation [63]. The fetal AA uptake during the last trimester of gestation has been estimated to be between 3.5 and 4.5 g/kg/day up to term [62]. Similarly, postnatal nitrogen balance studies in premature infants on PN have shown that an AA intake of 1.5–2.0 g/kg/day from the first day of life is needed to avoid a negative nitrogen balance [64]. Based on fetal accretion rates, AA intakes between 3.5 and 4.0 g/kg/day have been advocated during the stable growing period [31, 60] to promote growth and long-term neurological outcomes. However, aside from less postnatal growth failure [61, 65] and improved nitrogen/protein balance [61, 65, 66], recent systematic reviews and meta-analyses do not find clear beneficial effects with early higher or high dose AA intakes (>3.5 g/kg/d) [61, 65, 66]. In fact, studies on the safety of high AA intakes, with or without a balanced energy intake, are conflicting, but early and higher AA intakes increases the risk of abnormal blood urea nitrogen (BUN) concentrations and metabolic acidosis [65, 67, 68].

Even though BUN is frequently used to evaluate the adequacy of protein intakes in preterm infants, considering that BUN reflects protein degradation and AA oxidation, increased BUN concentrations may be due to several other reasons such as acute kidney injury, dehydration, inadequate concomitant energy intakes, or suboptimal amino acid composition. Increased BUN concentrations may also reflect higher protein intakes resulting in enhanced amino acid oxidation [61]. Therefore, attention is needed, when BUN levels are used as a marker of protein or AA overload during the first week of life in premature infants.

Recommendations for AA Supply

Practical recommendations for premature infants on PN are to provide (1.5–2.5) g/kg/day of AA on the first day of life and to gradually increase AA intake up to 2.5–3.5 g/kg/day [34]. AA intakes ≥2.5 g/kg/d should be accompanied by nonprotein energy intakes >65 kcal/kg/d and adequate micronutrient intakes to avoid hypophosphatemia and neonatal refeeding syndrome [69–71] (Table 7.1).

Carbohydrates

Intravenous Carbohydrates Solutions

Glucose is the only intravenous carbohydrate used for nutritional support with the exception of the glycerol content in IVLE. Early provision of carbohydrate supply is required to prevent hypoglycemia in premature infants. Glucose is readily available for brain metabolism and represents its main source of energy during PN.

Postnatal Glucose Metabolism

Early postnatal glucose infusion is essential in very preterm infants and an intake of 6–7 g/kg/day (4.2–4.9 mg/kg/min) is necessary to prevent early postnatal hypoglycemia resulting from the interruption of the materno-foetal glucose transfer and the low glycogen reserves of premature infants [36, 72].

After birth, glucose metabolism is frequently impaired as the mechanisms for glucose homeostasis are still immature. The endogenous glucose production is not completely suppressed by glucose intakes and the maximal glucose oxidation rate is generally limited to 17 g/kg/day (12 mg/kg/min) in term infants, but may be less in very preterm infants; <12 g/kg/d (8 mg/kg/min) [36, 72]. Very preterm infants are thus not only at risk of early hypoglycemia but also prone to hyperglycemia, in particular during PN. The incidence of hyperglycemia increases with decreasing gestational age and has been associated with increased mortality and neonatal morbidities like nosocomial infections, intraventricular hemorrhage, necrotizing enterocolitis, and impaired neurodevelopment [73, 74]. However, causality has not been proven in RCTs. When glucose intake exceeds total energy expenditure and the capacity for oxidation (energy production), excessive glucose is converted to fat (*de novolipogenesis*) [75]. This is an energy-consuming process which may increase CO_2 production and minute ventilation [76–78].

Hypo- and Hyperglycemia in Premature Infants

The definition of hypo- and hyperglycemia, as well as long-term consequences of these impairments, remains controversial. Reference plasma glucose concentrations are generally defined between 2.6 mmol/L (0.47 g/L) and 6.6 mmol/L (1.2 g/L). Hypoglycemia is regarded a metabolic emergency that needs to be rapidly corrected, most commonly by slow infusion of a glucose bolus (200 mg/kg = 2 mL/kg of 10% glucose solution) and by increasing nutritional intakes.

Premature infants on PN receive glucose at a continuous infusion rate and may thus often have plasma glucose concentrations higher than 6.6 mmol/L. A plasma glucose concentration up to 10 mmol/L (180 mg/dL) is usually well tolerated, but as mentioned earlier, higher concentrations are associated with increased mortality and morbidity [73, 74]. Moreover, hyperglycemia-induced glucosuria may cause osmotic diuresis, dehydration, and plasma hyperosmolarity [79, 80]. When faced with hyperglycemia, various contributing factors should be evaluated and properly addressed (i.e., high glucose and energy intakes, hypophosphatemia, stress, sepsis, pain, dehydration, ongoing intraventricular hemorrhage, and steroid treatment). Increasing AA intakes or the protein to energy ratio may contribute to improved glucose tolerance [65], but often total glucose intake needs to be reduced (10–15%) for a transient period of time. If blood glucose levels persist >10 mmol/L despite reasonable adaptation of the glucose infusion rate, insulin therapy is recommended [36]. Insulin may be initiated at a dosage between 0.02 and 0.05 IU/kg/h, but careful monitoring and appropriate adjustments are needed to avoid hypoglycemia [1, 80]. If not critically ill, adequate protein and energy intakes should be maintained to avoid nutritional deficits resulting in postnatal growth restriction.

Recommendations for Glucose Supply

It is recommended to start intravenous infusion of glucose at 4–5.5 mg/kg/min (6–8 g/kg/d) as soon as possible after birth to avoid hypoglycemia in very preterm infants or in infants at high risk of hypoglycemia (severe growth restriction, maternal diabetes) [36]. During the transitional period, intakes may gradually be increased up to 11.5–14.4 g/kg/day (8.0–10.0 mg/kg/min) according to tolerance, in order to provide adequate energy intakes (Table 7.1). The maximum glucose intake should not exceed the maximum glucose oxidation rate (12 mg/kg/min) or more than 60–75% of nonprotein energy intakes.

Lipids

Intravenous Lipid Emulsions

Intravenous lipid emulsions (IVLE) are important constituents of PN because lipids are high-density energy substrates, important building blocks for cellular components, and provide the essential polyunsaturated fatty acids (PUFAs), linoleic acid (omega-6), and α-linolenic acid (omega-3) [81, 82]. Linoleic acid is converted to arachidonic acid (ARA) and linoleic acid to docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). ARA and DHA account for ~25% of the total fatty acids of the brain, predominantly as structural components of neural cellular membranes [83]. Since preterm infants have low endogenous capacity for conversion of linoleic acid to ARA and alpha-linolenic acid to DHA and EPA [84], and these fatty acids accumulate rapidly during the last trimester and in early life, that is, the period of brain growth spurt [81, 84, 85], ARA and DHA are considered conditional essential for preterm infants. AA, DHA, and EPA are also precursors of prostaglandins and bioactive eicosanoids (lipoxins, resolvins, protectins, and maresins) that hold pro- and anti-inflammatory properties [82, 86].

Current commercially available IVLE are shown in Table 7.2. These IVLE differ by the source of their fatty acids (soy, safflower, coconut, olive, and/or fish oil) and their composition, tocopherol (vitamin E) and phytosterol content (Table 7.2) [87]. The conventional soybean oil-based IVLE has a high content of phytosterols and PUFAs (predominantly linoleic acid), which are considered to contribute to intestinal failure/PN associated liver disease (IF/PNALD) and to sustain inflammation.

The fatty acid composition of the newer IVLE have been developed to improve lipid clearance, reduce lipid peroxidation, and provide fatty acids that are either more immunological inert or evoke anti-inflammatory mechanisms [86]. Since very preterm infants are at risk of inflammation related neonatal comorbidities, there has been strong expectations for beneficial effects with newer IVLE. However, studies with composite IVLE are inconsistent in regard to their effects in reducing major preterm morbidities. The most

recent updated Cochrane review on IVLE for preterm infants, which included 29 studies and 2037 infants, did not find that any IVLE was more beneficial than any other for prevention of PNALD/cholestasis, growth, mortality, or any other neonatal outcome [88]. In patients with surgical conditions or established cholestasis, there was insufficient evidence to determine with any certainty whether fish-oil containing LEs offer any advantage in prevention or resolution of cholestasis or other clinical outcomes. Further research is needed to determine the advantages of IVLE with fish oil compared to other mixed IVLE, and to determine the safety of providing an unbalanced ratio of DHA (and EPA) to ARA in premature infants [89–92]. Meanwhile, due to the less balanced nutrition provided by pure soybean oil IVLE, it is recommended to use composite IVLEs with or without fish oil for PN lasting longer than a few days [35]. In cases of intestinal failure or PN associated liver disease, a reduction of IVLE dosage and/or the use of a fish-oil containing IVLE should be considered along with other measures to reduce common risk factors of liver disease.

Postnatal Lipid Metabolism

Lipid oxidation depends on lipid intakes, energy intakes, and energy needs for metabolism. During PN, lipid oxidation is inversely related to glucose intakes [75, 93]. If glucose is provided at a rate higher than the maximum glucose oxidation rate, oxidation of fatty acids ceases and glucose is converted to fat. Respiratory load and carbon dioxide production may be lowered when a part of energy intakes is provided by IVLE instead of a high proportion of glucose. Maximum lipid oxidation in neonates usually occurs when IVLE intakes provide 40% of nonprotein energy intakes, corresponding to 1 g of lipid for 3.6 g of glucose. Additionally, it has been suggested that nitrogen retention could be improved by adding IVLE to PN [31].

IVLE can be used from the first days of life and should be provided as an integral part of PN [35, 94, 95]. Since IVLE are isotonic they also reduce the osmolarity of the PN solution, making them more suitable for infusion in peripheral veins [31]. Continuous lipid infusion is generally preferred in neonates, but assessment of plasma triglyceride levels need to be monitored to avoid hyperlipidemia, particularly in small for gestational age (SGA) infants, and in neonates with high lipid intakes, hyperglycemia, sepsis, hypoxemia, or severe hyperbilirubinemia. Even if there are some controversies about the level of maximal plasma triglycerides tolerance in premature infants, there is general consensus that lipid intakes should be reduced when plasma triglycerides concentrations exceed 3.0 mmol/L (265 mg/dL) during continuous IVLE infusion [35]. However, since excess glucose intake may cause hypertriglyceridemia, glucose load should be considered before adjustments in lipid intakes are undertaken.

The use of carnitine supplementation during PN in premature infants is controversial. Carnitine is necessary for the transport of long-chain fatty acids across the mitochondrial membranes before fatty acids are utilized by beta-oxidization [35]. Carnitine is not routinely included in commercial PN solutions, and it has been demonstrated that in parenterally fed infants, plasma and tissue carnitine levels decline with postnatal age, suggestive of insufficient carnitine intake [96]. However, beneficial effects of parenteral carnitine supplementation on clinical outcomes are inconsistent and current recommendation is to consider carnitine supplementation on an individual basis (10–20 mg/kg/d) [35].

Recommendations for Lipid Supply

Lipid intakes during PN should represent 25–40% of nonprotein energy intakes in order to promote lipid oxidation and to reduce lipid deposition in fat mass. Current recommendations encourage the provision of IVLE as soon as possible after birth in all premature infants at a dosage of 1–2 g/kg/day. This dosage ensures sufficient provision of the essential fatty acids linoleic and α-linolenic acid. During the transitional postnatal period, IVLE can further be increased by 0.5–1 g/kg/day up to 3–4 g/kg/day according to metabolic tolerance (Table 7.1).

Fluids and Electrolytes

Postnatal Fluid and Electrolytes Metabolism

Birth is associated with major changes in water and sodium homeostasis. During the early transition phase, a physiologic contraction of extracellular fluid (ECF) volume takes place, and a net water and sodium loss is wanted – resulting in the "postnatal physiological weight loss of the newborn" [37, 97]. Due to renal immaturity, fluid and electrolyte disturbances are frequently observed in very preterm infants during this period.

Several mechanisms are responsible for the impaired water and sodium homeostasis in very preterm infants, including reduced glomerular filtration rate (GFR) and immature tubules [37, 98–100]. Compared to term infants, premature infants have higher transepidermal and insensible water losses. When these water losses are not anticipated or inadequately corrected for, the infants are put at risk of volume depletion and hypernatremia because the immature kidney has limited urine concentration ability [98–100]. In addition to reduced urine concentration ability, the preterm newborn infant also has limited ability to excrete an enhanced

water and sodium load. Following birth, developmental changes in glomerular function and tubular sodium handling occur that are mostly dependent upon gestational age. Indeed, postnatal maturation of GFR is less marked in the most premature infants compared with term infants, and GFR can be impaired by several factors and clinical conditions during the adaptation to extrauterine life [100].

High and low, but also large fluctuations in sodium concentrations have been associated with increased morbidity and mortality, including compromised cardio-respiratory functions and adverse developmental outcomes in preterm infants [101–106]. Altered sodium concentrations may be due to dehydration (weight loss above 10%) combined with or without inadvertent high sodium intakes, excessive water intake, or sodium retention [103–105]. To reduce the risk of patent ductus arteriosus, bronchopulmonary dysplasia, necrotizing enterocolitis, intraventricular hemorrhage, and long-term adverse outcomes a careful restriction of water is recommended, ensuring that physiological needs are met while avoiding dehydration [37, 107].

Chloride homeostasis also needs attention in premature infants because imbalanced sodium, potassium, and chloride intakes may promote metabolic acidosis or alkalosis [37]. Chloride requirements are generally considered similar to sodium requirements, but urine chloride excretion does not always parallel sodium excretion and chloride overload may affect acid-base status [108]. As for sodium, hidden or inadvertent chloride intakes are frequent because chloride is commonly combined with other nutrients, such as sodium, potassium, calcium, and AA, or with drugs like dopamine and dobutamine [108]. Excessive chloride intake increases acid load, and may result in metabolic acidosis. Thus, limiting chloride intakes and providing sodium and potassium intakes as organic phosphate or as sodium or potassium acetate/citrate in PN preparation might prevent hyperchloridemic metabolic acidosis [109–111].

Non-oliguric hyperkalemia (NHHK) in preterm neonates is defined as a plasma potassium level >6.5 mmol/L in the absence of acute renal failure [112]. Factors responsible for NOHK during the first week of life have extensively been described elsewhere [113, 114]. Other causes of early hyperkalemia may be birth traumas with hematomas/hemolysis, intracerebral hemorrhage, hypoxia, acidosis, or acute kidney injury [114].

Recent advances in neonatal medicine, such as widespread prenatal steroid use and early initiation of PN, have modified the course of postnatal fluid and electrolytes homeostasis [115–117]. By also reducing insensible water losses and optimizing early AA and energy intakes, it is possible to limit postnatal weight loss to 6–7% and to regain BW after 7 days on average in very preterm infants [19, 21, 56]. Such strategies have also improved the electrolyte homeostasis during the first 2 weeks of life. In particular, they have decreased dramatically the incidence of hypernatremia and NOHK [69, 109, 115]. Amino acid intakes ranging from 1.5 to 2.5 g/kg/day and given early after birth reduces catabolism and enhances the utilization of potassium [116]. If potassium and phosphate are not provided in sufficient amounts during the first days of life, early enhanced nutritional practices with sustained anabolic growth might put extremely preterm infants at risk of a refeeding like syndrome characterized by hypokalemia and hypophosphatemia [69–71]. Other causes of hypokalemia may be excessive gastrointestinal or renal losses, for instance, due to medications such as diuretics.

Postnatal Fluid and Electrolytes Monitoring

Rigorous monitoring of fluid and electrolyte homeostasis is required during the first week of life, especially in immature infants with high insensible water losses. Fluid and electrolyte balance should be assessed every 6–12 h during the first days of life by monitoring intakes, urinary output, body weight, plasma sodium concentration, and if needed acid-base status. Prevention of excessive insensible water losses is essential to maintain fluid and electrolyte homeostasis. Insensible water losses can be estimated by subtracting the weight change and the urinary output from the total fluid intakes. Additionally, excessive urine output (>5 mL/kg/h) may need to be replaced to avoid dehydration and hypernatremia. Excessive sodium and chloride intakes from medications should be controlled to avoid sodium and chloride overload. In very preterm infants, urine sodium fractional excretion is high during the first 1–2 weeks of life due to immature kidney functions. With improved tubular maturation (after the 1–2 second week of life), regular assessments of plasma and urine electrolyte concentrations may be helpful to adjust intakes.

Recommendations for Fluid and Electrolytes Supply

Current recommendations are to start with 60–80 mL/kg/day in older preterm infants or in infants with RDS and 80–100 mL/kg/day in more immature infants. To decrease transepidermal water losses, very premature and extremely premature infants should be kept within a double wall incubator and high-humidity environment [37]. Fluid supply should be increased progressively with careful monitoring of hydration status, allowing for a daily weight loss of 2–4%, with a final weight loss not exceeding 10%. A target fluid intake of between 140 and 160 mL/kg/day is estimated to maintain adequate fluid and electrolyte homeostasis and an appropriate weight gain (Table 7.1).

Sodium intake during the period of ECF contraction should be reduced to a minimum, allowing for a negative net sodium balance during the first 48 postnatal hours, until a weight loss of approximately 4–5% has occurred. Thereafter, intakes should be increased up to 3–5 mmol/kg/day (up to 7 mmol/kg/day in more immature infants). In clinical practice it is very difficult to completely avoid sodium administration on the 2 first days of life, as sodium is provided by other intakes (phosphate, and also other drugs). So the real challenge for the prescribing physician is to reduce as much as possible all inadvertent sodium intakes during the first 2 days of life.

Similar as for sodium, chloride should be supplied with caution during the period of ECF compartment contraction to allow for a negative chloride balance. Thereafter, 3–5 mmol/kg/day of chloride should be administered assuming the maintenance of a positive difference of 1–2 mmol/kg/day between the sum of sodium and potassium intakes and chloride intakes (Na + K–Cl = 1–2 mmol/kg/day). The use of sodium and/or potassium acetate or lactate (1–2 mmol/kg/day) instead of chloride in PN is helpful to prevent hyperchloridemia and metabolic acidosis (Table 7.1).

For potassium, an initial intake of around 1 mmol/kg/day is currently recommended on the first day of life to match higher protein and energy intakes from birth, providing that urine output is ascertained. Thereafter, intakes should be increased up to 2–3 mmol/kg/day in order to meet requirements for growth (Table 7.1).

Minerals: Calcium, Phosphorus, and Magnesium

Postnatal Mineral Metabolism

Fetal retention of calcium (Ca) and phosphorus (P) is dependent of growth and thus high during the last trimester of gestation. Estimating an average weight gain of 17 g/kg/d, the average Ca accretion is 3.4 mmol/kg/day and P accretion 2.6 mmol/kg/day [41]. Due to the interruption of placental transfer at birth and the high metabolic demand, a decrease in blood minerals concentrations may rapidly occur. In particular, it is well known that hypocalcemia may develop during the first days of life due to the relative immaturity of hormonal control (delayed parathyroid hormone increase) [1].

In addition to its implication in bone metabolism, phosphorus plays a critical role in energy metabolism. Hence, severe deficiency may induce several clinical disorders including muscle weakness, delay in weaning from respiratory support, glucose intolerance, and nosocomial infections [69, 70, 118, 119]. Extremely preterm or dysmature infants are particularly at risk for early hypophosphatemia due to their limited/depleted mineral stores and their very high growth rates. It has been shown that severe hypophosphatemia is potentiated by optimized AA intakes, warranting sufficient early supplies [69–71].

Reference values for hypophosphatemia differ between adults (1.0 mmol/L, 3 mg/dL) and preterm infants (1.6 mmol/L, 5 mg/dL) [1]. If laboratories use adult reference of plasma phosphate concentration, the diagnosis of hypophosphatemia may be easily missed with the risk of hypercalcemia, hypercalciuria, osteopenia, and nephrocalcinosis [120].

Optimal calcium to phosphorus ratio differs in parenteral and enteral nutrition due to the bypass of the gastrointestinal tract with PN, making Ca and P directly available for bone deposition [41]. Phosphorus retention is related not only to bone mineralization with a 1.7 calcium to phosphorus ratio (mmol/mmol) but also to lean body mass (LBM) accretion with the deposition of nearly 0.3 mmol (10 mg) of phosphorus for 1 g of protein accretion [120]. This needs to be taken into consideration when PN is initiated after birth. The recommended calcium to phosphorus ratio during PN is estimated to be between 0.8 and 1.0 (1–1.3 w/w) [41].

Fetal magnesium accretion is 0.12–0.20 mmol/kg/day (2.9–4.8 mg/kg/day), lower than that of calcium and phosphorous. The optimal magnesium requirements are not well defined for preterm infants on PN, and little attention is generally focused on postnatal magnesium homeostasis in neonates unless hypomagnesemia below 0.66 mmol/L (1.6 mg/dL) occurs in association with persistent and refractory hypocalcemia. Like for phosphorus, reference values of serum magnesium provided by laboratories are frequently the adult reference values (0.6–1.0 mmol/L). Studies in premature infants during the first 2 weeks of life show that their reference values are between 0.76 and 1.44 mmol/L, significantly higher than the adult reference range [121]. These studies also suggest that plasma magnesium concentrations are related to magnesium intakes, BW, and GA. Of note, magnesium concentrations are increased in cases of relative renal failure and in infants of mothers that have received magnesium sulfate before delivery. Antenatal magnesium sulfate administration is recommended in very preterm infants for the prevention of intraventricular hemorrhage [122–124]. In those infants, the postnatal magnesium concentrations are frequently between 1.4 and 1.8 mmol/L.

Minerals Sources

In contrast to enteral nutrition [41], calcium and phosphorus in PN are directly available for metabolism. Calcium may be provided in the form of calcium gluconate, calcium chloride, or calcium glycerophosphate. Calcium gluconate from glass containers should be avoided due to the risk of aluminum

contamination [125–127]. Calcium chloride is easy to use but its high chloride content needs to be considered in the electrolytes balance of the PN solution. Calcium glycerophosphate is not registered for use in PN, but may be prescribed from powdered anhydrous calcium glycerophosphate and reduces the risk of calcium-phosphate precipitations [1].

Phosphorus may be provided in the form of inorganic (sodium and potassium phosphate) or organic salts (glucose 1 phosphate, fructose 1–6 diphosphate, sodium glycerophosphate). Thus, phosphorus intake is also associated with sodium or potassium intake. Inorganic potassium phosphate induces a risk of precipitation that limits its use in PN. Organic phosphorus salts and especially disodium glucose-1-phosphate are widely used in PN solutions. However, their sodium content limits their utilization for premature infants, especially during the first days of life. To reduce sodium load and improve potassium intake during the early transition phase, the use of potassium salts over sodium salts should be considered.

Magnesium is generally provided as magnesium sulfate because magnesium chloride could induce anionic–cationic imbalance with the risk of metabolic acidosis.

Recommendation for Mineral Supply

Immediately after birth and during the first days of life, calcium supplementation should be given for preventing and treating early hypocalcemia. Early phosphorus administration is required to prevent severe hypophosphataemia, especially in SGA infants and very preterm infants receiving optimized AA and energy intake. In preterm infants exposed to antenatal magnesium sulfate, Mg intake should be adapted to postnatal blood concentrations.

In growing preterm infants on PN, the goal of mineral supply is to ensure optimal weight gain/growth and bone mineralization. Theoretical models of mineral accretion and average fetal weight gain have been used to estimate phosphorus and calcium requirements in parenterally fed preterm infants [41, 109]. Based on the most recent data in preterm infants receiving optimized PN, and in line with recent ESPGHAN guidelines, we recommend providing 0.8–2 mmol/kg/day of calcium (30–80 mg/kg/day), 1.0–2.0 mmol/kg/day of phosphorus (31–62 mg/kg/day), and 0.1–0.2 mmol/kg/day of magnesium (2.5–5.0 mg/kg/day) during the first days of life. Afterwards, intakes should increase progressively along with increases in macronutrients up to 1.6–3.5 mmol/kg/day for calcium (100–140 mg/kg/day) and phosphorus (77–108 mg/kg/day) and 0.2–0.3 mmol/kg/day for magnesium (5–7.5 mg/kg/day) (Table 7.1). In order to optimize the adequacy of mineral intakes in preterm infants on PN, regular monitoring of serum calcium, phosphate, magnesium, and alkaline phosphatase concentrations and urinary calcium and phosphate concentrations is recommended. The prevention of metabolic bone disease should be further assessed by periodic monitoring of vitamin D and may require bone mineral density assessment by appropriate techniques (e.g., Dual-energy X-ray absorptiometry).

Trace Elements

Trace elements are essential micronutrients involved in many metabolic processes. Their needs in premature infants during PN are not well defined, but Table 7.3 summarizes recent recommendations [40]. Micronutrient deficits are rare with current preparations of trace elements, except for zinc, which usually requires supplements, even during short-term PN. Zinc is required for the activity of a number of proteins, and it has a crucial role in maintaining quaternary structure stability of proteins and it participates in the regulation of gene expression, cell division, and growth [128]. Consequently, during anabolic processes resulting in higher protein synthesis, particularly after birth, the requirements of zinc increase. One recent study from Terrin et al. [129] has shown that in parenterally fed preterm infants zinc levels decrease from birth to day 28 of life and that there is a significant negative correlation between zinc levels and energy and protein intakes received during the first week of life. Zinc status should be periodically monitored in VLBW and ELBW infants on long-term PN and more often in those with high gastrointestinal fluid output (usually ileostomy losses), as they may have significantly higher zinc requirements.

In general, plasma levels of trace elements should be monitored during long-term PN (>4 weeks). Chromium and manganese frequently contaminates PN solution during preparation and additional supplementation is rarely necessary [130]. Excessive intakes are rare with current neonatal preparations, but in the case of cholestatic liver disease, copper and manganese toxicity may occur.

Table 7.3 Reasonable trace elements intakes for premature infants on parenteral nutrition

Iron	100–250 μg/kg/day
Zinc[a]	400–500 μg/kg/day
Copper[b]	40 μg/kg/day
Selenium	7 μg/kg/day
Chromium[c]	0.2 μg/kg/day
Molybdenum	1 μg/kg/day
Manganese[b]	0.5–1.0 μg/kg/day
Iodine	1–10 μg/kg/day

[a]Zinc to copper ratio should not exceed 20

[b]Copper and manganese intakes should be decreased in cholestatic liver disease

Commercial mixtures usually do not provide iron, but iron supplementation can usually be postponed during short-term PN (<3 weeks).

Vitamins

Vitamins are essential organic substances that humans cannot synthesize. Neonates have small vitamin stores and deficiencies may occur rapidly if not provided, especially in premature infants with high nutritional requirements and high metabolic rates. The optimal intake of vitamins for premature infants on PN is not well defined, and most studies were undertaken with commercial mixtures. Table 7.4 summarizes most recent recommendations [38].

There are few vitamin preparations designed for neonates on PN available on the market. They distinguish water-soluble and fat-soluble vitamins. Most pediatric vitamin formulations that are currently used in neonatal units are not designed for very preterm infants. Recent data suggest that additional intakes of fat-soluble vitamin A may provide some value for this patient population [38]. Additional vitamin E is however often not needed because the content of vitamin E is much higher in the newer composite LE than in soy-oil emulsions [38]. For premature infants, vitamin deficiencies are usually defined as below 200 µg/L for vitamin A and below 1 mg/dL for vitamin E, but for vitamin E a ratio below 0.8 mg/g of total lipid is also used. However, biological assessment of premature infant's vitamins status is only required in the case of long-term PN [38, 131].

Table 7.4 Reasonable vitamins supply for premature infants on parenteral nutrition

Water-soluble vitamins	
Thiamin (vitamin B1)	350–500 µg/kg/day
Riboflavin (vitamin B2)	150–200 µg/kg/day
Niacin	4–6.8 mg/kg/day
Pyridoxine (vitamin B6)	150–200 µg/kg/day
Folic acid	56 µg/kg/day
Cobalamin (vitamin B12)	0.3 µg/kg/day
Panthotenic acid	2.5 mg/kg/day
Biotin	5–8 µg/kg/day
Ascorbic acid (vitamin C)	15–25 mg/kg/day
Fat-soluble vitamins	
Vitamin A	700–1500 IU/kg/day
Vitamin D	80–400 IU/kg/day
Vitamin E[a]	2.8–3.5 IU/kg/day
Vitamin K[b]	10 µg/kg/day

1 mg niacin = 1 niacin equivalent (NE) = 60 mg tryptophan; 1 µg retinol equivalent = 3.33 IU vitamin A; 1 µg vitamin D (cholecalciferol) = 40 IU vitamin D (cholecalciferol); 1 mg tocopherol = 1 IU vitamin E

[a]Vitamin E need may be increased when using DHA and ARA parenterally

[b]0.5–1.0 mg vitamin K need to be given at birth

Fat-soluble vitamins are generally prepared in a 10% IVLE, whereas water-soluble vitamins are usually preserved as powder that needs to be dissolved by addition to IVLE, sterile water, or glucose solution. Several vitamins are light sensitive and need to be protected from light. Therefore, dilution of water- and fat-soluble vitamins in IVLE should be done to increase vitamin stability and to reduce peroxide load [38].

Individualized and Standardized PN Solutions

PN may be provided as separate infusions that merge at the infusion site (parallel infusions), as 2-in-1 solutions (carbohydrate, amino acids, and electrolytes) with the IVLE as a separate infusion, or with all components mixed in one bag (all-in-one solutions and 3-chamber bags). The development of ready-to-use industrially manufactured solutions, particularly multichamber bags, prolongs shelf life and minimizes the risks of inadvertent precipitations or contamination during compounding and storage [132].

Standard PN bags are formulated to meet the need of the majority of patients within an age or weight group, whereas individual tailored PN formulation are made to cover the specific requirements of an individual patient [29]. Both of these methods have advantages and disadvantages associated with their use. The main advantage of individualized solutions is that each solution is formulated for one individual patient and that they can be modified when the patient's nutritional needs and metabolic, electrolytes, or clinical status change. However, in premature infants, the clinical course may change rapidly, also necessitating adjustments of the individualized solution. The advantage of standardized solutions is that they include all the essential nutrients in fixed amounts, which eliminates the chances of inadvertent omissions or overload if they are used appropriately. Due to their lack of patient specificity some minimal adjustments are commonly needed, particularly during the first days of life.

Several studies suggest that the use of standardized ready-to-go PN solutions improve nutrition therapy in neonates [21, 22, 55, 56, 115, 133, 134], and standardized versus individualized PN is thus recommended for stable premature infants [29]. It is important to remember that vitamins and trace elements need to be added before administration, preferably by the pharmacy department.

Conclusion

Prematurity occurs during a critical period of development, and optimal nutritional support represents a major challenge for all healthcare providers involved in the nutritional care of

these infants. This chapter gives a comprehensive overview of nutrient requirements in preterm infants and provides an update on best practice recommendations.

Infectious Esophagitis

8

Salvatore Oliva, Sara Isoldi, and Salvatore Cucchiara

Introduction

Infectious esophagitis is relatively rare in an immunocompetent host and usually is an indicator of a primary or secondary immunodeficiency. In immunocompetent children, infectious esophagitis frequently is associated with conditions that compromise esophageal defense mechanisms [1–3]. The spectrum of esophageal infections has changed over the past few decades. Infectious esophagitis was rare before the advent of acquired immune deficiency syndrome (AIDS) and posttransplant immunosuppressive treatment regimens [1].

Though immunosuppression, in general, can result in infectious esophagitis, infections are most likely to occur in children with HIV infection, during chemoradiotherapy for hematologic malignancies and after solid organ and hematopoietic stem cell transplantation [3–7]. Infectious esophagitis has also been reported in 3% of patients with ataxia telangiectasia [8].

The risk of opportunistic infectious esophagitis in HIV is related to the CD4 count with patients noncompliant to highly active retroviral therapy (HAART) more likely to be infected [9]. Chemotherapy and radiation may predispose to esophageal infections due to the immunosuppression as well as the direct cytotoxic effects on the mucosal barrier. Hematological malignancies are more likely to be associated with infectious esophagitis than solid tumors, though the risk is attenuated with routine antimicrobial prophylaxis [10]. The risk of esophageal infections in bone marrow transplantation is higher in allogeneic than autologous transplants.

In an immunocompetent individual, impaired esophageal clearance of swallowed organisms may foster a permissive environment for the development of esophageal infections. These would include impaired saliva production, altered esophageal motility contributing to stasis, and gastric hypochlorhydria. Injury to the esophageal mucosa either from inflammation or endoscopic procedures may facilitate infection in certain instances [3, 4]. The most common cause of infectious esophagitis is Candida, which is a symbiont of the esophagus, but in case of impairment of host defenses, it can proliferate and develop adhesive plaques [11]. The second most common cause is cytomegalovirus (CMV), followed by human immunodeficiency virus (HIV), tuberculosis, varicella zoster virus (VZV), and human papilloma virus (HPV) [11].

Clinical Features

The clinical approach to evaluate a suspected infectious esophagitis is guided by the presence of any underlying immunosuppression, the presenting symptoms, and the physical findings. Pathologic gastroesophageal reflux is the most common cause of esophagitis in children. In previously healthy children, esophageal symptoms are likely to be caused by reflux esophagitis, whereas in immunocompromised patients, the physician needs to rule out infectious esophagitis. Secondary bacterial or fungal infections can be present in reflux esophagitis and Chagas disease, especially with severe inflammation and obstruction. Absence of reflux symptoms (long-standing heartburn, a water brash taste in the mouth, vomiting, spitting up in infants, pillow wetting, or coughing) does exclude reflux esophagitis. Achalasia, diffuse esophageal spasm, foreign body impaction, and mediastinal or retropharyngeal abscesses can cause esophageal symptoms and may result in secondary infection [2].

Patients with infectious esophagitis can present with esophageal, abdominal, or systemic symptoms; however, patients are often asymptomatic. Odynophagia and dysphagia are the most common symptoms of esophagitis, but they may not be apparent in small children [5]. In adults, only 59–79% of patients with documented infectious esophagitis

had these symptoms [4]. Odynophagia is usually indicative of underlying esophageal ulceration. The absolute CD4 count stratifies the risk of an opportunistic infection in HIV and coinfections may occur, especially with profound immunosuppression [12].

Diagnosis

Establishing a specific diagnosis is essential for managing of infectious esophagitis, particularly because fungal and bacterial superinfections occur commonly in viral esophagitis.

A key diagnostic challenge in infectious esophagitis is ascertaining the role of an isolated microorganism in disease causation as many purported pathogens are commensals that may be found even in healthy individuals [1]. Colonization of the oral cavity facilitates colonization of the esophagus following deglutition. Hence diagnosis of infection requires corroborative endoscopic and histological findings. The use of viral culture and polymerase chain reaction (PCR) may increase the diagnostic yield, however decreasing specificity partly due to contamination from latently infected cells. Serologic testing has little role in the evaluation of esophageal infection [1–3].

Esophagoscopy, Biopsy, and Brushing

The technique for performing endoscopy with videoendoscopes miniaturized to a diameter of 4.8 mm has made the procedure far more tolerable in immunocompromised patients, requiring less sedation and anesthesia and allowing the procedure to be performed even in newborns. These new instruments have biopsy capabilities comparable to older, wider endoscopes [2].

Characteristic macroscopic lesions are associated with some infectious agents. Macroscopic appearances overlap considerably, however, and histopathologic or immunohistochemical analysis (or both) of endoscopic and brush biopsy specimens is essential for diagnosis. Endoscopic biopsy specimens should be obtained from the edge and the base of the lesions. In CMV infection, specimens from the edge do not yield diagnostic information [13]. The pathologist should be alerted to the possibility of fungal, viral, and polymicrobial infections. Appropriate fixatives should be used for routine hematoxylin and eosin stain, Gram stain, and special stains for fungi and bacteria such as *Mycobacterium*. Immunohistochemical studies and DNA hybridization techniques often are required to establish the diagnosis [1].

Fungal Esophagitis

Candida

Candida is the most common cause of infective esophagitis [14], and immunosuppressed patients are prone to this infection. Candida esophagitis is common in HIV-infected patients, in whom it tends to occur when CD4 counts fall below 200 µl. Treatments with broad-spectrum antibiotics, acid-suppressive therapy, and inhaled corticosteroids are also risk factors [15–17]. In apparently immunocompetent individuals, predisposing medical conditions or risk factors are often identified [18]. The most common risk factors identified among studies are corticosteroids, antibiotics, and malignancy. Similarly, the use of proton pump inhibitors (PPI) has also been associated to the development of candida esophagitis; Hoversten et al. reported that PPI contributed to the development of infectious esophagitis in 63–81% of immunocompetent patients [19]. The causative organism is almost always *Candida albicans*, although other species are occasionally found [20]. Differentiation between different species is of clinical significance, as *glabrata* species usually exhibit azole resistance [11].

Patients present with dysphagia, odynophagia, and/or retrosternal chest pain. Esophageal candidiasis may be the initial presentation of disseminated disease in an immunocompromised patient. The majority of patients, particularly those who are immunocompromised, also have concomitant oropharyngeal candidiasis [20]. Nearly all patients with AIDS, oral candidiasis, and odynophagia have endoscopic evidence of esophageal candidiasis [5, 21, 22]. However, some of these patients ultimately proven to have esophagitis have no signs or symptoms at presentation. Children who develop esophageal candidiasis, despite being treated with HAART, are less likely to have typical symptoms (e.g., odynophagia and retrosternal pain) or to have concomitant oropharyngeal candidiasis [12]. Candida esophagitis can be distinguished into "acute infection," which is typical of severely immunocompromised patients and generally evolves into patient exitus; "subacute infection," which is generally related to complications such as esophageal pseudodiverticulum or stricture; and "chronic infection," which is typical of immunocompromised children [23].

A specific etiological diagnosis is established by endoscopy with or without biopsy or brushings. Endoscopy reveals the presence of characteristic confluent yellow-white plaques overlying and adherent to an erythematous mucosa. Remarkably, the presence of ulceration is unusual and should prompt further evaluation for an alternative etiology. Endoscopic findings without biopsy have been reported to

have a sensitivity and specificity of 100% and 83%, respectively, for a diagnosis of candida esophagitis [24].

The histological examination shows active esophagitis with budding spores and pseudohyphae within squamous debris, ulcer slough, and fibrino-purulent exudate. Invasion of mucosal and submucosal blood vessels is sometimes a prominent feature of invasive candidiasis [25]. *Candida* species are commensal organisms of the gastrointestinal tract and colonize the esophagus in about one-fifth of healthy adults, making histological evidence of fungal invasion into tissue or ulcer slough important [16]. Parakeratosis with neutrophils may call attention to the presence of *Candida*.

Brushings may be obtained and stained with Gomori silver or periodic acid-Schiff stains. Fungal culture is not performed routinely as it is generally not useful except in defining the species and drug sensitivities, especially in treatment resistant cases [25].

Candida can colonize preexisting ulcers or damaged mucosa of any etiology, and the pathologist should consider the possibility of dual pathology.

Expert consensus guidelines recommend systemic therapy with newer azole medications (fluconazole, itraconazole solution, or voriconazole) for esophageal candidiasis. Topical therapy may produce an initial response, but early treatment failures are common. Oral fluconazole 200–400 mg (3–6 mg/kg) daily for 14–21 days is recommended. If oral therapy cannot be tolerated, intravenous fluconazole 400 mg daily, amphotericin B, or an echinocandin, such as caspofungin, micafungin, or anidulafungin may be used [23, 26, 27]. Oral fluconazole and itraconazole suspension seem comparable in efficacy for initial therapy, and some patients whose disease fails to respond to fluconazole may see improvement with subsequent itraconazole therapy [28]. Although voriconazole has efficacy similar to that of fluconazole, it is associated with a higher rate of adverse events [29].

Other Causes of Fungal Esophagitis

Cases of esophagitis caused by *Aspergillus*, *Blastomyces*, *Cryptococcus*, and *Histoplasma* spp. have been described. Unlike Candida, these are not commensals and are acquired by significantly immunocompromised individuals from the environment. Primary infection of the esophagus is very unusual and has been described in immunocompromised patients. *Aspergillus* infection occurs as a result of contiguous spread from mediastinal infection [30, 31]. *Blastomyces* and *Histoplasma* infect the esophagus from a concomitant pulmonary infection or from disseminated infection [1]. Mediastinal fibrosis with esophageal obstruction and esophageal fistula may occur with histoplasmosis [31].

Optimal therapy has not been established, but systemic therapy, as for other manifestations of invasive infection with these organisms, has been successful. Currently, this approach would involve intravenous or oral azole agents or an amphotericin B preparation. Echinocandins (micafungin, caspofungin, or anidulafungin) may be useful for *Aspergillus* or *Histoplasma* infections, but they have no activity against cryptococci.

Viral Esophagitis

Herpes Simplex Virus

Herpes simplex virus (HSV) esophagitis is primarily a disease of immunocompromised patients and occurs most commonly in patients with solid organ and bone marrow transplants [32–34]. These patients may have life-threatening disseminated infection at the time of diagnosis [32]. It has also been reported in the setting of acute rejection [34]. In contrast to transplant recipients, it accounts for only 3–5% of esophagitis in HIV patients [35–37]. Most infections in immunocompromised patients probably represent viral reactivation as these patients have higher baseline seroprevalence rates. HSV esophagitis can occasionally occur in subjects with normal immune function, who usually have a self-limiting infection that resolves spontaneously within 1–2 weeks [38, 39].

Although the esophagus is the most frequent site of gastrointestinal involvement, HSV esophagitis is uncommon. The vast majority of documented cases are due to HSV-1, though HSV-2 esophagitis from heterosexual oro-genital contact in an immunocompetent patient has been described [40]. Interestingly, recent case reports and series report the association of eosinophilic esophagitis with HSV esophagitis, especially in the pediatric age population [41, 42]. However, the relationship between them has not been cleared yet.

Symptoms of HSV esophagitis are similar in both immunocompetent and immunocompromised patients. In the immunocompetent it is characterized by the acute onset of odynophagia, while 60–76% of patients exhibit retrosternal chest pain or heartburn [38, 43]. This may be associated with fever and systemic manifestations. Unlike in Candida, where oral disease is present in the majority of patients, coexisting herpes labialis and oropharyngeal ulcers are only seen in about one-fourth of patients [4, 38]. Symptoms may be more severe in immunocompromised patients with bleeding, per-

foration, tracheoesophageal fistula, and necrotizing esophagitis having been reported [44–46].

Endoscopic findings include nonspecific erosive esophagitis and discrete or coalescent superficial ulcers with an exudate. Vesicles that are the earliest manifestations are rarely seen. They coalesce to form ulcers often with normal intervening mucosa. Multiple esophageal ulcers are the commonest endoscopic finding seen in 59–86% of HSV patients, but these are nonspecific [38, 43]. The ulcers are usually small and discrete or occasionally confluent. The ulcers are "volcano-like" in appearance, in contrast to CMV ulcers which are linear or longitudinal and deeper. In addition to ulcers, friable mucosa and white exudates are commonly seen on endoscopy in HSV esophagitis. The distal esophagus is the commonest site of involvement; the entire esophagus may be involved in 15% of patients [38].

The diagnosis is usually based on a combination of histological findings and viral isolation from culture. Biopsies from the edge of the ulcers provide the highest diagnostic yield as the base of the ulcers often lack epithelial cells. Ulceration with neutrophils and an inflammatory exudate may be seen. Squamous cells may show viral cytopathic effects, including multinucleation, groundglass nuclei, and dense eosinophilic inclusions with a thickened nuclear membrane and a clear halo (Cowdry type A inclusion bodies). However, viral inclusions and multinucleated cells are not always identifiable in endoscopic biopsies [32] and may also be seen in other viral infections such as those caused by CMV and VZV. Aggregates of macrophages with convoluted nuclei have been identified adjacent to infected epithelium and may make the pathologist suspect herpes virus infection and prompt further investigation [47]. HSV isolation in the absence of histological findings is of questionable significance as it may represent asymptomatic viral shedding.

Acyclovir for 14–21 days has been advocated in the treatment of immunocompromised individuals with the use of intravenous preparations in those unable to swallow. In contrast to immunocompromised patients, HSV esophagitis in the immunocompetent is an indolent but usually self-limiting disease. The value of treatment with acyclovir is uncertain [43]. While case reports suggest therapeutic benefit in hastening illness resolution [39], the relative rarity of the condition precludes any randomized controlled trials, and spontaneous resolution usually occurs within 1–2 weeks. A search should be made for any underlying immunosuppressive illness in patients presenting with HSV esophagitis.

CMV

CMV is a significant pathogen in the immunocompromised subject, usually occurring in patients with AIDS [24], transplant recipients, malignancies, and those receiving immunosuppressive medications. These patients frequently have multiorgan involvement, while CMV infection is usually subclinical and asymptomatic in immunocompetent patients [48]. Indeed, serious symptomatic CMV esophagitis in immunocompetent patients is rare [49].

The most common gastrointestinal involvement in patients with CMV infection is colitis, followed by esophagitis [50].

Patients with CMV esophagitis clinically present with dysphagia, odynophagia, or nonspecific symptoms such as nausea, vomiting, abdominal pain, anorexia, and fever that reflect multiorgan or systemic involvement. Thrombocytopenia and leucopenia may be present but are not invariable.

Endoscopy may reveal variable findings from esophageal erosions to deep ulcers, located in the mid or distal esophagus with a halo of edema. In the setting of hematopoietic stem cell transplantation, they may be macroscopically confused with graft-versus-host disease. Stricture formation is relatively uncommon despite the occurrence of deep CMV ulceration [51].

Diagnosis needs a combination of histology and of demonstration of CMV in tissue specimens. The histological hallmark of CMV is the presence of cytomegalic cells on hematoxylin and eosin staining of mucosal biopsy. The infected cells are enlarged and contain Cowdry type A intranuclear inclusions with a surrounding halo ("owl's eye" inclusion bodies). The presence of "owl's eye" inclusions is highly specific, although not sensitive for the determination of CMV organ involvement. Hematoxylin and eosin staining have comparable sensitivity and specificity to immunohistochemical staining with monoclonal antibodies but at a lower cost [52]. Since CMV has a predilection for fibroblasts and not squamous epithelial cells, biopsies should be obtained from the base of ulcers. The use of CMV DNA PCR on mucosal biopsy specimens increases the detection of CMV, but only a fraction of these patients has typical histological changes [53]: noticeably, this increased yield with PCR may be due to contamination from latently infected cells. Likewise, the late CMV antigen assay has 89–100% sensitivity for CMV viremia but are not predictive for CMV disease [54, 55]. Conversely, CMV disease as detected on histology may be present even in the absence of CMV detection in the blood.

IV ganciclovir or foscarnet are first-line treatment for CMV disease. In patients with severe clinical symptoms and high risk of developing CMV esophagitis (CD4 count <50), treatment should be initiated before pathological confirmation. Oral valganciclovir has been shown to be non-inferior to IV ganciclovir for treating CMV in certain solid organ transplantation recipients [56]. However, IV ganciclovir is preferred in patients who do not tolerate oral treatment and those with life-threatening CMV disease. The use of foscar-

net has been limited by its nephrotoxicity. The role of maintenance treatment is not well defined. Reduction in immunosuppression should be individualized but considered in transplant recipients with CMV disease.

Other Viral Infections

VZV is rarely associated with esophagitis in severely immunocompromised patients. The typical cutaneous vesicular eruptions are usually present when esophagitis occurs. Esophageal VZV may be a harbinger of disseminated VZV [57]. The endoscopic appearance may be variable with vesicles and ulcers seen [58]. Esophago-bronchial fistula has been reported to occur in VZV infection in an AIDS patient [59]. Biopsies reveal ballooning degeneration, multinucleated giant cells, and intranuclear inclusion bodies similar to HSV, and viral culture is needed to distinguish the two viruses. Though VZV esophagitis is self-limited in immunocompetent patients, it is typically treated with acyclovir for routine and foscarnet for resistant cases.

HPV infection is generally associated to genital warts and cervical cancer. Endoscopic esophageal involvement include ulceration, hyperkeratosis, and papillomas [60]. Histology reveal the presence of koilocytosis, perinuclear clearing, and giant multinucleated cells [11]. HPV has been recognized as a risk factor of development of esophageal squamous papillomas, which are benign lesions of the esophagus [60]. Inconclusive data are available regarding the role of HPV in the development of esophageal squamous cell carcinoma [61]. A single treatment of liquid nitrogen cryotherapy has proven to be effective in treating diffuse esophageal papillomatosis [62].

Esophageal ulcerations have been very rarely reported in Epstein-Barr virus infection in both immunocompetent and immunocompromised patients [63]. The ulcers are deep, linear, and involve the mid-esophagus. Koilocytosis, epithelial thickening, and cell multinucleation are seen on biopsy. The number of patients is too small to draw any firm conclusion on treatment indications [64].

Bacterial Esophagitis

Bacterial infection is a rare cause of esophagitis. It typically occurs in immunocompromised hosts such as those with hematologic malignancies with neutropenia, bone marrow transplantation, diabetic ketoacidosis, and steroid therapy [65, 66]. It is usually polymicrobial and derived from oral flora (i.e., *Streptococcus viridians*, *Staphylococci*, and *Bacillus* spp). Esophagitis in frequently associated with bacteremia; hence, blood cultures always should be performed.

The diagnosis is made by demonstrating bacterial clusters on Gram stain with evidence of subepithelial bacterial invasion on endoscopic biopsies [67]. Treatment is with broad-spectrum antibiotics. Lack of response to appropriate therapy may indicate concomitant superinfection by other organisms or resistance to the drugs used. Repeat endoscopy is indicated for documenting eradication of infection.

Eosinophilic Esophagitis

9

Mason Nistel and Glenn T. Furuta

Introduction

During the last 20 years, an increasing number of clinical experiences and research studies identified the clinicopathological findings associated with children and adults who experienced unexplained feeding problems, recalcitrant gastroesophageal reflux disease (GERD) symptoms, dysphagia, and food impaction. These patients did not respond to GERD treatments and demonstrated distinct endoscopic abnormalities such as white exudates, furrows, and long segment narrowing, as well as dense esophageal mucosal eosinophilia that extended along the length of the esophagus. Other causes notwithstanding, these patients were found to have a chronic esophagitis of allergic etiology, and were responsive to elimination of dietary allergens or topically delivered steroids [1]. An increasing body of evidence demonstrates that the underlying etiology of these patients' symptoms, endoscopic findings, and eosinophilia are due to an overactive Th2 cytokine pathway [2]. Taken together, characterization and refinement of this constellation of findings led to the consensus diagnostic criteria defining eosinophilic esophagitis (EoE) as a chronic allergic inflammatory disease of the esophagus.

Historical Context

In the 1970s, use of endoscopy and mucosal biopsies in adults brought the initial link of esophageal eosinophilia with GERD. In 1993 and 1994, two studies provided comprehensive descriptions of adults with food impactions and/or dysphagia who were also found to have dense esophageal eosinophilia [3, 4]. Patients were distinct from those with GERD as they did not respond to acid blockade or had normal pH monitoring of the distal esophagus and were eventually termed to have eosinophilic esophagitis (originally EE but changed to EoE to eliminate confusion with erosive esophagitis). During the next decades, basic investigations identified an allergic pathogenesis, and clinical studies developed treatment algorithms using food eliminations and topical steroids [5–7].

Diagnostic Criteria

Between 2007 and 2019, collaborative efforts developed and revised the EoE diagnostic criteria four times [1, 8–10]. EoE is currently defined as a chronic, allergic, inflammatory esophageal disease characterized by symptoms of esophageal dysfunction and dense esophageal eosinophilia for which other causes have been ruled out. The 2007 consensus diagnostic guidelines were established by a multidisciplinary group of 31 physicians and defined EoE as a clinicopathologic disease of allergic nature thus distinguishing it from the more common GERD. At that time, diagnostic criteria required symptoms related to esophageal dysfunction such as dysphagia, food impaction, feeding intolerance/difficulties, and reflux, histologic findings of esophageal mucosal inflammation with >15 eosinophils/HPF, and a trial of proton pump inhibitors, a key element in ruling out GERD [8]. Updated consensus guidelines were published in 2011 that added chronicity to the definition, as well as inclusion of EoE pathogenesis via an immune/antigen mediated pathway in the setting of genetic predisposition. This position statement was the first to address a new phenotype of esophageal eosinophilia that responded to high-dose proton pump inhibitor (PPI), termed PPI-responsive esophageal eosinophilia (PPI-REE). Patients with PPI-REE exhibited symptoms of

esophageal dysfunction with pathology that demonstrated >15 eosinophils/HPF, normal pH monitoring, and remission on PPI therapy only [1]. In the 2013 consensus statement, the recommendation of 2–4 biopsies in both the proximal and distal esophagus was made along with a description of common EoE endoscopic findings (EREFS) [9]. Then, in 2018, the AGREE (*A* working *G*roup on proton pump inhibitor *R*esponsive *E*sophageal *E*osinophilia) meeting removed the PPI trial from the EoE diagnostic criteria, and suggested that patients with PPI-REE likely represented a subset of EoE [10]. This change was supported by similar RNA transcriptome data between patients with EoE and PPI-REE [11].

Other studies demonstrated that PPI-REE symptoms recurred upon discontinuation of PPI and subsequently responded effectively to dietary elimination therapy or topical steroids [12, 13]. The AGREE guidelines state that EoE cannot be definitively ruled out in patients who are on PPI at the time of endoscopy [10]. Current diagnostic criteria include symptoms of esophageal dysfunction including food impaction, dysphagia, food refusal, reflux symptoms, chest pain, and histologic findings of >15 eosinophils/HPF with exclusion of other causes of esophageal eosinophilia. Aside from EoE and GERD, other clinical causes of esophageal eosinophilia are rare and can often be distinguished by specific presentation or histology (Table 9.1). Providers should have heightened suspicion for EoE in patients with co-occurring atopic conditions such as asthma, eczema, food allergies, and family history of food impactions, esophageal dilation, EoE, or dysphagia. Except for diminished growth, no physical exam findings are pathognomonic of EoE [9].

Factors Complicating EoE Diagnosis

Multiple factors can complicate making a definitive diagnosis of EoE including treatment with systemic steroids or topical steroids for another indication (asthma, allergies) at the time of a diagnostic endoscopy, seasonality, inadequate mucosal sampling with too few biopsies, or biopsies obtained from a patient with longstanding mucosal inflammation. Given the frequent coexistence of asthma and other atopic conditions with EoE, clinical experiences identified that some patients with comorbid allergic diseases may be treated with systemic or topical corticosteroids that could partially reduce esophageal eosinophilia found at the time of a diagnostic biopsy [1]. Patients may present with features highly suspicious of EoE, such as recurrent food impactions, endoscopic findings or esophageal rings, or family history of unexplained esophageal strictures, but demonstrate mucosal eosinophilia less than the 15 eosinophil/HPF threshold. In this case, consideration, in association with the patient and family, should ensue regarding a limited medication trial to assess for symptomatic response and eventual repeat endoscopic assessment.

The seasonal timing of a mucosal biopsy may also influence mucosal eosinophilia. For instance, clinical studies have demonstrated that biopsies obtained in the fall and spring have increased esophageal eosinophilia compared to winter and summer, likely due to differences in pollen exposure. A retrospective analysis of 127 adults with EoE demonstrated seasonal variation in the frequency of EoE diagnosis that correlated with pollen levels [14]. Seasonality was also identified in a pediatric population through a retrospective review of 1,180 patients, 32 of whom were found to have definitive seasonal variation of their esophageal eosinophilia [15]. Thus, extent of eosinophilia in some patients may depend on the season, and the diagnosis could be missed if biopsies were obtained outside of an allergy season.

The diagnosis may also be missed because of the patchy nature of EoE and the resultant inadequate sampling of an affected area. Both adult and pediatric studies support obtaining mucosal biopsies in at least two different locations with a total of six samples in order to approach a sensitivity greater than 90% [16–18].

The natural history of EoE continues to evolve, but multiple studies indicate that a number of different phenotypes exist. An acute inflammatory pattern is well described in pediatrics to be exhibited by white exudates and linear furrows. In adult patients, the chronicity of the disease is demonstrated by the strictures and fibrosis [19, 20]. A prospective study of 70 adults included functional luminal-imaging probe (FLIP) evaluation during endoscopy to assess esophageal distensibility compared to level of epithelial eosinophilia and risk of food impaction. Patients with previous food impactions had significantly lower distensibility; however, no correlation to mean eosinophil density was found [21]. In this subset of patients with longstanding inflammation, biopsies may not meet the >15 eosinophil/HPF histologic threshold despite advanced symptomatic disease.

Clinical Presentation

Presenting Symptoms

Presenting symptoms of EoE vary based on age. Differences in reported symptoms may be due to the difficulty of younger patients to articulate their experiences. In the toddler age group, the most frequent symptoms are associated with GERD such as vomiting, regurgitation, as well as those related to feeding dysfunction or meal time problems [22]. Meal time behaviors may be nonspecific and include tantrums, spitting food out, poor appetite, and slow eating, all of which can be upsetting to families [22]. In addition to these symptoms, school age patients may also present with abdominal pain, reflux, and dysphagia [10, 23, 24].

Compensatory behaviors frequently develop and may be viewed as behavioral issues rather than as problems reflective of an underlying disease [22]. These behaviors are described with the acronym IMPACT: imbibe with meals, modify food (cutting into small pieces), prolong meal times, avoid hard textures, chew excessively, and turn away tablets/pills [25]. With these modifications, patients rarely progress to the point of frank failure to thrive or nutritional deficiency [22].

Adolescent and adult patients most commonly present with symptoms of dysphagia and food impaction and can also present with chest pain and heartburn [1]. Dysphagia may be described as the feeling that food is getting stuck or traveling slowly as well as gagging on food. Adult patients with EoE also can develop worsening of gastrointestinal symptoms with alcohol intake [26]. A novel syndrome found in some patients with EoE is referred to as food-induced immediate response of the esophagus (FIRE). This was recently described as an unpleasant or painful retrosternal sensation that occurs immediately and reproducibly after ingestion of a specific food or beverage [27]. Symptom latency is generally less than 5 minutes following the ingestion of the food and lasts less than 30 minutes with high symptom intensity. Patients clearly differentiate this phenomenon from EoE-related dysphagia or food impaction, and the most frequently implicated triggers include milk, wheat, nuts, fruits, wine, and beer. Rare presentation of EoE includes esophageal rupture or Boerhaave's syndrome [28].

Patients diagnosed with EoE have a high likelihood of concomitant atopic history [29]. A large retrospective analysis compared the risk of 7,722 EoE patients having atopic conditions to controls without EoE. Results were notable for risk ratios of 2.24, 2.19, 1.53, and 17.05 for allergic rhinitis, asthma, atopic dermatitis, and food allergies, respectively, in patients with EoE [30]. Similarly, a prospective study of 70 pediatric patients, 33 with EoE and 37 healthy controls, evaluated responses to methacholine challenge [31]. In the EoE cohort, 33% of patients had significant increase in airway hyperresponsiveness compared to 11% of controls. EoE occurs in patients with IgE-mediated food allergies at a rate of 4.7% compared to the lower rate in the general population of 0.4% [2].

Natural History

The natural history of EoE has yet to be defined, but several possibilities are proposed. A prospective study of 185 patients (88 children) identified 3 distinct EoE endotypes based on peak eosinophil count, a distinct set of genes identified in the EoE diagnostic panel (EDP), the EoE histologic scoring system (EoE-HSS), and the EoE endoscopic reference score (EREFS) [32]. Endotype 1 is the mildest and most steroid-sensitive. Endotype 2 has substantial inflammatory changes, demonstrates a Th-2 immune response, and is often steroid refractory. Endotype 3 is most common in adult-onset EoE, shows the lowest expression of epithelial differentiation genes, and the most severe esophageal narrowing, endoscopic, and histologic changes. Another consideration is that untreated EoE patients may progress from an acute inflammatory to a fibrotic pattern. During the acute stage, patients exhibit exudates and edema with reflux-like symptoms, whereas the fibrotic pattern is represented by strictures, dysphagia, and food impactions. A retrospective study of 379 children and adults with EoE determined that for each decade of life, the likelihood of developing a fibrostenotic phenotype more than doubled (OR 2.14) [33]. Similarly, in a retrospective review of 200 adult patients with EoE, a diagnostic delay of 0–2 years corresponded to a stricture prevalence of 17.8% compared to a diagnostic delay of >20 years which identified a stricture prevalence of >70.8% [20].

Endoscopic Findings

Esophageal endoscopic findings associated with EoE include loss of vascular pattern (LOVP), rings, white exudates, linear furrowing, strictures, and mucosal fragility or crepe paper esophagus, a finding defined by the creation of longitudinal rents following passage of the endoscope (Fig. 9.1 and Table 9.2). Each of these represent different inflammatory states [34]. For instance, LOVP and furrows reflect edema and exudates represent eosinophilic pus. In contrast, rings, strictures, and longitudinal rents likely reflect evidence of chronic inflammation. A 2012 meta-analysis of 4,678 adults and children showed that the most common endoscopic finding was linear furrowing (48%) followed by esophageal rings (44%) and LOVP (41%) [35]. When evaluated by age, rings and strictures were more prevalent in adults while chil-

dren present with significantly increased prevalence of white plaques (36%) and LOVP (58%). Importantly, 17% of cases appeared normal, emphasizing the necessity of obtaining mucosal biopsies when EoE is suspected regardless of mucosal appearance. Sensitivity, specificity, and positive predictive values of endoscopic signs are not presently sufficient for diagnosis; however, prevalence is high of at least one endoscopic finding in patients with EoE [35].

An endoscopic phenomenon referred to as the esophageal pull (tug) sign provides a strong independent predictor for diagnosis [36]. This sign is characterized by inability to completely close endoscopic biopsy forceps, prolonged tenting of the esophageal mucosa when the forceps is retrieved, and more force than usual needed to retrieve the forceps or the need of a "tug."

A validated EoE endoscopic scoring system called the EoE Reference Score (EREFS) uses the findings of exudates, rings, edema, furrows, and strictures to develop a numerical score [37]. EREFS is effective in providing valuable diagnostic information and monitoring in both adults and children. Validation of the score revealed good interobserver agreement of 71–81% for rings, furrows, exudates, and edema in addition to 79% and 92% for stricture and crepe paper esophagus, respectively [37]. A prospective pediatric study of 371 patients evaluated EREFS in 192 diagnostic endoscopies and 229 post-treatment endoscopies [38]. Outcomes of the study showed a strong correlation between composite EREFS score and the degree of eosinophilia and no significant correlations with individual endoscopic findings. The score was also able to differentiate newly diagnosed EoE patients from controls, and active EoE from inactive EoE.

Radiology

Several radiologic findings raise concern for the diagnosis of EoE including proximal esophageal narrowing, long segment narrowing, or prolonged retention of barium pill; however, there are no pathognomonic signs for EoE. Patients with a diagnosis of EoE may benefit from the use of contrast esophagram with barium pill to identify esophageal narrowing since occult strictures may be missed. In a retrospective study of 22 patients ranging in age from 2 to 20 years, 55% were found to have radiographic evidence of esophageal narrowing that had not been observed endoscopically [39]. Similarly, use of a barium-coated pill was shown to be of value in identifying occult narrowing in a retrospective study of three patients [40].

Histology

The histopathologic hallmark of EoE is dense esophageal eosinophilia with a diagnostic threshold of >15 eosinophils/HPF. The esophageal epithelium possesses characteristic features including thickening due to basal zone hyperplasia (normal is less than 3 cell layers), dilated intracellular spaces, and infiltration with other inflammatory cells including mast cells, T-cells, and B-cells (Table 9.3). Sampling of the lamina propria of the esophageal mucosa varies widely, but when obtained, it can appear fibrotic as defined by increased density of the collagen fibrils [41]. The EoE Histologic Scoring System (EoE-HSS) was developed to integrate elements of both eosinophilic and epithelial inflammation with grading (degree) and staging (extent) of each pattern [42]. Grade and stage scores are combined to create a composite score used to monitor therapeutic response.

Epidemiology

EoE incidence ranges from 2.1 to 12.8 cases per 100,000 people/year with pooled meta-analysis data reflecting a rate of 3.7/100,000 people/year (95% CI, 1.7–6.5) [43, 44]. Studies estimate EoE prevalence ranging from 2.3 to 90.7/100,000 people with pooled meta-analysis data reflecting prevalence of 22.7/100,000 (95% CI, 12.4–36) [43]. Prevalence is similar in Europe, North America, and Australia, but few studies have examined this in other countries. For instance, epidemiological data from other regions including Central/South America, Asia, and North Africa suggest that EoE is scarce [43].

A large retrospective study evaluated over 6,500 patients and found the male prevalence of EoE was twice that in females, and prevalence peaked in the 35–39-year age group with decreasing numbers after age 45 years [45]. Similar findings were reported with prevalence peaks during childhood and in the 30–40-year age group [9, 30].

Increased prevalence of EoE cannot be completely explained by increased recognition. Contributions from both genetic and environmental factors also play a role. For instance, several genetic variants include a single nucleotide polymorphism (SNP) in CCL26 which encodes eotaxin-3, downregulated epidermal barrier protein filaggrin, calpain 14 (CAPN14), and thymic stromal lymphopoietin (TSLP) [46]. Twin studies identified relative risk ratios for EoE within families ranging from 10 to 64 with higher values in male family members than female members [47]. EoE is passed on to 1.8–2.4% of relatives with 58% concordance among monozygotic twins and 36% concordance in dizygotic twins [47]. This higher-than-expected concordance among dizygotic twins further supports the role of environmental impact on EoE risk. Environmental factors that increase the risk of developing EoE include seasonality, lower population density, and early life events (prematurity, infection, antibiotic exposure) [47, 48]. In one study, breast feeding was associated with a decreased likelihood of developing EoE [47].

Table 9.3 Histologic findings associated with eosinophilic esophagitis

Peak eosinophil count >15/HPF
Epithelial basal zone hyperplasia: >15% of total epithelial thickness
Eosinophil abscesses: aggregate leading to epithelial architecture disruption
Eosinophil surface layering: rows of eosinophils in the upper one-third of epithelial layer
Dilated intracellular spaces with intercellular bridges
Lamina propria fibrosis/thickening
Surface epithelial alteration
Dyskeratotic epithelial cells

Collins et al. [128]

Clinical Associations with Esophageal Eosinophilia

At least four other clinical situations have been associated with the development of EoE or esophageal eosinophilia including *herpes simplex virus* (HSV) infection, oral or sublingual immunotherapy (OIT/SLIT), *Helicobacter pylori* infection, and celiac disease. Several case series document HSV infections preceding the development of EoE. For instance, in one study, 5 of 11 immunocompetent children with HSV esophagitis developed eosinophilic infiltration on follow-up esophageal biopsy [49]. Findings from this study and other case reports raise the question of whether HSV may be associated with EoE. An inverse relationship exists between *Helicobacter pylori* gastritis and the finding of esophageal eosinophilia [50]. This is curious given that *H. pylori* was definitively characterized in the 1980s, and the prevalence of infection has significantly decreased over a similar time course to the increased prevalence of EoE. Clinical observations have associated the use of SLIT or OIT with the frequent development of abdominal pain with subsequent endoscopic biopsies frequently demonstrating esophageal eosinophilia. To address this observation, 21 adults with IgE-mediated peanut allergy were evaluated with a baseline EGD prior to start of OIT [51]. The subjects had no GI symptoms but 5 were found to have >5 eosinophils/HPF and 3 had >15 eosinophils/HPF. Similarly, a meta-analysis in 2014 evaluating 711 patients demonstrated a rate of 3% that developed eosinophilia during immunotherapy course [52]. After discontinuation of OIT, symptoms and histology resolved in most cases. Whether this finding is a transient clinicopathologic finding or a chronic condition is yet to be determined.

Inherited connective tissue disorders have a predilection to develop various allergic phenotypes including EoE. Disorders such as Loeys-Dietz syndrome (LDS), Marfan syndrome, and Ehlers Danlos syndrome are caused by or associated with mutations in TGF-β. Implicated mutations result in increased protein levels of TGF-β which has been linked to the pathogenesis of EoE [53]. A retrospective study evaluated 58 patients with LDS (either heterozygous mutation TGF BR1 or TGF BR2) and found that 66% of patients reported GI complaints including poor growth, vomiting, abdominal pain, and dysphagia [54]. Ten of these patients had undergone upper endoscopy with 60% revealing histologic findings of EoE.

Esophageal eosinophilia can also be found in patients with celiac disease (CD). In a retrospective study, comparison of 421 patients with EoE and 763 patients with CD revealed that 3 children had both EoE and CD [55]. This corresponded with a 50- to 75-fold increased risk of each condition when diagnosed with the other. Treatment with gluten removal results in improvement in both conditions in 30–60% of patients [56].

Pathogenesis

EoE is a chronic inflammatory disease triggered by esophageal allergen exposure that leads to a cascade of events with increased Th2 cytokines, development of epithelial barrier dysfunction, and influx of inflammatory cells. Most often, this is triggered by food allergens, but recent evidence demonstrates the contribution by aeroallergens or other unknown stimuli [2, 14, 15]. In addition to basic studies identifying Th2 pathways, one of the strongest pieces of evidence supporting a food allergic cause is the remission induced by dietary elimination of proposed allergens [2].

Genetic Predisposition

A number of candidate genes increase susceptibility and subsequent development and progression of EoE. These include thymic stromal lymphopoietin (TSLP) on chromosome 5q22 and calpain 14 (CAPN14) on chromosome 2p23, as well as chromosome 1q21, the location of the epidermal differentiation complex which contains genes involved with squamous epithelial cell differentiation [2, 57]. One of the genes within this complex is filaggrin whose gene product is downregulated in EoE, thus leading to barrier dysfunction. Other contributing genes include STAT6 (Th2 adaptive immune response development and an intermediate for IL-4 and IL-13 signaling), EMSY (transcriptional regulation), and LRRC32 (a TGF-β binding protein) [2, 58, 59]. A study of 172 patient samples demonstrated a TSLP gain-of-function SNP found uniquely in EoE patient samples supporting this as a potential cause for increased disease risk compared to allergic controls [59]. This SNP was significantly increased in males with EoE compared to controls, but not in females suggesting one reason for increased EoE prevalence in males. Genome-wide association studies identified a dysregulated EoE transcriptome that is conserved in patients with EoE, but not found in patients with GERD [2, 6, 60]. The most highly expressed gene in the transcriptome is CCL26 which encodes eotaxin-3 with up to 53-fold increase compared to controls [6]. CCL26 is induced by IL-13 and is a critical mediator of eosinophilic inflammation. The importance of this gene in EoE pathophysiology is supported by an SNP in the CCL26 gene that portends increased disease susceptibility and in vivo murine models with eotaxin receptor (CCR3) deletions that provide protection from developing EoE [60]. Transcriptome analysis also revealed five mast cell genes that are highly induced in EoE supporting the role of this cell in disease pathogenesis [60]. Mast cells express the eotaxin receptor, CCR3, and thus their increased activity may be a result of elevated eotaxin-3 levels. Despite the discovery of multiple genetic susceptibility genes, the EoE disease concordance in dizygotic twins of 36% compared to nontwin siblings at 2.5% supports a complex interplay between genetic predisposition, environmental exposure, and epigenetics [47].

Inflammatory Cascade

Once esophageal epithelial cells are exposed to triggering antigens, TSLP transcription is upregulated via the Toll-like receptor 3 pathway (TLR3) leading to Th-2 adaptive immune response differentiation. Evidence for a Th-2 response in local dendritic cells is the increase in secretion of IL-4, IL-5, and IL-13 and upregulation of STAT6 downstream of the shared IL-4 and IL-13 receptor, IL-4Rα [2, 61]. IL-5 is a potent chemoattractant and activator of eosinophils; upregulation leads to eosinophil transmigration into the epithelium and increased eosinophil-derived granule protein deposition [2, 62]. Eosinophil granule products each have specific effects that may propagate EoE pathogenesis. Although not proven in EoE, eosinophil granule proteins are associated with a number of biological effects including the ability of major basic protein to disrupt epithelial barrier, eosinophil-derived cationic protein to increase cell membrane permeability, eosinophil-derived neurotoxin to potentiate the Th-2 response, and eosinophil peroxidase to induce local tissue injury [2, 46].

IL-13 also increases eosinophil chemotaxis and inflammation by two mechanisms. First, IL-13 can increase expression of eotaxin-3 via STAT6 leading to increased production of periostin, an independent facilitator of eosinophil

adhesion and recruitment [2, 46, 63]. Second, IL-13 can increase upregulation of CAPN14 that impairs esophageal epithelial barrier function by decreasing levels of the desmosome, desmoglein 1 (DSG1). CAPN14 also increases eosinophil chemotaxis and has direct effects on esophageal remodeling [58].

Barrier Dysregulation and Esophageal Remodeling

Esophageal inflammation and the EoE cytokine cascade can lead to development of impaired barrier function, likely due in part to downregulation of epidermal differentiation complex genes at 1q21 [64]. Impairment of the epithelial barrier occurs via IL-13 induction of CAPN14 which in turn decreases expression of desmosomal proteins DSG1 and filaggrin. DSG1 is one of the most downregulated genes in the mucosa of EoE patients, and diminished expression can result in increased intercellular spaces in the esophageal epithelium [57, 65]. Importantly, topical steroid treatment normalizes DSG1 protein levels [65]. Another implicated mediator of impaired barrier function is TGF-β. In vitro and ex vivo experiments have demonstrated that increased TGF-β decreases the epithelial tight junction molecule, claudin-7. Decreased claudin-7 allows for increased cell separation in the basal and suprabasal epithelial layers and resultant impaired barrier function [66]. Finally, eosinophil granule proteins can directly affect barrier function and raise the possibility of either initiating or perpetuating a response by allowing the passage of allergenic molecules [2, 65].

Esophageal remodeling is reflected by histologic changes including basal cell hyperplasia, dilated intracellular spaces, rete peg elongation, increased collagen deposition, fibrosis, and angiogenesis [2]. The etiology of underlying fibrosis in EoE is not certain, but a number of recent studies shed light on the potential role of TNF superfamily member 14 (LIGHT), elevated TGF-β through a functional SNP in the TGF-β gene, activation of TGF-β1 by Plasminogen activator inhibitor 1, and TGF-β-induced phospholamban expression [67–70]. These changes can lead to esophageal stiffening and/or dysmotility that increase the risk of dysphagia and food impactions [33, 71]. Two cell types, eosinophils and mast cells, are implicated in causing remodeling via increased levels of TGF-β. TGF-β potentiates esophageal remodeling via the SMAD signaling pathway (pSMAD2 and pSMAD3) [2, 63, 72]. This pathway upregulates fibrotic gene expression and leads to transformation of the resident fibroblast population to the contractile myofibroblast. Myofibroblasts can increase esophageal smooth muscle contraction with production of contractile proteins phospholamban and periostin. The EoE cascade may be cyclically potentiated by periostin that increases production of TSLP furthering the Th-2 pathway [65]. Successful treatment of EoE can decrease mast cells and TGF-β levels, thereby strengthening the hypothesis that mast cells are a large component in the pro-fibrotic changes and esophageal dysmotility observed in EoE [72].

Treatment

Current treatments for EoE include drugs, diet, and dilation [73]. A standardized definition for treatment response in EoE is lacking, but clinical trials currently use co-primary endpoints involving peak eosinophil counts and other histopathologic findings (see EoE-HSS) along with patient-reported symptoms. The overall goal of treatment includes improvement in symptoms, endoscopic and histologic findings, and normal growth and development [25].

Proton Pump Inhibitors

The AGREE consensus meeting of 2018 removed a PPI trial from diagnostic criteria for EoE and suggested that PPI-responsive esophageal eosinophilia (PPI-REE) is a likely subtype of EoE [10]. PPIs may have anti-inflammatory properties independent of acid blockade via blockade of the STAT6 transcription factor at the eotaxin-3 promotor [74–76]. This leads to the subsequent decrease of Th2 pathway eotaxin-3 secretion. Pre- and post-PPI treatment histopathology from 10 pediatric patients showed decreased expression of eotaxin-3 in the proximal esophagus and supported the hypothesis of acid-independent anti-inflammatory properties [74].

PPI therapy is effective for treating EoE demonstrated by a large meta-analysis of 618 patients (188 children) that showed clinical improvements in 61% of patients with histologic remission in 54% of children and in 50% of adults [77]. The reliability of PPI use to maintain remission continues to be studied. In a prospective study, 109 pediatric EoE patients were treated with high dose PPI therapy (1 mg/kg BID) for 8 weeks, and then responders were decreased to a maintenance regimen (1 mg/kg daily) for 12 months [78]. After the initial 8-week course, 66% of study participants were in histologic remission, and at follow-up endoscopy, a median of 14.5 months later, 70% of these patients remained in remission. Twelve of the subjects then had a dose decrease to 0.5 mg/kg daily for an additional 1 year with histologic remission maintained in 11 of 12.

One reason for variability in PPI responses may relate to PPI metabolism that can be divided into rapid, intermediate, and poor metabolizers. Phenotypes are dependent on CYP2C19 genotype, and the resultant plasma PPI levels and gastric pH levels are inversely proportional [79]. A retro-

spective cohort of 75 adult patients with initial PPI response were evaluated for long-term remission on PPI maintenance dosing in association with CYP2C19 genotyping [12]. Of the initial PPI responders, dosage was decreased to a lowest daily dose that maintained clinical remission with 45 patients receiving double dose (omeprazole 40 mg or equivalent) and 30 patients on single dose (omeprazole 20 mg or equivalent). Results of the follow-up endoscopies showed 55 patients with continued histologic remission and 20 that despite recurrence of esophageal eosinophilia remained asymptomatic. The only independent risk factors for patients with recurrence of esophageal eosinophilia were co-occurring rhinoconjunctivitis and patients with CYP2C19 rapid metabolizing genotype (leads to lower plasma PPI levels) showing an odds ratio (OR) of 12.5 and 8.6, respectively.

Adverse drug reactions associated with PPI use are rare, but the most common effects include nausea, abdominal pain, flatulence, headache, and diarrhea [80]. Additional adverse effects associated with longer term use have been described, both related and unrelated to acid inhibition [81].

Steroids

Systemic and topical corticosteroids induce clinical and pathological remission in EoE patients [82]. In 2008, a randomized clinical trial (RCT) compared systemic steroid and topical steroid therapies in 80 patients with EoE, and both had clinical and histologic improvement within 4 weeks, with minimal differences in efficacy [83]. Placebo-controlled trials using topical steroids including fluticasone propionate (FP) and oral viscous budesonide (OVB) have shown a 66% histopathologic improvement [84]. FP is dosed via a metered dose inhaler (MDI) inhaler, but instead of inhaling, the medication is puffed into the mouth and swallowed [85, 86]. OVB uses liquid budesonide mixed with Splenda or another thickening agent to increase viscosity for amplified contact time in coating the esophagus [87]. In a randomized study of 24 children, OVB induced a significant clinicopathological response compared to those treated with placebo [88]. A study comparing the efficacy of OVB and FP showed no significant difference in histologic remission at 71% and 64%, respectively [86]. Another topical steroid formulation used for EoE, ciclesonide, is delivered as a pro-drug that is converted to the active form des-CIC by esterases on the esophageal epithelial surface [89]. In one pilot study, ciclesonide led to clinicopathological remission, and in another, findings were less clear; further study is required to see if ciclesonide will offer continued benefit [90, 91].

All steroid medications raise concerns for systemic absorption and complications such as adrenal insufficiency, altered bone metabolism, and slowed linear growth, but these are uncommon with topical formulations. Comparison of systemic steroids with topical formulations showed 40% of the patients receiving systemic steroids developed weight gain, cushingoid features, and hyperphagia compared to none in the topical group [83]. The most common adverse drug reaction seen with topical steroid formulations is esophageal *Candida* infection with between 12% and 16% of patients effected [83, 86]. The rate of adrenal insufficiency in patients treated with topical corticosteroids varies between studies from 5% to 66% with the largest studies showing that adrenal insufficiency is unusual, and when it occurs, patients are generally also taking other topical steroid formulations for concomitant atopic conditions [92–96].

Elimination Diets

In the first therapeutic study using dietary elimination, an elemental diet induced a clinical and histological response and allergenic food addition led to disease reactivation [5]. This study, as well as others, showed the benefits of food elimination, but because of impact on quality of life and other factors, this may not be suitable for all [97, 98]. No testing platform is available to identify EoE-related food allergens reliably and thus an empiric approach remains the standard of care [98, 99].

Implementation of an empiric six-food elimination diet (SFED; excludes milk, soy, egg, wheat, peanuts/tree nuts, fish/shellfish) leads to a clinicopathological response rate of 72% [84]. This diet was first evaluated in a retrospective study from 2006 of 60 children receiving either SFED or elemental formula diet [98, 99]. Results of this study showed 74% histologic remission in SFED compared to 88% in the elemental formula diet. Wheat and milk have been found to be leading EoE causative antigens at 58% and 68%, respectively, but with significant heterogeneity between studies [98]. After empiric elimination, foods were added back every 6 weeks with repeat endoscopy in order to determine specific food triggers [99, 100].

Four food elimination diet (FFED; excludes milk, soy, egg, and wheat) is another dietary intervention with 64% achieving histologic remission, symptom remission in 34%, and symptom improvement in 91% [100]. Since milk is thought to be the most frequently implicated trigger in rechallenged patients, milk-only elimination has been compared to the FFED in a recent RCT [101]. Results showed equivalent histologic improvement, slightly lower symptomatic improvement in the milk-only group, but a significant improvement in the quality-of-life scores of milk-only elimination.

Recently, a step-up approach was proposed starting with the two most likely trigger foods, milk (all dairy) and gluten (stricter than just wheat to avoid cross-reactivity) [102]. This two-food elimination diet (TFED) led to histologic response

in 43% of participants. Those that did not respond were stepped up to the FFED. The step-up process helped limit the number of endoscopies required to find a food trigger by 20% during reintroduction. Limitations of elimination diets include potential reduction in quality of life and need for repeat endoscopic evaluation with the attendant costs and potential complications.

Allergy Medications

Medications used in other allergic conditions such as cromolyn, montelukast, and omalizumab are not effective in treating EoE. Lack of effect is likely because EoE is not an IgE-mediated allergic condition. In a retrospective study of 381 pediatric EoE patients, 14 were treated with cromolyn, a mast cell stabilizer, with no change in peak eosinophil count or symptom improvement [103]. Similarly, in an RCT of 41 adults that investigated maintenance of topical steroid induced remission, no symptomatic or histological differences were observed between montelukast, a leukotriene antagonist, and placebo [104]. The anti-IgE monoclonal antibody, omalizumab, has also been used in a small RCT of 30 adults and no difference in symptoms or eosinophil counts was reported [105].

Biologic Treatments

A number of clinical trials are studying novel biologic therapies that target various points in the EoE cytokine cascade.

Medications targeting IL-5 include IL-5 monoclonal antibodies mepolizumab and reslizumab and the IL-5Rα blocker benralizumab. Anti-IL-5 trials in both adults and pediatrics have shown reductions in mean eosinophil counts [106, 107]. However, in the adult study, no histologic remission (<15 eosinophils/HPF) was seen and only 8.8% of patients in the pediatric trial met the primary endpoint of <5 eosinophils/HPF with no difference in symptom improvement compared to placebo. A phase II RCT tested benralizumab in 20 patients with hypereosinophilic syndrome. Results showed both clinical and histologic efficacy as well as safety with no adverse events that limited treatment [108].

Several trials have studied both direct IL-13 blockade and IL-13 downregulation via IL-4Rα, the shared signaling intermediate between IL-13 and IL-4. The most promising has been the IL-4Rα blocker, dupilimab. In a phase II, placebo-controlled RCT with 47 patients, results showed significant improvement in symptoms, endoscopic and histologic findings, and a decrease in peak eosinophil count with 82.6% of patients below the threshold of <15 eosinophils/HPF compared to none in the placebo group [109]. Other trials have studied IL-13 monoclonal antibodies RPC4046 and QAX575 both of which have shown significant decrease in mean eosinophil counts compared to placebo. The RPC4046 study exhibited significant improvements in symptoms, EREFS score, and histology (EoE-HSS) with the most pronounced improvement found in steroid refractory patients [110]. The QAX575 study did not meet primary endpoint of 75% reduction in peak eosinophil count, and only demonstrated a trend toward decreased symptoms [111].

Other Medications

Multiple additional targets are under investigation including sialic acid binding Ig-like lectin 8 (Siglec-8), TSLP, integrins, and TGF-β. Siglec-8 is exclusively expressed by eosinophils and mast cells, and the Siglec-8 antibody (AK002) has preliminary data showing selective depletion of eosinophils and mast cells in blood and tissue [112]. An antibody directed toward TSLP, tezepelumab (AMG 157), is currently used in allergic asthma therapy but has not been studied in EoE [113]. Vedolizumab binds to integrin α4β7 and can decrease eosinophil recruitment in vitro. In a study of 5 patients with difficult-to-treat eosinophilic gastroenteritis, vedolizumab treatment led to a clinical and histologic improvement [114]. Finally, inhibition of TGF-β with the antihypertensive drug Losartan is currently under investigation [115].

Dilation

Esophageal dilation with either Maloney dilator (bougie) or through-the-scope (TTS) balloon dilation is an important component of EoE therapy that can improve dysphagia and reduce food impactions. Dilation does not reduce inflammation and should be combined with medical treatment or elimination diets to facilitate symptom improvement as well as histological remission [116].

Goals of treatment are to increase esophageal diameter to permit passage of food stuffs and limit food impactions. The desired outcome of dilation is symptomatic improvement of dysphagia and/or a mucosal tear or rent. The later finding indicates a stopping point and subsequent repeated dilations may be necessary [116, 117]. In adults, up to 95% of patients have improvement in symptoms after esophageal dilation with median duration of effect of 12 months [117]. Pediatric dilation studies are limited; however, a retrospective study evaluated 40 patients between 4 and 8 years of age with EoE who underwent 68 dilations [118]. The goal of initial dilation was 15 mm or the development of a deep rent. Study results showed an increase in pain, fever, or symptoms requiring evaluation in a clinic or emergency department compared to endoscopy without dilation, however no difference in adverse

event rate in dilated EoE patients compared to patients dilated for non-EoE indications.

The most common adverse event of dilation is pain. Perforation is unusual when dilations are performed sequentially [118]. In a 2017 meta-analysis of 845 EoE patients (87 pediatric patients), chest pain was the most common adverse event associated with dilation seen in up to 17% of cases [117]. Perforation in this study was rare occurring in 0.033% of procedures with only 1 reported transmural perforation. A prospective study of 105 patients who underwent 246 dilation procedures showed no difference in adverse events whether the dilation was performed with a bougie or a TTS balloon [119]. The only factor that significantly increased risk of adverse events was age with an increase of 12% for each additional year of life. When performed conservatively, dilation is a safe and effective component to EoE therapy, and the method of dilation should be guided by endoscopist experience and by type of stricture or narrowing present.

Maintenance Therapy

EoE is a chronic inflammatory illness which recurs after cessation of therapy [103]. Natural history studies show that untreated disease may progress to a fibrostenotic phenotype with esophageal narrowing and stricture [4, 19]. Because of the poor correlation between symptoms with endoscopic and histologic findings, and due to lack of clear consensus treatment goals (symptom improvement, endoscopic improvement, histologic remission, quality of life, etc.), expert opinion supports the use of a long-term anti-inflammatory regimen. Several studies have explored decreased dosing with surveillance of ongoing remission. One study found that decreasing PPI from BID to once daily maintained remission in 75–85% of patients [120]. Results are mixed on maintenance of remission with long-term topical steroids with one study showing that a decrease in daily fluticasone dosing from 1760 mcg to 880 mcg maintained remission in 73% of patients [85]. However, recent data from a retrospective study of 82 adult patients followed for a median of 2.2 years revealed a histologic relapse rate of 67% with no difference between high dose and low dose regimen (>0.5 mg or <0.5 mg daily dosing of budesonide respectively). In this study, high dose therapy did lead to longer time prior to histologic relapse [121]. Even less data are available to guide maintenance strategy for dietary elimination; however, studies consistently demonstrate continued remission in those that maintain elimination of trigger foods [122]. Recent data suggest that initially swallowed steroids are the most cost-effective choice, but long-term, elimination diets with determination of the food trigger may be the cheaper option [123].

Disease Monitoring

Once diagnosed with EoE, monitoring for resolution and/or recurrence of esophageal inflammation is important to detect ongoing inflammation that could lead to esophageal remodeling and fibrosis [33, 44]. Peripheral eosinophilia does not correlate accurately with esophageal eosinophil count or ongoing inflammation [124]. Monitoring may also be indicated with new symptom development or during re-exposure to eliminated food groups with dietary therapy. Sedated endoscopy is required for disease surveillance to obtain biopsies for assessment of disease. In some studies, endoscopy is performed 6 weeks after food reintroduction [102]. Outside of dietary therapy, no consensus guidelines exist on frequency of endoscopy.

Alternatives to sedated endoscopy include transnasal endoscopy (TNE) and others for monitoring EoE-related inflammation. A retrospective study published in 2019 of 294 TNEs completed in pediatric patients age 3–22 years demonstrated a 98% success rate with reduced cost and with no adverse events [125]. Biopsies obtained via this method had no difference in surface area of epithelial samples compared to previous EGD, and lamina propria was present in 35–40% (depending on size of forceps) compared to 49% with EGD samples. This study supports TNE as an alternative for certain patients. Other methods currently under investigation include the esophageal string test and the cytosponge. A recent prospective trial evaluated the esophageal string test in 134 participants with a 1-hour dwell time [124]. Results showed that eosinophil associated proteins (EAP) extracted from an esophageal string displayed strong correlation with EAP from endoscopically obtained biopsies and accurately identified active EoE, inactive EoE, and normal esophagus. Similarly, a prospective study of 80 adult patients who underwent 105 cytosponge procedures showed strong correlation with EGD biopsy ($r = 0.78$) and a sensitivity and specificity of 75% and 86%, respectively, in identifying inactive disease (<15 eosinophils/HPF) [126]. Recently, a novel EoE oral imaging agent, ^{99m}Technetium-labeled heparin, has been described that binds to major basic protein and can non-invasively evaluate and monitor EoE inflammation with single-photon emission CT (SPECT) [127]. A study involving five adult patients showed an ability to differentiate between patients with active eosinophilic inflammation, inactive EoE, or GERD with no adverse events.

Summary

Since the initial characterization in the 1990s of EoE as a discrete entity, great strides have been made in understanding the pathogenesis, diagnosis, and effective therapeutic

interventions. Endoscopic and histologic scoring systems, EREFS and EoE-HSS, now allow for more reliable measurement of disease activity and more consistent standardization for continuing natural history and treatment studies. The increasing incidence of EoE and the morbidity associated with untreated inflammation has led to a rapid push toward the development of disease-specific therapies both in the category of topical corticosteroids and more directed medications like monoclonal antibodies. Additionally, investigation is ongoing for less invasive testing and noninvasive biomarkers for disease surveillance. With the breakthroughs that have been made in the last 10 years and the current research in progress, it is likely that the diagnosis, treatment, and monitoring of EoE will continue to change rapidly in the near future.

Gastroesophageal Reflux

10

Yvan Vandenplas and Sébastien Kindt

Abbreviations

AAF	Amino acid formula
AR	Antireflux
BAL	Broncho-alveolar liquid
CM	Cow's milk
CMPA	Cow's milk protein allergy
eHF	Extensively hydrolyzed formula
ENT	Ear-nose-throat
GER(D)	Gastroesophageal reflux (disease)
H2 RA	H2 receptor antagonist
LES	Lower esophageal sphincter
LLM	Lipid-laden macrophages
NERD	Nonerosive reflux disease
PPI	Proton-pump inhibitor
TLESR	Transient lower esophageal sphincter relaxation

Introduction

The European and North American Societies of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN/NASPGHAN) published exhaustive consensus documents on the definition, diagnosis and management in 2009, which were updated in 2018 [1, 2]. There is a trend to diagnose gastroesophageal reflux disease (GERD) more frequently. Between 2000 and 2005, the diagnosis of GERD and acid-related conditions among infants more than tripled (from 3.4% to 12.3%) and increased by 30–50% in other age groups [3]. Whether this means a more appropriate diagnosis or a trend toward overdiagnosis is debatable.

Labeling an otherwise healthy infant as having a "disease" increases the parental interest in medicating their infant even when parents were told that medications are not effective [4]. These findings suggest that use of disease labels may promote overtreatment by causing people to believe that ineffective medications are both useful and necessary [4].

Definitions

Gastroesophageal reflux (GER) is the involuntary passage of gastric contents into the esophagus. GER is a normal physiological process occurring several times per day in every human, particularly after meals [5]. Most reflux episodes are of short duration, asymptomatic, and limited to the distal esophagus. Typically, a reflux episode is the consequence of a transient lower esophageal sphincter relaxation (TLESR), unrelated to prior swallowing. Physiologic GER is the consequence of increased abdominal pressure not accompanied by an increase of the LES pressure or when GER is associated with absence of symptoms, or during the first months of life accompanied with regurgitation, and occasionally with vomiting [2]. Healthy and sick individuals do not differ in the presence or absence of GER, but in the frequency, duration, and intensity of GER and in the association with symptoms or complications. Physiologic reflux becomes pathologic if esophageal clearance is insufficient, if acid buffering is insufficient, if gastric emptying is delayed, if abnormalities in epithelial restitution or repair occur, if there are anatomical abnormalities such as hiatal hernia, etc. Both in children and adults, GERD is defined as reflux causing troublesome symptoms and/or complications [2, 6]. GERD is reflux associated with esophageal and/or extra-esophageal symptoms impairing quality of life and/or mucosal damage. The vast majority of patients with GERD show no abnormalities on endoscopy or on histology from esophageal biopsies and suf-

fer nonerosive reflux disease (NERD). To be defined as GERD, reflux symptoms should be troublesome to the infant, child, or adolescent and not limited to the caregiver [2]. A major issue is the estimation of troublesome symptoms in young children because they cannot adequately report symptoms [5, 7]

Regurgitation, spitting up, posseting, and spilling are synonyms and are defined as the passage of refluxed gastric contents into the pharynx and above [2]. Regurgitation is mainly effortless, but may sometimes also be forceful. Even in infants, only a minority of the reflux episodes are accompanied by regurgitation. Regurgitation is a characteristic symptom of reflux in infants, but is neither necessary nor sufficient for a diagnosis of GERD, because regurgitation is not a sensitive nor a specific criterion [2, 5]. Up to 50% of all infants under the age of 4 months present at least one to several episodes of spilling per day [2, 8]. Regurgitation is distinguished from vomiting by the absence of a central nervous system emetic reflex, retrograde upper intestinal contractions, nausea, and retching. Vomiting is defined as an expulsion with force of the refluxed gastric contents from the mouth [2, 5]. Vomiting is a coordinated autonomic and voluntary motor response, causing forceful expulsion of gastric contents [2]. Vomiting associated with reflux is likely the result of the stimulation of pharyngeal sensory afferents by refluxed gastric contents. Bilious vomiting should not be diagnosed as GERD. Otherwise, healthy infants and children with reflux symptoms that are not troublesome and are without complications should not be diagnosed with GERD [1, 2]. In adults, heartburn or pyrosis is the most typical manifestation of GERD [6]. However, some adult patients complaining of heartburn do not have GERD, they have a syndrome called functional heartburn [9]. Since heartburn causes distress and pain, crying and distress in infants are often considered as the manifestation of heartburn in infants. However, there is no evidence to sustain this hypothesis [2, 10].

"Rumination" is characterized by a voluntary contraction of the abdominal muscles resulting in the habitual regurgitation of recently ingested food that is subsequently spitted up or reswallowed. Gagging, mouthing, and swallowing of refluxed material is identified as rumination [11].

Prevalence, Environmental and Genetic Factors

Determination of the exact prevalence of GER and GERD at any age is virtually impossible for many reasons: most reflux episodes are asymptomatic; symptoms and signs are nonspecific; and self-treatment is common. Alcohol, smoking, drugs, food components, excessive solid food and liquid intake, and overweight are GER-inducing variables. In adults, over-the-counter use of many medications such as aspirin and nonsteroidal anti-inflammatory drugs favor GER [12]. Race, sex, body mass index, and age are independently associated with hiatus hernia and esophagitis [13]. In adults, the prevalence of GERD (defined as symptoms of acid regurgitation, heartburn, or both, at least once a week) varies widely by country, with typical figures between 10% and 20%, whereas in Africa the prevalence was estimated at 7.6% [14]. In Asia, the prevalence ranges from less than 10% in China to more than 25% in India [6, 15–17].

About 20% of infants regurgitate more than 4 times a day and about 20% of mothers consider regurgitation as troublesome [2, 8]. Epidemiological data suggest that about 25% of adults sought medical advice for GER-related symptoms during the past year, with higher values with increasing age [18–21]. French data report a prevalence of GER in 10% and of GERD in 6% of all children 0–17 years old [19]. According to data obtained by the Health Improvement Network Incidence, the incidence of GERD in children is 0.84/1000 person-years [18]. The incidence decreases with age from 1.48/1000 person-years among 1-year-old children until the age of 12 years, whereupon it again increases to a maximum at 16–17 years of 2.26/1000 person-years for girls and 1.75/1000 person-years for boys [18]. According to epidemiologic data, children with GERD had double the risk to suffer an extra-esophageal condition such as asthma, pneumonia, or cough compared with children and adolescents with no diagnosis of GERD [18].

The rapidly increasing prevalence of obesity is related to the rising prevalence of GERD [6]. Total and abdominal obesity are risk factors for the development of GERD symptoms in children [22].

An autosomal dominant inheritance of hiatal hernia was described by discovering familial hiatal hernia in five generations of a large family, but without demonstrating the link to GERD. The genetic influence on GERD is supported by increased GER symptoms in relatives of GERD patients. GERD is associated with GNB3 C825T [23]. The concordance for GER is higher in monozygotic than dizygotic twins [24]. Family studies have revealed about 31% heritability of the disease [25]. Genes in question have been localized to chromosomes 9 and 13. A locus on chromosome 13q, between microsatellite D13S171 and D13S263, has been linked with severe GERD in five multiple affected families [26]. This could not be confirmed in another five families, probably due to genetic heterogeneity of GERD and different clinical presentation of patients [27]. A large GERD GWAS meta-analysis (80,265 cases, 305,011 controls) identified 25 independent genome-wide significant loci for GERD [28]. Further, 91% of the GERD risk-increasing alleles also increase Barrett's esophagus and esophageal adenocarcinoma, greatly expanding gene discovery for these traits [28]. Despite GERD polygenic basis, specific genetic loci such as rs10419226 on chromosome 19, rs2687201 on

chromosome 3, rs10852151 on chromosome 15, and rs520525 on the paired related homeobox 1 gene have been mentioned as potential risk factors [25]. The relevance of these findings for the general population remains unclear.

Pathophysiology

Transient lower esophageal sphincter relaxations (TLESRs) are the most important pathophysiologic mechanism causing GER at any age, from prematurity into adulthood [2, 6, 29]. TLESRs are a neural reflex, triggered mainly by the distention of the proximal stomach and organized in the brain stem, with efferent and afferent pathways traveling in the vagal nerve, activating an intramural inhibitory neuron which releases nitric oxide to relax the LES.

GER is influenced by genetic, environmental (e.g., diet smoking), anatomic, hormonal, and neurogenic factors (Fig. 10.1) [29]. Three major tiers of defense serve to limit the degree of GER, and to minimize the risk of reflux-induced injury to the esophagus. The first line of defense is the "antireflux barrier," consisting of the LES and the diaphragmatic pinchcock and angle of His. Compared to adults, infants have a short intraabdominal esophagus. When this line of defense fails, the second line of defense, esophageal clearance, assumes greater importance and limits the duration of contact between luminal contents and the esophageal epithelium. Anticipating the section on diagnostic techniques: results of esophageal pH monitoring and impedance taught us that chemical clearance is much slower than bolus or volume clearance (whether that is true or due to small remnants of refluxed acid that stick longer to the pH measuring material remains open for debate). Gravity and esophageal peristalsis serve to remove volume from the esophageal lumen, while salivary and esophageal secretions from esophageal submucosal glands neutralize acid. The third line of defense, tissue or esophageal mucosal resistance, is relevant when acid contact time is prolonged [29]. Esophageal mucosal defense can be divided in pre-epithelial (protective factors in saliva and esophageal secretions containing bicarbonate, mucin, prostaglandin E2, epidermal growth factor, transforming growth factor), epithelial (tight junctions, intercellular glycoprotein material), and post-epithelial factors [29]. There is a very important interindividual variation of reflux perception suggesting different esophageal sensitive thresholds. Additionally, the sensitivity threshold varies along the esophagus, with reflux reaching the proximal esophagus being more frequently perceived [30].

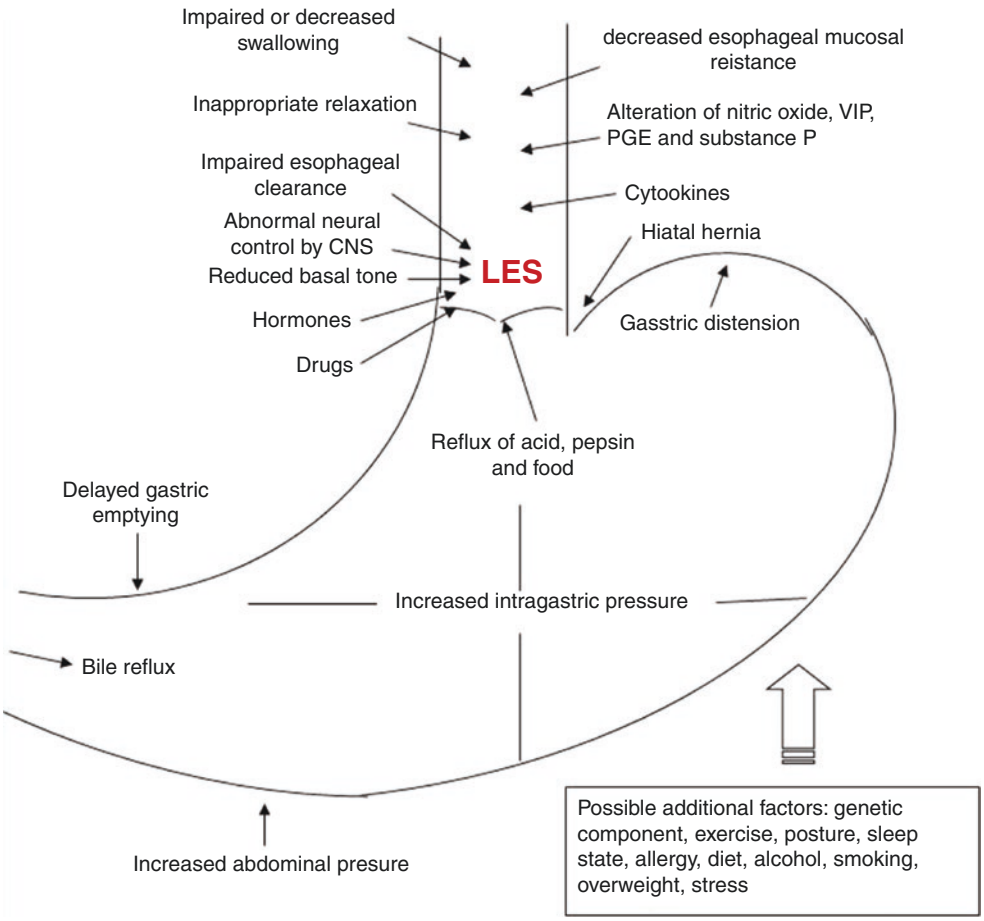

Fig. 10.1 Pathophysiologic mechanisms for GER. (Ref. [149])

Capsaicin levels and the transient receptor potential vanilloid receptor-1 play a role in the sensation of heartburn [31]. The esophageal mucosa contains acid-, temperature-, and volume-sensitive receptors. Proximal and distal esophageal mucosa of adult patients with nonerosive reflux disease has more superficial afferent nerves compared with controls or patients with erosive reflux disease or Barrett's esophagus [32]. Acid hypersensitivity in patients with nonerosive reflux disease might be partially explained by the increased proximity of their afferent nerves to the esophageal lumen, and therefore greater exposure to noxious substances in refluxate [32]. However, in infants, nonacid reflux is reported to cause more frequently and more severe crying and stress in infants than acid reflux [33, 34]. A widening of the intercellular spaces is reported in patients with esophagitis and in patients with endoscopy-negative disease [35]. Esophageal sensitivity to acid decreases when the esophagitis has healed. The presence of fat in the duodenum increases the sensitivity to reflux. Hyposensitivity as occurs in patients with Barrett's esophagus is a secondary phenomenon.

GER occurs during episodes of TLESR or inadequate adaptation of the sphincter tone to changes in abdominal pressure. All the factors responsible for maintaining the LES tone are not yet determined, but nitric oxide likely plays an important role [36].

Infants ingest more than twice the volume than adults per kg bodyweight (100–150 ml/kg/day compared to 30–50 ml/kg/day), causing more gastric distention, and as a consequence more TLESRs. Feeding frequency is higher in infants than in adults, resulting in more postprandial periods during which TLESRs are more common. When investigated in supine position, the frequency of TLESRs in healthy adults and these with acid GERD does not differ. In healthy adults, only 30% of the TLSERs are accompanied by acid reflux, but in patients with GERD, reflux occurs in 65% of the TLESRs. Thus, in adults, controls and GERD patients have the same number of TLESRs, but in patients with GERD, these TLESRs are more than twice as frequently accompanied with acid GER [37]. Normal individuals rarely experience TLESRs during sleep. Supine position eliminates all the beneficial gravitational effects of the upright position. Noxious materials, rather than air, are positioned at the cardia, available to move into the esophagus during TLESRs. A reflux is more likely to reach the pharynx in the recumbent than in the upright position. Both salivation and swallowing are markedly reduced during sleep, further impairing clearance. The upper esophageal sphincter is atonic during sleep, allowing reflux almost free to access the airways.

Delayed gastric emptying may increase postprandial reflux possibly by increasing the rate of TLESRs. Delayed gastric emptying has been documented in infants and children with symptomatic GER, particularly those with neurologic disorders. Abnormal gastric accommodation to a meal and prolonged postprandial fundic relaxation has been described in patients with GERD [38]. Esophageal acid exposure in patients with GERD is directly correlated with the emptying time of the proximal stomach. GERD was classically considered to be an acid peptic disease. But as a group, the majority of patients with reflux disease do not have a significant increase in gastric acid secretion. Recent analysis of postprandial acidity in the area of the gastroesophageal junction suggests that local acid distribution ("the gastric acid pocket") rather than total gastric secretion might be more relevant to the pathogenesis of GERD. The importance of the gastric acid pocket has been well established in adults, but has not been studied in children. Differences may exist in the degree of mixing of fundic contents leading to different distributions of acid in the stomach. Studies using pH monitoring, scintigraphy, and gastric magnetic resonance suggest that gastric mixing can be incomplete. Different layers of viscosity within the stomach might therefore influence the distribution of the gastric contents. A collection of acid in the gastric part of the esophageal junction was shown in adults in supine position, even in the postprandial period when stomach content was neutralized by the meal [38].

Hiatal hernia increases the number of reflux episodes and delays esophageal clearance by promoting retrograde flow across the esophagogastric junction when the LES relaxes after a swallow. This mechanism underlies the so-called rereflux phenomenon (recurrence of acid reflux while the esophageal pH is still below 4 after a previous acid reflux event) [39].

The majority of the studies on pathophysiologic mechanisms have been performed in adults and did not consider weakly acid and nonacid reflux. The refluxed material can be acid, weakly acid, or nonacid. Reflux may be a mix of gas and liquid or pure liquid, and may or may not contain bile. More than half of the acid and weakly acid reflux episodes are associated with reflux of gas [37]. Weakly acid reflux also occurs predominantly during TLESRs. With liquid meals, patients with GERD had a similar total rate of reflux episodes but a higher proportion of acid reflux events than controls [40]. Weakly acid reflux may be responsible for remaining symptoms in patients under antisecretory treatment. Components contributing to the noxiousness of refluxate are pepsin, bile acids and salts, and trypsin. The latter two depend on duodenogastric reflux preceding GER and are implicated in the genesis of strictures and Barrett's esophagus. Acid is emptied from the esophagus with one or two sequences of primary peristalsis, then the residual acidity in neutralized by swallowed saliva. Secondary peristalsis is the response to esophageal distension with air or water and is more important during sleep when peristalsis is reduced. Patients may have normal primary peristalsis but abnormal secondary peristalsis. Thus, nonacid reflux as occurs in the

postprandial period may be inefficiently cleared and cause prolonged esophageal distension, and thus cause symptoms of discomfort [33]. Esophageal clearance modulates the duration of reflux episodes, while mucosal resistance modulates the noxiousness of the components of refluxate. GER causes respiratory symptoms through different pathways such as (micro-)aspiration or may be vagally mediated (Fig. 10.2).

Neither *H. pylori* infection nor eradication of *H. pylori* obviously causes GERD [2, 41]. The presence of *H. pylori* is not an important pathophysiological factor in gastroesophageal reflux. On the other hand, its relationship with esophagitis appears to be inverse ratio. The fact that the *H. pylori* presence is statistically greater in the grade A esophagitis could confirm the hypothesis that the bacteria would slow down the development of the esophagitis [42]. Improvement in epigastric pain is significantly correlated with the improvement in GER symptoms but not with eradication of *H. pylori* [41].

The role of the upper esophageal sphincter in GERD and chronic respiratory disease, laryngitis, hoarseness, coughing, etc. has been insufficiently studied. Only patients with supraesophageal reflux disease were reported to have abnormal upper esophageal sphincter relaxation responses to rapid distension with saline [43]. The upper esophageal sphincter relaxes in response to esophageal body distention by gas, in contrast to its contractile response to esophageal body distension by fluid. Symptom presentation has not been linked to different pathophysiological mechanisms. Children presenting with upper airway disease or ear-nose-throat (ENT) manifestations may rather suffer from an insufficient upper esophageal sphincter, while patients with esophagitis may have more noxious reflux, insufficient clearing mechanisms, or a poor esophageal mucosal resistance. However, this has not been studied and is thus not demonstrated.

Symptoms and Signs

In normal 3- to 4-month-old infants, 3 to 4 episodes of GER are detectable during 5 min of intermittent fluoroscopic evaluation [44]. Normal ranges of esophageal pH monitoring report up to 31 ± 21 acid reflux episodes recorded within a 24-h period, but sample frequency, data handling by the recording device, and program do determine this incidence [45]. According to normal ranges proposed for impedance, a normal range up to 100 reflux episodes in 24 h has been proposed [46]. However, personal experience suggests that 100 reflux episodes is likely to be too high to be considered as normal. Normal acid clearance time was reported to be 151 s, while normal bolus clearance time was 25 s [47]. Less than 10% of infants and children have (acid and troublesome) GERD [45]. However, for ethical reasons, investigations were performed in symptomatic children.

While reflux does occur physiologically at all ages, there is also a continuum between physiologic GER and GERD (Tables 10.1 and 10.2). GERD is a spectrum of a disease that can best be defined as manifestations of esophageal or adjacent organ injury secondary to the reflux of gastric contents into the esophagus or, beyond, into the oral cavity or airways. The symptoms indicating the possibility of GERD differ according to age (Table 10.1). The list of most frequent differential diagnoses of vomiting in infants and children is listed in Table 10.3. Most important is to recognize alarm

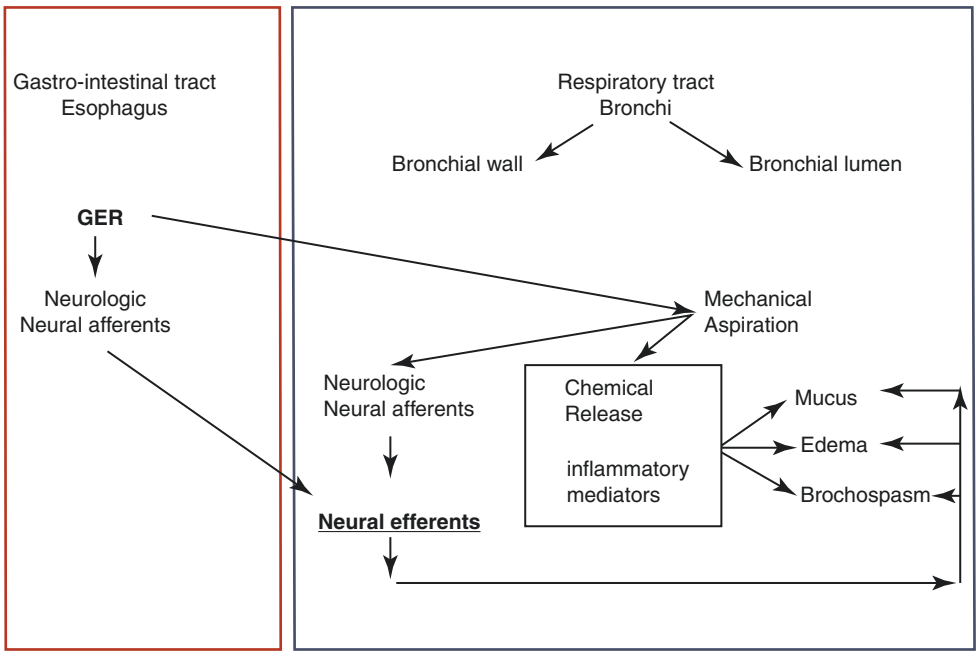

Fig. 10.2 Pathophysiologic mechanisms of GER causing respiratory disease

symptoms of GERD (Table 10.2). The clinician needs to be aware that not all regurgitation and vomiting in infants and young children is related with GERD. Bilious vomiting, gastrointestinal bleeding, consistently forceful vomiting, weight loss or failure to thrive, diarrhea, constipation, fever, lethargy, hepatosplenomegaly, abdominal tenderness, or distension should raise the possibility of an alternate diagnosis. Bulging fontanelle, macro- and/or microcephaly, and seizures raise the possibility of genetic and/or metabolic syndromes.

Belching or eructation occurs during a TLESR and is an important method of venting air from the stomach. Hiccups

are involuntary reflex contractions of the diaphragm followed by laryngeal closure. In some cases, hiccups cause or are related to GER.

Atypical symptoms such as epigastric pain, nausea, flatulence, hiccups, chronic cough, asthma, and hoarseness account for 30–60% of presentations of GERD [1, 2] (Table 10.1). Possible associations exist between GERD and asthma, pneumonia, bronchiectasis, brief resolved unexplained events (BRUEs), laryngotracheitis, and sinusitis, but causality or temporal association was not established, except for dental erosions and Sandifer syndrome [2, 5].

GER and Uncomplicated Regurgitation

Regurgitation is the most common presentation of infantile GER, with occasional projectile vomiting.

Over 50% of healthy infants have regurgitation that is physiologic, often decreasing from the age of 6 months onward and resolving without intervention in 95% of individuals by 12–18 months of age [2, 8] (Fig. 10.3). Daily regurgitation occurs more frequently in infants during the first 6 months of life than in older infants and children. Frequent regurgitation, defined as ≥4 times per day, occurs in about 25% of infants during the first months of life. About 20–25% of parents seek medical advice because of frequent infantile regurgitation, which corresponds to at least four episodes of regurgitation a day [2, 8]. Rome IV criteria consider >2 episodes of regurgitation per day during more than 3 weeks as a functional gastrointestinal disorder [11]. Functional gastrointestinal disorders are most of the time discussed separately although up to 75% of infants present with a combination of functional disorders, and not with just one [48].

A prospective follow-up study reported disappearance of regurgitation in all subjects before 12 months, although an increased prevalence of feeding refusal, duration of meals, parental feeding-related distress, and impaired quality of life was observed up to the age of 3 years, even after disappearance of symptoms [49]. Infants with spilling 90 days or more during the first 2 years of life, classified as frequent spilling, are more likely to have GER symptoms at 9 years of age [50]. Excessive regurgitation is one of the symptoms of GERD, but the terms excessive regurgitation and GERD should not be used as synonyms.

Although most studies report a comparable incidence of regurgitation in unselected populations of formula versus breastfed infants, Hegar et al reported a higher incidence in formula-fed infants [8]. This observation fits with the knowledge that GER and symptoms of GERD may be indistinguishable from those of food allergy [2, 5]. The incidence of cow milk protein allergy is 5–10 times higher in formula fed than in breastfed infants [51].

Although the "happy spitter" certainly exists and is not rare, many infants show some symptoms of distress and discomfort when regurgitating. Irritability and distress may accompany regurgitation and vomiting; however, in the absence of other warning symptoms, it is not an indication for extensive testing [1, 2]. Parental carrying-capacity or anxiousness ("parental coping") will determine if a physician is contacted by anxious parents or not. Infant regurgitation is a benign condition with a good prognosis, needing no other intervention than parental education and anticipatory guidance, and intervention on feeding frequency, volume, and composition will contribute to parental reassurance [1, 2]. Regurgitation is almost never a reason to stop breastfeeding. In formula-fed infants, thickened formula will alleviate regurgitation and promote parental reassurance. Overfeeding

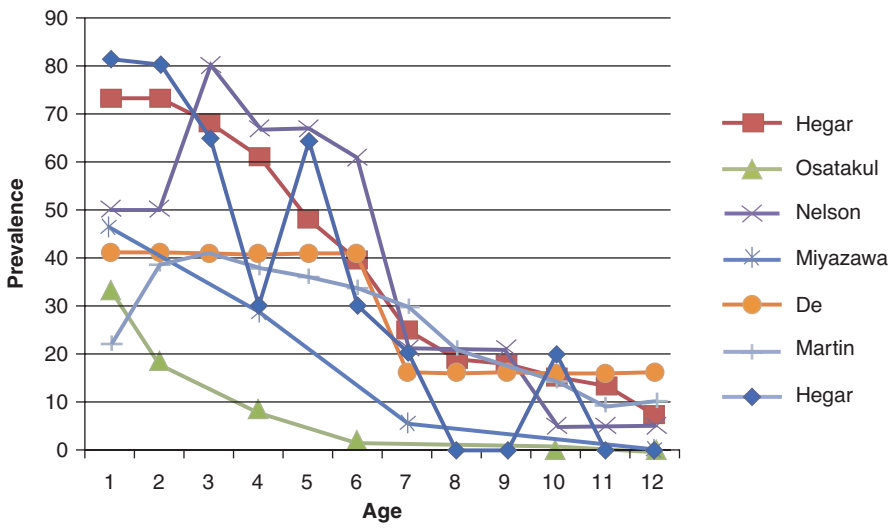

Fig. 10.3 Natural evolution of physiologic regurgitation. (Adapted from Ref. [10])

exacerbates recurrent regurgitation. Thickened or anti-regurgitation formula decreases overt regurgitation [1, 2].

GER(D) and Recurrent Regurgitation and Poor Weight Gain

If failure to thrive is documented, it is obvious that the infant is not a happy spitter. Poor weight gain is a crucial warning sign that necessitates clinical management. These infants need a full diagnostic workup starting with a dietary history to evaluate caloric intake. Hospitalization of these infants may be needed. Although regurgitation usually causes little more than a nuisance, very important regurgitation may induce caloric insufficiency and malnutrition. These infants are sometimes diagnosed as suffering nonorganic failure to thrive, a disorder that sometimes is attributed to social/sensory deprivation, socioeconomic, or maternal-child relation problems. GERD is only one of the many etiologies of "feeding problems" in infancy. Poor weight gain, feeding refusal, back-arching, irritability, and sleep disturbances have been reported to be related as well as unrelated to GERD [2, 52].

GER(D) and Cow's Milk Protein Allergy

Guidelines on the symptoms and management of cow's milk protein allergy (CMPA) unanimously report that persistent regurgitation and vomiting can possibly be manifestations of CMPA (Table 10.4: overlapping symptoms between GER(D) and CMPA) [2, 53]. The positive response to cow's milk protein elimination from the diet and relapse of symptoms is the cornerstone of the diagnosis of CMPA. An association between GERD and cow milk hypersensitivity was observed in both infants and children with severe GERD [54]. Simultaneous cow milk challenge and pH monitoring had limited value as a method to identify this subgroup [54]. Impedance has shown that the incidence of nonacid post-prandial reflux in decreased after a feeding with an amino acid-based formula compared to standard infant formula in these infants [34]. However, since amino acids or extensive hydrolysates have much more rapid gastric emptying than standard infant formula with intact cow milk proteins [55, 56], it is not possible to know if the decrease in GER is due to the enhanced gastric emptying or to an autoimmune mechanism.

Table 10.4 Signs and symptoms of GER(D) and CMPA

GER(D)	GER(D)+/- CMPA	CMPA
Aspiration	Apnea/ALTE/SIDS	Anaphylaxis
Back-arching	Colic	Angioedema
Bradycardia	Constipation	Bloody stools
Dysphagia	Failure to thrive	Diarrhea
Hematemesis	Feeding refusal	Eczema/dermatitis
Hiccups	Irritability	Itching
Hoarseness	Parenteral anxiety	Lip swelling
Laryngitis/stridor	Regurgitation	Nasal congestion
Melena	Sleep disturbances	Rhinitis
Nausea/belching	Vomiting	Urticaria
Respiratory infections	Wheezing	
Rumination		
Sandifer's syndrome

GERD and Esophagitis

Reflux esophagitis is reported to occur in 2–5% of the population. Esophagitis is defined as visible breaks of the esophageal mucosa [1, 2]. Histology is recommended to rule out Barrett's esophagus when suspected during upper GI endoscopy or to exclude other causes of symptoms such as eosinophilic esophagitis. Children with GER symptoms present esophagitis in 15–62%, Barrett's esophagus in 0.1–3%, and refractory GERD requiring surgery in 6–13% [1, 2, 45, 57]. In comparison, esophagitis is observed in only 20–40% of adults with heartburn, and Barrett's esophagus in 1.8–4% [58–63].

Hiatal hernia is more frequent in children with erosive esophagitis than without (7.7% versus 2.5%) [64]. Erosive esophagitis in 0- to 17-year-old children with GERD symptoms was reported to be 12.4% increasing with age [64]. The median age of the group with erosive esophagitis was 12.7 ± 4.9 years versus 10.0 ± 5.1 years in those without [64]. The incidence of erosive esophagitis was only 5.5% in those younger than 1 year [64]. The differences in incidence of esophagitis are determined by patient recruitment, differences of definition of esophagitis, and the availability of self-treatment. With an incidence of nearly 25%, acid-blocking medication is likely to be overprescribed to extremely low birth weight infants at the moment of discharge [65].

Esophagitis, identified by histology, occurs in 61–83% of infants with reflux symptoms severe enough to perform endoscopy. Although esophagitis may present with pain, it can also be asymptomatic. The group with asymptomatic esophagitis is in some ways the most problematic. Even severe esophagitis may remain asymptomatic as demonstrated by children who present with peptic strictures without having experienced any discomfort attributable to esophagitis. Patients with Barrett's esophagus can be almost symptom free. The more severe the lesions, the more nerve endings are damaged or destroyed. Typical substernal burning pain (heartburn, pyrosis) occurs in many children suffering from esophagitis. Odynophagia, which is pain on swallowing, usually represents esophageal inflammation. In nonverbal infants, behaviors suggesting esophagitis include crying, distress, irritability, sleep disturbance, and "colic." Infants frequently also appear very hungry for the bottle until

their first swallows and then become irritable and refuse to drink. Dysphagia, typical for eosinophilic esophagitis, has also been linked to esophagitis.

GER(D) and Eosinophilic Esophagitis

The impressive rise in prevalence of eosinophilic esophagitis (EoE) is still poorly understood [65, 66]. Especially in young infants, distinguishing EoE from reflux esophagitis may be difficult. In reflux esophagitis, the eosinophilic infiltrate is in theory limited to less than 5/per high power field (HPF) compared to primary EoE with >15 eosinophils per HPF. More recently, failure of PPI treatment as a condition to diagnose EoE brought reflux esophagitis back in the picture of EoE [67]. EoE necessitates proper treatment (hypoallergenic feeding, corticoids, montelukast, etc.). Patients with allergic esophagitis are often younger and have atopic features such as allergic symptoms or positive allergic tests, but have often no specific symptoms. Atopic features are reported in more than 90% and peripheral eosinophilia in up to 50% of patients, but of course depending on selection of patients. At endoscopy, a pale, granular, furrowed, and occasional ringed esophageal mucosa may appear [2]. While symptoms in older children are more oriented to dysphagia for solids, symptoms in infants are more reflux-like [68, 69]. Repeated endoscopy with esophageal histology in combination with response to treatment may in some cases be the only way out to separate reflux esophagitis from EoE in young children. The cornerstone of treatment is an elimination diet (targeted or empiric elimination diet, amino acid-based formula) and/or swallowed, topical corticosteroids [67]. Systemic corticosteroids are reserved for severe symptoms requiring rapid relief or where other treatments have failed [66]. Significant differences in general practice between pediatric and adult gastroenterologist were demonstrated with notable divergence from consensus guidelines [70]. Although elimination diets remain an appropriate option, the vast majority of adults suffering from EoE will be started on topical corticosteroids for long-term management, mainly as a result of the poor long-term compliance to elimination diets [71]. International practice variations are also apparent. An in-depth discussion on EoE is beyond the scope of this chapter.

GER(D) and Heartburn, Infant Crying, and Distressed Behavior

While the verbal child can communicate pain, descriptions of the intensity, location, and severity may be unreliable until the age of at least 8–12 years [5]. In adults, adolescents, and older children, heartburn and regurgitation are the characteristic manifestations of the reflux syndrome [6]. GERD in adolescents is more adult-like. Heartburn is a symptom of GERD with or without esophagitis. Heartburn is a predominant GER symptom in adults, occurring weekly in 15–20% and daily in 5–10% of subjects [72, 73]. Diagnosis and management of GERD in older children (>12 years) and adolescents follows the recommendations for adults [2]. According to parents, heartburn is present in 1.8% of 3- to 9-year-old healthy children and 3.5% of 10- to 17-year-old adolescents; regurgitation is said to occur in 2.3% and 1.4%, respectively, and 0.5% and 1.9% need antiacid medication [50]. According to self-reports, adolescents complain about heartburn in 5.2% and regurgitation up to the pharynx in 8.2%, while antiacids are taken by 2.3% and histamine receptor antagonists (H_2RA) by 1.3%, suggesting that symptoms of GER are not rare during adolescence and are underreported by parents or overestimated by adolescents [50]. In infants, the issue is more complicated. Since per definition "heartburn" suggests that the individual with heartburn feels a burning retrosternal pain, parents and healthcare providers almost automatically hypothesize that a "crying baby" or a "distressed baby" is likely to suffer from heartburn or "occult GER." As a consequence, acid-reducing medication is increasingly prescribed in infants [74, 75]. Several randomized controlled trials were performed for this indication, and for once all results come to the same conclusion: proton-pump inhibitors are useless to decrease crying and distressed behavior in newborns and infants [75]. Heine and coworkers identified no relation between crying duration and the result of pH monitoring [10]. In other words: many infants that regurgitate are distressed and cry, but only very few infants presenting with distressed behavior or crying without regurgitation suffer GER(D). Occult GER in infants is almost nonexisting.

The same amount of distress and crying may be evaluated by some parents as easily acceptable while it will be unbearable for other parents. In fact, the coping capacity of the parents decides if medical help is looked for. Many factors, such as tobacco smoke, may cause infant irritability. CMPA is another well-identified cause of infant irritability. There is substantial individual variability, and some healthy infants may cry up to 6 h a day [1, 2].

The concept that infant irritability and sleep disturbances are manifestations of GER is largely derived from adult data [1, 2]. In adults, sleep disturbance attributable to GERD symptoms has been demonstrated, with a beneficial effect of PPI [76, 77]. The developing nervous system of infants exposed to acid seems susceptible to pain hypersensitivity despite the absence of tissue damage. In adults, NERD is an accepted entity as it is the most frequent presentation of GERD. In adults, impaired quality of life, notably regarding pain, mental health, and social functioning, has been demonstrated in patients with GERD, regardless of the presence of esophagitis [78]. In

an unselected population, 28% of the adults report heartburn, almost half of them weekly, with a significant impact on the quality of life in 76%, especially if the symptoms are frequent and long lasting. Despite that, only half of the heartburn complainers seek medical help, although 60% takes medication [79]. Thus, some adults "learn to live with their symptoms" and acquire tolerance to long-lasting symptoms. In infancy and young children, verbal expression of symptoms is often vague or impossible, and persistent crying, irritability, back-arching, feeding, and sleeping difficulties have been proposed as possible equivalents of adult heartburn. Infants with GERD learn to associate eating with discomfort and thus subsequently tend to avoid eating and develop an aversive behavior around feeds, although behavioral feeding difficulties are also common in control toddlers [80]. Esophageal pain and behaviors perceived by the caregiver to represent pain potentially affect the response of the infant to visceral stimuli and the ability to cope with these sensations, both painful and nonpainful. A placebo-controlled randomized trial with proton-pump inhibitors in distressed infants showed an equal decrease in distressed behavior in the treatment and the placebo group [81]. Up to date, there is no evidence that acid-suppressive therapy is effective in infants who present solely with inconsolable crying or distressed behavior. Moreover, inappropriate administration of acid-blocking medication in infants should be avoided as this medication often causes adverse effects. In infants and toddlers, there is no symptom or group of symptoms that can reliably diagnose GERD or predict treatment response. Infants presenting with isolated distressed behavior or crying should get appropriate care, but acid GERD not resulting in regurgitation or vomiting but causing excessive crying and distress is exceptional.

GER(D) and Dysphagia, Odynophagia, and Food Refusal

Dysphagia is the difficulty of swallowing; odynophagia is pain caused by swallowing. Although GERD is frequently mentioned as a cause of dysphagia or odynophagia, there are no pediatric data showing this relation. Dysphagia is a prominent symptom in patients with EoE. Feeding difficulty and/or refusal are often used to describe uncoordinated sucking and swallowing, gagging, vomiting, and irritability during feeding. Thickeners are effective in improving swallowing mechanics [82]. A relation between GER, GERD, and feeding refusal has not been established. In case of acute feeding difficulties, a trapped foreign body should be among the list of possible differential diagnoses. In case of chronic feeding difficulties, achalasia should be considered.

GER(D) and Extra-Esophageal Manifestations

Although there is sufficient evidence to support an association between extra-esophageal symptoms and GERD, there is no evidence for a causal relationship. Laryngopharyngeal symptoms of GERD such as globus sensation, hoarseness, and chronic cough are becoming increasingly recognized. In the pediatric literature, little attention has been given to globus pharyngeus sensation, probably related to the fact that young children will experience difficulties to express this sensation. There is no evidence that medical treatment reduces extra-esophageal manifestations. Pulmonary microaspiration as demonstrated by pepsin detection in a bronchoalveolar lavage fluid is common in children with chronic lung diseases, suggesting that GER may contribute significantly to the disease pathogenesis [83]. The bronchoalveolar lavage pepsin concentration correlates positively with the number of proximal reflux events [83]. Protein oxidation in the bronchoalveolar lavage is higher in children with extensive proximal acidic reflux, suggesting that pulmonary microaspirations contribute to lung damage [83]. Children >1 year with GERD-related respiratory symptoms showed a significantly higher number of weakly alkaline refluxes than children with GERD-related GI symptoms [84]. This supports the hypothesis that respiratory symptoms are less related to acidity than GI symptoms [84].

GER(D) and Reactive Airway Disease

An etiologic role for GER in reactive airway disease has not been demonstrated, but the association between GERD and asthma is bidirectional: the asthma group has a 1.36 higher risk for GERD, and the GERD group has a 1.48 higher risk for asthma [85]. Prior severe asthma exacerbations (incidence rate ratio 3:45) and younger age increased the severe asthma exacerbation risk in all countries, whereas obesity, atopy, and GERD were a risk factor in some but not all countries. Rehospitalization rates were up to 79% within 1 year [86].

Different pathophysiologic mechanisms are proposed: direct aspiration, vagal mediated bronchial and laryngeal spasm, neural mediated inflammation. Esophageal acidification in infants with wheezing can produce airway hyperresponsiveness and airflow obstruction [87]. Few studies tempted to evaluate the opposite: the impact of asthma on the severity of GERD. Chronic hyperinflation as occurs in asthma favors many GER mechanisms. An association between asthma and reflux measured by pH or impedance probe has been reported in many studies [2]. Wheezing appears more related to GERD if it is nocturnal. A recent study reports a high prevalence of GER in children and adolescents with persistent asthma, equally distributed in the supine nocturnal and upright positions [88]. But there was no

correlation between the result of the pH metry and pulmonary function tests [88].

Very few prospective, randomized, and blinded treatment studies have been performed in children. In a series of 46 children with persistent moderate asthma despite bronchodilators, inhaled corticosteroids, and leukotriene antagonists, 59% (27/46) had an abnormal pH metry [89]. Reflux treatment did result in a significant reduction in asthma medication. Patients with a normal pH metry were randomized to placebo or reflux treatment: 25% (2 of only 8 children) of the treated patients could reduce their asthma medication, while this was not possible in any patient on placebo [89]. Another study found omeprazole ineffective in improving asthma symptoms and parameters in children with asthma [90]. Overall, although there seems to be an association between GER and asthma, the causal role of GER has not been demonstrated. There is no association between asthma control status and laryngopharyngeal reflux and GER [91]. Current evidence does not support the routine use of anti-GERD medication in the treatment of poorly controlled asthma of childhood [92]. Selection of patients is once more of importance. Children with asthma and heartburn should be treated with acid-reducing medication because of the heartburn, not because of the asthma. Many studies in children with extra-esophageal symptoms included children that also presented with typical reflux symptoms.

GER(D) and Recurrent Pneumonia

The reported mechanisms are similar to those for reactive airway disease. Direct aspiration during swallowing may be more relevant in this group. No test can determine whether reflux is causing recurrent pneumonia. Upper esophageal and pharyngeal pH and impedance recordings provided contradictory information. A new technique to record pharyngeal reflux had been developed (Restech→) [93]. However, results could not confirm the utility of this technique [94]. As a consequence, pharyngeal pH recording is no longer used.

Lipid-laden macrophages have been used as an indicator of aspiration, but their sensitivity and specificity for GER is poor. One study evaluating nuclear scintigraphy with late imaging reported that 50% of patients with a variety of respiratory symptoms had pulmonary aspiration after 24 h [95]. However, later studies failed to reproduce these findings [96]. Aspiration also occurs in healthy subjects, especially during sleep [1]. Weakly acid reflux events can be associated with a significant airway inflammation and injury that, because of the biochemical mechanisms involved, are likely not completely preventable and/or counteracted by antiacid treatments [97].

The role of reflux in patients with bronchopulmonary dysplasia and other chronic respiratory disorders is not clear. Today, the clinician has frequently no other option than to make management decisions based on inconclusive diagnostic studies with no certainty regarding outcome [1, 2]. As in reactive airway disease, it is very likely that nonacid reflux can cause airway manifestations.

GER(D) and Cystic Fibrosis

The incidence of GER in children with cystic fibrosis is very high. Excessive acid reflux exists in the majority of cystic fibrosis patients, even before respiratory symptoms develop [2, 98, 99]. CF patients also suffer from duodenogastroesophageal reflux of bile acids [100, 101]. In the majority of patients, typical GER symptoms are absent [99]. Therefore, diagnostic procedures should be considered, regardless of lacking symptoms. Patients with cystic fibrosis have a relatively high number of proximal reflux episodes [99]. Such episodes also indicate an increased risk for aspiration. It is possible that as well the acid and bile reflux are aggravating the respiratory symptoms, and that the respiratory symptoms aggravate the reflux. Aggressive medical and surgical reflux treatment in this patient group seems reasonable. In children with cystic fibrosis, a better weight gain was reported during PPI treatment; whether this is due to a reduction of acid reflux or better buffering of acid gastric content in the intestine is not clear. Almost half of the children with cystic fibrosis and symptoms suggestive for GERD have increased acid GOR and almost a quarter has delayed gastric emptying [100]. However, there is no relation between GOR and gastric emptying [100]. Lung transplantation exacerbates gastroesophageal reflux disease [102]. Reflux burden and fundoplication status do not impact lung transplant outcomes, but gastric dysmotility may be linked to allograft dysfunction in children [103]. An association between GERD and allograft injury was reported, encouraging a strategy of early diagnosis and aggressive reflux management in lung transplant recipients to improve transplant outcomes [83, 104].

GER(D) and Cough and ENT Manifestations

Both acid and weakly acid GER may precede cough in children with unexplained cough, but cough does not induce GER [105]. Objective cough recording improves symptom association analysis. Treatment for GERD should not be used when there are no clinical features of GERD, and pediatric GERD guidelines should be used to guide treatment and investigations [106]. Several studies revealed the presence of pepsin in the middle ear fluid, but with a huge variation in incidence varying from 14% to 73% [2, 107]. Pepsin in saliva appears to be associated with laryngomalacia, suggesting a role for salivary pepsin as a noninvasive marker of laryngopharyngeal reflux in patients with laryngomalacia [108]. Recent data showed that salivary pepsin to detect GERD is not ready for clinical application [109]. Also, bile acids have

been detected in middle ear liquid, even in higher concentrations than in serum [110]. The presence of pepsin and bile in middle ear fluid might as well be the consequence of reflux and vomiting at the moment of the acute middle ear infection than an argument to hypothesize that chronic GER may be at the origin of the chronic middle ear problem. Several epidemiologic studies suggest a low incidence of reflux symptoms in patients with recurrent middle ear infections.

Data suggesting a causal relation between reflux and upper airway disease in children are limited. Data from several placebo-controlled studies and meta-analyses uniformly have shown no effect of antireflux therapy on upper airway symptoms or signs [2]. Well-designed, prospective, placebo-controlled, blinded studies are needed. Another bias might be selection of patients: these studies are frequently set up in tertiary care centers in highly selected patient populations. The question is how representative these patients are for the bulk of children with upper respiratory and/or ENT manifestations.

GER(D) and Dental Erosions

Young children and children with neurologic impairment appear to be at greatest risk to have dental erosions caused by GER. Juice drinking, bulimia, and racial and genetic factors that affect dental enamel and saliva might be confounding variables that have been insufficiently considered [1, 2]. A positive correlation between mainly acid GERD and dental erosion has been as well confirmed as refuted, although the evidence for a relation between both seems to win the debate [110–113]. There are no long-term (intervention) follow-up studies in high-risk populations.

GER(D) and Sandifer Syndrome

Sandifer syndrome is an uncommon but specific manifestation of GERD. The presenting symptoms of Sandifer's may include any combination of abnormal movements and/or positioning of head, neck, trunk, and upper limbs, seizure-like episodes, ocular symptoms, irritability, developmental and growth delay, and iron-deficiency anemia [114]. Successful treatment of the underlying GERD led to a complete or near-complete resolution of the neurological symptoms in all of the reviewed cases [114].

GER(D) in Neurologically Impaired Children

Neurologically impaired children have more frequent, more severe, and more difficult to treat GERD than neurologically normal children. An ESPGHAN Working Group published a consensus statement on the diagnosis and management of GERD in neurologically impaired children [115]. Neurologically impaired children accumulate many risk factors for severe GERD: spasticity or hypotonicity, supine position, constipation, etc. Diagnosis of reflux disease in these children is often difficult because of their underlying conditions. Empiric treatment will often be initiated. Whether this group of patients has more severe reflux disease, or has less effective defense mechanisms, or presents with more severe symptoms because of the inability to express and/or recognize symptoms remains open for debate. Response to treatment, both medical and surgical, was reported to be poor in the neurologically impaired child compared to the neurologically normal child. However, surgical experience for multiple centers reports different experience with no differences in outcome related to neurological impairment [116–118]. Gastrostomy feeding may reduce aspiration but could exacerbate gastroesophageal reflux disease [115]. The impact of antireflux procedures in addition to gastrostomy is relatively unknown [115].

GER(D) and Apnea, Brief Resolved Unexplained Events, and Sudden Infant Death Syndrome

In adults, a relation between obstructive sleep apnea and GERD has been demonstrated [119, 120]. It is commonly assumed that nightly GER events causes sleep disturbance by arousal. However, a study combining polysomonography and pH/impedance monitoring challenged this hypothesis [121]. Literature can best be summarized as follows: series fail most of the time to show a temporal association between GER and pathologic apnea, apparent life-threatening events, and bradycardia [1, 122]. The term "brief resolved unexplained event" (BRUE) was created to replace "apparent life-threatening event," narrowing the definition and providing evidence-based guidelines for management. There are well-selected cases or small series that demonstrate that pathologic apnea can occur as a consequence of GER. A relation between GER and short, physiologic apnea has been shown [123]. GER is a frequent cause of interrupting sleep in infants, and nonacid GER is equally important as acid GER for causing arousal and awakening in infants [124, 125]. GER events preceded cardiorespiratory events in 83% of these associations [82, 99]. These GER events had a higher proximal extent [124]. Discomfort is significantly associated with reflux events and does not differ between weakly acidic and acid refluxes [126]. In general, GER is not related to pathologic apnea, significant bradycardia, and BRUE, but exceptions do exist [122]. Gastroesophageal reflux can cause sudden death in a vulnerable infant during a critical period of development through failure of "autoresuscitation" mechanisms [127].

GER(D) and Other Risk Groups

There are no data in literature that preterm babies have more (severe) reflux than term born babies, although many preterms are treated for reflux.

Symptomatic GER is extremely frequent in patients operated because of esophageal atresia and/or tracheoesophageal fistula because of serious structural and functional deficiencies [128]. The reflux in these children might be refractory to medical treatment. The high rates of wrap failure necessitate close follow-up [128].

Children with congenital abnormalities or after major thoracic or abdominal surgery are at risk for developing severe GERD.

GERD and Complications

Children with neurological impairment, chronic lung disease (especially cystic fibrosis), esophageal atresia, and chemotherapy have the most severe pathologic reflux and are at high risk for the development of complications of GERD [1, 2].

Barrett's esophagus, esophageal strictures, and adenocarcinoma are complications of chronic severe GERD. Barrett's esophagus is a premalignant condition in which metaplastic specialized columnar epithelium with goblet cells replaces the squamous epithelium of the esophagus. Although Barrett's esophagus is considered a premalignant condition, the incidence of carcinoma in pediatric population remains low [129]. Differences in esophageal mucosal resistance and genetic factors may partially explain the diversity of lesions and symptoms. Patients with esophageal atresia are at high risk of persisting GERD and Barrett's esophagus [130]. The development of Barrett's esophagus is related to GERD history. As Barrett's esophagus represents a premalignant condition, long-term systematic follow-up of the esophageal mucosa including multistaged biopsies is warranted, even in asymptomatic patients [130].

More than 60 years ago, in the absence of acid-blocking medication, esophageal strictures were reported in about 5% of children with reflux symptoms [131]. Currently, esophageal stenosis and ulceration in children have become rare. In a series including 402 children with GERD without neurological or congenital anomalies, no case of Barrett's esophagus was detected [57]. In another series including 103 children with long-lasting GERD, and not previously treated with a H_2 receptor antagonist (H_2RA) or a proton-pump inhibitor (PPI), Barrett's esophagus was detected in 13%. An esophageal stricture was present in 5 of the 13 patients with Barrett [132]. Reflux symptoms during childhood were not different in adults without or with Barrett [133]. Barrett has a male predominance, and increases with age. Patients with short segments of columnar-lined esophagus and intestinal metaplasia have similar esophageal acid exposure but significantly higher frequency of abnormal bilirubin exposure and longer median duration of reflux symptoms than patients without intestinal metaplasia [134]. There is a genetic predisposition in families in patients with Barrett's esophagus and esophageal carcinoma [1].

Peptic ulcer, esophageal, and gastric neoplastic changes in children are seldom observed. In adults, over the last 30 years, a decreased prevalence of gastric cancer and peptic ulcer with an opposite increase of esophageal adenocarcinoma and GERD has been noted. This has been attributed to independent factors among which changes in dietary habits such as a higher fat intake, an increased incidence of obesity, and a decreased incidence of *H. pylori* infection. The incidence of noninvasive in situ cancer has actually declined after 2003 [135]. Frequency, severity, and duration of reflux symptoms are related to the risk to develop esophageal cancer. Among adults with long-standing and severe reflux, the odds ratios are 43.5 for esophageal adenocarcinoma and 4.4 for adenocarcinoma at the cardia [136]. It is unknown whether mild esophagitis or GER symptoms persisting from childhood is related to an increased risk for severe complications in adults.

Diagnosis

It is beyond the scope of the subject to provide a detailed discussion on all diagnostic procedures for GERD. Detailed information regarding indications and pitfalls of radiologic contrast studies, nuclear reflux scintigraphy, ultrasound, endoscopy, manometry, gastric emptying tests, and electrogastrography can be found in review papers and guidelines [1, 2]. The applicability of the recent Lyon consensus for diagnosing GERD in adults needs to be discussed for its applicability in pediatrics [137]. According to the Lyon consensus, conclusive evidence for reflux on esophageal testing include advanced grade erosive esophagitis (LA grades C and D), long-segment Barrett's mucosa or peptic strictures on endoscopy, or distal esophageal acid exposure time (previously called "reflux index") >6% on ambulatory pH or pH-impedance monitoring "off" PPI [137]. A normal endoscopy does not exclude GERD, but provides supportive evidence refuting GERD in conjunction with distal acid exposure time <4% and <40 reflux episodes on pH-impedance monitoring off proton-pump inhibitors [137]. As a consequence, an acid exposure time between 4% and 6% is considered "gray zone". Reflux-symptom association on ambulatory reflux

monitoring provides supportive evidence for reflux-triggered symptoms, and may predict a better treatment outcome when present. When endoscopy and pH or pH-impedance monitoring are inconclusive, adjunctive evidence from biopsy findings (histopathology scores, dilated intercellular spaces), motor evaluation (hypotensive lower esophageal sphincter, hiatus hernia, and esophageal body hypomotility on high-resolution manometry), and novel impedance metrics (baseline impedance, post-reflux swallow-induced peristaltic wave index) can add confidence for a GERD diagnosis; however, diagnosis cannot be based on these findings alone [137]. An assessment of anatomy, motor function, reflux burden, and symptomatic phenotype will therefore help direct management. Future GERD management strategies should focus on defining individual patient phenotypes based on the level of refluxate exposure, mechanism of reflux, efficacy of clearance, underlying anatomy of the esophagogastric junction, and psychometrics defining symptomatic presentations. The Lyon Consensus goes beyond the previous classifications and defines endoscopic and functional parameters able to establish the presence of GERD [138]. The "Lyon Consensus" panel of experts confirmed that positive indices of reflux-symptom association, without other altered parameters, represent reflux hypersensitivity. GERD requires a customized management; it is crucial to assess frequency and severity of symptoms and their response to an optimal course of therapy as well as to explore the endoscopic alterations and consider other diagnoses responsible for persistent symptoms [139]. The Lyon consensus will contribute to diagnose GERD objectively, but seems not very useful for primary health care.

In adults, the diagnosis of GERD mainly relies on clinical history. Heartburn and acid regurgitation are considered the cardinal symptoms of GERD [137]. However, history in young children is considered poorly reliable up to the age of minimally 8 or even 12 years old. Therefore, questionnaires have been developed trying to improve history reliability. Orenstein developed the "infant GER-questionnaire" (I-GER) [140]. The questionnaire results in an objective, validated, and repeatable quantification of symptoms suggesting GERD. The I-GER was revised (the "I-GERQ-R") in 185 patients and 93 controls, resulting in an internal consistency reliability from 0.86 to 0.87, and a test-retest reliability of 0.85 [141]. However, according to data from Aggarwal and coworkers, the I-GER-Q has a sensitivity of only 43% and a specificity of 79% [96]. Moreover, pH metry results were not different according to a "positive" or "negative" score of the I-GER-Q [142]. Our group showed that not one question was found to be significantly predictive for the presence of esophagitis. In our hands, the Orenstein I-GERQ cut-off score failed to identify 26% of infants with GERD according to pH metry results or presence of esophagitis, but was positive in not less than 81% of infants with a normal histology of esophageal biopsies and normal pH metry [143]. Deal et al. developed two different questionnaires, one for infants and one for older children, and showed that the score was higher in symptomatic than in asymptomatic children [144]. Overall, it can be concluded that the correlation between the results of history obtained by questionnaires and of reflux investigations is poor.

Barium contrast radiography, nuclear scintiscanning, and ultrasound are techniques evaluating postprandial reflux and provide limited information on gastric emptying and pathologic GER. Normal ranges are not established for any of these procedures. Barium studies are not recommended as first-line investigation to diagnose GERD, but are of importance to diagnose anatomic abnormalities such as malrotation, duodenal web, and stenosis and may suggest functional abnormalities such as achalasia.

Nuclear scintigraphy may show pulmonary aspiration [95]. However, these findings could not be confirmed [96]. Aspiration of saliva and gastric contents occurs during sleep in healthy adults. Scintigraphy can estimate gastric emptying. But the 13C-octanoic acid (for solids) and 13C-acetate (for liquids) breath tests are more appropriate to measure gastric emptying in children [145, 146]. A putative role of delayed gastric emptying in GER(D) was raised by studies in the pre-PPI era, but its importance in the pathophysiology of GERD has been questioned ever since [147].

In the hands of an experienced investigator, ultrasound provides morphological and functional data with high sensitivity and positive predictive value for the diagnosis of GER [148]. Sonographic assessment of findings such as abdominal esophageal length, esophageal diameter, esophageal wall thickness, and gastroesophageal angle provide important diagnostic indicators of reflux and related to the degree of GER [148]. However, there is a need for standardization of the procedure and for defining diagnostic criteria [148]. The results of ultrasound are investigator dependent, and a relation between reflux seen on ultrasound and symptoms has not been established [1, 2]. Overall, ultrasound may detect GER but is not sensitive or specific to diagnose GERD. There is no indication for electrogastrography in the diagnostic workup of a patient suspected of GERD.

Endoscopy allows direct visual examination of the esophageal mucosa. Modern endoscopes are so miniaturized that upper GI endoscopy of preterm infants of less than 1,000 g has become technically easy. Operator experience is an important component to guarantee interobserver reliability [1, 2]. Macroscopic lesions associated with GERD include esophagitis, erosions, exudate, ulcers, strictures, hiatal hernia, etc. Redness of the distal esophagus in young infants is a normal observation because of the increased number of small blood vessels at the cardiac region. Endoscopy may also show a "sliding hernia," the stomach that is protruding in the esophagus especially during burping. Recent consen-

sus guidelines define reflux esophagitis as the presence of endoscopically visible breaks in the esophageal mucosa at or immediately above the GE junction [1, 2]. These mucosal breaks are classified according to the Los Angeles classification [149]. Endoscopy-negative reflux disease is common. There is a poor correlation between the severity of symptoms and presence and absence of esophagitis. Especially in infants, nonacid reflux was shown to cause at least as much distress as acid reflux. There is insufficient evidence to support the use of histology to diagnose or exclude GERD. However, biopsies of duodenal, gastric, and esophageal mucosa are mandatory to exclude other diseases [1]. More detailed information on pros and cons of histology can be found in the recent consensus papers [1, 2].

Esophageal manometry does not demonstrate reflux, but is of interest to analyze pathophysiologic mechanisms causing reflux, mainly by visualizing and measuring TLESRs, and is indicated in the diagnosis of specific conditions such as achalasia. With the avenue of solid-state catheters and high-resolution manometry, the pressure topography of the full length of the esophagus can be achieved [150]. In adults, high-resolution esophageal manometry should always be considered before antireflux surgery [151]. Ambulatory 24-h esophageal manometry, in combination with pH metry and/or impedance recording, is nowadays technically feasible. This technique is mainly used in (clinical) research and allows the objective demonstration of reflux-symptom association (e.g., in patients presenting with chronic cough).

Intraluminal esophageal acid perfusion provoking chest pain (Bernstein test) or using other end-points has found expanded use in practice and research in the USA, but has never been popular in Europe.

Ambulatory 24-h esophageal pH monitoring measures the incidence and duration of acid reflux, while impedance measures all types of reflux episodes, independent of pH. The technique offers the possibility to measure intragastric and esophageal pH simultaneously in older children. Both hardware (electrodes, devices) and software influence the results [1]. Esophageal pH metry is the best method to measure acid in the esophagus, but not all reflux causing symptoms is acid and not all acid reflux is causing symptoms. The cut-off of pH 4.0 was historically determined as the best cut-off in adults with heartburn. This cut-off was taken over for children, without ever testing if this was the best cut-off. Moreover, it is very unlikely that a pH of 4.1 or 3.9 has a different clinical meaning. Therefore, it is a shortcoming that modern analysis programs do no longer calculate the oscillatory index, which calculates the % oftie that the pH oscillates between 3.75 and 4.25 [152]. The oscillatory index provides information on the risk of erroneous interpretation of the pH metry [152]. The surface area below pH 4.0 was shown to correlate well with histologic esophagitis, while the reflux index, the % of time with pH <4.0 does not [153]. Esophageal pH metry is useful in evaluating the effect of a therapeutic intervention on reducing esophageal acid exposure. Medical treatment is focusing on the reduction of gastric acid secretion. Normal ranges have been established for pH metry. However, normal ranges depend also on the hard- and software used. The major indication of long-term recording of pH and/or impedance is the demonstration of an association between reflux and symptoms.

Multichannel intraluminal impedance (MII) measures electrical potential differences. A reflux episode is defined as a drop of the baseline impedance with >50%. The same criticism can be formulated as for pH monitoring: the clinical meaning of a drop with 49% or 51% is likely to be similar. Important to know also is that baseline is age dependent [154]. Moreover, esophagitis lowers the baseline; as a consequence, severe esophagitis might have a normalizing effect on MII results since baseline might be so low that a drop with >50% becomes unlikely. Interestingly, pH-only episodes, reflux episodes detected with pH metry but not with impedance (drop in pH without bolus movement) occur in young children [155]. While pH monitoring measures chemical clearance, MII measures bolus clearance. Therefore, reflux episodes last longer with pH monitoring than with MII. The detection of reflux by MII is not pH dependent, but in combination with pH metry, it allows detection of acid (pH < 4.0) and nonacid reflux, which can be divided further in weakly acid (pH 4.0–7.0) and alkaline reflux (pH > 7.0). Experience has shown that impedance needs to be performed in combination with pH metry, since pH-only events occur, mainly during the night and mainly in young infants. Also gas reflux is detected with MII, since liquid reflux causes a drop in impedance and gas reflux an increase. Interpretation of the recording is laborious and necessitates sufficient experience, since the automatic analysis is not standardized for children. Nevertheless, automated analysis seemed to be at least as reliable as analysis by experts [156]. Impedance seems especially of interest in patients with symptoms suggesting reflux but in the absence of esophagitis. Obviously, "more" reflux episodes are detected with MII-pH metry than with pH metry alone. The major clinical interest of MII seems to be demonstration of symptom association. Symptom Index, the percentage of reflux-related symptom episodes during a study period, does not incorporate the total number of reflux events in its calculation. Symptom association probability takes this limitation into consideration. But both parameters allow very well to interpret MII-pH as well off as on antiacid medication; the latter being of interest to differentiate between persisting (acid or nonacid) or absence of reflux in subjects with reflux symptoms refractory to clinical treatment. Debate regarding clinical normal data and validation of symptom association parameters in children are missing. The value of new metrics such as mean nocturnal baseline impedance of post-reflux swallow-induced peristal-

tic in children remains to be verified [137]. Also, the existence and implication of reflux hypersensibility (positive symptom association in the absence of pathologic reflux) and functional heartburn in children remains to be proven. Given the high cost of equipment and electrodes, the time needed for analysis and interpretation and the pros and cons in comparison to pH metry are debated.

Spectrophotometric esophageal probes to detect bilirubin are no longer used in children or adults and have been replaced by MII. Orel and coworkers showed that some children with esophagitis suffer from bile reflux [157].

Indirect techniques have been developed, mainly to diagnose GER(D) in patients with extra-esophageal manifestations. Accumulation of evidence regarding the determination of lipid-laden macrophages in bronchoalveolar liquid resulted in the conclusion that this method lacks sensitivity and specificity [1, 2]. More recent data show the presence of pepsin in bronchoalveolar lavage and middle ear fluid [1, 96]. Also bile salts are detected in middle ear fluid [158]. However, epidemiological data suggest a "protective" role of middle ear infection for the prevalence of GERD [1]. There is no data that acid-blocking medication has any effect on an ENT outcome as primary endpoint.

All GER investigation techniques test different aspects of reflux. Therefore, it is not unexpected that the correlation between the results of the different techniques is poor. There is no "always-best" investigation technique to diagnose GERD. "Logic interpretation" (but not evidence-based medicine) suggests that if the question asked is: "does this patient has esophagitis?", that endoscopy with biopsy is the best technique. If it is in the interest of the patient to measure acid GER episodes, 24-h pH metry is the preferred technique. But if quantification of all GER episodes is desired, MII-pH is likely to be the preferred technique. However, postprandial reflux is mainly weakly acid or alkaline, and postprandial reflux was considered to be not really relevant. Therefore, techniques measuring postprandial reflux (barium swallow, ultrasound, scintiscanning) are not recommended. Since therapeutic options are mainly limited to acid-reducing medication, it can be of interest to know the pH of the majority of the reflux episodes.

Therapeutic Options

Physiologic GER and regurgitation do not require medical drug treatment although they frequently cause parental distress and anxiousness. Any therapeutic intervention should strike a balance between intended improvement of symptoms and risk for adverse effects. Therapeutic options vary from reassurance, nutritional and positional treatment, prokinetics, and acid-reducing medications to surgery (Table 10.5).

Table 10.5 Schematic therapeutic approach in 2020

Phase 1	Parental reassurance Observation. Lifestyle changes. Exclude overfeeding
Phase 2	Dietary treatment (to decrease regurgitation and infant distress)
	Thickened formula, thickening agents, (thickened) extensive hydrolysates, or amino acid-based formula in cow's milk allergy
	Positional treatment (°)
Phase 3	For immediate symptom relief: Alginates (some efficacy in moderate GERD); antacids only in older children
Phase 4	Acid secretion blocking medication in ERD (proton-pump inhibitors are drug of choice; more safety data needed)
Phase 5	Prokinetics in NERD (theoretical concept, but no drug has been shown to be effective)
Phase 6	Laparoscopic surgery. Consider baclofen before surgery

Adapted from Vandenplas et al. [1]

Legend. Efficacy and safety data in infants and children for most anti-GER medication are limited

(°) limited data on 40-degree supine sleeping position in infants, *(N)ERD* (non) erosive reflux disease, *GERD* gastroesophageal reflux disease

Complications of Non-intervention

Although reviews on the natural evolution of regurgitation are available [8, 49, 50], there are only limited data on the natural history of GERD in infants and children because most patients do receive treatment at some point.

Traditionally, the impact of regurgitation on the long-term quality of life is trivialized since regurgitation is transitory in the vast majority of infants. However, recent data suggest a decreased quality of life in a number of parents of infants presenting with frequent regurgitation, even if the regurgitation has disappeared [80]. Infants spilling during 90 days or more during the first 2 years of life are at a greater risk for GER symptoms at 9 years [50]. Frequent versus infrequent infant spitting is related to a relative risk at 9 years of 2.3 (95% CI 1.3 – 4.0) for at least one GER symptom, of 4.6 (95% CI 1.5 – 13.8) for heartburn, of 2.7 (95% CI 1.4 – 5.5) for vomiting, and of 4.7 (95% CI 1.6 – 14.0) for acid regurgitation [50, 51]. It is unclear if regurgitation is less frequent in breastfed than in formula-fed infants, since data are contradictory [8, 50]. Gender is not a confounding factor, but smoking is [24]. Although symptoms improved in more than half of the infants with reflux esophagitis followed longitudinally for 1 year without pharmacotherapy, histology

remained abnormal in all [159]. But it is not known if treatment of regurgitation, GER, and GERD during infancy changes the outcome in adults.

In Conclusion: Although there is consensus that regurgitation and physiologic GER do not need medical drug treatment, some data suggest that nonintervention may have a negative impact on the quality of life of the child and the family.

Non-pharmacological and Non-surgical Therapies for GER

The most common reason for parents to seek medical help for young infants is frequent troublesome regurgitation and infant distress. Infants with troublesome regurgitation are difficult to distinguish from infants with mild to moderate GERD symptoms. The difference between "physiologic" and "pathologic" GER should not be regarded as a clear delineation, but as a continuum where "at some point" "normality" stops and "disease" begins. Parental coping plays a major factor in this process. Nonpharmacologic treatment such as reassurance, dietary, and positional treatment is recommended as an appropriate first approach in this group.

Reassurance while showing compassion for the impaired quality of life is of importance [2, 160, 161]. Keeping the infant for half an hour or so upright after feeding will also be helpful. In many situations, reassurance means observation of feeding and recommendations regarding appropriate handling of the child during and after feeding (Fig. 10.4: practical algorithm for the management of infant regurgitation). In formula-fed infants, the volume offered per feed should be appropriate according to the age and weight of the child [2, 160]. However, there are no data that relate ingested volume to frequency and volume of regurgitation, although it seems logic to hypothesize that feeding of large volumes favors regurgitations since it will increase TLESRs.

Similarly as for infant crying, parental report during a first consultation may overestimate the incidence of regurgitation [161]. These findings question the efficacy of "reassurance and guidance" which in most studies turns around 20%. The efficacy of "nonintervention" seems to bring the overestimation back to reality.

Excessive regurgitation in the absence of alarm signs such as failure to thrive is not a reason to stop or adapt breastfeeding. Anti-regurgitation (AR) formula decreases the number of episodes of regurgitation and increases the number of infants that do not regurgitate [162]. AR formula meets up to its expectations as it decreases visual regurgitation, but it does not systematically decrease acid reflux according to pH monitoring data [163]. AR formula is "anti-regurgitation" formula and not an "antireflux" formula. Commercialized thickened formula is preferred to thickening agents added to formula at home because the nutritional content of the thickening agent and its effect on osmolarity has been taken in account in the global composition of the commercialized formula [2, 160].

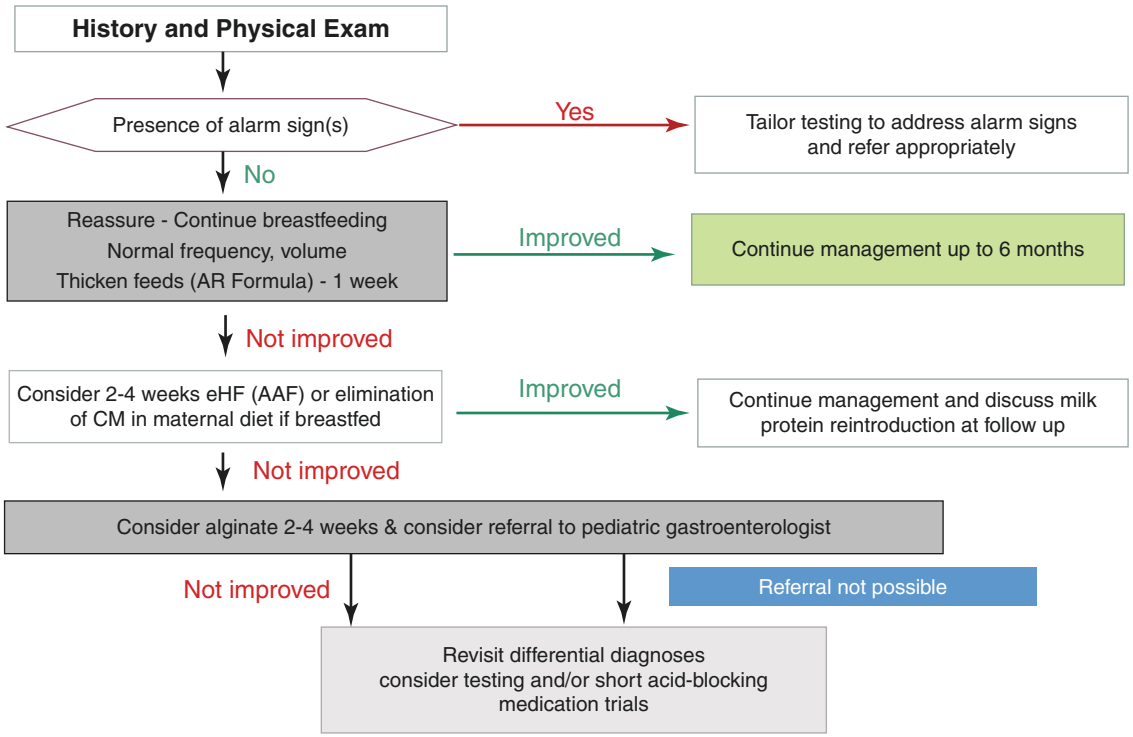
Bean gum is a popular thickening agent. Nutritional safety concerns have been raised based on the findings from an in vitro model that bean gum may hamper the absorption of micronutrients [164, 165]. However, in vivo data have contradicted this fear [166, 167].

Therefore, NASPGHAN and ESPGHAN recommend the use of AR formula, irrespective of the thickening agent (A1). Efficacy may be improved by changing the protein source to a partial or extensive hydrolysate [1, 163]. Partial hydrolysates may be more effective because of a better digestibility than intact protein and an enhanced gastric emptying [168]. CMPA may cause reflux, regurgitation, and vomiting and is often accompanied by a distressed behavior [1, 56]. Whether the efficacy of hydrolysates on reducing regurgitation, vomiting, and GER should be regarded as a proof of (non-IgE mediated) CMPA or because of an enhanced gastric emptying is not clear. The fact that postprandial weak acid reflux is increased after a cow milk challenge in children with CMPA [34] does not differentiate the pathophysiologic mechanism. A thickened extensive hydrolysate manages both conditions, and as a consequence does not differentiate between GERD and allergy [169].

Limited data suggest that probiotics, especially *Lactobacillus reuteri* DSM 17938 enhances gastric emptying and therefore decreases regurgitation [170, 171]. The same probiotic was shown to reduce regurgitation in breastfed infants [172].

Sleeping positions that have been suggested to reduce GER include prone, immediate right side with later left side after feeding, and supine 40° anti-Trendelenburg [173, 174]. Prone sleeping position is not recommended in infants because of the increased risk for sudden infant death. Van Wijk et al. concluded that the biggest benefit was achieved with a strategy of right lateral positioning for the first postprandial hour with a position change to the left thereafter to promote gastric emptying and reduce liquid GER in the late postprandial period [174]. However, independent studies reported a significantly increased risk of sudden infant death in side compared to the supine sleeping position [175, 176]. The results of a pilot study with the "Multicare AR-Bed®" suggest that this bed that nurses the infant in a 40-degree supine body position reduces regurgitation, acid reflux measured with pH monitoring, and reflux-associated symptoms evaluated with the I-GERQ (Fig. 10.5) [173].

In Conclusion: For noncomplicated reflux, management with medication is not recommended. Parental reassurance



AR: anti-regurgitation
eHF: extensively hydrolysed formula
AAF: amino acid formula
CM: cow's milk

18-9-2020

Fig. 10.4 Algorithm for the management of infant regurgitation

Fig. 10.5 The Multicare AR-Bed

and education regarding regurgitation and lifestyle changes are recommended. Positional treatment by keeping the infant upright for half an hour decreases regurgitation. Excessive regurgitation is not a reason to stop breastfeeding. Frequency and volume of formula should be adapted to the infant's weight and age. Thickened AR formula is effective in reducing regurgitation [1, 2, 177]. Data regarding probiotics are too limited to recommend routine administration. Hydrolyzed protein may offer an additional benefit.

Pharmacological Therapies for GERD

Pharmacotherapeutic agents used to treat GERD encompass antisecretory agents, antacids, surface barrier agents, and prokinetics. Pharmacologic treatment of infants with reflux symptoms is problematic as many infants have GER and little correlation is noted between reported symptoms and endoscopic or pH findings.

Prokinetics and Other Non acid-Reducing/Blocking Medication

From the pathophysiologic point of view, prokinetics are the most logic therapeutic approach to treat NERD in infants, since acid reflux is of minor importance in this age group. However, there is no effective and safe prokinetic agent on the market. Cisapride was probably the prokinetic drug for which efficacy data were strongest, although only a decrease of the reflux index (% time pH was <4.0) has been shown.

Cisapride significantly reduced the reflux index (weighted mean difference –6.49; 95% CI –10.13 to –2.85; $P = 0.0005$) [178]. But cisapride was taken off the market in the beginning of this century by the American and European authorities because of its cardiac adverse effects such as QT prolongation and torsades de pointes.

Other prokinetics are metoclopramide and domperidone. The efficacy studies with metoclopramide are limited and outdated [179, 180]. The seven metoclopramide studies performed in children under the age of 2 years are all from before 1990 and used a variety of outcomes [179, 180]. Compared to placebo, metoclopramide appears to reduce daily symptoms (SMD –0.73; 95% CI –1.16 to –0.30), and to reduce the reflux index (WMD –2.80%; 95% CI –5.58 to –0.01) [179]. Metoclopramide has a high incidence of adverse effects such as lethargy, irritability, gynecomastia, galactorrhea, and extra-pyramidal reactions and has caused permanent tardive dyskinesia. The most commonly reported adverse effects associated with the use of metoclopramide in children—extra-pyramidal syndrome, diarrhea, and sedation—were reversible and of no long-term significance [181]. No guideline recommends metoclopramide to treat GERD [1, 2, 180].

A systematic review of studies on domperidone identified only four randomized controlled trials in children, none providing evidence for efficacy [182]. Domperidone occasionally causes extra-pyramidal central nervous system side effects [65]. Domperidone-treated infants infrequently (i.e., <5%) displayed QTc prolongation at doses used for the management of GORD in infants [183]. Pathological QTc intervals were noted among a small number of infants, which supports the possibility of domperidone-associated risk of prolonged QTc interval [184].

Nevertheless, the lack of efficacy and the cardiac effects of domperidone did result in withdrawal of domperidone for infants [185–187]. As a consequence, domperidone is not recommended in GERD management [188]. Since 2019, the use of domperidone in newborns, infants, children (under 12), and adolescents weighing less than 35 kg is no longer approved at the European level. Other prokinetic molecules such as mosapride, itopride, prucalopride, and renzapride have not or insufficiently been studied in children.

In adults, metoclopramide and domperidon neither are recommended for the treatment of GERD [189]. Nevertheless, other prokinetics have been studied for their potential benefit in GERD patients, albeit in small studies. Itopride decreased both symptoms as well as pathologic reflux [190]. Recently, the combination of acotiamide with PPI demonstrated a significant improvement of symptoms as well as reflux parameters over PPI alone [191]. Combining mosapride with PPI was, on the other hand, not more effective than PPI alone in GERD [192–194].

Bethanechol, a direct cholinergic agonist, was studied in a few controlled trials and has uncertain efficacy and a high incidence of adverse effects [1, 2]. Baclofen is a gamma-aminobutyric acid (GABA)-B receptor agonist used to reduce spasticity in neurologically impaired patients. Baclofen was shown to reduce the number of TLSERs and acid GER during a 2-h test period and to accelerate gastric emptying [195]. Baclofen can be used as supplemental therapy to proton-pump inhibitors in children with refractory GER, although failure rate is around 33% [196]. The data on baclofen are very limited, and the high incidence of adverse events does not justify its widespread use. Also abaclofen did not fulfill its promises. However, experience is different in adults. In adults, add-on therapy with baclofen validated its ability to reduce GERD symptoms as well as to reduce acid exposure [197, 198], even in the presence of a hiatal hernia [199]. M0003 is a specific and high-affinity 5-HT4 agonist for the treatment of upper GI disorders, focusing initially on severe gastroparesis and pediatric reflux. Clinical studies have been postponed.

Erythromycin was mostly studied in infants with feeding problems and has been very poorly studied in GER [200]. Erythromycin was shown to not reduce GER in preterm infants [201]. Moreover, prolonged use is associated with loss of efficacy because of tachyphylaxis. In adults, azithromycin was shown to reduce acid reflux in patients with a small hiatal hernia and to reduce reflux after lung transplant [202, 203].

In conclusion Although the prokinetic concept is of interest, there is no effective prokinetic on the market. All prokinetics have a high incidence of adverse effects. The North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) and European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) practice guidelines concluded that there is insufficient evidence to justify the routine use of prokinetic agents [1, 2].

Alginate(-Antacids) and Mucosal Protectans

Alginate(-antacids) have mainly been validated in adults. Their key therapeutic advantage is their rapid onset of action, within minutes from ingestion. Results showed a marginal but significant difference between Gaviscon Infant and placebo in average reflux height being better for placebo [204]. Although the NASPGHAN/ESPGHAN guidelines did not recommend alginates because of lack of evidence [2], the NICE guidelines and a Cochrane review concluded that the evidence was sufficient to recommend a 2-week trial [205, 206]. An open trial showed improvement of clinical symptoms but also of impedance parameters during 24-h administration of alginate [207].

There is more experience with mucosal protectans in adults than in children. In adults, some studies indicate adequate symptom relief and improvement of quality of life with the combination of chondroitin sulfate and hyaluronic acid in a bioadhesive formulation alone or when combined with PPI [208, 209]. However, as data in children are lacking, mucosaprotectants so far have no role in the management of GERD in children [1, 2].

In conclusion: Based on expert opinion, there may be a transitory place for alginates in patients with GERD in whom rapid symptom resolution is required, but there is no evidence for this recommendation. The value of hyaluronic acid and chondroitin sulfate in children remains unknown and should therefore not be recommended as yet.

H^2-Receptor Antagonists (H_2RAs) and Proton-Pump Inhibitors (PPIs)

Ranitidine is by far the most popular H_2RA. Since PPIs are more effective to suppress acid than H_2RAs, PPIs are considered the preferred option for the treatment of acid GERD in children and adults [210]. Some infants presenting symptoms assumed to be caused by acid GER fail to respond to acid suppression [211]. It has been shown in adults and children that PPIs do not reduce the incidence of reflux episodes [212, 213]; they change the pH of the refluxate from acid to nonacid or weakly acid.

Because PPIs in liquid formulation are only available in a very limited number of countries, H_2RA sirup remains popular since it is available worldwide, making it easier to administer in infants and young children. However, ranitdine has been withdrawn from the market in many countries because of the presence of nitrosamines, a carcinogen [214]. The sirup does also contain minimal amounts of alcohol. The prescription rates of antiacid medications are still on the increase [215]. Between 2002 and 2009, there was an 11-fold increase of the use of PPI in the USA [2]. In 2010, lansoprazole was the 9th and ranitidine the 14th most prescribed drug in children under 2 years of age in the USA [74].

Since gastrin release after a meal is one of the most potent activators of H^+–K^+-ATPase, PPI should be administered long enough before a meal to be absorbed, but not eliminated, by the time the proton pump is activated [216]. It may be preferred to administer PPI once a day, before breakfast because young children eat frequently during the day. PPI must be protected from gastric acid by enteric coating; the granules and tablets should not be crushed, chewed, or dissolved as gastric acid secretion may alter the drug. If the microgranules are enteric coated, the capsules can be opened and administered orally or via a feeding tube, in suspension in an acidic medium such as fruit juice, yogurt, or apple sauce. A "home-made" liquid formulation, produced by dissolving the granula, not the microgranula, in 8.4% bicarbonate solution has been developed [1, 2].

Omeprazole is approved in the USA and Europe for use in children older than 1 year of age; in the USA, lansoprazole is approved as well. Esomeprazole is approved in the USA for short-term treatment of GERD with erosive esophagitis in infants aged from 1 to 12 months [177]. In Europe, approval for esomeprazole is identical to the approval of omeprazole. Pharmacodynamics and -kinetics have been studied for many PPI molecules in different age groups. In children aged 6 to 16 years with GERD, currently available pantoprazole delayed-release tablets can be used to provide systemic exposure similar to that in adults [217]. Recommended dosages of antiacid medications are listed in Table 10.6. When PPI need to be administered through a nasogastric tube, the most satisfactory results were obtained with lansoprazole orally disintegrating tablet [218]. A 5 ml volume of water diluent for suspension and a 10 ml volume of flush-through water made it possible to deliver the full lansoprazole dose [219].

Authorities seem to approve PPIs in neonates, infants, and children rather on pharmacologic studies than on effectiveness in the treatment of GERD [216, 219]. Rectal administration of PPI has scarcely been investigated; there are no data comparing its efficacy with oral intake.

Table 10.6 Drugs and recommended dosages for the treatment of GERD

Drug (commercial name)[a]	Recommended dosage	Max dosage (adults)
Prokinetics		
Metoclopramide (Primperan®)	0.4–0.9 mg/kg/day	60 mg
Domperidone (Motilium®)	0.80–0.9 mg/kg/day	30 mg
Baclofen (Lioresal®)	0.5 mg/kg/day	80 mg
Antacids		
Sodium alginate (Gaviscon®)		
Histamine-2-receptor antagonist (H2RA)		
Ranitidine (Zantac®)	5–10 mg/kg/day	300 mg
Nizatidine (Axid®)	10–20 mg/kg/day	300 mg
Famotidine (Pepcidin®)	1 mg/kg/day	40 mg
Proton-pump inhibitors (PPIs)		
Omeprazole (Losec®)	1–4 mg/kg/day	40 mg
Esomeprazole (Nexium®)	10 mg/day (weight <20 kg)	
	20 mg/day (weight >20 kg)	40 mg
Lansoprazole (Prezal®, Prevacid®)	2 mg/kg (infants)	30 mg
Panotoprazole (Pantomed®)	1–2 mg/kg/day	40 mg
Dexlansoprazole (Dexilant®)	>12 years	60 mg

[a]All these drugs can be prescribed under pharmacologic name (except Dexlansoprazole)

The belief that many infants do present with (excessive) crying because of (excessive) esophageal acid exposure has become extremely popular over the past 10 years. Many infants have periods of unsettledness, irritability, and distress during the first months of life. Spilling due to reflux of gastric contents is also seen very frequently. These are in general part of the normal patterns of infancy that resolve with time. In recent years, these normal developmental processes have increasingly been ascribed to pathology and treated with medical therapies, including acid suppressants [220]. GERD may cause excessive crying in infants [52]. The concept that infant irritability and sleep disturbances are manifestations of GER is largely extrapolated from adult descriptions of heartburn and sleep disturbances that improve with antacid therapy [1, 2, 221]. However, there is no evidence to subscribe to this hypothesis in children. In the study by Heine et al., all infants with pathological GER presented with frequent vomiting, and "silent" pathological reflux did not occur, indicating that pathological GER is an unlikely cause of infant irritability under the age of 3 months [52]. Several placebo-controlled prospective trials with PPIs in infants presenting with "excessive crying and reflux-like symptoms" have been performed and show negative results, with an increased incidence of adverse events in the PPI group sometimes as being the only difference in outcome [81, 217, 219]. Antiacid medications are among the most commonly prescribed medications in neonatal intensive care units in the USA because they are administered to treat clinical signs thought to be caused by GER, such as apnea, bradycardia, or feeding intolerance, despite the lack of evidence of efficacy in this population [74, 222]. Use of antireflux medications at the time of discharge seems to be common for extremely low birth weight infants [65]. The lack of evidence for a benefit of PPIs in neonates seems not to determine the beliefs of physicians [223]. Prolonged treatment of pediatric patients with PPIs has not caused cancer or significant abnormalities [219]. However, many adverse effects related to PPI use have been reported in both children and adults, such as small bowel intestinal overgrowth, idiosyncratic reactions, drug-drug interactions, hypergastrinemia, hypochlorhydria, and many others [1, 2, 215]. Idiosyncratic reactions occur in up to 12–14% of children taking PPIs: headache, diarrhea, constipation, nausea [1, 2]. Acid suppression or hypochlorhydria causes an abnormal gastrointestinal microbiome and bacterial overgrowth in up to 30% of patients [224]. As a consequence, the prevalence of infectious respiratory and gastrointestinal tract infections is increased [215]. PPIs are associated with an increased risk of colonization and infection with *Clostridium difficile*. PPIs, particularly if administered for <30 days or in a high dose, showed an association with community-acquired pneumonia [215]. Acute interstitial nephritis has repetitively been attributed to PPI [225]. Hypomagnesemia is reported as a rare but severe complication. PPI are reported to be associated with an impairment of bone mineralization [215]. Gastric acid suppression predisposes patients to develop allergy [215, 226]. Antiacid medication during pregnancy was reported to increase the risk to develop asthma in the offspring [215]. In adults, retrospective studies detected an association of long-term PPI use and dementia, further questioning its widespread use in the youngest [227, 228].

Where PPI definitively inactivate the H^+–K^+-ATPase, potassium-competitive acid blockers reversibly inhibit it. The long-term efficacy of vonoprazan in GERD has been demonstrated in adults [229]. However, according to a meta-analysis, this effect was not superior to PPI in general, with the possible exception of rabeprazol [230, 231]. No studies have studied its potential in children.

In adults, awareness of possible side effects of inappropriate PPI treatment initiated research on deprescribing PPI [232]. During this process, some patients will experience rebound acid hypersecretion as a result of PPI-induced hypergastrinemia. This results in symptom recurrence, hampering cessation of treatment. It is therefore mandatory to warn the patient of this possibility. Different approaches are possible: on-demand treatment, dose reduction, and abrupt cessation of PPI. In 2017, a meta-analysis conducted by the Cochrane collaboration indicated that on-demand treatment resulted in a reduction of pill burden, with possible associated increased in GI symptoms [233]. Based on results from different studies, dose reduction is possible in 50–88% of GERD patients [232]. There are insufficient data to favor one approach above the other. Guidelines for deprescribing PPI in adults are available [234, 235]. Both guidelines focus on the need to limit the duration of PPI treatment and emphasize the importance of lifestyle measures, as well as the use of alternative medication like H2RA of antacids. Stopping of PPI is a matter of debate in pediatrics. Most centers arbitrarily decrease the dosage by 50% during 1 week. However, since there are no studies, there is absence of evidence.

In conclusion: If acid-reducing medication is indicated, PPIs are the best choice. PPIs are effective in healing reflux esophagitis in children of all ages but do not improve GER-related symptoms in infants. PPIs are overused in newborns, infants, and young children. Adverse effects of PPIs should be considered, as they are frequent, and the drug is often prescribed when not indicated. Knowledge on the best approach to stop long-term inappropriate PPI treatment is lacking.

Surgery and Therapeutic Endoscopic Procedures

Different antireflux surgical approaches do exist. In general, experience seems to be the best guidance for choosing the technique. Antireflux procedures in the USA were

reported to be most commonly performed in children during a period of life when regurgitation is normal and physiologic and objective measures of GERD are difficult to interpret [236]. In contrast, in Europe, antireflux surgery is considered as a treatment of last resort in children with GERD refractory to pharmacological therapies [237]. Recent data suggest that the selection of patients who will benefit from surgery might be enhanced by automated impedance manometry pressure-flow analysis, which relates bolus movement and pressure generation within the esophageal lumen [237]. In adults, most benefit from antireflux surgery is observed in patients with typical reflux symptoms well controlled with PPI and patients with demonstrated pathologic esophageal acid exposure [238]. The management of antireflux surgery in PPI-refractory GERD is mainly based on expert opinion [239].

Fundoplication in children reduces GER without altering esophageal motility [240]. Primary fundoplication provided control of symptoms in almost 90% of patients and also reduced the rate of esophagitis. Failure of primary fundoplication occurred in 15% of patients, and an underlying disorder, esophageal atresia, and hiatoplasty increased the risk of failure [241]. The LOTUS study prospectively evaluated the efficacy of omeprazole versus antireflux surgery in GERD adult patients over a 5-year time interval. After controlling for study dropout, no difference in remission rate was identified between both groups [242]. Nevertheless, prior adult series report that between 37% and 62% of patients are again on PPIs a few years after surgery [243, 244]. Since laparoscopic antireflux surgery is much less invasive than open surgery, causing less operative pain, faster recovery, shorter hospital stay, and a better cosmetic result, only laparoscopic surgery should be performed. Long-term outcome of open and laparoscopic interventions is similar. While antireflux surgery in certain groups of children may be of considerable benefit, a failure rate of up to 22% has been reported [1]. Long-term follow-up after laparoscopic fundoplication produces a good clinical result and a good quality of life [245]. Surgery for GER patients have a significant improvement in their quality of life, not only by the reduction of their symptoms but also in enhancing from the nutritional status [246]. Efficacy of antireflux surgery in neurologically impaired children may be similar to normally developed children [247].

The outcome of antireflux surgery does not seem to be influenced by different surgical techniques, although postoperative dysphagia may occur less after partial fundoplication [247]. Laparoscopic fundoplication is a safe procedure in infants ≤5 kg without increase of postoperative complications, recurrence, or mean operative time [248]. Failure of Nissen fundoplication is particularly frequent in patients previously operated upon for esophageal atresia or congenital diaphragmatic hernia [249]. A redo Nissen is indicated if symptoms of GER recur, but the proportion of failure of a redo is even higher [249].

Table 10.7 Studies evaluating the efficacy of PPI in newborns, infants, and children (updated 2019)

Author (year)	Paper (Ref)	Age	Results
Gold BD (2007)	OA [256]	12–17 years	Symptom improvement
Gilger MA (2008)	OA [257]	1–11 years	Symptom improvement
Baker R (2010)	OA [258]	1–5 year	Pantoprazole effective in GERD with esophageal symptoms
Higginbotham TW (2010)	Rev [259]	Infants and children	PPIs are not effective in common infant GERD-associated symptoms
Tolia V (2010)	OA [260]	1–11 years	Esomepazole heals macroscopic and microscopic erosive esophagitis
Winter H (2010)	OA [261]	1–11 month	No significant differences between pantoprazole and placebo in withdrawal rates due to lack of efficacy
Van der Pol R (2011)	Rev [262]	Infants	PPIs not effective in reducing GERD symptoms
Lee JH (2011)	OA [263]	4–18 years	PPIs are effective
Winter H (2012)	(OA) [264]	1–11 month	No significant differences between esomeprazole and placebo in withdrawal rates due to lack of efficacy
Ummarino D (2012)	OA [265]	1–181month	PPI > H^2RA for respiratory symptoms
Davidson G (2013)	OA [266]	Neonates	PPIs are not effective
Tjon JA (2013)	Rev [267]	0–16 years	RCTs and systematic reviews: lack of efficacy of PPIs, specifically in young infants
Shashidhar H (2013)	Rev [268]	0–18 years	PPI are effective in healing reflux esophagitis in children of all ages but do not improve GER-related symptoms in infants
Tighe M (2014)	Rev [205]	0–16 years	Moderate evidence was found to support the use of PPIs, along with some evidence to support the use of H_2 antagonists in older children with GERD PPI in infants with functional GER have demonstrated variable benefit
Gold BD (2017)	OA [269]	12–18 years	PPI are effective in NERD in adolescents
Gremse D (2019)	OA [270]	12–18 years	PPI are effective in erosive esophagitis in adolescents
Shimizu T (2019)	OA [271]	1–14 years	PPi are effective in gastric acid-related disease

OA original article, *rev* review

The table is not exhaustive but lists the papers on PubMed between 2007 and 2019 with "proton-pump inhibitor infant" and "proton-pump inhibitor pediatric" as search terms and illustrates the differences in outcome according to age of the patients

Children with underlying conditions predisposing to the most severe GERD comprise a large percentage of many surgical series. The robot-assisted Nissen fundoplication in children is a safe alternative to conventional laparoscopic surgery [250]. Cardiaplication results in an increase in cardia yield pressure in young pigs. This procedure may be an alternative antireflux operation for infants [251].

Therapeutic endoscopic procedures are rarely indicated and should only be performed in units where there is experience [252]. Different endoscopic techniques have been developed over the years, but only the transoral incisionless fundoplication procedure and radiofrequency application survived the test of time [253]. The transoral incisionless fundoplication procedure can complement the current surgically and medically available options for children with GERD, especially in complicated patients such as those with neurological impairment [254]. In a small series, radiofrequency application resulted in complete symptom remission in 5 of 6 children with recurrent GERD after previous antireflux surgery [255]. Total esophagogastric dissociation is an operative procedure that is useful in selected children with neurologic impairment or other conditions causing life-threatening aspiration during oral feedings (Table 10.7).

In conclusion: Surgery in indicated when symptoms are life-threatening or when a child beyond the age of 2–3 years is depending on chronic treatment with antiacid medications. In neurologically impaired children, the risk and benefit of a surgical intervention should be well balanced. Nissen fundoplication in neonates and young infants should only be reserved to selected infants failing medical therapy and suffering from life-threatening complications of GERD [177]. Local experience with a given surgical procedure seems the best outcome predictor.

Esophageal Achalasia

11

Efstratios Saliakellis, Anna Rybak, and Osvaldo Borrelli

Introduction

Achalasia literally denotes the inability to relax (from the Greek words α—"not," χάλασις—"relaxation"). Sir Thomas Willis first described the classical symptomatology of achalasia in a patient with dysphagia to liquid food in 1672 [1]. He treated this individual by dilating the esophagus using a sponge attached to the tip of a whalebone. The term "achalasia" was first introduced in 1924 by Hurst in an attempt to describe the inability of the lower esophageal sphincter (LES) to relax in affected individuals [2]. Despite the lack of a clear explanation of the etiopathogenesis of the disease, an effective surgical treatment was proposed by Heller in 1913 [3].

Esophageal achalasia is a primary motility disorder of the esophagus. It is clinically characterized by various degrees of dysphagia to solids and liquids in the absence of other conditions that could possibly cause the same clinical symptoms (e.g., esophageal stricture, eosinophilic esophagitis). The radiological cardinal features consist of abnormal esophageal peristalsis, dilation of the esophageal body, and "bird-beak" appearance at the level of the LES with concomitant delayed emptying of the contrast material from the esophagus. Endoscopically, this condition is generally characterized by esophageal dilation, presence of saliva or undigested food within the esophagus, and resistance in passing the endoscope through the LES. Manometrically, this clinical entity is defined by the presence of variable impairment of esophageal peristalsis and inability of the LES to relax following swallowing [4]. Primary or idiopathic achalasia is the appropriate term to be used when there is no clear etiology for the disease, whereas in secondary achalasia the cause is by definition known [5].

Epidemiology

There are relatively limited data regarding the incidence of esophageal achalasia in children. It is, however, a rare disease [6], and according to three more recent studies its incidence in the pediatric population has been estimated between 0.1 and 0.3 cases annually per 100,000 children [7–9]. This clinical entity can be encountered at any age; however, it seldom occurs in infancy as only 6% of the diagnoses have been made in this age group [10]. The peak incidence of the disease occurs between 30 and 60 years of age [11, 12]. Although there are data in adult population revealing equal gender distribution, childhood achalasia is more frequent in males than females [10]. Available data do not support any racial predilection among affected individuals [4].

Heredity

The majority of patients with achalasia are sporadic cases. Familial achalasia is less frequent [10] and is more commonly encountered among monozygotic twins and offspring of consanguineous parents. The latter may be suggestive of an autosomal recessive inheritance [13–15].

Etiopathogenesis

Despite the fact that achalasia was described more than 300 years ago, its etiopathogenesis remains largely enigmatic [16]. This condition is likely to be multifactorial in origin [5]. It has been postulated that host genetic factors, autoimmunity, and environmental influences contribute to the initiation of an inflammatory neurodegenerative process. The end result is a reduction in the number of the ganglion cells in the myenteric plexus of both esophageal body and LES [17]. During the initial stage of the disease, the neurodegenerative process affects the inhibitory neurons and their

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_11

neurotransmitter nitric oxide (NO) more than the excitatory neurons and neurotransmitters, such as acetylcholine, resulting in both high-amplitude non-propagative contractions of the esophageal body and non-relaxing LES, which is described by the term "vigorous achalasia" [17–20]. The disease gradually progresses, and cholinergic neurons are affected as well leading to "classical achalasia," which is characterized by very low-amplitude esophageal body contractions or aperistalsis in addition to an inability of the LES to relax in response to deglutition [21–24]. There are data suggesting that neurodegeneration might not be limited to the esophagus only as abnormalities (Wallerian degeneration) have been also demonstrated in the vagus nerve of affected humans and experimental animal models [25, 26]. Furthermore, abnormal findings in the brainstem (Lewy bodies), prolonged gastric emptying time, and disturbed response of gastric secretions to hypoglycemia have also been reported in achalasic patients [27–29].

Despite many advances in our understanding of achalasia [30], the triggers of neurodegeneration are poorly defined. Infections by various agents (e.g., measles, varicella-zoster virus, herpes simplex viruses type 1, 2, 6, human herpesvirus 6, Epstein–Barr virus, human papillomaviruses) have all been implicated in the pathogenetic process [31, 32]. However, the role of these viruses has been questioned by other authors [33, 34]. Thus, with the exception of Chagas disease caused by Trypanosoma cruzi, there is inadequate evidence to support a definitive causative association between infections and esophageal achalasia [35]. Autoimmunity has also been proposed as a key factor in the pathogenesis of esophageal achalasia. The latter was postulated by the identification of inflammatory cells [21, 36–38]. Moreover, the identification of specific human leukocyte antigen (HLA) class II histocompatibility antigens in combination with the presence of antimyenteric autoantibodies [39, 40] further strengthened the hypothesis of the autoimmunity involvement in the disease's pathophysiology. However, these findings have not been confirmed by subsequent studies [41, 42]. In conclusion, current evidence suggests that there may be an element of autoimmune predisposition to achalasia for certain individuals, but the available data do not support a definition of achalasia as an autoimmune disease.

Certain reports of achalasia in siblings, monozygotic twins along with familial cases [43–46] raised the possibility of a potential genetic hereditary influence. The latter is particularly true for the cases of achalasia in the context of Allgrove syndrome in which a correlation has been identified between the esophageal dysmotility and the ALADIN gene [47, 48]. The potential genetic basis of this clinical entity is further highlighted by the association of achalasia with other diseases with proven genetic influence (Trisomy 21, Parkinson disease, Rozycki syndrome) [49–51]. Moreover, specific polymorphisms in the genes of NO synthase (NOS), vasoactive peptide (VIPR1), interleukin-23 receptor (IL-23R), interleukin-10 (IL-10) promoter, and protein tyrosine phosphatase non-receptor 22 (PTPN22), along with abnormalities of guanylate cyclase (the major nitric oxide receptor) and disruptions in the nitric oxide signaling, may be associated with achalasia providing additional data regarding the pathophysiology of idiopathic achalasia. However, more studies are required to further elucidate the details of the downstream responses that ultimately impair the esophageal body motility and render the LES incapable of relaxation [52–58].

In contrast to idiopathic achalasia in which the cause remains largely unknown, in secondary achalasia, the causative factor can be identified. Table 11.1 depicts certain pathologies which are associated with achalasia-like motility disorders [59–72].

Table 11.1 Pathologies associated with achalasia-like esophageal dysmotility

Chagas disease
Tumors (e.g., leiomyoma, Hodgkin's disease, gastric carcinoma; "pseudoachalasia")
Sarcoidosis
Hereditary cerebellar ataxia
Eosinophilic esophagitis
Hirschsprung's disease
Chronic idiopathic intestinal pseudo-obstruction
Multiple endocrine neoplasia type 2b
Miscellaneous (e.g., juvenile Sjogren's syndrome, moyamoya disease, Ondine's curse, autism)

Clinical Presentation

The clinical picture of achalasia depends on the duration of symptoms and the age of the child at the time of the diagnosis [73]. It has been reported that childhood achalasia is more common in males and is largely occurring in school-age children (7–12 years). However, achalasia may occur during infancy [74]. Cases have also been reported in premature neonates as young as 29 weeks of gestation and as small as 900 g [75, 76]. The mean duration of symptoms prior to diagnosis was less than 3 years in 80% of the children, and the chief complaints are represented by dysphagia and emesis [10]. Table 11.2 summarizes the clinical symptoms of the children reported in the literature [77]. Noteworthy, children younger than 5 years of age present more frequently with vomiting, whereas dysphagia is the predominant complaint in older children [73]. Dysphagia is progressive and initially confined to solids, and in later stages to both solid and liquid. The child usually reports a sensation of food getting "stuck" in the esophagus ("chest") which is usually relieved by multiple swallowing efforts or by washing the food bolus down

Table 11.2 Chief complaints in childhood achalasia

Chief complaints in childhood achalasia	Frequency (%)
Regurgitation/vomiting	80
Dysphagia	76
Loss of body weight	61
Respiratory tract symptoms	44
Thoracic pain	38
Faltering growth	31
Regurgitation at nighttime	21

with liquids. The troublesome deglutition leads to limited oral intake (food refusal) and subsequently in suboptimal weight gain (failure to thrive) or weight loss. As the disease progresses, the esophagus becomes dilated and the patient may experience regurgitation of undigested food or saliva that accumulates at nighttime while the child is asleep, leading also to episodes of recurrent coughing and choking. The latter may predispose the child to a significant risk of chest infections or even sudden death due to aspiration of esophageal contents [78].

Diagnostic Approach

Diagnosis is often delayed due to several factors, including its low incidence and the inability of younger children to report the symptoms, which are often nonspecific. Moreover, most of the related symptoms and signs, such as emesis, respiratory involvement, and failure to thrive, are commonly attributed to gastroesophageal reflux (GER) disease. Therefore, a detailed history and a careful clinical examination are paramount as they can expedite the diagnostic process by guiding the physician in the correct choice of investigations which will eventually establish the diagnosis. Some individuals will have associated alacrima and adrenal insufficiency (AAA syndrome) and may have dermal hyperpigmentation secondary to high blood adrenocorticotropic hormone (ACTH) concentrations. Radiological, endoscopic, and manometric procedures represent the diagnostic arsenal and are the recommended modalities for the diagnosis of achalasia [4]. Esophageal achalasia needs to be distinguished from other conditions that present with regurgitation, vomiting, and dysphagia. Table 11.3 presents the entities that physicians should include in the differential diagnosis of esophageal achalasia [4, 67, 79–87].

Radiology

Upper gastrointestinal (GI) contrast series (esophagography/esophagogram/barium swallow) provides a convenient way to assess the anatomy of the upper GI tract. They are usually readily available and as a result can expedite the diagnostic assessment or confirm the diagnosis in many of the suspected cases of achalasia. In spite of its undisputed usefulness, reports from adult studies showed that esophagogram can be nondiagnostic in up to one-third of cases [88]. These data, however, were not substantiated in the pediatric population where 92% of the studies demonstrated abnormal findings [10].

The esophagogram usually reveals various degrees of esophageal body dysmotility with or without esophageal dilation, narrowing of the lumen at the level of esophagogastric junction (EGJ; "bird-beak" or "rat-tail" appearance), poor emptying of the contrast material into the stomach, and prominent tertiary contractions in the case of vigorous achalasia [10, 89–92] (Figs. 11.1, 11.2, and 11.3). Esophagography supports the diagnosis in the case of an equivocal manometry and can also demonstrate findings of end-stage achalasia (e.g., tortuosity and angulation of the esophageal body, megaesophagus) which may modify the clinical decision regarding the most appropriate therapeutic approach [4, 93–97]. Additionally, radiology can be used as an objective tool to evaluate the response to treatment (the so-called timed barium esophagogram (TBE), which measures the height of the barium column in the upright position after an ingestion of a large barium bolus) [98, 99], and as a predictor of treatment's efficacy [100–102].

Upper Gastrointestinal Endoscopy

Endoscopy has an important role in the diagnosis of achalasia as it rules out clinical entities that can mimic achalasia, such as eosinophilic esophagitis and other causes of pseudoachalasia. It can also alter the initial working diagnosis for patients erroneously treated for GER [4, 103, 104]. The major endoscopic findings raising a high index of suspicion for achalasia include esophageal dilation, presence of retained saliva or food along with resistance while negotiating the LES. Mucosal abnormalities detected during endoscopic examination may be due to food stasis and candida infections. However, it is not unusual to witness an unremarkable upper GI endoscopy in the early stages of the disease [4].

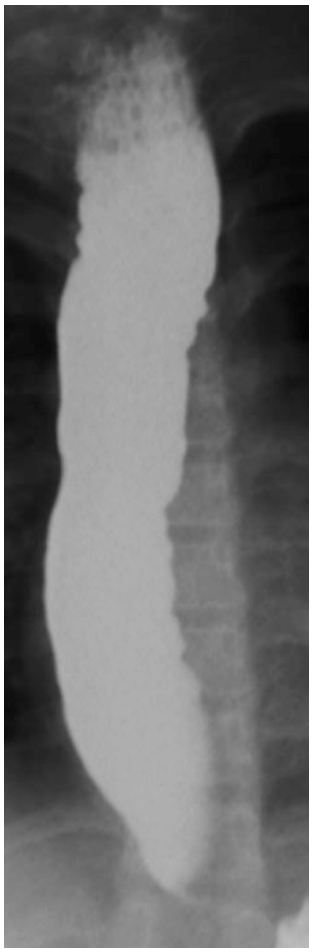

Fig. 11.1 Image of esophagus from barium esophagram in an 11-year-old female with achalasia. There is food residue in the upper esophagus. The esophagus is dilated and shows numerous irregular contraction waves (tertiary contractions)

Of significant note, an increased number of eosinophils have been reported in the esophageal biopsies of achalasia patients [105]. While the interplay among achalasia and esophageal eosinophilic infiltration needs to be further elucidated, it has been suggested that the latter does not represent a distinct clinical entity. Thus, the presence of esophageal eosinophils in patients complaining of dysphagia may warrant further diagnostic work-up to rule out other potential etiologies, including achalasia [106]. High-resolution manometry (HRM) is considered an invaluable tool for discriminating these two entities as they generally have distinctive motor patterns [107–109].

Except for its diagnostic role, upper gastrointestinal endoscopy has been proposed to be a useful intraoperative tool that can help in guiding the extent and adequacy of Heller's myotomy and also enables the operators to assess the integrity of the esophageal mucosa during the procedure [110].

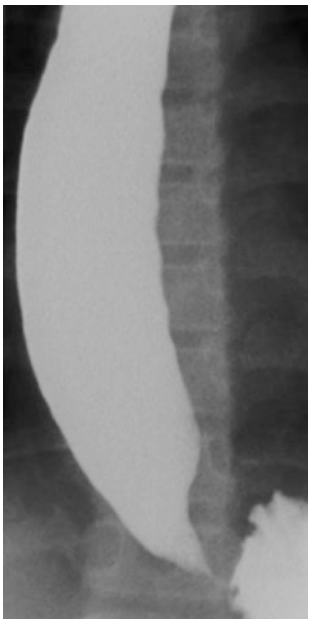

Fig. 11.2 Lower esophagus from barium esophagram in an 11-year-old female with achalasia. The lower esophagus is dilated; there is tapered ("beak-like") narrowing of the gastroesophageal junction

Manometry

Esophageal manometry provides a highly sensitive and specific method for defining the esophageal motility pattern [111]. This is especially true for the combined high-resolution esophageal impedance manometry [112]. Pediatric patients are assessed with a standardized protocol that involves single and multiple rapid wet swallows and solid swallows [109]. The esophageal motor abnormalities found in patients with achalasia are classified into three subtypes of achalasia according to recently introduced Chicago classification [113]. All three subtypes are characterized by elevated integrated relaxation pressure (IRP—a variable which quantifies residual LES pressure): type I is defined by completely failed esophageal body peristalsis (Fig. 11.3b), in type II there is abnormal peristalsis accompanied by pan-esophageal pressurization in more than 20% of the test swallows (Fig. 11.3c), and type III also demonstrates an impaired contractile pattern with fragmental preservation of distal peristalsis or the presence of premature (spastic) contractions in more than 20% of the swallows (Fig. 11.3d) [113]. Available data in pediatrics suggest that there is a high intra- and interrater variability in diagnosing esophageal achalasia along with its subtypes (Chicago classification) when using HRM as a diagnostic modality [114, 115]. The results of the "European achalasia trial" demonstrated that HRM may facilitate clinical decision regarding the most appropriate initial treatment according to the manometric subtype [116]; there are also

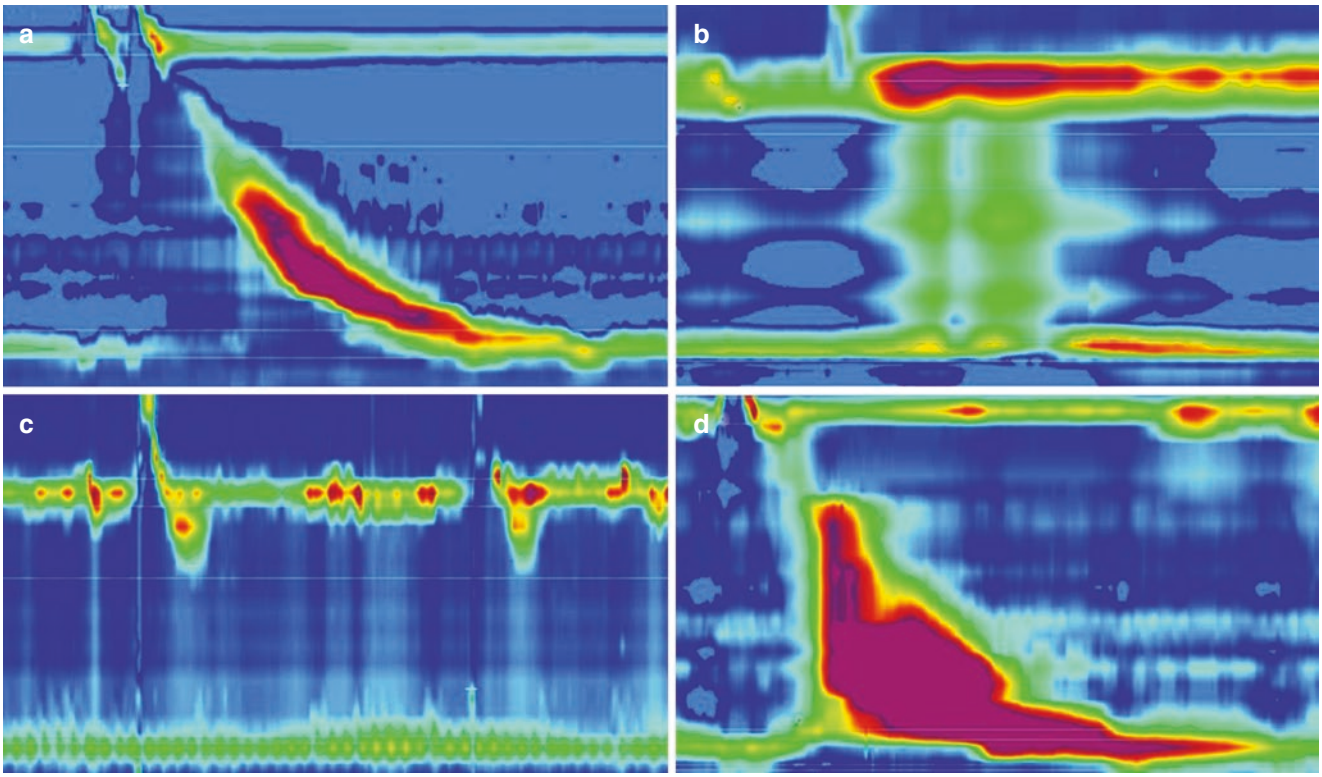

Fig. 11.3 High-resolution esophageal manometry in a healthy (**a**) and three achalasic children. Type I (**b**) is characterized by the absence of distal pressurization to greater than 30 mmHg. In type II (**c**), pressurization to greater than 30 mmHg occurs in at least two of ten test swallows, whereas patients with type III (**d**) disease have spastic contractions with or without periods of compartmentalized pressurization

data supporting the fact that preoperative HRM in children may help in predicting the response to surgery [117]. Furthermore, some data suggest that intraoperative HRM along with the novel imaging tool "EndoFLIP" are safe and useful techniques in determining the adequacy of Heller's myotomy, and therefore decreasing potential future recurrence of symptoms [118–123].

Finally, dysfunction of the upper esophageal sphincter (UES), such as an increased resting pressure, shorter relaxation after swallowing, and shorter interval to pharyngeal contractions after UES relaxation, has been demonstrated in achalasia patients. The clinical significance of such findings is still not well understood [124, 125].

Management

The therapeutic management of achalasia includes pharmacological, interventional, and surgical options. None are curative but they aim in providing symptomatic relief of the EGJ obstruction without addressing the esophageal body dysmotility [126, 127]. However, there is some evidence suggesting potential improvement of the esophageal motility after surgical treatment for achalasia [128].

Pharmacological Therapy

Oral pharmacological treatment is the least effective in managing achalasia [129]. Isosorbide dinitrate and nifedipine act by relaxing the smooth muscles and by blocking the calcium channels, respectively; both reduce the LES pressure [130, 131]. They are administered prior to meals and are considered a temporary measure until a more definitive treatment, either dilatation or surgery, is provided. Oral pharmacotherapy alone is recommended in adult patients who are not willing or eligible for dilatation or surgery and in whom endoscopic botulinum toxin injection (EBTI) has previously failed [4].

Endoscopic Botulinum Toxin Injection

Intrasphincteric botulinum toxin injection blocks the presynaptic cholinergic terminals in the LES and therefore inhibits the secretion of acetylcholine at the neuromuscular junction. The latter results in chemical denervation with consequent opposition of the excitatory effect of acetylcholine and disruption of the relentless contraction of LES [4]. The experience of EBTI in the treatment of childhood achalasia is

relatively limited. The method involves the endoscopic injection of 25 units of botulinum toxin in each one of the four LES quadrants (100 units in total) [73]. Similar to pharmacotherapy, EBTI offers a short-term symptom relief, as pneumatic dilatation (PD) or Heller myotomy (HM) will be eventually required for a more sustained clinical improvement [132, 133].

Pneumatic Dilatation

The goal of performing a forceful esophageal dilatation is to stretch and disrupt the LES fibers to such an extent that it alleviates EGJ obstruction without inducing GER [4, 134]. The procedure is performed under general anesthesia, and patients undergoing dilatation need to be eligible for surgery in the unfortunate event of esophageal perforation [4]. A balloon dilator is inserted with fluoroscopic or endoscopic guidance [71, 135]. The non-radiopaque polyethylene balloon dilators are preferred over the bougienage or the standard balloon dilators as the latter are not effective enough in rupturing the LES fibers and achieving adequate symptoms' control. The modern dilators are of graded size (3.0, 3.5, 4.0 cm); however, for technical reasons PD is usually performed only in children older than 6 years of age or those weighing over 20 kg [4, 71]. After the correct position is confirmed, the balloon is distended for 60 s with pressures that vary among institutions from 2 to 12 psi [71, 135]. Balloon distention until obliteration of its waist while under fluoroscopy is more important for achieving symptom control than balloon distention time [4]. It is advisable that all patients are observed for a certain period of time prior to discharge home, and if symptomatic, they need to be assessed with a gastrografin esophagogram to exclude potential esophageal perforation. The incidence of esophageal perforation in adults who underwent PD for achalasia was reported between 4% and 12% [135]. No cases of post-PD esophageal perforations were documented in recent pediatric studies [71, 135–137]. Small asymptomatic perforations are managed conservatively (intravenous antibiotics, total parenteral nutrition), whereas immediate surgical intervention is mandated for free perforations [138, 139]. The majority of perforations occur during the first dilatation most probably due to inaccurate placement and distention of the dilator; GER has been reported in 15–35% of the patients who underwent dilatation for achalasia treatment [78, 140]. The latter is of important significance as recurrence of symptoms in post-PD patients may be due to reflux-related distal esophageal stricture. Thus, treatment with proton pump inhibitors (PPI) is warranted in post-PD patients complaining of GER symptoms. Other potential post-PD complications include aspiration pneumonia and pain that may require prolonged hospitalization [136].

PD achieves adequate control of symptoms ranging from 67% after the first dilatation to 87.5% after subsequent procedures [71, 135]. Available data suggest that although PD achieves immediate symptom relief, it bears a significant likelihood of symptoms' recurrence that will require subsequent interventions in the form of either repeat PD or surgery [73, 136, 137, 141]. It is worth mentioning that minimally invasive surgical techniques have challenged the role of PD as the first-line treatment in childhood achalasia, and the recently published data question the efficacy of PD as HM was proven to be significantly superior to dilatation [73, 136, 137, 142].

Surgery

The mainstay of surgical treatment for achalasia is Heller's myotomy, which was first described in 1913 [143]. Over the past decades, HM has evolved from the open thoracotomy to the minimally invasive laparoscopic technique, which has become the procedure of choice among surgeons due to its high efficacy, faster recovery, and minimum morbidity rate [136, 141, 142, 144–147]. Moreover, robot-assisted HM techniques have been recently described in pediatric patients and resulted in promising outcomes [148, 149]. The resolution of symptoms after HM largely depends on the length of the myotomy; this should be long enough to diminish the EGJ obstruction but not excessively long so that it induces postoperative GER. The optimal length of HM in children of different age groups has not been established yet. One report advocates an incision length between 4 and 6 cm that ends 5 mm distally to EGJ along with minimal mobilization of the adjacent anatomical structures [150]. The role of both "EndoFLIP" and intraoperative manometry appears to be very promising in determining the optimal myotomy length [118–123].

The addition of a fundoplication after HM and also the type of the anti-reflux procedure are still a matter of debate. An anti-reflux procedure reduces the risk of postoperative GER but at the same time increases the likelihood of dysphagia, as it creates a high-pressure zone to an esophageal body with an already impaired motility [151–153]. An anti-reflux procedure may be warranted when a wide mobilization of the esophagus is inevitable in order to technically facilitate the myotomy [150]. Regarding the most appropriate type of the anti-reflux procedure, there are data revealing that a loose Nissen, Toupet, Dor, or Thal fundoplication along with HM fundoplication are safe and result in good outcomes in the treatment of childhood achalasia [95, 137, 142, 145, 154, 155]. The American College of Gastroenterology advocates PPI treatment in achalasia adult patients complaining of heartburn post-HM in spite of the presence of a fundoplication [4].

Patients who have developed "end-stage" achalasia and failed myotomy are candidates for esophagectomy with gastric transposition [4, 95, 136, 137]. However, esophagectomy bears greater morbidity and mortality compared to laparoscopic HM; dysphagia requiring PD can still recur up to 50% of the adult patients that underwent esophagectomy for "end-stage" achalasia [156].

Emerging Treatments

POEM is an acronym for "peroral esophageal myotomy": it is a novel technique developed in Japan [157, 158], whereby the endoscopist performs an LES myotomy by creating a submucosal tunnel using a forward-viewing endoscope. The overall success in adult studies has been more than 80% at 12-month follow-up [158]. There are relatively limited data regarding the applicability, safety, and efficacy of this method in childhood achalasia. Recently published studies (including a systematic review with meta-analysis) revealed that POEM in pediatric patients was effective and safe, but clearly further evidence is needed in order to assess its long-term outcomes (e.g., sustained therapeutic effect, incidence of post-POEM gastroesophageal reflux disease) and its efficacy/safety compared to other therapeutic options for childhood achalasia [159–169].

There is little evidence that other techniques for treating achalasia such as removable self-expanding metallic stents are efficacious, and moreover there is a paucity of studies in children in order to evaluate the safety and efficacy of such treatments in pediatrics [170–172].

Follow-Up and Surveillance

Currently, there is a lack of consensus regarding the optimal short- and long-term follow-up of children treated for esophageal achalasia. It is, however, advisable that pediatric patients receive regular follow-up assessment to ensure a sustained relief of their pre-treatment symptomatology along with an assessment of their physical growth and overall development [172].

Patients treated for achalasia have a normal life expectancy [173]. Despite an increased risk of esophageal carcinoma in patients with achalasia [174–176], there are limited data to support regular screening for cancer. Thus, the American College of Gastroenterology, the American Society for Gastrointestinal Endoscopy, and the International Society for Diseases of the Esophagus do not advocate routine endoscopic surveillance for patients with esophageal achalasia [4, 163, 172, 177]. Nevertheless, radiological or endoscopic surveillance is recommended by numerous authorities for the assessment of adult patients treated for achalasia as they are at an increased risk for developing end-stage disease with megaesophagus. This approach with regular evaluation in 3-year intervals is particularly proposed if the disease has been diagnosed for more than 10 to 15 years [178]. Clearly, more data are required for the implementation of such recommendations in childhood achalasia.

Conclusion

Childhood esophageal achalasia is an enigmatic disease. Contemporary diagnostic modalities (upper GI contrast series, endoscopy, HRM) offer rapid and accurate diagnoses. Current data suggest that laparoscopic HM combined or not with an anti-reflux procedure seems to be the therapeutic procedure that offers the most durable and sustained long-term symptom relief.

Helicobacter Pylori Gastritis and Peptic Ulcer Disease

12

Zrinjka Mišak and Iva Hojsak

Abbreviations

AMO	Amoxicillin
BabA	Blood antigen-binding adhesin
CagA	Cytotoxin-associated gene A
CLA	Clarithromycin
COX-1	Cyclooxygenase-1
^{13}C-UBT	^{13}C-urea breath test
dupA	Duodenal ulcer promoting
ELISA	Enzyme-linked immunosorbent assay
ESPGHAN	European Society of Pediatric Gastroenterology, Hepatology and Nutrition
FISH	Fluorescence in situ hybridization
GGT	Gamma-glutamyl transpeptidase
H. pylori	*Helicobacter pylori*
IDA	Iron deficiency anemia
MALT	Mucosa-associated lymphoid tissue
MET	Metronidazole
NASPGHAN	North American Society for Pediatric Gastroenterology Hepatology, and Nutrition
NSAIDs	Nonsteroidal anti-inflammatory drugs
OipA	Outer inflammatory protein A
OMV	Outer membrane vesicles
PAMPs	Pathogen-associated molecular patterns
PCR	Polymerase chain reaction
PPI	Proton pump inhibitors
PRRs	Pattern recognition receptors
SabA	Sialic acid-binding adhesin
T4SS	Type IV secretion system
VacA	Vacuolating cytotoxin A
WB	Western Blot

Introduction

Helicobacter (H.) pylori is a Gram-negative, microaerophilic spiral bacterium that infects the stomach. Stomach colonization causes chronic gastritis that can remain silent, due to the dynamic equilibrium between the bacterium and its human host, or evolve into more severe diseases, such as atrophic gastritis, peptic ulcer, lymphoma of the mucosa-associated lymphoid tissue (MALT), or gastric adenocarcinoma [1, 2]. Difference in the consequences of *H. pylori* infection could be at least partially explained by the high variability of colonizing *H. pylori* strains and host response to this microbe [3].

The discovery of *H. pylori* as a major cause of peptic ulcer disease had a significant impact on its perception and treatment. The importance of the discovery was awarded by the Nobel Prize in 2005 to Marshall and Warren who proved the etiological role of *H. pylori* in gastritis and peptic ulcer disease.

Children differ from adults with respect to *H. pylori* infection in terms of the prevalence of the infection, the complication rate, the near-absence of gastric malignancies, age-specific problems with diagnostic tests and drugs, and a higher rate of antibiotic resistance [4, 5].

Bacterial Pathogenesis

H. pylori pathogenesis, still not fully elucidated, is mediated by a complex interplay between bacterial, host, and environmental factors [6, 7]. When *H. pylori* reaches the gastric lumen, in order to establish successful and persistent colonization, the bacterium employs different mechanisms (Fig. 12.1): (1). to survive under acidic stomach condition, (2). to move toward epithelium cells, (3). to attach to host cells by adhesins/receptors interaction, and (4). to cause tissue damage [6, 7].

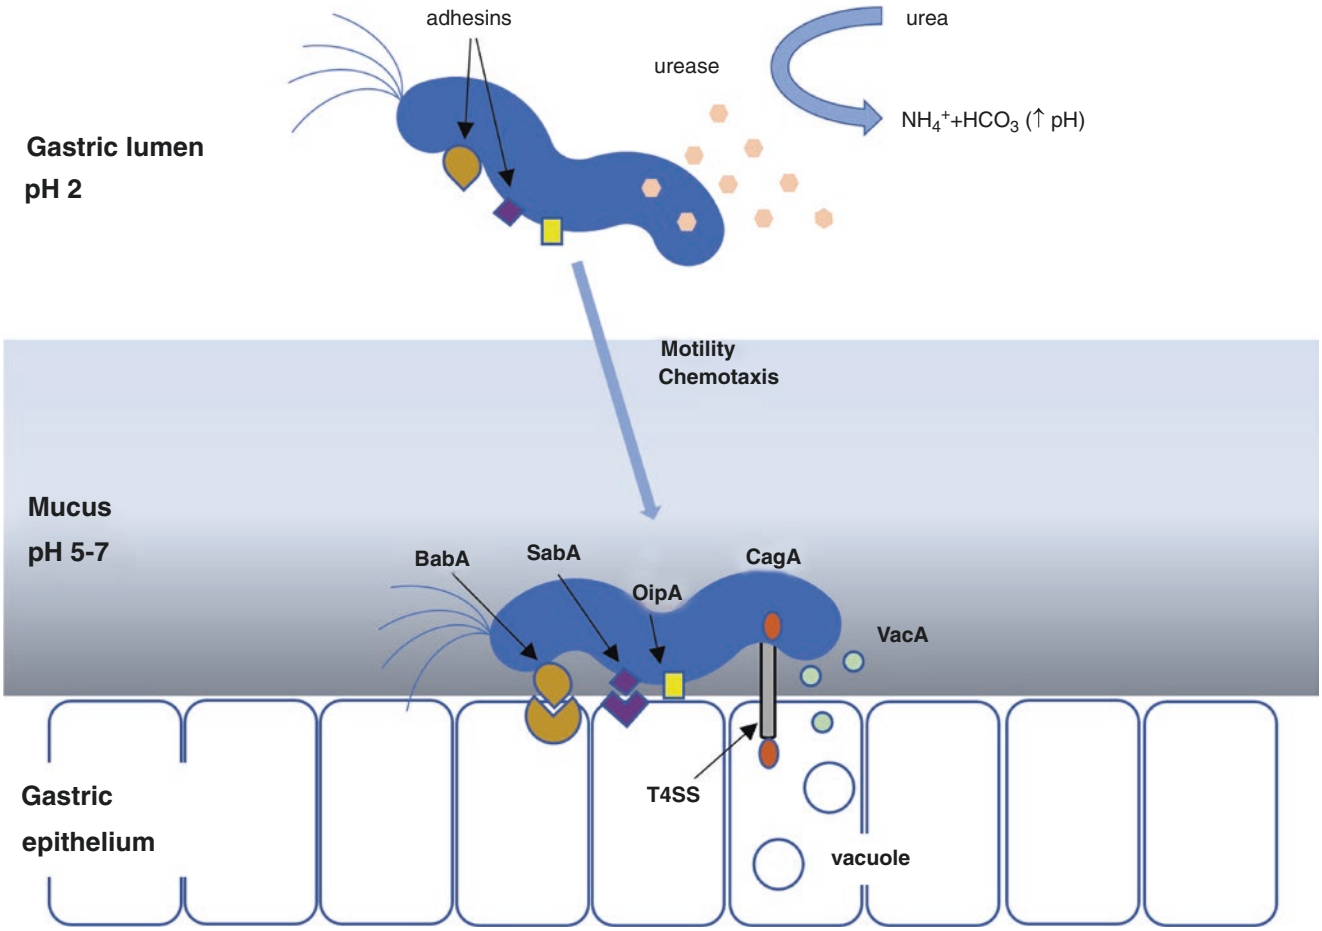

Fig. 12.1 *H. pylori*-associated factors that enable colonization and persistence. Initially, *H. pylori* produces urease which raises the pH through ammonia production. Directed by chemotaxis and enabled by bacterial helical rod-shaped and flagellar-based motility, *H. pylori* moves toward the gastric epithelium. There, colonization of the gastric mucosa is mediated by surface adhesins like SabA and BabA. Finally, *H. pylori* releases several effector proteins/toxins, causing host tissue damage. These factors include cell-bound components (OipA), externally secreted molecules (VacA), and antigens that need to be introduced to a host cell via the type IV secretion system (T4SS) (CagA protein)

Survival in the Acidic Environment

H. pylori prefers neutral or close to neutral pH (pH 5.5–7.5), and in order to survive the acidic environment of the gastric lumen where pH is around 2.0 it has developed some adjusting mechanisms. For this purpose, *H. pylori* produces large amount of urease, a nickel-containing enzyme, which requires efficient uptake of nickel from the environment for its activity. Urease converts urea to ammonia which is transported outside of bacterial cell raising the pH of the surrounding area. In addition to the urease, for ammonia production, *H. pylori* possesses also two aliphatic amidases and aspartase [7–9].

Movement Toward Epithelial Cells

Because of its characteristic helical shape and flagellar motility, *H. pylori* can swim in gastric content and can penetrate the mucus layer in corkscrew-like movement [6, 8, 9]. Four to eight sheathed flagella are situated on a single or on both poles of the bacterium [6]. The number of flagella seems to play an important role in bacterial speed during movement [9]. *H. pylori* flagella can provide different movements according to the media in which the bacterium is located: in liquid media "swimming motility," in soft agar "spreading," and on the surface of solid media, "swarming" movements are observed [6]. More than 40 proteins are involved in the biosynthesis and operation of flagella, making motility one of the most complex processes in the bacteria [7].

Besides flagella, *H. pylori* mobility also depends on chemotaxic action which allows the bacterium to control its swimming behavior and directs itself toward higher pH. *H. pylori* has four chemoreceptors, of which the transducer-like protein is the most important one, located in the bacterial membrane or in the cytoplasm [6, 9]. As a response to extracellular chemical signals (such as mucin, sodium bicarbonate, urea, sodium chloride, and some specific amino acids)

and following interaction with their respective ligands, molecular signal transduction cascade is initiated, which causes a change in the direction of rotation of the flagellar motors [6, 8, 9].

Directly adjacent to the gastric surface epithelium lies the mucus layer that has near-neutral pH [8]. *H. pylori* crosses the gastric mucus layer and starts colonizing the gastric mucosa by adhering to the gastric epithelium where necessary nutrients and protection from the host immune system are obtained [9].

Attachment to Host Cells by Adhesins/ Receptors Interaction

H. pylori colonization of the gastric mucosa is mediated by surface adhesins including blood group antigen-binding adhesin (BabA), sialic acid-binding adhesin (SabA), neutrophil-activating protein, and other adhesins. One of the most well-characterized adhesins is BabA, which binds to the Lewis b ABO blood group antigen expressed on host gastric epithelium cells [6–8]. Bacteria with high BabA expression are more virulent and carry increased risk of peptic ulcer disease and gastric cancer, although the presence of BabA is not correlated to gastric-related diseases in Asians [6, 7]. SabA adhesin plays a critical role in assisting *H. pylori* to adhere to and colonize the gastric epithelium cells of a patient with gastritis. In patients infected with SabA-positive strains, the density of *H. pylori* is dramatically higher than in patients infected with SabA-negative strains [7].

On the other hand, neutrophil-activating protein is highly associated with the chronic gastritis, and infiltration of neutrophils and mononuclear cells into the gastric mucosa [7]. Other adhesins identified are heat shock protein 60, adherence-associated proteins, *H. pylori* outer membrane protein, and lacdiNAc-binding adhesin [7].

Causing Tissue Damage

H. pylori has a number of virulence factors which influence colonization and disease severity [8, 9]. These factors include cell-bound components, externally secreted molecules, and antigens that need to be introduced to a host cell via the type IV secretion system (T4SS) (such as CagA protein) [10].

Similar to other Gram-negative bacteria, *H. pylori* produces outer membrane vesicles (OMVs) that contain various virulence factors. OMVs are continuously shed from the surface of *H. pylori* during infection. Various biologically active compounds of *H. pylori* present in OMVs can be internalized into host cells where they influence signaling pathways, promote apoptosis of gastric epithelial cells, and affect immune responses leading to disease development. The following proteins of *H. pylori* OMVs have been identified: vacuolating cytotoxin (VacA), cytotoxin-associated gene A (CagA), blood group antigen-binding adhesin, sialic acid-binding adhesin, outer inflammatory protein A (OipA), *H. pylori* neutrophil-activating protein, adherence-associated lipoprotein, and urease [10].

CagA is an oncoprotein and one of the most important and best-studied virulence factors [8, 9]. It is encoded by *cagA* gene contained in a *cag* pathogenicity island, a region that also possesses the coding sequence of a type IV secretion system (T4SS) [6, 8]. Two types of CagA protein are recognized, Western- and East Asian-type [7].

CagA can affect the host cell in several aspects, such as the formation of gastric epithelium cell pedestals, the change of the cytoskeleton, affecting the proliferation of cells, and stimulating the gastric epithelium cells to secrete IL-8, as CagA-positive strains are directly associated with acute gastritis, gastric ulcer, and gastric cancer development [7, 8].

When *H. pylori* makes contact with host cells, CagA is translocated and injected into the host cell cytoplasm (via T4SS) where it activates various oncogenic pathways [8, 9]. Within the host cell, CagA undergoes tyrosine phosphorylation at a Glu-Pro-Ile-Tyr-Ala (EPIYA) motif and consequently promotes the cell changes [6, 8, 9]. EPIYA-A and EPIYA-B segments have been found in most *cag*A-positive *H. pylori* strains, while EPIYA-C and EPIYA-D segments are related to Western and Eastern strains, respectively. Strains containing EPIYA-D are associated with a higher risk of cancer development, while among Western-type strains, the number of EPIYA-C motifs has been considered to be the most important risk factor for developing cancer [6].

However, the presence of *cagA* usually coincides with the presence of other virulence factors, which can influence one another [8].

VacA, one of the major virulence factors in *H. pylori* infection, was named for its ability to induce numerous large vacuoles in host cells [6, 8]. Unlike CagA, it forms an autotransporter structure to secrete itself without the need for host cell contact [8]. Besides vacuolation, VacA can embed into the host cell membrane, having the characteristic of an anion-selection channel that can release bicarbonate and organic anions in the host cytoplasm [7]. It can also disrupt the barrier function of epithelial cells, allowing leakage of crucial nutrients such as iron, nickel, and amino acids that likely improve *H. pylori* growth [8]. Consequently, the integrity of cell structures is destabilized, leading cells to collapse [6]. In addition, VacA disrupts the balance of cell proliferation and death by affecting genes that regulate the cell cycle; it can induce acute inflammatory responses and might also participate in inducing immune tolerance and persistent *H. pylori* infection through its activities on T-cells and antigen-presenting cells [6, 7].

All *H. pylori* strains contain *vacA* genes, but not all strains produce functional VacA. This is due to polymorphisms within the *vacA* gene, particularly at the amino terminus (s region: s1a, s1b, s1c, and s2), in the middle of the gene (m region: m1, m1T, m2), and in an intermediate region (i

region: i1, i2, i3) [7, 8]. Numerous studies have shown association of certain subtypes with different clinical pictures, although not always consistent in different parts of the world [7].

The role and the significance of *hom*A and *hom*B genes are still uncertain. It seems that *hom*A and *hom*B genes are not independent markers of *H. pylori* virulence; however, they may act synergistically with other known virulence genes, causing severe gastritis in children [11].

The prevalence of duodenal ulcer-promoting gene (*dupA)* gene was shown to be significantly higher in strains from duodenal ulcer patients than those from gastritis or gastric cancer patients [9]. Furthermore, the presence of functional *dup*A has been considered to be a protective factor for gastric carcinoma development. Besides, *dupA* seems to provide a higher acid resistance to the bacterium and might also promote an increase in the production of IL-8 that leads to mucosal inflammation and polymorphonuclear leukocyte infiltration. Interestingly, the relation between *dup*A-positive *H. pylori* strains and duodenal ulcers has been observed in Asian, but not in the Western population [6].

OipA, in synergy with other virulence factors, contributes to both adhesion and increased inflammation by inducing enhanced IL-8 production. It might be related to changes in cell proliferation, reduction of cell–cell junctions and is possibly associated with carcinogenicity [6, 8, 10].

H. pylori gamma-glutamyl transpeptidase (GGT) functions as a virulence factor, although it had not been identified as a virulence factor in other bacteria [8]. GGT is an enzyme, hydrolase, that catalyzes the conversion of glutamine into glutamate and ammonia, and the hydrolysis of glutathione into glutamate and cysteinylglycine [6]. Its activity leads to the production of reactive oxygen species, which induces cell-cycle arrest, apoptosis, and necrosis. In addition, GGT inhibits T-cell proliferation and dendritic cell differentiation, and the higher GGT activity has been observed in peptic ulcer patients [6, 8].

Immunologic Aspects

H. pylori infection induces complex host immune responses, involving both innate and adaptive mechanisms. Given the initial contact with the pathogen, various *H. pylori* antigens bind to gastric cell receptors, including toll-like receptors located on epithelial cell membranes or found in intracellular vesicles. Such interaction promotes signaling pathways followed by proinflammatory cytokine release. Besides receptor activation, injection of CagA through T4SS also leads to the production of cytokines. Subsequently, gastric mucosa is infiltrated by neutrophils and mononuclear cells. Moreover, CD4+ and CD8+ T-cells, components of adaptive immunity, are also recruited. Regarding general cytokine profiles in *H. pylori*-positive patients, studies have suggested a Th1-polarized response, characterized by scarce IL-4 and enhanced levels of gamma interferon, tumor necrosis factor, IL-1β, IL-6, IL-7, IL-8, IL-10, and IL-18. With the exception of IL-10, which seems to play a role in limiting the inflammatory response, other increased cytokines might promote proinflammatory effects during *H. pylori* infection [6].

In summary, after entering the host stomach, *H. pylori* utilizes its urease activity to neutralize the hostile acidic condition, while factors affecting movement toward host gastric epithelium cells are shape, flagella-mediated motility, chemotaxis, and adherence. Specific interactions between bacterial adhesins with host cell receptors enable successful colonization and persistent infection [7]. Finally, *H. pylori* releases several effector proteins/toxins, causing host tissue damage. In addition, host immune system is activated, further leading to the formation of clinical diseases such as gastritis and ulcer [6, 7]. Once the persistent infection is established, the bacterium stays within the stomach for lifetime unless eradicated [9].

Epidemiology and Transmission

Over the last decades, a continuous decrease in *H. pylori* prevalence has been reported from different areas around the world, and not only in developed Western countries but also in countries like China and Iran [12]. However, *H. pylori* prevalence varies between countries, with lowest prevalence of 5–10% in Western Europe and the USA and very high prevalence in developing countries of even 80% [13, 14]. An increased prevalence in developing countries is mainly due to the combined effects of poor living conditions, poor hygiene, and overcrowding [15]. In developing countries, *H. pylori* infection is acquired predominantly during early childhood, and although previously it was reported that in the more developed areas the infection gradually increases with age with the highest incidence rate in childhood and adolescence [16, 17], the recent long-term follow-up study performed in Ireland showed that *H. pylori* almost never occurs after early childhood also in developed country [18].

The modes of *H. pylori* transmission are still not entirely clarified, but person-to-person contact, especially within family members, is the most commonly implicated mechanism through oral–oral, fecal–oral, or gastric–oral route, although environmental exposure routes are also possible [19]. It has been described that transmission primarily occurs between mothers and their offspring or between siblings [17, 20]. Currently available evidence indicate that especially in populations with low *H. pylori* prevalence the infected mother is likely to be the main source for childhood *H. pylori* infection [20]. However, only few studies have longitudinally examined factors which influence *H.*

pylori transmission. In the well-designed longitudinal study, Muhsen et al. included Israeli Arab children aged 3–5 years from three villages in northern Israel which were followed up for 3–4 years [21]. Having *H. pylori*-infected sibling was identified as an independent risk factor for both early and persistent *H. pylori* infection. It was also shown that persistent *H. pylori* infection in older siblings always precedes infection in younger siblings especially if the age difference was less than 3 years [22]. In a recent DNA-based transmission study, in which stool specimens were used to genotype *H. pylori* strains, it was reported that strains were not shared between spouses while similar strains were frequently found in mother and child pairs and in siblings. However, as in some families there were members with unique strains, it was suggested that also in developed countries sources of infection outside of the immediate family may exist [23].

Due to very close interpersonal contact between children in day-care centers, it was proposed that their attendance could also be a risk factor [16]. However, a meta-analysis of 16 studies did not confirm this hypothesis, but it included studies substantially varied in the methodology; they were performed in different types of childcare, in different age groups, with different exposure durations which all resulted in a high heterogeneity in the meta-analysis [16].

There is some evidence of positive correlation between the presence of *H. pylori* in the oral cavity and gastric mucosa [24]. Moreover, it seems that eradication rate is significantly higher in stomach than in oral cavity. These results suggest that infected dental plaque, saliva, or other parts of the oral cavity may be a source for infection and reinfection of *H. pylori* through oral–oral route [24]. On the other hand, some epidemiological data do not support oral–oral transmission as cohabiting couples are infected with different strains and treated adult patients are not infected by their untreated infected partner [23].

Gastritis

Gastritis is defined as histologically confirmed inflammation of the gastric mucosa mainly composed of lymphocytes, plasma cells, histiocytes, and granulocytes within the lamina propria [25]. *H. pylori* is by far the most common etiological agent causing gastritis in adults and children. The most common site of infection is the antrum, which is an absorptive rather than a secretory region of the stomach enabling the slightly higher pH at which the organism can survive [26]. In the initial phase of *H. pylori* infection, the gastric mucosa becomes acutely inflamed with impairment in the acid secretion [27]. In large majority of patients, gastritis progresses to chronic active gastritis which is characterized by the presence of both mononuclear and neutrophilic ("active") inflammation [25]. In children, the "active" or neutrophilic count is lower than that reported in adults.

In adults, *H. pylori* infection causes three main gastritis types; mild pangastritis where inflammation evenly affects the whole stomach, antrum-predominant gastritis where the degree of inflammation is strongest in the antrum and acid secretion tends to be increased, and the most infrequent phenotype affecting only approximately 1% of infected subjects body-predominant gastritis with even atrophic changes and impaired gastric acid secretion [27]. Antrum-predominant gastritis may subsequently be complicated by duodenal ulcer, while corpus-predominant atrophic gastritis increases the risk of gastric cancer [28]. Whether this distinction between gastritis types exists already in children or it develops later in life is still unknown [29].

In addition to the topographic expression of *H. pylori*-induced chronic gastritis, the characterization of gastritis needs to include report on the activity and chronicity of inflammation and on the development of atrophic changes with or without intestinal metaplasia [30].

H. pylori gastritis has unique features in children, such as the nodular aspect of the gastric antrum, antral predominance of gastritis in most patients, and uncommon diagnosis of gastric atrophy and intestinal metaplasia. Nodular gastritis is usually characterized as an endoscopic appearance which has been described as gooseflesh-like or cobblestone markings on the gastric mucosa (Fig. 12.2) [31]. Antral nodularity seen on endoscopy is histologically associated with inflammatory cell infiltrates and lymphoid follicles, and it is the only sign with a high positive predictive value for the presence of *H. pylori* infection [32].

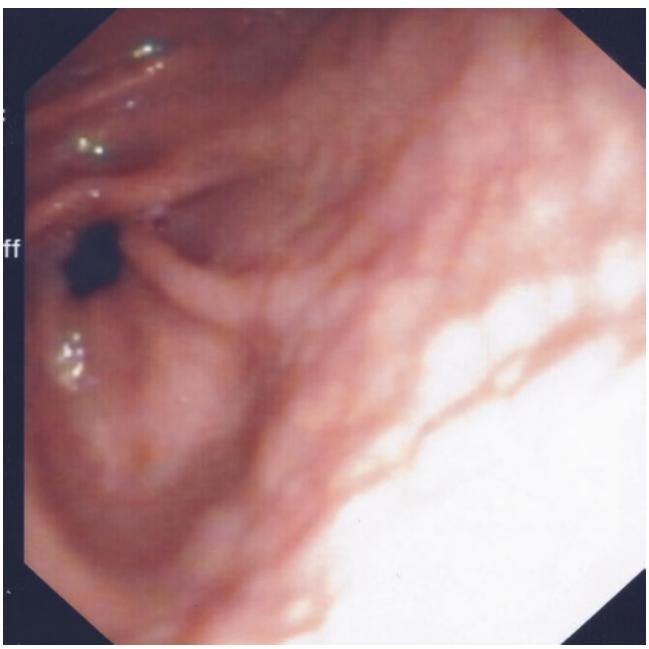

Fig. 12.2 Antral nodularity associated with *H. pylori* infection

After successful eradication therapy, the neutrophils quickly disappear, and any persistence of neutrophils and/or mononuclear infiltrate could be an indication of the treatment failure.

Peptic Ulcer Disease

Gastritis and peptic ulcer disease were previously considered as separate diseases; however, better understanding of the pathomechanisms and discovery of *H. pylori* revealed the close relation between those two entities. Peptic ulceration of the stomach or duodenum, either primary or secondary, is almost always accompanied by abnormalities of the gastric mucosa, either a gastritis or a gastropathy [33]. Peptic ulcer disease is the ultimate loss of mucosal integrity and develops when the protective mechanisms of the gastrointestinal mucosa, such as mucus and bicarbonate secretion, are overwhelmed by the damaging effects of gastric acid and pepsin [34]. By the definition, peptic ulcers are deep mucosal lesions that disrupt muscularis mucosa layer of gastric or duodenal wall. They occur in the stomach mainly in antrocorporeal mucosal transitional zone along the lesser curve or in proximal duodenum, duodenal bulb [35]. Peptic ulcers are more common in duodenum than in stomach, and *H. pylori* is the most frequent cause. Other etiological factors associated with gastritis and peptic ulcer disease are presented in Table 12.1.

Table 12.1 Causes of gastritis and peptic ulcer disease

Primary	*H. pylori*-associated *H. pylori*-negative (idiopathic) Hypersecretory states: Zollinger–Ellison syndrome G-cell hyperplasia/hyperfunction Systemic mastocytosis Cystic fibrosis Hyperparathyroidism Short bowel syndrome Renal failure
Secondary	Stress ulcers Drugs Aspirin Nonsteroidal anti-inflammatory drugs (NSAID) Corticosteroids Chemotherapy Valproic acid Alcohol Potassium chloride Immune/allergic Allergic gastritis and eosinophilic gastritis Graft-versus-host disease Henoch–Schönlein gastritis Coeliac disease Autoimmune disease Granulomatous gastritides: Crohn's disease Foreign body reaction Idiopathic Sarcoidosis Histiocytosis X Tuberculosis Menetrier disease Other infections: Helicobacter heilmannii Cytomegalovirus Phlegmonous gastritis and emphysematous Herpes simplex Influenza A Syphilis Candida albicans Histoplasmosis Mucormycosis Anisakiasis Radiation gastropathy

Available literature suggests that the lifetime risk for the development of peptic ulcer disease in *H. pylori*-positive patients ranges between 10% and 20% [36]. Peptic ulcer disease occurs less frequently in children than in adults. A large prospective European multicenter study including more than 1400 symptomatic infected children found gastric or duodenal ulcers in 3.5% of children below 6 years of age, 4.6% children aged 6–11 years, and in 10.4% of those older than 12 years [37]. Subsequent, prospective, also European multicenter study found that even 8.1% of children had ulcers or erosions [38]. In a retrospective review of 619 Chinese children who had undergone upper endoscopy for investigation of upper gastrointestinal symptoms, Tam et al. [39] have found peptic ulcers in 6.9% of children.

The discovery of *H. pylori* has turned the pathogenesis of peptic ulcer disease from a hyperacid disease to an infectious and immunopathogenetic disease where a variety of ulcer-promoting host and bacterial factors are involved in the complex pathogenesis [27]. However, despite that, gastric acid secretion remains important factor of peptic ulcer disease development. Patients with *H. pylori* gastritis and duodenal ulcers present with a much higher gastric acid output following gastrin stimulation than patients with *H. pylori* gastritis but without duodenal ulcer [40]. The mechanisms controlling acid secretion are hormonal and very complex in nature. The hormonal drive is exerted by hypergastrinemia, which was originally interpreted to result from the alkalization induced by *H. pylori.* Higher pH around G cells interrupts the negative feedback control, and they continue to release gastrin [27]. Another explanation for hypergastrinemia could be the *H. pylori*-induced impaired synthesis and release of somatostatin [27]. Somatostatin is a hormone that inhibits gastrin synthesis and subsequently inhibits acid secretion. Moreover, *H. pylori* virulence factors also contribute to development of peptic ulcer disease. In children, as in adults, *CagA* and *VacA* genes are the most frequently implicated virulence factors associated with increased risk of peptic ulcer disease [41].

In gastric ulcer, the role of acid and *H. pylori*, although certainly contributory, is of less dominance as compared to duodenal ulcer [27].

Epigastric pain or discomfort exacerbated by the meal is often a symptom of peptic ulcer disease in children; however, it may also be a presenting symptom of more common disorders such as non-ulcer dyspepsia and constipation among others [33]. Other presenting symptoms include anorexia, nausea, early satiety, recurrent vomiting, and anemia. Up to 25% of children with duodenal ulcers can present silently, approximately 25% with bleeding and antecedent pain, and the rest with abdominal pain or recurrent vomiting [33, 42]. Among all clinical signs, epigastric tenderness, pain awakening the child at night, hematemesis, melena, and stunted weight gain can be considered as significant risk factors for ulcers or erosions independently [38]. Acute gastrointestinal bleeding is the most common complication of childhood peptic ulcer disease and may occur with longstanding antecedent epigastric pain, whereas a perforated peptic ulcer occurs more rarely [39].

Other Causes of Peptic Ulcer Disease

In adult patients, the second most common cause of peptic ulcer disease is the use of nonsteroidal anti-inflammatory drugs (NSAIDs) [43]. NSAIDs inhibit cyclooxygenase-1 enzyme (COX-1) and reduce prostaglandin synthesis, consequently diminishing gastric mucosal blood flow and decreasing a production of the mucus-bicarbonate barrier [44]. In children, gastric ulcerations from NSAID ingestion are not nearly as frequent as in adults [33]. When occurs in children, NSAID-induced ulcer is typically presented as hemorrhagic antral gastropathy and ulceration of the incisura. Other drugs associated with drug-induced gastropathy and ulcers are anticoagulants and corticosteroids [45].

Other very rare causes of peptic ulcer disease in children include hypersecretory states like Zollinger–Ellison syndrome and antral G-cell hyperplasia, and should be suspected in children with severe or recurrent duodenal and gastric ulcers, resistant to proton pump inhibitors (PPI) treatment and in children with multiple ulcers. Other conditions associated with acid hypersecretion are systemic mastocytosis, short bowel syndrome during the first year after surgical resection, hyperparathyroidism, cystic fibrosis, and renal failure [46].

Stress-related ulcers usually occur 24 h after the onset of severe critical illness including shock, hypoxemia, acidosis, sepsis, burns, head injury, encephalopathy, major surgery, and multiple organ system failure [33]. Stress erosions are typically multiple and asymptomatic until cause, sometimes severe, gastrointestinal bleeding.

Gastritis and gastric ulcerations are found in 50–60% of children with Crohn's disease [47]. Focally enhanced gastritis is an inflammatory lesion often found in Crohn's disease and involves discrete inflammatory foci containing lymphocytes, histiocytes, and granulocytes [48]. Focally enhanced gastritis, although to much lower extent, could also be found in ulcerative colitis and inflammatory bowel disease unclassified.

Ménétrier's disease is a rare disorder of unknown etiology characterized by enlarged gastric rugal folds. It is a protein-losing gastropathy, clinically presented with nonspecific gastrointestinal symptoms such as nausea, vomiting, anorexia, weight loss, and hypoalbuminemia [49]. Cytomegalovirus and *H. pylori* are the most frequently found pathogens associated with this condition.

Celiac disease-associated lymphocytic gastritis is characterized by an intense lymphocytosis of the foveolar and surface epithelium and chronic inflammation in the lamina propria. Celiac disease may manifest with dyspeptic symptoms and histological changes which normalize after gluten withdrawal [50, 51].

Eosinophilic-mediated gastritis may be a presentation of food allergy (allergic gastritis) or be a primary disease (primary eosinophilic gastritis), as gastric infiltration by eosinophils is a pathological feature found in both conditions. Allergic gastritis mainly affects young infants with cow's milk protein allergy, but multiple food intolerances may also occur. Most common symptoms include vomiting, hematemesis, poor weight gain, or symptoms of delayed gastric emptying [52]. Primary eosinophilic gastritis may manifest at any age and may affect any part of the gastric wall. In mucosal form, children may present with vomiting, abdominal pain, and gastric blood loss; motility disturbances and gastric outlet obstruction may occur if muscular layer is affected [53, 54]. Serosal forms produce eosinophilic ascites and peritonitis [55]. Eosinophilic gastritis may also be a part of the eosinophilic gastroenteritis.

Other causes of primary and secondary gastritis and peptic ulcer disease in children are presented in Table 12.1.

Malignancy

H. pylori is considered the leading cause of gastric cancer worldwide and because of that, in adult population, it is listed as a number one carcinogen. A causal relation between *H. pylori* infection and the risk of gastric malignancies, including cancer and MALT lymphoma, has been clearly proved. However, in children *H. pylori*-related malignancy is extremely rare even in Japan where gastric cancer is prevalent in adults [56]. Evidence increasingly indicates that *H. pylori*-related gastric carcinogenesis is likely to be the result of a well-choreographed interaction between the pathogen

and host, which is dependent on strain-specific bacterial factors, host genotypic traits, and permissive environmental factors [2]. Various factors influence malignant potential including age of infection, bacterial genotype, host immune response, and host genetics. It has been suggested that chronic gastritis, gastric atrophy, intestinal metaplasia, and gastric cancer develop progressively, stepwise over decades, in predisposed individuals infected with *H. pylori* [57].

Incomplete intestinal metaplasia has been described in the gastric mucosa of *H. pylori*-infected children, suggesting that it can develop even during childhood and evolve into complete intestinal metaplasia in adults [58]. Moreover, other studies have reported a significant incidence of gastric atrophy (42–55%) and intestinal metaplasia (13–21%) in children [59]. Interestingly, a higher incidence of atrophic gastritis has been observed in children from countries with high incidence of gastric cancer [60, 61]. Moreover, current evidence suggests that in high-risk populations the eradication of *H. pylori* may have the potential to decrease the risk of gastric cancer [62]. There are certain *H. pylori* genotypes associated with more severe inflammation of gastric mucosa in pediatric patients including CagA, VacA, and BabA, and their detection could be of importance in areas with high risk of carcinoma [63]. In support of this is a report which found that in high-risk population even children have a high prevalence of *H. pylori* virulence markers—CagA and VacA [64].

In the pediatric population, there are only a few studies with a small number of patients regarding the association between *H. pylori* infection and precancerous lesions in both gastric antrum and corpus [59]. There are reports which presented children with *H. pylori* infection who subsequently developed high-grade B-cell lymphoma which resolved after *H. pylori* eradication even without chemotherapy [65, 66]. All these data indicate that *H. pylori* could be associated with malignancies in children; however, the risk seems to be substantially lower than in adults [67].

Clinical Presentation of *H. pylori* Infection

Recurrent Abdominal Pain Abdominal complaints including pain, cramps, and nausea are very common in pediatric population. Usually, they are unspecific and can be symptoms of various organic diseases but are very often caused by functional gastrointestinal disorders. If a child with recurrent abdominal pain has no alarm signs or symptoms, it is most likely that the pain is functional pain. Alarm signs include persistent right upper or right lower quadrant pain, dysphagia, odynophagia, persistent vomiting, gastrointestinal blood loss, involuntary weight loss, deceleration of linear growth, delayed puberty, unexplained fever, and a family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease. Whether *H. pylori* infection without peptic ulcer disease can cause recurrent abdominal pain remains unclear. Large epidemiological studies found association between recurrent abdominal pain and different social and familial factors like single-parent household, family history of peptic ulcer disease, or functional pain but not to *H. pylori* status of the child [68]. A performed meta-analysis on the relationship between recurrent abdominal pain and *H. pylori* infection in children included 38 case–control, cross-sectional and prospective studies and found no evidence for relation between recurrent abdominal pain and *H. pylori* infection in children [69]. The only pain type found associated with *H. pylori* infection was epigastric pain [69]. Several interventional but uncontrolled studies showed improvement of symptoms after the eradication of *H. pylori*; however, these studies have several biases; treatment success was not monitored and eradication of the bacteria not reported, and in other studies follow-up period was very short, for a few weeks only [70–73]. Based on these results, there is not enough evidence to support a causal relation between *H. pylori* gastritis and abdominal pain in the absence of peptic ulcer disease. Searching for *H. pylori* is, therefore, not recommended in children that otherwise fulfill the criteria of functional abdominal pain, unless upper endoscopy is performed during the diagnostic work-up in search for organic disease [5, 63].

Iron Deficiency Anemia Iron deficiency anemia (IDA) is common in children and adolescents and has variety of causes. Although previously suspected, as demonstrated in several well-conducted studies, there is no causal relationship between IDA and *H. pylori*. In children with refractory iron deficiency anemia who have not responded to initial iron supplementation therapy or had a rapid relapse, there is a possibility that anemia may be due to blood loss associated with peptic ulcer disease or iron utilization by the bacteria. Hence, if there is a clinical indication for upper endoscopy (if the child has alarm symptoms or other causes of iron deficiency anemia such as celiac disease or chronic inflammatory diseases are to be excluded), it is suggested that biopsies to confirm or rule out the presence of *H. pylori* infection may be considered. Noninvasive testing for *H. pylori* in the case of refractory IDA is not recommended. This is in agreement with clinical guidelines by the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and by the North American Society for Pediatric Gastroenterology Hepatology and Nutrition (NASPGHAN) [5].

Growth There are a number of longitudinal studies that support the hypothesis that *H. pylori* infection might influence growth rate in children [74]; however, none are adequately

Table 12.2 Clinical indication for testing for *H. pylori* infection (based on ESPGHAN/NASPGHAN recommendations [5])

Justified testing for *H. pylori*	Gastrointestinal symptoms suggestive of organic disease, serious enough to justify upper endoscopy Gastric and duodenal ulcers
Considered testing for *H. pylori*	Children with refractory iron deficiency anemia when other causes have been ruled out Idiopathic thrombocytopenic purpura
Not justified testing for *H. pylori*	Functional abdominal pain Upper respiratory tract infections Periodontal disease Food allergy Sudden infant death syndrome Growth impairment

designed to evaluate confounders of growth including other gastrointestinal infections in childhood, socioeconomic status, living conditions, etc. Despite new information concerning the effect of *H. pylori* infection on poor growth, the need for well-designed studies remains. Based on published data, there is insufficient evidence that *H. pylori* infection is causally related to growth impairment in childhood [4]. Therefore, it is not recommended to test for *H. pylori* infection when investigating causes of short stature [5].

Chronic idiopathic thrombocytopenic purpura. The role of *H. pylori* in the development of chronic idiopathic thrombocytopenic purpura continues to evolve. *H. pylori* infection has been proposed to be associated with thrombocytopenic purpura based on a significantly increased platelets count following *H. pylori* eradication in approximately half of adult patients [75]. Data on children are limited; however, recent studies have implicated that eradication of *H. pylori* could induce a better treatment response in chronic idiopathic thrombocytopenic purpura [76]. Therefore, it is suggested that noninvasive diagnostic testing for *H. pylori* infection should be employed. If the noninvasive test is positive, it has to be decided individually, based on the platelet count, whether an upper endoscopy is needed before prescribing eradication therapy [5] (Table 12.2).

Diagnostic Procedures

According to ESPGHAN/NASPGHAN evidence-based guidelines for *H. pylori* infection in children, diagnostic procedures should aim to determine underlying disease and not to detect *H. pylori* [5]. Current recommendations for children do not approve "test-and-treat" approach recommended for adults [5].

Tests that detect *H. pylori* are divided into noninvasive and invasive tests. The invasive tests are used in clinical practice and the noninvasive ones mostly in epidemiology and to assess the outcome of an eradication treatment. Invasive tests require endoscopy and gastric tissue biopsy for detecting the bacterium and include culture, rapid urease test, histopathology, polymerase chain reaction (PCR), and fluorescence in situ hybridization (FISH) tests [77]. On the other hand, noninvasive tests include different methods for the detection of *H. pylori* antigens in stool, detection of antibodies against *H. pylori* in different biological materials including serum, urine, and oral samples, and widely used ^{13}C-urea breath test (^{13}C-UBT) [77].

The initial diagnosis of *H. pylori* infection should be performed using invasive gastric biopsy-based methods and should be based on positive bacterial culture or *H. pylori* gastritis on histopathology (using the updated Sydney classification) plus at least one other positive test such as rapid urease test or molecular-based assays (PCR or FISH). The initial diagnosis of *H. pylori* infection should not be based on noninvasive tests (i.e., ^{13}C-UBT, *H. pylori* stool antigen test) or other noninvasive methods. A positive noninvasive test, however, supports the diagnosis in cases in which positive histology is the only invasive test available.

Noninvasive Tests

Among noninvasive diagnostic tests, stool antigen test and ^{13}C-UBT have higher accuracy than serological or urinary antibody-based tests [78], and current guidelines recommend against using antibody-based tests for *H. pylori* in serum, whole blood, urine, and saliva in the clinical setting [5].

^{13}C-urea Breath Test For this test, patient swallows carbon-labeled urea, the non-radioactive ^{13}C (the use of low radioactive 14C-UBT is not recommended in children). If the patient is infected, the labeled urea is metabolized by the urease produced by *H. pylori* and, using the mass spectrometer, the increase of the expired $^{13}CO_2$ is detected [5]. Meta-analysis on the performance of the ^{13}C-UBT showed good accuracy in children older than 6 years of age (sensitivity 96.6%, specificity 97.7%) [79]. A crucial question for all tests performed in a pediatric population is whether the accuracy of the applied method is influenced by the age of the tested child. ^{13}C-UBT requires patient cooperation; moreover, patients need to fast before testing and drink without tracer withhold in the mouth. All that makes ^{13}C-UBT difficult to perform in children younger than 6 years of age and may at least in part explain the lower specificity reported in young children [80, 81].

Stool Antigen Tests Because *H. pylori* and its macromolecules such as proteins and DNA are shed in feces, stool-based tests have become developed [82]. Several commercial enzyme-linked immunosorbent assay (ELISA) tests for *H. pylori* stool antigens are available. The main differences

among these tests are the nature of the detecting antibodies; some kits use a polyclonal anti–*H. pylori* antibody, whereas other assays use monoclonal antibodies [82]. Meta-analysis on stool antigen-detection tests revealed that ELISA monoclonal antibodies have the best performance, with sensitivity and specificity of 97% compared to ELISA polyclonal antibodies (sensitivity of 92%, specificity of 93%), and to one-step monoclonal antibody tests (sensitivity of 88%, specificity of 93%) [82]. So far, two-step monoclonal stool antigen test has achieved the accuracy of the ^{13}C-UBT, which is considered the reference standard of the noninvasive tests [5]. Use of stool tests is generally more convenient in pediatric patients than the ^{13}C-UBT. It has several advantages: stool samples can be obtained from children without their active collaboration and are transportable by mail for analysis, the cost is lower compared to ^{13}C-UBT, and it is not age-dependent; therefore, validation studies in adults may be extrapolated to children [4].

Detection of the Antibodies The systemic immune response against *H. pylori* typically shows a transient rise in specific IgM antibodies, followed by a rise in IgG and IgA antibodies that persist during infection [83]. Since IgM antibodies against *H. pylori* are detected only transiently, they have little value for the serological diagnosis of infection [84]. Many tests based on the detection of antibodies in serum, saliva, and urine are commercially available, easy to perform, and inexpensive. However, the main problems are low sensitivity and test-to-test variability [5]. Current serologic tests are not useful for monitoring eradication of infection after therapy since they cannot distinguish between current or past *H. pylori* infection, and the antibody titers usually remain positive several months after the infection has been eradicated [83]. Taking that into account, tests based on the detection of antibodies (IgG, IgA) against *H. pylori* in serum, whole blood, urine, and saliva are not reliable for use in the clinical setting [5].

Invasive Tests

Although noninvasive tests yield high sensitivity and specificity, endoscopy with biopsies remains the only method that can detect lesions associated with the infection but also other possible causes of the patient's symptoms [77]. In *H. pylori* infection, endoscopy may show normal gastric mucosa or reveal erythema, erosions, ulcers, and, especially in children, antral nodularity.

The site from which a biopsy is taken and the number of biopsies affect the accuracy of *H. pylori* diagnosis. Normally, the highest bacterial count is found in the antrum; because of that the optimal biopsy site is the mid-antrum at the lesser curvature [85]; however, in cases of low gastric acidity and during the PPI treatment, the bacteria may be present only in the gastric body.

Furthermore, due to patchy density of *H. pylori*, the sensitivity increases with the number of biopsies taken.

At least six gastric biopsies should be taken for the initial diagnosis of *H. pylori* infection: two biopsies from the antrum and two from the corpus for the histopathological evaluation (applying the updated Sydney classification), at least one biopsy from the antrum and one from the corpus for culture (if available) and at least one biopsy for any additional diagnostic tests from the antrum (rapid urease or molecular-based assays) [5].

Regarding histopathology, the updated Sydney system for the gastritis classification emphasizes the importance of combining topographical, morphological, and etiological information in order to generate reproducible and clinically useful diagnoses. Classification is based on the location of gastritis and the presence of different histological parameters including inflammation, activity, atrophy, intestinal metaplasia, and *H. pylori* infection which are graded as mild, moderate, and marked [30]. Updated Sydney classification was not assessed in pediatric patients; however, it can help in order to unify the histopathology reports.

Biopsies should be stained with hematoxylin and eosin because this is the best method to detect atrophy and intestinal metaplasia. Special staining (Giemsa or silver stain) and immunohistochemistry should be used for the detection of *H. pylori* (Fig. 12.3). In children, hematoxylin and eosin and Giemsa stains have a sensitivity of 82% and specificity of 95% in detecting *H. pylori* gastritis [86]. With decreasing prevalence of the infection in pediatric populations in many areas of Europe and North America, the positive predictive values of the diagnostic test results decrease; test with a sen-

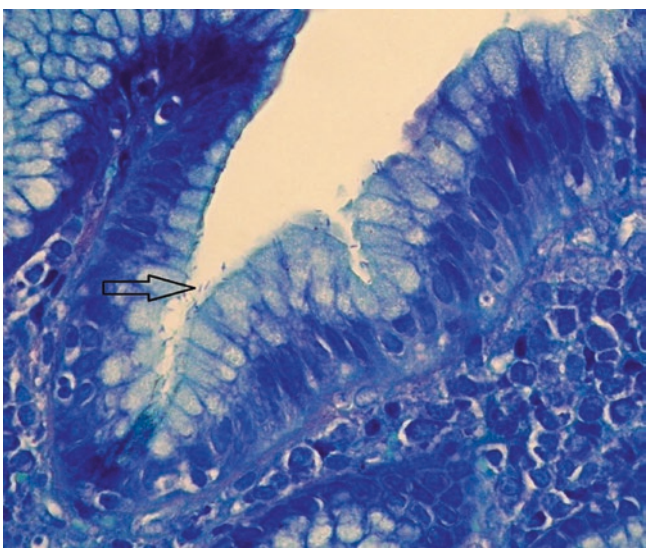

Fig. 12.3 Giemsa staining demonstrates gastric *H. pylori* bacteria (arrow)

sitivity of 90% has a positive predictive value of only 50% if the prevalence of the infection in the population is 10% [4]. Sensitivity for histology ranges from 66% to 100% and for rapid urease tests performed on the biopsies from 75% to 100% [77]. The only method that consistently has 100% specificity is culture, but sensitivity varies depending on the experience of the laboratory [77]. Current guidelines recommend that antimicrobial susceptibility of *H. pylori* should be obtained to tailor the eradication treatment accordingly. It is important to note that before testing for *H. pylori*, it should be waited for at least 2 weeks after stopping PPIs and 4 weeks after stopping antibiotics. If the culture is negative or not available, it is recommended that the diagnosis of *H. pylori* infection should be based on two tests and not only on a positive histology [5].

In summary, current guidelines recommend endoscopy with gastric biopsies from the gastric antrum and body and confirmation of infection with either positive bacterial culture or positive histopathology plus one other positive test [5].

Treatment for *Helicobacter pylori* Infection

Updated evidence-based guidelines from ESPGHAN and NASPGHAN recommend treatment for *H. pylori* in all children in whom peptic ulcer disease was detected during endoscopy [5]. Whether it is necessary to eradicate *H. pylori* in children with gastritis but without peptic ulcer disease remains questionable because there is not enough evidence which proved that bacterium eradication improves abdominal complaints in the absence of peptic ulcer. Therefore, the decision to treat *H. pylori*-associated gastritis without duodenal or gastric ulcer is subject to the judgment of the clinician and the patient and family, taking into consideration the potential risks and benefits of the treatment in every individual patient.

First-Line Treatment

First-line eradication therapy has four different regimens: (1). triple therapy with a PPI and amoxicillin and metronidazole or clarithromycin; (2). quadruple bismuth salts with PPI, amoxicillin, and metronidazole; (3). sequential therapy; and (4). concomitant therapy (Tables 12.3 and 12.4) [5].

Standard triple therapy, a combination of two antibiotics and a PPI, has been recommended as a first-line therapy since the first published pediatric guidelines. The goal of treatment is at least a 90% eradication rate at the first attempt [5]. However, reported eradication rate is much lower mainly due to antibiotic resistance. Antibiotic resistance is mostly found in clarithromycin and metronidazole. The overall incidence of clarithromycin resistance in children in Western countries is high, and current reports indicate prevalence of more than 20% in treatment-naïve patients [37, 87–90] and resistance rate is even much higher in some countries like China where clarithromycin resistance rate was higher than 80% [91]. Similarly, some areas have also high levels of resistance rate to metronidazole, more than 20% [37, 87, 91,

Table 12.3 First-line treatment options for *H. pylori* infection in children (based on ESPGHAN/NASPGHAN recommendations [5])

H. pylori susceptibility	Suggested treatment		
	Medication	Dosage	Duration
Known susceptibility			
Susceptible to CLA + susceptible to MET	PPI + AMO + CLA[a] or sequential therapy	Standard dose	14 days 10 days
Resistant to CLA + susceptible to MET	PPI + AMO + MET[a] or Bismuth-based[b]	Standard dose	14 days
Resistant to MET + susceptible to CLA	PPI + AMO + CLA[a] or Bismuth-based	Standard dose	14 days
Resistant to MET + resistant to CLA	PPI + AMO + MET[a] or Bismuth-based[b]	High dose for AMO	14 days
Unknown susceptibility	PPI + AMO + MET[a] or Bismuth-based[b] or Concomitant therapy (PPI + AMO + MET+CLA)	High dose for AMO	14 days

PPI proton pump inhibitor, *AMO* amoxicillin, *CLA* clarithromycin, *MET* metronidazole

[a]In case of penicillin allergy, if the strain is susceptible to CLA and MET, standard triple therapy with MET in place of AMO can be used; if the strain is resistant to CLA, use bismuth-based therapy with tetracycline instead of AMO in older than 8 years

[b]Bismuth-based—in children <10 years 262 mg QID, in children >10 years old 524 mg QID

Table 12.4 Dosage regimen for *H. pylori* eradication in pediatric patients (based on ESPGHAN/NASPGHAN recommendations [5])

	PPI		AMO		MET		CLA	
	Morning dose	Evening dose	Morning dose	Evening dose	Morning dose	Evening dose	Morning dose	Evening dose
Standard dose								
15–24 kg	20 mg	20 mg	500 mg	500 mg	250 mg	250 mg	250 mg	250 mg
25–34 kg	30 mg	30 mg	750 mg	750 mg	500 mg	250 mg	500 mg	250 mg
>35 kg	40 mg	40 mg	1000 mg	1000 mg	500 mg	500 mg	500 mg	500 mg
High dose								
15–24 kg			750 mg	750 mg				
25–34 kg			1000 mg	1000 mg				
>35 kg			1500 mg	1500 mg				

PPI proton pump inhibitor, *AMO* amoxicillin, *CLA* clarithromycin, *MET* metronidazole

92]. In a meta-analysis of 23 studies (with specified pediatric age groups) published in 2018, the prevalence of resistance to clarithromycin in children was from 10% in Eastern Mediterranean region and 19% in Americas region to 85% in Western Pacific region; to metronidazole from 20% in Europe to 40% in Americas region and 81% in Eastern Mediterranean region, and to levofloxacin from 4% in Europe region to 29% in Eastern Mediterranean region [93]. Based on the negative effect of antibiotic resistance on treatment outcomes, the rates of resistance in the area where the child lives should be taken into account when deciding on the initial therapeutic regimen for eradication [5]. In areas with high or unknown primary antibiotic resistance rate, culture and susceptibility testing should be performed in order to select proper treatment regimen [5].

Decreasing eradication rates with these standard triple regimens have led to the development of alternative treatment options, like sequential therapy, bismuth-based therapy, and concomitant therapy.

Sequential therapy is a two-step, 10-day therapy typically consisting of a PPI combined with amoxicillin given for the first 5 days, followed by a triple therapy including a PPI, clarithromycin, and metronidazole/tinidazole for another 5 days [94]. Meta-analysis comparing sequential to standard triple therapy found that sequential therapy is superior to 7-day standard triple therapy, however, not significantly better than 10-day or 14-day triple therapy [94]. However, more recent studies performed in Europe showed that eradication rates with sequential therapy were only 56% when clarithromycin resistance was present, while in case of strains susceptible to both clarithromycin and metronidazole primary eradication rates with a high-dose sequential 10-day regimen in children were 85.8% in the intention to treat analysis [5]. Therefore, current guidelines suggest that sequential therapy should not be given if the strain is resistant to metronidazole or clarithromycin, or if susceptibility testing is not available [5].

Bismuth-based quadruple therapy is also recommended as an alternative first-line therapy. Well-designed, randomized, multicenter studies of *H. pylori* eradication in children comparing bismuth-based regimens to the alternative recommended first-line therapies are lacking, but studies performed in adults indicate that bismuth-based therapies are effective. The results from the pediatric European register for treatment of *H. pylori* showed that when given as first treatment, bismuth-containing triple therapies were more efficacious than those containing PPI (77% versus 64%) [95, 96]. More recent studies evaluated bismuth-based quadruple therapies and showed higher eradication rates than standard triple therapy. According to current guidelines, it is recommended that bismuth quadruple therapy can be used in children if *H. pylori* antimicrobial susceptibility is unknown or in the setting of dual resistance to clarithromycin and metronidazole [5].

Concerning concomitant therapy, it was shown for adult patients that concomitant quadruple therapy (PPI and amoxicillin, metronidazole, and clarithromycin given for 10 to 14 days) was one of the most effective treatments, with a high eradication rate and acceptable frequency of adverse events. Currently, no studies assessing concomitant therapy in the pediatric setting are available. However, in children with primary double resistance to clarithromycin and metronidazole, concomitant therapy may be an option [5].

The duration of eradication therapy is still controversial. There are limited well-designed studies specifically addressing the optimal treatment duration in children. However, in adults, a recent systematic review showed that 14-day duration of treatment improves eradication rates compared to 10-day, and both are superior to 7-day treatment. Therefore, it is recommended that the duration of triple therapy should be 14 days [5]. It has been reported that, especially taking into account compliance rate, there is no benefit from longer duration of therapy [96, 97].

Rescue Therapy in Children Who Failed First-Line Treatment (Table 12.5).

Emerging evidence suggests the development of secondary antibiotic resistance in children who failed initial eradication therapy [98]. Therefore, when *H. pylori* treatment fails, rescue therapy should be individualized considering antibiotic susceptibility, the age of the child, and available

Table 12.5 Rescue therapies (after the failure of first-line therapy) for treating *H. pylori* infection in pediatric patients (based on ESPGHAN/NASPGHAN recommendations [5])

Initial antibiotic susceptibility	Past treatment regimen	Rescue treatment
Susceptible to CLA + susceptible to MET	Triple therapy using AMO + CLA Triple therapy using AMO + MET Sequential therapy	Triple therapy using AMO + MET Triple therapy using AMO + CLA Tailored treatment for 14 days after second endoscopy or treat like double resistance (Table 12.3)[a]
Resistant to CLA	Triple therapy using AMO + MET	Treat like double resistance (Table 12.3)[a]
Resistant to MET	Triple therapy using AMO + CLA	Tailored treatment for 14 days after second endoscopy or treat like double resistance[a] (Table 12.3)[a]
Unknown primary antimicrobial susceptibility	Triple therapy or sequential therapy	Tailored treatment for 14 days after second endoscopy or treat like double resistance (Table 12.3)[a]

PPI proton pump inhibitor, *AMO* amoxicillin, *CLA* clarithromycin, *MET* metronidazole
[a]In adolescents, levofloxacin or tetracycline may be considered

antimicrobial options. If possible, primary culture with antibiotic sensitivity testing should be performed to guide second-line therapy. If culture (and standard susceptibility testing) is not possible, molecular tests (including FISH) can be used to detect *H. pylori* and clarithromycin and/or fluoroquinolone resistance in gastric biopsies [78]. If primary culture and sensitivity testing are not available, when deciding on second-line therapy the initial therapy should be taken into account with avoidance of previously given regimens [5, 99]. As studies suggest that increasing acid suppression and antibiotic dose (metronidazole and amoxicillin) may improve efficacy of eradication therapy, using such regimens may be considered in children. Also, based on efficacy proved in adults, regimens using levofloxacin or tetracycline may be applied in adolescents.

Another option as a salvage therapy may be a quadruple therapy which consists of PPI, metronidazole, amoxicillin, and bismuth [5]. However, this regimen is complicated to administer, and bismuth salts are not widely available.

Although the studies on the ideal duration of therapy for second-line treatment are not conclusive, a longer duration of therapy of up to 14 days is recommended [5].

Assessment of Eradication

All children who received treatment for *H. pylori*, even if they have no symptoms, should undergo the evaluation of the treatment success. The absence of symptoms is not reliable and does not necessarily mean the *H. pylori* is eradicated. The recommended tests for *H. pylori* eradication assessment are noninvasive tests: ^{13}C-UBT and a two-step monoclonal ELISA test for the detection of *H. pylori* antigen in stool [5]. As previously presented these tests have a high sensitivity and high specificity and are not invasive. A follow-up endoscopy is not routinely indicated unless other causes of ulceration are suspected or if biopsies are needed for culture and antibiotic susceptibility testing [5].

Eradication therapy reduces the amount of *H. pylori* in the stomach, even when eradication failed because that antibiotic or PPI therapy can cause false-negative test results [100]. Therefore, assessment of eradication should be performed with noninvasive test at least 4 weeks following completion of therapy [5].

Ménétrier Disease in Children

13

Jasmina Kikilion, Elvira Ingrid Levy, and Yvan Vandenplas

Abbreviations

HP	*Helicobacter pylori*
MD	Ménétrier disease
TGF-α	Transforming growth factor alpha

Introduction

Ménétrier disease (MD) was described by the French pathologist Pierre Ménétrier in 1888 [1, 2]. MD is an uncommon acquired self-limiting disorder in children [3, 4]. Pathogenesis and etiology are not yet fully understood [4].

Up to now, there are only approximately 60 cases of children with MD reported in literature [3, 4]. Most of these are case series. In this chapter, we discuss etiology and propose guidance to diagnosis and management.

Clinical Manifestations

Since there are no pathognomonic features described to diagnose MD, it continues to be a clinicopathological diagnosis. Symptoms described in adults (males more often affected than females) include vomiting, nausea, abdominal pain, diarrhea, weight loss, malnutrition, and peripheral edema secondary to hypo-albuminemia [1, 5]. In children, there is often a prodromal faze caused by a transient viral infection, followed by edema and gastrointestinal symptoms including emesis, epigastric pain, anorexia, diarrhea, vomiting, and abdominal pain (Table 13.1) [3, 4]. Edema is caused by hypo-albuminemia as a result of protein-losing edema of the gastric mucosa [4]. The average age of affected children is 2–5 years [6], but a case series from Gökçe et al. describes two cases of neonatal MD, both presenting with edema as major symptom [4]. As in children a spontaneous remission is common, it is possible that the disease is associated with *Helicobacter pylori* (HP) infection or transient infections such as cytomegalovirus (CMV) [4, 5]. These associations will be discussed later in this review.

There is a wide variation in clinical manifestations depending on the age of the patient. It is important to list MD in the differential diagnoses of edema occurring in combination with gastrointestinal symptoms.

Table 13.1 Menetrier disease in summary in children [1–9]

Triggers	Herpes simplex virus, Giardia lamblia, Mycoplasma pneumonia, CMV[a], and HP[b]
Symptoms	Edema, emesis, epigastric pain, anorexia, diarrhea, vomiting, and abdominal pain
Diagnostics	Endoscopy in combination of biopsy and cultures
Treatment	Self-limiting Supportive therapies: Albumin, diuretics, fluid restriction, high-protein diet, acid inhibitors, ganciclovir

[a]*CMV* Cytomegalovirus
[b]*HP Helicobacter pylori*

Pathophysiology and Etiology

The pathogenesis of MD is not yet fully understood [3, 4]. Observational studies in transgenic mice showed a relation between the possible overexpression of transforming growth factor alpha (TGF-α) and the development of gastric changes that are characteristic of MD [5]. TGF-α inhibits gastric acid production and stimulates growth of gastric epithelial cells [1]. TGF-α is a ligand that mediates signal transduction by binding epidermal growth factor receptor (EGFR), which leads to increased cellular proliferation [5]. More specifically in MD disease, overexpression of TGF-α redirects the gastric progenitor cells to surface mucous cell differentiation

at the disadvantage of parietal and chief cell differentiation [5]. Remarkable is the observation that the gastrin levels in serum are normal, despite lower gastric acidity, which is a stimulus for increased production of gastrin [1].

In children, MD disease is transient and in general it is believed to be associated with infections such as herpes simplex virus, Giardia lamblia, Mycoplasma pneumonia, CMV, and HP [3–6]. Possible pathogenic mechanism is damage of the gastric mucosa caused by infection, which may lead to the production of abnormal local TGF-α [3]. CMV infection in the stomach causes elevation of intracellular messengers and activation of proto-oncogenes that causes an increase in the production of TGF-α in mucosal cells [6]. Some case reports show an association with some medications and allergies [4]. Several cases show MD with CMV and HP co-infection, although they propose that HP has the most causative role in the disease [4, 7]. However, given the high incidence of HP infection, these associations may just be by coincidence. A case series of two siblings with CMV-associated MD proposes the hypothesis that genetic factors could stimulate an increased production of TNF-⟨ in response to CMV infection [6].

A unique, fourth-generation pedigree with autosomal dominant gastropathy exhibiting the typical clinical, endoscopic, and pathological MD-like findings, though in the absence of protein loss and with no increase in the levels of gastric TGF-α, proposes a genetic predisposition to develop MD [8].

In conclusion, the pathogenesis has still to be explored further; however, there is evidence of overexpression of TGF-α with transformation of the gastric mucosa which is possibly mediated by genetics and provoked by an infectious trigger.

Diagnosis and Histological Findings

Diagnosis of MD starts with a thorough history of the patient, in which contact with family members with possible HP infection must be investigated. To confirm the diagnosis of MD, gastroscopy, biopsies, and cultures must be performed. Endoscopic findings are thickened gastric mucosal folds, and these are predominantly present in the body and the fundus of the stomach, relative sparing the antrum (Table 13.1) [5]. The most striking feature of MD, a histological sine qua non, is foveolar hyperplasia (expansion of the surface mucous cells) that leads to thickening of the gastric mucosa. There is a loss of parietal cells due to atrophic oxyntic glands, which secondarily leads to an increase of the gastric pH (normal pH of gastric fluid is 1–3, but in MD pH is rather 4–7) [1, 5]. Additionally, deep glands are often dilated, forming cysts. Histologically, there is a chronic inflammatory cell infiltration at the lamina propria with the presence of eosinophils and plasma cells, hyperplasia of smooth muscle, and edema [1, 5].

Other diseases with similar endoscopic findings are hypertrophic lymphocytic gastritis, eosinophilic gastritis, Zollinger–Ellison syndrome, polyposis syndrome, gastric malignancies, and lymphoma [5, 6]. To investigate a possible association of juvenile polyposis syndrome with MD, a new mechanism that involves TGF-α-SMAD 4 pathway inactivation and TGF-α overexpression related to HP infection has been proposed [8].

Concluding, the golden standard for the diagnosis of MD is to perform gastroscopy with biopsy and the typical histological findings.

Treatment

Management of MD in children is often supportive as most of the cases that are reported are associated with transient infections. As infection resolves spontaneously, MD usually resolves within several weeks to months [4, 5]. If there is evidence of HP infection, eradication can be considered, although there is a case described where MD resolved without the use of antibiotics [3, 6]. As HP is the only causative organism described that is not a transient infection, we think of the possibility that the association of MD and HP is a coincidence.

Supportive treatment includes albumin infusion to correct the hypo-albuminemia and diuretics, fluid restriction, and high-protein diet [2, 3]. Acid inhibitors such as proton pump inhibitors and H2 receptor blockers and anticholinergic agents are used to protect the stomach. Preference for acid inhibitors was not reported. Ganciclovir treatment can be considered if there is evidence for active CMV infection and if the patient is immunocompromised, very young or if spontaneous improvement does not occur [4, 6].

In adults and adolescents with chronic and severe diseases, chirurgical therapy like partial or total gastrectomy can be considered [2, 5]. Further clinical trials with cetuximab, an immunoglobulin that binds to epidermal growth factor receptor and prevents binding of TGF-α, showed promising results with rapid improvement of symptoms after the first administration in adults [1].

In conclusion, the treatment of MD in children is mainly supportive with in some cases correction of hypo-albuminemia with albumin infusions, and administration of diuretics is needed (Table 13.1).

Conclusion

MD is a rare condition in children of which the pathophysiology and etiology are not yet fully understood. New possible mechanisms and the involvement of genetics in the pathophysiology of MD have been suggested and are further investigated. Some viral, bacterial, and parasite infections are associated with the condition. The disease can only be diagnosed by gastroscopy and histology of gastric biopsies. The disease is self-limiting, and supportive therapy is advised.

Viral Diarrhea

14

Alfredo Guarino and Eugenia Bruzzese

Epidemiology and Etiology

Although childhood diarrhea deaths have declined more than 80% from 1980 to 2015, diarrhea is still the second leading cause of death due to infections among children below 5 years of age worldwide after lower respiratory tract infections [1, 2], and it is estimated that almost 2 million children aged less than 5 years die each year in the world accounting for almost 20% of total child deaths. African and South-East Asia Regions account for 78% of all diarrhea deaths occurring among children in the developing world, and 73% of these deaths are concentrated in 15 developing countries [2, 3]. A too slow progressive reduction is observed and the Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) estimated that in 2016, diarrhea was the fifth leading cause of death among children younger than 5 years with a rate of 70.6 deaths per 100.000. Diarrhea was responsible for 8.92% of all deaths in children younger than 5 years in 2016, with an estimated incidence of 1.75 episodes per child younger than 5 years. The number of diarrhea deaths among children younger than 5 years decreased by more than 50%, and also diarrhea incidence decreased between 2000 and 2016 [4]. Childhood wasting, unsafe water, and unsafe sanitation were the leading risk factors for diarrhea [4]. Table 14.1 shows mortality rates and incidence of diarrhea due to the main etiological agents.

Nevertheless, acute diarrhea is still a major problem in both developing and industrialized countries, but with two distinct consequences. In developing countries, enteric infections are highly common, and acute gastroenteritis is also responsible for a high mortality rate, whereas in industrialized countries, the incidence of diarrhea and the mortality is much lower than in poor countries, although not negligible. Gastroenteritis hospitalizations continue to require significant inpatient resources also in the United States; from 2010 to 2011 about 4/1000 children were hospitalized for acute gastroenteritis with an estimated direct cost of $200 million annually [5].

Table 14.1 Mortality rates and incidence of acute diarrhea in children under 5 years of age due to specific viral agents in 2016

	Deaths per 100.000 (95% UI)	Episodes per 1000 (95% UI)
Adenovirus	1·3 (0·8–1·8)	22·4 (16·0–30·1)
Norovirus	1.7 (0.8–3.1)	76.8 (30.1–159.6)
Rotavirus	20.3 (16.6–24.5)	408.6 (311.6–533.1)

Modified from GBD 2016 Diarrhoeal Disease Collaborators [4]

Rotavirus is the leading cause of acute gastroenteritis [4], and it is the most frequent agent of severe diarrhea in children <5 years of age, worldwide. Rotavirus infections affect virtually all children by the age of 5 years [6]. The Global Rotavirus Surveillance Network recently described the impact of Rotavirus on hospital admissions for acute gastroenteritis in children younger than 5 years in different countries with different vaccination programs. In countries that had not introduced specific vaccine in their national immunization programs, Rotavirus was detected in 38.0% of admissions for acute gastroenteritis annually whereas in those that have introduced the vaccine, Rotavirus was detected in 23.0%, showing a 39.6% relative decline following vaccine implementation [7]. Similar results have been recorded in Europe [8], where Rotavirus accounts for 55% of hospitalizations and one-third of emergency department visits due to community-acquired acute gastroenteritis in children aged <5 years. The burden of community-acquired Rotavirus gastroenteritis occurs in children aged <2 years with a peak in infants aged <6 months. It has a seasonal pattern, peaking in winter, coinciding with common respiratory infections. Every year, approximately 500,000 children younger than 5 years die because of diarrhea with Rotavirus being the most frequent pathogen in developing countries [7]. In industrialized countries, where there is generally good access to health care, mortality due to Rotavirus gastroenteritis is low.

https://doi.org/10.1007/978-3-030-80068-0_14

It has been estimated that in Europe approximately 6500 children died each year as a result of Rotavirus infection in the prevaccine era [9]. The mortality was due to severe and fast dehydration in previously healthy children and not only in children from identifiable risk groups. Recently, a total of 4161 stool specimens from children less than 5 years of age, hospitalized with acute gastroenteritis, were analyzed to investigate the specific etiology of diarrhea in Italy using real-time PCR technique. Rotavirus was the prevalent virus (24.7%) followed by Norovirus (19.6%), adenovirus (5.3%), and astrovirus (3%). Co-infections were detected in 8.3% of patients with viral gastroenteritis, and Rotavirus with Norovirus (70.6% of co-infections) or with astrovirus (9.6%) were the most common associations [10]. However, hospital admissions and deaths from Rotavirus gastroenteritis and all-cause acute gastroenteritis have declined following the progressive incorporation of Rotavirus vaccines into national immunization programs [7]. In the United States, before the introduction of specific vaccine in 2006, Rotavirus caused an estimated 20–60 deaths, 55,000–70,000 hospitalizations, 205,000–272,000 emergency department visits, and 410,000 outpatient visits each year [11]. After 10 years, hospitalizations and emergency department visits due to Rotavirus AGE were reduced by a median of 67% [12]. Rotavirus infection is therefore a major cause of hospitalization in children with acute gastroenteritis with substantial impact on healthcare resources and costs. Before Rotavirus vaccination programs the estimated average cost for an episode of diarrhea in inpatient was US$ 2300. Costs for acute diarrhea are not negligible, particularly if the so-called societal costs are considered. After Rotavirus vaccine introduction, the annual cost reductions ranged between $134 million and $257 million [13].

During the past four decades, there has been a dramatic increase in the number of newly recognized etiologic agents of gastroenteritis. Since 1970, more than 20 different microorganisms (viruses, bacteria, and parasites) have been recognized as etiological agents. Nevertheless, in up to 50% of acute gastroenteritis cases, the causative agent remains undiagnosed with traditional laboratory methods. This low diagnostic proportion stimulated research to use new tools such as broad-range PCR tests, pan-viral microarrays, and viral metagenomics for virus identification in patients with acute diarrhea. Although many viruses have been identified in fecal samples of patients with diarrhea, their causal relationship with diarrhea is largely unknown (Table 14.2).

In addition to Rotaviruses and Noroviruses, Apoviruses of the Caliciviridae, human Astroviruses of the Astroviridae family, and human enteric Adenoviruses of the Adenoviridae family are among the medically important viruses causing gastroenteritis in children. These agents are associated with outbreaks in semiclosed communities in all age groups and in immunocompromised patients and are able to induce severe, long-lasting diarrhea that occasionally may be fatal. The viruses most frequently responsible for acute gastroenteritis in children belong to four distinct families: Rotaviruses, caliciviruses, astroviruses, and enteric adenoviruses. Rotavirus and Norovirus are the two leading agents of acute diarrhea. Other viruses, such as toroviruses, picornaviruses (the Aichi virus), and enterovirus 22, play a minor epidemiological role. Finally, selected viruses induce diarrhea only in children at risk; these include Cytomegalovirus, Epstein–Barr virus, Picobirnaviruses, and HIV [14]. Very recently, a novel Coronavirus, SARS-COV-2 responsible for an acute respiratory syndrome, has been associated with gastrointestinal symptoms of acute gastroenteritis with vomiting and diarrhea being particularly frequent in pediatric patients [15].

Table 14.2 Role of different viruses in the etiology of acute diarrhea in children

Established	Probable	Possible in selected children or in outbreaks
Rotavirus	Torovirus	HIV Sapoviruses Caliciviruses
Norovirus	Aichi virus Enterovirus 22	Cytomegalovirus
Adenovirus		Epstein–Barr virus Picobirnavirus
Astrovirus	SARS-CoV-2	Coronavirus

Pathophysiology of Viral Diarrhea

In the classic and simple view, the pathogenesis of diarrhea may be divided into osmotic and secretory. Viral diarrhea was originally believed to be the consequence of endoluminal fluid accumulation osmotically driven by non-absorbed nutrients due to cell invasion and epithelial destruction by enteropathogenic agents. It is now known that several mechanisms are responsible for diarrhea, depending on the specific agents and the host features. In addition, selected viruses have multiple virulence pathways that act synergistically to induce diarrhea.

The mechanisms of diarrhea induced by group A Rotaviruses have been extensively investigated and provide a paradigm of the pathophysiology of viral diarrhea [16–18]. Rotavirus has both a tissue- and cell-specific tropisms, and it infects the mature enterocyte of the small intestine. The first step is virus binding to specific receptors located on the cell surface, the GM1 ganglioside. However, different Rotavirus strains bind in either a sialic-acid-dependent or sialic-acid-independent fashion. Most Rotaviruses, including all human strains, infect polarized enterocytes through both the apical and the basolateral sides, in a sialic-acid-independent man-

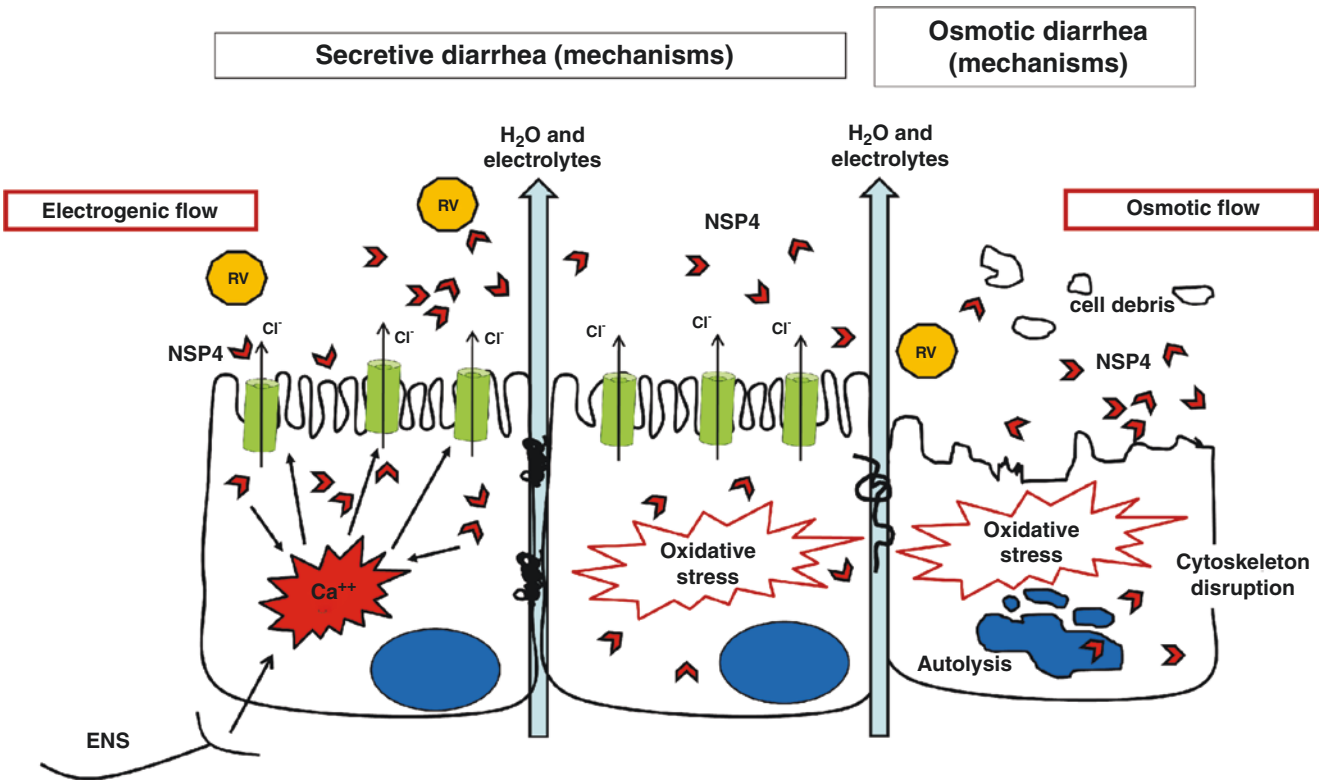

Fig. 14.1 Mechanisms of secretive and osmotic diarrhea induced by Rotavirus. During infection, Rotavirus interacts with enterocytes both as viral particles and through the NSP4 enterotoxin. In the first phase, NSP4 mobilizes intracellular calcium that, in turn, acts as the chloride channel CaCC. This event generates an electrogenic force which draws water and electrolytes into the intestinal lumen underlying the secretory diarrhea. Oxidative stress is an additional mechanism activated by NSP4 that affects secretory diarrhea. In the second phase, Rotavirus damages intestinal cells and epithelium resulting in an increase in intestinal permeability. Cellular debris, proteins, and other molecules released during cytotoxic damage generate an osmotic force underlying the osmotic diarrhea

ner, suggesting the presence of different receptors. The early stages of Rotavirus binding involve the viral protein (VP4) spike attachment and cleavage. After binding, Rotavirus enters into the cell by a multistep process that requires both VP7 and VP4 proteins. Infection of the villous enterocytes leads to cell lysis, thereby reducing the digestive–absorptive surface and not absorbed nutrients and driving fluids into the intestinal lumen through an osmotic mechanism (Fig. 14.1).

However, the destruction of villus-tip cells induces a compensatory proliferation of crypt cells. These immature enterocytes physiologically maintain a secretive tone, thus contributing to diarrhea with ion secretion, as the result of the imbalance between absorptive villous and secretory crypt cells. Thus, the cytopathic effect of Rotavirus results in both osmotic and secretory diarrhea. Histological changes induced by Rotavirus infection occur within 24 h of infection in animal models.

The enteric nervous system may also play a direct role in inducing fluid secretion, similar to that induced by cholera toxin and other intestinal secretagogues. The molecular mechanisms of fluid secretion have also been investigated. Rotavirus induces an increase in intracellular calcium levels, which is responsible for the disassembly of microvillar F-actin, the perturbation of cellular protein trafficking, the damage of tight junction, with a disruption of cell–cell interaction, and cytolysis. Rotavirus-induced diarrhea may be also associated with an increase in intestinal motility through the stimulation of myenteric nerve plexus [18]. In children with Rotavirus infection, the onset of diarrhea is abrupt and occurs in the absence of histological changes, suggesting that in the initial phase of the infection a secretory pathway is responsible for diarrhea. The identification of the nonstructural protein (NSP4), an enterotoxin produced by Rotavirus, responsible for fluid secretion but not for epithelial damage may explain this phenomenon. NSP4 is a multifunctional virulence factor (VF). It is released from infected cells and enters the cells through a specific receptor causing calcium-dependent chloride secretion. NSP4 also alters plasma membrane permeability and is cytotoxic. NSP4 is the only Rotavirus gene product capable of eliciting intracellular calcium mobilization. NSP4 also contributes to diarrheal pathogenesis by directly altering enterocyte actin distribution and paracellular permeability. Finally, NSP4 plays a role in the inhibition of the Na^+-dependent glucose transporter

Table 14.3 Mechanisms involved in Rotavirus-induced diarrhea

Mechanism	Effect
Enterocyte damage	Nutrient malabsorption/osmotic diarrhea
Crypt cell proliferation	Ion and water secretion/secretory diarrhea
NSP4 production	Increase in intracellular calcium, chloride secretion/secretory diarrhea
NSP4 inhibition of SGLT-1	Glucose malabsorption/osmotic diarrhea
Neuromediated vascular ischemia	Secretory diarrhea induced by neurotransmitter release
Inflammation	NF-kB, IL-8, Rantes release/osmotic, and secretory diarrhea
Stimulation of myenteric nerve plexus	Increase in intestinal motility

NSP4 nonstructural protein, *NF-κB* nuclear factor kappa B, *IL* interleukin, *SGLT-1* Na^+ -dependent glucose transporter

(SGLT-1). Glucose absorption as well as disaccharidase activities are impaired in Rotavirus enteritis, whereas the Na/amino acid co-transporters are not involved. Finally, Rotavirus diarrhea may also have an inflammatory component. The induction of cytokines is important in developing an inflammatory and immune response, especially in intestinal infection caused by bacteria. In Rotavirus infection, limited inflammation is detected by histological studies, suggesting that cytokines are effective in inducing a host immune response to Rotavirus diarrhea. However, it has been shown that Rotavirus-infected enterocytes activate nuclear factor kappa B (NF-κB) and the production of chemokines interleukin (IL)-8, Rantes, and growth-related oncogene (GRO)-a, of interferon (IFN)-α, and of granulocyte/macrophage–colony-stimulating factor (GM-CSF).

In conclusion, the primary target of Rotavirus is the enterocyte, which is induced to secrete fluids and electrolytes and is subsequently destroyed. On the other hand, the enterocyte acts as a sensor to the mucosa with the production of viral and endogenous factors and the activation of other cell types including neurons. Thus, Rotavirus-induced diarrhea is a multistep and multifactorial event, in which fluid secretion and cell damage are observed in a precise sequence, as shown in an intestinal cell line-based experimental model (Table 14.3) [17].

Clinical Signs and Symptoms of Viral Diarrhea

Usually, viral diarrhea has an abrupt onset and lasts 3–5 days. Generally, it is a benign condition with spontaneous recovery. In very few cases, diarrhea may be persistent lasting more than 7–15 days. Risk factors for persistent diarrhea in children are young age, early weaning, malnutrition, and immunodeficiency. In selected children, an acute onset may coincide with the first manifestation of celiac disease.

The predominant symptoms of acute gastroenteritis, regardless of the causative etiologic agent, are diarrhea and vomiting, associated or not with fever and abdominal pain. None of the symptoms that usually characterize Rotavirus-induced gastroenteritis has a strong predictive value. However, there are selected features that may help a differential diagnosis of viral versus bacterial infection [19, 20].

Children with viral intestinal infection generally have larger volumes of watery stools, suggesting small bowel involvement, and vomiting and fever are more frequent than in bacterial diarrhea. Each of these features contributes to dehydration. Another feature of viral gastroenteritis is its frequent association with respiratory symptoms due to the coinciding peak of common respiratory infections (Table 14.4).

In contrast, the presence of symptoms suggesting colitis, such as a high number of diarrheal episodes with small amount of stools, blood in the stools, high fever, and abdominal pain, is more likely associated with bacterial etiology (Table 14.4).

The severity of acute gastroenteritis is reflected by the degree of dehydration. This should be evaluated at first observation and during the follow-up to establish the efficacy of rehydration treatment. However, high persistent fever and lethargy suggest more severe clinical conditions and systemic involvement. Moreover, benign seizures, not related to electrolyte imbalances, have been reported for Rotavirus- and Norovirus-induced gastroenteritis [21, 22], but severe encephalopathies were reported in a recent surveillance study conducted in Germany on about 100 cases of severe diarrhea [23].

Clinical pattern of viral gastroenteritis is also associated with the specific pathogen (Table 14.5). When compared with other viral infections, Rotavirus infection is more frequently associated with high-grade fever (>38 °C), frequent diarrheal episodes (>7/day), and long-lasting diarrhea that results in significantly higher severity scores [24]. In contrast, children with Norovirus infection have significantly more episodes of vomiting than other viral infections, and in some cases, vomiting may be the only gastrointestinal symptom and up to 20% of children are present without diarrhea. However, Norovirus is only slightly less clinically severe than Rotavirus as agent of gastroenteritis in young children

Table 14.4 Clinical features associated with viral and bacterial agents of acute diarrhea in children

Viral diarrhea	Bacterial diarrhea
Watery diarrhea	High fever
High volume stools	Bloody stools
Vomiting	Dysentery
Fever	Abdominal pain
Presence of respiratory symptoms	Neurological signs

Table 14.5 Main clinical features of viral gastroenteritis related to specific etiologic agent

	Preferred age	Transmission route	Incubation	Symptoms		
				Diarrhea	Vomiting	Fever
Rotavirus	<5 years	Fecal–oral	1–3 days	+++	++	++
Norovirus	All ages	Fecal–oral, water, foods, environment	12 hours–2 days	++	+++	+
Adenovirus	<2 years	Fecal–oral	3–10 days	++	+	+

according to a systematic analysis. Intestinal infections due to adenovirus, on the other hand, seem to have milder clinical features [24].

Diagnosis

Most children with acute diarrhea have viral gastroenteritis. Microbiological examination is not helpful in the majority of cases and should be reserved for special circumstances. In fact, regardless of etiology, most children do not require any etiology-based treatment, and therefore identification of a specific pathogen is not generally needed. Microbiological investigation should, however, be performed during outbreaks, especially in childcare settings, schools, hospitals, or residential settings to identify the pathogen and establish its source in the attempt to reduce transmission. Stool samples should also be taken from children with bloody diarrhea, a history of recent foreign travel, and from young or immunocompromised children with high fever for whom antibiotic treatment is considered. Finally, it is also recommended to investigate children in whom diarrhea persists for more than 10–14 days, or when a noninfectious etiology for diarrhea is suspected, such as inflammatory bowel disease (IBD) (Table 14.6) [19].

Several techniques are available to identify the specific etiology of viral diarrhea. The gold standard is viral culture but its clinical application is limited, due to the costs, the delay in the results, and the complexity of the procedures. Immunofluorescence or latex agglutination is widely used to identify fecal viruses. Various molecular techniques offer easy, quick, and reliable diagnosis of viral gastroenteritis. In clinical laboratories, polymerase chain reaction (PCR)-based assays are considered as gold standard for the detection of viruses. Specific PCR is currently available for Norovirus, Rotavirus, adenovirus, cytomegalovirus, and other less common viruses. Among different techniques used to explore new viruses, such as conventional and next-generation sequencing, metagenomic has been a promising approach to study genetic material directly from samples and bypass the need for culturing the virus [25, 26]. Virome capture sequencing is another approach for viruses, in which millions of probes cover the entire genome of several viral taxonomies [27]. In Table 14.7, a list of main diagnostic methods for enteric viruses is presented. Diagnosis of viral gastroenteritis is performed detecting viral antigen or nucleic acid in fresh stool samples during the acute illness. Diagnosis of Rotavirus infection is generally made detecting Rotavirus antigen in stools using commercially available enzyme immunoassay (EIA) or latex particle agglutination test. Both are easy and inexpensive and have 90% sensitivity and 95% specificity. Other methods for Rotavirus detection include electron microscopy, viral isolation, and RNA polyacrylamide gel electrophoresis. Reverse transcription–polymerase chain reaction (RT-PCR) is not used in clinical practice because the test has too high sensitivity, and it may detect virus when it is not causing disease [28]. Real-time RT-PCR is the preferred laboratory method for detecting Noroviruses. This assay has high sensitivity, is able to detect less than 10 Norovirus copies, and allows a semiquantitative estimation of viral load. The assay is generally performed on stools, but it can also be used for other biological samples such as vomitus, foods, water, and environmental specimens mainly for outbreak evaluations.

Table 14.6 Indications to microbiological evaluation in children with acute diarrhea

Condition
Age < 3 months
Shock or septic appearance
>10 liquid stools/day, high fever, dysentery, bloody stools
Recent history of travel
Immunocompromised children
Outbreak
Protracted or chronic diarrhea

Table 14.7 Diagnostic tools for enteric viruses' identification

Diagnostic assay	Specific technique	Etiologic agent
Cell culture		Rotavirus
Electron microscopy		Rotavirus
Serological	ELISA, Bioluminescent EIA	Rotavirus, Astrovirus, Adenovirus
Nucleic acid based	PCR variants (Multiplex RT-PCR, Real-Time RT-qPCR, Immuno-PCR) isothermal amplification	Norovirus
Next-generation methods	Mass spectrometry, NGS, Microarray	Sapoviruses of the Caliciviridae, Human Astroviruses of the Astroviridae

Differential diagnosis of viral gastroenteritis may include food poisoning, which may be eventually indirectly related to microbial etiology. Food poisoning has a more rapid onset, often with vomiting and is more common in children than in infants, being related to ingestion of at-risk foods. On the other hand, when diarrhea is persistent, lasting more than 7–10 days, a different etiology should be considered [29]. Common causes of persistent diarrhea include small intestinal bacterial overgrowth, lactose intolerance, and cow's milk protein intolerance. In addition, chronic inflammatory conditions of the small and/or large intestine such as celiac disease or IBD may have an acute onset or be triggered by viral enteritides.

Specific Viruses

Rotavirus

Rotavirus is a double-stranded RNA virus belonging to the Reoviridae family. The virion, 70–75 nm, is composed of a three-layered protein capsid that encompasses 11 distinct segments of genomic RNA, each coding for a different capsid or nonstructural protein. The internal core contains VP 1, 2, and 3; the inner capsid contains VP4; the two outer capsid proteins encoded by genes 4 and 7, namely VP4 and VP7, represent the only established neutralization antigens of the virus. The protective role of antibodies directed against these proteins has been confirmed in both experimental animal models and humans. A possible role has been suggested for antibodies directed at the inner capsid protein VP6, which is not associated with in vitro neutralization. The nonstructural proteins NSP1, NSP2, and NSP4 are VFs in mice. Rotavirus groups A–F have been described, but only groups A, B, and C have been identified in humans. Most human infections are caused by group A Rotaviruses that are classified into serotypes by a dual classification system based on neutralizing antigens on two outer capsid proteins, VP7 (G serotype) and VP4 (P serotype). To date, 14 G serotypes and 11 P serotypes have been identified in humans. There is substantial genetic diversity within each G- and P-type. Predominant serotypes vary from year to year and from region to region. G1P is the globally predominant strain, representing over 70% of Rotavirus infections in North America, Europe, and Australia. G9 strains now constitute the predominant strains in some parts of Asia and Africa, and G8 strains are proportionally more frequent in Africa [30–32]. In South America, G5 strains have emerged in children with diarrhea, and G9 is associated with more severe disease in Latin America [33].

Specific strains may express stronger VFs, which could be related to the severity of symptoms. More severe presentations may also be related to the reintroduction of strains in areas where they have been previously absent. The epidemiology of Rotavirus shows a link with cold seasons with a higher incidence during fall and winter.

Transmission occurs by fecal–oral route, both through close person-to-person contact and by fomites. Viruses are shed in high concentrations in the stool of Rotavirus-infected persons. Children shed large numbers of viruses in stool, during the acute illness but they may shed Rotavirus 2 days before and up to 10 days after the onset of symptoms. The virus may also be transmitted by respiratory droplets. Spread within families, institutions, hospitals, and childcare settings is common. Rotavirus is a major cause of acute gastroenteritis in children attending childcare. Rotavirus is also responsible for nosocomial infection during the winter with an incidence as higher as 3% hospitalization in a meta-analysis of 20 studies in Europe and North America [34], prolonging hospital stays and increasing medical costs [35, 36].

The incidence of nosocomial infections is directly related to the duration of hospital stay, and the incidence of nosocomial Rotavirus-induced gastroenteritis may be as high as 8–10/1000 child-days of hospitalization.

The incubation period for Rotavirus diarrhea is short, usually less than 48 h. Rotavirus is able to determine a large spectrum of disease, ranging from asymptomatic shedding to severe dehydration, seizures, and even death. Rotavirus gastroenteritis typically begins with acute onset of fever and vomiting followed 24–48 h later by watery diarrhea Symptoms generally persist for 3–8 days, although protracted episodes have been reported occasionally. Fever is usually of low grade and occurs in up to half of all infected children. Vomiting occurs in 80–90% of infected children, and it is usually brief, lasting 24 h or less in most children. Dehydration and electrolyte disturbances are the major complications of Rotavirus infection and occur most often in the youngest children. In hospitalized children, gastroenteritis associated with Rotavirus is more severe than in cases in which Rotavirus was not detected, with more severe dehydration, higher incidences of vomiting and parenteral rehydration. Children with immunodeficiency, particularly those with T-cell immunodeficiencies or severe combined immunodeficiency (SCID), and children after bone marrow transplantation are at higher risk of severe and prolonged diarrhea and central nervous system complications.

Norovirus

Noroviruses are single-stranded RNA viruses belonging to the family *Caliciviridae*. The prototype virus of the Noroviruses, Norwalk virus, was identified in 1972. The availability of molecular diagnostic methods based on reverse transcription-PCR (RT-PCR) highlighted the etiologic role of Norovirus in epidemic and sporadic gastroenteritis [37]. Norovirus is now a well-documented leading

agent of epidemic gastroenteritis in all age groups, causing >90% of nonbacterial and ≈ 50% of all-cause epidemic gastroenteritis worldwide [38]. The impact of Norovirus disease may be much greater than previously thought, and the disease may be more severe in selected populations.

The Norovirus genome comprises a single-stranded, positive-sense, polyadenylated RNA of approximately 7.5 kb in length, encompassing three open reading frames (ORFs 1–3).

Noroviruses encompass five distinct genogroups (GI–GV) with GI, GII, and GIV infecting humans. The Norovirus genogroups are further divided into genotypes and variants (subgenotypes) based on the sequence diversity.

The mechanisms of Norovirus-induced diarrhea are not well defined. Many viral factors can interfere with basic cellular functions. Several observations showed that, in infected mucosa, villus length decreased by 25%, whereas crypt length was unchanged. Villus blunting and the shortening of the villi observed in this viral infection depend on the Norovirus infection of intestinal epithelial cells located on the apical area of villi. Infected cells undergo an increase in cell death rates with a reduction of the overall absorptive surface.

Evaluations of human intestinal biopsies from Norovirus-infected showed an active Cl^- secretion, consistent with cystic fibrosis transmembrane conductance regulator (CFTR) activation. A reduction of occludin expression as well as claudins 4 and 5 corresponding with a marked decrease in transepithelial resistance has also been observed. In addition, Norovirus produces two proteins, p48 and p20. The former interferes with cell proteins involved in the regulation of vesicle trafficking, whereas p20 impairs actin cytoskeleton structure leading to intestinal barrier dysfunction.

Intestinal mucosal immunity is also affected by Norovirus. Dendritic cells were depleted in Norovirus-infected mucosa associated with an altered antibody response but dendritic cells were required for a dissemination of the virus to secondary lymphoid tissues supporting the idea that enteric viruses can use dendritic cells to facilitate their dissemination within the host [39]. In addition, VF1 expression enables Norovirus to establish efficient infection interfering with interferon-mediated response pathways and apoptosis [40, 41]. Finally, gut microbiota is highly altered in patients with Norovirus gastroenteritis resulting in a low grade of diversity and increased proteobacteria [42]. Elevated proteobacteria is a common feature in patients with dysbiosis, and a reduction in the diversity is associated with several altered functions of gut microbiota [43].

Norovirus gastroenteritis may occur in three distinct epidemiological settings, and is associated with a broad spectrum of clinical outcomes. First, foodborne gastroenteritis generally affects large numbers of healthy adults over a short time period, with symptoms typically resolving within 1–3 days Second, healthcare-associated infection, which occurs in semiclosed settings such as hospital wards and residential/care homes, can be very challenging to contain. Elderly and compromised individuals are frequently affected and are at high risk of prolonged clinical course, typically 4–6 days, with a not negligible mortality rate. However, its shedding persists in immunocompromised subjects. Third, Norovirus gastroenteritis may occur sporadically in children, where Norovirus is the second most common cause of acute viral gastroenteritis after Rotavirus, often requiring hospitalization. Compared with Rotavirus enteritis, the duration of vomiting and diarrhea is significantly longer but Norovirus infection is slightly less severe in terms of severity score and need of intravenous (IV) rehydration compared to Rotavirus infection. In different geographical areas, Norovirus is more prevalent in winter. In the United States, Noroviruses cause 20 million episodes of gastroenteritis every year and are increasingly recognized as a cause of severe disease, leading to more than 900 deaths and substantial rates of hospitalization, major losses for outbreaks, productivity losses missed school/workdays. The total cost is estimated to be as high as 10.6 billion based on an estimate of almost 70/1000 persons per year [44, 45]. Of those estimates slightly less than half are related to children, where Norovirus has become the major pathogen in post Rotavirus vaccine era [46].

SARS-CoV-2 Virus

A novel Coronavirus, named SARS-CoV-2, has been responsible for a viral pandemic with hundreds of millions of infections and more than 5 millions of deaths. The coronavirus disease 2019 (COVID-19), has a spectrum of clinical manifestations ranging from fever, dry cough, and dyspnea to pneumonia, acute respiratory distress syndrome, and multiple organ failures. Less frequently, patients with SARS-CoV-2 infection present nausea, vomiting, and diarrhea. Diarrhea is a frequent symptom in coronavirus infections; it was detected in up to 30% of patients with MERS-CoV and 10.6% of patients with SARS-CoV infection [47]. Similarly, data from early reports of the current pandemic suggest that gastrointestinal symptoms are not uncommon in patients with COVID-19 [48, 49]. A cohort study of 140 COVID-19 patients showed that gastrointestinal symptoms were observed in almost 40% of the patients, including nausea (17%), diarrhea (13%), and vomiting (5%) [50]. Atypical cases of SARS-CoV-2 infection characterized by gastrointestinal symptoms were reported [51]. Clinical studies show an incidence of diarrhea ranging from 2% to 50% of cases [15], and the frequency of diarrhea and vomiting was higher in newborns and infants than in adults [15]. The majority of evidences simply described the presence of diarrhea in patients affected by COVID19 without a specific character-

ization in terms of number of evacuations, stool consistency, and duration of symptoms. SARS-Cov-2 was found in the stools, and viral RNA shedding in stool was detectable for longer period than in nasopharyngeal swabs raising the hypothesis of fecal–oral route as a transmission pathway. There are many hypotheses to explain why COVID-19 causes digestive symptoms but the exact molecular mechanism needs to be further investigated. SARS-CoV-2 and SARS-CoV showed a high genomic homology indicating that the new virus could bind ACE2 and infect humans. Structural studies showed that the new SARS-CoV-2 not only binds ACE2, but its binding affinity for human ACE2 is 10–20 times stronger than its 2003 SARS-CoV predecessor. Second, SARS-CoV-2 indirectly damages the digestive system through a chain of inflammatory responses. Another possible factor might be antibiotic-associated diarrhea; patients with more severe COVID19 frequently received a cocktail of antibiotics and antiviral drugs, responsible for changes in the composition and function of digestive tract flora [52]. Several case series describing the clinical presentation of COVID19 in adults showed that patients without digestive symptoms were more likely to be cured and discharged than patients with digestive symptoms. This could be due to either viral replication in the gastrointestinal tract causing more severe disease or that patients who do not initially have typical respiratory symptoms present with later stages of disease [48]. No data on the efficacy of antidiarrheal drugs are available, but an adequate rehydration and potassium monitoring should be performed as in all patients with diarrhea. Scattered data indicate that these symptoms disappeared after antiviral therapy (oral lopinavir and ritonavir), supporting the link between symptom and COVID-19 disease.

Evaluation and Treatment of Children with Acute Diarrhea

The initial clinical approach to the child with acute gastroenteritis is clinical evaluation. Hydration status in children should be assessed based on easily observed signs and symptoms. Dehydration should be estimated using a score system. An easy to use and reliable score system to evaluate dehydration in children is the Clinical Dehydration Scale (CDS) [53]. It consists of four clinical items: general appearance, eyes, mucous membranes, and tears, each of which is scored 0, 1, or 2 to a total score of 0–8 (Fig.14.2).

Severe dehydration is an indication for hospital admission and for IV rehydration. Indications to hospital admission are reported in Table 14.8.

Specific antiviral treatment is generally not needed to treat Rotavirus infection. The current treatment of acute Rotavirus gastroenteritis consists of oral rehydration solution (ORS) and early introduction of feedings, like any other form of acute diarrhea [19]. Adequate fluid and electrolyte replacement and maintenance are the key to managing viral gastroenteritis. Oral rehydration is the preferred method unless the child has intractable vomiting that would require IV rehydration. Children who are mildly or moderately dehydrated should receive 50–100 ml/kg of ORS over 4 h and should be reevaluated often for changes in hydration status.

Clinical item	0	1	2
General appearance	Normal	Thirsty, irritable or lethargic	Drowsy,cold or sweaty; comatose or not
Eyes	Normal	Slightly sunken	Very sunken
Mucous membranes	Normal	Sticky	Dry
Tears	Normal	Decreased	Absent

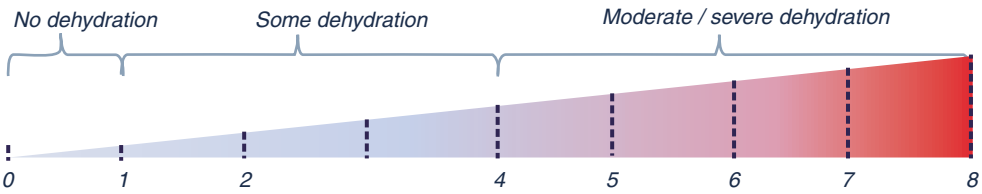

Fig. 14.2 Clinical dehydration scale for children with acute diarrhea

Table 14.8 Indications to hospital admission in children with acute diarrhea

Age < 3 months
Shock
Severe dehydration (>9% of body weight)
Neurological abnormalities (lethargy, seizures)
Intractable or bilious vomiting
Failure of oral rehydration
Suspected surgical condition
Caregivers cannot provide adequate care at home and/or there are social or logistical concerns

Reduced osmolarity ORS (50/60 mmol/L of Na) is the first-line treatment for children with acute gastroenteritis. Reduced osmolarity ORS is more effective than full-strength ORS (75/90 mmol/L of Na) as measured by key clinical outcome indicators as stool output, vomiting, and need for supplemental IV therapy. The so-called ESPGHAN (the European Society for Pediatric Gastroenterology Hepatology and Nutrition) solution, containing 60 mmol/L of Na, may be used in children with acute gastroenteritis as it has been used successfully in several randomized clinical trials (RCTs) and in a number of non-RCTs. However, several data including a recent in vitro study challenged the optimal composition of ORS [54].

The second step of treatment of acute diarrhea, in children with mild-to-moderate dehydration, is early resumption of feeding after rehydration therapy. It is recommended that (1) breastfeeding should be continued throughout rehydration; (2) the usual age-appropriate diet should be started immediately after initial rehydration (4–6 h); (3) dilution of formula or use of a modified milk formula is usually unnecessary. To continue feeding is important for limiting the nutritional consequences of decreased intake and for stimulating digestion and absorption of essential nutrients during diarrheal illness. A systematic review showed that lactose-free diet in children who are not breastfed may result in shorter duration of diarrhea. However, most of the trials included in the review were from children hospitalized in developed countries [55]. In children in low- and middle-income countries, where the double burden of diarrhea and malnutrition is greatest, the use of locally available age-appropriate foods should be promoted for the majority of acute diarrhea cases particularly if the access to milk formulas and specific expensive ingredients is limited [56]. In persistent diarrhea, withdrawal of lactose should be considered.

Enteral or intravenous (IV) rehydration is needed in selected conditions and is usually applied in children in hospital. The former is effective and has no side effects and should be preferred. Children who are severely dehydrated with changes in vital signs or mental status require emergency IV rehydration. For children presenting with shock, rapid IV infusion of isotonic crystalloid solution (0.9% saline or lactate Ringer's solution) with 20 ml/kg bolus should be used. For children with severe dehydration without shock, rapid IV rehydration with 20 ml/kg/h of 0.9% saline solution for 2–4 h is indicated. A dextrose-containing solution may be used for maintenance [57] .

There is solid and compelling data demonstrating the efficacy of selected probiotics as an adjunct to rehydration therapy in reducing the intensity and duration of symptoms. The guidelines of ESPGHAN [19] and the Universal Guidelines [58] for the management of acute gastroenteritis in children recommend the use of two different probiotics, *Lactobacillus rhamnosus* strain GG (LGG) and *Saccharomyces boulardii* in adjunct to the ORS for the treatment of acute diarrhea in children [59, 60]. Both *Lactobacillus* GG and *S. boulardii* reduce the duration of diarrhea by approximately 1 day. *Lactobacillus* GG is particularly effective in Rotavirus-induced diarrhea. In developed countries, *Lactobacillus* GG given in a daily dose of 10 billion colony-forming units (CFU) per day has proven effective in reducing the risk of protracted diarrhea and the duration of hospitalization in Rotavirus gastroenteritis [61, 62] although a recent large size high-quality study found no evidence of efficacy in North American children in emergency department setting [63].

Other pharmacological interventions have been studied in the attempt to reduce the duration of acute diarrhea and for some there is proof of efficacy. Diosmectite can be considered in the management of acute gastroenteritis as it is effective in reducing the duration of diarrhea [19]. A Cochrane systematic review concludes that smectite used as an adjuvant to rehydration therapy may reduce the duration of diarrhea in children with acute gastrointestinal infections, may reduce stool output, but has no effect on hospitalization rates or need for intravenous rehydration [64].

A recent meta-analysis assessed the efficacy of Racecadotril as an adjunct to ORS compared with ORS alone or with placebo. Compared with placebo, Racecadotril significantly reduced the duration of diarrhea and the need for IV rehydration [65]. Recently, a Cochrane systematic review evaluating trials conducted in children between 3 months and 5 years, both outpatient and inpatient from France, Spain, Peru, India, Kenya, and Ecuador, showed that Racecadotril is a safe drug but has limited benefit in improving acute diarrhea. The beneficial effect of Racecadotril is to reduce the risk of rehydration failure. No sufficient data are available to evaluate the effect on duration of diarrhea, number of stools, and length of hospital stay [66].

In Table 14.9, the active intervention for acute gastroenteritis is reported.

Diarrhea treatment (ORS, zinc, antibiotics for dysentery, and management of persistent diarrhea) and use of Rotavirus vaccine were responsible for nearly 50% of the reduction of diarrhea mortality from 1980 to 2015. Improvements in

Table 14.9 Interventions to be considered for active treatment of viral diarrhea

	Lactobacillus rhamnosus strain GG (LGG)	*Saccharomyces boulardii*	Smectite	Racecadotril
Stool volumes reduction	+	+	+	+

Setting	In/outpatients	In/outpatients	In/outpatients	Inpatients
Cost	Low	Low	Low	Low
Palatability	++	±	–	+

nutrition and improvements in water, sanitation, and handwashing were even more important interventions effective in reducing the burden of infectious diarrhea. To further minimize the diarrhea-related mortality, all these interventions should be scaled up [67].

Because vomiting may make difficult or impossible oral rehydration, ondansetron may be used in single dose to overcome the peak phase and allow ORS administration. Although loaded with an FDA and EMA warning for potential cardiac severe effects, it is often used in emergency settings to reduce admission related to the need for IV rehydration [68].

Management of Viral Diarrhea in Immunocompromised Children

Management of acute gastroenteritis in children generally does not require microbiological investigation because acute infectious diarrhea is a self-limited disease and its treatment is independent of the etiology so that the identification of specific pathogen is not needed. Only in selected conditions and situations, it may be necessary to investigate the cause of diarrhea in order to establish a specific etiologic treatment. Immunocompromised children, mainly children with chronic diseases treated with immunosuppressive and immunomodulatory medications, are at high risk of infectious diarrhea. Viruses like Rotavirus, Norovirus, sapovirus, and adenovirus are the most common agents of infectious diarrhea in immunocompromised children and are responsible for severe prolonged disease course and complications like hypovolemia, dehydration, electrolyte imbalance, and malabsorption. Despite an etiologic treatment is possible for acute bacterial diarrhea, no specific drug is available for treatment of viral diarrhea. The oral administration of human serum immunoglobulins to treat Rotavirus- and Norovirus-induced diarrhea in immunocompromised patients has been previously reported [69, 70]. Recently a retrospective cohort review assesses the efficacy of oral immunoglobulin (OIG) in treating hospitalized immunocompromised children with diarrhea. Nineteen children immunocompromised for solid organ transplant, malignancy, and inflammatory bowel diseases were treated with oral immunoglobulins 100–300 mg/kg/day for 2–5 days. Eighteen of 19 children (95%) showed a significant reduction of stool output within 10 days of initiation of therapy; a complete symptom resolution was documented in 42% of patients [71].

Vaccines for Viral Diarrhea

Enteric viral infections are still a leading cause of mortality and morbidity in young children in both low- and middle-income countries, and in immunocompromised patients. Vaccination is an effective preventive approach against the fecal–oral transmitted infection particularly in resource-limited countries where sanitation systems and supply of safe drinking water are not easily achievable. Developing effective vaccines for enteric pathogens continues to be very challenging also because of a limited understanding or characterization of immune correlates to protection. Vaccine-induced IgG antibody responses are often measured, but assessment of IgA particularly mucosal IgA responses should be emphasized. The greatest challenge in the development of new vaccines is represented by the heterogeneity among genotypes or serotypes of viral pathogens. Vaccines are available only for few enteric pathogens including Rotavirus and cholera. No vaccines are available for most other enteric viral and bacterial pathogens responsible for acute gastroenteritis. Despite a progressive decrease in diarrhea-related deaths, Rotavirus is still a major cause of mortality mainly in developing countries. Rotavirus disease is prevented by vaccination, but there are cultural, organizational, and financial barriers to the implementation of immunization, the main being that families, physicians, and policy-makers wrongly believe that Rotavirus diarrhea is not

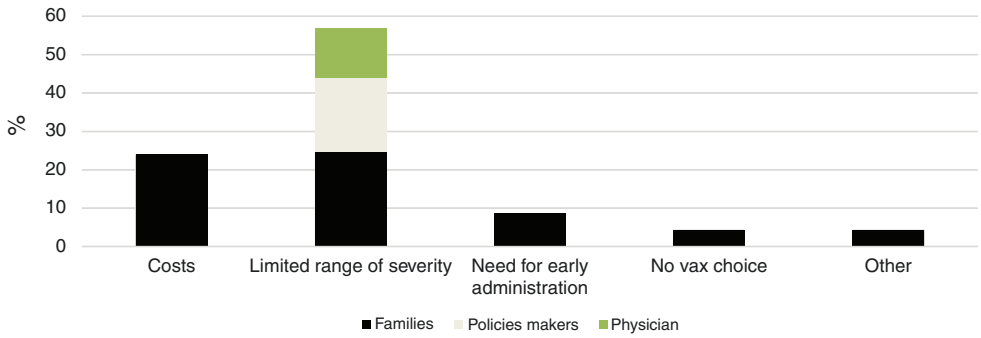

Fig. 14.3 Major barriers toward immunization against Rotavirus. (Modified from: Lo Vecchio et al. [75])

a severe disease (Fig. 14.3). WHO and other authorities recommend universal immunization and consider it a priority in countries with high Rotavirus gastroenteritis-associated deaths, such as in south and southeastern Asia and sub-Saharan regions. Vaccine development strategies are based on live-attenuated Rotavirus vaccines that can be administered by the oral route. The goal for a Rotavirus vaccine is to replicate the degree of protection against the disease induced by the first natural infection that occurs in infants. Therefore, the primary outcome of a vaccine program is the prevention of moderate to severe disease. Rotavirus vaccines decrease the number of children admitted to the hospital with dehydration and decrease the burden of office visits or telephone calls due to Rotavirus gastroenteritis.

At present, there are several vaccines two of which were distinctly developed. The first is a live-attenuated oral monovalent Rotavirus vaccine derived from a G1P8 human Rotavirus strain attenuated through serial passages in cell culture. It provides 85% protection against severe rotaviral gastroenteritis and 100% protection against the most severe dehydrating rotaviral gastroenteritis episodes [72]. The other vaccine is a pentavalent reassortant oral vaccine derived from a G6P [5] bovine Rotavirus strain and common human Rotavirus strains carrying G1, G2, G3, G4, and P [8] human Rotavirus surface proteins. It has a three-dose schedule with the first dose within 6 weeks of age and the last by 24 weeks of age. Its efficacy against Rotavirus gastroenteritis of any severity was 74% and against severe Rotavirus gastroenteritis was 98% [73].

In 2007, the WHO recommended inclusion of Rotavirus vaccine in the immunization programs of Europe and America and, in 2009, expanded the recommendation to all infants over the age of 32 weeks worldwide. Other qualified institutions and agencies included Rotavirus universal immunization as a major priority to reduce the mortality for acute gastroenteritis [19].

The burden of Rotavirus disease in the United States and elsewhere has been reduced significantly since the introduction of Rotavirus vaccines.

Data from eight high-income and middle-income countries showed a 49–89% reduction of Rotavirus-associated hospital admissions and a 17–55% of all-cause gastroenteritis-associated hospital admissions among children younger than 5 years, within 2 years of vaccination policy. Hospitalization rates were reduced from 60 to 93% depending on vaccine coverage, age groups, and Rotavirus season. Studies have also evaluated the impact of Rotavirus vaccination on all-cause gastroenteritis or diarrhea-related hospitalizations, emergency visits, and outpatient or physician office visits, and consistent reductions were seen for all these parameters. Effective Rotavirus vaccines are most needed in resource-poor countries, where mortality associated with Rotavirus is high. Although Rotavirus vaccines resulted less effective in developing countries than developed countries (50–64% vs. 85–98%), the burden of disease prevented by vaccination is greater in developing countries, probably due to the greater baseline incidence of severe Rotavirus disease. Initial results from African countries that have implemented routine Rotavirus vaccination supported the efficacy of Rotavirus vaccines. There are several hypotheses to explain the difference in the efficacy of Rotavirus vaccination between developing and developed countries. Poor nutritional status, enteric co-infections, or the interference of anti-Rotavirus antibodies in breast milk may hamper live virus vaccines, which are more common in children leaving in resource-poor countries. Even considering a lower efficacy, the use of live Rotavirus vaccines should be implemented in these countries to reduce the high mortality due to Rotavirus gastroenteritis. Overall, the live-attenuated Rotavirus vaccine has been substantially effective in reducing the burden of Rotavirus infection [74]. Although the effectiveness of the rotavirus vaccine is widely demonstrated, its implementation is still low; barriers to implementation vary in relation to setting but elevated cost of vaccine, limited perception of RV illness severity by the families, public-health authorities or physicians and the timing of administration are still the major barriers to large-scale Rotavirus vaccination programs (Fig. 14.3) [75]. Implementation of Rotavirus vaccine has been included in the priorities of interventions against childhood mortality [76].

Unlike Rotavirus for which vaccines have been licensed and recommended, there is no vaccine licensed for the

single-stranded RNA Norovirus which now is the most common viral cause of gastroenteritis in developed countries where Rotavirus vaccines have been introduced [77]. In contrast to Rotavirus which exclusively infects children, Norovirus causes gastroenteritis in people of all ages mostly among young children and the elderly over 65 years. The typical clinical outcome of Norovirus infection is acute gastroenteritis but it can cause also severe dehydration and death if infection progresses without intervention and treatments. The high disease burden caused by Norovirus particularly associated with foodborne disease and outbreaks and the potential severe outcomes in both children and elderly people has led to develop vaccines for the prevention of Norovirus disease.

In conclusion, despite major achievements in reducing death rates particularly in children in deprived settings, viral gastroenteritis remains a huge problem that needs urgent interventions. In addition also in rich countries, viral diarrhea should not be neglected as it is responsible for economic and health losses and for a total burden of death that probably exceeds that induced by diseases that are certainly more severe but also much more rare. This translates into a risk of death that is reversed in the general population of children when compared to children that are affected by a more severe but also much less rare disease.

Bacterial Infections of the Small and Large Intestine

15

Rachel Bernard and Maribeth Nicholson

Introduction

Diarrhea is the result of an imbalance of ion and water movement through the intestinal epithelium. In normal conditions, the intestine absorbs 8–9 L of fluid while only 100–200 mL are excreted in the stools daily [1–3]. In addition, the intestine absorbs nutrients while simultaneously forming a selective barrier to dangerous substances and pathogenic bacteria. Finally, the intestine is colonized with a wide community of bacteria that exert many beneficial functions, collectively known as the intestinal microbiome [4]. Resident commensal and foreign bacteria interact intimately with the gut epithelium and affect host cellular and innate immune responses [5]. Enteric pathogens may hamper the physiological handling of electrolytes and water transport processes by secreting toxins that disturb the function and/or the structure of the intestinal epithelium [6].

A number of cellular and molecular mechanisms are implicated in infectious diarrhea induced by bacteria, viruses, and parasites. Pathogen-specific virulence factors affect a wide range of cell functions such as ion absorption and secretion, barrier function, and membrane-trafficking pathways causing fluid accumulation in the intestinal lumen [7, 8].

Several bacterial enterotoxins are able to increase chloride (Cl−) secretion and to reduce sodium (Na+) absorption by acting on apical membrane-located transporters or on the lateral spaces between cells, regulated by tight junctions (TJs) [9–11]; other pathogens induce cell damage by targeting the cytoskeletal network which is directly implicated in paracellular fluid absorption [12, 13]. Invasive pathogens cause an inflammatory diarrhea characterized by an increase in polymorphonuclear cells (PMNs) in the lamina propria leading to an excess of cytokine secretion and activation of the enteric nervous system via neuropeptides, eventually resulting in dysenteric diarrhea. Furthermore, a specific class of *Escherichia coli*, the enteropathogenic *E. coli* (EPEC), induces diarrhea through damage of the apical enterocytes, thereby reducing the intestinal absorptive surface [14]. Regardless of the mechanism, diarrhea is the manifestation of an altered movement of ions and water that follows an osmotic gradient. The pathophysiology of diarrhea is summarized in Fig. 15.1.

Intestinal Ion Transport and Barrier Functions

In normal conditions, fluid transport across the intestinal epithelial cells is a finely balanced process between fluid absorption and fluid secretion. Dysregulation of the normal intestinal ion transport and barrier functions leads to diarrhea. Transporters, pumps, and ion channels mediate the flow of solutes through the cell membrane and water follows passively. Absorption function of the apical enterocytes depends on both the electroneutral and the electrogenic cotransporters and exchangers [15]. Major ion transporters involved in electrolyte absorption include the sodium–hydrogen exchanger (Na+, H− exchanger or NHE), the chloride–bicarbonate (Cl−, $HCO3^-$) exchanger, and the epithelial sodium channel (ENaCs) [16]. There are several NHEs positioned on the apical membrane of small intestinal villus and surface epithelial cells in the colon that play a major role in Na+ and water absorption [17]. NHE1 is located on the basolateral surface of the enterocyte, whereas NHE2 and NHE3 have an apical localization [18, 19]. The relative contribution of NHE2 and NHE3 depends on their localization within the intestine; NHE3 is the main mediator of electroneutral Na+ uptake [20]. The electrogenic ion absorption is the second major source of apical ion absorption through specific channels. The ENaC is the most prominent apical Na+ channel in

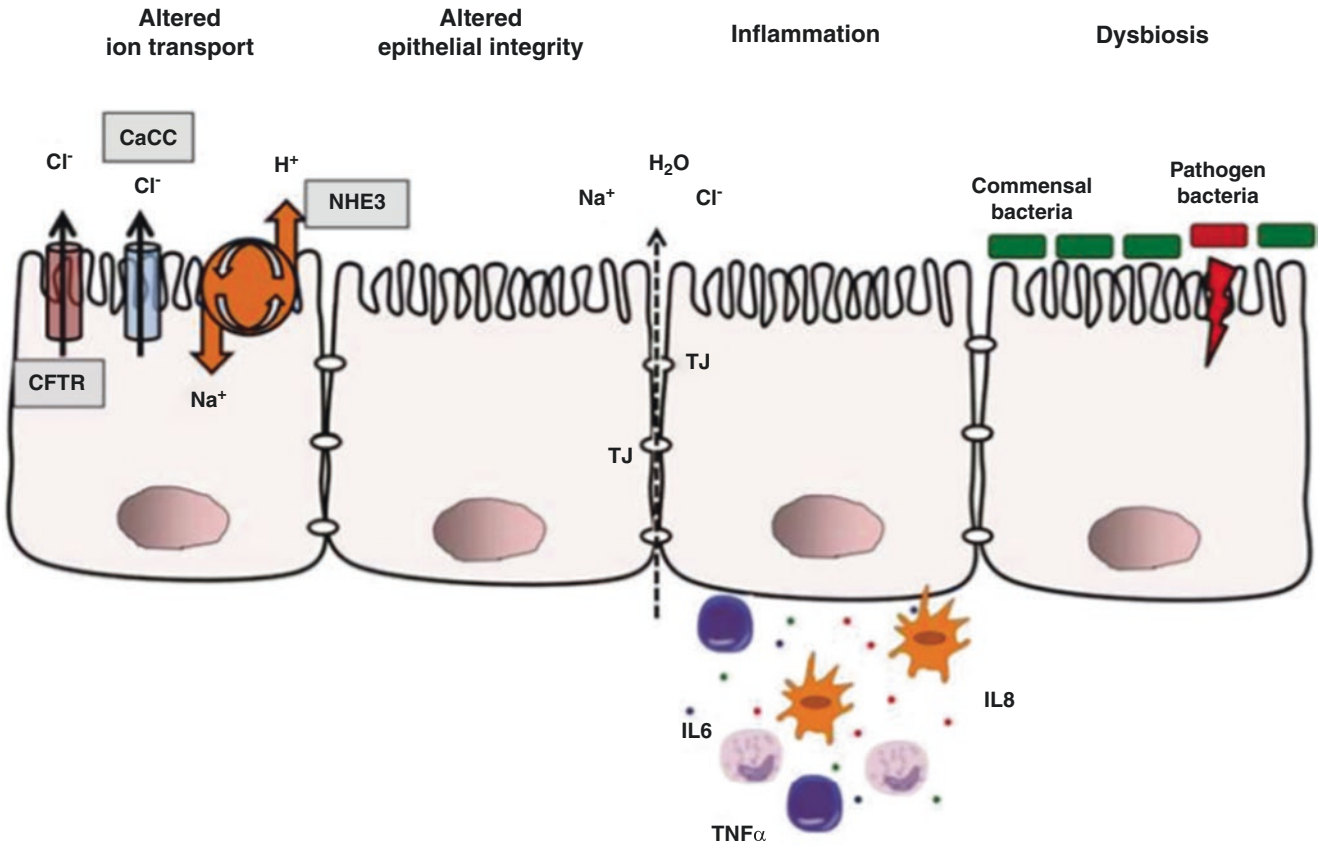

Fig. 15.1 General mechanisms causing diarrhea. Bacterial toxins can affect intestinal epithelial functions through different mechanisms. Chloride secretion and water secretion depend on the altered functionality of CFTR, CaCC, and NHE channels. Alterations in TJ structures alter the electric gradient causing the movement of both ions and water. Pathogen bacteria induce inflammation through the recruitment of immunity cells and the upregulation of pro-inflammatory cytokines. Finally, an altered gut microbiome composition (dysbiosis) supports pathogen infections. *CFTR* cystic fibrosis transmembrane conductance regulator, *CaCC* calcium-activated chloride channels, *NHE* Na^+, H^+-exchanger, *TNFα* tumor necrosis factor-α. *IL* interleukin

the colon and allows Na+ influx into the cell along its electrochemical gradient [16].

A basal level of fluid secretion is necessary for accomplishing the nutrient digestive functions and is mediated by three main transporters comprising the cystic fibrosis transmembrane conductance regulator (CFTR), the Na+/K+/2Cl cotransporter type 1 (NKCC1), and calcium-activated chloride channel (CaCC) transporter [21]. In the intestine, water secretion is a passive process driven by active ion secretion, predominantly by Cl-secretion. The CFTR channel is located on the brush border and is regulated by cyclic AMP (cAMP) and cyclic guanosine monophosphate (cGMP) [22]. cAMP and cGMP are stimulated by secretagogues, and the channel is responsible for chloride efflux and thus water secretion in basal conditions [3]. Initially, chloride is taken up across the basolateral membrane via NKCC1, which facilitates the uptake of Na+, K+, and 2Cl-ions across the basolateral membrane, and thereby supplies chloride for secretion via an electroneutral process [23]. Chloride accumulation is a passive process driven by the Na+ concentration gradient which is maintained by the basolateral Na+/K+-ATPase [24]. Two distinct potassium channels are located in the basolateral membrane allowing for potassium recycling, thus preventing cellular depolarization and ultimately preserving the electrical driving force for chloride exit from the cell. Therefore, chloride accumulates until apical chloride channels are opened. The bulk of chloride output occurs via the cAMP-dependent CFTR chloride channel [25]. However, there is an additional class of chloride channels, the CaCC, that are expressed in the enterocyte apical membrane [21]. These channels drive chloride secretion in response to agonists of cytosolic calcium [21].

The most common mechanism of bacterial diarrhea is the release of bacterial toxins. Bacterial enterotoxins activate signaling molecules such as cAMP, cGMP, or intracellular Ca2+, which, in turn, opens cellular Cl– channels leading to an increase in Cl– secretion and consequently of water secretion [26]. The intestinal epithelium forms a selective barrier between the lumen (the external environment) and the body. The electrochemical gradients also depend on TJs that

provide a barrier necessary for an efficient transcellular transport [27]. The TJs also support a polarized distribution of membrane proteins on the basal and apical compartments of epithelial cells. The plasma membranes of adjacent intestinal epithelial cells are linked through the TJs, where claudins, zonula occludens 1 (ZO1), occludin, and F-actin interact. E-cadherin, alpha-catenin 1, beta-catenin, catenin delta1, and F-actin interact to form the adherens junction [28]. The loss of barrier function, as a consequence of TJ disruption, impairs the vectorial absorption and secretion by the intestinal epithelium. During an infection, the redistribution of apical and basal proteins provides new attachment sites for bacteria. Several bacterial toxins act on the TJ protein functions inducing an epithelial damage. At least four toxins produced by *Clostridium spp*. and a toxin produced by selected *E. coli* strains have been demonstrated to affect intestinal TJs [29, 30].

In this complex scenario, different bacterial species, each with one or more virulence factors, induce diarrhea in a specific mode. This includes the interaction with a specific receptor, the release of virulence factors such as adhesion molecules or enterotoxins, and a cascade of events occurring within the enterocyte.

Bacterial Diarrhea

Vibrio cholerae

This comma-shaped, gram-negative rod is easily identified in the stool using gram stain and is responsible for cholera, a potentially fatal acute diarrheal disease in humans. Although cholera is now rare in developed countries, it remains a major cause of diarrheal morbidity and mortality in many developing countries [31].

V. cholerae is a diverse species with both pathogenic and non-pathogenic variants. Only cholera toxin-producing strains are associated with the clinical development of cholera. Serogroups *V. cholerae* O1 and O139 have caused widespread epidemics, although only *V. cholerae* O1 remains a current cause of global outbreaks [32]. Other toxin-producing serogroups of *V. cholerae* have been associated with small outbreaks of cholera, and non-toxin-producing strains can cause a cholera-like illness associated with gastroenteritis and sepsis. The infection is transmitted by the fecal–oral route and is spread through feces-contaminated food and water. Virtually, all cases of non-O1 *V. cholerae* infections in the United States are associated with eating raw shellfish. The period of incubation ranges from a few hours to 5 days [33, 34].

V. cholerae possess a single flagellum and is highly motile, which enables it to swim through mucus and arrive at the mucosal surface [35]. During infection, *V. cholerae* secretes several toxins, but the most important of these is cholera toxin (CT), an enterotoxin that causes profuse diarrhea when it colonizes the small intestine. CT consists of a single copy of the A subunit and five copies of the B subunit. The B subunit binds to the plasma membrane, while the A subunit activates adenylate cyclase resulting in elevated cAMP production. The production of cAMP leads to secretion of chloride via the CFTR domain [36, 37]. Na+ absorption is also decreased through the apical sodium transporters, NHE2 and NHE3 [38]. Overall, this leads to an increase in NaCl levels in the intestinal lumen and drives water by osmotic force.

In addition to CT, *V. cholerae* produces several other toxins that contribute to the enterotoxicity of this pathogen by modulating ion secretion and altering barrier function. The toxins that directly affect ion secretion include the accessory CT (ACE), which stimulates Ca2+-dependent Cl− secretion and the non-agglutinable *V. cholerae* heat-stable enterotoxin (NAG-ST), which activates guanylyl cyclase, thus stimulating cGMP production and leading to protein kinase G (PKG)-mediated activation of CFTR. *V. cholerae* cytolysin (VCC) creates anion permeable pores into the cell wall [39], and zonula occludens toxin (Zot) interacts with tight junctions affecting the paracellular pathway [40].

Symptoms range from asymptomatic colonization to severe diarrhea associated with dehydration and shock. Vomiting is frequent, although fever less common. Stools are classically described as “rice water” due to the presence of mucus in clear stools but are frequently without associated tenesmus. Profuse watery diarrhea and vomiting may lead to significant fluid and electrolyte losses that can occur at a rate of 1 L/hour, causing a massive dehydration which can occur within 12 hours of symptom onset. Although mild symptoms may be clinically indistinguishable from other causes of gastroenteritis, the profound loss of fluids and dehydration are unique to severe cholera [41].

As with many other infectious diarrheal diseases, the mainstay of therapy for *V. cholerae* is aggressive rehydration, which can be done orally in the absence of severe volume depletion or shock. Intravenous fluids should be urgently administered in those with severe hypovolemia, preferable with Lactated Ringer’s [42, 43]. In general, there are no long-term complications of cholera when it is appropriately treated. Electrolyte abnormalities, pneumonia potentially from aspiration in the setting of vomiting, and shock have been described and associated with mortality [44].

Antibiotics (e.g., macrolides, tetracyclines, and fluoroquinolones) are an adjunctive therapy for patients with severe volume depletion and may be of particular use in epidemic settings as they decrease the duration of shedding. Antibiotic therapy is recommended for patients with severe dehydration secondary to *V. cholerae* gastroenteritis since it reduces the duration of diarrhea by approximately 50% and bacterial

shedding by about 3 days [45]. Overall, most guidelines updated in the last decade recommend single-dose azithromycin as the preferred first-line therapy for children and doxycycline as first-line therapy for cholera in adults [46]. Ciprofloxacin can be used for susceptible strains. Antibiotic therapy is usually not needed for gastroenteritis caused by non-cholera *Vibrio spp*. Currently, there are two internationally licensed oral cholera vaccines used in areas with endemic cholera and during cholera outbreaks [47].

Salmonella

Salmonellae are motile gram-negative bacilli that cause several clinical infections in humans, including gastroenteritis, enteric fever, bacteremia and endovascular infection, and focal metastatic infections such as osteomyelitis or abscess [48]. Although there are many types of *Salmonella*, they are frequently divided into two main categories: those that produce typhoid and enteric fever and those that induce gastroenteritis.

Salmonella Typhi and *Salmonella* Paratyphi colonize only humans and cause enteric fever or typhoid fever, a systemic illness characterized by high-grade fever, gastrointestinal symptoms, and occasional neurologic manifestations. Infections are acquired through close personal contact or through the ingestion of water or food contaminated with human feces. Typhoid fever continues to represent a global health problem, with more than 11–17 million cases/year [49]. Chills, headache, cough, weakness, and muscle pain are frequent prodromes, and most symptoms resolve within 4 weeks without antimicrobial treatment [50]. Gastrointestinal perforation, due to necrosis of Peyer's patches in the bowel wall, is a known complication seen in week 2 and 3 of the disease but occurs more commonly in adults than children [51].

In contrast, infections with nontyphoidal *Salmonella* are increasing in developed countries and are frequently isolated from the stool of patients with gastroenteritis. In the United States, nontyphoidal salmonellosis is one of the leading causes of foodborne disease, and *Salmonella* Enteritidis and *Salmonella* Typhimurium are among the serotypes most frequently isolated. *Salmonella* Enteritidis is the leading bacterial cause of foodborne diarrheal outbreaks in the United States, with eggs and contaminated raw fruits and vegetables identified as major vehicles [52].

Salmonella gastroenteritis is most commonly associated with ingestion of poultry, eggs, and milk products, as well as contact with pets, including reptiles and live poultry. Symptoms of *Salmonella* gastroenteritis typically occur within 8–72 hours following exposure and are clinically indistinguishable from gastroenteritis caused by many other pathogens. Among children, the diarrhea can progress to grossly bloody stools [53]. Severe extra-intestinal infections can include life-threatening sepsis and focal infections in the meninges, bones, and lungs. Nontyphoidal *Salmonella* gastroenteritis is usually self-limited. Fever generally resolves within 2–3 days, and diarrhea within 4–10 days [54].

Salmonella are pathogenic through their ability to invade, replicate, and survive in human host cells, resulting in an inflammatory ileocolitis. *Salmonella* enter into the submucosal lymphoid system through the ileum and colon by selectively using fimbriae to adhere and attach to specialized epithelial cells overlying Peyer's patches known as M (microfold) cells [55]. Sa*lmonella* pathogenesis includes plasmid-encoded virulence factors that encode proteins vital for bacterial spread and invasion, survival within macrophages after phagocytosis, and signaling to neutrophils, causing cell destruction [56]. Additionally, the *Salmonella* Pathogenicity Islands (SPIs) encode multiple virulence factors, including Type III secretions systems (TTSS) which deliver a variety of effectors into intestinal epithelial cells [56]. Enterotoxins may also play a role in *Salmonella* gastroenteritis as well as the production of signaling molecules which trigger fluid secretion and diarrhea in the host [57]. Overall, microbial invasion of the mucosa results in an acute inflammatory reaction with disruption of the epithelial barrier, resulting in the presence of mucus, red blood cells, and polymorphonuclear leukocytes in the stool. The bacteria can also disseminate from the intestines to cause systemic disease.

Antibiotics should not be used in an otherwise healthy child with *Salmonella* gastroenteritis as they have not demonstrated efficacy and do not prevent complications. A systematic Cochrane Review showed that antibiotic therapy of *Salmonella* gastroenteritis did not significantly affect the duration of fever or diarrhea in otherwise healthy children or adults compared to placebo or no treatment [58]. In addition, adverse treatment events include prolonging fecal excretion of *Salmonella* and antimicrobial resistance [58]. Antimicrobial therapy is indicated in the setting of severe disease and in patients at higher risk for complications or invasive disease, including children younger than 3 months of age or those with chronic gastrointestinal tract disease, malignant neoplasms, hemoglobinopathies, HIV infection, or other immuno-suppressive illnesses or therapies [59] (Table 15.1). Bloody diarrhea does not necessarily indicate the need for antibiotic treatment. Secondary *Salmonella* bacteremia, with potential extra-intestinal focal infections, occurs more often in children with certain underlying conditions, and in neonates or young infants. Antibiotic therapy with azithromycin is suggested for well-appearing patients. Alternatively, ampicillin or trimethoprim–sulfamethoxazole may be considered for susceptible strains, once susceptibilities are available [59]. Fluoroquinolones are an additional option [59, 60].

Table 15.1 Bacterial infections of the gastrointestinal tract

Pathogen	Signs and symptoms	Transmission	Incubation	Antibiotic indications
Vibrio cholerae	Profuse watery diarrhea and vomiting, potentially leading to severe dehydration	Contaminated food or water	Hours–5 days	Severe dehydration
Salmonella	Watery diarrhea, dysentery Extra-intestinal infections include sepsis and focal infections in the meninges, bones, and lungs	1. Contaminated food such as eggs, poultry, milk products 2. Contact with contaminated animals such as reptiles	8–72 hours	High-risk children: infants less than 3 months of age and children with underlying hemoglobin disorders or immune deficiency
Clostridioides difficile	Watery diarrhea, dysentery, fever, and abdominal pain Septicemia, pseudomembranous colitis, and perforation can occur in severe cases	Ingestion of spore in susceptible host	2–3 days	Symptomatic patients (> or equal to 3 unformed stools in 24 hours)
Shigella	Watery diarrhea, dysentery, fever, malaise, anorexia, occasional vomiting, and tenesmus Complications include HUS, seizures, rectal prolapse, intestinal obstruction, and colonic perforation	Contaminated food or water	3 days	1. High-risk children; immunocompromised patients and children with severe toxemia or suspected bacteremia 2. Culture-proven and symptomatic patients in daycare, institutions, or hospitalized children 3. Children with suspected shigellosis during an outbreak setting or with a positive culture in a household or daycare contact
Campylobacter	Watery diarrhea, dysentery, vomiting Complications including Guillain–Barre syndrome and reactive arthritis	1. Contaminated water or food such as unpasteurized milk or poultry 2. Direct contact with animals or animal products	3–6 days	Dysenteric form and to reduce transmission in daycare centers and institutions
Yersinia	Prolonged watery diarrhea, dysentery, fever, vomiting, and abdominal pain Exudative pharyngitis and cervical adenitis may also be present	Contaminated water or food including undercooked pork	4–6 days	Severe dehydration
Escherichia coli[a]				
ETEC	Watery diarrhea, abdominal cramps, and vomiting Occasional fever	Contaminated food or water	10–72 hours	Severe dehydration[a]
EPEC	Watery diarrhea, fever, abdominal cramps, and vomiting Can be severe in infants	Contaminated food or water	9–12 hours	Severe dehydration[a]
EHEC	Crampy abdominal pain, vomiting, and watery diarrhea are the first symptoms; can progress to dysentery Fever absent or low grade Possible severe complications such as HUS	1. Contaminated food or water 2. Direct contact with infected animals	3–4 days	Severe dehydration[a]
DAEC	Watery diarrhea rarely associated with vomiting or abdominal pain	Contaminated food or water	Unknown	Severe dehydration[a]
EAEC	Prolonged watery, mucoid diarrheal illness with low-grade fever, and little or no vomiting	Contaminated food or water	8–48 hours	Severe dehydration[a]
EIEC	Watery diarrhea, dysentery	Contaminated food or water	4–7 days	Severe dehydration[a]

[a]Treatment recommendations for non-STEC-confirmed *E. coli*

Clostridioides (Formerly *Clostridium*) *difficile*

Clostridioides difficile is a gram-positive toxin-producing anaerobe that exists in a highly resistant spore form in the environment. *C. difficile* infection (CDI) is now recognized as the most common cause of antibiotic-associated diarrhea and the leading cause of gastroenteritis-associated death in the United States with approximately 12,800 deaths in 2017, although incidence rates vary dramatically worldwide [61].

Increasing incidence of CDI has been demonstrated in both adults and children. Data from 22 freestanding children's hospitals demonstrated a rise in the incidence of *C. difficile* infection (CDI) from 2.6 to 4 cases per 1000 admissions from 2001 to 2006 [62]. An additional study from a national database of hospitalized children reported a doubling of the incidence rates of CDI from 2003 to 2012 [63]. Increasing incidence is likely multifactorial, including the emergence of virulent strains (NAP1/BI/027), the increased use of antibiotics, and alterations in diagnostic testing methods, such as the transition to highly sensitive nucleic acid amplification-based testing (NAAT).

The pathogenesis of *C. difficile* largely depends on the altered balance of the intestinal microbiota, allowing pathogenic strains of *C. difficile* to infect the intestine [64]. Outside of the colon, *C. difficile* exits in spores which are highly heat, acid, and antibiotic resistant. If ingested and able to colonize the intestine, they convert to a vegetative toxin-producing form. *C. difficile* disease activity is related to the production of one or more toxins: toxin A (TcdA), toxin B (TcdB), and the *C. difficile* transferase toxin (CDT) [65]. Whereas TcdA and TcdB are considered the primary virulence factors, CDT may increase the severity of CDI in certain clinical strains. After undergoing receptor-mediated endocytosis, TcdA and TcdB disrupt the epithelial tight junctions and induce epithelial cell death, causing direct injury to the colonic epithelium. In addition, the toxins stimulate epithelial cells to release proinflammatory cytokines and neutrophil chemoattractants, which lead to the acute inflammatory response which is characteristic of CDI [66]. This disruption of the epithelial barrier and intense inflammatory response with associated tissue damage is thought to contribute to the formation of pseudomembranes, a manifestation of severe CDI. Alternatively, CDT intoxication leads to loss of the actin-based cytoskeleton of the host cell wall, formation of microtubule-based cell protrusions that increase pathogen adherence, and enhanced production of inflammatory cytokines [66].

Antibiotic use continues to be the most widely recognized risk factor for CDI, although additional risk factors have been identified in children including the presence of comorbidities such as malignancy and inflammatory bowel disease and the use of acid suppression [67]. However, CDI can occur in the absence of antibiotic history and in a large case–control study of pediatric patients, >40% had no antibiotic use in the 12 weeks prior to CDI diagnosis [68].

C. difficile can cause a range of disease manifestations, from asymptomatic colonization or mild diarrhea to severe CDI complicated by toxic megacolon, hypotension, shock, and death. Asymptomatic colonization is more common in infants and children <3 years of age, although the mechanisms for this remain unclear. In healthy infants younger than 1 month of age, *C. difficile* has been recovered from an average of 37% of the infant's stools, with a range of 25–80% of infants harboring *C. difficile* as a harmless commensal. This rate continues to decline until age one year when the rate is ~10% in healthy infants [69–71]. Symptomatic disease is less common in infants and young children, although it has been described. Asymptomatic colonization has also been described in children with medical comorbidities. Children with cancer, cystic fibrosis, and inflammatory bowel disease have asymptomatic colonization prevalence of 30%, 50%, and 17%, respectively [72–74]. There are significant difficulties differentiating CDI from *C. difficile* colonization in these patients.

For most patients, symptomatic CDI begins several days or weeks after antibiotic therapy. Acute onset and mild-to-moderate watery diarrhea is the most common clinical feature. Fever and abdominal pain are common, and gross blood is occasionally apparent [75]. Severe and fulminant CDI is less common in children than adults, but recurrent CDI occurs in approximately 12–30% of pediatric patients [76–78]. Recurrent CDI is the return of CDI after initial symptom resolution and generally occurs 1–2 months after the initial infection. Risk factors in children include malignancy, community-acquired CDI, receipt of concomitant antibiotics, and the presence of a tracheostomy tube [76, 77, 79].

The diagnosis of CDI relies on a combination of clinical and laboratory features and can be challenging in the pediatric patient. Current laboratory testing for *C. difficile* detection relies on the detection of *C. difficile* toxin and/or toxigenic *C. difficile* organism and cannot differentiate colonization from CDI. Most commonly, testing is performed by nucleic acid amplification-based testing (NAAT) alone or as part of a multistep algorithm including enzyme immunoassay for glutamate dehydrogenase (GDH) or toxin [80]. Toxigenic culture and cell culture cytotoxicity assays are rarely performed in clinical settings due to slow turnaround times and need for technical expertise. Testing for CDI should be performed on symptomatic children with acute onset diarrhea (≥3 unformed bowel movements per 24 hours) with clinical features suggestive of CDI or known risk factors. Testing should be limited in children <3 years of age unless there is a high suspicion for CDI [81].

Discontinuing the inciting antibiotic, when able, is an important step in CDI management. An initial episode of mild-to-moderate CDI in a pediatric patient can be treated

with either oral metronidazole (30 mg/kg per day orally in four divided doses) or oral vancomycin (40 mg/kg per day in four divided doses) (Table 15.1) [80]. Although randomized controlled trials in adults have found vancomycin to be more efficacious for CDI than metronidazole [82, 83], prospective studies in children are lacking. Oral vancomycin is the preferred agent for children with severe or fulminant infection. In those unable to tolerate oral therapy, rectal vancomycin and IV metronidazole can be considered. Recurrent CDI can be treated with a second course of the same antibiotic in the setting of a first recurrence. The optimal management of subsequent recurrences is not well established but may include the use of oral vancomycin given in a pulsed-tapered fashion or fidaxomicin [80]. Alternative therapies include the use of rifaximin, nitazoxanide, intravenous immunoglobulin, and fecal microbiota transplantation (FMT). In a study of 372 pediatric patients with CDI who underwent FMT, 81% had a successful outcome with no recurrence of CDI at 2 months post-FMT [84]. Additional study in children is warranted.

Shigella

Shigella is a gram-negative, non-lactose-fermenting, nonmotile bacillus that causes 88 million cases of diarrhea and approximately 164 associated deaths worldwide per year [85]. There are four species of *Shigella*: *S. dysenteriae* (serogroup A), *S. flexneri* (serogroup B), *S. boydii* (serogroup C), and *S. sonnei* (serogroup D). *Shigella sonnei* is the main species type in developed countries, and outbreaks occur predominantly in institutions such as daycare centers. In developing countries, *S. flexneri* and *S. dysenteriae* predominate and most cases are transmitted by fecal–oral spread and contamination of common food and water sources [86]. *S. dysenteriae* is the most dangerous *Shigella* species due to its production of Shiga toxin, an enterotoxin that induces intestinal secretion of solutes and water.

Shigella is highly contagious and requires a significantly lower inoculum to causes disease than many other bacterial enteritidis [87]. All four species of *Shigella* are invasive and cause an inflammatory diarrhea. The cellular responses to various steps of the invasion process are the primary cause of the inflammation. *Shigella* strains cross the colonic enterocytes through M-cells (cells that overlie mucosal lymphoid follicles) by using a type III secretion system (T3SS) protein [88]. The T3SS injects bacterial proteins into the host cell that activate host cytoskeletal signaling pathways. *Shigella*-induced macropinocytosis occurs through extensive rearrangements of the host cell cytoskeleton. *Shigella* also has strategies to escape the entry vacuole, move freely in the host cytosol, replicate in the host's intracellular compartment, and spread from cell to cell [89]. The destruction of macrophages after emergence from M-cells causes an initial release of IL-1β, which attracts polymorphonuclear leukocytes (PMNs). PMNs amplify inflammation and can cause many of the symptoms of the disease. *Shigella* also disrupts tight junction proteins including claudin-1, ZO-1, ZO-2, and dephosphorylates occludin [90].

After an incubation period averaging 3 days, *Shigella* gastroenteritis classically begins with fever, malaise, anorexia, and occasional vomiting. Initial watery diarrhea can progress to dysentery (bloody diarrhea) within hours to days. Small-volume mucoid stools with blood are present in approximately 50% of children with Shigellosis [91]. In an immunocompetent host, symptoms are generally self-limited and last no more than 7 days. Rare manifestations may occur, including hemolytic uremic syndrome (HUS) in children, thrombotic thrombocytopenic purpura (TTP) in adults, seizures, reactive arthritis, rectal prolapse, intestinal obstruction, and colonic perforation. Neonates and children with an underlying immunodeficiency are at higher risk of complications [92].

Diagnosis is made via stool culture, although the presence of white blood cells and red blood cells on microscopy is suggestive [93, 94]. Molecular testing platforms using polymerase chain reaction (PCR) are also appropriate, although do not allow for susceptibility testing. In the absence of specific antibiotic treatment, children with *Shigella* gastroenteritis shed the organism for up to 4 weeks; children with immune deficiency shed for much longer, even in the absence of symptoms.

The goals of antibiotic therapy for *Shigella* include cure and hastening eradication of the organism from the feces. Several controlled studies have shown that appropriate antibiotic treatment of *Shigella* gastroenteritis significantly reduces duration of fever, diarrhea, and fecal excretion of the pathogen, and thus infectivity [95–97]. This has a large impact on transmissible populations such as children attending daycare centers and those admitted to hospitals or other institutions. Antibiotic treatment may also reduce the complications including the risk of HUS after *S. dysenteriae* infection [98].

However, antimicrobial therapy is not recommended for most children with mild disease or spontaneous recovery. Empiric antimicrobial therapy for shigellosis in children is recommended in high-risk individuals such as immunocompromised patients and children with severe toxemia or suspected bacteremia (signs of suspected bacteremia include leukocytosis, hypothermia, temperature >39 °C [102.2 °F], and lethargy) after blood and stool cultures have been collected (Table 15.1) [59]. Ill patients in daycare, institutions, or children that are hospitalized with symptomatic culture-proven *Shigella* should also be treated. Antibiotics may also be warranted in children with suspected shigellosis during an outbreak setting, or with a positive culture in a household or daycare contact [99, 100].

Antibiotic susceptibility testing is essential for management of patients with suspected *Shigella* infection [101]. Worldwide, antimicrobial resistance is an increasing problem, and patterns of resistance vary geographically. Oral azithromycin and parenteral ceftriaxone are the suggested first-line treatments of shigellosis in the United States in children <18 years of age if the antibiotic susceptibility of the isolate is unknown [102]. Trimethoprim–sulfamethoxazole or ampicillin should be used only if the isolated strain is known to be susceptible given the high worldwide resistance [103]. Parenteral therapy is indicated for children who cannot tolerate oral medications and have immunodeficiency, or patients with bacteremia. Intravenous ceftriaxone for 5 days is the first-line parenteral therapy. Ciprofloxacin for 5 days is an alternative to ceftriaxone if there is no other safe or effective option. The WHO guidelines recommend ciprofloxacin as first-line treatment and pivmecillinam, azithromycin, or ceftriaxone as second-line therapy [104]. Persistent fever, bloody stools, or stool frequency after 3 days of therapy may be a sign of treatment failure [105].

Campylobacter

Campylobacter are small, spiral-shaped gram-negative bacilli [106]. *Campylobacter* enteritis is typically caused by *Campylobacter jejuni* or *Campylobacter coli* which are common commensals in the intestinal tracts of animals. Approximately, 90% of infections are due to *C. jejuni* in most regions, although the clinical symptoms related to *C. jejuni* or *C. coli* are indistinguishable [107]. *Campylobacter* enteritis is transmitted by the fecal–oral route via direct contact with animals or animal products such as poultry and unpasteurized milk or via contaminated water [108, 109]. Most *Campylobacter* infections are transmitted through the preparation and/or consumption of chicken. Person-to-person transmission is uncommon.

After 3–6 days of incubation, typical gastroenteritis symptoms begin abruptly with vomiting and profuse diarrhea. In most children, diarrhea lasts 4–5 days and is usually mild and self-limited. Bloody stools may be present in more than half of children and mimic intussusception, and severe abdominal pain, when present, may uniquely resemble acute appendicitis [110]. Ultrasound can be helpful in differentiating bacterial ileocecitis from acute appendicitis. Fever can occur but is less common in older children [111]. Acutely, *Campylobacter* enteritis can be associated with cholecystitis, peritonitis, rash, and myocarditis or pericarditis. Late-onset complications include reactive arthritis, similar to what follows other diarrheal infections, and Guillain–Barre syndrome (GBS) [112, 113]. Between 30% and 40% of GBS is attributable to *Campylobacter* infection and neurologic symptoms generally develop 1–2 weeks after infection [114].

Campylobacter's spiral shape and long polar flagella promotes motility and chemotaxis enabling the organism to invade and colonize the intestinal tract [115, 116]. Adhesion and attachment of the organism are multifaceted and fimbriae-like filaments, and adhesion-related molecules aid in this process [117–119]. A high-molecular-weight plasmid, pVir, has been identified in some clinical Campylobacter isolates and has been shown to enhance the invasive capabilities of *C. jejuni* [120, 121]. Pathogenic *C. jejuni* strains also produce cytolethal distending toxin (CDT), a nuclease which may play a role in suppressing innate immunity by inducing death of macrophages and inducing a local inflammatory response [122, 123].

The diagnosis of *Campylobacter* is established by stool culture or culture-independent techniques, such as nucleic acid amplification tests (NAAT) or polymerase chain reaction (PCR). Supportive therapy including hydration and the correction of fluid and electrolyte losses is the mainstay of treatment in children. Antibiotic therapy for *Campylobacter* gastroenteritis is recommended mainly for the dysenteric form (bloody stools, high fever) and to reduce transmission in daycare centers and institutions (Table 15.1) [124]. In most locations, the first-line drug is azithromycin, but the choice should be based on local resistance patterns [59]. A meta-analysis of 11 double-blind, placebo-controlled trials showed that antibiotic treatment of gastroenteritis caused by *Campylobacter* spp. reduces the duration of intestinal symptoms by 1.3 days [125]. The effect was more pronounced if treatment was started within 3 days of illness onset and in children with *Campylobacter*-induced dysentery.

Yersinia

Yersinia species are gram-negative coccobacilli and facultative anaerobes. *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* are two important human enteropathogens that cause yersiniosis and are widely distributed in the environment, with swine as the major reservoir [126]. Infection is transmitted predominantly through the fecal–oral route; yersiniosis is often caused by the consumption of undercooked pork products or contaminated drinking water [127].

Y. enterocolitica uniquely passes through the stomach epithelial cells and localizes in lymphoid tissue and regional mesenteric lymph nodes [128]. This invasion process is due in part to *Yersinia's* elaborate mechanisms to buffer the gastric acidity, such as producing urease that releases ammonia from urea and provides relative acid resistance [129]. The process of adhesion and invasion mainly comprises the proteins encoded by three genes, *yadA*, *invA*, and *ail* [130]. Yersinia also expresses many virulence factors which are temperature dependent and aid in organism survival in different environments [131]. Both chromosomal and plasmid-

derived virulence factors play a role in *Yersinia* pathogenesis. The virulence of *Y. enterocolitica* strains mostly depends on the presence of the plasmid of *Yersinia* virulence (pYV), the most known and important virulence marker of *Y. enterocolitica* [132]. Another important immune evasion mechanism of *Y. enterocolitica* includes the injection of *Yersinia* outer membrane proteins (Yops) into host cells by T3SS [133]. Additionally, enterotoxin Yst is one of the most significant factors leading to diarrhea in yersiniosis [134].

The incubation period is 4–6 days with foodborne transmission. Acute yersiniosis is characterized by fever, vomiting, abdominal pain, and watery diarrhea, which may contain blood [135, 136]. In children, high fever and vomiting are common, with abdominal pain observed less frequently. Accompanying presenting symptoms include exudative pharyngitis and cervical adenitis, which are unique to *Yersinia* and less commonly associated with other bacterial enteritidis. Sore throat was reported by up to 20% of patients in some reports [137, 138].

The onset of symptoms can be more subacute, while the duration of diarrhea can be longer than for other causes of acute bacterial gastroenteritis [139]. Diarrhea typically lasts for 14–22 days, but fecal excretion may persist for 7 weeks or longer. Both abdominal complications and extra-intestinal complications are uncommon. Pseudoappendicitis has been described as acute yersiniosis can present with right lower abdominal pain, fever, and vomiting [140]. Bacteremic spread may rarely result in abscess formation and granulomatous lesions in the liver, spleen, lungs, kidneys, and bone, as well as meningitis and septic arthritis. The most common post-infectious sequelae are erythema nodosum, reactive arthritis, uveitis, and Reiter's syndrome [141]. Stool culture is the preferred test for patients with intestinal symptoms. In the setting of pharyngitis or septicemia, throat and blood cultures may be diagnostic as well. *Yersinia* can also be cultured from surgical specimens such as the appendix or mesenteric lymph nodes [142].

Antibiotic treatment is not warranted in most cases of acute yersiniosis, and limited data are available regarding antibiotic efficacy [143]. Parenteral therapy with third-generation cephalosporins or oral ciprofloxacin or trimethoprim–sulfamethoxazole is recommended in pediatric patients with bacteremia, extra-intestinal infections, or immunocompromised hosts (Table 15.1). Production of beta-lactamases generally makes *Yersinia* resistant to penicillin and cephalosporins [144].

Escherichia coli

E. coli is an abundant facultative anaerobe and normal inhabitant of the human colon and typically colonizes the gastrointestinal tract within hours after birth [145]. It is a gram-negative, lactose-fermenting motile bacillus of the family *Enterobacteriaceae*. Currently, 186 somatic (O) and 53 flagellar (H) antigens are recognized [146]. *E. coli* includes a heterogeneous group of microorganisms capable of exerting various possible interactions with the host, ranging from a normal inhabitant to that of a highly pathogenic organism [147].

Six distinct categories of *E. coli* are currently recognized as diarrhea-associated pathogens: enterotoxigenic *E. coli* (ETEC), enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), diffusely adherent *E. coli* (DAEC), enteroaggregative *E. coli* (EAggEC), and enteroinvasive *E. coli* (EIEC) (Table 15.1). Worldwide, *E. coli* is one of the most frequent causes of bacterial gastroenteritis [148].

Enterotoxigenic *E. coli* (ETEC)

Among the six recognized diarrheagenic strains of *Escherichia coli*, ETEC has been shown to be the most common bacterial enteric pathogen in several developing countries [149]. Transmission of ETEC occurs by ingestion of contaminated food and water, most commonly in resource-limited settings. ETEC is also an important cause of traveler's diarrhea with the incidence of ETEC in travelers from industrialized regions to developing countries estimated to be between 30% and 45% [150]. ETEC requires a relatively high inoculum and has a short incubation period (10–72 hours). The key symptom is watery diarrhea, which may also be accompanied by fever, abdominal cramps, and vomiting. In its most severe form, ETEC can cause cholera-like severe diarrhea and dehydration. The illness is generally self-limited, lasting less than 5 days. It is not uncommon for children in the developing world to experience 7 or more severe episodes of diarrheal illnesses in a year, with several due to ETEC [151]. Thus, ETEC has been associated with short- and long-term nutritional consequences in infants and children.

The pathogenesis of disease due to ETEC consists of ingestion of bacteria, intestinal colonization via expression of fimbriae, and the manifestation of virulence factors. ETEC strains elaborate on two classes of enterotoxins, namely, the heat-labile (LT) and the heat-stable (ST) enterotoxins [152]. LT is similar to cholera toxin (CT) and induces chloride secretion and inhibits sodium absorption by increasing the intracellular cAMP levels. ST is a small peptide that causes an increase of intracellular cGMP to also induce secretion of free water into the intestinal lumen causing secretory diarrhea [153]. The jejunum is a major target of ST-induced anion secretion that is mediated by CFTR. ST binds to its receptor guanylate cyclase C (GCC) on the apical surface of enterocytes, resulting in the generation of cGMP. This in turn activates a cGMP-dependent kinase (cGKII) leading to an

intracellular signaling cascade that ultimately leads to chloride efflux from the CFTR and inhibition of sodium uptake through the apical membrane of jejunal enterocytes [154].

Enteropathogenic *E. coli* (EPEC)

EPEC was the first group of *E. coli* serotype shown to be pathogenic for humans and has been responsible for devastating outbreaks of nosocomial neonatal and infant diarrhea worldwide, occurring most commonly in children less than age 2 [155]. EPEC is a leading cause of persistent diarrhea (lasting 14 or more days) in children in developing countries and may be associated with the development of malnutrition [156]. EPEC has a short incubation period (9–12 hours) before the development of non-bloody watery diarrhea. Additional symptoms may include fever, abdominal cramps, and vomiting.

EPEC strains are defined by the characteristic "attaching and effacing" (A/E) effect they elicit and by their inability to produce Shiga toxin. The ability to produce A/E lesions, which is characterized by microvilli destruction, direct interaction with epithelial cells, and effacement of microvilli, has also been detected in strains of Shiga toxin-producing *E. coli* (enterohemorrhagic *E. coli* [EHEC]) [157, 158]. Two subclasses of EPEC have been distinguished based on the presence of certain virulence factors: typical EPEC (tEPEC) and atypical EPEC (aEPEC). Typical EPEC strains possess a large virulence plasmid called EPEC adherence factor plasmid (pEAF) that encodes bundle-forming pili (BFP), while the atypical EPEC lack the pEAF. The locus of enterocyte effacement (LEE) is a specific chromosomal region containing genes necessary for formation of the A/E lesion as well as the T3SS [159]. The T3SS mediates the translocation of effector proteins from the bacterial cytosol into the infected cells.

A variety of mechanisms contribute to disease establishment and EPEC-mediated diarrhea illness. Microvilli destruction is responsible for the loss of absorptive surface and osmotic diarrhea. Intestinal pathogens can also disrupt the barrier by directly altering the distribution or phosphorylation of TJ proteins [160]. EPEC is also able to directly modulate host cell electrolyte transport and water transport, thereby contributing to the establishment of diarrhea [161]. These observations suggest that EPEC-induced diarrhea is a multifactorial process with alterations of electrolyte, solute, and water transport.

Diagnostic techniques such as single-target, multiplex, and quantitative PCR assays have become more widely available for the identification of EPEC [162]. Typical EPEC can be identified by a molecular detection panel specific for the pEAF. In contrast, tests that target the LEE (via detection of the *eae* gene, which encodes intimin) can identify isolates that lack the pEAF (by definition, aEPEC). Notably, the cause–effect relationship between EPEC detection in the stool and diarrhea is hampered by the high number of healthy carriers [163].

Enterohemorrhagic *E. coli* (EHEC)

EHEC is another major intestinal pathogen that is a subset of Shiga toxin-producing *E. coli* (STEC). *E. coli* O157:H7 is a particularly virulent EHEC serotype, although non-O157 serotypes also account for a large number of infections [164].

EHEC adheres to epithelial cells, expresses a T3SS, and causes "attaching and effacing" lesions much like EPEC. Unlike EPEC, infection with EHEC may cause severe symptoms including bloody diarrhea and life-threatening hemolytic uremic syndrome (HUS). These symptoms are due to the production of Shiga toxin which elicits luminal fluid accumulation in the intestine [165, 166]. The predominant transmission is through the ingestion of contaminated food. Crampy abdominal pain and non-bloody diarrhea are the first symptoms, sometimes associated with vomiting. Diarrhea always becomes bloody and abdominal pain worsens, lasting 1–22 days. Fever is usually absent or low grade [167].

In children, HUS is the most dangerous complication and is related to the circulation of Shiga toxins. Toxin-mediated microangiopathic injury leads to a prothrombotic state in the host and the formation of microthrombi. If extensive, these intravascular microthrombi can cause acute kidney injury [168]. HUS is usually diagnosed between 5 and 12 days after the onset of diarrhea. Risk factors include young age, bloody diarrhea, fever, an elevated leukocyte count, and treatment with antibiotics or antimotility agents [166, 169]. If a child has a recent diarrheal illness and presents with oliguria, paleness, easy bruising, or lethargy, evaluation for HUS is warranted. The classic trial of HUS includes hemolytic anemia, thrombocytopenia, and elevated creatinine [170].

Diagnosis of EHEC is made by stool culture or rapid stool assay for Shiga toxin. Reliable diagnostic testing early in illness is paramount and is associated with attenuated renal injury in *E. coli* O157:H7 infections [171].

Diffusely Adherent *E. coli* (DAEC)

DAEC comprises strains defined by a pattern of expressing Afa/Dr adhesins (Afa/Dr DAEC), in which the bacteria adhere to the epithelial cells in a diffused distribution [172]. Although the implication of DAEC strains in diarrhea remains controversial, multiple studies have confirmed the relationship between Afa/Dr DAEC and

diarrhea in children. In particular, the diarrhea illness susceptibility is age related and has been demonstrated to show an increased incidence in children <1 to 5 years of age [173]. The gastrointestinal symptoms include self-limiting watery diarrhea rarely associated with vomiting or abdominal pain. The diagnosis is mainly based on the DNA probe technique and on the pattern of adherence of the microorganism to HEp-2 cells [174, 175]. Given the technical problems of both assays, their use is limited to epidemiological surveys.

Enteroaggregative *E. coli* (EAEC)

EAEC are diarrheagenic bacteria defined by the characteristic aggregative adherence (AA) pattern on HEp-2 epithelial cells in culture. They have been especially associated with cases of persistent diarrhea in both the developed and developing world [176–178]. EAEC is transmitted by the fecal–oral route by food or contaminated water. Typical clinical features are a watery, mucoid, secretory diarrheal illness with low-grade fever, and little or no vomiting. However, bloody stools have been reported [179].

EAEC is detected by the classic cultured AA pattern in human epithelial cells or on a glass substrate in a distinctive stacked-brick formation. However, this gold standard method is time-consuming and DNA probes or a multiplex PCR is recommended to increase the ability to detect EAEC strains [180].

Enteroinvasive *E. coli* (EIEC)

EIEC strains are genetically, biochemically, and clinically nearly identical to *Shigella* [181]. They also show a similar epidemiological pattern and are endemic in developing countries. The role of EIEC in industrialized countries is limited to rare foodborne outbreaks. EIEC can rarely produce dysentery [182].

Treatment of Diarrheagenic *E. coli*

Generally, antibiotics should not be routinely administered for the treatment of *E. coli*. Although antibiotics may be effective in reducing diarrhea duration, most causes of *E.coli*-associated diarrhea will self-resolve [183]. In addition, antibiotic therapy is associated with antibiotic resistance and other adverse effects. For example, antibiotic therapy for Shiga toxin-producing *E. coli* (EHEC 0157:H7) does not significantly affect the clinical course or duration of fecal excretion of the pathogen and can increase the risk of HUS [184].

Antibiotic therapy is reasonable in patients with non-STEC *E coli*-associated diarrhea if symptoms are severe (i.e., associated with fever, requiring hospitalization) or diarrhea is bloody [59]. A lower antibiotic threshold is reasonable in immunocompromised patients [185]. Azithromycin is the treatment of choice for children. Fluoroquinolones had long been the first choice for treatment of travelers' diarrhea, but there has been emergence of resistance to this antibiotic class. TMP-SMX and ampicillin have also developed resistance worldwide, especially in children [186, 187].

Acknowledgments The authors wish to express their appreciation to Drs. Vittoria Buccigrossi and Maria Immacolata Spagnuolo, authors of this chapter for the first edition, on whose work they relied to build this updated chapter.

Intestinal Parasites

16

Phoebe Hodges and Paul Kelly

Introduction

Diarrhoeal diseases are the second leading cause of mortality in children under 5 years globally and kill approximately 525,000 children under the age of 5 annually [1]. A significant proportion of diarrhoeal disease in children is caused by parasitic infections, principally amoebae, flagellates and coccidia. Helminth infections, when heavy, can cause specific clinical syndromes. Parasitic infections can contribute to impaired growth and development in children which in turn has implications for cognitive function, education and economic productivity in later life [2].

Protozoa

Amoebae

Several species of *Entamoeba* are known to infect humans (see Table 16.1) although some of these species are likely to be non-pathogenic. It was previously thought that only a small proportion of those infected with *Entamoeba histolytica* showed symptoms, however, it later became apparent that many asymptomatic individuals were in fact colonised by a noninvasive parasite *E. dispar*, the cysts of which are morphologically indistinguishable from those of *E. histolytica* [3]. These cysts are typically between 10 and 15 μm in size and contain up to four 'ring and dot' nuclei. Other species with morphologically identical cysts were later described (*E. moshkovskii* and *E. bangladeshi*), and this has led to a change in the nomenclature when reporting this finding on stool microscopy to *E. histolytica/E. dispar/E. moshkovskii/E. bangladeshi* or E. complex [4]. These other species are considered non-pathogenic or less pathogenic; however, more

Table 16.1 Entamoeba and its characteristic

Entamoeba species	Characteristics and disease
E. histolytica	Causes invasive amoebiasis (haemorrhagic colitis or hepatic amoebiasis) in about 10% of carriers, many of whom have mild symptoms or are asymptomatic
E. dispar	Confirmed to be a separate entity from *E. histolytica* in 1993 [3], appears to be non-pathogenic, may be as many as 450 million new infections each year
E. moshkovskii	Reported to be present in 21% of stool samples from pre-school age children in Bangladesh [7] and in 15.9% of stool samples from patients attending rural clinics in northern South Africa [8] but was not significantly associated with diarrhoea, although in other studies an association with diarrhoea has been found [9, 10]
E. Bangladeshi	Initially identified in 2012 in stool samples from children living in Mirpur, Bangladesh [11], this species has been isolated from stools of not only asymptomatic children but also from those with diarrhoea
E. coli	Cysts are 15–30 μm in diameter with up to eight ring and dot nuclei
E. hartmanni	Smaller cysts (<10 μm) with up to four ring and dot nuclei. Generally considered to be non-pathogenic although a correlation was found between diarrhoea and *E. hartmanni* colonisation in school children in Indonesia [12]
E. gingivalis	Identified in periodontal pockets in patients with periodontitis [13]
E. polecki (subtypes 1–4)	Non-pathogenic species producing uninucleate cysts. Four subtypes have been described, of which subtype 4 appears to be the commonest in humans [14]
E. chattoni	Now referred to as *E. polecki* subtype 2
E. Struthialis	Now referred to as *E. polecki* subtype 3

evidence on this subject is required. Of those colonised with *E. histolytica,* many will not experience symptoms and only about 10% will develop invasive amoebiasis (haemorrhagic colitis or hepatic amoebiasis). This is partly dependent on individual host factors and immune responses, for example, invasive amoebiasis occurs more frequently in men for reasons that are not yet understood. People who develop amoebic liver abscess have been found to have significantly higher titres of IgG1, IgG2 and IgG3 than individuals who are asymptomatic carriers of *E. histolytica* and interleukin (IL-4) levels are higher in patients with invasive amoebiasis [5]. Higher levels of interferon-gamma production, which are associated with nutritional status, have also been associated with reduced susceptibility to amoebic dysentery [6].

In some settings, *Entamoeba histolytica* is one of the commonest pathogens isolated in children presenting with diarrhoea. A study of aetiology of diarrhoea in Bangladeshi infants identified *E. histolytica* as the second most common pathogen after rotavirus in moderate-to-severe episodes of diarrhoea [15]. In primary school children in South West Ethiopia, it was found to be the commonest intestinal parasitic infection excluding helminthic infections [16]. It is recognised that malnourished children are particularly susceptible to amoebiasis and this may be due to heterogeneity in signalling pathways associated with leptin, a nutritional hormone which is suppressed in malnutrition. It was demonstrated in a cohort of Bangladeshi children that a polymorphism in the leptin receptor was associated with increased susceptibility to amoebiasis [17].

Amoebiasis is transmitted by ingestion of cysts in food or water contaminated with human faeces hence although its distribution is worldwide, it is more commonly seen in geographical areas where sanitation is poor. In travellers returning from low-income countries to high-income countries who present with gastrointestinal symptoms as a result of infection, *E. histolytica* has been found to be the third most commonly isolated pathogen [18]. Amoebiasis affects as many as 50 million people globally each year and has been estimated to cause 55,000 deaths annually [19, 20].

Following ingestions of cysts, excystation occurs in the terminal ileum or colon to give rise to the motile trophozoite stage which adhere to colonic epithelial cells through interaction of the galactose and *N*-acetyl-D-galactosamine-specific lectin (Gal/GalNAC lectin) and lipopeptidophosphoglycan on the surface of the trophozoite and toll-like receptor (TLR) 2 on intestinal epithelial cells [21]. KERP1 is another protein of the trophozoite membrane which binds to the brush border, and has been identified as a potential virulence factor in *E. histolytica* as expression of the gene *kerp1* has been linked to amoebic liver abscess in an animal model [22]. Cysteine proteases and in particular CP-A5 have also been identified as important virulence factors of *E. histolytica* involved in destruction of the extracellular membrane and tissue invasion through proteolytic activity. Located at the amoebic surface, CP-A5 binds to enterocytes triggering a pro-inflammatory response via phosphatidylinositol 3-kinases (PI3) kinase/AKT signalling [23].

Invasion of trophozoites through the mucosa and into the submucosal tissues gives rise to the pathognomonic flask-shaped ulcers. Presenting symptoms are classically bloody diarrhoea, abdominal pain and weight loss. A small percentage may develop complications such as fulminant amoebic colitis, toxic megacolon or amoebomas (granulation tissue within the wall of the colon which can lead to obstruction). Trophozoites penetrating into the portal system and thereby into the liver cause hepatocyte necrosis and abscess formation, which is uncommon in children and more frequently seen in adult males. Patients who develop amoebic liver abscess may do so many years after living in or travelling to endemic areas, and at this stage, stool microscopy is likely to be negative for cysts or trophozoites (Fig. 16.1).

Diagnosis of *E. histolytica* infection using stool microscopy alone is problematic for the reasons outlined above, namely, that cysts of *E. histolytica* are morphologically indistinguishable from cysts of at least three other species. Identification of trophozoites is diagnostic, however, these are usually only seen in stool samples examined within 30 minutes. Antigen detection enzyme-linked immunosorbent assay (ELISA) tests can be used; however, these are less sensitive than real time polymerase chain reaction (PCR) which can distinguish between *Entamboeba* species and is the gold standard for diagnosis. Serology should be carried out in patients with suspected amoebic liver abscess as it is almost always positive in these cases. In patients with acute colitis, flexible sigmoidoscopy and biopsy may be indicated to distinguish, for example, between other conditions such as inflammatory bowel disease [24].

Fig. 16.1 Aspirate from an amoebic liver abscess, often described as resembling 'anchovy sauce'

Treatment is with metronidazole or tinidazole followed by a luminal amoebicide such as diloxanide, iodoquinol or paromomycin. Asymptomatic carriers of *E. histolytica* should be treated with a luminal amoebicide alone to prevent onward transmission.

Endolimax nana

Endolimax nana is an intestinal protozoon, the cysts of which are distinct as they are smaller than those of other intestinal amoebae (7–10 micrometres) and contain four nuclei. As with *Entamoeba*, it is spread via the faecal-oral route through ingestion of contaminated food or water. Studies of school-aged children in Côte d'Ivoire have found the prevalence of this intestinal parasite to be greater than 80% [25, 26]. Global prevalence has been estimated to be around 3.4% [27]. *Endolimax nana* is generally considered to be a non-pathogenic parasite although there are case reports and series linking co-infection with *Endolimax nana* and *Blastocystis* with diarrhoeal symptoms [28, 29].

Iodamoeba bütschlii

Iodamoeba bütschlii, another non-pathogenic intestinal amoeba, can be identified by its oval cysts 9–12 micrometres in size containing a glycogen mass, often referred to as a vacuole, which stains brown with iodine. The trophozoite stage is found in the colon while the cyst stage is responsible for transmission [30]. *Iodamoeba bütschlii* was identified in stool samples of 11.9% of school-aged children in a study of intestinal parasite infections in a highland district of Peru, however, prevalence of diarrhoeal symptoms was not reported in this study [31].

Giardiasis

Giardia intestinalis (Fig. 16.2) (also known as *G. lamblia* or *G. duodenalis*) is a flagellate protozoon which is transmitted by ingestion of infective cysts in contaminated food or water or from hands or fomites. Ingestion of as few as ten cysts constitutes an infective dose. Cysts are oval and measure between 8 and 12 μm with immature cysts containing two nuclei and mature cysts containing four 'ring and dot' nuclei. Excystation occurs in the small intestine, releasing motile trophozoites which are pear-shaped, measure 12–15 μm in size with eight flagella and contain two nuclei. These divide by longitudinal binary fission and can attach to the mucosa of the proximal small bowel via a ventral adhesive disk. Colonisation of the small bowel by this organism results in malabsorption and some of the symptoms of giardiasis include diarrhoea, foul-smelling stools, abdominal bloating and cramping, flatulence, malaise and weight loss.

Given that giardiasis is spread by the faecal-oral route, as with amoebiasis, prevalence would be expected to be highest in countries with poorer sanitation and hygiene standards. A review of outbreaks of water-borne parasitic infections between 2004 and 2010 found that the majority of reported outbreaks in fact occurred in high-income nations. Of the 22 reported outbreaks of giardiasis, only two were from outside the US, Europe or Australasia, however, this is extremely likely to be due to greater access to facilities for detection, surveillance and reporting in these settings [32]. The majority of these outbreaks were due to contaminated or inadequately treated drinking water sources; however, one outbreak in Trondheim, Norway originated from a child day care centre. Prevalence of giardiasis among children in limited-resource settings is likely to be extremely high, at least when measured by molecular diagnostics. The Etiology, Risk Factors and Interactions of Enteric Infections and Malnutrition and the Consequences for Child Health and Development (MAL-ED) projects, which were conducted at various sites in India, Bangladesh, Brazil, Nepal, Tanzania, South Africa, Pakistan and Peru, found that giardia was detected at some stage in the stool samples of two-thirds of the 1741 children who were followed up to 2 years of age [33] (Fig. 16.2).

Diagnosis is by identification of cysts on wet preparation microscopy, although sensitivity may be hindered by the intermittent nature of cyst shedding from the gut, and at least three stool samples taken on separate days should be examined (as for optimum diagnosis of most parasites). The sensitivity of microscopy in the MAL-ED study was found to be 46% when compared to enzyme immunoassay. Other more costly methods of diagnosis with higher sensitivity include direct fluorescence antibody staining of cysts, antigen detection by enzyme-linked immunosorbent assay (ELISA), small bowel biopsy or PCR.

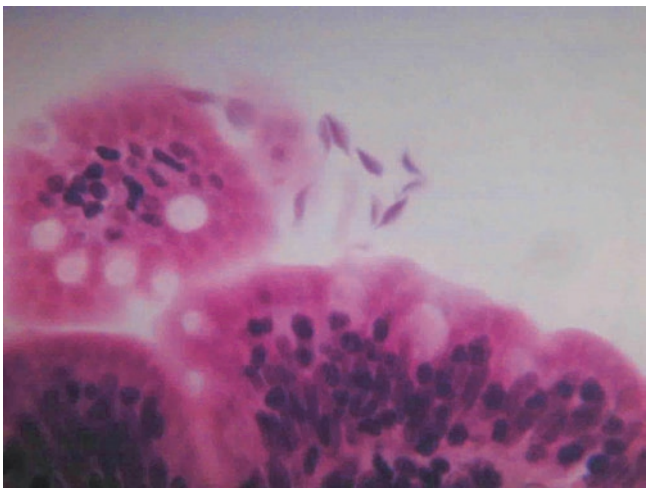

Fig. 16.2 Small bowel biopsy with trophozoites of *Giardia intestinalis* seen in cross section

As with *Entamoeba histolytica*, the clinical course and symptomatology in those colonised with *G. intestinalis* differs from individual to individual. Studies of localised outbreaks show that some individuals develop an acute self-limiting diarrhoeal illness, some develop persistent diarrhoea with malabsorption and others are asymptomatic [34, 35]. Whilst giardiasis is certainly a well-recognised cause of diarrhoea in travellers returning from endemic areas [36], there is much debate about whether paediatric giardiasis in high-prevalence areas is associated with acute diarrhoeal illness. In MAL-ED, detection of *G. intestinalis* in surveillance stool samples was not found to be associated with an increased risk of acute diarrhoeal illness. It was, however, found to be associated with poorer growth outcomes (weight and length attainment) at 2 years of age. Detection of *G. intestinalis* was also found to be associated with an increase in intestinal permeability as measured by the lactulose mannitol recovery ratio, a marker which is often used as a surrogate measure of environmental enteric dysfunction. This may partly account for the poorer growth outcomes in these children [33].

Cyst shedding in adults who are infected with *G. intestinalis* is at lower levels than in children, suggesting that some degree of immunity is acquired over time in those who are continually exposed to this pathogen. Individuals who are immunocompromised are more likely to suffer from severe or prolonged giardiasis due to reduced production of anti-*Giardia* antibodies [37]. In addition to antibody production, a role has been identified for mast cell production of IL-6 in the immune response to *Giardia* [38].

Treatment of giardiasis is with metronidazole or tinidazole, or single dose albendazole for a duration of 5–10 days which has similar efficacy. Increasing numbers of treatment-refractory cases of giardiasis are, however, being noted, with rates of cases refractory to treatment with nitroimidazoles registered at the Hospital for Tropical Diseases in London rising from 15% in 2008 to 45% in 2013 and the majority of these cases originating from Asia [39]. Following a waterborne outbreak of giardiasis in Bergen, Norway, a cohort of patients experiencing persistent gastrointestinal symptoms despite metronidazole were investigated and ongoing infection with *G. intestinalis* was found in 32.3% of patients [35]. However, there are also high rates of functional gastrointestinal disease (FGID) and post-infectious chronic fatigue syndrome in people who have previously been infected but have cleared the infection. In people who had laboratory-confirmed giardiasis during the 2007 outbreak in Bergen, immunological differences were found between those who went on to develop FGID symptoms and those who did not, with significantly increased levels of CD8 T cells found in those with FGID, 5 years after the outbreak [40].

Dientamoeba fragilis

This is a flagellate protozoon related to trichomonads, which takes its name from its rapid degeneration or 'fragility' when outside the human body. It has only recently become recognised as a probable pathogen as opposed to a commensal of the human gastrointestinal tract, with correlations made between *D. fragilis* carriage and symptoms of abdominal pain and diarrhoea and resolution of symptoms coinciding with *D. fragilis* clearance following antibiotic treatment. Trophozoites are binucleate measuring 9–12 μm and can be identified by light microscopy after fixation and staining, however, *D. fragilis* can also be detected using PCR techniques. The mechanism of transmission of *D. fragilis* in humans is incompletely understood. Although a cyst stage has been described in stool samples from patients known to be infected, this was at a prevalence of only 0.01%, making the role of the cyst stage in transmission uncertain. The prevalence of pseudocysts or precysts was much higher at 32.6% [41]. One theory relating to the transmission of *D. fragilis* is that the organism may be transmitted via a vector, with *Enterobius vermicularis* eggs having been proposed for this role and the detection of *D. fragilis* DNA in *Enterobius* eggs supporting this hypothesis [42].

There is a growing body of evidence for the pathogenicity of *D. fragilis*. A study of 695 children in California conducted from 1976 to 1978 found *D. fragilis* in 9.4% based on examination of stool samples, and 91% of these children were found to be suffering from gastrointestinal symptoms including abdominal pain, diarrhoea and anorexia. Half of these children were also noted to have a peripheral eosinophilia. Symptoms were found to be lessened or resolved following treatment with metronidazole or diiodohydroxyquin [43]. In a more recent study of school children in Sweden, prevalence of *D. fragilis* among children in two schools was found to be 60%, significantly higher than the 15% prevalence found in clinical samples submitted to the regional laboratory for parasitological examination. Prevalence was higher (95%) amongst children who were found to have *Enterobius vermicularis*, supporting the hypothesised role for this helminth in transmission of *D. fragilis*, and also in children who complained of gastrointestinal symptoms, supporting the pathogenicity of this organism [44].

It seems reasonable that in patients with gastrointestinal symptoms in whom all other causes have been ruled out, treatment of dientamoebiasis should be prescribed. Various antimicrobial agents have been reported as successfully leading to elimination of *Dientamoeba* infection, including clioquinol, iodoquinol, metronidazole, paromomycin, secnidazole and ornidazole, however, there is little evidence as regards the relative efficacy of these treatments [45].

Balantidium coli

This is the only ciliate known to infect humans and is the largest of the gastrointestinal protozoa, with the ciliated motile trophozoite measuring 60–70 μm and the cyst measuring 50–60 μm in diameter. Both cysts and trophozoites are readily recognisable by wet preparation microscopy.

The reservoir host of this organism is the pig and infections are commoner in individuals who have contact with these animals, although human-to-human transmission can occur. Distribution of *B. coli* is worldwide and prevalence has been estimated at between 0.02% and 0.1%. *B. coli* seems to have a low level of virulence, and infection in humans may be subclinical although dysentery and death can occur, with mortality resulting from haemorrhagic dysentery and shock or colonic perforation. Treatment with metronidazole is effective [46].

As with other gastrointestinal protozoan infections, outbreaks are more frequent in developing countries where people are more likely to live in close proximity with their livestock and the water supply may be contaminated with human or porcine faecal matter. A large outbreak of balantidiasis involving 110 people on the island of Truk in the Western Pacific, where many residents kept pigs, occurred after a typhoon hit the island resulting in the destruction of usual water collection systems so that residents were forced to use contaminated water from streams and wells [47]. However, *B. coli* has also been described as a commensal in such populations. A study of 2124 apparently healthy children from rural Aymara Indian communities in Bolivia where the main economic activities are livestock breeding and agriculture revealed an overall prevalence of *B. coli* of 1.2% with more than half of the pigs in these communities being found to be infected. The authors concluded that *B. coli* should be considered an endemic anthropozoonosis in this region, and it is likely to have similar endemicity in other regions where the environment is highly contaminated with faecal material. However, it should be noted that 30% of the children in this study had malnutrition and were heavily parasitised with protozoan and helminth species, shedding doubt on the apparent commensalism of this organism [48].

Blastocystis

Previously known as *Blastocystis hominis*, but now undergoing taxonomic revision through molecular analysis, this is a genetically diverse stramenopile with at least 17 different subtypes which are microscopically indistinguishable. The pathogenicity of this organism remains unclear but it is very prevalent amongst humans, with one study reporting universal prevalence in children living in the Senegal River Basin [49]. As with other intestinal parasites, prevalence in developed countries has been shown to be significantly lower, with prevalence in Europe, for example, being estimated at 30% [50]. Diagnosis is by microscopy of wet-film preparations or fixed and stained preparations, however, this method has been found to have a sensitivity of only 48% as opposed to 98% diagnostic sensitivity with PCR [51]. *Blastocystis* has been implicated in gastrointestinal disease, including irritable bowel syndrome (IBS) and a putative condition which has been termed 'blastocystosis', symptoms of which have been described to include abdominal pain, bloating, diarrhoea and flatulence [52], however, there is no definitive evidence for its role as a pathogenic agent.

First-line treatment is with metronidazole but the efficacy of this is variable and persistence of symptoms following treatment has been reported suggesting resistance or incomplete clearance of the organism, with one study even demonstrating increased rates of growth of *Blastocystis* following treatment with low concentration metronidazole [53]. Trimethoprim–sulfamethoxazole and paromomycin have also been used to some effect [54]. Antimicrobial treatment should only be prescribed in symptomatic individuals in whom no other potential causative organisms have been identified.

Coccidia

These are intracellular parasites which can infect immunocompetent individuals but are of greater clinical concern in the immunocompromised, in whom they can cause severe and prolonged infections. Transmission is by the faecal oral route with sporozoite-containing, resistant oocysts being shed in the faeces and ingested in faecally contaminated water or food. Following ingestion, excystation occurs and sporozoites are released which then adhere to enterocytes and follow either a perpetuating asexual reproductive cycle or a sexual reproductive cycle giving rise to the formation of sporozoite-containing oocysts.

Cryptosporidium (Fig. 16.3)

Cryptosporidium parvum and *C. hominis* are responsible for the majority of cases of cryptosporidiosis in humans, however, there are a number of other species which can also infect humans. The Global Enteric Multicenter Study (GEMS) which investigated the aetiology of diarrhoeal disease in children in sub-Saharan Africa and South Asia found that *Cryptosporidium* was the second most common causative organism in infants of 0–11 months [55]. In developed countries where cryptosporidi-

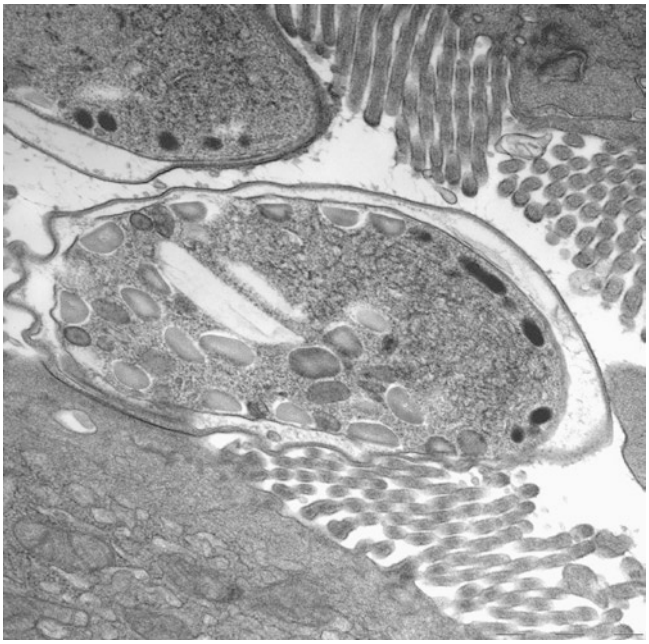

Fig. 16.3 Transmission electron micrograph showing cryptosporidium on intestinal epithelial cell

osis is not endemic, localised outbreaks may occur centred around childcare settings or swimming pools, while larger water-borne outbreaks related to contamination of public water supplies have been reported in the US and Europe [56, 57]. Cryptosporidiosis causes watery diarrhoea and is self-limiting in immunocompetent individuals with symptoms lasting up to 2 weeks, but can have a more severe course in those who are immunocompromised, spreading to extraintestinal sites including the biliary tract and rarely the lungs [58].

Diagnosis can be made by microscopic identification of oocysts 5–6 ⌠m in diameter in the stool after modified Ziehl-Neelsen or auramine staining. Direct fluorescence antibody tests for faecal antigens are also available, and PCR is widely used for diagnosis as well as genotyping.

Nitazoxanide can reduce the duration of symptoms and infectious period for immunocompetent individuals, however, it has not been found to have any benefit in children who are human immunodeficiency virus (HIV) seropositive even at high doses with prolonged treatment of up to 28 days [59, 60]. In this setting, the mainstay of treatment would be initiation of antiretroviral therapy. Immune reconstitution to a CD4 count of >100 cells/mm^3 usually results in resolution of symptoms.

Cyclospora cayetanensis

This is a small bowel parasite, the oocysts of which are distinguishable from those of cryptosporidium by their slightly larger size (8–10⌠ m). Oocysts of *Cyclospora* stain variably with modified Ziehl-Neelsen and safranin reportedly produces a more consistent stain [61]. Cyclosporiasis presents with symptoms of abdominal cramps, anorexia, nausea, weight loss and prolonged diarrhoea, which can last for up to 6 weeks although duration of symptoms is reportedly longer in those who are immunosuppressed [62]. In areas of endemicity, children younger than 5 years seem to be at higher risk of experiencing symptoms of diarrhoea in relation to *Cyclospora* infection, and it may be the case that recurrent exposure to this pathogen at an early age results in a degree of immunity and asymptomatic infection in later life [63]. In non-endemic areas, *Cyclospora* has been identified as a cause of diarrhoea in travellers returning from endemic area, with seasonal outbreaks reported consistently in recent years in travellers returning from certain areas of Mexico suggesting that these outbreaks may be related to a contaminated food or drink item being supplied to hotels in these regions [64]. Outbreaks have also been reported as a result of the importation of salad and soft fruit from endemic regions [65]. Treatment is with trimethoprim–sulfamethoxazole which should be continued as secondary prevention in immunosuppressed individuals.

Cystoisospora belli

Oval oocysts measuring 25–30⌠m can be detected in the faeces by microscopy following staining with iodine or Ziehl-Neelsen staining. Sporozoite-containing sporocysts may be visible within these oocysts. Commercial PCR assays are also available. As with *Cryptosporidium*, this parasite is endemic to tropical and subtropical areas and causes self-limiting watery diarrhoea in immunocompetent individuals with symptoms lasting for up to 10 days. It is an uncommon cause of diarrhoea in immunocompetent children even in endemic regions (isolated in 2% of stool samples of children presenting with diarrhoea to a hospital in New Delhi, India [66] and is of greater clinical significance in HIV-positive adults in low-income settings [67]. Treatment is with trimethoprim–sulfamethoxazole which can be continued as secondary prevention in patients who are immunocompromised.

Helminths

Nematodes (Roundworms)

Enterobius vermicularis (Pinworm) (Fig. 16.4)

Of all the helminths, this is the most widely distributed worldwide with around 300 million cases annually and is common in temperate as well as tropical regions. This parasite is particularly prevalent in children and occurs in outbreaks centred around group settings such as day care centres or playgroups. European frequency analyses place the prevalence of this parasite in school-age children somewhere between 12.7% and 28.5% [68, 69]. When eggs are ingested, they hatch in the small bowel and travel to the colon where

Fig. 16.4 Endoscopic image showing *Enterobius vermicularis* in the colon

adult worms live in the caecum and appendix. Gravid female worms migrate to the anal canal and lay their eggs in the perianal area. These eggs adhere to the skin by a glue-like matrix which promotes itching of the perianal area and transmission is often via contaminated hands. The most frequently reported symptom is pruritus ani which often leads to disturbed sleep as female worms predominantly lay their eggs at night. Extraintestinal manifestations are rare but reported, including vulvovaginitis and urinary tract infections from migration of worms with or without adherent bacteria into the vagina. Diagnosis is via identification of the eggs under a microscope. These can be collected by applying adhesive tape to the perianal region (Sellotape method) and then transferring onto a slide. Treatment is with a single dose of albendazole or mebendazole and good attention to hygiene including frequent washing of clothes and bed linen. The entire household should receive treatment and this should be repeated after 2 weeks due to the high rate of reinfection from residual eggs on fomites.

Ascaris lumbricoides

This is a soil-transmitted helminth, the eggs of which need contact with the soil in the optimal conditions of warm temperatures and moisture in order to mature and become infective. The soil-transmitted helminths largely affect populations of developing countries with tropical or subtropical climates, particularly the rural poor. The WHO estimates that 24% of the world's population are infected with soil-transmitted helminths, with *Ascaris* being the most prevalent of these. In regions where prevalence of any soil-transmitted helminth exceeds 20%, WHO recommends preventive chemotherapy for all preschool- and school-aged children with single dose albendazole or mebendazole on an annual basis or a biannual basis where prevalence exceeds 50% [70]. The evidence for benefit of mass drug administration for helminthic infections is mixed, with the DEVTA trial undertaken in north India being the largest trial to date to examine the effects of deworming on mortality in children. This cluster-randomised trial included one million children aged 1–6 years and found that 6 monthly treatment with albendazole reduced prevalence of worm infection by half but was not associated with any significant survival or growth benefit, although the authors noted that this was a lightly infected population [71].

Ascaris is transmitted via the faecal oral route when eggs are ingested. They hatch in the duodenum and larvae subsequently migrate through the gut mucosa into the portal circulation and then via the systemic circulation to the lungs, where they penetrate the alveoli, ascend the trachea and are swallowed. Migration of the larvae through the lung can result in pulmonary eosinophilia (Loeffler's syndrome) and symptoms of dry cough, shortness of breath and fever, however, the vast majority of infections are asymptomatic. Malabsorption in individuals with very heavy intestinal infection can contribute to malnutrition. Female worms can grow up to 40 cm in length and lay up to 200,000 eggs per day and if the worm burden is large, they can rarely cause obstruction of the small intestine leading to perforation. Other less common presentations resulting from migration of worms to extraintestinal sites include pancreatitis and biliary obstruction. Diagnosis is by identification of the characteristic ova in stool samples either by direct smear, Kato-Katz preparation or formol ether concentration. Treatment is with benzimidazole antihelminthic drugs; either a single dose of albendazole or mebendazole twice daily for 3 days.

Trichuris trichiura (Whipworm)

Also a soil-transmitted helminth, as with *Ascaris*, eggs of *Trichuris* become infective after contact with soil and when ingested, hatch in the small intestine. Adult worms are 3–5 cm long and burrow into the epithelium of the caecum and colon with the posterior end of the worm in the lumen, causing *Trichuris* colitis which may result in diarrhoea or dysentery, abdominal pain, anaemia, and in severe cases, rectal prolapse caused by oedema. Female worms produce 3000–5000 eggs per day and diagnosis is made by identification of these characteristic ova in stool specimens using the same techniques as described above for *Ascaris*. Benzimidazole treatment is commonly used but should be for 3 days as single dose treatment is much less effective at achieving parasite clearance than in ascariasis [72].

Hookworm

Necator americanus and *Ancylostoma duodenale* both fall into this category, with *Necator* being the more common of the two. As with the other soil-transmitted helminths, both are widespread throughout the tropics. Transmission commonly

occurs when infective larvae in the soil penetrate the skin, usually the soles of the feet, although ingestion of the larvae of *A. duodenale* also leads to infection. Larvae in the skin penetrate the blood vessels and migrate through the lung, ascend the trachea and are swallowed. In the small intestine, the larvae mature into adult worms which attach to the mucosa causing iron-deficiency anaemia. *A. duodenale* tends to cause more blood loss than *N. americanus* and the degree of anaemia is proportional to worm burden. Some groups are particularly susceptible to anaemia including children who are co-infected with other parasites such as malaria and *Schistosoma.* These worms can live for up to 10 years in the intestinal tract, causing chronic anaemia which can lead to heart failure and stunting in children. Other presenting symptoms include epigastric pain, dry cough caused by migration of the larvae through the lungs and itching at the site of larval penetration of the skin. In the case of dog or cat hookworms (*Anycylostoma braziliense* and *Ancylostoma caninum*), a migrating rash known as cutaneous larva migrans can occur. This is caused by movement of the larvae through the superficial layers of the skin. Albendazole is more effective for treatment of hookworm than mebendazole and combination therapies with pyrantel pamoate, oxantel pamoate and levamisole achieve an even higher cure rate and may help to reduce the risk of developing resistance to benzimidazoles [73]. Campaigns for increased use of footwear in at-risk populations are an important part of public health measures to control this disease.

Strongyloides stercoralis (Fig. 16.5)

Strongyloidiasis occurs generally in tropical or subtropical regions but has been described in more temperate climates including North America and Europe. *Strongyloides stercoralis* is a soil-transmitted helminth which infects humans when free-living larvae in the soil penetrate the skin. These larvae then migrate via the heart to the lungs, ascend the trachea and are swallowed. In the small intestine, adult female worms 2 mm in length invade the mucosa and can reproduce asexually, producing first stage larvae which are either passed in the stool to continue the external life cycle or mature into infective larvae within the host, penetrating the gut mucosa and thereby continuing a cycle of autoinfection which can lead to chronic infection of the host without re-exposure. These persistent infections have been observed to last for more than 50 years in some cases, for example, ex-prisoners of war on the Thai-Burma railway [74]. Although prevalence of strongyloidiasis seems to increase with age, high rates of infection of children in at-risk populations have been reported, for example, 10% prevalence was found in children aged 2–12 years in a rural Amazonian community in Peru [75] and 21% prevalence was reported in school children in Western Angola [76]. Although many acute infections are asymptomatic, some will experience diarrhoea and abdominal pain or rarely cough or wheeze due to migration of larvae through the lungs. Symptoms of chronic infections include larva currens (the pruritic rash caused by migration of larvae through the skin during autoinfection) and non-specific gastrointestinal symptoms including intermittent diarrhoea and malabsorption. A rare but sometimes fatal complication of strongyloidiasis is hyperinfection or disseminated strongyloidiasis which can occur in the immunosuppressed, particularly those with HTLV-1 co-infection or taking systemic steroid treatment. Hyperinfection occurs when massive larval migration takes place from the gastrointestinal tract to the peritoneum and other extraintestinal sites, resulting in peritonitis and Gram-negative septicaemia [77].

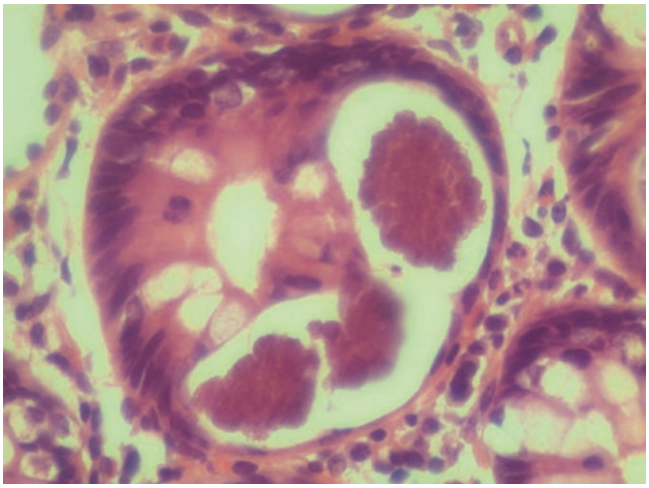

Fig. 16.5 Haematoxylin- and eosin-stained duodenal biopsy showing *Strongyloides stercoralis* adult worms

Diagnosis by stool microscopy is unreliable as larval shedding in the stool is intermittent, and other methods such as charcoal or agar plate culture, serological testing, or duodenal biopsy should be employed where available as adjuncts to direct stool microscopy. Ivermectin is the drug of choice for treatment of strongyloidiasis although thiabendazole appears to be equally effective in terms of cure rate but is associated with a higher rate of adverse events [78].

Cestodes (Tapeworms)

Taenia solium (pork tapeworm) and *Taenia saginata* (beef tapeworm) are transmitted to humans by ingestion of undercooked meat which contains cysticerci (larval stages) of the parasite. In the small intestine, the cysticercus develops into a tapeworm over a period of 10 weeks and attaches to the mucosa of the small intestine by means of suckers on the scolex (anterior end of the worm). These tapeworms can grow to considerable lengths, with adults generally being around 5 m in length, and consist of segments or proglottids

which mature and become gravid, eventually lysing and releasing eggs. Pigs and cattle become infected when they ingest vegetation contaminated with eggs or gravid proglottids which have been passed in faeces of infected humans. *Taenia solium* is of clinical significance as it can cause cysticercosis when cysts invade extraluminal tissues. Neurocysticercosis which occurs when cysticerci enter the brain is the foremost cause of acquired epilepsy in endemic regions, being responsible for about 30% all cases of epilepsy in studies from Latin America, sub-Saharan Africa and Southeast Asia [79]. Intestinal taeniasis does not usually cause symptoms, however, the host might observe tapeworm segments in the faeces, or occasionally experience weight loss or abdominal pain. Diagnosis can be made by identification of ova or gravid proglottids in faeces, and although the eggs of these two species are indistinguishable it is possible to distinguish between gravid proglottids of *T. solium* and *T. saginata* microscopically based on the number of uterine branches. Single oral dose praziquantel (10 mg/kg) is effective for treatment of intestinal infections, alternatively single oral dose niclosamide can also be used.

Diphyllobothrium latum (fish tapeworm) infects humans when they ingest undercooked fish containing plerocercoids (infective larvae of *D. latum*). Diphyllobothriasis does not generally result in symptoms although some may experience non-specific abdominal symptoms. As this parasite competes for host vitamin B12, infection can result in megaloblastic anaemia. Treatment is with single dose praziquantel or niclosamide as with taeniasis.

Hymenolepis nana (dwarf tapeworm) is a smaller species of tapeworm which grows up to 40 mm in length in the intestine and, although distribution is global, prevalence is particularly high in children living in areas with poor access to sanitation. For example, prevalence in children of one refugee population in Pakistan was shown to be 42% [80]. Humans become parasitised when they ingest arthropods containing cysticercoids which develop into adult tapeworms in the small intestine. Alternatively, infection can occur when an embryonated egg from contaminated food, water or fomites is ingested, or by autoinfection whereby eggs in the small intestine release first stage larvae which then penetrate the villus, develop into cysticercoid larvae and are released back into the intestinal lumen on rupture of the villus where they mature into adult worms and continue the infective cycle without passing through the external environment. Symptoms of headache, fever, fatigue and diarrhoea are reported. Treatment is with praziquantel 25 mg/kg as a single dose or alternatively with niclosamide or nitazoxanide.

Strategies for control and prevention of the parasites discussed above include inspection of meat, thorough cooking and/or freezing of fish and meat (freezing meat at -20C for 12 hours and fish at −18C for 24–48 hours), and improved hygiene and sanitation measures in populations.

Persistent Diarrhea in Children in Developing Countries

17

Jai K. Das, Zahra Ali Padhani, and Zulfiqar A. Bhutta

Introduction

In the year 2018, 5.3 million children under the age of 5 years died [1]; around 29% of these deaths were due to diarrhea, pneumonia, and malaria [2]. After respiratory diseases, diarrhea constitutes a serious public health challenge, especially as it constitutes 63% of the global burden and a leading cause of death among children under the age of 5 years and is the second leading cause of infant mortality [3]. The diarrhea burden is specifically concentrated in Asia, Africa, and South America and is the cause of every one in eight child mortality annually of children under the age of 5 years [4, 5].

Diarrhea is defined as "the passage of three or more loose or liquid stools per day (or more frequent passage than is normal for the individual)" [6]. The common risk factors for diarrhea include young age, low socioeconomic status, suboptimal breastfeeding, early weaning, malnutrition, low maternal education, seasonal variations, lack of handwashing, poor hygiene and sanitation practices, and untreated water supply at home [3, 7–9].

Diarrhea has been classified into three types by common clinical criteria. *Acute watery diarrhea* is brief and lasts several hours or days (1–3 days) and is often due to gastrointestinal pathogens including viruses (rotaviruses and caliciviruses) and bacteria (including *Escherichia coli* and *Vibrio cholerae*). *Acute bloody diarrhea*, also called dysentery, is marked by stools containing blood and/or mucous; common pathogens include *Entamoeba histolytica* (amoebic dysentery) or *Shigella* species (bacillary dysentery). *Persistent diarrhea* refers to episodes of diarrhea (either watery or dysentery) that last 14 days or longer. It is majorly caused by *E. coli*, *Shigella* or *Cryptosporidium*. Although less common than acute diarrhea, prolonged and persistent episodes of diarrhea in childhood constitute a significant portion of the global burden of diarrhea and these lengthy episodes are increasingly implicated in childhood undernutrition [10], micronutrient deficiencies (such as folate, vitamin A, and zinc), immune deficiency, adverse neurodevelopment outcomes, and higher morbidity and mortality from other diseases [11]. As mortality from acute watery diarrhea is decreasing, the proportion of deaths due to persistent diarrhea has increased and recent studies estimate that between 5% and 18% of all episodes are persistent diarrhea, and though a small portion of episodes, they are responsible for significant diarrheal morbidity and up to 50% of all diarrhea-related deaths since persistent diarrhea has a high case fatality rate [12, 13]. It is estimated that diarrheal incidence and mortality among children under the age of 5 years are associated with 40.25 million disability adjusted life years (DALYs) lost in 2016 [14]. After accounting the long-term sequel of malnutrition and diarrhea, the DALYs double by 40% to 55.78 million years [14]. These findings indicate the continuing need to focus on prevention and management of childhood diarrhea, especially in developing countries where most of the burden lies. But there is scarcity of data on persistent diarrhea, and it is likely that the diminished publication output also reflects reduced research interest in the subject [15]. Although effective interventions exist, which can not only halt the progression from acute diarrhea to persistent diarrhea and its sequelae, but also have a substantial impact on total diarrhea burden and mortality, these interventions do not have universal access. The integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhea (GAPPD) by the

United Nations Children's Fund (UNICEF) reported that interventions such as handwashing with soap can reduce the risk of diarrhea by 31%, similarly other interventions like improved sanitation can reduce the risk by 36%, improved water quality can decrease the risk by 17%, oral rehydration solution (ORS) reduces the risk by 69%, zinc by 23%, and vitamin A by 23% [16]. There is a 10.5 times greater risk of mortality among children not breastfed during 0–6 months, with 28% (RR 2.28–10.52) risk of mortality due to diarrhea [16]. An analysis using the Lives Saved Tool (LiST), a methodology to estimate the effect of increasing the use of a package of interventions, has shown that if water, sanitation, and hygiene (WASH), breastfeeding, ORS, rotavirus vaccine, vitamin A supplementation, zinc for the treatment of diarrhea, and antibiotics for dysentery are scaled up to at least 80% and that for immunizations to at least 90%, then 95% of diarrheal deaths in children younger than 5 years could be eliminated [17].

Etiology

The cause of persistent diarrhea in developing countries is associated with serial enteric infection (without enough recovery time), which follows an acute episode of diarrhea [4]. In developed countries, children are not likely to be exposed to malnutrition and enteric infections, however, it is most likely to be caused due to celiac disease, food allergies, and inflammatory bowel disease (IBD). In developing countries, persistent diarrhea may increase the risk of malnutrition and intercurrent illnesses such as respiratory diseases [18].

Persistent diarrhea is usually caused by infections which includes bacteria (*Aeromonas*, *Campylobacter*, *C. difficile*, *E. coli*, *Plesiomonas*, *Salmonella*, *Shigella*), parasites (*Cryptosporidium, Cyclospora*, *E. histolytica*, *Giardia*, *Microsporidia*), and viruses (rotavirus, norovirus) [3]. A few pathogens have been particularly associated with persistent diarrhea or are preferentially identified when an episode becomes persistent, such pathogens include enteroaggregative *E. coli* (EAEC), and enteropathogenic *E. coli* (EPEC), *Cryptosporidium*, *Shigella*, *Campylobacter*, *Yersinia*, and *Giardia lamblia* [18–20]. These pathogens cause continuous damage to mucosal lining of the intestine.

The exact cause of persistent diarrhea within population is still poorly understood and individual mechanism of action is still unknown [19]. The original infectious agents are particularly virulent and difficult to clear (e.g., *Shigella* species) [18]. These agents cause destruction of villus tips which leads to intestinal damage and reduced intestinal absorptive surface area, which in turn interferes with the absorption of nutrients. Disrupted intestinal flora and delayed healing cause prolonged diarrhea and exposure to enteropathogens which cause a new infection before the recovery of the previous infection leading to persistent diarrhea [18].

Based on the pathogenic processes and clinical features, diarrheagenic *E. coli* (DEC) has been clustered into six pathotypes. The six pathotypes are EPEC, EAEC, enterohemorrhagic *E. coli* (EHEC), enterotoxigenic *E. coli* (ETEC), diffusely adherent *E. coli* (DAEC), and enteroinvasive *E. coli* (EIEC) [21–23]. In epidemic situations, *E. coli*, *Clostridium difficile*, and *Vibrio cholerae* have been reported as the causative agents of diarrhea in China [24, 25], Iran [26], Nigeria [27], and Yemen [28, 29]. In Bangladesh, *Cryptosporidium* (an intestinal parasite) was reported in chronic diarrheal cases, whereas *Giardia lamblia* was reported in acute and chronic cases of diarrhea in Peru [18, 30].

Risk Factors

The risk factors of persistent diarrhea includes medications (antibiotics), malnutrition, altered immune system, lack of access to clean water, poor sanitation, intolerance to food products (lactose, gluten), thyroid, metabolic and intestinal disorders, and reduced intestinal blood flow [3, 31, 32].

Persistent diarrhea is commonly seen in association with significant malnutrition and the relationship between persistent diarrhea and malnutrition is bidirectional. The evidence of micronutrient deficiencies, especially of zinc and vitamin A in malnourished children with persistent diarrhea, indicates impaired immunological mechanism that is associated with an increase in inflammatory mediators, leading to tissue damage caused by enteric infection. Malnutrition also increases the chances of death due to persistent diarrhea [3]. It impairs tissue repair mechanisms, and the infection tends to be more severe for longer duration. Lactose intolerance is prevalent in many children with persistent diarrhea, but the role of specific dietary allergies in inducing and perpetuating enteropathy of malnutrition is unclear. Several studies have highlighted the high risk of prolonged diarrhea with lactation failure and early introduction of artificial feeds in developing countries. In particular, the administration of unmodified cow or buffalo milk is associated with prolongation of diarrhea, suggesting the potential underlying role of cow's milk protein allergy (CMPA) and milk protein enteropathy [33]. Inappropriate management of acute diarrhea is also an important risk factor. The association of prolongation of diarrhea with starvation and inappropriately prolonged administration of parenteral fluids has been recognized for over half a century [34]. Continued breastfeeding is important, and unnecessary food withdrawal and replacement of luminal nutrients, especially breast milk, with non-nutritive agents is a major factor in prolonging the mucosal injury after diarrhea. In particular, routine administration of antibiotics, antimotility agents, and semistarvation diets should be

avoided in cases of prolonged diarrhea [35]. There is now clear evidence supporting the enteral route for nutritional rehabilitation of malnourished children with persistent diarrhea [36] as starvation has been shown to have deleterious effects on the intestinal mucosa [37] with a reduction in gastrointestinal structure and function. It is therefore imperative that malnourished children with persistent diarrhea should receive enteral nutrition during their period of rehabilitation. High stool frequency, not being breastfed, young age, and acquiring diarrhea in the rainy season have also been identified as risk factors for prolonged diarrhea [38].

HIV has also shown association with persistent diarrhea. It affects several cellular mechanisms, for example, it causes the release of transactivating factor protein (Tat) by the virus which impacts enterocytes, both as an enterotoxin and a viral cytotoxin. This impairs cell growth, proliferation, and inhibition of ion transport [39]. In an immune-suppressed setting, infection with opportunistic agents such as *Blastocystis hominis*, *Candida albicans*, and *Cryptosporidium* leads to mucosal injury and diarrhea. HIV directly and indirectly causes malnutrition, immune impairment, and intestinal dysfunction. Antiretroviral therapy may also cause persistent diarrhea [10].

The aforementioned risk factors highlight the importance of recognizing that optimal management of diarrheal episodes is essential to progression to persistent diarrhea. It is natural that given the close relationship between diarrheal disorders, malnutrition, and HIV, persistent diarrhea is widely recognized as a nutritional disorder and that optimal nutritional rehabilitation is considered a cornerstone of its management.

Consequences of Persistent Diarrhea

As diarrhea becomes "persistent," malnutrition becomes increasingly manifest secondary to anorexia and impaired nutrient balance resulting from mucosal injury, malabsorption, and nutrient losses [40]. This sequence is supported by the observation that *Shigella* infection – characterized by intense tissue catabolism and nutrient losses – almost doubles the risk of persistent diarrhea [41], dehydration [3], and why bloody diarrhea (caused by *Shigella* spp. in 45–67% cases and *Campylobacter* in 35–37% cases) so often reported to be a risk factor for persistent episodes [3, 42]. Children with bloody diarrhea are at high risk of morbidity and mortality [3]. The importance of *Shigella* is reflected in the report from at a large hospital center in Bangladesh that the frequency of persistent diarrhea diminished as the isolation rate of *Shigella* decreased between 1991 and 2010. Mucosal injury also explains why by day 14 the manifestations of persistent diarrhea are primarily those of a malabsorption and malnutrition syndrome that requires careful dietary and nutritional management until the mucosal damage is reversed and new normally functioning epithelial cells are regenerated.

There are several reasons why malnutrition should both predispose to and follow persistent diarrhea. These range from achlorhydria with increased risk of small bowel contamination, systemic immune deficiency, intestinal and pancreatic enzyme deficiency, and altered intestinal mucosal repair mechanisms following an infectious insult. An independent relationship has also been demonstrated between cutaneous anergy and the subsequent risk of development of persistent diarrhea [43]. There has been much interest in the possibility that such transient immune deficiency may also be a marker of concomitant micronutrient deficiency [44]. The most striking example of the critical role that the immune system plays in the pathogenesis of persistent diarrhea is the relationship of HIV/AIDS. This is exemplified by the host of studies linking persistent diarrhea with cryptosporidiosis [45] and other parasitic infections [46] in Africa and Asia.

A clear understanding of alterations in intestinal morphology and physiology is crucial toward the development of interventional strategies, but there has been little progress in our understanding of this problem in developing countries. This has been largely due to a paucity of studies formally evaluating intestinal biopsy findings in representative populations. A wide variety of pathological changes has been described after persistent diarrhea, however, ranging from near-normal appearance to mucosal flattening, crypt hypertrophy, and lymphocytic infiltration of the mucosa [47]. Recent elaborate electron microscopic studies of intestinal mucosa in persistent diarrhea reveal patchy villous atrophy and intraepithelial lymphocytic infiltration as well as severe mucosal damage and villous atrophy [48, 49]. Poor intestinal repair is regarded as a key component of the abnormal mucosal morphology. However, the exact factors underlying this ineffective repair process and continuing injury are poorly understood. The end result of this mucosal derangement is reduced absorption of luminal nutrients, as well as increased permeability of the bowel to abnormal dietary or microbial antigens [50]. Alterations of intestinal permeability in early childhood may reflect changes in intestinal mucosal maturation [51] and may be affected by concomitant enteric infections [52].

Management

It is imperative to consider the child's age and clinical manifestations to determine proper treatment in cases of persistent diarrhea. A paucity of diagnostic facilities limits the microbiologic evaluation of diarrhea in many parts of the world. Lack of awareness regarding cow's milk protein allergy and immunodeficiency-associated diarrhea is of par-

Table 17.1 Impact of interventions to prevent and control diarrhea

Intervention	Effect estimates
Water sanitation and hygiene	31–48% risk reduction for diarrhea by handwashing with soap and 31–52% risk reduction for diarrhea with improved water quality
Exclusive breastfeeding for 6 months	165% (10.5 times greater risk of death) increase in diarrhea among 0- to 6-month-old infants if not breastfed Not breastfeeding exclusively results in excessive risk of diarrhea prevalence (RR 2.15–4.90), incidence (RR 1.26–2.65), mortality (RR 2.28–10.52) and all-cause mortality (RR 1.48–14.40) in infants 0–5 months
Adequate complementary feeding among children 6–23 months, including adequate micronutrient intake	6% reduction in all child mortality
Preventive zinc supplementation	23% reduction in diarrhea-related mortality
Preventive vitamin A supplementation	23% reduction in all-cause mortality
Vaccines for rotavirus	74% reduction in very severe rotavirus infection 47% reduction in rotavirus hospitalization
Vaccines for cholera	52% effective against cholera infection
ORS	69% reduction in diarrhea-specific mortality
Prevention of HIV in children	2% reduction in all child mortality
Dietary management of diarrhea	Lactose-free diets reduce the duration of diarrhea treatment failure significantly by 47%
Therapeutic zinc supplementation	66% reduction in diarrhea-specific mortality 23% reduction in diarrhea hospitalization 19% reduction in diarrhea prevalence
Antibiotics for cholera	63% reduction in clinical failure rates 75% reduction in bacteriological failure rates
Antibiotics for *Shigella*	82% reduction in clinical failure 96% reduction in bacteriological failure rates
Antibiotics for cryptosporidiosis	52% reduction in clinical failure rates 38% reduction in parasitological failure rates
Community-based intervention platforms for prevention	160% increase in the use of ORS 80% increase in the use of zinc in diarrhea 76% decline in the use of antibiotics for diarrhea
Community case management (CCM)	CCM of diarrhea with zinc and ORS reduced diarrheal deaths among children under the age of 5 years by 93%
Financial support schemes	Conditional transfer programs: 14% increase in preventive healthcare use, 22% increase in the percentage of newborns receiving colostrum, and 16% increase in the coverage of vitamin A supplementation

ticular concern. Optimal prevention and management of acute diarrheal illnesses are the ideal strategies to prevent persistent diarrhea. Treatment is focused on reversing dehydration (if present), nutritional interventions including balanced protein energy, pancreatic enzyme replacement therapy (PERT), micronutrient supplements, and judicious use of antibiotics for certain types of inflammatory diarrhea. Oral rehydration solutions, micronutrient supplementation, algorithm-based diet regimens, and good supportive care are sufficient in most children above 6 months of age with persistent diarrhea (Table 17.1).

Rapid Resuscitation, Antibiotic Therapy, and Stabilization

Most children with persistent diarrhea and associated malnutrition are not severely dehydrated and oral rehydration may be adequate. Indeed, routine use of intravenous fluids in severe acute malnutrition should be avoided; acute severe dehydration and associated vomiting may require brief periods of intravenous rehydration with Ringer's lactate. Acute electrolyte imbalance such as hypokalemia and severe acidosis may require correction. More importantly, associated systemic infections (bacteremia, pneumonia, and urinary tract infection) are well-recognized complications of severe acute malnutrition in children with persistent diarrhea and a frequent cause of early mortality. Almost 30–50% of malnourished children with persistent diarrhea may have an associated systemic infection requiring resuscitation and antimicrobial therapy [53, 54]. Children with bloody diarrhea (caused by *Campylobacter*, *Shigella*, or some parasites) require antibiotic therapy for enteric pathogens. Ceftriaxone, ciprofloxacin, and pivmecillinam have shown to be effective against local strains of *Shigella* [55], whereas azithromycin and fluoroquinolones are highly effective against *Campylobacter* gastroenteritis. Treatment against strain of *Shigella* is recommended to be changed if no improvement is observed within two days of treatment.

Emergence of antibiotic resistance strains of enteric pathogens are a great threat worldwide. For example, multidrug resistance has been reported against *Shigella* sp. in Ethiopia [56], Nigeria [57], and Mozambique [58]. In such instances, fortified food therapy (such as zinc and iron), immunotherapy [59–61], lactose-free diet [62], fecal microdata transplantation (used in *Clostridium difficile*-associated diarrhea) [63], and probiotics [64–66] are the alternative treatment options against the enteric pathogens. It should be emphasized that there is little role for oral antibiotics in persistent diarrhea as in most cases the original bacterial infection triggering the prolonged diarrhea has disappeared by the time the child presents. Possible exceptions are appropriate treatment for dysentery [67] and adjunctive therapy for cryptosporidiosis in children with HIV and persistent diarrhea [68].

Oral Rehydration Therapy

Death by persistent diarrhea is usually caused by malnutrition or by hypovolemia (dehydration). It is over 40 years since the efficacy of oral rehydration therapy (ORT) was clearly demonstrated, following discovery of glucose-stimulated sodium uptake by intestinal villus cells [62, 69, 70]. This is the preferred mode of rehydration and replacement of on-going losses. The net effect is expansion of the intravascular compartment and rehydration, usually sufficient for all but the most severely dehydrated patients require initial intravenous fluids [71]. World Health Organization (WHO) has recommended a new low osmolarity solution for the management of diarrhea [72], which contains 75 mmol/L glucose, 75 mEq/L sodium, and 20 mEq/L potassium, at an osmolarity of 245 mOsm/L. Potassium chloride can also be added in ORS solution (to provide 40 mEq/L of potassium) for severely malnourished children with depleted potassium levels. In general, the standard WHO oral rehydration solution is adequate, while recent evidence indicates that hypo-osmolar rehydration fluids [73] as well as cereal-based oral rehydration fluids may be advantageous in malnourished children. A number of modifications have been proposed, for example, cereal (rice)-based ORT, addition of certain amino acids (glycine, alanine, or glutamine) to further increase sodium absorption and/or hasten intestinal repair, or supplementation with zinc, but none have been shown to be consistently superior to low osmolality ORS [74, 75]. However, in Nigeria, homemade fluids and cereal-based oral therapies have proven to be effective in the management of diarrhea [76].

Enteral Feeding

Nutritional rehabilitation can break the vicious cycle of chronic diarrhea and malnutrition and is considered the cornerstone of treatment. It is exceedingly rare to find persistent diarrhea in exclusively breastfed infants, and with the exception of situations where persistent diarrhea accompanies perinatally acquired HIV infection, breastfeeding must be continued. Although children with persistent diarrhea may not be lactose intolerant, administration of a lactose load exceeding 5 g/kg/day may be associated with higher purging rates and treatment failure. Alternative strategies for reducing the lactose load while feeding malnourished children who have prolonged diarrhea include addition of milk to cereals such as rice and noodles and replacement of milk with fermented milk products such as yogurt. Lactose-free diet and low-sucrose and -carbohydrate diet has also been effective in minority of the cases. Mattos et al. [77] claimed that yogurt-based diet is recommended as the first choice for the nutritional management of a mild to moderate persistent diarrhea. A cheap and an easily available yogurt-based diet can be used in mild chronic diarrhea illness of uncomplicated and without enteropathy. Bhutta et al. [36] suggested algorithm for the diagnosis and management of persistent diarrhea (Fig. 17.1). Elimination diet is considered when allergic enteropathy is induced by a cow's milk protein or soy protein [78]. Rarely, when dietary intolerance precludes the administration of cow's milk-based formulations or milk, it may be necessary to administer specialized milk-free diets such as a comminuted or blended chicken-based diet or an elemental formulation. Although effective in some settings, the latter are unaffordable in most developing countries. In addition to rice-lentil formulations, the addition of green banana or pectin to the diet has also been shown to be effective in the treatment of persistent diarrhea [79, 80]. Among children in low- and middle-income countries, where the dual burden of diarrhea and malnutrition is greatest and where access to proprietary formulas and specialized ingredients is limited, the use of locally available age-appropriate foods should be promoted for the majority of diarrhea cases. Nutritionally complete diets comprising locally available ingredients can be used at least as effectively as commercial preparations or specialized ingredients. The usual energy density of any diet used for the therapy of persistent diarrhea should be around 1 kcal/g, aiming to provide an energy intake of a minimum 100 kcal/kg/day, and a protein intake of between 2 and 3 g/kg/day. Additionally, potassium should also be included in the diet providing approximately 5 mEq/kg per day. In selected circumstances when adequate intake of energy-dense food is problematic, the addition of amylase to the diet through germination techniques may also be helpful. Recent WHO guidelines recommend that children with severe acute malnutrition who present with either acute or persistent diarrhea can be given ready-to-use therapeutic food (RUTF) in the same way as children without diarrhea, whether they are being managed as inpatients or outpatients. And these chil-

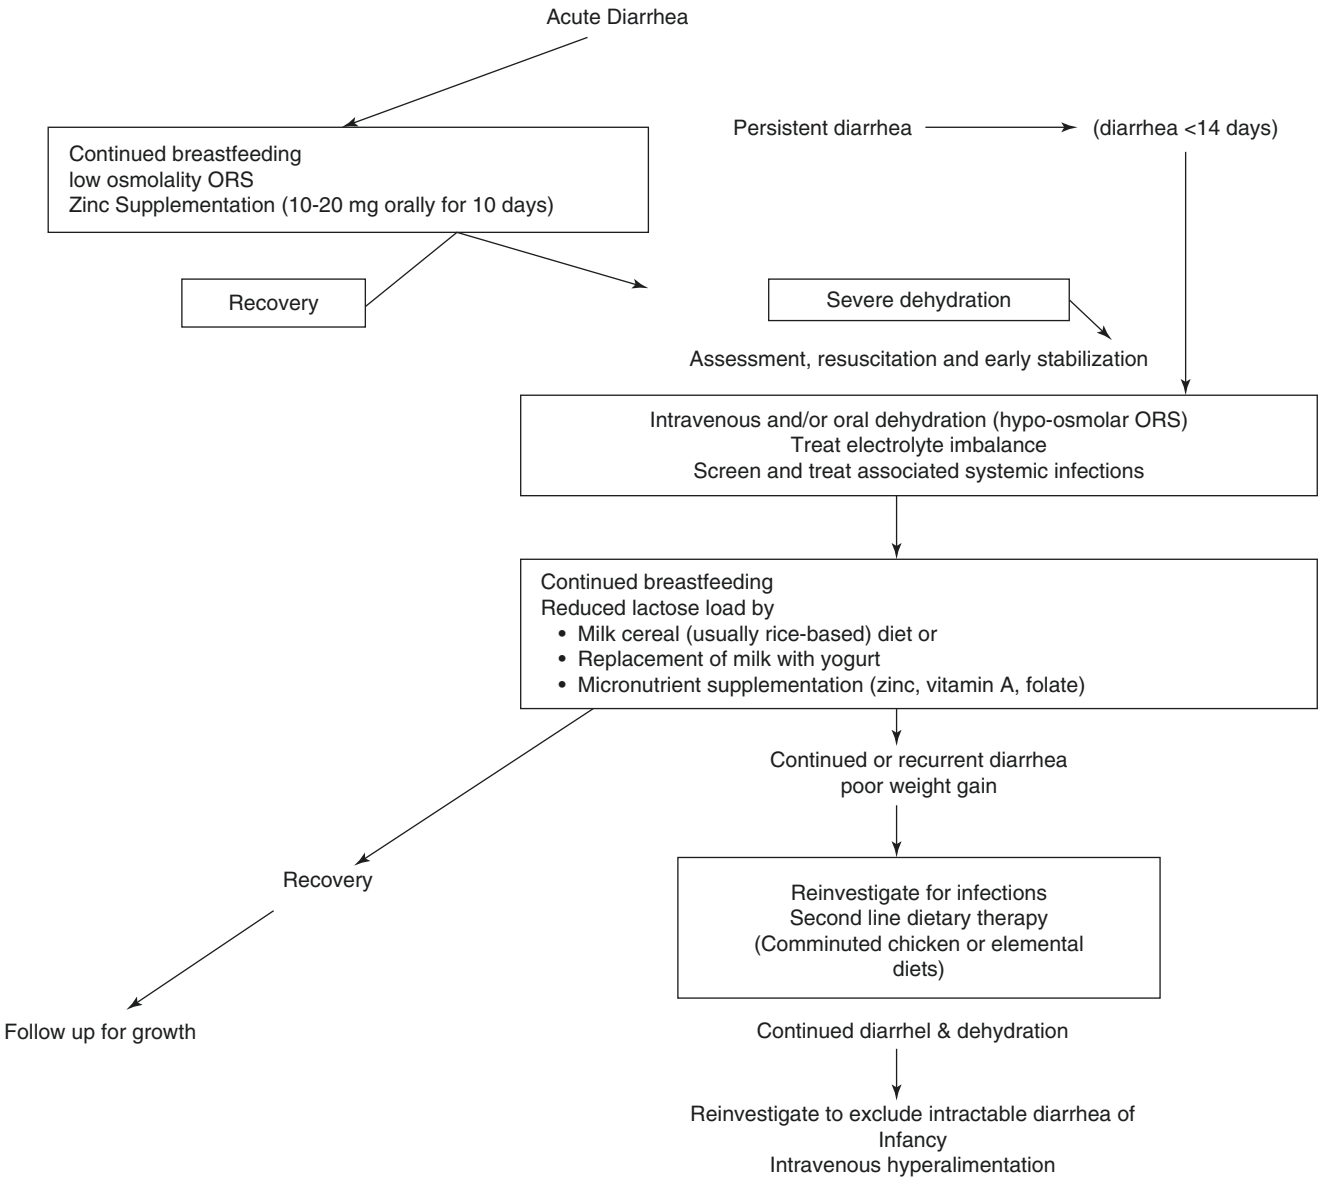

Fig. 17.1 Algorithm of diagnosis and management of persistent diarrhea

dren with severe acute malnutrition (SAM) are typically managed by a course of broad-spectrum antibiotics with a gradual increase in full caloric intake. Hypophosphatemia is common during the refeeding syndrome which is mitigated by providing phosphorus-rich food such as milk-based feed to the children [3].

Micronutrient Supplementation

It is now widely recognized that most malnourished children with persistent diarrhea have associated deficiencies of micronutrients including copper, folic acid, zinc, iron, vitamin A, and minerals [81]. This may be a consequence of poor intake and continued enteral losses and requires nutritional rehabilitation [82]. While the evidence supporting zinc administration in children with persistent diarrhea is persuasive, it is likely that these children have multiple micronutrient deficiencies. Concomitant vitamin A administration to children with persistent diarrhea has been shown to improve outcome [83, 84], especially in HIV endemic areas [85]. In Bangladesh, a combination of vitamin A, zinc, and ORS has proven to be effective at reducing child mortality caused by diarrhea [86]. WHO recommended 10 mg/day of zinc for 10–14 days for children <6 months and 20 mg/day for children >6 months [87]. Zinc has shown a significant effect among children >6 months with shortened duration of persistent diarrhea by approximately 16 hours [88, 89]. However,

zinc decreases the absorption of copper and causes copper depletion in the body [89]. While the association of significant anemia with persistent diarrhea is well recognized, iron replacement therapy is best initiated only after recovery from diarrhea has started and the diet is well tolerated. Thus, in July 2019, WHO has recommended to administer folate, iron, vitamin A, copper, and magnesium twice a day for two weeks [90].

Antidiarrheal Drugs

Antidiarrheal drugs are not recommended due to their inefficiency, side effects, and possibly also as causing prolonged release of enteric pathogens. Similarly, antiemetic drugs are also not encouraged because of the sedation caused by them which may interfere with ORT.

Pancreatic Enzyme Replacement Therapy (PERT)

Persistent diarrhea causes pancreatic exocrine insufficiency due to decreased stimulation to pancreas caused by prolonged mucosal injury. PERT prescribed in conjunction to regular treatment has proved to be beneficial in replacing pancreatic enzyme deficiency. Studies from Indonesia identified children (6–60 months) with pancreatic enzyme deficiency through fecal elastase-1 test [91, 92]. These children were provided with PERT (8371 United States Pharmacopeia [USP] units of lipase) three times a day for a month. This therapy showed decrease in duration of diarrhea by 3–7 days in the intervention group when compared to the placebo group.

Improved Case Management of Diarrhea

Improved management of diarrhea through prompt identification and appropriate therapy significantly reduces diarrhea duration, its nutritional penalty, and risk of death in childhood. Improved management of acute diarrhea is a key factor in reducing the burden of prolonged episodes and persistent diarrhea. The WHO/UNICEF recommendations to use low-osmolality ORS and zinc supplementation for the management of diarrhea, coupled with selective and appropriate use of antibiotics, have the potential to reduce the number of diarrheal deaths among children through Community Case Management (CCM) and Integrated Management of Childhood Illness (IMCI). Community-based interventions to diagnose and treat childhood diarrhea through community health workers leads to a significant rise in care-seeking behaviors for diarrhea and are associated with significantly increased use of ORS and zinc at household level as well as reduction in the unnecessary use of antibiotics for diarrhea by 75% [93].

Other Potential Modalities

The factors associated with persistent diarrhea are small intestinal mucosa injury, persisting infective colonization, and bacterial particles and toxins that are translocated into the host cell and downregulated host immune system. These circumstances alter interrelation between the normal flora and the host, which can worsen prolonged inflammation. The rationale for using probiotics in the treatment of persistent diarrhea lies in their ability to survive and reproduce in the host's gut and in their proven role in the treatment of acute diarrhea. Recent evidence suggests modest effect of probiotics with reduced duration of persistent diarrhea and stool frequency [94]. Because of probiotics known immunomodulatory effect and very significant mortality and morbidity rate from persistent diarrhea in developing countries, it is imperative to highlight the necessity for well-designed studies to define the role of probiotics in persistent diarrhea.

Follow-Up and Nutritional Rehabilitation in Community Settings

Given the high rates of relapse in most children with persistent diarrhea, it is important to address the underlying risk factors and institute preventive measures. These include appropriate feeding (breastfeeding, complementary feeding) and close attention to environmental hygiene and sanitation. This poses a considerable challenge in communities deprived of basic necessities such as clean water and sewage disposal.

In addition to the preventive aspects, the challenge in most settings is to develop and sustain a form of dietary therapy using inexpensive, home-available, and culturally acceptable ingredients which can be used to manage children with persistent diarrhea. Given that the majority of cases of persistent diarrhea occur in the community and that parents are frequently hesitant to seek institutional help, there is a need to develop and implement inexpensive and practical home-based therapeutic measures [95] and evidence indicates that it may be entirely feasible to do so in community settings [96, 97].

Conclusions

Persistent diarrhea remains an existential threat, especially among children under 5 years of age in resource-limited countries where quality of life and access to health care are low.

Persistent diarrhea in children contributes to childhood malnutrition and mortality. Most of the knowledge and tools (bioinformatics, metagenomics) needed to prevent diarrhea-associated mortality in developing countries, and especially persistent diarrhea, are available. These require concerted and sustained implementation in public health programs. Given the emerging evidence of the long-term impact of childhood diarrhea on developmental outcomes [98], it is imperative that due emphasis is placed on prompt recognition and appropriate management of persistent diarrhea besides the focus on improving child nutrition and hygiene.

HIV and the Intestine

18

Andrea Lo Vecchio and Francesca Wanda Basile

Introduction

The pandemic spread of HIV has been reversed over the last three decades, and in 2015, the United Nations embraced the ambitious target to end the AIDS epidemic by 2030 as a part of the Sustainable Development Goals [1].

The introduction of successful interventions for a timely diagnosis, together with the advancements in pediatric antiretroviral treatment (ART), are shaping the natural history of HIV infection in childhood, which is evolving into a chronic disease, the control of which strictly depends on accessibility and adherence to ART [2].

ART has dramatically changed the spectrum of HIV-associated complications, but the gastrointestinal (GI) tract remains a major target, especially in resource-limited countries where a significant proportion of children are still present with features of advanced disease; at this stage, GI symptoms and failure to thrive are frequent, as they reflect the combined effects of opportunistic infections, HIV enteropathy, and immune impairment. In this scenario, healthcare costs, morbidity, and mortality are substantially increased, particularly for those children with severe malabsorption and malnutrition requiring repeated hospitalizations. In many such cases, a multidisciplinary approach involving specialists in gastroenterology, HIV/infectious diseases, nutrition, surgery, and microbiology is needed (Fig. 18.1).

The Spectrum of GI Disorders in HIV Infection

The GI system is a topographical target of HIV infection and ART. Symptoms can involve any tract of the GI from the oral cavity to the large intestine, liver, and pancreas. This paragraph provides an overview of the GI involvement in HIV, and topics are discussed in detail in the specific sections.

In the ART era, many of the common HIV-related disorders have vanished but they can still be observed in children who are failing on treatment or who access the healthcare system already with features of advanced disease.

For this reason, the approach to GI symptoms in any HIV-infected children with adequate virological and immunological control should parallel that of any other non-HIV patient living with a chronic health condition. In this scenario, drug history is the first step to rule out any specific ART side effects, as transient drug-induced GI symptoms like abdominal distension, nausea, and diarrhea are common, particularly in the first year of ART. Up to 29% of patients on any class of antiretrovirals experience mild-to-moderate diarrhea. Pancreatitis and hepatitis are infrequent but are potentially severe complications associated with the use of antiretrovirals.

Table 18.1 summarizes ART-associated GI and hepatic adverse events [3–11].

Intestinal dysfunction is a specific syndrome almost inevitably seen in children at advanced stages, which has the features of a malabsorption disorder. Clinical manifestations may be limited or absent and not necessarily associated with severe diarrhea. As a consequence of the reduction in the intestinal absorptive surface and increased permeability, the predominant features are steatorrhea, micronutrient deficiencies, and progressive failure to thrive. The absence of any GI pathogen, despite extensive microbiological investigation, defines HIV enteropathy [12].

In patients with advanced HIV disease, the stage of immunodeficiency, reflected by the age-specific CD4+ lymphocyte

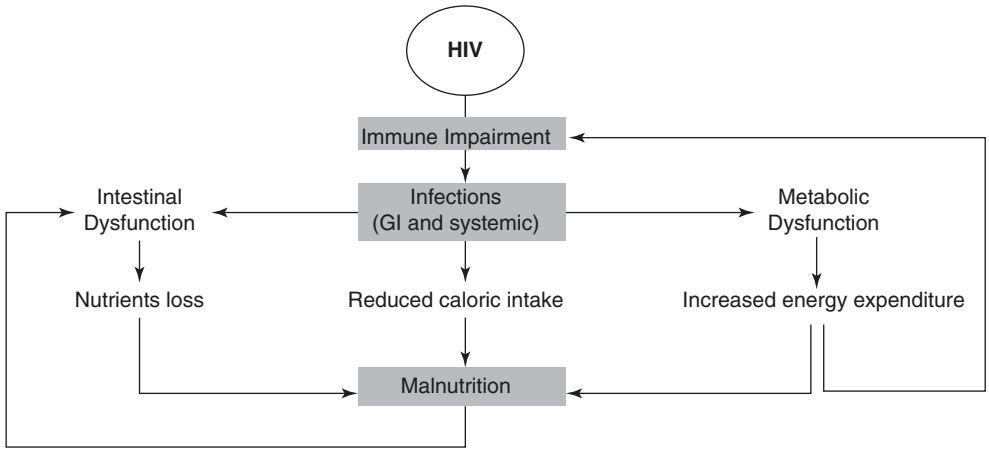

Fig. 18.1 Pathway of malnutrition and gastrointestinal disorders in children with HIV infection. A complex interplay exists among these conditions

Table 18.1 ART-associated GI and hepatic adverse events

Adverse event	ART	Incidence	Clinical characteristics	Management
Nausea/vomiting	Protease inhibitors and all ARV	<15%	Early onset, usually improves within 2 months since the beginning of ART Nausea can present with or without vomiting and abdominal discomfort	Reassure patient and recommend taking protease inhibitor with food If persistent emesis, consider switching to a different regimen (with smaller tablet size)
Diarrhea	Protease inhibitors and all ARV	Up to 29%	Early onset, usually improves within 2 months Nonbloody, and usually nonwatery, mild-to-moderate diarrhea Some FDC tablets contain lactose that may trigger diarrhea in patients with lactose intolerance	Rule out infections and other organic causes of persistent/chronic diarrhea Reassure patient. Dietary modifications may help. Treat dehydration if present If persistent/severe symptoms, consider switching to a different regimen
Drug-induced liver disease (idiosyncratic hepatotoxicity, hypersensitivity, and hyperbilirubinemia)	*Hepatitis:* all ARV (strong association with nevirapine and efavirenz) *Indirect hyperbilirubinemia:* atazanavir *Hepatic steatosis:* zidovudine	1–9% (severe hepatitis and hypersensitivity reaction <1%)	*Hepatitis, hyperbilirubinemia:* early onset, usually in the first months of therapy *Steatosis:* develops after years The clinical scenario of liver disease ranges from asymptomatic hypertransaminasemia to severe hepatitis with lactic acidemia and rash in hypersensitivity reactions ATV-associated hyperbilirubinemia is usually an isolated finding with normal transaminases	Rule out infections (HAV, HBV, HCV, EBV and CMV) Asymptomatic hypertransaminasemia: treatment discontinuation, if ALT < 5 × UNL Symptomatic hepatitis: stop all ART and other potentially hepatotoxic drugs. If on nevirapine, permanently discontinue Isolated hyperbilirubinemia does not require atazanavir discontinuation
Pancreatitis	NRTIs and protease inhibitors	<2%	Can develop any time, usually after months of ART Acute pancreatitis with significantly raised serum lipase and amylase	Stop the offending drug and do not reintroduce Symptomatic management

count, should always be looked at because frequency (and the etiology) of opportunistic infections (OI) is related to the CD4 count and rises exponentially with lower CD4+ counts. Intestinal infections are a major cause of morbidity and mortality, especially for children, and where the availability of ART is limited. Candidiasis, the most common HIV-related fungal infection, usually involves mouth and throat. Cryptosporidium and mycobacterium avium complex (MAC) are common GI opportunistic pathogens in developing countries, while, in high-income settings, CMV prevails. Of note, although, in the ART era, the number of cases of diarrhea by OI has fallen dramatically worldwide, the total number of patients experiencing diarrhea has changed very little, probably as a consequence of the global increase in GI diseases (infectious and noninfectious) unrelated to immunodeficiency [13].

HIV-associated malignancies, like Kaposi sarcoma and non-Hodgkin B-cell lymphomas, often affect the GI tract and may present with symptoms like diarrhea, rectal bleeding, or acute abdomen.

Overt hepatic disease is not frequent in HIV-infected children, but isolated hepatomegaly or mild hypertransaminasemia is a common finding often associated with nutritional deficiencies, nonalcoholic fatty liver disease (NAFLD), medication-associated liver injury, or coinfection with chronic viral hepatitis (HBV or HCV), which should always be ruled out [14].

Exocrine pancreas impairment, although rare in children on ART, may be considered as a component of the HIV-associated digestive dysfunction, and the diagnostic workup of HIV-related diarrhea should include measurements of fecal pancreatic enzymes [15].

In resource-limited countries, undernutrition is a frequent comorbidity in HIV-infected children who present late and malnutrition enteropathy can precipitate intestinal dysfunction; it is often impossible to understand to what extent undernutrition is the consequence of primary food insecurity, HIV enteropathy, or OIs. In the majority of cases, it is likely to be a multifactorial event that contributes significantly to the morbidity and mortality of children with advanced HIV disease [16].

In conclusion, the intestinal involvement in HIV infection is closely related to access to ART and shows a geo-economical pattern. In high burden settings with limited access to health services, intestinal OIs are still a major problem, and there is a complex interplay among malabsorption, immune impairment, and undernutrition. In children receiving ART, there is a residual intestinal dysfunction, with no or limited symptoms specific to HIV infection or treatment.

Pathophysiology of HIV-Associated Intestinal Damage

Since the discovery of HIV as the causative agent of AIDS, histological abnormalities of the GI tract were observed, and the term "HIV enteropathy" was first used in 1984. HIV enteropathy was classically diagnosed in AIDS patients with symptoms of refractory intestinal dysfunction when other etiologies have been ruled out [17].

Enterocyte damage and mucosal atrophy have become the histological hallmark of HIV enteropathy, but other common findings include inflammatory infiltrates of lymphocytes, crypt hyperplasia, and villous blunting, in the absence of detectable enteric pathogens [18].

In recent years, there have been great advancements in the understanding of this condition, and the scientific discoveries have shed light on the complex mosaic of interactions between HIV and gut. HIV does primarily target gut-associated lymphoid tissue (GALT) but has also shown the ability to affect the intestinal barrier at all levels, via direct and indirect mechanisms.

HIV-associated intestinal damage begins at the early stages of the infection. The clinical spectrum of the disease encompasses a variety of manifestations ranging from a subclinical impairment of the mucosal barrier function (when effective ART is promptly initiated) to the "classical" picture of chronic intestinal failure in advanced HIV disease characterized by increased intestinal permeability, bile acid and vitamins malabsorption, lactose intolerance, protein-losing enteropathy, and failure to thrive [19, 20].

The damage to mucosal immunity is early and somehow irreversible. Antiretroviral therapy, although started immediately, can only partially counteract it. This aspect of HIV-associated intestinal damage has acquired increasing importance due to its role in microbial translocation, and therefore, as a contributing factor to the chronic inflammation state that is characteristic of people living with HIV despite good virologic response [21–23].

In the early phases of the acute infection, GALT becomes a site of intense viral replication and CD4+ T-cell destruction. Activated memory T cells expressing C-C chemokine receptor type 5 (CCR5) are largely represented in the gut and constitute a preferential target for HIV. More than half of the GI CD4+ cells are infected by the virus, meaning that the intestine constitutes an important viral reservoir [24, 25].

Another mechanism of intestinal immune barrier damage involves the ability of the virus to elicit a local response that leads to an increase in proinflammatory cytokines (IL-6, IL-10, and IFN-γ) in the lamina propria, similar to the pathogenesis of GI damage in inflammatory bowel diseases [26]. The inflammatory cytokines, particularly IFN-γ, are also responsible for the depletion of mucosal Th17, a key population of CD4+ T cells in maintaining gut immune homeostasis. Moreover, HIV exerts a direct cytotoxic effect on this CD4 subset; thus, acting synergistically. Th17 produces the interleukin IL-17, which together with IL-22 produced by Th22 have a pivotal role in blocking microbial translocation from the gut lumen [27, 28].

The complex interplay between HIV and GI is not limited to its damage to the immune system.

A direct "virotoxic" effect on the intestinal barrier has been hypothesized for the first time more than 20 years ago [29]. There is convincing evidence that the virus acts both at the cellular (enhancing enterocyte apoptosis) and paracellular level (disrupting tight and adherens junctions). As a consequence, the intestinal wall becomes leaky and this structural loss further contributes to microbial translocation [30].

Intestinal epithelial apoptosis is an early event during HIV infection [31]. It has been demonstrated that the intracellular imbalance between antioxidant defenses and reactive oxygen species (ROS), in favor of the latter, is involved in enterocyte apoptosis [32]. Tat, a transactivating peptide secreted by HIV-infected cells and essential for viral replica-

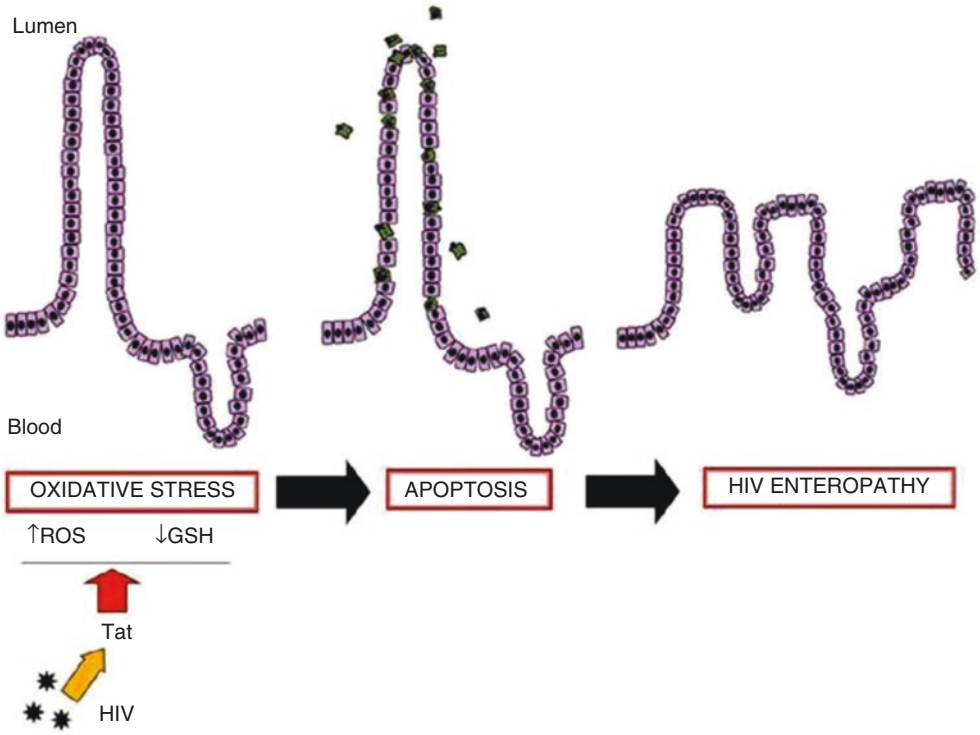

Fig. 18.2 Schematic representation of the mechanism of HIV Tat-induced intestinal epithelium damage. Tat triggers oxidative stress by increasing the ROS intracellular level and affecting the GSH/GSSG ratio. This leads to programmed cell death (apoptosis) and epithelial damage. Together with altered ion secretion and glucose transport, these steps could represent key mechanisms in HIV enteropathy. ROS reactive oxygen species, GSH glutathione, Tat transactivator factor, HIV human immunodeficiency virus. (Reprinted from Ref. [33] with permission)

tion, has been identified as a key mediator in this process (Fig. 18.2).

In support of the role of Tat via an oxidative stress-mediated pathway, increased epithelial apoptosis has been observed in ex vivo jejunal specimens from HIV-positive patients at baseline and from HIV-negative specimens exposed to Tat [33, 34]. In addition to the ROS-mediated mechanism, several interleukins (e.g., IL-18, IL-6, and IL-8) produced by the enterocytes during the infection, play a role in increased intestinal permeability through the downregulation of the macromolecules that form both tight and adherens junctions [34, 35].

Gut Microbiota in HIV Infection

The intestinal microbiota is a key component at the frontline of the gut barrier. Its diversity is physiologically influenced by multiple factors including age, sex, diet, and sexual behaviors. In recent years, research has focused on the impact of HIV infection on gut microbial community composition and function.

Increasing evidence suggests that the dysbiosis observed in people living with HIV is associated with increased circulating markers of microbial translocation and systemic inflammation, such as IL-6, lipopolysaccharide (LPS), and soluble CD14 (sCD14), in both adults and children [36].

HIV affects the balance of commensal bacteria, increasing the proportion of pathobionts (commensal bacteria that have harmful potential in a permissive context) [37].

Overall, the most common finding at the phyla level is the increase in Proteobacteria and a decrease in Firmicutes, which include *lactobacilli, streptococci, staphylococci,* and *clostridia*. More specific alterations within the phyla involve the shift from *Bacteroides* to *Prevotella* spp. (Bacteroidetes), and the increase in members of the family Enterobacteriaceae such as *Escherichia, Klebsiella* and *Yersinia* spp. Pathobionts are usually associated with a proinflammatory condition, and in vitro experiments have demonstrated that some species may act in synergy with HIV, boosting the secretion of IL-10 and TNF-a from infected peripheral mononuclear cells [38–40].

Gut microbiota research has just recently focused on perinatally infected children, who exhibit lower alpha diversity (species richness) and increased beta diversity (interindividual diversity) compared with uninfected children. The findings from a Zimbabwean study are similar to the findings in the adult population and show an abundance of *Prevotella* and *Corynebacterium* at the genus level. Moreover, children with severe immunosuppression (CD4 $\leq$ 400/mmc) have enriched Enterobacteriaceae. Such family is frequently involved in microbial translocation, but the clinical implications of this finding need to be investigated further. Notably, the results from the Zimbabwean

cohort are in line with a similar study that examined the gut microbiome of perinatally infected children from a high-income country. However, it has to be noted that some minor discrepancies exist regarding the relative abundance of specific taxonomic groups [41, 42].

Also HIV-exposed (but uninfected) infants exhibit a different gut microbiota from unexposed children, which is characterized by an abundance of the taxa Lachnospiraceae. Such difference does not seem to be pathogenic per se, as judged by normal microbial translocation and inflammation markers in these infants. Results are slightly different between studies according to the main nutritional source (breast milk vs. formula feeds) [43, 44].

As seen with other manifestations of the HIV-induced intestinal damage, long-course ART can counteract gut dysbiosis. Perinatally infected children show a restored microbiota (alpha diversity) after more than 10 years on treatment. ART duration, however, does not seem to impact on beta diversity [42, 45].

A variety of drugs can affect gut microbial composition, but little is known about the direct effect of antiretroviral drugs. It is a shared opinion that antiretrovirals have a distinct impact on the intestinal microbiota, but to date the quality of existing studies is undermined by several confounding factors. It appears that regimens based on a protease inhibitor have the most harmful effect [46].

Cotrimoxazole, commonly prescribed for prophylactic use in HIV-infected children, does not modify the microbial composition and exhibits an antibiotic effect on gut resident *Streptococci* that reduces intestinal and systemic inflammation [33].

Intestinal Barrier Damage Response to ART and Novel Strategies

Intestinal dysfunction, if present, improves shortly after initiation of ART, in parallel with the immune reconstitution in blood and a decrease in viral load which is seen both in blood and rectal mucosa [29].

The beneficial effects of therapy on GALT are not able to fully revert the damage caused by HIV in the initial phases of the infection, and subclinical impairment of the GI immune and barrier function has been documented in up to one-third of HIV-infected patients on treatment, regardless of the ART regimen [47].

Such damage, associated with intestinal dysbiosis, creates a permissive environment for microbial translocation, which has emerged as a driver for the persistent systemic inflammation seen in people living with HIV.

However, it has to be noted that the majority of the results are based on cohorts of ART-experienced adults and teenagers with the most diverse backgrounds and ART histories; only in recent times, the research has been focusing on groups of "tested and treated" individuals, where an early start of the antiretroviral treatment may further decrease the proviral reservoir in the GALT and possibly reduce the long-term consequences of the intestinal damage [22, 48].

Recent evidence from pediatric studies supports this hypothesis and downsizes the role of microbial translocation. Irrespective of the relative abundance of HIV-susceptible memory CD4+ T cells in the gut compared with adults, perinatally HIV-infected infants started on a very early ART have a smaller proviral reservoir in GALT and progressively lower levels of chronic inflammation and microbial translocation biomarkers; confirming the hypothesis that prompt therapeutical intervention in the acute phases of the infection is effective in limiting the intestinal damage [49–51].

In parallel, research has focused on additional strategies to modulate dysbiosis, like the supplementation with probiotics and prebiotics. Prolonged use of probiotics is associated with an increase in CD4+ count and Th17 subset in GALT and peripheral blood, reduction in inflammation markers and T-cell activation, and recovery of gut barrier integrity. Prebiotic mixtures are also promising modulators of the immune function and gut microbiota composition. A multicenter randomized controlled trial in South Africa showed that the administration of a prebiotic/probiotic combination induced a strong bifidogenic effect on healthy HIV-exposed infants, but more data from controlled trials to endorse the routine use of probiotics in the pediatric HIV population are needed [52–55].

Upper Gastrointestinal Symptoms

Patients with HIV/AIDS, either on ART or not, frequently complain about symptoms related to upper gastrointestinal tract involvement (oral cavity, esophagus, and stomach).

Oral thrush, dysphagia, difficulty swallowing, or odynophagia may be secondary to opportunistic infections and are reported by naïve or not compliant children and adolescents, or by those who are failing ART. Feeding refusal and weight loss may be the only signs in neonates and infants.

Upper GI opportunistic infections, including Candida species, herpes simplex virus, and cytomegalovirus, are often the underlying cause of such symptoms, and their likelihood is related to the degree of immunosuppression, resulting quite common in subjects with a CD4+ count <200 cells/ul.

Thrush, appearing white-yellow, hard-to-remove plaques due to Candida infection, is a characteristic sign in young HIV/AIDS infants and children. Since oropharyngeal candidiasis and esophagitis are concomitant in 75% of cases, an upper GI endoscopy is mandatory in all severely immunosuppressed children with oral thrush to exclude distal esoph-

agus involvement, especially in patients who show loss of appetite, dysphagia, fever, or weight loss [56]. A history of oropharyngeal candidiasis or antibiotic administration (either prophylactic or therapeutic) is virtually always present in children with esophagitis. Most severe Candida infections can cause necrotizing esophagitis, bleeding, and, occasionally, esophagus perforation.

In the pre-ART era, Candida was by far the first cause of esophageal complaints, and empirical treatment with fluconazole—instead of endoscopy—was considered as the best strategy, especially in patients with oral thrush. With endoscopy being more routinely performed in HIV-infected patients, causes of esophagitis other than Candida have emerged: CMV, HSV, and idiopathic esophageal ulcers in particular. CMV esophagitis may result in severe ulceration or stenosis. Idiopathic esophageal ulcers are probably immunologically mediated, caused by HIV itself [57, 58].

Patients with HIV are more likely to have hypochlorhydria, although the reasons are still unclear. This condition predisposes to GI infections but seems to reduce the incidence of symptoms related to esophageal reflux or peptic ulceration compared to uninfected subjects. This association seems to be true also in low- to middle-income settings, despite the high prevalence of *Helicobacter pylori*. Surprisingly, the hypochlorhydria appears to be reversed by antiretroviral therapy, and peptic ulceration (and gastroesophageal reflux) may increase in HIV-infected populations receiving ART [16].

Subjects receiving ART frequently complain of nausea, dyspepsia, anorexia, or vomiting as a common side effect of antiretroviral drugs (mainly old-generation PI) [59]. Empirical treatment with proton-pump inhibitors has to be considered on a case-by-case basis in HIV-infected patients because these drugs could reduce the oral absorption of selected protease inhibitors [60]. Atypical presentation of opportunistic infections should always be considered in this population and upper endoscopy is recommended for differential diagnosis if symptoms persist. Multiple biopsies are needed since macroscopic normal appearing mucosa does not exclude opportunistic infections. However, less than 2% of adults complaining of dyspepsia and undergoing ART receive a diagnosis of opportunistic infections, with CMV as the most prevalent opportunistic agent [61]. Chronic nonspecific gastritis (mononuclear cell infiltrate) is the most common diagnosis in patients presenting with these symptoms.

Lower Gastrointestinal Symptoms

HIV infection and diarrhea are closely connected in a vicious circle encompassing undernutrition, malabsorption, impairment of immune response, and deterioration of the clinical conditions.

Diarrhea has been reported in as many as 90% HIV-positive children in Africa and 40–80% of those living in high-income countries in the pre-ART era. Parallelly, up to 25% of children accessing hospitals for diarrhea turn to be HIV infected in high-prevalence settings.

HIV infection increases the risk of diarrhea, worsening the symptoms and prolonging its duration. In a recent large study in Mozambique, among 2000 children seeking care for diarrhea, HIV-infected children showed a fivefold increased risk of moderate-to-severe diarrhea, were more frequently hospitalized, and more likely malnourished, stunted, or wasted. In this population, a seven- to tenfold higher mortality rate was reported compared to uninfected subjects presenting either with moderate-to-severe (34 vs. 5/1000 person-weeks at risk) or less severe diarrhea (5 vs. 0.5/1000 person-weeks at risk) [62].

Chronic diarrhea is a hallmark of advanced HIV disease, and several intestinal pathogens, including *Salmonella*, CMV, *Cryptosporidium*, *Mycobacterium*, and *Isospora*, are responsible for AIDS-defining conditions. However, chronic diarrhea may have multiple causes in this population, including HIV-induced enteropathy, small intestinal bacterial overgrowth, malnutrition, and antiretroviral treatment itself.

In underprivileged areas, HIV enteropathy and environmental enteropathy may overlap and the two conditions may be morphologically and functionally indistinguishable with subtle consequences, including malabsorption of micronutrients and drugs, bacterial translocation, and impaired responses to vaccines.

In the era of widespread ART, the etiology and severity of diarrhea vary significantly according to accessibility and adherence to antiretroviral treatment.

Table 18.2 reports a list of the commonest agents in HIV/AIDS children. The likelihood of opportunistic infections is linked to the severity of immunodeficiency, and 200 CD4+ cell/ul seems to be a quite reliable threshold exposing to higher or lower risk of opportunistic agents.

Cryptosporidium, *Giardia*, *Mycobacterium avium*, *Cytomegalovirus*, and ETEC have recently been confirmed as main agents of chronic diarrhea in treatment-naïve children. In children under treatment, common enteric pathogens, including viruses, or other causes of chronic diarrhea should be investigated.

Table 18.2 Main agents causing diarrhea in HIV-infected children

Bacteria	EPEC, Shigella, Salmonella, Listeria, and Mycobacteria
Viral agents	Norovirus, Cytomegalovirus, Herpes simplex, Bocavirus, Rotavirus, Adenovirus, Aichi virus, and Astrovirus.
Parasites	Cryptosporidia, Giardia, Isospora, Hookworm, Strogyloides stercoralis, and Hymenolepis nana
Fungi	Microsporidia (i.e., *Enterocytozoon bieneusi)*, Histoplasma, Candida, and Cryptococcus

Bacterial Diarrhea

The overall incidence of bacterial diarrhea in HIV-infected treatment-naïve adults is at least 100-fold greater than in the general population, and infections in HIV-infected subjects tend to be more protracted and severe than in immunocompetent individuals [63].

The rate of single bacteria found in stools of HIV-infected patients depends on the settings (rural vs. urban and high vs. low income) and the diagnostic methodology.

Campylobacter jejuni and *Salmonella* are frequently isolated in diarrheic stools of children with or without HIV infection. Both infections are usually self-limiting in otherwise healthy children, and do not require specific antibiotic treatment unless in specific conditions and clusters. HIV-positive patients are at higher risk of prolonged and severe infections from *Campylobacter jejuni* and invasive nontyphoid *Salmonellae* infections. The risk of multisite *Salmonella* infections is 300-fold increased in advanced HIV disease; hence, this condition is classified as an AIDS-defining illness.

Similarly, *E. coli*, *Shigella,* and *Clostridium* were recognized to cause more frequently diarrhea in HIV-infected patients. A large retrospective study in the United States reported *Clostridium difficile* as the most common cause of diarrhea in HIV-infected adults, accounting for more than 50% of cases [63]. In the same population *Shigella*, *Campylobacter,* and *Salmonella* were found in 14%, 13.8%, and 7.4% patients with diarrhea, respectively.

In a recent study in Kenya, typical EPEC was found in stools of HIV-infected children three times more commonly than in HIV-uninfected children, also after adjustment for confounding factors. Additionally, EPEC was identified more commonly among the immunosuppressed children [64].

Mycobacteria may cause GI infections presenting with diarrhea. Diarrhea is a relatively uncommon symptom of M. tuberculosis infection but may be more common in M. avium complex infection.

Whole stool samples and rectal swabs are both adequate for culturing typical bacteria (i.e., *Salmonella, Shigella, Campylobacter,* and *Yersinia*) and provide similar diagnostic yield. However, the diagnostic workup of HIV-infected children should include the search of Clostridium toxins and the typization of enteropathogenic *E. coli*. The use of molecular diagnostic tools may be helpful.

Bacterial diarrhea may have a severe course in HIV-infected children, and should be treated aggressively. The use of specific antibiotics should be carefully considered even in children who show a mild course of the disease, particularly in those who have a moderate-to-severe immune impairment. Some children may require empiric treatment for symptom control or prevention of the risk of extraintestinal spreading of the infection.

Viral Diarrhea

Viruses are the pathogens most frequently responsible for acute diarrhea in children, and usually have an acute and self-limiting course in immunocompetent subjects. However, viral enteropathy may be dangerous in HIV-infected children, and mainly in treatment-naive children. At least one virus was isolated in about 75% of HIV-infected children with diarrhea, compared to 65% of HIV negative, and frequently a higher viral load is detected in the stools of HIV-infected children.

Classic viral enteric pathogens include group A rotaviruses, noroviruses, astrovirus, and enteric adenovirus. More recently, emerging agents such as bocavirus and aichi virus have been considered as potential etiological agents of diarrhea. Besides, about 15% of HIV-infected children demonstrate more than one virus in the stools and without a clear relationship with intestinal symptoms.

Rotavirus is the major cause of viral diarrhea in countries where specific vaccination has not been routinely introduced. Children with HIV infection experience more severe rotavirus infections, with a higher risk of prolonged hospitalization and a higher fatality rate than non-HIV-infected children [65]. However, more recent studies in Tanzania and Brazil observed that the detection rate of rotavirus in children with acute diarrhea was higher in HIV-negative than in HIV-positive children [66].

The introduction of antirotavirus immunization is changing the epidemiology of intestinal infections in countries that promoted a large-scale implementation. However, there is evidence of a relevant variability in the immunogenicity of rotavirus vaccines across world countries. A lower immunogenicty has been observed in regions with high prevalence of HIV, such as Africa, if compared with high-income areas such as Europe of USA [67]. Although HIV infection is generally not a contraindication for immunization, high HIV prevalence in the region may result in lower rates of vaccine immunogenicity, efficacy, and population immunity.

Norovirus is fast becoming a major cause of medically attended gastroenteritis in countries with high rotavirus vaccine coverage. This agent, with a predominance of GII.4 and GII.12 genogroups, seems to be more common in HIV-infected children than HIV-negative patients and may also induce severe and chronic disease manifestations in those children [68]. A three times higher frequency of norovirus among patients with CD4+ T-lymphocyte counts <200 cells/mm^3, as well as the higher viral loads among HIV-1-seropositive children, and particularly among those more severely immunocompromised, highlights the opportunistic character of norovirus.

Comparative studies demonstrated also a higher frequency of bocavirus and adenovirus and a rare occurrence of astrovirus in seropositive children rather than healthy children.

Aichi virus, recently identified as responsible for acute diarrhea outbreaks, has been isolated in diarrheic stools of HIV-infected children with a tenfold higher frequency than those reported in HIV-negative children, suggesting the inclusion among the opportunistic pathogens infecting children with AIDS [69].

Cytomegalovirus (CMV) may act as an opportunistic enteric agent inducing severe colitis or enterocolitis, or even an intractable diarrhea syndrome in severely immunocompromised children. CMV is by far the major opportunistic etiology of colitis in HIV-infected subjects. As for other opportunistic infections, the introduction of ART significantly reduced the rate and lethality of CMV infection [70].

Clinical symptoms reported in children with CMV enteritis include chronic diarrhea, abdominal pain, and bleeding. Mucosal ulceration may sometimes result in bleeding and perforation of the large bowel. The infection of the endothelial cells and ensuing vasculitis may play a major role in the development of thrombosis, local ischemia, and ulceration of the GI mucosa. Symptomatic infection is more common and severe in children with low CD4+ counts and in those aged below 12 months. The latter may also develop a protein-losing enteropathy, with loss of albumin and immunoglobulins that further impair the child's nutritional status and immune response.

Diagnosis can be difficult because the virus may remain latent for long periods and neither serological test nor positive urine test indicates active disease. Intestinal endoscopy may show mucosal edema/erythema, hemorrhages, erosions, and ulcers; however, nearly 25% of normal gross endoscopy can have evidence of CMV infection on histopathology, with typical intranuclear and intracytoplasmic inclusion bodies [71].

In adults, CMV and other herpesviruses, as well as enteric adenovirus and bocavirus, frequently coinfect patients harboring parasites, including *Isospora belli*, *Giardia duodenalis, Strongyloides stercoralis,* and *Entamoeba histolytica/Entamoeba dispar*.

Parasitic Diarrhea

Numerous parasites cause diarrhea in HIV-infected children. The detection rate in diarrheic stools of HIV-infected children living in low-income countries varies between 24 and 57% depending on nutritional status, contact with animals, socioeconomic conditions, sanitary facilities, and access to safe water and to ART [64, 72, 73].

Either parasites with pathogenic activity in the general population (*Giardia lamblia*, *Entamoeba histolytica*, *Blastocystis hominis*, *Strongyloides stercoralis,* and other soil-transmitted helminths) or opportunistic parasites, including *Cryptosporidium parvum*, *Isospora belli, and Cyclospora cayetanensis,* may cause diarrhea in HIV-infected subjects. The spore-forming opportunistic protozoa cause intracellular infection and can lead to severe intestinal injury and prolonged diarrhea in children with impaired immunity. *Cryptosporidium* species, *E. histolytica/dispar*, *hook worm,* and *taenia* species are the intestinal parasites more frequently associated with CD4+ T-cell counts <350 cells/μμL in ART-naïve patients. The risk of opportunistic infection is almost null in children under treatment, but it is stratified according to the duration of ART (higher in the first 24–36 months) [73].

In addition to intestinal manifestation, ART-naïve children are also more prone to develop systemic symptoms related to parasite infection, such as severe anemia secondary to pathogens like hookworm*, Strogyloides stercoralis,* and *Hymenolepis nana*.

Identification of parasites may be difficult on direct microscopy and the diagnosis may be missed. The use of molecular diagnostic tools in epidemiological investigations provides new insights into species characterization and transmission pathways.

A recent study in Ethiopia used PCR-RFLP analysis of the small subunit rRNA to identify a large number of *Cryptosporidium* species and subtypes associated with different clinical manifestations in HIV-infected subjects. The two species more frequently isolated and strongly associated with diarrhea in HIV-infected children were *C. parvum* (mostly subtype IIa) and *C. hominis.* Patients with *C. hominis* or other rare species (i.e., *C. meleagridis/C. felis/C. canis,* and *C. xiaomi*) were more likely to have vomiting compared with Cryptosporidium-negative patients [74].

Differences in the geographical distribution of *C. parvum* and *C. hominis* are generally considered a reflection of differences in infection sources and transmission routes. *C. hominis* is transmitted almost exclusively among humans, whereas *C. parvum*, especially its IIa subtype family, is more likely transmitted zoonotically.

Fungal Diarrhea

Although they usually infect the upper GI tract, Candida species are frequently isolated from the stool of HIV-positive patients. Their role in determining diarrhea is still unclear since the frequency seems to be similar in HIV-infected children presenting with or without diarrhea [75]. Single reports associate Candida species infection and antibiotic-associated diarrhea [76].

Histoplasmosis that usually occurs asymptomatically in healthy children may cause disseminated infections in HIV-

infected children with variable clinical picture depending on the immunological status.

Microsporidia are obligate intracellular parasitic fungi causing chronic diarrhea, particularly among immunocompromised patients. Some species such as *Enterocytozoon bieneusi* and *Encephalocytozoon intestinalis* have been proposed as etiological agents of persistent diarrhea and failure to thrive in malnourished children. Studies in Africa (Nigeria), Asia (Malaysia), and Europe (Portugal) identified *Enterocytozoon bieneusi* as the most commonly isolated species in HIV/AIDS subjects. Children are less susceptible than adults to this kind of infection that start from the small bowel or proximal colon, causing chronic watery diarrhea and wasting, and then disseminate in most severe cases.

Noninfectious Diarrhea in HIV

Now that HIV infection is becoming a "chronic disease," at least for children and adolescents living in middle-/high-income countries with immediate and regular access to ART, other noninfectious etiologies may emerge as a differential diagnosis of chronic diarrhea, including celiac disease, inflammatory bowel diseases, or functional gastrointestinal diseases.

Usually, all HIV-infected subjects seeking care for chronic diarrhea, in the absence of an identifiable infectious cause, receive a diagnosis of "HIV enteropathy," also based on their immunological status.

There is no evidence of an increased incidence of celiac diseases in HIV-infected subjects. However, the diagnosis of celiac diseases in HIV-infected children presenting with chronic diarrhea is challenged by the possibility of false-positive tissue transglutaminase antibodies, the presence of villus atrophy on intestinal biopsy (also directly induced by HIV), and past reports of diarrhea resolution following empiric or self-administered gluten-free diets. In HIV-infected subjects, HLA typing may be essential before introducing a gluten-free diet [77–79].

Some clinical and radiological findings reported in HIV-infected subjects may mask an inflammatory bowel disease (IBD), such as severe intestinal infections with mucosal ulceration or perforation (i.e., CMV, herpes, and viruses) or the presence of bowel wall thickening (i.e., IRIS or malignancies). However, the risk of inflammatory bowel diseases seems to be similar in HIV-infected and noninfected subjects. Theoretically, HIV-related CD4+ lymphocytes depletion may be beneficial for patients with inflammatory bowel diseases. In small case series, HIV status was related to Crohn's disease remission and with a lower probability of IBD relapse [80, 81].

Pancreas and Liver in HIV-Infected Children

Exocrine pancreatic dysfunction is frequently associated with digestive dysfunction in advanced HIV. A reduction in fecal levels of pancreatic elastase and chymotrypsin has been found in up to one-third of HIV-infected children. Clinical manifestations may not be evident, but pancreatic insufficiency (fecal elastase <200 μg/g) can lead to fat and micronutrient malabsorption and should be ruled out in any patient with chronic diarrhea/steatorrhea. Selected cases may benefit from pancreatic enzyme supplementation [82, 83]. Pancreatitis may be an unusual (<2%) but serious drug adverse effect, mainly with selected nucleoside analog reverse-transcriptase inhibitors (Table 18.1) [15]. Endocrine pancreatic function is not frequent, but insulin resistance mostly secondary to dyslipidemia is seen in up to 10% children on ART and is associated with a higher body mass index but not with visible lipodystrophy [84, 85].

Liver disease is a common cause of morbidity and mortality among people living with HIV. There are several mechanisms of HIV-associated liver injury, including direct viral damage, opportunistic infections, ART-related hepatotoxicity, NAFLD, and HBV/HCV coinfection, although advancements in HIV and HCV treatment have dramatically changed the etiology and prognosis of chronic liver disease.

Liver toxicity is also a rare but potentially serious adverse event associated with ART (Table 18.1), with variable frequency according to antiretroviral regimens. Integrase inhibitors have minimal impact on liver function.

Noninvasive tools for liver function assessment are reducing the need for liver biopsy, which remains the gold standard, and are useful indicators to screen for fibrosis and cirrhosis in adults. AST-to-platelet ratio index (APRI) and fibrosis-4 (FIB-4) are, respectively, used and their role in pediatrics is promising [7, 14].

Data from a large cohort of HIV-infected children demonstrated a global incidence of liver disease at 5.8% pre-ART, and a low incidence of hypertransaminasemia post-ART initiation (less than 2/1.000 cases) in those with normal liver function at baseline. Hepatic dysfunction is more frequent in hepatitis B or C coinfected children, among whom more than half has an APRI score suggestive of fibrosis [14].

However, isolated hepatomegaly with normal or slightly raised transaminases (ALT<3 × UNL) is a relatively common finding in HIV-monoinfected children, which could be associated with nutritional deficiencies or NAFLD. Approximately 10% of children with persistent liver enzymes elevation may have underlying NAFLD and fibrosis; hence, periodic noninvasive liver assessment including liver ultrasonography and fibroscan is recommended in this subgroup [86].

Vaccination programs and newborn prophylaxis have reduced the burden of HBV in developed countries, but the global prevalence of HIV-HBV coinfection is still estimated at 1–49% according to the examined setting. Children living with HIV and HBV are at greater risk of hepatic disease and fibrosis, and the widespread use of lamivudine in ART favors the development of HBV resistance mutations. It is, therefore, essential to evaluate the HBV serostatus before the initiation of ART, and, in case of coinfection, prefer a lamivudine-sparing regimen or to include anti-HBV drugs for those who need HBV treatment [87].

HCV infection as well may be more severe in HIV-infected children than in HIV-negative individuals, as more than a quarter present with advanced fibrosis in late adolescence. Direct-acting antivirals are a safe and effective option for HCV treatment in vertically infected HIV young adults, but more data are needed for their use in adolescents and children [88].

HIV-Associated GI Malignancies

The risk of developing malignancies in HIV children is mostly related to the degree of immunosuppression and exposure to oncogenic viruses. Early ART has overall reduced the incidence of malignancies, but worldwide people living with HIV remain at higher risk. In recent estimates from a South African pediatric cohort, the most frequent cancers were the AIDS-defining Kaposi Sarcoma and non-Hodgkin lymphomas with incidence rates of 34 and 31/100,000 children per year [89].

Visceral Kaposi Sarcoma (KS) and non-Hodgkin intestinal lymphomas are HIV-associated GI malignancies and may present with nonspecific GI symptoms.

Although both are associated with the oncogenic human herpesvirus-8, HIV-associated (or epidemic) KS is a separate epidemiological entity from African (or endemic) KS, which is an aggressive tumor that affects HIV-negative children of endemic African countries and shows a predominant lymph nodal involvement.

HIV-associated KS is an AIDS-defining condition that can involve the GI tract and it is often a challenging diagnosis, especially in resource-limited settings, as it requires a high index of suspicion and availability of digestive endoscopy services. Intestinal KS may present with ascites, diarrhea, rectal bleeding, and sometimes intestinal obstruction. Upper GI KS can present with dysphagia [90].

Burkitt and Burkitt-like lymphomas and diffuse large-cell lymphomas are the subtypes that most likely affect the GI tract in HIV-infected patients and can present as bulky masses that cause intestinal obstruction [91, 92].

Nutritional Challenges in Children Growing with HIV

Many factors impact on the nutritional status of HIV-infected children, including HIV-related malabsorption, antiviral treatment, and opportunistic infections. Malnutrition enteropathy and HIV enteropathy are phenotypically indistinguishable, and they frequently overlap in clinical settings.

In HIV enteropathy, failure to thrive is usually the consequence of sugar and fat malabsorption [93]. Common micronutrient deficiencies, not exclusive of advanced disease, include iron, folate, B12, and vitamins A and E. Severe vitamin A and zinc deficiencies may increase the risk of intestinal and extraintestinal infections.

Early ART improves nutritional outcomes, although the risk of wasting in the first 5 years of life remains overall higher in HIV-infected children compared to noninfected, and poor growth correlates with delay in sexual maturation [94, 95].

Hence, a regular nutritional follow-up is recommended, particularly in resource-limited settings, and nutritional interventions may be best delivered during the first years of ART to ensure a stable growth after the catch-up phase [96]. Caloric intake should be determined quantitatively because the infection and its complications are associated with increased energy expenditure. Besides, it should be considered that several heterogeneous conditions—ranging from oral/esophageal candidiasis and ageusia, to anorexia related to ART or psychological status—can reduce food intake [12].

On the other side, the global burden of metabolic syndrome does not spare perinatally HIV-infected adolescents in both high- and low-income countries, who have higher rates of insulin resistance and dyslipidemia and may be at higher risk of pathological weight gain since the introduction of integrase inhibitors [97, 98]. These findings point toward the usefulness of an integrated nutritional and metabolic screening in HIV-infected youths—including homeostasis model assessment of insulin resistance (HOMA-IR), lipid panel, and anthropometric measurements—to detect at-risk patients who may benefit from early interventions [84, 99].

HIV and Malnutrition in Resource-Limited Settings

HIV and undernutrition are deeply connected and represent a major health challenge in most resource-limited settings. Severe acute malnutrition (SAM) is often the first AIDS-defining illness and the majority of children are not on ART at the time of admission to a nutritional rehabilitation unit.

Weight loss and SAM are also a common problem in children who are failing or nonadherent to ART. Overall, children with SAM and HIV infection have greater mortality rates (up to 30%) and more than 10% need readmission after discharge. Profuse diarrhea is one of the major drivers of morbidity and mortality in this setting [16, 100].

Currently, the nutritional management for HIV-infected children with SAM is the same as the noninfected, but there is room for the implementation of the optimal feeding regimen for such fragile patients. In the outpatient setting, the use of ready-to-use therapeutic foods for uncomplicated SAM is recognized as a useful measure to halt progression to complicated SAM [101, 102].

Vitamin A administered periodically reduces mortality. Selenium may affect positively intestinal barrier integrity and reduce systemic inflammation [103]. Iron supplementation in HIV-infected children is beneficial on immune and hematological parameters, but routine iron supplementation has not been endorsed as it increases the risk of malaria [104]. Similarly, there is discordant evidence on the use of zinc. In conclusion, despite the existing studies, there is no conclusive evidence on routine use of micronutrient supplements in nutritional programs for children living with HIV as the benefits need to be weighted in randomized controlled trials [105, 106].

Finally, several factors have to be considered when starting on ART a child with SAM, including the risk of IRIS and the high prevalence of TB in this setting.

The Spectrum of Functional GI Disorders

19

Heidi E. Gamboa and Manu R. Sood

Introduction

Functional Gastrointestinal Disorders (FGID), also known as Disorders of Gut-Brain Interaction (DGBI), can manifest with a wide variety of symptoms caused by abnormalities within gastrointestinal motility, visceral hypersensitivity, altered mucosal and immune function, altered gut microbiota, and central nervous system gut afferent input processing. Gut dysfunction has been closely linked to emotional wellbeing and life stressors. Traditional Buddhist thinkers and Ancient Greeks Plato, Aristotle, and Hippocrates first postulated the concept that the mind and body function as singularity, referred to as holism from the Greek work *holos* or whole. In the fourth century, a paradigm shift occurred which shifted from holism to biomedicine. In 1637, Rene Descartes proposed the separation from mind and body known as dualism; this concept has dramatically affected the way we evaluate patients in modern medicine [1]. Ignorance about the biopsychosocial model of health can lead to dismissing illness without pathology as trivial or behavioral and some physicians find it difficult to empathize with their patients [2]. The concept of holism started to remerge in the nineteenth century. In 1833, William Beaumont demonstrated the association of emotions such as anger and fear with gastric mucosal morphology and function [3]. There was a surge of studies reporting the effects of emotion on gastrointestinal function (motility and sensory) in the twentieth century. These data provided evidence that the gut is physiologically responsive to external stimulation and subsequent emotional responses.

Introduction of the biopsychosocial model in the late 1970s set the stage for further research and understanding of FGID. In 1977, George Engel, an internist and psychoanalyst, challenged the tradition biomedical approach which looked at disease to be "fully accounted for by deviations from the normal of measurable biological variables" and proposed a new holistic theory that illness results in the combination of biological, psychological, and social components interacting at variable degrees [3–5]. The combination of these components determines disease severity (Fig. 19.1) [6]. This biopsychosocial model allowed better understanding of human illness by integrating biomedical thought and clinical observations, provided a framework to evaluate biomedical processes and how they are affected by psychosocial factors leading to a unique patient experience, and lastly it created a multidisciplinary team approach to assessing GI conditions by including a biopsychosocial assessment. This changed research outcomes dramatically, no longer focusing solely on morbidity and mortality but rather health-related quality of life, health care use, daily function, and symptom severity.

The complex interaction between the brain, enteric nervous system, endocrine, and the immune system, which helps to regulate the bowel function, is called the brain gut or more recently the microbiome brain-gut axis [7]. The brain-gut axis is comprised of the enteric nervous system, which is broadly organized into the myenteric and submucosal plexuses and communicates with the brain through the neural pathways, as well as the immune and endocrine systems [8]. The sympathetic and parasympathetic branches of the autonomic nervous system (ANS) connect emotional arousal and central autonomic brain circuits with the enteric nervous system. This extensive neural network innervates visceral smooth muscles and other end-organs within the GI tract and regulates the GI secretory, sensory, motor, endocrine, and immune functions. This complex network communicates information from the emotional and cognitive centers of the brain via neurotransmitters to the gastrointestinal tract and vice versa [9]. However, the bowel function can be modulated by intrinsic neural circuits within the wall of the gastrointestinal tract bypassing the central nervous system via the myenteric and

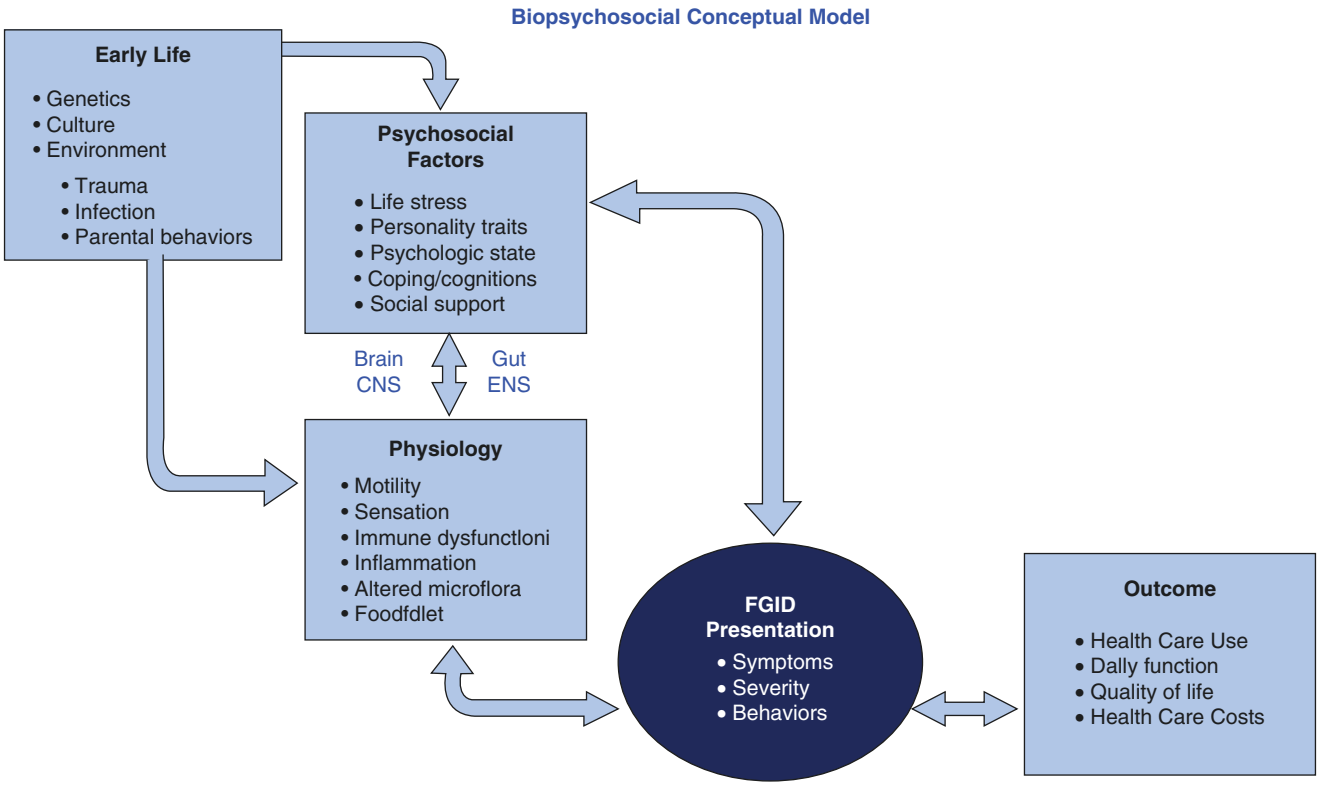

Fig. 19.1 A biopsychosocial conceptualization of pathogenesis, clinical experience, and effects of functional GI disorders. There is a relationship between early life factors (genetics, culture, and environment) that can influence the psychosocial milieu of the individual, their physiological functioning, as well as their mutual interaction (brain-gut axis). These factors influence the severity of the clinical presentation of the disorder and the clinical outcome. (Reproduced from Drossman et al. 1998 with permission from the Rome Foundation) [3]

submucosal plexuses of the enteric nervous system and other reflex circuits such as the gastrocolic and ileocolic reflexes. Gut luminal contents including the microbiome and immune system participate in this autoregulation. This complex neural network in conjunction with endocrine and immune system maintains gut and body homeostasis to ensure optimal bowel function for digestion and absorption of nutrients and elimination of waste. Symptoms can result from the disruption of gut function and homeostasis triggered by food (lactose and food intolerance), changes in gut microbiome-immune interaction (postinfectious IBS), or autonomic nervous system disease (diabetic gastroparesis) [7].

Disorders of the autonomic nervous system, such as postural orthostatic tachycardia syndrome (POTS) and diabetic neuropathy, can also manifest with gastrointestinal symptoms. These disorders are commonly associated with a broad spectrum of symptoms, for example, headaches, nausea, vomiting, and pain [10–12]. In addition to the gastrointestinal tract, the ANS also regulates cardiac function and the heart rate variability has been proposed as one of the objective measures of balance between the parasympathetic-sympathetic arms of the ANS. Gastrointestinal symptoms of autonomic dysfunction can be reproduced in the upright position with resolution of symptoms once the child is supine [13]. Frequently, patients with POTS or orthostatic intolerance may have overlapping gastrointestinal symptoms not produced by an orthostatic challenge. Orthostatic disorders are commonly associated with other comorbid conditions such as migraine headaches, fibromyalgia, chronic fatigue, nausea, sleep disorders, and abdominal pain [10]. It is important to differentiate symptoms that present with change in position versus those that are present irrespective of body position, as this will determine the treatment of choice.

Biopsychosocial Model of Functional Gastrointestinal Disorders

The main focus of the biopsychosocial model is the concept that illness is not a result of a single factor but rather a combination of factors involving early life (genetics, culture, and environment), psychosocial factors, and physiology which later impacts the interactions of the brain-gut (central nervous system-enteric nervous system) axis [7, 14, 15]. It is important that each aspect of the biopsychosocial model is addressed and treated. For example, if a patient presents with pain associated with IBS but also has depression and anxiety and a history of abuse, each of these areas can potentially

lead to the perception of pain and the patient's overall experience of illness [16]. The severity of symptoms affects the clinical outcome and vice versa. It is important to identify the severity of symptoms and limitations in daily functioning in order to determine an appropriate treatment plan. Equally important is the response from the family to the child's complaints, which may amplify the patient's symptoms and illness experience [17, 18]. When a physician validates patient's symptoms, engages them in conversation, and provides empathy, it not only builds trust but also reduces symptom severity and health care seeking behavior [19]. In the biomedical approach, both physicians and patients were in search of an organic disease as a cause for illness leading to increased health care costs due to referrals, tests, medications, and possible surgeries. This can lead to increased anxiety, frustration, and dissatisfaction among both the physician and patient. Breaking this cycle and approaching patients with DGBI by a biopsychosocial model is imperative to improving their quality of life and health care outcomes.

Genetic susceptibility influences future behaviors and experience of illness. DGBI can result from polymorphisms affecting the motor function, membrane permeability, and visceral sensitivity, which has been reported in patients with IBS [20, 21]. In addition, stress may affect epigenetic expression of these genes leading to visceral hypersensitivity and other motor function abnormalities in DGBI [22].

Culture plays an important role in the child's expectation and perception of their illness. Fitting in with the cultural and society norms and functioning as a meaningful contributor to society is critical to psychological wellbeing of an individual. Based on cultural norms and influences, this determines whether a patient seeks medical attention, is self-treated, or ignored. For example, in Mexico diarrhea is often not seen as an illness requiring medical attention since it is so common [23]. In Arapesh, pregnant women did not report morning sickness because they did not believe the child existed until after birth [24]. Even expression of pain varies among cultures [25]. The role of a physician is also very important within cultures, where some cultures accept patient-centered care as a norm with shared decision-making, where other cultures see this as a sign of weakness or lack of knowledge on behalf of the physician [26]. It is critical to understand the patient's belief system and set of cultural norms in order to involve them in decision-making.

Early life events involving feeding and elimination are often the first experiences in a child's life of confrontation. According to the psychoanalytic theory, the child's early innate impulses to eat and defecate meet external confrontation and naturally, they are prone to resolution of these conflicts. With time, they will learn to comply or resist environmental control of these functions by refusing to eat, defecate, or acting out. The behaviors learned during this time frame are pivotal in the development of autonomy, learning right from wrong, and adopting socially acceptable behaviors such as bowel functioning. Functional defecation disorders, for example, infant dyschezia and learned feeding disorders can develop due to confrontation experienced during early life [27]. Other children will develop abnormal patterns of defecation out of defiance or control leading to fecal incontinence and pain as toddlers.

Unresolved stress due to traumatic life events or daily life stressors can impact the way an individual experiences their illness in various ways (1) producing psychophysiological effects on gastrointestinal motor and sensory functioning, (2) amplifying symptoms due to brain processing of afferent gut input such as hypervigilance, and (3) developing poor coping skills and health care seeking [28–30]. It is important to recognize chronic and daily life stressors when establishing a treatment plan, as these events can lead to poor outcomes and decreased quality of life. A history of physical or sexual abuse has been linked to symptom severity and outcomes. Inflexibility and inability to recover or adapt to adverse early life events are possible mechanisms for increased risk of DGBI [31]. In cases where individuals have developed maladaptive behaviors, behavioral intervention is needed to correct these behaviors and change the way individuals view their illness [29].

Parental beliefs and behaviors through a child's life can have a positive or negative impact on how a child experiences illness. A child of a mother who reinforces illness behavior will have more reported severe abdominal pain and school absences than a child whose mother does not reinforce this behavior [17]. In a recent clinical trial, children reported more pain when parents showed sympathetic response to their complaints, compared to parents who ignored the complaints [32]. In addition, children's abdominal pain has been shown to be associated with parental anxiety and depression [33]. A child learns how to cope with various situations in life based on modeling their parent's response to their own experiences, the same way that parent's personality traits may also influence illness experience. For example, a parent who excessively worries or catastrophizes may also reward a child's somatic complaints reinforcing this illness behavior.

A child's psychological status may influence gastrointestinal physiology, leading to the development of a DGBI and its symptomatic and behavioral expression influencing outcomes. Psychological factors can be divided into either longstanding, or trait, features such as personality or psychiatric disorders and short-term, or state, features such as psychological distress. Though a patient's symptoms of anxiety and depression may not meet the criteria based on current psychiatric classification systems, this does not discredit their potential impact on functional gastrointestinal symptoms. Comorbid depression has been linked to poor outcomes in patients with DGBI, including increased health

care utilization, decreased functioning, poor treatment compliance, and overall poor quality of life [29]. Anxiety leads to increased autonomic arousal, which can interfere with gastrointestinal motility and sensitivity leading to hypervigilance and decreased pain tolerance [34]. Recognizing these conditions and familiarizing oneself with psychological and psychopharmacologic interventions can affect the long-term outcome of patients with DGBI [35, 36].

Approach to Patients with Disorders of Gut-Brain Interaction

A careful consideration of the biopsychosocial model in approaching patients with DGBI is critical in patient satisfaction and outcomes. Effective communication is an essential part of developing a trusting patient-physician relationship. Overreliance on technology to the detriment of effective communication can be counterproductive. Focusing on the four main principles of effective communication (active listening, addressing the patients' agenda, providing empathy, and validation of patients' beliefs and concerns) aids in improving diagnosis and clinical decision-making by creating a trusting environment in which patients feel comfortable sharing both their clinical and psychosocial information [37, 38]. This creates a holistic view of the patients' symptoms, allowing a provider to see the full impact it has on their health care quality of life. Effective communication allows patients to collaborate in their treatment plan through shared decision-making, improving patient compliance, and motivating them to share the responsibility of their disease burden. Effective verbal and nonverbal communication can decrease overall time spent on making a positive diagnosis by forming a trusting relationship where the patient feels comfortable sharing personal information and participating in shared decision-making. It allows the patient to feel heard, sharing their expectations and goals for the encounter, allowing for improved outcomes for the patient by reducing symptom severity, emotional distress, improves satisfaction and coping, improves adherence to treatment and decreased overall health care costs. For the provider, effective communication skills training has been shown to decrease emotional exhaustion and burnout. The provider-patient relationship is the most commonly reported indicator for physician satisfaction [39]. The Rome Foundation has made efforts to improve education for medical trainees by offering free study guides to improve communication skills (https://romedross.video/2YphMDd) and for self-learning educational videos (https://romedross.video/2KPTYzC). Table 19.1 is a list of verbal and nonverbal methods that can be applied to improve patient-provider communication [37]. In order to

Table 19.1 Verbal and nonverbal behaviors affecting communication

Behavior	Facilitates	Inhibits
Nonverbal		
Clinical environment	Private, comfortable	Noisy, physical barriers
Eye contact	Frequent	Infrequent or constant
Listening	Active listening—questions relate to what the patient says	Distracted or preoccupied (e.g., typing)
Body posture	Direct, open, relaxed	Body turned, arms folded
Head nodding	Well time	Infrequent, excessive
Body proximity	Close enough to touch	Too close or too distant
Facial expression	Shows interest and understanding	Preoccupation, boredom, disapproval
Voice	Gentle tone	Harsh, rushed
Touching	Helpful if well timed and used to communicate empathy	Insincere in inappropriate or not properly timed
Synchrony (arms, legs)	Concordant	Discordant
Verbal		
Question forms	Open ended to generate hypothesis	Rigid or stereotyped
	Closed ended to test hypothesis	Multiple choice or leading questions ("You didn't… did you?"
	Use of patient's words	Use of unfamiliar words or jargon
	Facilitates patient discussion by "echoing" or affirmative gestures	Interruptions, undue control of conversation
	Uses summarizing statements	Not done
Question/Interview style	Nonjudgmental	Judgmental
	Follows the lead of patient's prior comments (patient centered)	Follows own preset agenda or style
	Use of narrative thread	Unorganized questioning
	Appropriate use of silence	Interruptions or too much silence
	Appropriate reassurance and encouragement	Premature or unwarranted reassurance or encouragement
	Communicated empathy	Not provided or not sincere
Recommendations	Elicits feedback and negotiates	No feedback, directly states views
Asks/provides medical information	As appropriate to the clinical issues	Too many biomedical questions and too detailed information

(continued)

Table 19.1 (continued)

Behavior	Facilitates	Inhibits
Asks/provides psychosocial information	Elicits in a sensitive and nonthreatening manner	Ignores psychosocial data or asks intrusive or probing questions
Humor	When appropriate and facilitative	None or inappropriate humor

Permission from the Rome Foundation [37]

Table 19.2 Rome IV Foundation 12-step approach to patients with DGBI

1. Improve patient satisfaction and engage the patient in the visit through verbal and nonverbal communication
2. Obtain a history through active listening and a non-judgmental, patient centered interview
3. Establish patient expectations and reason for the visit
4. Well-administered physical exam and directed investigations
5. Determine what the patients understands as the underlying cause of their condition and concerns regarding outcomes
6. Identify patient understanding of their symptoms and provide an explanation taking the patients beliefs into consideration
7. Reconcile patients' expectations on improvement and the provider's ability to help
8. Explain how stressors can impact symptoms consistent with patients' belief system
9. Set boundaries
10. Shared decision-making
11. Make treatment recommendations consistent with patient interests and beliefs
12. Establish long-term relationship with patient and primary care provider

Adapted from Drossman et al. 2016 [3]

improve patient satisfaction, adherence to treatment, and outcomes, the Rome IV Foundation created a 12-step approach to building patient-physician relationships with patients with DGBI (Table 19.2) [3].

Physical Exam

The physical exam is a rite of passage for medical professionals. The significance of a physical exam is more profound than simply the structure of the human body [40]. The human body embodies not only bones and organs but is a symbol of history, culture, and politics. The concept of embodiment rejects mind/body dualism and looks at the body as a whole situated in society to better understand how illness and pain further defines how an individual lives their human experience [40, 41]. The role of the physician in a white coat and the patient donning a gown signifies a power imbalance, allowing the physician to lie his/her hands on the body implies vulnerability and trust on behalf of the patient. These actions must be done attentively and compassionately to preserve the trust and respect of the patient and further deepen the patient-provider relationship.

The role of the physical exam is not only to diagnose a specific problem but may have a positive or negative impact on the patient depending on how it is performed. Studies completed on the placebo effect have demonstrated that it is not only the pill that is responsible for the neurobiological effects on the patient but the ritual surrounding the patient-provider encounters including positive expectations [42]. On the other hand, there can be a nocebo effect, where negative expectations may have an adverse effect on the patient [43]. Taking into consideration the placebo and nocebo effects, a physical exam administered with warmth and empathy can have a positive impact on the patient and aid in building a stronger patient-provider relationship. This can also lead to increased satisfaction and meaningfulness in the provider's practice.

Symptom-Based Approach to Functional Gastrointestinal Disorders

Over the past 30 years, the Rome Foundation has forged a path for research on FGID and developed symptom-based criteria to diagnose FGID. The Foundation has emphasized that in order to advance the field of FGID, we need to address the following: (1) the term "functional gastrointestinal disorders" lacked precision and carries some degree of stigma. (2) The diagnostic criteria are not practical in the clinical setting and lack meaningful subsets of diagnoses to identify physiological biomarkers that may lead to targeted treatment options. (3) The degree to which psychological comorbidities impact the severity of the condition, degree of disability, and centrally mediated treatment options was unclear. (4) Lack of investigative pathways to determine proper diagnostic testing based on severity and disability prior to implementing the diagnostic criteria. (5) Lack of cultural diversity in knowledge acquisition. (6) Multiple changes were made to the Rome IV diagnostic criteria released in 2016 to address previously recognized limitations including removing the term "functional" when not needed to improve specificity and decrease potential stigma associated with these conditions.

The current Rome IV diagnostic criteria are based on symptoms rather than physiological criteria, which makes them more practical for clinical use. The disorders are classified into anatomic regions, with pediatric DGBI further categorized into neonate/toddler and child/adolescent DGBI (Table 19.3) [6]. The presentation of DGBI is dependent on the age and stage of development. Functional symptoms of childhood may accompany normal development or may arise from abnormal internal or external stimuli such as the retention of feces in the rectum due to a history of painful bowel movements, which leads to maladaptive behavioral responses.

One of the limitations of using symptom-based diagnostic criteria in pediatrics is the difficulty in getting an accurate

Table 19.3 Functional GI disorders: Neonate/toddler and child/adolescent

Functional nausea and vomiting disorders
Infant regurgitation[a]
Cyclic vomiting syndrome (CVS)
Functional nausea and functional vomiting
Functional nausea
Functional vomiting
Rumination syndrome
Aerophagia
Functional abdominal pain disorders
Infant Colic[a]
Functional Dyspepsia
Postprandial distress syndrome
Epigastric pain syndrome
Irritable bowel syndrome (IBS)
IBS with predominant constipation
IBS with predominant diarrhea
IBS with mixed bowel habits
IBS unclassified
Abdominal migraine
Functional abdominal pain – NOS
Functional defecation disorders
Functional diarrhea[a]
Infant dyschezia[a]
Functional constipation
Non-retentive fecal incontinence

[a]Conditions found only in neonates and toddlers

description of the symptoms and associated triggers, especially in young children. Further, the Rome criteria alone do not address the psychological impact on illness behavior, functional disability, and severity of disease, which influence treatment and outcomes.

Prevalence

Functional gastrointestinal disorders are common disorders among children and adolescents. In a large-scale prevalence study of US children ages 4–18 years, 23.1% of the children qualified for at least one DGBI. The most common DGBI were functional constipation and abdominal migraine. Children who met the criteria for DGBI have lower quality-of-life scores than those without a DGBI. Children were also more likely to have a DGBI, if the parent also had a DGBI[44].

Functional Nausea and Vomiting Disorders

There are a spectrum of disorders that fall under this category, including cyclic vomiting syndrome (CVS) and abdominal migraines (see Chap. 28). In chronic functional nausea, the bothersome symptom is nausea, which occurs at least twice weekly for a minimum of 2 months. The symptom is generally not associated with meals or vomiting. Functional nausea can occur in conjunction with other pain-predominant DGBI. Recent data indicate a high number of comorbidities and psychosocial disability [45]. Autonomic disorders, such as POTS, are frequently associated with refractory nausea, particularly in adolescent females [10]. Family history of migraine is commonly reported. Based on clinical presentation, predominant symptoms, and severity of disability, a clinician can determine the appropriate diagnostic and treatment plan. Studies have shown that extensive diagnostic workup has a low yield in the absence of red flags [46]. With a detailed history and physical exam, diagnosis may be made prior to the recommended time frame in the Rome criteria. It is important to consider additional etiologies, which may mimic these conditions such as intestinal malrotation and ureteropelvic junction obstruction [47–50]. Treatment is phenotype specific. Although pediatric data are sparse, empiric therapy with tricyclic antidepressants and cyproheptadine at similar doses as used for CVS prophylaxis is generally first-line therapy (see Chap. 28). Other migraine agents and anticonvulsants, such as topiramate or valproic acid, can be considered, especially in refractory cases [51].

Functional Abdominal Pain Disorders

Functional abdominal pain disorders (FAPD) can be subclassified into functional dyspepsia, irritable bowel syndrome (IBS), abdominal migraine, and functional abdominal pain – not otherwise specified (FAP-NOS) depending on specific details regarding pain location, severity, quality, and associated symptoms (Table 19.3). It is important to identify any red flags such as unintentional weight loss, blood in the stools, persistent right upper or lower abdominal pain, persistent vomiting, dysphagia, odynophagia, arthritis, family history of inflammatory bowel disease, or nocturnal diarrhea which may prompt additional work or endoscopy evaluation.

Since varied factors can contribute to the development and progression of FAPD, the management of these disorders can often involve multiple treatments and should be tailored for individual patient needs based on the severity and duration of their symptoms. Management begins with a thoughtful discussion of the diagnosis and treatment options with the family and the child. The biopsychosocial model of FAPD development and tailoring treatment strategies to the individual child are important. Dietary triggers should be identified and eliminated, and cognitive behavioral therapy (CBT) has been shown to be very effective [52]. Four types of psychotherapies have been identified to be the most beneficial for patients with DGBI: cognitive behavioral therapy, psychodynamic interpersonal therapy, mindfulness/acceptance-based therapy, and gut-directed hypnotherapy [53–55].

Mild Symptoms

Patients with minor symptoms, which are infrequent, not affecting daily activities, causing psychological distress, or leading to increased visits to the doctor's office, can be managed by education, reassurance, and diet. They tend to have less psychiatric comorbidities and a better quality of life. Supplements such as peppermint oil or herbal combination preparation STW 5 (Iberogast®) have been shown to improve abdominal pain in patients with IBS and functional dyspepsia [56, 57]. A food diary may be helpful for patients to identify certain triggers leading to worse symptoms.

Moderate Symptoms

Patients who have intermittent disruptions in their daily lives, missing occasional school days, other activities, and a more frequent symptom profile with poorer quality of life require closer follow-up of symptoms and monitoring of psychological stressors. These patients would benefit from keeping a symptom diary for 1–2 weeks and associated triggers. Pharmacotherapy should be directed at the predominant symptom causing the most disruption in daily life. Asking the patient, "Of all the symptoms we discussed today, which one is the most bothersome?" is very helpful in improving patient satisfaction and outcomes. Psychological treatment should be utilized in patients who identify specific stress triggers and who are motivated to participate. Multiple therapies have been shown to decrease anxiety and improve quality-of-life measures such as cognitive behavioral therapy, mindfulness, meditation, and relaxation [34].

Severe Symptoms

Patients with severe symptoms of DGBI are best cared for by a multidisciplinary team involving psychiatry, psychology, nutrition, and gastroenterology and pain management. In addition to the gastrointestinal symptoms, these patients have significant psychological comorbidities and dysfunction in daily life and poor quality of life. They have increased psychological distress due to chronicity of their symptoms and often have comorbid psychiatric conditions such as depression and anxiety. These patients may suffer from early childhood trauma, decreased coping skills, and a poor social support system. In their previous health care experience, they may have felt stigmatized with their condition being told, "It's all in their head" and deny any potential involvement of psychosocial factors often refusing psychological and psychiatric treatments. They often seek multiple opinions with unrealistic expectations of a cure for their symptoms. Establishing a trusting patient-provider relationship is the foundation for treatment of these patients and can prevent "doctor shopping" behavior. Patients must understand that the provider is listening to their concerns and is addressing their complaints without bias. The Rome IV 12-step approach to patients withDGBI addresses the main principles in establishing a solid patient-provider relationship while improving patient satisfaction and outcomes. In addition to the 12- step approach, providers should perform diagnostic and therapeutic interventions based on objective findings rather than at the request of the patient. Predominant psychiatric comorbidities (anxiety and depression) in need of treatment should be identified and treated appropriately. The Rome IV Foundation working team published a guide on Neuromodulators for Functional Gastrointestinal Disorders (Disorders of Gut-Brain Interaction) for treatment of psychiatric comorbidities and chronic pain syndromes. See Fig. 19.2 for pharmacological treatment options [36].

Gastrointestinal tract activity is mediated through neurotransmitters and neuropeptides, which are found in both the central nervous system and the intestine. These substances can impact both human behavior and GI function. It is important to identify which areas of the brain-gut access are most affected to guide the treatment plan. As pain becomes more severe, patients may develop additional comorbidities as they suffer from chronic pain leading to the need for additional psychological and behavioral interventions. Acetylcholine is the primary excitatory neurotransmitter in the parasympathetic nervous system that drives motility in the gastrointestinal tract. Disturbances in acetylcholine secretion and metabolism can have a major impact on motility and secretion in the gut leading to gastroparesis and constipation. Sympathetic division of the autonomic nervous system participates in neuromodulation via serotonin, norepinephrine, and dopamine. They act primarily by inhibiting activity in the gastrointestinal tract by decreasing secretions, motility, and sphincter relaxation. Modulation of the serotoninergic system has been shown to affect the pain threshold in patients with DGBI.

Functional Defecation Disorders

Functional defecation disorders are the most commonly reported DGBI. Functional constipation can present as early at the neonatal period (see Chap. 27). Recognizing this condition and treating appropriately has major health care implications. In a Dutch tertiary hospital, one-fourth of children diagnosed with functional constipation continued to experience symptoms into adulthood. Risk factors for poor clinical outcomes in adulthood were identified, including late referral to a specialized clinic after failing first-line therapies [58]. Consider other conditions that may mimic functional constipation such as ultrashort segment Hirschprung disease and

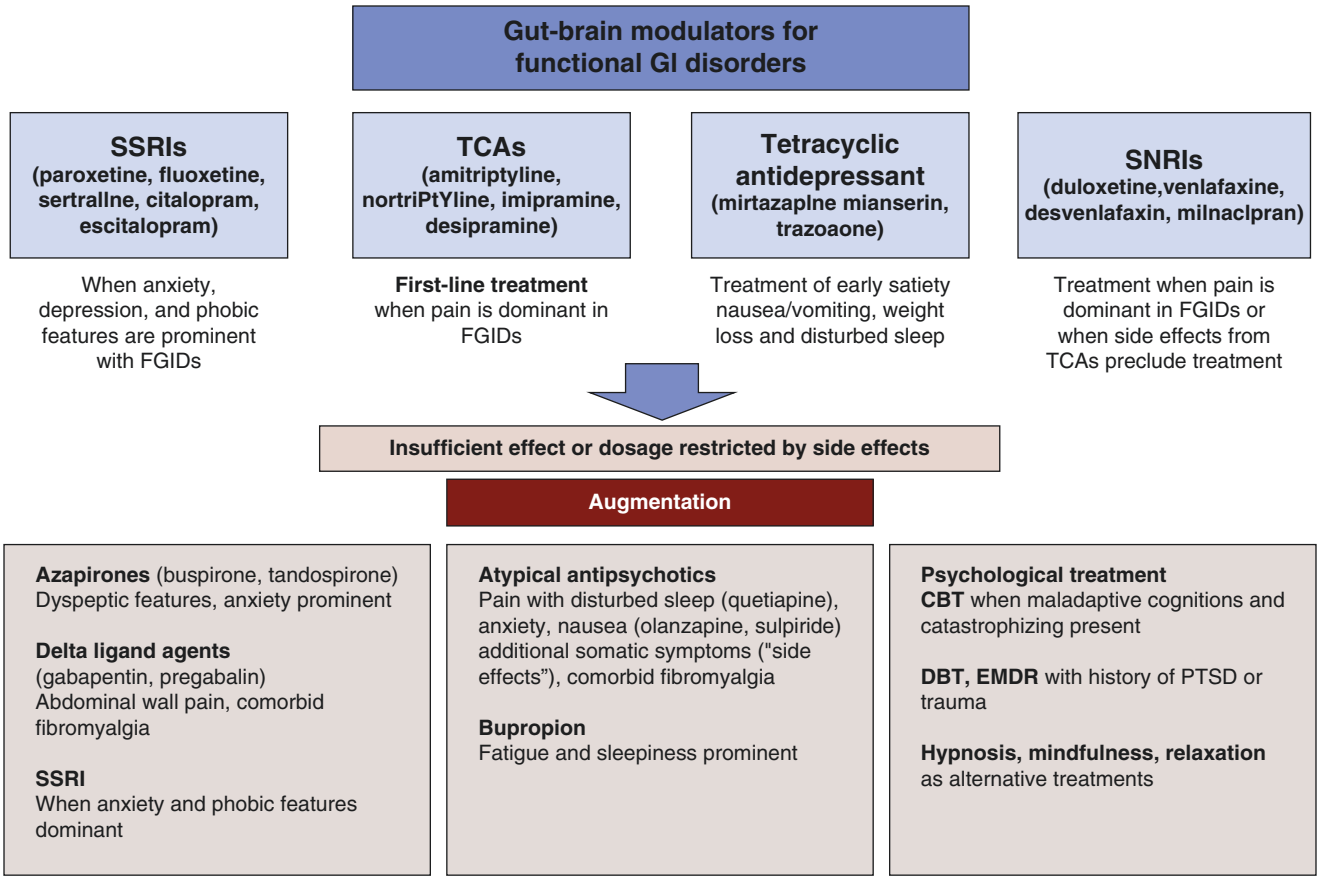

Fig. 19.2 Summary of the clinical characteristics that can be considered when selecting gut-brain neuromodulating pharmacotherapy to treat FGID. Those drugs in the upper part of the figure can be considered as first-line options. In the lower part of the figure, the pharmacologic options most often used to augment treatment effects are depicted, as well as some nonpharmacologic treatment alternatives. (DBT—dialectical behavior therapy, CBT—cognitive behavioral therapy, EMDR—eye movement desensitization and reprocessing) (Reproduced from Drossman et al. 2018 with permission from the Rome Foundation) [36]

anal stenosis in a child who presents in infancy with constipation. In addition, it is necessary to consider inflammatory conditions in toddlers who present with nonretentive fecal incontinence.

In constipation predominant irritable bowel syndrome, the lower abdominal pain persists, despite adequate laxative therapy. Soluble fiber such as methylcellulose and adequate fluid intake are generally recommended. Tricyclic antidepressants can worsen the constipation because of the anticholinergic activity, and agents with less anticholinergic activity are generally preferred for pain modulation [36].

Infant Dyschezia

Uncoordinated defecation can result in discomfort, crying, and straining in an infant. It is associated with the passage of soft stool several times a day. The disorder can be confused with functional constipation or infantile colic. The reported prevalence of dyschezia is between 0.9% and 5.6% and most infants improve by 3–6 months of age. Management involves parental reassurance and support. Overuse of laxatives or stimulants should be avoided, as they are generally not helpful. Instead, teaching the parents to flex the hips on the abdomen to relax the pelvic floor, gentle massage of the abdomen and of the perineum may help the infant to have a successful bowel movement.

Functional Diarrhea

This is characterized by passage of four or more unformed stools for ≥4 weeks with onset in infancy or preschool years in an otherwise healthy and thriving child. It is also known as Toddler diarrhea or chronic nonspecific diarrhea. Parents often report stool containing undigested food, especially vegetables like peas, carrots and corn. Rapid oro-anal transit due to immature bowel motility and excessive dietary intake of fructose, for example, fruit juices or squash have been implicated in the pathophysiology. It is important to differentiate this from malabsorption disorders and celiac disease (see Chaps. 38, 39, and 41).

Disorders of gut-brain interaction are a complex group of disorders that require a holistic approach to patient care. By taking time to listen to each patient and their story, the provider can create and long-lasting patient-provider relationship that not only improves patient outcomes but also provides meaning and satisfaction to the practice of medicine.

Disorders of Sucking and Swallowing

20

Francesca Paola Giugliano, Erasmo Miele, and Annamaria Staiano

Introduction

The development of feeding skills is an extremely complex process influenced by multiple anatomic, neurophysiologic, environmental, social, and cultural factors. Oral feeding in infants should be efficient to preserve energy for growing. Moreover, it should be safe so as to avoid aspiration, and it should not compromise respiratory status. This can only be achieved if sucking, swallowing, and breathing are properly coordinated [1]. This entire process is dynamic because of ongoing growth and development. Functional feeding skills, which depend on the integrity of anatomic structures, undergo changes based on neurologic maturation and experimental learning. Eating/feeding requires active effort by infants who must have exquisite timing and coordination of sucking, swallowing, and breathing to be efficient [2].

A variety of neurological, neuromuscular conditions in children and infants can impair the physiological phases of sucking/swallowing and cause disorders of feeding and dysphagia. The causes of feeding and swallowing problems include combinations of structural deficits, neurologic conditions, respiratory compromise, feeder–child interaction dysfunction, and numerous medical conditions, such as genetic, metabolic, and degenerative disease [3].

In recent years, there has been an increase in infant swallowing disorders as a result of improved survival rates for infants born prematurely or with life-threatening medical disorders. Negative experiences related to feeding, such as intubation, tube feeding, or airway suctioning may further disturb sucking and swallowing development [4]. Disorders of feeding and swallowing in children are serious and potentially fatal problems. Aspiration due to dysphagia may lead to severe pulmonary disease, and impaired oral and pharyngeal function may rapidly result in failure to thrive. Prompt evaluation of swallowing disorders is therefore critical.

The differential diagnosis of dysphagia in children is wide. The diagnostic workup can be extremely difficult and exhaustive in many cases. Because of this complexity, multidisciplinary team evaluations should be conducted.

Successful rehabilitation of children with swallowing disorders requires knowledge of the parameters of normal and abnormal swallowing plus skill in the integration of a variety of essential therapeutics techniques.

Epidemiology

Data on the incidence of swallowing disorders are lacking, because in clinical practice, disorders of swallowing are often considered in the general context of a feeding disorder. Feeding (or eating) is different from swallowing. Eating is primarily an oral phase function that includes oral preparation and oral transit of a bolus [5]. Feeding is a complex process that involves a number of phases in addition to the act of swallowing, including the recognition of hunger (appetite), the acquisition of the food, and the ability to bring the food to the mouth [6]. The estimated prevalence of feeding problems in the pediatric population ranges from 25% to 35% in normally developing children to 40–93% in children with developmental delay [7, 8]. Early sucking and swallowing problems were reported to be present in 35–48% of infants with different types of neonatal brain injury [9]. However, knowledge of the true epidemiology of pediatric dysphagia remains largely unavailable because of the lack of a standardized reporting system assessing dysphagia in all of the possible contexts that may occur in infants and children [10].

Etiology

Disorders of sucking/swallowing may be caused by multiple etiologic factors that may interfere with the child's ability to coordinate swallowing and breathing maneuvers and may be manifested as a unique set of symptoms. Potential causes responsible for three broad categories include (1) immaturity, delay, or a defect in neuromuscular control; (2) anatomic abnormality of the aerodigestive tract; (3) systemic illness. The magnitude of the dysfunction depends on the balance between the extent of the structural or functional abnormality and the child's compensatory adaptations [11]. Disorders associated with sucking/swallowing difficulties are reported in Table 20.1 [12, 13].

Pathophysiology

The fetus is capable of swallowing amniotic fluid in utero, indicating that the motor program for swallowing is functioning before gestation is complete.

However, oral feeding is not initiated in preterm infants before 32 weeks of postconceptional age, partly because the coordination of sucking, swallowing, and respiration is not established [14]. Even at 34 weeks, minute ventilation during sucking decreases more than that of infants at 36–38 weeks. Therefore, the coordination between swallowing and breathing is not yet fully organized at 34 weeks of postconceptional age [15, 16].

Anatomic structures, which are essential to competent feeding skills, undergo growth that changes their physical

Table 20.1 Differential diagnosis of dysphagia

Prematurity		
Upper airway obstruction	Nasal and nasopharyngeal	Cohanal atresia, stenosis, septal deflections and abscess, infections, tumors, sinusitis
	Oropharynx	Defects of lips and alveolar processes, cleft lips or palate, hypopharyngeal stenosis, craniofacial syndromes or sequences (e.g., Cruzon, Treacher Collins syndrome, and Pierre Robin sequence)
	Laryngeal	Laryngeal cleft and cyst, laryngomalacia, subglottic stenosis, and paralysis
Congenital defects of the larynx, trachea, and esophagus	Laryngotracheoesophageal cleft	–
	Tracheoesophageal fistula with associated esophageal atresia	–
	Esophageal anomalies (e.g., strictures, webs)	–
	Vascular anomalies	Aberrant right subclavian artery
		Double aortic arch
		Right aortic arch with left ligamentum
Acquired anatomic defects	Trauma	External trauma, intubation, endoscopic, and foreign body
	Chemical ingestion	–
Neurologic disorders	Central nervous system	Trauma
		Hypoxia and anoxia
		Cortical atrophy, hypoplasia, agenesis
		Infections (meningitis, brain abscess)
Peripheral nervous system disease	Trauma	–
	Congenital defects

relationship to one other and consequently affects their function. The swallowing mechanism, by which food is transmitted to the stomach and digestive organs, is a complex action involving 26 muscles and 5 cranial nerves. The neurophysiologic control involves sensory afferent nerve fibers, motor efferent fibers, paired brainstem swallowing centers, and suprabulbar neural input. Structural integrity is essential to the development of normal feeding and swallowing skills [17]. The central patterning of aeroingestive behavior is based on volitional and reflexive control mechanisms and benefit from sensory feedback to modify the spatiotemporal organization of the feed sequence to allow safe swallow [18]. Central pattern generators (CPGs) are primarily composed of adaptive networks of interneurons that activate groups of motor neurons to generate task-specific motor patterns [19]. The essential components of the masticatory CPG are found between the rostral poles of the fifth and seventh motor nuclei. Although they are normally synchronized by commissural axons, each hemisection side can generate a rhythm [20]. Mastication patterns differ greatly between foods and change systematically during a chewing sequence based on sensory feedback. Functional imaging has revealed that swallowing is controlled through a network of cortical areas which shares loci with other ororhythmic movements including speech [21].

Deglutition is generally divided into phases of swallowing based on anatomic and functional characteristics: preoral, pharyngeal, and esophageal [22, 23].

Anatomic Considerations

An understanding of the anatomy of the pharynx is essential to a thorough understanding of the swallowing process. The anatomy changes during development. The tongue, the soft palate, and the arytenoids mass (arytenoids cartilage, false vocal cords, and true vocal cords) are larger relative to their surrounding chambers when compared with the adult [24]. In the infant, the tongue lies entirely within the oral cavity, resulting in a small oropharynx [25, 26]. In addition, a sucking pad, composed of densely compacted fatty tissue that further reduces the size of the oral cavity, stabilizes the lateral walls of the oral cavity. The larynx lies high in the infant, and the tip of epiglottis may overlap the soft palate. These anatomic relationships are ideal for the normal infant feeding pattern of suck or suckle feeding from a breast or a bottle in a recumbent position [26]. In the infant, the larynx sits high in the neck at the level of vertebrae C1 to C3, allowing for the velum, tongue, and epiglottis to approximate, thereby functionally separating the respiratory and digestive tracts. This separation allows the infant to breathe and feed safely. By age 2–3 years, the larynx descends, decreasing the separation of the swallowing and digestive tracts [7].

Development and Normal Swallowing Function

Swallowing skills develop progressively during fetal and neonatal maturation [27]. At approximately 26 days' fetal age, the developmental trajectories of the respiratory and swallowing systems diverge and start to develop independently. Swallowing in fetuses has been described as early as 12–14 weeks' gestational age. A sucking response can be provoked at 13 weeks' postconceptional age by touching the lips [28]. Real sucking, defined by a posterior–anterior movement of the tongue, in which the posterior movement is dominant, begins at 18–24 weeks' postconceptional age [29]. Between 26 and 29 weeks' there is probably no significant further maturation of sucking [30]. By week 34, most healthy fetuses can suck and swallow well enough to sustain nutritional needs via the oral route, if born at this early age. Sucking movements increase in frequency during the final weeks of fetal life due to an increase in amniotic fluid swallowed by a fetus during pregnancy from initially 2–7 ml a day to 450 ml a day. This is approximately half of the total volume of amniotic fluid at term [31]. The normal maturation of sucking and swallowing during the first months of life after full-term birth can be summarized by increased sucking and swallowing rates, longer sucking bursts, and larger volume per suck [16]. The skill of safe and efficient oral feeding is based on oral-motor competence, neurobehavioral organization, and gastrointestinal maturity [32]. Two forms of sucking are distinguished: nutritive sucking (NS) and non-nutritive sucking (NNS). NS is an infant's primary means of receiving nutrition while NNS is regarded as an initial method for exploring the environment. The rate of NNS is approximately twice as fast as that of NS [33]. In NS, however, the ability to integrate breathing with sucking and swallowing is essential for coordinated feeding [1] and it becomes consistent by 37 weeks' gestation [34]. By increasing the intra-oral space, the infant begins to suppress reflexive suckle patterns and starts to use voluntary suck patterns. In contrast to suckling, true sucking involves a raising and lowering of the body of the tongue with increased use of intrinsic musculature. Most of the infants complete the gradual transition from suckling to true suck by 9 months of age. This is considered a critical step in the development of oral skills that will permit handling of thicker textures and spoon-feeding [35].

As with sucking, chewing patterns emerge gradually during infancy. Between birth and 5 months of age, a phasic bite-release pattern develops. At this series of jaw openings and closing begins as a reflex and evolves into volitionally

controlled bite. True chewing develops as the coordinated activity of the tongue, cheeks, and jaws to participate in the breakdown of solid food. The eruption of the deciduous teeth between ages of 6 and 24 months provides a chewing surface and increases sensory input to facilitate the development of chewing [35].

The concept of a "critical period" is relevant to feeding development. A critical period refers to a fairly well-delineated period of the time during which a specific stimulus must be applied to produce a particular action. After such a critical period, a particular behavior pattern can no longer be learned. Critical periods have been described for chewing and for taste. The critical period for chewing is that time following the disappearance of the tongue protrusion reflex that should occur around 6 months of age [36]. Critical periods have also been reported for introduction of tastes. Newborn infants detect sweet solutions, reject sour flavors, and are indifferent to the taste of salt [37]. Mc Farland and Tremblay emphasized that sensory experience is crucial to optimize pattern formation and brain development during the critical period for attainment of swallowing proficiency [38].

Current knowledge of the swallowing mechanism is derived mainly from radiographic studies, which have been in use since the early 1900s. Plain films of the pharynx were replaced in the 1930s by cineradiography, which was subsequently in the 1970s replaced by videofluoroscopy. Videofluoroscopy permits instant analysis of bolus transport, aspiration, and pharyngeal function [39]. Using this descriptive method, deglutition can be divided into four phases: oral preparatory phase, oral voluntary phase, pharyngeal phase, and esophageal phase (Table 20.2) [13, 40].

The oral preparatory phase occurs after food is placed into the mouth. The food is prepared for pharyngeal delivery by mastication and mixing with saliva. This is a highly coordinated activity that is rhythmic and controlled to prevent injury to the tongue. The tongue is elevated toward the palate by the combined actions of the digastric, genioglossus, geniohyoid, and mylohyoid muscles. Intrinsic tongue muscles produce both the initial depression in the dorsum that receives the food and the spreading action that distributes the food throughout the oral cavity. The buccinator muscles hold food in the mouth in edentulous infants and help to generate suction in neonates. In this phase, the soft palate is against the tongue base, secondary to contraction of the palatoglossus muscles, which allows nasal breathing to continue [7, 41].

Table 20.2 Phases of normal deglutition

Phase	Activities	Time
Pre-oral (voluntary)	Food introduced into oral cavity	Varies; depends on substance
Oral phase (voluntary/ involuntary)	Bolus formation and passage to pharynx	Less than 1 s
Pharyngeal phase (involuntary)	Respiration ceases. Pharyngeal peristalsis. Epiglottis closes. Larynx closes, elevates, and draws forward. UES relaxes	1 s or less
Esophageal phase (involuntary)	Esophageal peristalsis. Opening of lower esophageal sphincter	8–20 s

Reprinted with permission from Ref. [13], Table 15.2, p. 236

During the oral propulsive phase, the bolus is propelled into the oropharynx. The oral phase is characterized by elevation of the tongue and a posterior sweeping or stripping action produced mainly by the action of styloglossus muscles. This propels the bolus into the pharynx and triggers the "reflex swallow." The receptors for this reflex are thought to be at the base of the anterior pillars, but there is evidence that others exist in the tongue base, epiglottis, and pyriform fossae. Sensory impulses for the reflex are conducted through the afferent limbs of cranial nerves V, IX, and X to the swallowing center. Oral transit time is less than 1 s [7, 42].

The pharyngeal phase of deglutition is the most complex and critical. The major component of the pharyngeal phase is the reflex swallow. This results from motor activity stimulated by cranial nerves IX and X. Swallowing is elicited involuntary by afferent feedback from the oral cavity and has a duration of approximately 530 ms [1]. The reflex swallow may be triggered by a voluntary oral phase component or any stimulation of the afferent receptor in and around the anterior pillar [7]. Bolus passage through the pharynx is accompanied by soft palate elevation, lingual thrust, laryngeal elevation, and descent upper esophageal sphincter (UES) relaxation and pharyngeal constrictor peristalsis. The pharyngeal phase commences as the bolus head is propelled past the tongue pillars and finishes as the bolus tail passes into the esophagus [42]. Once it begins, the pharyngeal phase is very quick, 1 s or less [7]. It is characterized biomechanically by the operation of three valves and several propulsive mechanisms. During pharyngeal swallowing, respiration is inhibited centrally [43]. The larynx closes and the palate elevates to disconnect the respiratory tract. The UES opens to expose the esophagus. At the completion of the pharyngeal phase, the airway valves (larynx, palate) open and the UES closes so that respiration can resume [42].

Pharyngeal bolus transit occurs in two phases: an initial thrust phase and a mucosal clearance phase [44]. Bolus thrust, which propels most of the bolus into the esophagus, is provided by lingual propulsion, laryngeal elevation, and gravity. The tongue has been linked to a piston, pumping the bolus through the pharynx [45]. Patients with tongue impairment cannot generate large bolus driving forces despite an intact pharyngeal constrictor mechanism [46]. Laryngeal elevation creates a negative postcricoid pressure to suck the

oncoming bolus toward the esophagus, and the elevated larynx holds the pharyngeal lumen open to minimize pharyngeal resistance [45].

As the bolus enters the pharynx and is stripped inferiorly by the combined effects of gravity, the negative pressure mentioned above, and the sequential contractions of the pharyngeal constrictors, the soft palate moves against the posterior pharyngeal wall to close off the nasopharyngeal port. The bolus divides around the epiglottis, combines, and passes through the cricopharyngeal muscle or UES [7].

UES refers to the high-pressure zone located in between the pharynx and the cervical esophagus. The physiological role of this sphincter is to protect against reflux of food into the airways as well as prevent entry of air into the digestive tract [47]. Posteriorly and laterally, the cricopharyngeus muscle is a definitive component of the UES. The Cricopharyngeus muscle has many unique characteristics: it is tonically active, has a high degree of elasticity, does not develop maximal tension at basal length, and is composed of a mixture of slow- and fast-twitch fibers, with the former predominating. These features enable the cricopharyngeus muscle to maintain a resting tone and yet be able to stretch open by distracting forces, such as a swallowed bolus and hyoid and laryngeal excursion. The cricopharyngeal muscle, however, constitutes only the lower one-third of the entire high-pressure zone. The thyropharyngeus muscle accounts for the remaining upper two-thirds of the UES. The UES function is controlled by a variety of reflexes that involve afferent inputs to the motor neurons innervating the sphincter [47]. Based on functional studies, it is believed that the major motor nerve of the cricopharyngeal muscle is the pharyngoesophageal nerve. Vagal efferents probably reach the muscle by the pharyngeal plexus, using the pharyngeal branch of the vagus [48]. The superior laryngeal nerve may also contribute to motor control of the cricopharyngeal muscle [6]. Sensory information from the UES is probably provided by the glossopharyngeal nerve and the sympathetic nervous system. There is probably little or no contribution by the sympathetic nervous system to cricopharyngeal muscle control [48].

The relaxation phase begins as the genioglossus and suspensory muscle pulls the larynx anteriorly and superiorly. The bolus is carried into the esophagus by a series of contraction waves that are a continuation of the pharyngeal stripping action [7]. Proposed functions of the UES include prevention of esophageal distention during normal breathing and protection of the airway against aspiration following an episode of acid reflux [6, 48]. Qualitative abnormalities of UES have been documented in infants with reflux disease [49].

The esophageal phase occurs as the bolus is pushed through the esophagus to the stomach by esophageal peristalsis. Esophageal transit time varies from 8 to 20 s [26].

Dysphagia

Dysphagia is an impairment of swallowing involving any structures of the upper gastrointestinal tract from the lips to the lower esophageal sphincter [50]. Dysphagia in children is generally classified as either oral dysphagia (abnormal preparatory or oral phase) or pharyngeal dysphagia (abnormal pharyngeal phase).

Oral dysphagia is seen most commonly in children with neurodevelopmental disorders. Infants with oral dysphagia often have an impaired oral preparatory phase. These children typically demonstrate poor lingual and labial coordination, resulting in anterior substance loss and poor labial seal for sucking or removing food from a spoon. Other abnormal patterns include jaws thrust and tongue thrust on presentation of food. Oral dysphagia also may involve the oral phase of swallowing. Children with impaired oral phase function often have difficulty in coordinating the "suck, swallow, breathe" pattern of early oral intake, resulting in diminished endurance during oral feeds. Apraxia of oral swallow as well as reduction of oral sensation also is common. Other deficits include reduced bolus formation and transport, abnormal hold patterns, incomplete tongue to palate contact, and repetitive lingual pumping [26].

Oropharyngeal dysphagia results from either oropharyngeal swallowing dysfunction or perceived difficulty in the process of swallowing. Major categories of dysfunction are as follows: (1) an inability or excessive delay in initiation of pharyngeal swallowing, (2) aspiration of ingestate, (3) nasopharyngeal regurgitation, and (4) residue of ingestate within the pharyngeal cavity after swallowing. Each of these categories of dysfunction can be subcategorized using fluoroscopic and/or manometric data [29].

Clinical Signs/Symptoms

Clinical signs and symptoms of sucking/swallowing disorders in infants and children are listed in Table 20.3 [13].

Complications

Malnutrition

In the severely affected child with impaired swallowing, poor oral and/or pharyngeal function may lead to decreased energy intake as a consequence of prolonged feeding time and the inability to ingest adequate volumes, and malnutrition may result [6]. Malnutrition has many adverse effects. The most significant effects are on behavior and immune status. Malnutrition negatively influences immune status. This leads to recurrent infections that

Table 20.3 Clinical signs and symptoms of dysfunctional sucking/swallowing

Clinical signs
Failure to thrive
Meal-time distress
Refusing food
Nasal regurgitation
Wet or hoarse voice
Drooling
Spitting
Vomiting
Gastroesophageal or pharyngeal reflux
Symptoms
Oral-tactile hypersensitivity
Feeling of obstruction
Odynophagia
Atypical chest pain
Respiratory manifestations
Coughing
Choking
Stridor
Change in respiration pattern after swallowing
Apnea and bradycardia (predominantly in infants)
Noisy breathing after feeding
Chronic recurrent wheezing
Chronic recurrent bronchitis, pneumonia, and atelectasis

Reprinted with permission from Ref. [13], Table 15.3, p. 239

increase caloric requirements but decrease intake, leading to worsening nutritional status. In addition, malnutrition causes behavioral apathy, weakness, and anorexia, which can all profoundly affect feeding, and secondarily, nutritional status. Thus, although malnutrition is often a direct result of poor feeding skills, it can also have compounding and even perpetuating effect on feeding problems in children [26].

Sialorrhea

Sialorrhea, or excessive drooling, is defined as the unintentional loss of saliva and other oral contents from the mouth. Drooling usually occurs in patients with neurologic disease complicated by abnormalities of the oral phase of deglutition. Clinical complications of drooling include soaking of clothes, offensive odors, macerated skin, and if "posterior" drooling occurs, aspiration [51].

Respiratory Complications

Respiratory complications of swallowing disorders include apnea and bradycardia, choking episodes, chronic or recurrent pneumonia, bronchitis, and atelectasis [52].

Apnea and bradycardia may result from stimulation of laryngeal chemoreceptors without evidence of aspiration or as a consequence of hypoxemia. Hypoxemia may result from the effects of direct aspiration on gas exchange, from apnea triggered by laryngeal and nasopharyngeal chemoreceptors, or in patients with compromised lung function as a result of normal decrease in minute ventilation that occurs with the suckle feeding [53–55]. Symptoms such as chronic recurrent coughing, choking, and postprandial congestion or wheezing generally indicate the occurrence of aspiration. Infants, especially premature infants, appear to be at an increased risk of respiratory disease from dysfunctional swallowing [9]. Clinical manifestations of dysfunctional sucking/swallowing in infants are primarily apnea and bradycardia during feeding, although chronic/recurrent respiratory problems (congestion, cough, and wheezing) are also seen [52]. Congested or noisy breathing during and following feeding is also a common complaint of parents of infants with dysfunctional swallowing. Dysphagia can also be an important but underrecognized cause of chronic/recurrent bronchitis, asthma, and pneumonia in infants [9].

Respiratory disease secondary to dysphagia in an older child is typically seen in a neurologically impaired host [56, 57]. Apnea and bradycardia are uncommon in older children. Bronchitis, pneumonia, atelectasis, and recurrent wheezing are more likely to be seen in this population. Feeding and swallowing evaluation should be considered in those with CNS injury affecting cranial nerve function and difficult-to-control chronic/recurrent bronchitis, wheezing, pneumonia, or asthma. Tracheobronchomalacia, a complication of chronic inflammation of the major airways, occurs commonly. Dysfunctional swallowing is also encountered in children with a tracheostomy. The tracheostomy may interfere with normal laryngeal function during swallowing and predispose to aspiration [50].

Aspiration may also occur in children with disorders of swallowing after an episode of gastroesophageal reflux; also, acid reflux may result in bronchospasm, pneumonia, or apnea [58, 59].

The most obvious sign that a person may have aspirated is the post-swallow cough, but in the swallowing-impaired children other more insidious indicators may be present. "Silent aspiration" with no clinical signs can account for over half of all cases of radiologically defined aspiration [50, 60].

Diagnosis

Feeding disorders and dysphagia in infants and children can be both physiological and behavioral in nature [61].

The evaluation of feeding and swallowing dysfunction is best performed as a multidisciplinary process with coordinated input from a variety of team members, including pedi-

atricians, pediatric gastroenterologists, developmental pediatricians, speech–language pathologists (SLP), occupational therapist, and pediatric dietitians [62]. The goals of this evaluation include the following: (1) ascertain whether oropharyngeal dysphagia is likely and identify the likely etiology, (2) identify structural etiologies of oropharyngeal dysfunction, (3) ascertain the functional integrity of the oropharyngeal swallow, (4) evaluate the risk of aspiration pneumonitis, and (5) determine if the pattern of dysphagia is amenable to therapy [63].

The investigation and management of swallowing disorders are summarized in Fig. 20.1 [13, 50].

History

A comprehensive history, obtained from individuals directly involved in caring for the child (e.g., parents, feeding specialist), is essential in evaluating children with swallowing disorders. The evaluation begins with a focused feeding history, including current diet, textures, and route and time of administration, modifications, and feeding position. Medical comorbidities that may affect swallowing need to be investigated.

Child's caretakers also should be questioned regarding associated symptoms, such as oral aversion, weak sucking, irritable behavior, gagging and choking, and disruptions in

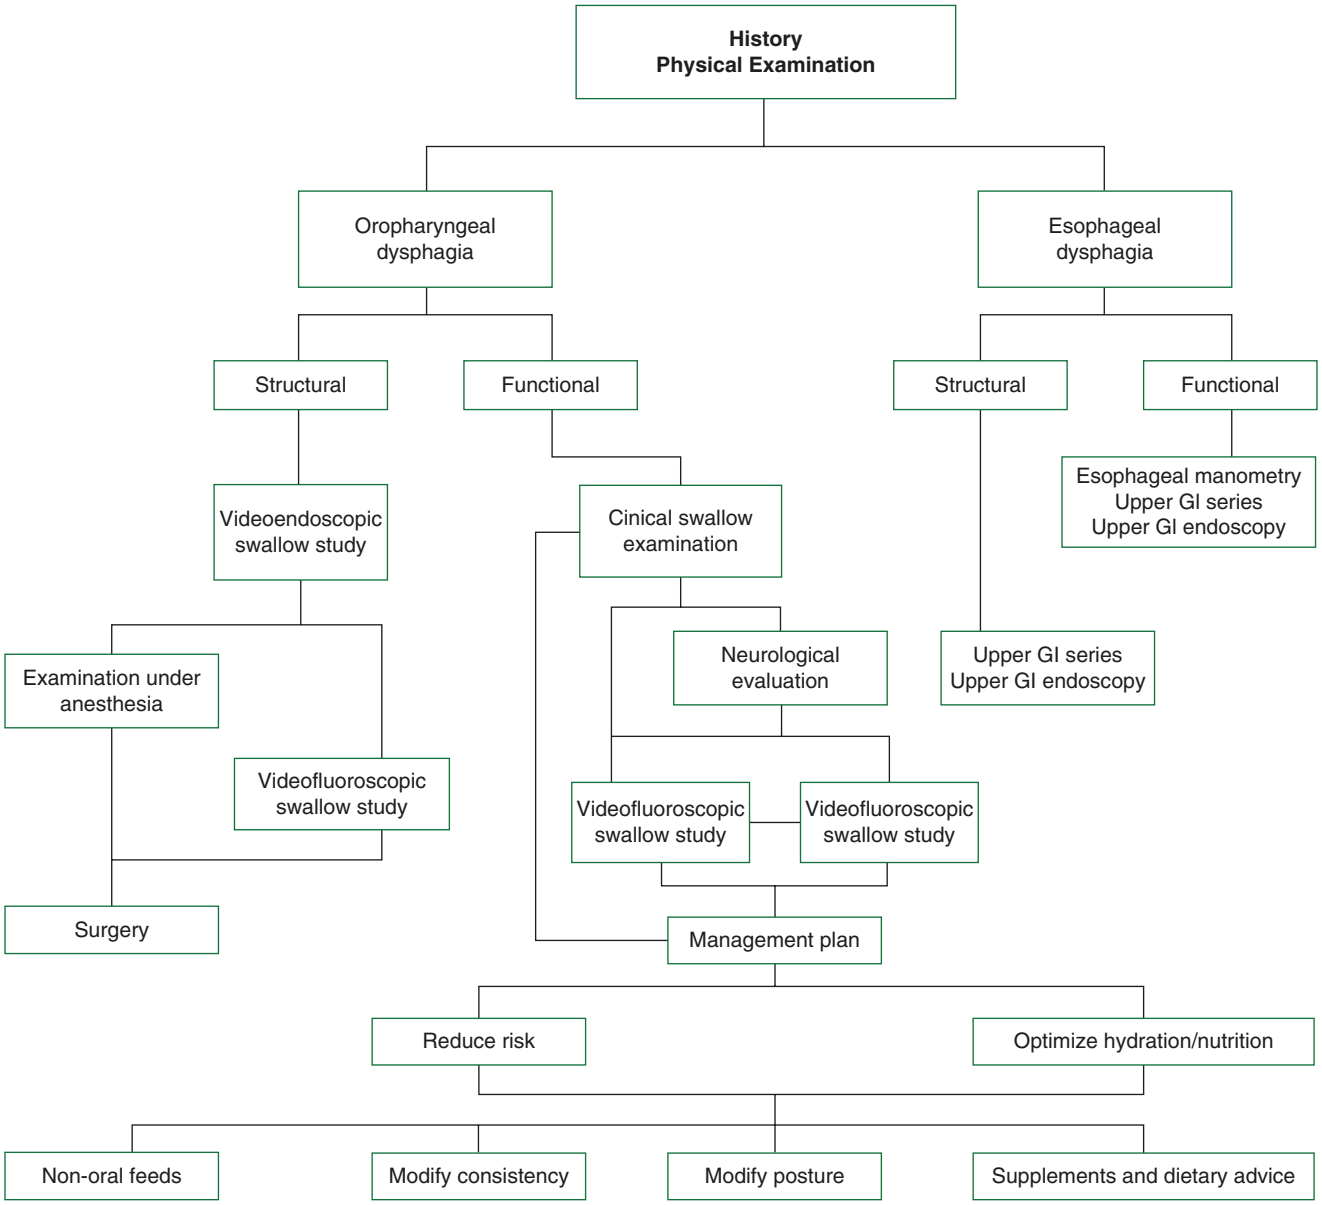

Fig. 20.1 Flowchart for the investigation and management of dysphagia in children. (Adapted by permission from BMJ Publishing Group Limited, from Ref. [50] and reprinted with permission from Ref. [13])

breathing or apnea. Postural or positional change during feeding may also be reported in children with dysphagia. Odynophagia and emesis may be related with pharyngeal and/or esophageal disorders. A history of recurrent pneumonia may indicate chronic aspiration; a history of stridor in relation to feeding may indicate a glottic or subglottic abnormality contributing to feeding disorders. Determining whether these symptoms occur before, during, or after the swallow helps localize the affected phase [27, 28].

In addition, nutritional and psychological assessment should be evaluated. Many patients with swallowing disorders have concurrent illness that may increase metabolic needs. Psychological assessments help to identify behavioral and parental factors that may be contributing to a feeding disorder. Psychosomatic causes of dysphagia should be considered in adolescents with dysphagia [7, 64, 65].

Physical and Clinical Evaluation

In dysphagic patients, physical examination aims to: (1) characterize the underlying systemic or metabolic disease when present; (2) localize the neuroanatomical level and severity of a causative neurological lesion when present; and (3) detect adverse sequelae such as aspiration pneumonia or nutritional deficiency [29].

There are four key questions that physicians and nurses in primary care can ask parents when an infant or young child presents at the office or clinic with parental concerns related to feeding [66].

The answers help determine whether a comprehensive clinical feeding and swallowing assessment is needed, even though the answers do not necessarily define the problem:

- How long do mealtimes typically take? If more than about 30 min on any regular basis, there is a problem. Prolonged feeding times are major red flags pointing to the need for further investigation.
- Are mealtimes stressful? Regardless of descriptions of factors that underlie the stress, further investigation is needed. It is very common for parents to state that they "just dread mealtimes."
- Does the child show any signs of respiratory stress? Signs may include rapid breathing, gurgly voice quality, nasal congestion that increases as the meal progresses, and panting by an infant with nipple feeding. Recent upper respiratory illness may be a sign of aspiration with oral feeds, although there may be other causes.
- Has the child *not* gained weight in the past 2–3 months? Steady appropriate weight gain is particularly important in the first 2 years of life for brain development as well as overall growth. A lack of weight gain in a young child is like a weight loss in an older child or adult.

Following the physical examination, the focus is on the upper aerodigestive tract, beginning with an examination for structural and functional abnormalities. Oral cavity anatomic abnormalities, such as ankyloglossia, cleft lip or palate, or macroglossia, need to be excluded [7]. The palatal gag is perhaps the most assessed reflex and should be evaluated [51]. A hyperactive gag can result in significant feeding difficulties, and in the past an absent gag reflex was considered as an indication to stop oral feeding [9, 56].

It is critical that observation of the feeding process be included [62]. This part of the examination is best performed in conjunction with a feeding and swallowing specialist, such as a SLP or an occupational therapist. This examination includes assessments of posture, positioning, patient motivation, oral function, efficiency of oral intake, and clinical signs of safety. During the feeding trial, the presence of abnormal movements such as jaw thrust, tongue thrust, tonic bite reflex, and jaw clenching is noted. A variety of therapeutic positions, techniques, and adaptive feeding utensils may be used [6, 27].

A variety of assessment scales may be used to detail and quantitate results of the swallowing evaluation. However, all assessments are based on similar observations of feeding structure and function [67].

The clinical evaluation differs according to the patient age. In infants, from birth till 1 year of age, including those in the Neonatal Intensive Care Unit (NICU), the evaluation includes the assessment of prefeeding skills, the readiness for oral feeding, and the evaluation of breast- and bottle-feeding ability. For toddlers (ages 1–3 years) and pre-school/school-age children/teenagers (ages 3–18 years), the evaluation may also include a review of any past diagnostic test and any current treatment programs, the assessment of current skills and limitations at home and at school, patient acceptance of liquids and solid food, and the grade of independence or need for supervision and assistance during the feeding [68].

Usually, a careful developmental, medical, and feeding history provides clues to the diagnosis that guide the selection of further diagnostic tests. Only after all reasonable physical causes have been ruled out, should a feeding or swallowing disorder be attributed to a purely behavioral cause [7].

Diagnostic Tests

Radiographic Assessment

The Videofluoroscopic Swallow Study (VFSS) also known as modified barium swallow, represents the gold standard method for evaluation of children with swallowing disorders [69]. A videofluoroscopic swallow study is ideally performed

Fig. 20.2 Lateral fluoroscopic projection of a child showing contrast material in the valleculas, pyriform sinuses, laryngeal vestibule, and esophagus

by a consultant radiologist and specialist and the SLP [70]. A series of swallows of varied volumes and consistencies of contrast material are imaged in a lateral projection, framed to include the oropharynx, palate, proximal esophagus, and proximal airway. Studies are recorded on videotape to permit instant replay, in slow motion if necessary, and examination of both the presence and mechanism of swallowing dysfunction. As such, the videofluoroscopic study provides a dynamic view of all the stages of swallowing (oral preparatory, oral, pharyngeal, and upper esophageal), therefore assuring evidence of all four categories of oropharyngeal swallowing disorders: (1) inability or excessive delay in initiation of pharyngeal swallowing, (2) aspiration of ingestate, (3) nasopharyngeal regurgitation, and (4) residue of ingestate within the pharyngeal cavity after swallowing. Furthermore, the procedure allows for testing of the efficacy of compensatory dietary modifications, postures, swallowing maneuvers, and facilitatory techniques in correction or observed dysfunction. Generally, the videofluoroscopic evaluation is completed by esophagography to evaluate the esophageal phase of deglutition (Fig. 20.2) [29]. A nasogastric tube does not alter the findings of videofluoroscopic swallowing study and does not increase the risk of aspiration; however, it might increase the incidence of respiratory compromise when aspiration is present [71]. The disadvantage of the technique is related to the ionizing radiation exposure that imposes a time-limited examination and the need for patient cooperation. In order to ensure that the radiation dosage amount is as low as reasonably achievable (ALARA) [72], the radiologist and the SLP work together following the International Commission on Radiological Protection (ICRP) guidelines [68].

Fiberoptic Endoscopic Examination

Pediatric fiberoptic endoscopic examination (FEES) is a relatively new diagnostic method to add to the current armamentarium of techniques for evaluating dysphagia and/or aspiration. FEES is performed by passing a flexible laryngoscope into the oropharynx after anesthetizing the nares and nasopharynx [73]. It allows to diagnose many of the laryngeal disorders that may affect the child, while at the same time evaluating the swallowing mechanism itself. The procedure involves five components: assessment of anatomy (as it affects swallowing), evaluation of movement and sensation of critical structures, assessment of secretion management, direct assessment of swallowing function for food and liquid, and patients' response to therapeutic maneuvers. Compared to the VFSS, FEES does not imply radiation exposure to the infant as well as no barium ingestion. In addition, FEES allows the visualization of the pharyngeal and laryngeal anatomy and assesses secretion management. Moreover, the procedure is less expensive and it can be performed at the bedside whether the patient transportation is not possible or difficult. FEES can be repeated more frequently to assess patient improvement as there is no risk related to radiation exposure and it can be also used to assess breastfeeding. Unlike the VFSS, FEES does not allow the visualization of the oral phase and the contractions of the tissue surrounding the end of the endoscope during the swallow cause a temporary condition called "white-out" where the passage of the bolus and movement of the structures cannot be observed. In experienced hands, this test can be performed in children with minimal discomfort. Possible described adverse effects are epistaxis, laryngospasms, reaction to topical anesthesia and vasovagal response [74–76]. A variation of the FEES, the fiberoptic endoscopic evaluation of swallowing with sensory testing (FEESST), utilizes an air pulse stimulus of mechanoreceptors within the larynx to study the laryngeal adductor response (LAR). The study can be performed safely in premature infants, in children, and in adults [77].

Ultrasonography

Ultrasound imaging has been used to a limited extent in the assessment of oral phase dysphagia. Using a transducer positioned in the submental region, ultrasonography allows observation of the motion of structures in the oral cavity,

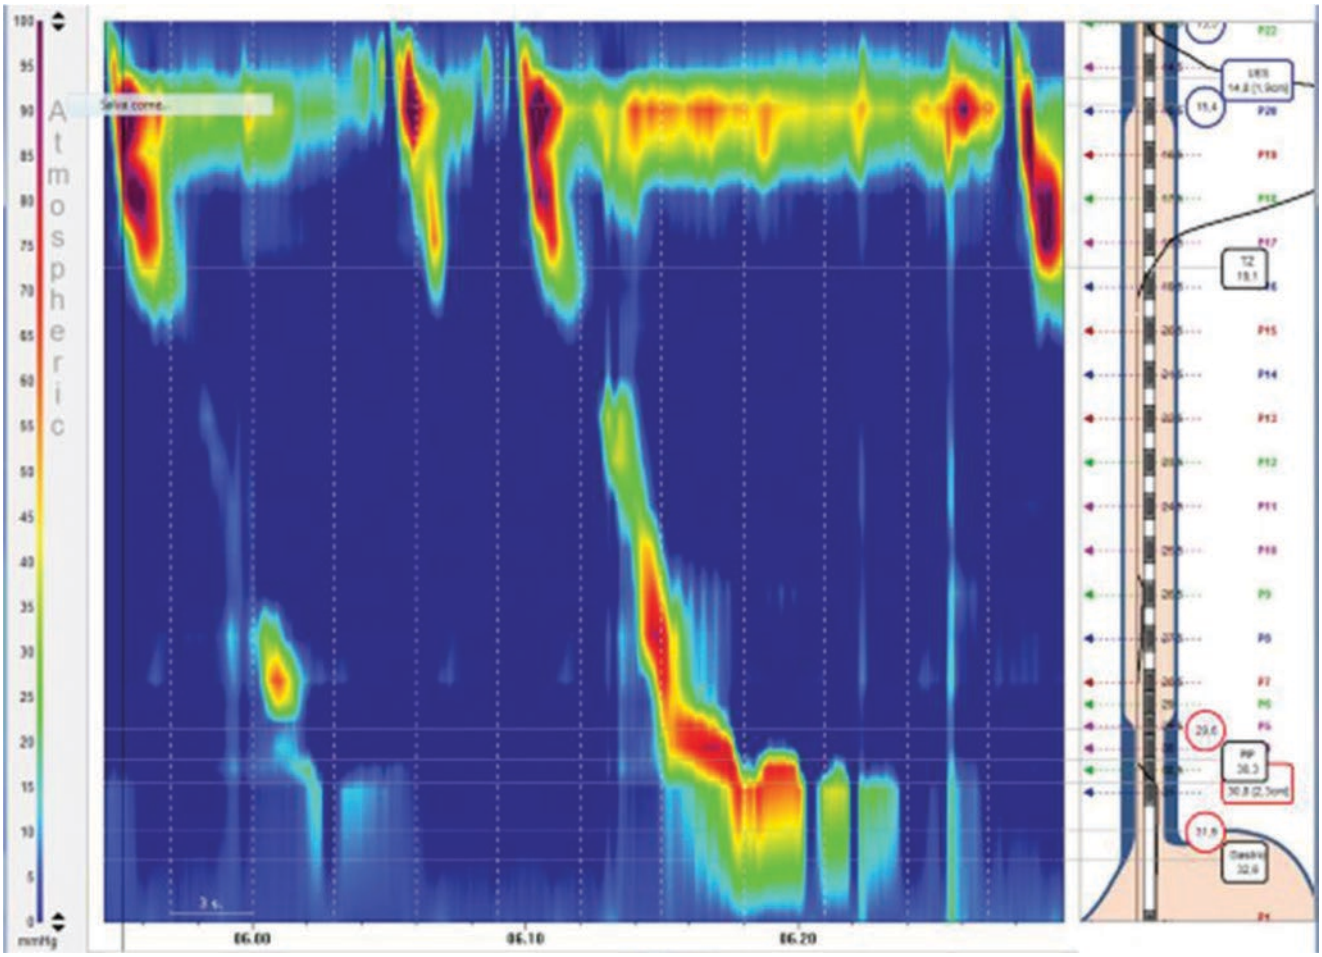

Fig. 20.3 Esophageal pressure topography plotting: complete peristaltic chain studied with a 21-lm catheter. The three *inter-segmental* troughs are indicated in the figure, and the pressure amplitudes represented by the isobaric contour regions are shown in the *color legend* (in mmHg above gastric baseline pressure; pressures below the first isobaric contour are shown in *blue*). SW swallow

such as the tongue and floor of the mouth during feeding and deglutition, but lacks sensitivity in visualizing pharyngeal motion and determining whether aspiration has occurred. Ultrasonography may be particularly useful in distinguishing an infant's inability to latch on from maternal factors contributing to feeding difficulties [14]. Unfortunately, laryngeal penetration and aspiration are not easily detected because of the shadows cast by the laryngeal structures [9, 34, 78].

Pharyngeal Manometry

Intraluminal manometry, performed using a transnasally positioned manometric assembly, can quantify the strength of pharyngeal contraction, the completeness of UES relaxation, and relative time of these two events. Most studies indicate that the manometry of the UES and pharynx provides useful information primarily in patients who have symptoms of oropharyngeal dysfunction. The coordination of muscle activity at various levels can be obtained by simultaneous recording of pressure in the pharynx, at the level of cricopharyngeus, and in the esophagus. Anatomic references are not available with this technique [49, 79]. Recently, manometry equipment has evolved to allow more precise and detailed evaluation of esophageal function with high-resolution manometry and esophageal pressure topography plotting [80] (Fig. 20.3).

Scintigraphy

Scintigraphy is a radionuclide evaluation using Technetium-99m-labeled sulfur colloid mixed in the infant's formula. It has been proposed as an alternative and perhaps more sensitive way of quantifying aspiration, transit times, gastroesophageal reflux, and pharyngeal residue. Based on a case report, the radionuclide salivagram has also been used to document aspiration of saliva. The major limitations of this

technique are the poor definition of the anatomy and the poor sensitivity for detecting aspiration during swallowing in children with prior aspiration problems. At the present, the use of this technique in pediatric age is limited [76, 81].

Treatment Options

Optimal management strategies are critical for infants and children with feeding and swallowing problems. According to the World Health Organization's International Classification of Functioning, Disability, and Health (ICF) framework, the main treatment goal should aim to promote a functional mealtime experience for children and families, facilitating the patient participation by ensuring a safe and efficient feeding [68]. The management of swallowing dysfunction involves a team approach. Individuals involved in addition to the medical team include a swallowing expert (speech–language pathologist or occupational therapist), a nutritionist, and the family. Since swallowing abnormalities arise from a diverse group of underlying disorders, management techniques must be individualized. This heterogeneity is also reflected in the fact that patients have different potentials to recovery [6].

Although total oral feeding may not be a realistic goal, it is the universal hope of caregivers. Professionals are obligated to point out prerequisites for oral feeding and to discuss the probability that an in individual child may reach the goal. These management decisions are typically made on the basis of clinical observations and assessments. In addition, important information is obtained through an instrumental assessment by videofluoroscopic swallows study. A methodical videofluoroscopic swallowing study: (1) defines the anatomy of the oropharynx; (2) detects dysfunction as evident by aspiration, poor clearance, or poor control of the bolus; (3) determines the mechanism responsible for the dysfunction; and (4) examines the short-term effects of the therapeutic strategies designed to eliminate or compensate for that dysfunction [82]. Management decisions may incorporate nutritive recommendations, medical and surgical decisions, position guidelines, oral-motor/swallow practice, and behavioral intervention [83].

The clinical and instrumental evaluation of children with sucking and swallowing disorders should allow for the recognition of treatable anatomic or inflammatory lesions.

A child may refuse to eat even if his anatomic abnormality has been corrected because of learned aversion to feeding. Behavior therapy often can overcome this type of conditioned food refusal [7, 65].

Various therapeutic approaches may improve the efficiency and safety of feeding. Management techniques involve devising compensatory strategies to minimize swallowing-related complications [84].

Table 20.4 Swallowing strategies for pediatric dysphagia

Behavioral training	
Dietary modification	Thickened liquids
	Thin liquids
Proper intrabolus placement	Modify feeding utensils and bolus presentation
Swallowing exercises	Supraglottic swallow
	Supersupraglottic swallow
	Effortful swallow
	Mendelsohn maneuver
Modification in body tone posture seating and positioning	Head tilt
	Chin tuck
	Head rotation
	Lying on side, elevation
Suckle-feeding-valved feeding bottle	–
Cricopharyngeal myotomy	–
Facilitatory techniques	Biofeedback
	Thermal stimulation
	Gustatory stimulation
Provide alternate means of enteral nutrition	Nasogastric feeding
	Gastrostomy tube (surgical or endoscopic)

These include changing the textures of foods; pacing of feeding; changing the bottle or utensils; and changing the alignment of the head, neck, and body with feeding (Table 20.4) [13, 80].

Frequently, children with severe anatomic disorders but normal neurological function develop their own adaptive strategies to allow for safe oral feeding. Unfortunately, many children with feeding disorders have non-correctable neurologic or anatomic abnormalities that make oral feeding difficult or unsafe. Some patients cannot obtain adequate nutrition by mouth because of a risk for aspiration. Thus, supplying a portion of patient's nutrition by nasogastric or gastrostomy feeding may be beneficial [7]. For those children who have been intubated, management includes teaching techniques that will facilitate transitioning from non-oral to oral feeding. However, there is little evidence that non-oral feeding reduces or eliminates the risk of aspiration [85–87].

The strongest evidence-based recommendation that can be made pertains to diet modification. Furthermore, the literature provides reasonable evidence of the plausibility of swallowing therapy but minimal evidence of efficacy. Nonetheless, although no hard evidence supports its efficacy, the available data are inconclusive and swallowing therapy has not been proven ineffective. Thus, the current weight of opinion, combined with the convincing demonstration of biological plausibility for specific techniques and the consistency of low-grade evidence, is the basis to recommend that swallowing therapy should be used. Large-scale randomized, controlled trials are needed to clarify the current recommendations [29].

Prognosis

Prognosis depends on underlying conditions that predispose to impaired sucking and swallowing. However, the early recognition of feeding problems, diagnosis of underlying disorders, and appropriate intervention improve outcomes for the child and the family.

Defecation Disorders in Children: Constipation and Fecal Incontinence

21

Desiree F. Baaleman, Shaman Rajindrajith, Niranga Manjuri Devanarayana, Carlo Di Lorenzo, and Marc A. Benninga

Part 1: Constipation

Definition

Constipation is a bothersome problem for many children and parents. It is characterized by infrequent, large, hard, or painful stools, with or without fecal incontinence, and may be accompanied by abdominal pain. In approximately 95% of children, no organic cause is found: these children suffer from functional constipation, which is one of the most common functional gastrointestinal disorders in children [1, 2]. Currently, the most widely accepted criteria to diagnose functional constipation in children are the Rome IV criteria (Table 21.1) [3, 4]. Compared to the Rome III criteria, the duration of complaints in order to diagnose pediatric functional constipation was shortened from 2 to only 1 month [5, 6]. In addition, a differentiation was made for children who are or are not toilet trained. These changes were necessary to facilitate early treatment and because most toddlers younger than 2.5 years of age are not (yet) toilet trained.

Table 21.1 Rome IV criteria for functional constipation [3, 4]

Diagnostic criteria for infants up to 4 years of age:
Must include at least two of the following for a minimum of 1 month: 1. Two or fewer defecations per week 2. History of excessive stool retention 3. History of painful or hard bowel movements 4. History of large-diameter stools 5. Presence of a large fecal mass in the rectum In toilet-trained children, the following additional criteria may be used: 1. At least one episode/week of incontinence after the acquisition of toileting skills 2. History of large-diameter stools that may obstruct the toilet
Diagnostic criteria for children from 4 years of age:
Must include at least two of the following occurring at least once per week for a minimum of 1 month with insufficient criteria for a diagnosis of irritable bowel syndrome: 1. Two or fewer defecations in the toilet per week in a child of a developmental age of at least 4 years 2. At least 1 episode of fecal incontinence per week 3. History of retentive posturing or excessive volitional stool retention 4. History of painful or hard bowel movements 5. Presence of a large fecal mass in the rectum 6. History of large-diameter stools that can obstruct the toilet After appropriate evaluation, the symptoms cannot be fully explained by another medical condition

The use of these diagnostic criteria is important because using a single clinical feature to define functional constipation, such as low bowel frequency, can be misleading. It has been shown that around 0.4–20% of otherwise healthy children have at least one feature of the Rome criteria for functional constipation [7, 8]. Furthermore, bowel frequency is known to vary in different regions of the world depending on diet, genetics, and environmental factors [7, 9]. Therefore, it is imperative that the clinician's perspective is flexible and that he or she understands the abnormalities in bowel habits in context of local and patient variables. In addition, the use of diagnostic criteria is essential for research purposes to select subjects and evaluate treatment success [10].

Several studies have assessed the diagnostic capability of the Rome IV criteria to identify functional constipation in children. Studies comparing the prevalence of functional constipation according to Rome III and Rome IV criteria found no significant differences in prevalence [1, 11, 12]. An Italian study including over 200 children and adolescents, aged 0–17 years, found good agreement between the two criteria for diagnosing functional constipation [13].

Prevalence

Constipation is a global public health problem. Reported prevalence ranges from 0.5% to 32.2%, with a worldwide pooled prevalence of 9.5% (95% CI 7.5–12.1) [14]. Studies from Europe show a prevalence ranging from 11.7% to 18.2% [13, 15], and a recent North-American study found functional constipation to be one of the most prevalent functional gastrointestinal disorders among both toddlers (18.5%), and children and adolescents (14.1%) [1].

Prevalence in Latin America range from 6.4% to 10.7% [11, 16], and studies in Asia show a wide range in prevalence of functional constipation from 8.0% in Sri Lanka, 18.3% in Indonesia, to 32.3% in Taiwan [17–19]. Studies evaluating the prevalence of constipation in African countries remain scarce; one study in Nigeria reports a high prevalence of 27% [20]. The differences in reported prevalence need to be interpreted with caution, as the wide variations found may partly be due to differences in definitions used, differences in age groups included, and heterogeneity of survey methods. However, all together these data underscore the magnitude of the disease burden of children with constipation all around the globe.

Physiology of Defecation

Human defecation is the act of eliminating waste materials (feces) from the digestive tract and involves a coordinated number of neurological, muscular, physiological, and behavioral functions. In the colon, intraluminal contents are extracted and the remnant is gradually propelled through the colon. In the transverse colon, pacemaker cells initiate propagation waves in both retrograde (toward the ileum) and antegrade (toward the anus) direction. A few times a day large contractions of colonic smooth muscle result in the antegrade propagation of intraluminal contents. These contractions are called high amplitude propagating contractions (HAPCs) [21]. HAPCs can be propagated from cecum to rectum and are associated with movement of colonic content and defecation [22–24]. Colonic motor activity has a circadian pattern and increases after awakening and eating a meal [22]. Eventually, after propagation, the intraluminal contents arrive in the rectum which acts as a reservoir. During rest, the anal canal is closed by the tonic activity of the internal and external anal sphincters, together with the anal cushions. Further filling of the rectum leads to distension of the rectal wall, which subsequently triggers a transient relaxation of the internal anal sphincter, called the rectoanal inhibitory reflex (RAIR). The RAIR is controlled by the enteric nervous system and partly regulated by the sacral cord [25]. The relaxation of the internal anal sphincter allows descent of rectal contents into the upper anal canal, resulting in a perception of their nature and a possible urge to defecate. The levator ani, puborectalis, and external anal sphincter then remain in a state of continuous contraction (the postural reflex) to keep the feces in the anal canal [25]. Finally, at an appropriate time, the external anal sphincter and pelvic floor muscles relax, and the abdominal wall contracts to empty the anal canal and distal rectal contents.

Risk Factors

Table 21.2 shows the risk factors for developing constipation in children. In contrast to adult studies which show constipation to be more prevalent among females, a recent meta-analysis found no difference in the prevalence of constipation between boys and girls [14, 26]. The same meta-analysis found evidence for associations between the presence of constipation and geographical location, psychological factors, and dietary habits. Geographically, children living in the Americas and Europe seem to have a higher risk of constipation compared to children living in Asia [14].

Psychological stress is another risk factor that predisposes children to develop constipation. The origin of the effect of psychological stress may lay in line with the brain-gut axis described in functional abdominal pain disorders [4]. The brain-gut axis describes the continuous interaction between brain and gut in regulating digestive and immune processes, and the coordination of the physical and emotional state of

Table 21.2 Putative risk factors for childhood constipation

Category	Risk factor
Lifestyle	Poor sleep Decreased physical activity
Dietary	Low fiber intake Low intake of fruit and vegetables Consumption of junk food Not having regular meals with parents Cow's milk protein allergy
Psychological	Home-related stresses School-related stresses Adverse life events including abuse Subjected to bullying Anxiety Depression Psychological maladjustment Autistic spectrum disorders
Social	Lower social class Hostile and aggressive family environment

the entire organism (sleep, hunger, stress) with the activity in the gastrointestinal tract [27]. Common school and home-related stressful life events, as well as adverse life events, such as abuse, predispose children to develop constipation [14, 18, 28–30]. However, in a recent study including Palestinian refugee preschool children, the prevalence of constipation was comparable to prevalence rates among older children worldwide. In that study, stressful life events and trauma exposure did not seem to play an important role in the development of functional constipation [31]. Irregularities in daily life, like absence of parents at home, not having regular meals with parents, and inadequate sleep also seem to be associated with the development of constipation [32, 33]. In addition, the refusal of having bowel movements at school toilets, and bullying are important risk factors to develop constipation [32, 33]. The association between constipation and obesity remains controversial as studies report conflicting data [34]. Decreased physical activity and less outdoor play have been associated with the presence of constipation and may be the reason for conflicting associations in obese children [35–38]. When evaluating dietary factors, low consumption of fruits and vegetables [32, 33, 36, 38], low consumption of fiber [36, 39], and frequent consumption of fast foods [32] are associated with constipation. Studies have suggested that a decreased fluid or fiber intake and cow's milk allergy may be causes of constipation [40–42]. The data on these topics however remain scarce. In infants, breastfeeding seems to be protective for the development of constipation [38, 43]. No association was found between cesarean section and the development of constipation in infants [44]. A randomized field trial performed in Brazil found that promoting healthy infant feeding practices was effective in reducing the prevalence of constipation among children at 6 years of age [45].

Quality of Life

Children with constipation have poor health-related quality-of-life (HRQoL) scores in all domains, namely social, school, physical, and emotional functioning [46, 47]. Children with constipation report even lower HRQoL scores compared to children suffering from organic diseases such as gastroesophageal reflux, and inflammatory bowel disease [47]. Surprisingly, a recent meta-analysis found no evidence for a difference in HRQoL between children with and without fecal incontinence [46]. Factors thought to be responsible for the impaired HRQoL include the chronic nature of the condition, psychosocial comorbidities, and adverse social effects of symptoms like school absenteeism, fecal incontinence, or clogging of toilets at school [48–51]. In addition, children with constipation often suffer from an array of somatic symptoms which are in turn associated with lower HRQoL [50].

Healthcare Burden

Constipation is a leading cause for medical consultation in children. A prospective study in the United States has shown that from childhood to early adulthood, individuals with functional constipation have higher medical care use, including high outpatient costs and emergency department utilization compared to matched controls [52]. The use of medical resources by children with constipation is substantially higher than that of other chronic episodic conditions such as asthma (seven times) and migraine headaches (three times) [52]. In an analysis of national emergency department sample records for emergency room visits of children of all ages across the United States, 17 per 100.000 emergency department visits were visits because of fecal impaction [53]. Furthermore, children with constipation are noted to have higher number of days of school absenteeism [51, 54] and children with fecal incontinence show poorer school performance [51]. Implications of these findings on education of children are substantial as poor education invariably leads to poor earning capacity and is associated with poorer health [55].

Pathophysiology

In more than 95% of pediatric cases, no underlying organic cause for constipation can be found, and these children are therefore diagnosed with functional constipation [2]. In the 5% of children with an organic cause for constipation, the etiology varies from Hirschsprung's disease, anorectal malformations, neuromuscular disease, to metabolic and endocrine disorders. A list of organic causes is provided in Table 21.3.

Table 21.3 Organic causes of constipation in children

Anatomical causes
Anorectal malformation
Intestinal obstruction
Metabolic and endocrine causes
Celiac disease
Cystic fibrosis
Dehydration
Diabetes mellitus
Hypo- or hypercalcemia
Hypokalemia
Hypothyroidism
Neurogenic conditions
Hirschsprung's disease
Autonomic neuropathy
Botulism
Chagas disease
Myelodysplasia
Myelomeningocele
Myotonic dystrophy
Neurofibromatosis
Neuronal intestinal dysplasia
Pseudo-obstruction (e.g., myopathies, mitochondrial disorders)
Spinal cord abnormalities (e.g., tethered cord)
Other causes
Starvation (secondary to anorexia nervosa)
Depression
Immobility
Medications (e.g., opiates, anticholinergics, antidepressants, chemotherapy)
Sexual abuse

The pathophysiological mechanisms of functional constipation in children are multifactorial and remain incompletely understood. However, available studies on physiology of the colon and rectum have shed some light upon the subject.

Infants and Young Children

Especially in young children, stool withholding is the major contributing factor in the development of constipation. Some studies found that even over 90% of constipated young children show withholding behavior [56–58]. Typically, when a child feels the urge to pass stools, he or she tightens gluteal muscles and stands on tip toe to prevent the stool to pass. This behavior may be the result of a prior painful or frightening experience of defecating, strict early toilet training, stubbornness, and/or concentration on other, more fun activities than going to the bathroom. During the process of withholding stools, the rectum compliance increases, i.e., the rectum has a greater capacity to distend and relaxes more in response to distension [59]. Because of the increase of rectal compliance, larger stool volumes are required to reach the intrarectal pressure which triggers an urge to defecate. With the retention of stool and the continuous absorption of water by colonic and rectal mucosa, the stool becomes dry, hard, and (more) difficult to pass. Passing a painful stool then leads to an anticipation of pain which in turn triggers withholding behavior. The child gets into a vicious cycle of delaying defecation, leading to prolonged retention of stool, leading to dilation of the rectum and a delayed urge sensation, leading to further retention of stools, which become hard, large, and painful, resulting in more anticipated pain triggering withholding behavior, etc. In accordance with this developed aversion toward defecation, a self-efficacy scale has been developed to measure the child's confidence and motivation in the act of defecating [60]. Self-efficacy improved in children after their first clinic visit, and treatment success was associated with further improvement of self-efficacy [61]. Self-efficacy may have improved because of treatment success or may play a role in achieving treatment success which would make it an interesting therapeutic target. In addition to this intentional or subconscious withholding of stools when feeling an urge to defecate, a subset of children may "teach" themselves to withhold their stool even during defecation. The act by which during defecation a child contracts instead of relaxes his or her pelvic floor and external anal sphincter is called dyssynergic defecation, anismus, or pelvic floor dyssynergia. This paradoxical contraction may be responsible for further hampering defecation and is found in about 40% of children with constipation [62, 63]. Some suggest this contraction is the manometric equivalent of stool withholding [64].

Children and Adolescents

For older children, stool withholding may play a less important role, and other contributing factors have been identified in the development of constipation. In a subset of children, local colonic factors may play a role in the development of constipation such as delayed intraluminal colonic transport by decreased (segmental) propagation, which may result in delayed colonic transit times [65, 66]. With the use of colonic manometry, several abnormalities have been identified in children with constipation, including reduced frequency or premature termination of HAPCs, or abnormal colonic response to stimuli, such as a meal [67]. Children with intractable constipation may have a reduced number of postprandial retrograde cyclic propagating motor patterns and have an increased incidence of spontaneous long-single motor patterns [68]. A total absence of high amplitude propagating contractions may also be found in children with intractable constipation [69]. These factors may contribute to poor propulsion of fecal material along the colonic lumen resulting in symptoms of constipation.

Rectal sensitivity to oncoming fecal matter is crucial for normal rectal function. There is a subset of children with constipation who demonstrate poor rectal sensation [70]. Furthermore, several studies in children have shown increased rectal compliance [63, 71] and a megarectum [72]. These factors are closely interrelated and lead to attenuation

of rectal sensation and lack of desire to evacuate, leading to low bowel frequency.

Other psychological factors may also play a role. A study investigating differences in sensory patterns found that children with chronic constipation showed significantly higher sensory scores than a matched normative sample [73]. The authors hypothesize that children with high sensitivity may be avoidant of toileting and, therefore, experience higher levels of fecal retention. The effect of sensory responsiveness on the timing of defecation may also explain the associations between constipation and both internal and external behavior problems and behavioral disorders (such as autism spectrum disorder or attention-deficit/hyperactivity disorder) [74–77]. This may play a more pronounced role in older children, as a study has shown that children with later onset of symptoms were more likely to have behavioral or developmental issues [78]. In addition, parents may influence the development or continuation of constipation in their children. Studies have shown that parental personality, psychological and physical health, and child-rearing practices differ significantly between parents of children with functional constipation and parents of control subjects [79, 80]. High levels of frustration or irritability toward the child were shown to have a negative effect on fecal incontinence symptoms. This emphasizes the importance of educating the parents about functional constipation and the effect of their parenting practices.

The gut microbiome may also play a role in the pathophysiology of constipation within the brain-gut axis via endocrine, immune, and neural pathways [81]. Small studies have found differences in microbiota between healthy individuals and children and adults with functional constipation; however, the reported characteristics of microbiota related to functional constipation differ among studies [82–84]. Next to a role for the microbiome via the brain-gut axis, gut microbiota may modulate gastrointestinal motility as reported in animal studies, or by metabolites and fermentation products having osmotic effects and causing increased gas production [85, 86]. The microbiome may be affected by the diet, which is also thought to be a factor in the pathophysiology of constipation.

Final Pathway for Both Age Groups

Pathophysiological mechanisms described for both age groups, including important risk factors described earlier, are shown in Fig. 21.1. These combined factors lead to retention of stools in the rectum and colon. Since colonic and rectal mucosas are designed to absorb water, stool becomes dry, hard, and large. Accumulation of feces, leading to dilatation of the colon is associated with premature termination of HAPCs [65], and mechanical dilation of the rectum inhibits motor function of the proximal and distal hemi-colon through reflex mechanisms [88, 89]. In addition, accumulation of feces may elongate the colon [90]. This in turn leads to the release of nitric oxide by activating mechanosensory and myenteric descending neuronal nitric oxide synthase. Nitric oxide inhibits action potential firing in other myenteric sensory neurons driving peristaltic nerve circuits, inhibiting colonic contractile activity (occult reflex), thereby seriously hampering evacuation [91, 92]. It has been shown that children with increased rectal wall compliance have prolonged colonic transit time which further strengthens the possibility of occult reflex [71]. However, even though increased rectal compliance is found to be associated with more severe symptoms, it does not predict treatment success or change after successful treatment [70]. Interactions of these inextricably linked mechanisms in a complex manner, rather than in isolation, lead to generation and propagation of symptoms in children with constipation.

Clinical Evaluation

The most important tool in diagnosing defecation disorders in children is the clinical evaluation. A thorough history and physical examination, including rectal examination when only one symptom of the Rome IV criteria is present, can be sufficient to identify functional defecation disorders, exclude possible organic causes, and recognize complications. During history taking and physical examination, one should always be aware of alarm symptoms of constipation indicating organic causes of constipation or signs of physical abuse (see Box 1).

Clinical History

Although the presenting features are obvious in most children, in some children clinical features may be subtle. Therefore, a high degree of suspicion is essential during history taking. Onset and duration of symptoms need to be clarified first. A very early onset in infancy suggests the possibility of organic diseases such as Hirschsprung disease, anorectal malformations, and metabolic diseases. However, breastfeeding may be responsible for a wide range in defecation patterns which should not be directly considered abnormal [93–95]. Details of bowel habits are the cornerstone in diagnosing constipation. The use of validated stool scales for infants (Amsterdam stool scale and Brussels Infant and Toddler Stool Scale) and children (modified Bristol stool scale) help to obtain more accurate description of stools [96–98]. Apart from gathering information on bowel habits, it is important to look for other gastrointestinal and urinary symptoms, the effect of constipation symptoms on daily life, and to identify risk factors that may contribute to persistence of symptoms. Moreover, abdominal pain is noted in 10–70% of children with constipation. When the abdominal pain does not improve after resolution of constipation symptoms, the diagnosis of irritable bowel syndrome (IBS) should be considered [4]. Although the Rome criteria consider IBS and functional con-

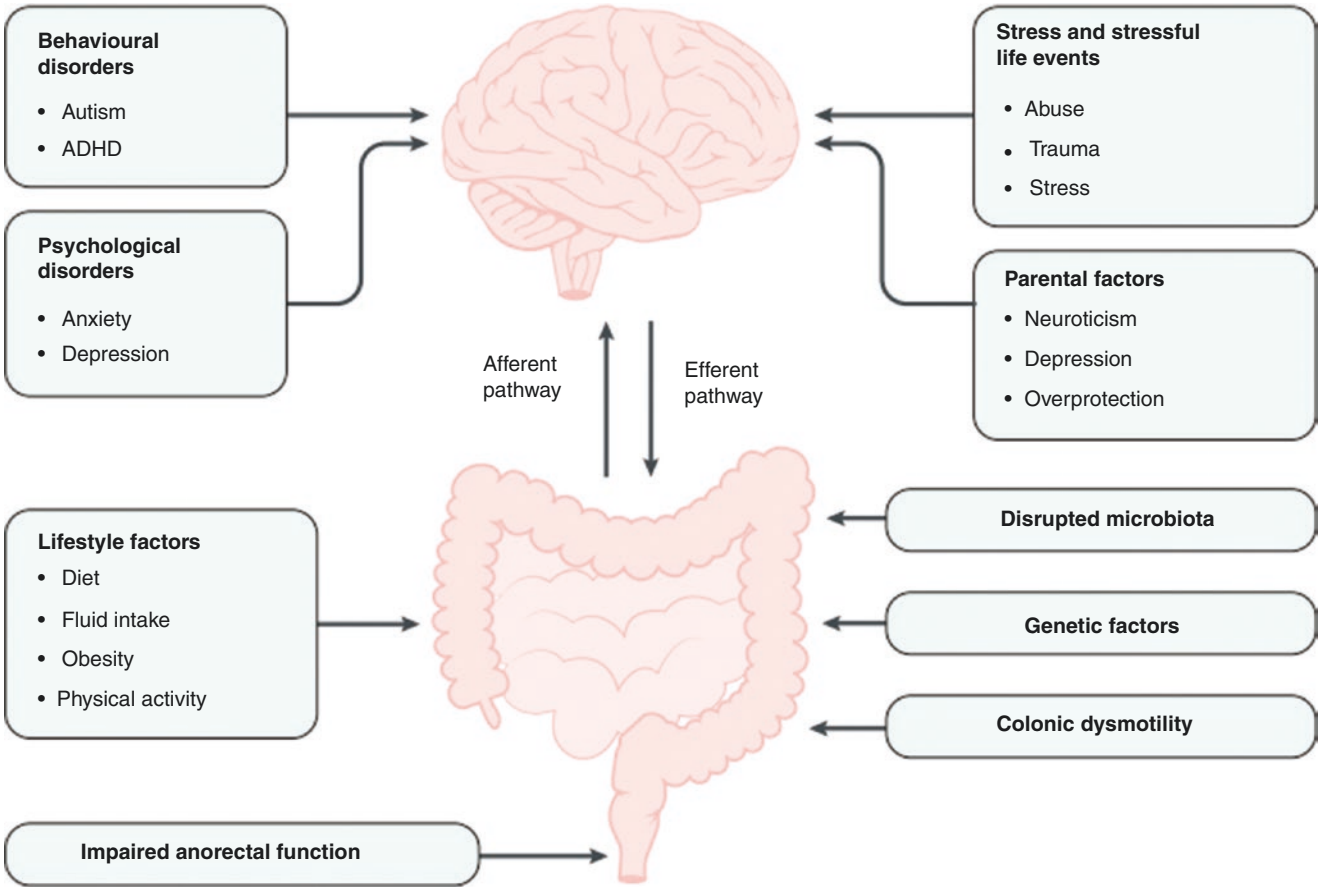

Fig. 21.1 An overview of the multifactorial pathophysiology of functional constipation. Psychological and behavioral factors are thought to affect the brain-gut axis both via efferent and afferent pathways. (Reused with permission from Vriesman et al. [87]). *ADHD* attention-deficit/hyperactivity disorder

stipation as different entities, evidence is accumulating that suggests that the two are part of a disease continuum. In this continuum, diagnosing one or the other may not only be a challenge, but the patient may actually move between diagnoses over time, switching from IBS to functional constipation or vice versa [99, 100]. In the majority of children who struggle with fecal incontinence, the incontinence is secondary to constipation. However, in approximately 5–10% of the children (mainly boys), fecal incontinence may occur without other symptoms of constipation. According to the Rome IV criteria, these children should be diagnosed with non-retentive fecal incontinence and should be treated accordingly. Part 2 of this chapter will discuss this separate clinical entity in detail. Poor appetite, nausea, vomiting, and abdominal bloating are other important features that need to be elicited during history taking. Lower urinary tract symptoms including urinary incontinence are also seen in some children, and refractory vulvovaginitis is a known feature, especially in prepubertal girls [101–104].

Past medical history, specially concentrating on factors that may cause constipation, such as medications or previous surgical corrections of anorectal malformations and Hirschsprung's disease, is also an important part in the evaluation [105, 106]. Dietary history particularly concentrating

Box 1 Alarm Symptoms of Constipation

Acute symptoms

- Delayed passage of meconium (first meconium after 48 hours of life)
- Fever, bilious vomiting, or diarrhea in a young infant, especially if there are other signs or risk factors for Hirschsprung's disease (e.g., Trisomy 21)
- Rectal bleeding (unless attributable to an anal fissure)
- Severe abdominal distension

Chronic symptoms and signs

- Very early-onset constipation (<1 month old)
- "Ribbon" stools (very narrow in diameter)
- Failure to thrive
- Extraintestinal symptoms (especially neurologic deficits)
- Physical findings suggestive of anorectal disorder, sacral spine abnormality, or sexual abuse (e.g., anteriorly displaced anus, scars, extreme fear of anal exam).
- Family history of Hirschsprung's disease, celiac disease, or hypothyroidism

on fiber content is an integral part as underconsumption of fiber may lead to constipation [36, 107–109]. When symptoms arise after introduction of cow's milk to the infant's diet, cow's milk allergy may play a role [42].

Psychological abnormalities also need to be uncovered as there is an association between children with functional constipation and behavioral problems [74–77]. In addition, stressful life events such as physical, sexual, and emotional maltreatment need to be evaluated carefully in children with constipation as these factors are known to predispose to the development of constipation [14]. Finally, consequences of constipation should be discussed. Studies have shown that children with functional constipation have a reduced health-related quality of life [46]. Children with constipation, with or without fecal incontinence, may often have to deal with feelings of shame, peer rejection, and bullying. Creating a comfortable place for them to defecate, like the teacher's bathroom in school, may contribute to adequate treatment and resolution of symptoms, as well as increasing their quality of life.

Physical Examination

Physical examination should start with assessment of growth. Faltering growth and short stature are alarm features of organic causes (endocrine, metabolic, etc.) of constipation.

Abdominal examination may reveal the presence of abdominal distension and past surgical scars from abdominal surgery. Palpable fecal masses in the lower abdomen indicate increased fecal loading, and this may be present in about 50% of children with constipation [110]. Gaseous distension is more in favor of constipation-predominant irritable bowel syndrome ("IBS-C").

Perianal examination may reveal abnormal position of the anus [111]. Fecal smears and perianal excoriation of skin indicate presence of fecal incontinence. Fissures and anal tags can also be seen in children with chronic constipation who pass hard stools, but may also indicate sexual abuse. A patulous anus (loose, open) is the result of a loss of tone of sphincter muscles due to damage or dysfunction of the muscles, or disturbances in their innervation, and can be associated with fecal incontinence [112, 113].

Digital rectal examination is not necessary in children whom already fulfill Rome IV criteria for a diagnosis of functional constipation [95]. However, if the diagnosis is unclear, if there is doubt between the diagnosis of non-retentive fecal incontinence and functional constipation, or if conventional treatment fails, digital rectal examination is indicated. During the examination, one should assess resting tone, squeeze pressure of the sphincter complex, and rectal fecal loading. Findings suggestive of Hirschsprung's disease are a tight anal canal with an empty ampulla. A digital rectal examination in patients with Hirschsprung's disease may temporarily relieve the obstruction and therefore result in an explosive release of gas and stool (blast sign or squirt sign). Findings suggestive of functional constipation are an enlarged rectum filled with (hard) stool. However, it is important to note that a lack of stool in the rectum does not exclude the diagnosis of functional constipation.

In addition to physical examination focused on the gastrointestinal tract, their neurological, cognitive, and social development should also be assessed, and dysmorphic features should be noted. This is necessary to identify children with syndromes, neurological disorders, or behavioral disorders mentioned earlier who are at risk to develop constipation [76, 114]. Neurological examination should concentrate specially on features of spina bifida, motor and sensory deficits in the lower limbs, and perianal sensory testing. One should evaluate perianal sensory loss and absence of anal wink.

Investigations

Constipation is a clinical diagnosis. With the use of current diagnostic criteria, additional testing to diagnose and successfully treat children is not necessary in most children with defecation disorders. However, if the diagnosis is still uncertain, if there is a suspicion for an organic cause of constipation, or if children do not respond to conventional medical treatment, focused additional investigations are indicated. The most commonly used additional tests include laboratory tests, imaging tests, and functional tests.

Laboratory Tests

At initial presentation, laboratory testing should only be performed in the presence of alarm signs suggestive of a metabolic cause of constipation. The additional value of routine testing of celiac disease or hypothyroidism has not been demonstrated [115–117]. Testing may include a complete blood count, biochemical profile, thyroid function, and celiac screening. As the association between cow's milk allergy and constipation remains controversial, testing for cow's milk allergy is not recommended, but a 2- to 4-week trial of avoidance of cow's milk may be considered [95].

Radiological Tests

One of the main reasons to perform imaging studies is to differentiate children with functional constipation with overflow incontinence from those with non-retentive fecal incontinence [95]. In addition, imaging is more often used in children who are not able to adequately report on their bowel symptoms, as may be the case in children with autism spectrum disorder [118].

Ultrasonography has been used to assess the degree of fecal retention in the rectum. Using a transabdominal approach, several studies have measured the rectal diameter to determine fecal loading in the rectum using different methods, and have

shown that children with chronic constipation have a larger rectal diameter compared to controls [119–121]. The results are promising, and the wide availability and noninvasive nature of the test makes it an ideal investigation. However, methods need to be standardized, and larger studies evaluating the reliability of measurements with blinding of the examiners are needed before routine use of ultrasonography in the assessment of children with constipation is recommended.

Plain abdominal X-rays are still often used to demonstrate fecal loading in the colon and rectum in order to diagnose constipation, and several scoring systems have been proposed to assess the degree of fecal loading [122, 123]. However, sensitivity and specificity of these scores are variable, and the inter- and intraobserver reliability is poor [124]. Moreover, studies have shown that the use of abdominal X-rays as tool to diagnose constipation may even be harmful. A large multicenter retrospective study found that children diagnosed with constipation who received an abdominal X-ray were twice as likely to return to the emergency department with a clinically significant alternate diagnosis like acute appendicitis [125]. A recent study showed that education on the unreliability of abdominal X-rays in the emergency department lowered the percentage of abdominal X-rays performed on healthy patients discharged home with a diagnosis of constipation while keeping the number of important return visits to the ED low [126]. Based on the current evidence, abdominal radiography is rarely justified when assessing constipation in children and children presenting with abdominal pain [95, 127].

Colonic transit time is usually assessed by using radiological methods. It generally gives an idea of propulsive function of the colon and may help to identify segments with abnormal motility. It is usually conducted using radiopaque markers or scintigraphic methods. In marker studies, radiopaque markers are ingested with a meal or swallowed as a capsule, and abdominal X-rays are obtained to count the number of markers in different segments of the colon. In scintigraphy, the patient is given a meal containing a radioisotope, and multiple images are taken using a gamma camera to assess the radioisotope count in each region. A delayed colonic transit time can indicate slow-transit constipation but may also result from withholding behavior in children [128, 129].

The use of barium (contrast) enema as an initial diagnostic tool for the evaluation of children with constipation is not recommended [95]. Contrast enemas are sometimes used in the evaluation for Hirschsprung's disease or to plan surgical intervention after diagnosis. However, rectal biopsy or anorectal manometry is more reliable in diagnosing Hirschsprung's disease, and the radiographic location of the transition zone does not always correlate accurately with the level of aganglionosis [130, 131].

Although the literature on the additional value of defecography in children with constipation is limited, the test is sometimes used to evaluate children with intractable constipation. Defecography is a dynamic radiologic test used to visualize anorectal function at rest and during voluntary defecation. It can be used to identify children with pelvic floor dyssynergia and structural abnormalities, including intrarectal intussusception, rectocele, or rectal prolapse [132]. A recent study examining the value of fluoroscopic defecography in 51 children with prolonged colonic transit times found abnormal defecography results in 27 patients (52.9%) [133]. Structural abnormalities were the most common abnormal finding (n = 15), followed by pelvic floor dyssynergia (n = 10) and a combination of the two (n = 2). However, the authors state that children with minor structural abnormalities continued medical treatment, and additional therapeutic consequences of defecography findings were not reported. Therefore the additional value of the test and its findings remains unclear.

Magnetic resonance imaging of the spinal cord should be considered in children with additional neurological abnormal findings to diagnose spina bifida occulta and terminal filum lipoma. In children without neurological abnormalities, the prevalence of lumbosacral spine abnormalities is low, and the significance of the abnormalities is unclear [134].

Functional Tests

Anorectal manometry allows assessment of the neuromuscular function of the anus and the rectum. With the use of a catheter in the anus and rectum, pressures in the anal canal can be measured and defecation dynamics can be visualized. The catheter contains a balloon placed in the rectum which can be inflated to mimic fecal rectal filling. By inflating the balloon, the nerves in the rectum should initiate a relaxation of the internal anal sphincter, resulting in a decrease in pressure. This rectoanal inhibitory reflex is absent in patients with Hirschsprung's disease, anal sphincter achalasia, after circular rectal myomectomy, or in some patients with (corrections of) anorectal malformations [135]. If manometry is performed awake, children can verbalize rectal sensation during different balloon inflations, and they can be asked to push and squeeze to evaluate anal sphincter function [135]. In case the child contracts instead of relaxes the anal sphincter, when attempting to expel the inflated balloon, a diagnosis of pelvic floor dyssynergia is made. However, because of the unnatural lateral position and setting (with presence of medical personnel), the results of this maneuver may be falsely positive [135]. Anorectal manometry testing may be considered in children with a low suspicion for Hirschsprung's disease in order to exclude Hirschsprung's disease (when there is a high suspicion, a rectal biopsy is indicated), or to evaluate for anal achalasia

or pelvic floor dyssynergia [135, 136]. However, the significance of these last two findings remains controversial as children with anal achalasia have only been minimally described in the literature and therapeutic modalities to treat pelvic floor dyssynergia, including biofeedback, have not proven their advantage over conventional treatment [63, 137, 138]. Next to conventional anorectal manometry testing, a new high-resolution catheter with 256 sensors providing a three-dimensional visualization of the anal canal has been developed. The topographic pressure measurements may demonstrate longitudinal and radial asymmetry of the anal canal and may allow for a better visualization of anatomical impaired anorectal function, as well as better understanding of the mechanisms of fecal continence in children [139]. Its usefulness in daily practice and impact on treatment have yet to be determined.

Colonic manometry allows the measurement of pressure/peristaltic movements of multiple regions within the colon in real time and helps to discriminate between normal colonic physiology and colonic myopathies and neuropathies [21]. A number of colonic motor patterns have been identified, such as antegrade HAPCs, low-amplitude propagating sequences, non-propagating contractions, and retrograde propagating pressure waves [67]. Studies have suggested that colonic manometry findings may predict outcomes of surgical interventions, and that an abnormal colonic manometry may be predictive of surgery [135, 140–142].

Management

Effective management of constipation requires a multifaceted approach. A stepwise management protocol is shown in Fig. 21.2. The main steps include lifestyle modification, toilet training, use of laxatives and enemas, biofeedback/pelvic floor physiotherapy, nerve stimulation, and surgical interventions. However, it is important to realize that the data in the pediatric literature to support evidence-based use of treatment strategies are limited, especially regarding old laxatives such as lactulose and bisacodyl. Therefore, the management mostly depends on individual experiences.

Lifestyle Modifications

As stated earlier, constipation is associated with psychological stress related to home, school, and society [18, 31, 48, 75]. These factors need to be addressed during consultation. Children with psychological stress need to be identified and coping mechanisms need to be taught. Home- and school-related punishment is another factor that is known to predispose children to develop constipation which can easily be avoided [28].

Although the prevalence of constipation is associated with a low intake of fiber, a high-fiber diet has not shown to relieve constipation [107, 143, 144]. Current treatment guidelines recommend a diet with a normal fiber intake (around 5g + the age of the child in years) [95]. Similarly, increase in the consumption of water (aside from the extra fluid necessary for laxative dissolvent) has also not shown to be beneficial in the treatment of constipation [145].

Other interventions with respect to previously described risk factors for constipation like decreased physical activity and frequent consumption of fried food have not yet been studied. However, general advice for a healthy lifestyle is never inappropriate and may be beneficial for the child's bowel habits. Following on the hypothesis on the effect of the microbiome on children with constipation, pre-, pro-, and synbiotics have become of interest as treatment modalities. However, so far current evidence does not support the use of these compounds as a single or additional therapy for treatment of functional constipation in children [146, 147].

Toilet Training and Behavioral Therapy

Stool withholding plays a crucial role in the development of constipation in young children. Children with constipation need to relearn how to properly pass stools in the toilet. As the first step, a negative attitude regarding stools needs to be eliminated. This facilitates and prepares the child's mentally to pass stools in the toilet or potty. The child is encouraged to use the toilet whenever he or she feels an urge and regularly after each meal as the postprandial gastrocolic reflex facilitates generation of propagating contractions which help to evacuate stools. The proper seating method (upright posture) to bring the anorectum in the correct angle to facilitate the passage of stools needs to be taught. Proper positioning of legs and relaxing the pelvic floor and anal sphincters should also be explained. Once the child masters these techniques, it is necessary to teach proper straining methods. This process needs to be a regular practice and may be encouraged with a reward system [148]. Evidence indicates that adding behavioral therapy to conventional laxatives has benefits in treating children with constipation [149, 150]. It is obvious that behavioral therapy alone cannot cure constipation. However, given the importance of stool-withholding behavior (especially in infants and younger children), toilet training and behavioral modifications are mandatory parts in the day-to-day clinical management of these children.

Subsequently, parents should be educated on the effects of their thoughts, attitudes, and behavior toward the child with constipation and fecal incontinence. Studies have shown that parental child-rearing attitudes are associated with defecation

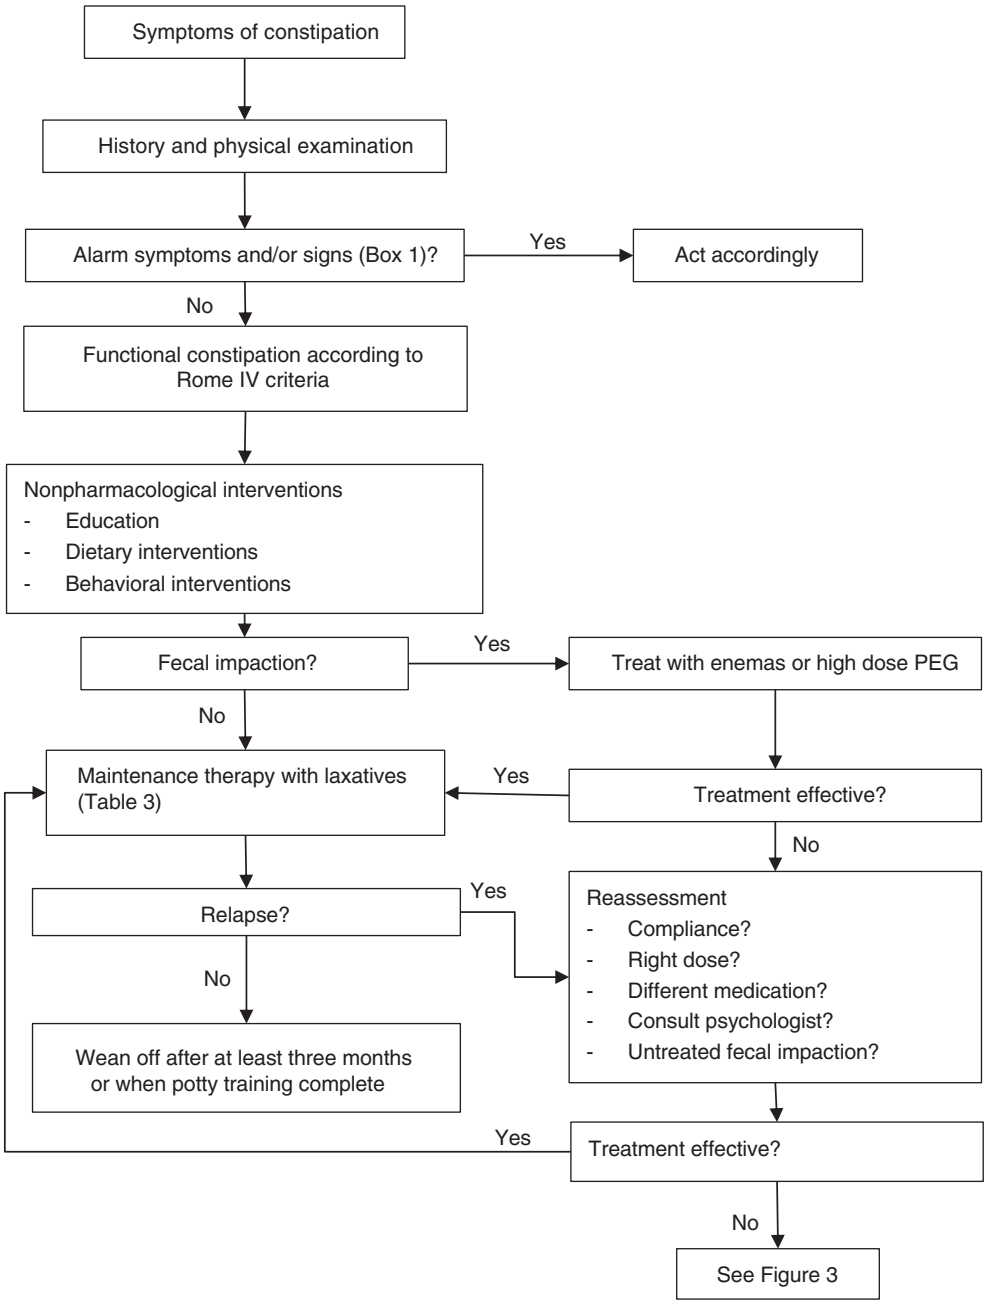

Fig. 21.2 Algorithm for initial presentation of symptoms of constipation. A suggested stepwise approach for the evaluation and treatment. (Modified with permission from Vriesman et al. [87]) *PEG* polyethylene glycol

and fecal incontinence frequency [80]. High levels of frustration or irritability toward the child have a negative effect on symptoms of fecal incontinence. Parents should be made aware that the episodes of fecal incontinence are not the child's fault and the child is not purposely losing stools. By avoiding blame and praising positive behavior, education on parental influence may enhance treatment [79, 151]. Moreover, in order to assure treatment adherence, parents should be educated on two main reasons for children with constipation having watery stools, namely "overflow diarrhea" and regular diarrhea. Overflow diarrhea is a result of severe constipation, and these are soft stools which pass around a solid, obstructing, fecal mass and can result in overflow incontinence. Regular diarrhea could be a consequence of too high laxative dose or may be caused by gastroenteritis.

Pharmacological Treatment

In addition to education, keeping a bowel diary, and starting toilet training, pharmacological treatment is part of the first step in treating children with constipation [95]. Pharmacological treatment is based on two cornerstones: disimpaction of the rectum and maintenance therapy.

Fecal Disimpaction of the Rectum

Disimpaction of the rectum is indicated whenever a child diagnosed with constipation presents with fecal impaction defined as: "a hard mass in the lower abdomen identified on physical examination or a dilated rectum filled with a large amount of stool on rectal examination or excessive stool in the distal colon on abdominal radiography" [95, 152, 153]. After evacuation of the fecal mass, children are more likely to respond to maintenance therapy [154]. Disimpaction can be achieved with high doses of oral laxatives or with enemas containing stimulant ingredients such as sodium phosphate or sodium docusate. In severe cases, or when the child refuses oral and rectal medications, manual disimpaction under general anesthesia is indicated. Studies comparing disimpaction with oral laxatives with disimpaction with enemas found both routes to be effective but found some benefit for the use of rectal enemas. Children using rectal enemas experienced a faster relief of symptoms, and high doses of polyethylene glycol (PEG; 1.5 g/kg/day) caused more fecal incontinence [152, 153]. However, despite therapeutic advantages of rectal treatment, it is imperative to realize the invasive nature of rectal therapy. This is especially important to keep in mind when the child has perianal pain, anal fissures, or suffers from morbid fear of manipulations around the perianal region. Although rectal disimpaction may be uncomfortable for the child and parent, usually the idea is more freighting than the act itself, and a practical advantage is the predictability of the timing of the evacuation of the fecal mass. Current guidelines recommend a high dose of orally administered PEG based on the argument that PEG can be easily administered orally [95]. Based on prior experience and possible fear of the child, the physician should come up with a best plan for fecal impaction individualized for each patient. One randomized trial in Jordan compared the effectivity of PEG (1.5 g/kg/day) and lactulose (4–6 ml/kg/day) in treating fecal impaction and found a faster response is the lactulose group, indicating lactulose may also be an alternative treatment option for disimpaction.

Maintenance Therapy

Once disimpaction is achieved, it is imperative to initiate maintenance therapy. This facilitates passage of stools and prevents re-impaction. Table 21.4 shows the details of drugs that are currently used in the management of childhood constipation. First choice of maintenance treatment are osmotic laxatives such as PEG. If PEG is not available, lactulose is the laxative of choice. As additional or second-line treatment, milk of magnesia (magnesium peroxide), mineral oil (liquid paraffin), and stimulant laxatives (senna or bisacodyl) may be considered [95]. In children with constipation after repaired anorectal malformations, stimulant laxatives are the first choice of maintenance treatment as modification of stool consistency by an osmotic laxative may lead to fecal incontinence [155]. According to current guidelines, maintenance therapy should continue for at least 2 months [95]. Discontinuation of treatment may be considered when all symptoms of constipation symptoms are resolved for at least 1 month and treatment should be decreased gradually. When children are in the developmental stage of toilet training, medication should be continued until toilet training is achieved.

Osmotic Laxatives

Osmotic laxatives are the group of choice used in the maintenance phase. As a group, they exert an osmotic effect which helps to increase the water content in the colon and hence softening stools in a dose-related response while being only minimally systemic absorbed and with minimal adverse effects. Lactulose and PEG are the two most commonly used osmotic laxatives. Due to its ease of administration, its effectiveness, and good safety profile, PEG is the laxative of first choice. Multiple studies have demonstrated the superiority of PEG over placebo, lactulose, mineral oil, and milk of magnesia (magnesium hydroxide) [156–162]. However, the results of these studies ought to be interpreted with caution due to quality and methodological concerns, as well as clinical heterogeneity, and short follow-up. Two types of PEG are available (PEG 3350 and PEG 4000) with or without addition of electrolytes [163]. The numbers after PEG correspond with the molecular weight of the drug molecule and the addition of electrolytes is thought to minimize the risk of electrolyte imbalances. A randomized controlled trial could not prove noninferiority of PEG 3350 with electrolytes compared to PEG 4000, but concluded that both treatments are likely to have similar long-term efficacy and safety [164]. Overall fluid intake may be a confounding factor in the effectivity of PEG treatment, where poor fluid intake may decrease effectivity [165]. An adult study found that PEG 4000 with orange flavor (Forlax) has at better taste than PEG 3350 with electrolytes (Movicolon) [166]. Questions on the safety of long-term use of PEG in children have been raised due to reports of neuropsychiatric events and the use of PEG 3350, but the United States Food and Drug Administration (FDA) states that based on current available data no action is required [167]. As previously mentioned, co-occurrence of behavioral problems and functional constipation has been extensively described and may explain the reports of neuropsychiatric events [74–77]. In addition, a case-control study found no sustained elevated blood levels of neurotoxins (ethylene glycol and diethylene glycol) in children who used PEG 3350 daily compared with healthy controls [168]. It is important to discuss any parental concerns, misperceptions, and satisfaction on the use of laxative as parental perceptions have been shown to be associated with PEG treatment adherence, which overall is found to be low (37%) [169] (Fig. 21.3).

Table 21.4 Pharmacological agents for childhood functional constipation

Drug	Evidence	Side effects	Dose
Osmotic laxatives			
Polyethylene glycol (PEG)	Improves consistency and frequency of stools, and straining	Diarrhea and abdominal distention	Maintenance: 0.3–0.8 g/kg per day; disimpaction: 1–1.5 g/kg per day (for maximum of 7 days)
Lactulose	Improvement of symptoms of mild to moderate constipation; safe to use in young children	Abdominal gas, bloating, and cramping	7 months–18 years: 1–2 g/kg per day in 1–2 doses
Milk of magnesia (magnesium hydroxide)	Evidence of efficacy is poor	Diarrhea	2–5 years: 0.4–1.2 g per day; 6–11 years: 1.2–2.4 g per day; 12–18 years: 2.4–4.8 g per day
Lubricants			
Mineral oil (liquid paraffin)	Evidence on efficacy is of poor quality	Skin irritation and reduced absorption of fat-soluble vitamins; risk of lipid pneumonitis with aspiration	1–3 ml/kg per day (maximum 90 ml per day)
Stimulant laxatives			
Bisacodyl (diphenylmethane)	Improvement of symptoms	Oral: diarrhea and abdominal pain Rectal: abdominal pain and anal discomfort	Oral or rectal: 3–10 years: 5 mg per day in 1 dose before bedtime; >10 years: 5–10 mg per day in 1 dose before bedtime
Sodium picosulfate (diphenylmethane)	Improvement of symptoms	Diarrhea and abdominal pain	4–5 years: 3 mg; >6 years: 4–6 mg per day in 1 dose
Senna (anthraquinone)	Clinical experience suggests effectiveness, but no large randomized trials have been performed	Diarrhea and abdominal pain; in young children risk of dermatitis	2–6 years: 2.5–5 mg/day in 1–2 doses; 6–12 years: 7.5–10 mg/day in 1–2 doses; >12 years: 15–20 mg/day in 1–2 doses
Rectal enemas for fecal disimpaction			
Sodium docusate	Evidence supports effect on fecal impaction	Abdominal pain and anal discomfort	<6 years: 60 ml; >6 years: 120 ml
Sodium phosphate	Evidence supports beneficial effect on fecal impaction	Water and electrolyte disturbances, especially in young children; do not use when suspicious of Hirschsprung disease	2.5 ml/kg (maximum of 133 ml per dose)
Sodium lauryl sulfoacetate	Evidence supports effect on fecal impaction	Abdominal pain and anal discomfort	1 month–1 year: 2.5 ml/dose; >1 year: 5 ml/dose

Lubricant Laxatives

Although there are no placebo-controlled trials involving lubricant laxatives, two trials comparing mineral oil with lactulose have noted statistically significant better response rates with mineral oil [170, 171]. When comparing mineral oil with PEG, PEG was found to be superior due to higher response rates and/or fewer adverse events [161, 172]. It is important to note that due to the risk of life-threatening lipoid pneumonia, mineral oil is not recommended for young infants and children with swallowing difficulties, especially those who are neurologically impaired [173].

Stimulant Laxatives

Bisacodyl and senna stimulate peristaltic movements and enhance fecal evacuation. Bisacodyl can be taken orally and as suppository. Senna can only be taken orally. There are no good quality trials which evaluate stimulant laxatives in childhood constipation. Studies comparing senna with lactulose and mineral oil demonstrated that children using senna had a poorer response [174, 175]. A recent study including long-term retrospective data of 164 children showed that bisacodyl is effective and well tolerated in children with functional constipation refractory to conventional treatment [176]. Another study evaluating the effect of bisacodyl on colonic motility found that in 93% of children with intractable constipation, bisacodyl induced HAPCs [69]. Despite the lack of well-designed trials, these drugs are commonly used in day-to-day clinical practice, often combined with osmotic laxatives.

New Drugs

Due to the fact that many children treated for functional constipation remain symptomatic after 6–12 months of treatment [177] and 25% of children remain symptomatic into adulthood [178], new drugs have been studied. Some of these new therapies seem promising. However, difficulties arise in extrapolating adult data to the pediatric population

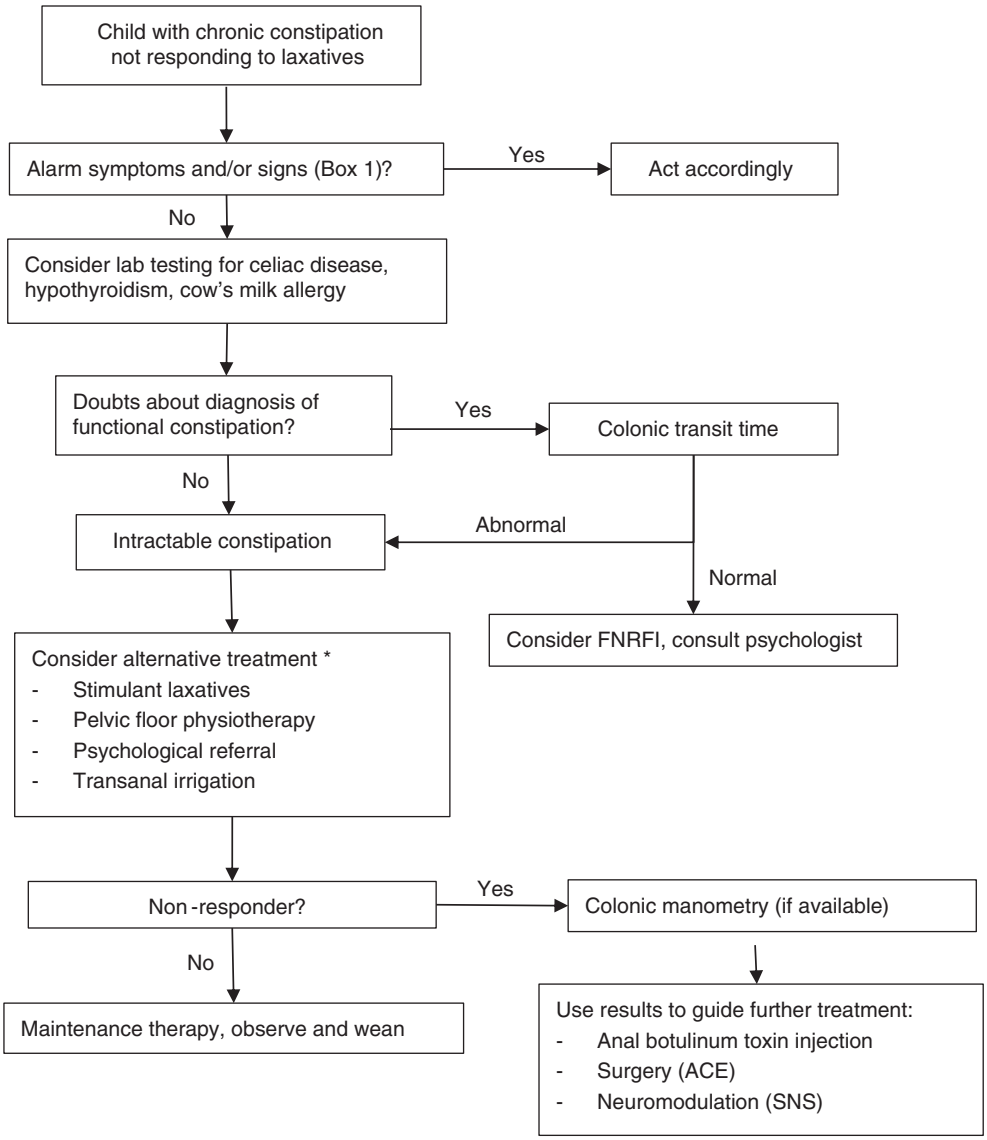

Fig. 21.3 Algorithm for children with functional constipation not responsive to laxatives. A suggested stepwise approach for the evaluation and management of children with chronic functional constipation who do not respond to conventional strategies. *FNRFI* Functional non-retentive fecal incontinence, *ACE* antegrade continence enema, *SNS* sacral nerve stimulation. *Assess compliance and dosage, use of other medication, and combination therapy. (Modified with permission from Vriesman et al. [87])

due to differences in pathophysiology, pharmacodynamics, pharmacokinetics, and importance of different outcome measures in the two populations. Lack of high-quality placebo-controlled randomized controlled trials and high heterogeneity make it challenging to assess the benefits of these novel treatments. In addition, the relatively high costs of these novel agents have to be taken into consideration. To ensure the setup of comparable, high-quality studies, recommendations for pharmacological clinical trial for children with constipation have been published [10].

Prosecretory Agents

Prosecretory agents modulate epithelial channels in the gut, thereby promoting the intestinal secretion of fluids and enhancing stool volume, resulting in an improvement in gastrointestinal transit [179]. Currently available agents include lubiprostone, linaclotide, and plecanatide.

Lubiprostone

Lubiprostone is a locally acting chloride channel activator specific to the gastrointestinal tract. It promotes intestinal secretion of chloride ions and fluid and gastrointestinal motility and has a good track record in treating adults with constipation [180, 181]. In an open-label pediatric trial, lubiprostone was shown to be safe and effective in improving spontaneous bowel movements, reducing episodes of FI, and reducing many other symptoms of constipation [182]. However, early findings of a double-blind, placebo-controlled, multicenter trial studying lubiprostone in children with functional constipation found no significant difference between groups in the primary endpoint (increase of >1 bowel movement above baseline and >3 weekly bowel movements for at least 9 weeks, with responses for 3 of the final 4 treatment weeks) [183]. Some beneficial effects on secondary endpoints (spontaneous bowel movement fre-

quency and painfulness, straining, and stool consistency) suggest that lubiprostone may still provide clinically relevant benefits.

Linaclotide

Linaclotide promotes intestinal fluid secretion by activating the guanylate cyclase C-receptor. It is approved for the treatment of adults with functional constipation, but pediatric data remain scarce [184]. Preliminary results from a multicenter, randomized, double-blind, placebo-controlled, parallel-group, safety and efficacy dose-finding study in children with constipation-predominant irritable bowel syndrome showed that linaclotide was safe and well tolerated at daily doses up to 145 and 290μg in patients aged 7–11 and 12–17 years, respectively. A trend toward greater efficacy was observed with increasing doses for the primary endpoint and secondary endpoints related to bowel habits [185]. Results from a retrospective study in a combined population of children with functional constipation (68%) and irritable bowel syndrome (32%) found the majority of patients with functional constipation experienced an improvement of symptoms, but side effects, such as diarrhea and abdominal pain, were common and nearly a third of patients had stopped taking linaclotide within the first months of treatment mostly because of these side effects [186]. Future research is warranted before linaclotide should be used in children with functional constipation.

Plecanatide

Plecanatide is a new guanylate cyclase C-receptor agonist approved for the treatment of adults with constipation in the United States. No data are available on the use of plecanatide in children.

Serotonergic Agents

Serotonin is a central and enteric neurotransmitter that increases the release of enteric acetylcholine by binding to 5-hydroxytryptamine 4 receptors in the gut, which results in an increased secretion and enhances gut motility [187]. Several selective serotonin agonists have been developed to treat functional constipation including prucalopride, velusetrag, and naronapride. So far, only prucalopride is FDA approved to use in adults with constipation. Prucalopride has a clear gastroprokinetic activity and selective and high affinity for 5-HT4 receptor agonists that stimulate lower gastrointestinal motility. Although the results of an open-label trial in children looked promising [188], a large multicenter pediatric randomized controlled trial showed that prucalopride was not more effective in increasing stool frequency or decreasing fecal incontinence frequency compared to placebo and its use is therefore not recommended [189]. The lack of benefit of prucalopride in children compared to adults is likely the result of the high prevalence of stool withholding in children as in a study in adults with rectal evaluation disorders prucalopride was not superior to PEG [190]. This indicates that a prokinetic drug is not likely to affect rectal evacuation, resulting in the inability to overcome stool withholding in children.

Biofeedback and Pelvic Floor Physiotherapy

Anorectal function can be modified with the use of biofeedback or pelvic floor physiotherapy [191]. Biofeedback training entails teaching children how to coordinate muscle relaxation with the use of anorectal monitoring instruments in order to amplify physiological processes and make physiological information accessible to the child's consciousness [63]. Pelvic floor physiotherapy consists of exercises, practicing a stabilized posture on the toilet, teaching effective straining to defecate, increasing awareness of sensations, and exercising adequate pelvic floor muscle functions [192]. The purpose of both treatments is to improve anorectal function and sensation [193]. Several studies have shown efficacy of biofeedback in correcting defecation dynamics, but well-conducted large randomized controlled trials failed to find additional clinical benefits of biofeedback in children with functional constipation [63, 194]. Moreover, normalization of defecation dynamics was not associated with treatment success [195]. In contrast, pelvic floor physiotherapy has shown to be more effective than standard medical care in the treatment of children with constipation [192]. Differences in outcomes between both therapies may be explained by the differences in providers; biofeedback is usually provided by a medical care provider, whereas pelvic floor physiotherapy is provided by a physiotherapist. The broader approach of pelvic floor physiotherapy focused on children's awareness of all their bodily sensations, while learning to recognize and resolve abnormal functions, or to prevent fecal incontinence, also may explain the difference in effect.

Trans-anal Irrigation

During trans-anal irrigation, a catheter or a cone is inserted in the anus through which a large volume of water is infused to clear fecal contents in the rectum and parts of the colon. It is an accepted treatment in children and adults with bowel disorders. Recent studies using trans-anal irrigation in children with bowel dysfunction have reported high success rates, both in clinical outcomes and in effect on quality of life [196–199]. Experience in children with functional constipation is limited to a few cohort studies reporting positive effects [196, 197, 200]. Even though no randomized controlled trials exist, due to its conservative nature and reported effectivity, it is recommended to try trans-anal irrigation before considering surgical interventions in children with intractable constipation [201]. A recent multicenter evaluation on adherence to trans-anal irrigation showed that performing at least one irrigation under a nurse's supervision, discontinuing constipation treatment, and advising to irrigate daily was related to continuation of trans-anal irrigation [202].

Neuromodulation

Although its working mechanism is far from clear, neuromodulation has been identified as a successful therapeutic modality for elimination disorders and is gaining increasing interest [203]. There are both invasive and noninvasive modalities available: implantable or transcutaneous sacral nerve stimulators, percutaneous or transcutaneous posterior tibial nerve stimulators, or interferential therapy.

Sacral nerve stimulation (also known as sacral neuromodulation) is currently the most established form of neuromodulation in children with defecation disorders. It involves electrical stimulation of the sacral nerve root via an electrode surgically placed in the sacral foramen. This electrode is connected to a pulse generator that is implanted within the subcutaneous fat of the buttock, often after an initial trial period during which the pulse generator remains external [204]. The electrical pulses are thought to modulate anorectal function at the pelvic afferent or central level [205]. Multiple studies have shown sacral nerve stimulation to be effective in treating children with constipation [203, 206]. However, the results of these studies must be interpreted with caution as they only contain small sample sizes and none of them were sham-controlled. In addition, a recent review on the effectiveness of sham nerve stimulation in adults showed sham stimulation is associated with both clinically and statistically meaningful improvements [207]. Next to this, reported complication rates of sacral nerve stimulation are high (18–55%) [203]. A proportion of children require additional surgery for lead revision, device removal, or device replacement, most often performed because of lead displacement or malfunction, local pain or numbness, and local infection [206, 208]. Therefore, noninvasive techniques have become more of interest as treatment modalities, and before using sacral nerve stimulation on a regular basis, a well-designed sham-controlled trial with a larger patient sample and a long-term follow-up is needed to evaluate its effectiveness and identify risk factors for complications.

Transcutaneous stimulation may involve stimulation with current delivered as spikes aiming to produce muscle contraction (functional electrical stimulation) or nerve stimulation (transcutaneous nerve stimulation), or with alternating current to intersect deeper within the tissue (interferential stimulation) [209]. Transcutaneous nerve stimulation delivered of the sacral nerve has only been studied in children in one pilot study with small patient sample ($n = 14$) with both lower urinary tract dysfunction with constipation and showed improvement according to Rome III criteria [210]. Transabdominal (interferential) electrical stimulation involves the generation of two sinusoidal currents that cross within the body with the use of four electrode pads applied on the skin of the abdomen and lower back [211]. Using this technique, Clarke et al. showed in eight children with slow-transit constipation a generation of significantly higher frequency of high amplitude and total propagatory sequences [212]. In addition, the same research group showed, in a randomized sham-controlled trial in children with slow-transit constipation, that transabdominal electrical stimulation (delivered by a physiotherapist (three 20-min sessions a week)) substantially improved colonic transit time, but no data on clinical symptoms were reported [213]. They also found an improvement in quality of life; however, the basal quality-of-life scores in the two groups were not similar, thus precluding any valuable conclusion [214]. Long-term follow-up of 30 children all recruited during previous mentioned studies showed that over 62% of subjects perceived improvement of at least one symptom (defecation, soiling, abdominal pain) lasting over 2 years in 27% to 37% of subjects [215]. Further studies are needed to confirm these findings and to determine the use of transcutaneous sacral nerve stimulation and interferential electrical stimulation in clinical practice.

Posterior tibial nerve stimulation entails electrical stimulation of the posterior tibial nerve at the level of the medial malleolus with the use of a needle (percutaneous) or self-adhesive electrode (transcutaneous) and is derived from acupuncture. Stimulation of the tibial nerve is thought to modulate bowel function through indirect stimulation of similar sacral nerves as stimulated during sacral nerve stimulation. Only one small study including eight children with fecal and urinary incontinence has investigated the effect of posterior tibial nerve stimulation and found improvement in symptoms [216]. Until more evidence on the effectiveness of this treatment becomes available, posterior tibial nerve stimulation is reserved for the academic setting.

Surgical Interventions

When all conventional therapies fail and symptoms of constipation continue to greatly disrupt quality of life, surgical treatment may offer benefit [95]. Currently used surgical interventions include procedures focused on the anal sphincter (anal botulinum toxin injections, anal dilation, and anal myectomy) and procedures focused on the colon (antegrade continence enemas, colostomy, and colonic resection). To date, no clinical guidelines on the surgical treatment of children with constipation exist and surgical decision-making differs widely among physicians [217]. Available evidence is mainly of low quality, contains only small heterogeneous patient samples, and there is a clear lack of qualitative outcomes assessors [218, 219]. In general, a step-up approach from least to most invasive procedure is followed.

Although only limited evidence is available, injection of botulinum toxin (single or multiple) into the anal sphincter seems to be safe and effective in children with functional constipation regardless of anal sphincter dynamics [220–222]. Botulinum toxin blocks the release of acetylcholine from neurons resulting in temporary chemical paralysis of muscle fibers, thereby relaxing anal sphincter muscles. It is speculated that disruption of the vicious cycle of stooling withholding may be achieved with botulinum toxin injec-

tion leading to functional recovery and normal stooling patterns. However, it is not uncommon to need repeat injection after 3–6 months. Temporary adverse effects frequently encountered include transient anal and abdominal pain and occurrence of fecal incontinence [223]. Because of the need for repeat injection and the requirement of general anesthesia, this is an expensive treatment. A recent randomized controlled trial evaluating the additional effect of anal botulinum toxin injection to standard bowel management treatment including a stimulant laxative (senna) in children with obstructed defecation did not find a significant effect of the injection on defecatory symptoms as measured by the Rintala score [224].

Anal myectomy and anal dilation have been largely abandoned by surgeons due to the risk of weakening the anal sphincter to the point of causing persistent fecal incontinence [217].

Common diagnostic workup before surgical colonic interventions often includes colonic motility testing [140, 142]. If segmental colonic dysmotility is present, it feels intuitive to remove or bypass the dysmotile colonic segment. However, even though this indeed has favorable outcomes [225], the dysmotility also seems to be potentially reversible and can improve after successful medical treatment [141, 226, 227]. The first procedure often considered in colonic surgery is a Malone appendicostomy or laparoscopic-assisted percutaneous cecostomy in order to allow the use of antegrade continence enemas. With the creation of an opening of the colon on the abdominal wall, the colon can be antegradely flushed. Effective cleansing agents include PEG solution and normal saline, combined with a stimulant laxative (bisacodyl or glycerin) if needed. Despite high success rates and good clinical outcomes, complications are common and include granulation tissues around stoma, leakage, and minor infections [218, 219]. Major complications such as fistulae, peritonitis, and stenosis of the stoma have been reported in a minority of patients [219]. Other surgical procedures such as sigmoid resection, colorectal resection, subtotal colectomy, and proctocolectomy with ileoanal anastomosis are only reserved for children with intractable constipation who failed to respond to all other therapeutic modalities [228, 229].

Part 2: Fecal Incontinence

Introduction and Epidemiology

Fecal incontinence is defined as passing stools in inappropriate places by a child whose development age is over 4 years [4]. Like constipation, fecal incontinence is a widespread problem, affecting up to 4.2% of children over 4 years of age [230]. It is more common among younger children, males, children with a positive family history and children from low socioeconomic strata and is associated with the occurrence of important life events such as the birth of a younger sibling and other psychological factors [230–236]. In addition, bullying, psychological stress, behavioral and upbringing problems, and poor social and school performances are commonly seen in children with fecal incontinence [51, 237].

Once organic causes are excluded, functional fecal incontinence may be the result of functional constipation or may occur on its own as functional non-retentive fecal incontinence (FNRFI). The vast majority of children with fecal incontinence have constipation-associated (retentive) fecal incontinence; only 5–10% of children can be diagnosed with FNRFI [231, 238, 239]. As the first already has been discussed in detail in the first part of this chapter, this section is devoted to FNRFI.

Functional Non-retentive Fecal Incontinence

Children with FNRFI pass normal stools in the toilet with a normal defecation pattern. They do not show features of constipation such as withholding behavior, pain, or difficulty in passing stools. However, they pass entire stools in inappropriate places for at least once a month. The Rome IV criteria to define FNRFI are given in Box 2.

A recent meta-analysis reported that the prevalence of FNRFI ranges from 0% to 1.8%, with a worldwide pooled prevalence of 0.4% (95% CI 0.2–0.7) [14]. The pathophysiological mechanism underlying FNRFI is still an enigma to pediatric gastroenterologists. Several studies have demonstrated normal colonic transit times (both segmental and total) in children with FNRFI [239, 240]. A study reporting data of colonic transit times in 161 children with functional defecation disorders showed that children with constipation-associated fecal incontinence were more likely to have significantly delayed total colonic transit compared to children with FNRFI [240]. Similarly, anorectal manometry and rectal barostat studies in children with FNRFI found that all parameters (rectal compliance, sensory thresholds) are within the normal range [59]. Many caregivers are convinced that fecal incontinence is the result of behavioral problems, and thus patients are often seen by a mental healthcare professional [232]. Indeed, children with FNRFI have significantly more behavioral problems than their healthy counterparts [241, 242]. However, most abnormalities in psychological parameters like anxiety or depression symptoms did not reach clinically significant levels and many of them disappeared after successful treatment. This suggests that in children with FNRFI, the fecal incontinence and behavioral abnormalities may be intertwined with each other and play an important role in each other's persistence [243]. Next to behavioral problems, urinary incontinence is commonly encountered in children with FNRFI indicating common physiological disturbances of

the bladder and the bowel [102, 232]. Bladder bowel dysfunction is an emerging new concept that describes concomitant malfunctioning of the lower urinary tract and the gastrointestinal tract [244, 245]. Treatment of urinary incontinence can positively affect FNRFI symptoms, and adequate treatment of FNRFI is often accompanied by a reduction in the number of urinary incontinence episodes [245, 246]. These findings suggest a combined, possibly neurodevelopmental, or behavioral disorder responsible for bladder and bowel dysfunction.

Box 2 Diagnostic Criteria for Non-retentive Fecal Incontinence [4]

At least a 1-month history of the following symptoms in a child with a developmental age older than 4 years:

1. Defecation into places inappropriate to the sociocultural context.
2. No evidence of fecal retention.
3. After appropriate medical evaluation, the fecal incontinence cannot be explained by another medical condition.

Clinical evaluation of children with defecation disorders has been discussed previously in the first part of this chapter. In addition to the described clinical evaluation, it needs to be stressed that digital rectal examination is important in children presenting with fecal incontinence only. It provides information on the presence of a fecal mass, anorectal sensation, and sphincter tone, and is essential to exclude functional constipation as cause of fecal incontinence [243]. Next to a detailed clinical evaluation, due to the high co-occurrence of behavioral disorders in children with FNRFI, it is recommended to screen for psychological difficulties with the use of validated questionnaires such as the Strengths and Difficulties Questionnaire or the Child Behavior Checklist [243, 247, 248].

Except for determining colonic transit time when the distinction between functional constipation and FNRFI is not apparent on clinical history and physical examination, additional investigations are not considered useful in the routine workup of children with fecal incontinence [243].

Management of children with FNRFI is challenging and often fraught by successes and failures [234]. Education and strict toilet training following an individualized behavioral routine and positive reinforcement are the four main cornerstones in management [243]. Rewarding should be focused on praising the scheduled toilet sits instead of periods without accidents, as most episodes of fecal incontinence occur involuntarily [249]. Conventional treatment modalities such as oral or rectal laxatives and biofeedback are not helpful [243, 250, 251]. Loperamide, an opiate receptor agonist, was found to be effective in a case report [252]. It is hypothesized that loperamide improves sphincter function and thereby prevents fecal incontinence. Further studies are needed to assess its efficacy and safety. When prescribing loperamide, careful supervision is required to prevent the development of constipation. Fecal incontinence in children with functional constipation with or without pelvic floor dyssynergia has been successfully treated with pelvic floor physiotherapy, or trans-anal irrigation, which may be also of value in children with FNRFI [196, 200, 253]. However, evidence for these treatments is children with FNRFI is lacking. A recent randomized controlled trial evaluating the additional value of transabdominal electrical stimulation to pelvic floor physiotherapy in 34 children with bladder bowel dysfunction found that in all children in the combined intervention group demonstrated improvement of daytime incontinence [254]. These findings indicate that pelvic floor physiotherapy and neuromodulation may be of value in the treatment of children with urinary and fecal incontinence. Although treatment is challenging and patients with FNRFI usually run a relapsing and remitting course, long-term follow-up demonstrates that in the majority (85%) of patients, symptoms have resolved by the age of 18 years [232].

Hirschsprung's Disease and Intestinal Neuronal Dysplasias

22

Massimo Martinelli and Annamaria Staiano

Introduction

Hirschsprung's disease (HD) is a heterogesneous genetic disorder, resulting from an anomaly of the enteric nervous system of neural crest cells origin. HD is a congenital malformation characterized by the absence of parasympathetic intrinsic ganglion cells in the submucosal and myenteric plexus. It is the result of the premature arrest of the craniocaudal migration of vagal neural crest cells in the hindgut, between the fifth and twelfth week of gestation, to form the enteric nervous system and is therefore regarded as a neurocristopathy [1].

Epidemiology

HD occurs in approximately 1 of each 5000 live births and with a male predominance of 4:1. It is generally sporadic, although in 3–7% of cases a genetic transmission has been reported [2]. The risk for short segment disease is 5% in brothers and 1% in sisters of index cases; for long segment disease, the risk is 10%, regardless of sex [2].

Etiology

HD is characterized by the congenital absence of ganglion cells in the submucosal and myenteric plexuses in the distal bowel and variable proportion of the colon proximally. The embryonic disorder is a lack of the craniocaudal migration, differentiation, and maturation of neuroblasts from the neural crests, by the fifth to the twelfth week of gestation; the earlier the migration ceases, the longer the aganglionic segment will be. The aganglionic segment is permanently contracted, causing dilatation proximal to it [3]. HD may be classified according to the length of the aganglionic segment: the classic form (short segment 70–75% of cases) is limited to the rectum and sigmoid colon; the long segment, or subtotal colonic disease (10–15%), generally involves the bowel up to the splenic flexure; total colonic aganglionosis (TCA: 3–6%) may extend to involve a variable amount of the short bowel; and total intestinal aganglionosis is sometimes associated with intestinal malrotation or volvulus [2]. Ultrashort segment aganglionosis is considered a functional alteration, without any detectable histological finding. Although longer aganglionic segments tend to produce more dramatic symptoms, some patients with even short segment disease deteriorate rapidly [4].

Pathophysiology

The hallmark of diagnosis is the absence of ganglion cells from the myenteric and submucosal plexuses, as seen on a full-thickness or suction (mucosal-submucosal) biopsy of the rectum. Proximal contents fail to enter the unrelaxed, aganglionic segment. The lack of non-adrenergic-non-cholinergic inhibitory innervation is responsible for a tonic contraction of the affected segment, with absence of peristalsis and proximal dilation of the gut [5].

Morphologically, ganglionic cells are absent from the narrowed segment and for some distance (1–5 cm usually) into the dilated segment. The pattern of nerve fibers is abnormal also; they are hypertrophic with abundant, thickened bundles. Specific stains for acetylcholinesterase are used to highlight the abnormal morphology [6, 7].

In recent years, new insights in the pathophysiology of HD have been gained. It has also been suggested that abnormal expression of muscular neural cell adhesion molecule is likely to be associated with an arrest in the craniocaudal migration of neural cells to their most distal location [8]. Furthermore, the lack of nitric oxide (NO)-producing nerve

fibers in the aganglionic intestine probably contributes to the inability of the smooth muscle to relax, thereby causing lack of peristalsis [9]. In addition, in the aganglionic segments, interstitial cells of Cajal are scarce and their network appears to be disrupted [10].

Genetics

HD occurs as an isolated trait in 70% of patients, is associated with chromosomal abnormality in 12% of cases, trisomy 21 being by far the most frequent (>90%). Additional congenital anomalies are found in 18% of cases, including gastrointestinal malformation, cleft palate, polydactyly, cardiac septal defects, and craniofacial anomalies. The higher rate of associated anomalies in familial cases than in isolated cases (39% vs. 21%) strongly suggests syndromes with Mendelian inheritance [2]. Isolated HD appears to be a multifactorial malformation with low, sex-dependent penetrance, variable expression according to the length of the aganglionic segment, and suggesting the involvement of one or more gene(s) with low penetrance [2]. These parameters must be considered for accurate evaluation of the recurrence risk in relatives. Segregation analyses suggested an oligogenic mode of inheritance in isolated HD. With a relative risk as high as 200, HD is an excellent model for the approach to common multifactorial diseases [11].

A large number of chromosomal anomalies have been described in HD patients. Free trisomy 21 (Down syndrome) is by far the most frequent, involving 2–10% of ascertained HD cases [12]. Syndromes associated with HD can be classified as: [1] pleiotropic neurocristopathies; syndromes with HD as a mandatory feature; and occasional association with recognizable syndromes. The neural crest is a transient and multipotent embryonic structure that gives rise to neuronal, endocrine and paraendocrine, craniofacial, conotruncal heart, and pigmentary tissues. Neurocristopathies encompass tumors, malformations, and single or multifocal abnormalities of tissues mentioned above in various combinations. Multiple endocrine neoplasia type 2 (MEN 2) and Waardenburg syndrome are the most frequent neurocristopathies associated with HD [13, 14].

Waarderburg syndrome (WS), an autosomal dominant condition, is by far the most frequent condition combining pigmentary anomalies and sensorineural deafness, resulting from the absence of melanocytes of the skin and the stria vascularis of the cochlea. The combination of HD with WS defines the WS4 type (Shah-Waardenburg syndrome). Indeed, homozygous mutations of the endothelin pathway and heterozygous SOX10 mutations have been identified in WS4 patients with CNS involvement including seizures, ataxia, and demyelinating peripheral and central neuropathies [15].

A wide spectrum of additional isolated anomalies has been described among HD cases with an incidence of sporadic types varying from 5% to 30% [2, 16]. No constant pattern is observed. These anomalies include distal limb, sensorineural, skin, gastrointestinal, central nervous system, genital, kidney, cardiac malformations, and facial dysmorphic features.

These data highlight the importance of a careful assessment by a clinician trained in dysmorphology for all newborns diagnosed with HD. Skeletal x-ray and cardiac and urogenital ecographic survey should be systematically performed. The observation of one additional anomaly to HD should prompt chromosomal studies.

Molecular Genetics

Several genes have been implicated in isolated HD, the two major ones being the proto-oncogene *RET* (*RET*) and the endothelin B receptor (*EDNRB*) [2].

The RET Signaling Pathway

The first observation was about an interstitial deletion of chromosome 10q11.2 in patients with TCA and mental retardation [17]. The proto-oncogene *RET*, identified as disease causing in MEN 2 and mapping in 10q11.2, was regarded as a good candidate gene owing to the concurrence of MEN 2A and HD in some families and the expression in neural crest-derived cells. Consequently, *RET* gene mutations were identified in HD patients [18]. Expression and penetrance of a *RET* mutation is variable and sex dependent within HD families (72% males and 51% females). Over 100 mutations have been identified including large deletions encompassing the *RET* gene, microdeletions and insertions, nonsense, missense, and splicing mutations [19–21]. Haploinsufficiency is the most likely mechanism for HD mutations. Biochemical studies showed variable consequences of some HD mutations (misfolding, failure to transport the protein to the cell surface, abolished biological activity).

Despite extensive mutation screening, a *RET* mutation is identified in only 50% of familial and 15-20% of sporadic HD case [22]. However, most families with few exceptions are compatible with linkage at the *RET* locus [23]. Mutations in RET ligand, like GDNF, GFRA1-4, NTN, persephin (*PSPN*), and artemin (ARTN), may occur, but are not sufficient to lead to HD.

The Endothelin Signaling Pathway

A susceptibility locus for HD in 13q22 was suggested for three main reasons: a significant lod score at 13q22 in a large

inbred Old Order Mennonite community with multiple cases of HD; de novo interstitial deletion of 13q22 in several patients with HD; and synteny between the murine locus for *piebald-lethal* (*sl*), a model of aganglionosis, and 13q22 in humans. Subsequently, an *EDNRB* missense mutation was identified in the Mennonite kindred (W276C) [24, 25]. Both *EDNRB* and *EDN3* were screened in large series of isolated HD patients, and *EDNRB* mutations were identified in approximately 5% of the patients. It is worth mentioning that the penetrance of *EDN3* and *EDNRB* heterozygous mutations is incomplete in those HD patients, de novo mutations have not hitherto been observed, and that S-HD is largely predominant [26].

SOX10

The last de novo mouse model for WS4 in human is *dominant megalon* (*Dom*). The *Dom* gene is *Sox10*, a member of the SRY (sex determining factor)-like, high-mobility group (HMG) DNA-binding proteins. Subsequently, heterozygous *SOX10* mutations have been identified in familial and isolated patients with WS4 (including de novo mutation) with high penetrance [27].

Clinical Signs/Symptoms

The clinical symptoms of HD usually start at birth with the delayed passage of meconium. More than 90% of term neonates, and <10% of children with HD, pass meconium in the first 24 h of life [1, 28, 29]. Thus, HCSR must be suspected in any full-term infant who does not pass meconium in the first 24 h of life and in the premature infants who have excessively delayed the passage of meconium (7–8 days) [29]. Failure of the distal bowel to relax and allow the passage of stool leads to functional obstruction and to secondary dilatation of the bowel proximal to the aganglionic segment. Affected children may present with severe dysmotility causing obstructive symptoms, ribbon-like stools, and frequently, failure to thrive. In >90% of affected patients, the symptoms start during the neonatal period, and in the majority, the diagnosis is made during the first 3 months of life, whereas <1% are diagnosed during adult life [30].

In infants and children, the presentation is often less dramatic and may not mimic acute intestinal obstruction. Severe constipation and recurrent fecal impaction are more common. Physical examination reveals a distended abdomen and a contracted anal sphincter and rectum in most children. The rectum is devoid of stool except in cases of short-segment aganglionosis. As the finger is withdrawn, there may be an explosive discharge of foul-smelling liquid stools, with decompression of the proximal normal bowel.

Complications

Over the past four decades, enterocolitis has been a major cause of morbidity and mortality in infants and children with HD. The mean incidence is 25%, but the range is great (from 17% to 50%) and may be differently estimated depending on the way it is diagnosed. Mortality rates range from 0% to 33%, probably reflecting differences in the diagnostic criteria [31]. Mortality also appears to be associated with other factors, such as trisomy 21. Pathogenesis is thought to be related to fecal stasis with proliferation of colonic bacteria, and therefore, a delayed HD diagnosis seems to be a significant risk factor [32]. The classic clinical manifestations described for enterocolitis include abdominal distension, explosive diarrhea, vomiting, fever, lethargy, rectal bleeding, and shock [33]. Abdominal radiographs show the Intestinal "cut-off" sign in the rectosigmoidal region with absence of air distally. Other common findings are small bowel dilatation in 74% and multiple air-fluid levels [34]. Because of the risk of perforation, contrast enema should not be performed in the presence of clinical enterocolitis.

Postoperative enterocolitis has been associated with fairly high rate of mortality in several series. In fact, when examining the deaths related to HD, several groups found that approximately 50% of deaths resulted from complications directly related to an enterocolitis episode [35, 36].

Rectal washouts should be the initial approach in the care of a child, regardless of age, who presents with enterocolitis. Along with washouts, intravenous antibiotics or oral metronidazole (in mild cases) should be used. Should the disease process fail to improve or the infant's condition deteriorate, the performance of a leveling colostomy should be considered [35, 36].

Diagnosis

For diagnosis of HD, the subjects' history is crucial. The main elements to obtain are: the age of the appearance of symptoms; whether the passage of meconium has been normal or delayed; and whether the child presented with episodes of functional intestinal obstruction. In addition, a functional (idiopathic) megacolon must be ruled out. A clinical comparison of functional and congenital megacolon is reported in Table 22.1. When the history (early onset of constipation, absence of fecal soiling) and/or the physical examination (empty rectal ampulla) suggest an organic cause, anorectal manometry (ARM) should be performed. ARM evaluates the response of the internal anal sphincter to inflation of a balloon in the rectal ampulla [37]. When the rectal balloon is inflated, there is normally a reflex relaxation of the sphincter. The rectoanal inhibitory reflex is absent in patients

Table 22.1 Differentiating types of megacolon in children

Signs and symptoms	Functional fecal retention (acquired)	Colonic neuromuscular disorders (congenital)
Soiling	Common	Rare
Obstructive symptoms	Rare	Common
Large-caliber stools	Common	Rare
Stool-withholding behavior	Common	Rare
Enterocolitis	Never	Possible
Associated upper-GI Symptoms	Never	Common
Symptoms from birth	Rare	Common
Localization of stools	Rectum	Rectal and extra-rectal

with HD; there is no relaxation, or there may even be para-

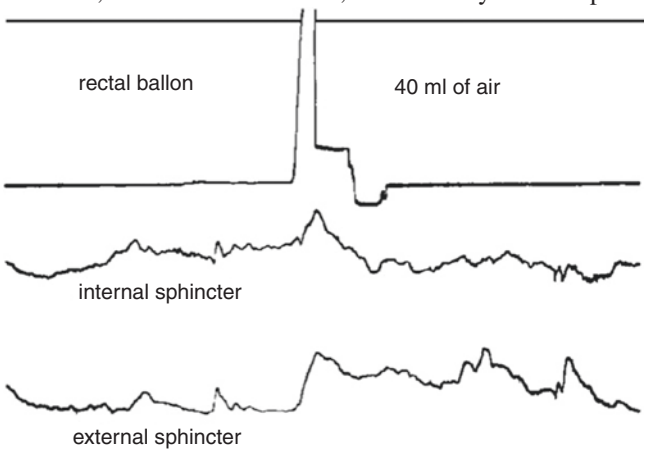

Fig. 22.1 Anorectal manometry in a 1-month-old boy with Hirschsprung's disease. Distention of a rectal balloon with air for 1 second produces no decrease of anal pressure

doxical contractions of the internal anal sphincter (Fig. 22.1). Although the absence of the rectoanal inhibitory reflex is specific for the diagnosis of HD, the role of ARM is still debated. A comprehensive systematic review by de Lorijn et al. [38] compared the diagnostic accuracy among rectal suction biopsy (RSB), ARM, and barium enema (BE) for the diagnosis of HD. Although RSB gave the highest mean sensitivity and specificity (93% and 98%, respectively), ARM showed similar values (91% and 94%). ARM has the advantages of being a less-invasive method without the exposure to ionizing radiation. The limitations include the need for the patient to be in a normal physiologic and quiet state to avoid possible artifacts [38, 39]. Because specificity is lower for ARM compared with RSB [37], ARM cannot reliably replace histology and biopsies. In 2013, a practical guideline was published by ESPGHAN GI committee and clearly stated that ARM should not be used as a sole diagnostic tool for HD in neonates and infants [40]; however; ARM is a useful screening test in older children presenting with chronic constipation and further symptoms suggesting HD (empty rectal ampulla, non-responsiveness to standard therapy, early-onset constipation). If the rectoanal inhibitory reflex is absent, these patients should be referred for RSB to confirm the diagnosis of HD. If the rectoanal inhibitory reflex is present, HD could be reasonably excluded [40]. BE is helpful in the assessment of a transition zone between aganglionic and ganglionic bowel and in giving an estimation of the length of an aganglionic segment. Demonstration of the transition zone is easier if no effort is made to cleanse the bowel (Fig. 22.2). In the newborn, dilatation of the proximal ganglionic bowel may not have developed, and radiological diagnosis may be more difficult. The sensitivity and specificity for recognition of a transition zone have been reported to be 80% and 76%, respectively [41]. The BE may not show a transition zone in cases of total colonic HD or may be indistinguishable from cases of functional constipation when ultra-short-segment HD is present. Therefore, a BE should not be performed as an initial diagnostic tool because it does not represent a valid alternative to RSB or ARM to exclude or diagnose HD; however, BE may have some use as an additional investigation in diagnosed cases to assess the length of the rectosigmoid aganglionic segment before surgery [40]. Nevertheless, the diagnosis requires histological evidence. The easiest means of obtaining adequate diagnostic tissue in rectal biopsies in infants is by rectal suction biopsy [42]. An accurate diagnosis is only possible if 2–3 suction biopsies are taken 2–3 cm above the dentate line and if they include enough submucosa [43]. Biopsies taken closer to the dentate line may be misleading because of a normal zone of submucosal hypoganglionosis or even aganglionosis [43]. The histological diagnosis is based on the demonstration of the total absence of ganglionic cells in the affected segment of the intestine with an overgrowth of large nerve trunks in the intermuscular and submucosal zone (Figs. 22.3 and 22.4). Acetylcholinesterase (AchE) activity in normal colon shows only few fibers in the lamina propria and muscolaris mucosae; in HD there is an increase in thick, knotted acetylcholinesterase-positive nerve fibers in the muscolaris mucosae and lamina propria and hypertrophied nerve trunks in the submucosa. Techniques for histopathological diagnosis include analysis of hematoxylin and eosin (H&E)-stained paraffin sections, snap-frozen sections stained for AchE, and immunostaining for neuronal markers. Knowles et al. stated that insufficient data exist to firmly recommend one approach over the other; however, the combination of AchE and H&E staining increases the diagnostic accuracy because it improves the identification of submucosal ganglion cells, as well as demonstrates the abnormal nerve fiber distribution in

Fig. 22.2 Barium enema showing a long, narrowed segment in a child with Hirschsprung's disease

the left colon [43]. The potential value of immunohistochemistry has been evaluated in a number of studies. Calretinin is an immunohistochemical marker that may be a potential alternative to AchE [44, 45]. Calretinin is normally present in the perikarya and nerve processes of a subset of enteric ganglion cells. Immunoreactivity is lost in the aganglionic segment of HD [45]. A comparative study shows that calretinin is as sensitive and specific as AchE [46].

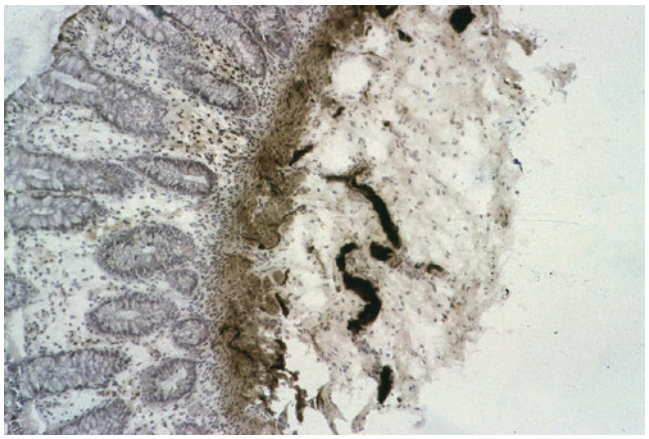

Fig. 22.3 Rectal suction biopsy in a child with functional constipation. Note the presence of clusters of neuron in the submucosa and acetylcholinesterase activity showing only few wispy fibers

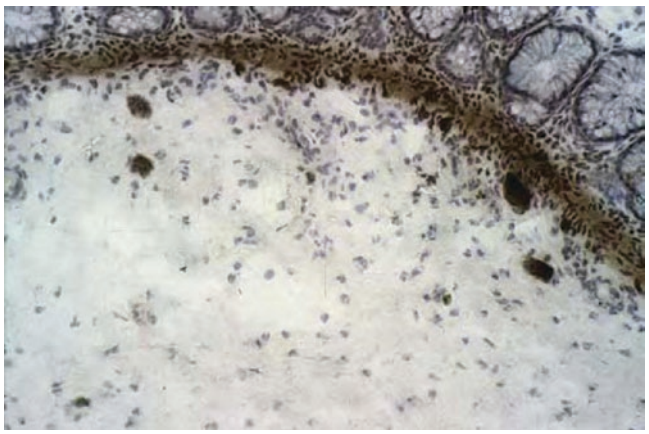

Fig. 22.4 Intense acetylcholinesterase activity in a patient with Hirschsprung's disease. Note the absence of neurons and the presence of increase in thick-knotted nerve fibers in the muscularis mucosae and lamina propria. In addition, hypertrophied nerve trunks are visible in the submucosa

Treatment

The treatment of HD consists of resecting the aganglionic segment of the rectum and colon, pulling down normally innervated bowel, and anastomosing this bowel at the anorectal region, while preserving the sphincter muscle. The previous gold standard of two- or three-stage pull-through with a preliminary stoma has slowly been progressively replaced by a one-stage approach in many centers [47–50]. More recently minimally invasive approaches to the one-stage pull-through have become popular. These consist of pull-throughs utilizing laparoscopic abdominal and pelvic mobilization of the rectum and the transanal Soave procedure, which does not include any intra-abdominal dissection [47–53]. The one-stage approach, either by laparotomy or by

combined laparoscopy and transanal dissection, has been advocated even in the newborn period.

The results of the one-stage approach in small infants appear to be at least as favorable as those in which a staged procedure with a colostomy was used. Recently, the use of the one-stage definitive procedure for small infants with HD has increased. One-stage pull-through procedures using laparoscopy appear to be associated with shorter hospital stays, shorter time until full feeding is reached, and superior cosmetic results [51–53].

Short- and Long-Term Prognosis

Despite adequate resection of the aganglionic segment, some patients may continue to have persistent bowel dysfunction [54]. Postoperative bowel dysfunction includes constipation, fecal incontinence, and a continuous risk of enterocolitis. An altered distribution and impaired function of ICC, resulting in defective generation of electrical pacemaker activity, have been suggested to be one of the mechanisms contributing to dysmotility in patients operated on for HD [55]. Investigations include barium studies to delineate strictures or leaks, and further biopsy to exclude residual aganglionic bowel. If the definitive operation fails because of an impassable stricture, disruption, or residual disease, further secondary surgery may be necessary, and a different operation may then lead to an acceptable result. Data are accumulating to indicate that HD, a disorder once known recognized exclusively to involve an aganglionic segment of distal colon, also affects motor function in other parts of the gut [54]. The variability in manifestations could reflect the heterogeneity of basic genetic defects now recognized as being responsible for the phenotypic expression of HD. Abnormalities in esophageal motility are common, and duodenal motor dysfunction is present in 48% of patients [5].

Miele et al. have reported a systematic study of various aspects of gastrointestinal motor function in children with HD long after removal of the aganglionic colonic segment, observing gastrointestinal symptoms, including vomiting, distension, and poor growth, persisted long after surgery [56]. Abnormalities in duodenal motor activity have also been observed in these children shortly after operation [57].

Intestinal Neuronal Dysplasia

Intestinal neuronal dysplasia (IND) or hyperganglionosis, a condition that clinically resembles HD, was first described by Meier-Ruge in 1971 [58]. It is often associated with HD and may cause failure of clinical improvement after resectional pull-through surgery. In 1983, Fadda et al. classified IND into two clinically and histologically distinguished subtypes, called type A and B. Type A occurs in less than 5% of cases and is characterized by congenital aplasia or hypoplasia of the sympathetic innervation, presenting acutely in neonatal period with episodes of intestinal obstruction, diarrhea, and bloody stools. Type B, which is clinically indistinguishable from HD: it is characterized by a malformation of the parasympathetic submucous plexus and accounts for more than 95% of cases of isolated IND [59].

The incidence of isolated IND varies from 0.3% to 40% of all suction rectal biopsies [60]. The incidence varies considerably among different countries; some investigators have a reported that 25–35% of patients with HD have associated IND [59, 61]. However, others rarely encountered IND in association with HD [62]. Part of this discrepancy may be due to the persisting confusion over the essential diagnostic criteria. For a long time, IND has been diagnosed on the basis of four histological criteria applied to acetylcholinesterase-stained suction rectal biopsies. In 1991, on the recommendations of a working party (the Consensus of German Pathologists), Bouchard et al. published diagnostic criteria for IND using suction rectal biopsy specimen. These comprised two obligatory criteria: hyperplasia of submucosal plexus and an increase in acetylcholinesterase-positive nerve fibers in the adventitia around submucosal blood vessels. Two additional criteria might be used: neuronal heterotopia and increased acetylcholinesterase-positive nerve fibers in the lamina propria [63]. The latest morphometric criteria are summarized as follows: >8 neurons/ganglion (so-called giant ganglia) in >20% of a minimum of 25 submucosal ganglia in patients older than 1 year [64]. However, concern has been expressed whether intestinal neuronal dysplasia can be safely diagnosed by mucosal and submucosal alteration alone, without myenteric plexus abnormalities. Submucosal hyperganglionosis may reflect a normal age-related phenomenon due to immaturity, with clinical and histochemical normalization after the first year of life. Furthermore, it has been reported that most of the patients with submucosal IND have a spontaneous clinical improvement which is sometimes associated with histological normalization [65, 66]. To date, submucosal intestinal neuronal dysplasia has been reported in several disorders such as intestinal malformations, meconium plug syndrome, cystic fibrosis, gastroschisis, pyloric stenosis, and inflammatory processes involving the gut. The high frequency of histological abnormalities in young infants may represent a normal variant of postnatal development rather than a pathological process. Investigations using more refined and morphometric methods in rectal specimens from infants and children without bowel disease are needed to define the normal range for different ages [66]. Therefore, most of the evidence suggests that the histological appearance of so-called IND is a normal variant related to age. Owing to the lack of sufficient normative data, IND remains a histological

description with poorly established clinical significance [40, 43]. Patients with IND have been subjected to multiple types of treatment; however, most patients with IND can be treated conservatively. If bowel symptoms persist after at least 6 month of conservative treatment, internal sphincter myectomy should be considered. The rapid AchE technique has been found to be of great value in determining the extent of IND intraoperatively [67].

Genetic Aspects

Studies have been performed to investigate the potential role of HD associated RET, GDNF, EDNRB, and EDN3 genes in the development of IND. They demonstrated that only three RET mutation were detected in patients with HD, no mutation in this gene was observed in IND and mixed HD/IND patients, HD and HD/IND patients showed overrepresentation of a specific RET polymorphism in exon 2, while IND patients exhibited a significantly lower frequency of the same polymorphism comparable with that of controls. These findings may suggest that IND is genetically different from HD.

A homozygous mutation of the EDNRB gene in spotting lethal (sl/sl) rats leads to HD phenotype with long segmented aganglionosis. The heterozygous (+/sl) EDNRB-deficient rats revealed more subtle abnormalities of the enteric nervous system (ENS): the submucous plexus was characterized by a significantly increased ganglionic size and density and the presence of hypertrophied nerve fiber strands, resembling the histopathological criteria for IND. Other animal model, likes Ncx/Hox11L.1-deficient mice, suggests that many other genes could be involved in the pathogenesis of IND [68].

Intestinal Pseudo-Obstruction

23

Efstratios Saliakellis, Anna Rybak, and Osvaldo Borrelli

Introduction

The term "pseudo-obstruction" literally denotes the absence of a true mechanical occlusion. Intestinal pseudo-obstruction can be either acute or chronic in nature, reflecting the duration of obstructive symptoms [1, 2]. Chronic intestinal pseudo-obstruction (CIPO) was first described in 1958 by Dudley and colleagues to report a series of 13 patients with symptoms suggestive of intestinal occlusion. These patients underwent exploratory laparotomies, which failed to identify a mechanical cause for their symptomatology [3]. In subsequent years, the existence of this pathological entity in both adults and children was substantiated by a number of other clinicians [4–7].

In 2018, an ESPGHAN-led group of experts introduced the term "pediatric intestinal pseudo-obstruction" (PIPO) in order to distinguish pediatric from adult-onset CIPO. The aforementioned group of experts defined PIPO as a clinical entity "characterized by the chronic inability of the gastrointestinal tract to propel its contents mimicking mechanical obstruction, in the absence of any lesion occluding the gut." The group defined "chronic" as persistence of symptomatology for 2 months from birth or at least 6 months thereafter [8].

The pathophysiologic mechanism of PIPO is represented by abnormal antegrade propulsive activity of the gastrointestinal (GI) tract as a result of processes that affect its neurons, muscles, or interstitial cells of Cajal (ICC) [9]. This functional failure results in a number of clinical symptoms such as abdominal distention with or without abdominal pain, nausea, vomiting, and a reduced inability to tolerate enteral nutrition [10]. These symptoms are, however, nonspecific, and the condition can remain undiagnosed for a long period of time during which patients may undergo multiple diagnostic investigations and often repeated surgical explorations in an effort to identify the cause [10].

Although by definition the small intestine is always involved, any part of the GI tract can be affected in PIPO [1, 2, 8]. Esophageal involvement may lead to dysphagia from impaired peristalsis, in some cases akin to that seen in achalasia [11, 12]. Involvement of the stomach results in poor feed tolerance from gastroparesis suggested by the presence of delayed gastric emptying, while the large bowel by delayed colonic transit and constipation and the anorectum by sphincter dysfunction and defecation disorders [1].

This chapter focuses on various aspects of PIPO and attempts to address areas of controversy by exploring the most recent advances in the overall approach and management of this clinical entity.

Epidemiology

PIPO is a rare disease with scanty epidemiological data and poorly defined incidence and prevalence in both adult and pediatric populations. One of the few initiatives to elucidate its epidemiology suggested that approximately 100 infants are born in the USA every year with PIPO, suggesting an incidence of approximately 1 per 40,000 live births [13, 14].

Adult studies reveal that the disease is more frequent in females [15–17]. In a national survey conducted in Japan, 138 cases of chronic intestinal pseudo-obstruction were identified, with an estimated prevalence of 1.0 and 0.8 cases and incidence of 0.21 and 0.24 cases per 100,000 males and females, respectively [18]. Moreover, a recently published nationwide survey for PIPO in Japan revealed that the prevalence of PIPO, among children younger than 15 years, was 3.7 per one million children. In the aforementioned population, 56.5% of children had developed PIPO during the neonatal period [19].

Undoubtedly, the development of national registries is of paramount importance to delineate more precise epidemiologic characteristics of this orphan clinical entity.

Classification

Classification of PIPO is challenging. Conditions can be classified by whether they primarily affect intestinal nerves (neuropathy), smooth muscle (myopathy), or ICC (mesenchymopathy) and can be further subdivided into primary or secondary, congenital or acquired, mode of inheritance or what part of the GI tract is involved. Where classification is not possible, they are defined as idiopathic. In truth, there is a considerable overlap [1, 2, 8].

In primary PIPO, the disease is usually localized to GI tract, whereas in secondary cases, there is a systemic disorder that affects GI tract motility. It must be noted though that in some cases of primary PIPO extra-GI involvement may also be present, such as the urinary tract (hollow visceral myopathy and megacystis microcolon intestinal hypoperistalsis syndrome), the nervous system (central, peripheral, autonomous), and/or mitochondria (mitochondrial neurogastrointestinal encephalomyopathy, MNGIE) [2, 20–22]. Table 23.1 depicts the classification of PIPO. In children the disease may manifest with symptoms either during the neonatal period (neonatal-onset form) or later (infantile or late-onset form); the majority of PIPO cases are congenital and primary, whereas in adults secondary forms of CIPO (mostly due to systemic disease) are more frequent [8, 23]. Based on histological findings, both primary and secondary PIPO can be further categorized into neuropathies, myopathies, and mesenchymopathies [24–29].

Table 23.1 Classification of Pediatric Intestinal Pseudo-obstruction [8]

Primary PIPO
Sporadic or familial forms of myopathy and/or neuropathy and/or mesenchymopathy that relate to disturbed development, degeneration, or inflammation [7, 20, 28–51]
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) and other mitochondrial diseases [52–54]
Hirschsprung's disease (e.g., total intestinal aganglionosis)[a] [55–57]
Neuropathy associated with multiple endocrine neoplasia type IIB [58–60]
Secondary PIPO
Conditions affecting GI smooth muscle
Rheumatological conditions (dermatomyositis/polymyositis, scleroderma, systemic lupus erythematosus, Ehlers–Danlos syndrome) [61–72]
Other (Duchenne muscular dystrophy, myotonic dystrophy, amyloidosis, ceroidosis, or alternatively reported as brown bowel syndrome) [73–83]
Pathologies affecting the enteric nervous system (familial dysautonomia, primary dysfunction of the autonomic nervous system, neurofibromatosis, diabetic neuropathy, fetal alcohol syndrome, post-viral-related chronic intestinal pseudo-obstruction, e.g., CMV, EBV, VZV, JC virus) [84–99]
Endocrinological disorders (hypothyroidism, diabetes, hypoparathyroidism, pheochromocytoma) [100–104]
Malrotation or gastroschisis [105–107]
Neuropathy post neonatal necrotizing enterocolitis [108]
Idiopathic (i.e., where forms of PIPO classified as above do not, as yet, have a defined etiopathogenesis)

CMV cytomegalovirus, *EBV* Epstein–Barr virus, *VZV* varicella-zoster virus, *JC* John Cunningham, *GI* gastrointestinal
[a]Needs to be excluded in all cases of PIPO

Etiology and Pathophysiology

The integrity of GI sensorimotor function relies on precise coordination between the autonomic nervous system, enteric nervous system (ENS), ICC, and smooth muscle cells. Any noxious stimulus, irrespective of its origin and etiology, that affects the neuromuscular elements and control of GI tract can lead to impaired peristalsis and the stasis of luminal contents [1]. A variety of disorders and pathophysiological mechanisms can potentially affect the structure or function of the neuromuscular elements of the GI tract and lead to PIPO (Table 23.1) [8]. Neurological (e.g., multiple endocrine neoplasia (MEN) type IIb, familial dysautonomia) and metabolic (e.g., diabetes mellitus) conditions may affect the extrinsic GI nerve supply [23]. Neurotropic viruses may evoke an inflammatory process targeting both the ENS and extrinsic neural pathways [97]. Paraneoplastic syndromes may also exert a destructive effect on the ENS by initiating an inflammatory process that targets the neurons of ganglia located in the submucosal and myenteric plexuses. This is mediated by both a cellular infiltrate and production of circulating antineuronal antibodies [23, 109]. Some pathologies (e.g., muscular dystrophy) may target enteric smooth muscle fibers, whereas others such as dermatomyositis, scleroderma, Ehlers–Danlos syndrome, and radiation enteritis may distort both ENS and gut smooth muscle leading to a mixed neuromyopathic disorder [14, 110, 111]. Finally, although entities such as celiac disease, hypothyroidism, hypoparathyroidism, and pheochromocytoma presumably cause PIPO by affecting the GI neuromuscular integrity, the exact mechanism is not fully understood.

Genetics

Although there has been considerable progress, the elucidation of the genetic basis of PIPO has been rather limited. The majority of PIPO cases are sporadic [8]. Some familial cases of PIPO have been recognized, but there appear to be several patterns of inheritance, perhaps reflective of the great heterogeneity of PIPO conditions. Both autosomal dominant and

recessive modes of inheritance have been described for neuropathic and myopathic types of PIPO [5, 15, 16, 110, 112]. More specifically, rare autosomal dominant mutations in the *SOX10* gene, which encodes a transcription factor important in ENS development, result in a PIPO clinical phenotype along with features such as sensorineural deafness and pigmentary anomalies [113, 114]. Homozygosity on the region 8q23–q24 has been implicated in the pathogenesis of an autosomal recessive form of PIPO characterized by severe GI dysmotility, Barrett's esophagus, and cardiac anomalies [115, 116].

X-linked inheritance (locus Xq28) with recessive transmission has been described in PIPO [17, 117, 118]. Mutations of filamin A *(FLNA)* and L1 cell adhesion molecule *(L1CAM)* genes, which are both located on chromosome Xq28, result in predominantly myopathic and neuropathic forms of PIPO, respectively. Additional involvement of the central nervous system, heart (patent ductus arteriosus), and blood (thrombocytopenia) in both conditions has also been described [118–120].

Mutations in mitochondria are increasingly implicated in PIPO. Mutations in the thymidine phosphorylase gene (*TYMP*, also termed as endothelial cell growth factor-1, *ECGF1*), or in the polymerase-γ gene (*POLG*) result in recessive myopathic forms of PIPO. The former is the cause of MNGIE, whereas the latter leads to a form without encephalopathy. Apart from the GI dysmotility, MNGIE is characterized by severe malnutrition, opthalmoplegia, and leucoencepalopathy on brain MRI [121–123]. Furthermore, mutations in the following genes, *actin G2* [44], *RAD21* [124], and *SGOL1* [125], have been identified in recessive forms of PIPO with an associated syndromic phenotype.

Of note, with the advancement in genetic testing, novel mutations (MYLK, LMOD1, MYL9, MYH11, PDCL3, and ACTG2 variants) were identified and were subsequently related to the etiopathogenesis of megacystis microcolon intestinal hypoperistalsis syndrome [126–132].

Histopathology

In adults, GI histology is reported to be normal in approximately 10% of CIPO cases, while in the experience of the authors, this figure is likely to be higher in children. However, its role in PIPO remains crucial in order to inform prognosis and also guide further investigations for systemic diseases that require specific treatment; therefore, an adequate full-thickness biopsy is recommended whenever surgery is being considered [29]. Recent initiatives are addressing a more standardized and hopefully effective histological approach to diagnosis in GI motility disorders such as PIPO [29, 133, 134].

On the basis of histology, PIPO is classified into neuropathy, myopathy, or mesenchymopathy [29, 135]. However, mixed forms (e.g., neuromyopathy) are also recognized [29].

Neuropathies and myopathies can be further subdivided into inflammatory and degenerative. Inflammatory neuropathies are characterized by an infiltration of T lymphocytes and plasma cells in the myenteric plexuses (myenteric ganglionitis) and neuronal axons (axonopathy) [136–138]. It has been proposed that five or more lymphocytes per ganglion are required for the diagnosis of myenteric ganglionitis [137, 139]. Of note, patients with lymphocytic infiltration of the myenteric plexuses may also develop increased titers of antinuclear antibodies (ANNA-1/anti-Hu, anti-voltage-gated potassium channel or VGKC) [49, 140–142]. These immunologic responses may result in neuronal degeneration and loss by activating apoptotic and autophagic mechanisms [143]. Infiltration of the myenteric ganglia with other cells such as eosinophils and mast cells has been described, but their exact clinicopathological significance is yet to be clarified given limited data [144–146]. All these data support the role of the immune system in the pathogenesis of inflammatory PIPO [135, 147].

Degenerative neuropathies are poorly understood given the limited amount of available data [133, 147–149]. Main histopathologic characteristics of this group include a decrease in the number of intramural neurons along with changes in nerve cell bodies and axons [46, 150]. It has been postulated that apoptotic mechanisms are involved in the degenerative process potentially caused by aberrant calcium signaling, mitochondrial disorders, production of free radicals, and abnormalities in the function of glial cells [151, 152].

Similarly to neuropathies, myopathies are also divided into inflammatory and degenerative. Inflammatory myopathies, also reported by the term "leiomyositis," are characterized by infiltration of T lymphocytes into both the circular and longitudinal enteric muscle layers. This process if not treated appropriately with immunosuppressive agents may lead to a severe clinical picture of PIPO [121, 123].

The histopathologic findings in degenerative myopathies include smooth muscle fiber vacuolization and fibrosis [153]. Diverticula may also be present especially if the longitudinal muscle coat is more affected compared to the circular muscle layer [147, 154].

Novel immunohistochemical techniques, such as smooth muscle markers, namely, smoothelin, smooth muscle myosin heavy chain, and histone deacetylase 8, may reveal histiopathologic subtleties otherwise not detectable with conventional immunostaining and histochemistry methods [29].

Mesenchymopathies are defined by ICC abnormalities (decreased density of ICC network, intracellular abnormalities) and have been demonstrated in patients with chronic intestinal pseudo-obstruction [8, 9, 155]. Although sufficient

data exist regarding their role in the pathogenesis of diabetic gastroparesis, further research is required regarding ICC involvement in the etiopathogenesis of other GI motility disorders [26].

Clinical Picture

In a few cases, the diagnosis of PIPO is suggested in utero by ultrasonographic findings of polyhydramnios, abdominal distention, and megacystis; however, the majority of cases present in the neonatal period or early infancy [9, 10, 156]. The symptomatology varies according to the age at diagnosis and the part of the GI tract, which is primarily affected. Approximately, one-third of children with congenital PIPO (myopathic and neuropathic) have intestinal malrotation [156]. Cardinal signs and symptoms of PIPO include those of obstruction, namely abdominal distention (88%), vomiting (72%, which can be bilious), and constipation (61%). Abdominal pain (44%), failure to thrive (31%), and diarrhea (28%) may also be part of the clinical picture [20, 122].

Dehydration (which can be severe) and malnutrition are often underdiagnosed especially given that weight can be an unreliable measure due to pooling of significant volumes of fluid (third spacing) within distended gut loops. Intraluminal gut content stasis can also lead to small bowel bacterial overgrowth which can further exacerbate symptoms of diarrhea and abdominal distention [62].

PIPO may also manifest with extraintestinal signs and symptoms, such as recurrent urinary tract infections or neurologic abnormalities [155]. Furthermore, patients may complain of symptoms indicative of an underlying disorder that accounts for secondary PIPO (e.g., proximal muscle weakness in dermatomyositis) [10, 156].

The clinical course of PIPO is characterized by exacerbations and remissions, where the former can be precipitated by a number of factors such as surgery, general anesthesia, infections, and emotional stress [8]. In the most severe cases, the natural course of the disease leads to worsening intestinal function and ultimately to intestinal failure [8]. This is especially true in cases where the diagnosis and/or institution of appropriate treatment has been delayed.

Diagnosis

PIPO should be suspected in children with early onset, chronic, recurrent, or continuous signs of intestinal obstruction especially where a surgical cause cannot be established (e.g., repeated "normal" exploratory laparotomies). The diagnosis of PIPO should follow a structured algorithm as proposed by the ESPGHAN-led expert group [2, 156, 157]. Although a detailed history, clinical examination, and laboratory tests may suggest the presence of PIPO, or help elucidate its cause, the ESPGHAN-led expert group proposed that the definitive diagnosis requires at least two out of the four following criteria [158]:

(i) Objective measure of small intestinal neuromuscular involvement (manometry, histopathology, transit studies)
(ii) Recurrent and/or persistently dilated loops of small intestine with air fluid levels
(iii) Genetic and/or metabolic abnormalities definitively associated with PIPO
(iv) Inability to maintain adequate nutrition and/or growth on oral feeding (needing specialized enteral nutrition and/or parenteral nutrition support)

Careful clinical history and physical examination may help in defining the onset, the severity and progression of the disease, and the part of the GI tract primarily affected, and they also provide useful information regarding associations (e.g., family history), potential secondary causes (e.g., medications), and complications (e.g., dehydration). Laboratory tests [e.g., serum electrolytes, thyroid-stimulating hormone (TSH), lactic acid, specific autoantibodies] are useful in cases of secondary PIPO and in order to assess the clinical state of the patients admitted acutely or undergoing a diagnostic protocol.

Imaging

Plain abdominal radiographs may demonstrate a dilated GI tract, with air-fluid levels, whereas contrast GI series can reveal anatomical abnormalities (e.g., malrotation, microcolon) and exclude the presence of gut occlusive lesions (Fig. 23.1a) [159]. It needs to be kept in mind that a water-soluble substance should be used instead of barium in order to prevent flocculation and inspissation of the contrast material.

Novel imaging modalities such as cine MRI have been recently performed with promising results in adult series, but there are no data regarding their applicability and usefulness in pediatrics [160, 161].

Endoscopy

Endoscopy may identify fore- or hindgut mechanical occlusion previously missed on radiology, and it allows duodenal biopsies to exclude mucosal inflammation [9, 162, 163]. Novel techniques (e.g., natural orifice transluminal endoscopic surgery—NOTES) may revolutionize the role of endoscopy in the diagnosis of gut motility disorders by

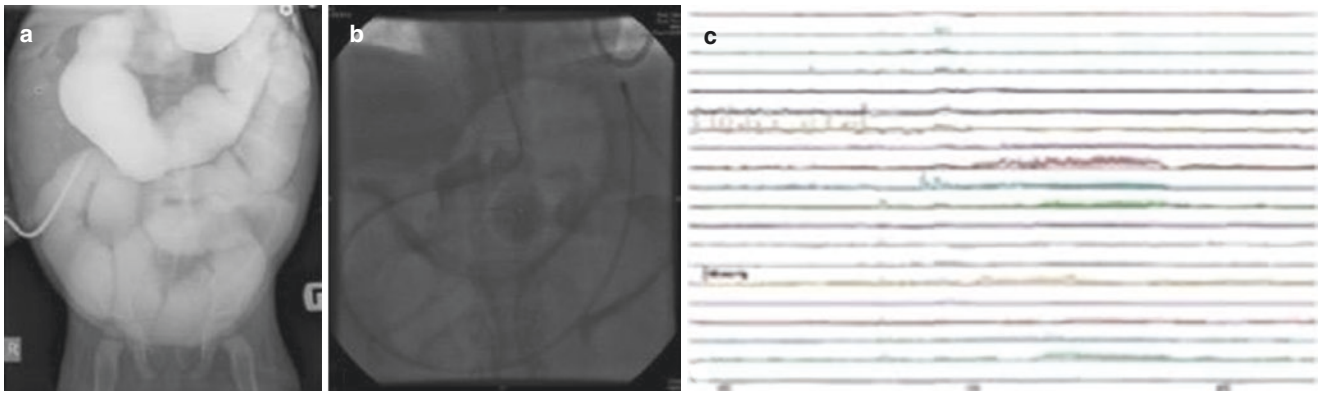

Fig. 23.1 Investigation findings of a 3-year-old boy with a history of recurrent episodes of abdominal distension and vomiting since the neonatal period, and now showing a marked reduction in enteral feed tolerance. (**a**) Contrast follow-through study (administered via gastrostomy) showing filling of grossly dilated small intestinal loops, without any apparent hold up or change in caliber. (**b**) Plain abdominal radiograph taken following placement of antroduodenal manometry catheter into the same patient performed under fluoroscopic guidance. The tip of the catheter has been advanced beyond the duodenojejunal junction to facilitate optimal manometric recording of both the stomach and small intestine. (**c**) Antroduodenal manometry tracing from patient showing the presence of some gastric antral contractions and a migrating motor complex (phase III activity) passing down the small intestine. The amplitude of small intestinal contractile activity is very low (not exceeding 20 mmHg) suggesting a diagnosis of myopathic chronic intestinal pseudo-obstruction

providing the ability of full-thickness biopsy sampling in a safe and minimally invasive way [164].

Motility Investigations

These studies are performed to assess the GI motility and to define the underlying pathophysiologic process, and these studies form the hallmark of diagnosis in pediatrics. Investigations include GI manometries (esophageal, antroduodenal, colonic, anorectal), GI scintigraphy (e.g., gastric emptying, colonic transit), electrogastrography, and radiopaque markers. The usefulness of novel technologies, such as SmartPill, remains to be determined [165–167].

Although in children with PIPO the involvement of GI may be generalized, the small intestine is always affected; thus, antroduodenal manometry remains the most discerning test, and its optimal placement is pivotal (Fig. 23.1b) [168–170]. Neuropathic cases manifest with uncoordinated contractions, which are of normal amplitude, whereas in myopathic PIPO, motor patterns have normal coordination; however, the amplitude of intestinal contractions is low (Fig. 23.1c) [171, 172]. Additionally, manometry may facilitate the dynamic assessment of potential pharmacotherapeutic options and feeding strategies (e.g., feasibility of oral or enteral feeds) as well as indicate disease prognosis [156, 173, 174].

In the most challenging cases, exploratory surgery (laparotomy or laparoscopic-assisted procedures) may be required to definitively exclude mechanical obstruction from PIPO. One however should bear in mind that surgery may precipitate a pseudo-obstructive episode and may also lead to adhesions formation, which can further complicate future diagnostic or therapeutic procedures. Where possible, investigations and then diagnostic/therapeutic surgery should be performed in timeline sequence and in referral center.

Histopathology along with genetics can also be very useful in establishing or confirming the diagnosis of PIPO, highlighting the underlying pathophysiologic process, thus aiding the overall management.

Differential Diagnosis

PIPO has to be differentiated from mechanical obstruction; the latter is usually characterized by marked abdominal pain (in keeping with the abdominal distention), specific radiologic signs, and manometric patterns [111, 175]. Acute functional obstruction (e.g., postoperative ileus), functional GI disorders (e.g., rumination syndrome), and pediatric condition falsification should be considered and appropriately investigated and managed [9].

Treatment

The therapeutic approach in PIPO is threefold as it aims to (i) preserve growth and development by maintaining adequate caloric intake, (ii) promote GI motility with combined medical and surgical interventions, and (iii) treat disease-related complications or underlying pathologies that cause secondary PIPO. Despite the limited effects of the currently applied therapeutic modalities, refinements and evolution in nutritional, medical, and surgical strategies have considerably

improved the overall management of PIPO [155]. Acute management of episodes of pseudo-obstruction is generally treated conservatively by nil by mouth, intravenous fluid, and drainage of stasis through nasogastric (NG) tube or preformed ostomies. Careful attention to fluid and electrolytes is imperative.

Nutrition

The role of nutrition in PIPO is of paramount significance as it is well known that gut motility improves with optimal nutritional support and declines in the face of under- or malnutrition [176–180]. In the long term, approximately one-third of PIPO patients require either partial or total parenteral nutrition, another third require a degree of intragastric or intra-enteral feeding, whereas the remaining children are able to tolerate sufficient oral nutrition. However, within all of groups, patients able to tolerate feeds may require some dietary modification in order to maintain enteral nutrition and avoid bezoar formation (e.g., bite and dissolvable feeds, restriction diets, hydrolyzed formula).

Although parenteral nutrition is lifesaving, it is associated with significant risk of complications, such as central line infections and liver disease, and therefore maintaining patients on maximally tolerated enteral nutrition is always strongly encouraged [169, 178]. In the more severe PIPO cases, continuous rather than bolus feeds administered via a gastrostomy or jejunostomy may be better tolerated particularly in children with impaired gastric motor function [8, 181–184].

Medications

The therapeutic role of drugs in PIPO patients is mainly limited to the control of intestinal inflammation, suppression of bacterial overgrowth, and promotion of GI motility [185].

Prokinetics (e.g., metoclopramide, domperidone, erythromycin, azithromycin, octreotide, neostigmine, pyridostigmine) usually combined with antiemetics (e.g., promethazine, ondansetron) have been used in an attempt to improve the GI motor function and reduce the severity of nausea and vomiting [186–191]. The use of some of these agents is limited by variable efficacy and unacceptable extraintestinal side effects (e.g., metoclopramide, neostigmine). The best-studied and tested prokinetics, that is, cisapride and tegaserod have been withdrawn from the market due to safety concerns [169, 192]. The need for new prokinetics with increased safety and efficacy has resulted in new products (e.g., prucalopride, aprepitant, ghrelin), but there are limited data of their use in pediatric PIPO, further impacted on by restricted availability and licensing [178, 193, 194].

Undoubtedly, current medical regimens for PIPO are based on limited literature and/or expert opinion (e.g., combined use of octreotide and erythromycin) and are yet to be tested in future in the context of controlled trials [178, 193].

Surgery

Surgery remains a valuable intervention on patients with PIPO as it has a multidimensional role in both the diagnostic (e.g., full thickness biopsies) and therapeutic processes (e.g., insertion of feeding tubes, formation of decompressing ostomies such as gastrostomy, ileostomy) [195, 196].

Indeed, adequate bowel decompression is crucial not only in providing symptomatic relief by reducing the frequency and the severity of pseudo-obstructive episodes but also in limiting further deterioration of the intestinal motor activity secondary to chronic distention, and in enhancing the tolerance of enteral feeding [197]. Long decompression enteral tubes and extensive bowel resections are approaches mainly reported in adult CIPO cohorts but remain untested in terms of practicality, efficacy, and safety in pediatrics [198–201]. Rate of significant surgical complications, such as stoma prolapse, infection, and leakage can be significant.

Novel surgical methods involve implantation of devices providing electrical pacing of the GI neuromusculature, but data in children are scanty and limited [8, 15–17, 144].

Small bowel transplantation remains the only definitive cure. Recent advances in both surgical techniques (e.g., multivisceral transplantation) and immunosuppression strategies have resulted in improved outcomes and survival as reported by centers with the relevant expertise showing a survival rate of 50% at 3 years [13, 25, 31, 202–206].

Natural History and Prognosis

Both pediatric and adult chronic intestinal pseudo-obstructions have a severe clinical course, characterized by repetitive relapses and remissions. Unfortunately, the low index of suspicion among physicians along with lack of well-defined diagnostic criteria and readily available facilities in performing specialized diagnostic tests (e.g., manometry) often accounts for delays in the diagnosis and repetitive unnecessary investigations and surgery [206].

The majority of the patients complain of symptoms, which progressively worsen and impact upon the tolerance of enteral nutrition and increasing reliance on total parenteral nutrition [179, 180]. The latter in conjunction with disease-related adverse events (e.g., central line infections, impairment of the liver function, immunosuppression after small bowel transplantation, surgical procedures) accounts for

high morbidity, poor quality of life, and mortality rates up to 30% [13, 25, 31, 202–206].

Despite recent diagnostic and therapeutic advances, PIPO in children remains a serious, life-threatening disease with significant impact on the well-being not only of patients themselves but also of their families [206].

Summary

PIPO is a debilitating disease with poorly defined etiopathogenesis, which is reflected on the limitations encountered in both the diagnostic process and therapeutic management. Clearly, multinational initiatives are required to raise awareness and evolve current diagnostic modalities and therapeutic options.

Gastrointestinal and Nutritional Problems in Neurologically Impaired Children

24

Paolo Quitadamo and Annamaria Staiano

Introduction

The increasing survival of children with severe central nervous system damage accounts for a major challenge for medical care. Although the primary problems for individuals with developmental disabilities are physical and mental incapacities, several clinical reports have indicated that brain damage often results in significant gastrointestinal dysfunction [1–4]. The enteric nervous system contains more neurons than the spinal cord, and thus, it is not surprising that insults to the central nervous system may affect the complex integrated capacities underlying feeding and nutrition [5].

The increased awareness of such conditions, together with a better understanding of their etiology and interplay, is essential to achieve an optimal global management of this group of children.

Feeding and Nutritional Aspects

Historically, severe malnutrition has been accepted as an unavoidable and irremediable consequence of neurological impairment. Poor nutritional status was often marked by linear growth failure, decreased lean body mass, and diminished fat stores [6, 7]. Over the past two to three decades, multidisciplinary feeding programs providing comprehensive evaluation and treatment of feeding disorders in children with developmental disabilities have been instrumental in improving the nutritional status and quality of life and reducing the hospitalization rates [8]. Nutritional assessment and nutritional interventions in neurologically impaired children are a challenge for physicians but should be part of the child's comprehensive care and rehabilitation.

Assessment of nutritional status is the first step in the clinical nutritional evaluation of children with neurological impairment. In these children, measurement can be difficult and the references commonly used in pediatric patients tend to misinterpret undernutrition. Whenever possible, weight measurement should be obtained on a digital scale or, if the child is unable to stand, on a wheelchair scale [9]. Standing height or supine length can be used in children who can stand or lay down straight. However, accurate evaluation of stature may not be possible because of spasticity, joint contractures, or scoliosis. In children who are unable to stand upright due to skeletal deformity, alternative measurements for the height assessment should be segmental lengths, such as knee-heel length, tibia length, and ulnar length, assessed by sliding calipers [9, 10]. Special equations or charts can then be used to calculate the standing height [11]. Assessment of nutritional status in neurologically impaired children should not be based on weight and height measurements alone, but should include the evaluation of body composition [9, 10]. The three most commonly used measurements to calculate growth charts in typically developing children, such as weight-to-height ratio, height for-age, and weight-for-age, are poor predictors of body composition in this group of patients [9]. Weight measurements do not distinguish between muscle and fat mass percentages. Neurologically impaired children have higher fat percentages and lower lean masses than typically developing children. Body mass index is not recommended especially when derivative measures of body length are used [9]. Therefore, parameters to assess malnutrition and overnutrition in the handicapped child have to be adjusted. Children should be studied as for anthropometric parameters, body composition, bone status, and laboratory nutritional values [9, 12]. An algorithm for the suggested approach to the nutritional assessment of the neurologically impaired child (from ref. 9) is reported in Fig. 24.1.

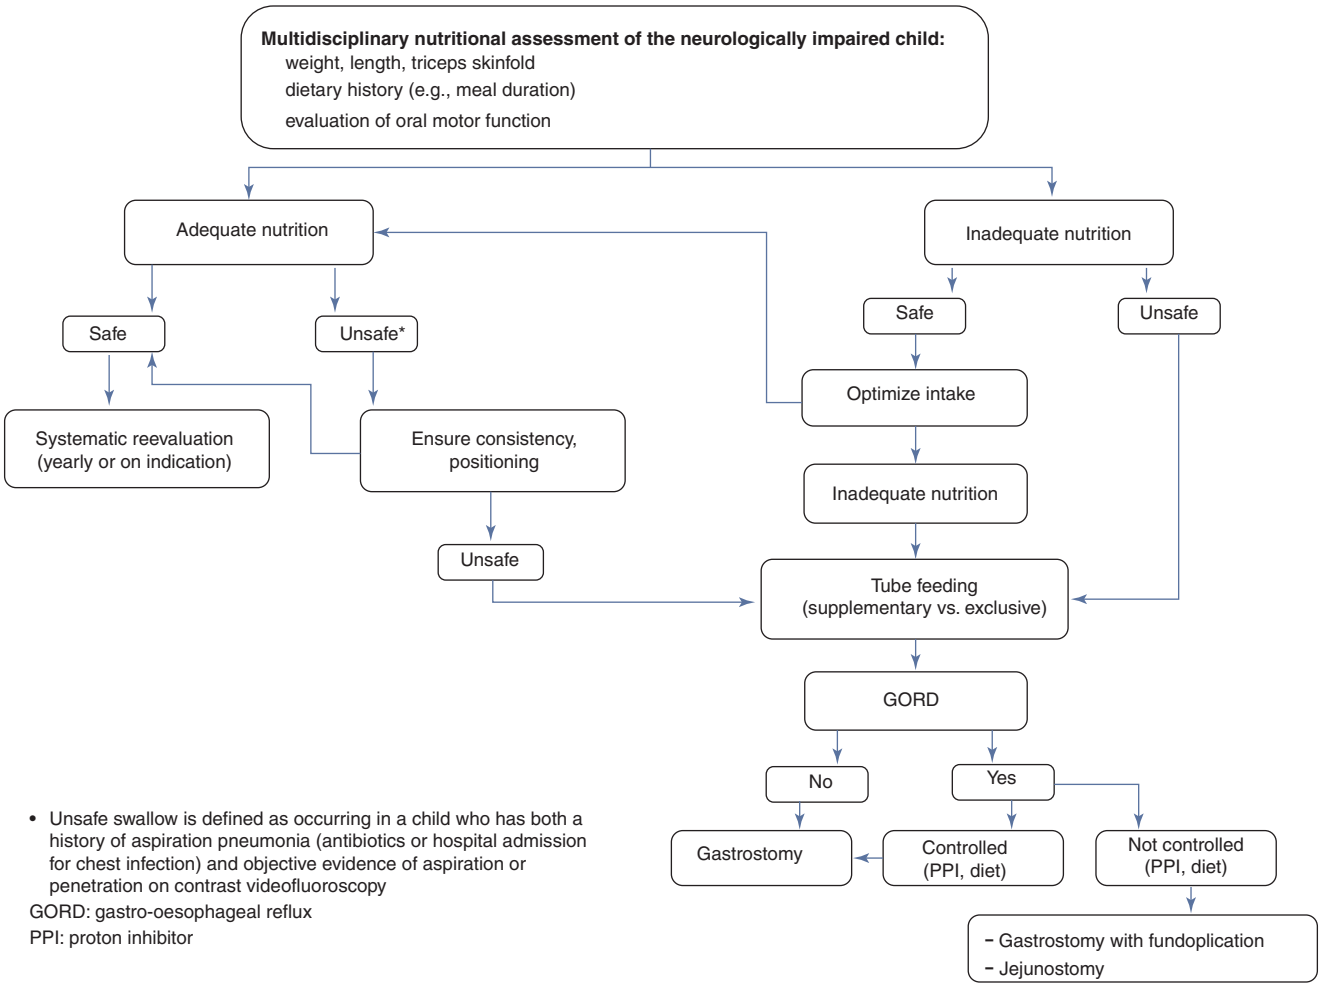

Fig. 24.1 Algorithm for the nutritional evaluation of the neurologically impaired child. (Reproduced from ref. 9 with permission)

The true prevalence of undernutrition in neurologically impaired children is unknown. It has been estimated that approximately one-third of them are undernourished and many exhibit the consequences of malnutrition [13]. Yet, the incidence and severity of malnutrition increases with the duration and the severity of neurological impairment [14–16]. Moreover, it should be considered that no single, universally accepted definition of undernutrition in children exists, neither in typically developing nor in neurologically impaired children [17, 18]. For clinical practice, ESPGHAN recommends the use of 1 or more red flag warning signs, including physical signs of undernutrition, such as pressure sores and poor peripheral circulation, weight for age z score <−2, triceps skinfold thickness <tenth centile for age and sex, mid-upper arm circumference or muscle area <tenth percentile, faltering weight, and/or failure to thrive [9]. These recommendations are mainly based on experts' opinion and low−/moderate-quality studies. Recently, they have validated some screening tools aimed to identify risk of feeding and swallowing difficulties or undernutrition earlier and to assess if further assessment is needed [19].

The predominant nutritional deficit in neurologically impaired children is in energy intake, with only 20% of these children regularly ingesting 100% of their estimated average requirement. Moreover, half of the children with severe disabilities consumed less than 81% of the reference nutrient intake for copper, iron, magnesium, and zinc, with that influenced by their large consumption of milk [20, 21]. Nutritional support is essential for the care of neurologically impaired children. Undernourished handicapped children might not respond properly to intercurrent diseases and suffer unnecessarily. On the other hand, restoring a normal nutritional status results in a better quality of life in many. Assessment of nutritional status requires a proper follow-up of height, body weight, and assessment of the standard deviation score. By so doing, negative changes are easily discovered and appropriate nutritional intervention can be initiated. An individualized intervention plan that accounts for the child's nutritional

status, feeding ability, and medical condition should be determined. Energy requirements must be individualized considering mobility, muscle tone, activity level, altered metabolism, and growth. The easiest and least invasive method to increase energy intake is to improve oral intake. Food caloric density may be increased by adding modular nutrients, modifying recipes or using high-calorie formulas. Children who cannot chew effectively may be able to receive the same foods blenderized into a puree of acceptable consistency. Those who can tolerate solids but not liquids can have commercial thickeners added to their fluids. Oral feeding skills may be improved with therapy, even if the results may be disappointing [22–24]. Adequate positioning of the child during meals and appropriate food temperature are furthermore important. However, oral intake can be maintained as long as there is no risk of aspiration, the child is growing well, and the time required to feed the child remains within acceptable limits.

When oral intake is unsafe, insufficient, or too time-consuming, enteral nutrition should be initiated. The type of enteral access will depend on the anticipated duration of enteral nutrition support as well as the clinical status of the child. Nasogastric tubes are minimally invasive but are easily dislodged and have local complications such as sinusitis, congestion, otitis, and skin irritation. Generally, nasogastric feeds should only be used for short-term nutritional support (less than 3 months). For long-term enteral nutrition support, a gastrostomy should be considered (Fig. 24.1). Gastrostomies are more invasive but are also more convenient and esthetically acceptable. Gastrostomy placement has been shown to reduce feeding time, food-related choking episodes, frequency of chest infections, and family stress and to improve weight and nutritional status significantly in children with severe neurologic impairment [25, 26]. However, percutaneous endoscopic gastrostomy (PEG) is not without complications or concerns. Minor catheter infections, perforation, and an overall lessened length of survival have been described in both adult and pediatric population [27–32].

The anatomy and function of the stomach should be carefully evaluated before the placement of the feeding tube. The coexistence of gastro-esophageal reflux (GER) may require a simultaneous fundoplication, and delayed gastric emptying must necessitate pyloroplasty or duodenal placement of the distal portion of the tube. Physiologically designed formulas of increased caloric and protein density can be used for gastric and nasogastric infusion, as palatability is no longer an issue. The choice between bolus and drip may depend on esophagogastric function, the volume to be delivered, or the home care needs of the child and his or her caregivers. Often patients may benefit from a combination of daytime bolus and nocturnal continuous feeds, the latter providing 30–50% of the child's nutrient needs thus allowing more freedom for daily activities. When safety of oral feeding is not an issue, these enteral techniques can merely supplement the child's own nutrition, with caregivers continuing to feed the child actively. This dual feeding method often provides great satisfaction to parents and caregivers, because the mealtime interaction is improved when there is no longer need for force-feeding of medication or nourishment.

Gastrointestinal Problems

Chronic gastrointestinal (GI) disorders are very common in children with neurological impairment, being reported a prevalence of up to 92% [33]. Dysphagia, rumination, GER, delayed gastric emptying, abdominal pain, and constipation have all been described in this group of children, potentially contributing to feeding difficulties and carrying challenging long-term management issues.

Dysphagia

Oral motor dysfunction is a frequent concomitant and often one of the first signs of neuromuscular impairment. Related swallowing problems have been shown to affect up to 90% of neurologically impaired children, being major contributors to malnutrition [1, 34]. This is not surprising since the development of oral-motor skills mirrors general neurological maturation and requires the coordination of the movement of several striated muscles in the mouth, pharynx and esophagus by six cranial nerves, the brain stem, and the cerebral cortex. In addition, anatomic abnormalities such as cleft palate, laryngeal clefts, and tracheoesophageal fistula may accompany neurologic deficits as part of a congenital or genetic syndrome. Dysphagia may manifest as distress during meals (including coughing, choking, and refusal of feeding), chronic or episodic aspiration-related respiratory disorder, and failure to thrive. Barium swallow, cine-swallow, radionuclide esophageal clearance scan, and esophageal manometry may all be of some help in the clinical assessment. Successful management of dysphagia is central to the child's well-being and ability to achieve his or her potential. Neurologically impaired children often show greater problems with liquid foods, thus requiring the use of thickener products. Oral motor exercise approaches using sensory modalities may help improving muscle strength and oral coordination. Nevertheless, in most cases, the presence of unsafe swallows and/or long-lasting distressed meals finally lead to the choice of enteral nutrition.

Gastro-esophageal Reflux

Several reports have demonstrated the high incidence of GER in neurologically impaired children. GER symptoms such as vomiting, rumination, and regurgitation are found in 20–30% of the intellectually disabled population [35]. GER-related iron deficiency anemia and hematemesis are noted in 10–20% of patients. In the Netherlands and Belgium in a large cohort of more than 1500 patients, a randomly selected intellectually disabled population was tested with pH-metry during 24 hours. A pathological pH test (defined as a duration of a pH of <4 for more than 4% of the measured time) was seen in 48% of cases [36]. These patients were subjected to endoscopy and reflux esophagitis was found in 96%: 14% had grade I esophagitis, 33% had grade II, 39% had grade III, and 13% had grade IV (Savary Miller classification). Barrett's esophagus was found in 14% and peptic strictures in 4% of cases. This study was repeated for the group under the age of 14, and similar findings were seen. In fact, GER disease was found even in the absence of overt symptomatology. Prolonged supine position, increased intra-abdominal pressure secondary to spasticity and scoliosis, a coexisting hiatal hernia have been supposed to be contributing factors to the increased frequency of GER. Central nervous system dysfunction, however, is likely to be the prime cause, being GER probably a part of the generalized dysmotility of the foregut, if not of the entire intestine. Decreased resting pressure and increased frequency of transient relaxations of the lower esophageal sphincter, together with motility abnormalities, are probably a consequence of neuromuscular incoordination.

Currently the most accurate way of diagnosing GER is 24-hour esophageal pH impedance recording, which allows not only to quantify the amount of reflux episodes but also helps in establishing the temporal relationship between GER and the symptom complex in question. The diagnostic work-up should then include upper GI endoscopy with multiple esophageal biopsies and upper GI barium study, in order to evaluate the mucosa and to look for the possible presence of strictures, diverticuli, or hiatal hernia. Radionuclide studies such as gastro-esophageal scintigraphy should also be performed, due to the higher incidence of delayed gastric emptying which may contribute to GER [37, 38]. An esophageal manometry evaluating visceral motility may be helpful to detect the underlying pathophysiological mechanisms, especially when surgery becomes necessary.

Although children with neurologic impairment are more likely to have intractable reflux and eventually require some surgical procedures, medical therapy should be tried first. When surgery becomes advisable, the Nissen fundoplication is currently the most widely used technique to strengthen the antireflux barrier and relief symptoms [39].

Constipation

Infrequent stool passage and hard bowel movements are very common in neurologically impaired children. The incidence of constipation was around 61% in a large cohort of mentally handicapped children in Dutch and Belgian institutions [40]. Total and sequential colonic transit times have been shown to be prolonged and delayed at the level of the left colon and rectum in this group of children, implying a probable defect in gut innervations [3]. The problem is usually exacerbated by prolonged immobility, inadequate fiber intake, and medications. Unfortunately, recognition and therefore effective management of constipation are often delayed because their other disabilities overshadow those related to defecation. Therapeutic approach needs to be tailored to the individual patient. Oral or rectal disimpaction should be followed by promotion of regular bowel habits, through dietary modifications, positioning, and use of medications. A significant number of children with neurological impairment need to be on chronic doses of laxatives, which are usually effective in enabling regular defecations. However, when medical treatment fails, a surgically placed appendicostomy should be considered.

Cyclic Vomiting Syndrome

25

Katja Kovacic and BU K Li

Introduction

Despite improved characterization, recognition, and understanding of cyclic vomiting syndrome (CVS) in the past three decades, without a delineated pathophysiologic cascade, it remains classified as a functional gastrointestinal disorder. The hallmark symptoms described by Samuel Gee in 1882 remain applicable today and include stereotypical, severe episodes of vomiting punctuating symptom-free periods or baseline health [1]. Earlier clinical diagnosis has been facilitated by more specific consensus diagnostic criteria defined by the North American Society for Pediatric Gastroenterology, Hepatology & Nutrition (NASPGHAN; 2008) and Rome IV criteria (2016), the former being quantitatively more rigorous by requiring three to five vs two total episodes (Table 25.1) [2, 3]. Although there is considerable clinical overlap between migraine conditions such as abdominal migraines and CVS, the predominant and most consistent symptom during episodes best defines the illness, that is, abdominal pain is termed abdominal migraine, and conversely vomiting is denoted CVS. The continuum between CVS and migraine was suggested by Whitney already in 1898 and corroborated by other authors in 1998 [4, 5]. In a cross-sectional school survey in Scotland, Abu-Arafeh described a probable developmental progression from CVS to abdominal migraine and migraine headaches (median ages 5, 9, and 11 years and comparative prevalence 1.9%, 4%, and 11%, respectively) [6]. This suggestion of a natural history that begins with CVS and ends with migraines reproduces initial reports by Barlow in 1984 who labeled this progression as the "periodic syndrome." [7] Although some experience all three phases, the majority trade CVS for migraines beginning at age 10 and an estimated 75% will develop migraine headaches by age 18 years.

Table 25.1 NASPGHAN and Rome IV diagnostic criteria

NASPGHAN
1. At least five attacks in any interval or a minimum of three attacks during a 6-month period.
2. Episodic attacks of intense nausea and vomiting lasting 1 h to 10 days, occurring at least 1 week apart.
3. Stereotypical pattern and symptoms in the individual patient.
4. Vomiting during attacks at least 4 times/h for at least 1 h.
5. Return to baseline health between episodes.
6. Not attributed to another disorder.
Rome IV
1. Two or more periods of intense unremitting nausea and paroxysmal vomiting, lasting hours to days within a 6-month period.
2. Episodes are stereotypical in each patient.
3. Episodes separated by weeks to months with return to baseline health between episodes.
4. Symptoms not attributed to another medical condition.

All respective criteria must be met to meet consensus definitions for both NASPGHAN and Rome IV

Inclusion of an ICD-10 code specific to CVS has enabled more complete epidemiologic surveys, documenting a 2% prevalence of adult CVS in the USA [8]. Yet, typical misdiagnoses continue today, including gastroenteritis, food poisoning, gastroesophageal reflux, and eating disorders, delaying accurate diagnosis by a median 2.6 years. In our consecutive series, CVS was second only to gastroesophageal reflux as a cause of recurrent vomiting [9]. Two school-based surveys estimated the frequency to be 2% in Scottish and Turkish children and the incidence of new cases of CVS was reported to be 3.15 per 100,000 children per year in Irish children [6, 10]. In our series, the average age of onset was 4.8 years with a predominance in girls over boys (57:43) (Table 25.2) [11].

Pathophysiologic connections have been made with mitochondrial disease, autonomic dysfunction, and the stress

response. Current research is focused on the identification of neuroendocrine mechanisms and novel therapeutic targets.

Cyclic vs. Chronic Patterns of Vomiting

An important clinical clue to the diagnosis of CVS is the pattern of vomiting. Based on the temporal pattern, children with recurrent vomiting can be delineated into cyclic and chronic groups. The *cyclic group* has an intense, but intermittent pattern of vomiting with peak emesis of at least 4/hr and minimum week-long period between episodes [12]. The *chronic group* has a low grade, daily pattern of emesis with <4 emesis/hr and >2 episodes per week [12]. Two-thirds of all children with recurrent vomiting fit into the *chronic* or continuous pattern of vomiting. These children rarely appear acutely ill or become dehydrated. Conversely, the *cyclic* pattern is associated with more intense vomiting, ill-appearance (pallor, lethargy), migraine features and these affected children more often require IV hydration compared with the chronic group (62% vs 18%) [9].

Recognizing these two patterns is also important because the groups differ significantly in symptom and diagnostic profile. In those with the cyclic vomiting pattern, nongastrointestinal disorders including neurologic (including CVS and abdominal migraine), renal, endocrine, and metabolic ones predominate over gastrointestinal disorders by a ratio of 5:1 [12, 13]. In contrast, in the chronic group, gastrointestinal disorders (mostly peptic disease) predominate over nongastrointestinal causes for vomiting by a ratio of 7:1 (Table 25.3) [12, 14]. This implies the need to center the diagnostic workup on extra-intestinal disorders in children who present with the *cyclic* vomiting pattern, while on upper GI tract disorders in the *chronic* vomiting pattern.

Clinical Patterns

CVS has a distinctive on-off temporal pattern of vomiting that serves as an essential criterion for diagnosis. CVS is distinguished by the "on" pattern of discrete, recurrent, and severe episodes of vomiting, which are stereotypical within the individual as to time of onset (usually early morning), duration (hours or days), and symptomatology (pallor, listlessness). The "off" pattern occurs during week or month-long intervals when the child resumes completely normal or baseline health (e.g., if there is other chronic disease), although 12% may have interepisodic symptoms of daily nausea and/or mild vomiting [14]. Interepisodic symptoms should always prompt workup for alternate or additional diagnoses. During the episodes, the most common symptoms are listlessness (93%) and pallor (91%) that can even mimic semicoma or shock. Other symptoms include relentless nausea, abdominal pain, low grade fever or hypothermia, intermittent flushing, diaphoresis, drooling, and diarrhea. Although found in significantly higher frequency than in patients with chronic GI disorders, fewer than half have migraine features of headache, photophobia, and phonophobia [15].

The duration of episodes generally ranges from hours to days with a median duration of 27 hours [15]. Episodes are always self-limited although a few may last longer than 1 week and require escalating medical care and nutritional support. About 49% of patients have "cyclic" or "calendar-timed" intervals predictable within a week, most commonly 4 weeks, and the remainder have "sporadic," unpredictable attacks; 42% have onset of their episodes early morning or upon awakening (1–8 am). Many have a remarkably rapid onset (median 1.5 hours) and resolution (median 6 hours) from the last emesis to the point of being able to eat and be playful. The 67% with a prodrome have pre-emesis pallor, diaphoresis, abdominal pain, and headache, but rarely the visual disturbances seen in a classical migraine aura. The prodromal phase may have therapeutic implications as there may be sufficient time to intervene medically to prevent the start of the emetic cycle.

The vomiting in CVS is uniquely rapid-fire and peaks (during the worst episode) at a median frequency of six times an hour and averages 22 times per episode. The vomiting is typically projectile and contains bile (80%), mucus, and occasionally blood, the latter usually the result of prolapse gastropathy. The bilious nature often raises concern for an obstructive lesion. The intense nausea and retching differ from that associated with emesis from gastrointestinal disorders in that it persists even after complete evacuation of gastric contents as if independent of gastric feedback. Many describe nausea as the most distressing symptom, only relieved during sleep. Due to the unrelenting nausea during episodes, these children appear much more debilitated when compared to those with gastroenteritis, often curled into a fetal position, listless, and withdrawn to the point of being unable to walk or interact. Anorexia, nausea, midline abdominal pain, and retching are the most common gastrointestinal symptoms.

Certain unusual observed behaviors during CVS episodes can raise questions about an underlying psychiatric disorder. There are children who drink compulsively and then vomit

Table 25.3 Differential diagnosis of cyclic vomiting [13]

	Chronic pattern	Cyclic pattern
Gastrointestinal	Peptic injury (esophagitis, gastritis, duodenitis)	Anatomic causes (malrotation, volvulus, duplication cyst)
	Eosinophilic esophagitis/gastroenteritis	Cholelithiasis/biliary dyskinesia
	Celiac disease	Pseudo-obstruction
	Inflammatory bowel disease	Recurrent/chronic pancreatitis
	Giardiasis	
	Chronic appendicitis	
	Gastroparesis	
Infectious	Chronic sinusitis	Sinusitis and infections may be triggers
Genitourinary	Pyelonephritis, pregnancy	Acute hydronephrosis due to ureteropelvic junction obstruction or stones
Metabolic	Rare	Mitochondrial disorders (MELAS)
		Organic acidemias
		Aminoacidurias
		Fatty acid oxidation defects
		Urea cycle defects
		Acute intermittent porphyria
Endocrine	Adrenal hyperplasia	Addison disease
		Diabetic ketoacidosis
		Pheochromocytoma
Neurological	Chiari malformation	Migraine (headaches, abdominal)
	Subtentorial neoplasm	Autonomic dysfunction
Psychiatric/ behavioral	Munchausen by proxy (rare)	Munchausen-by-proxy (rare)
	Rumination/functional vomiting	Bulimia nervosa

and describe that this maneuver dilutes the bitter bile and aids in evacuating it. Others take prolonged, hot showers or baths until the hot water supply is exhausted. This behavior has been increasingly associated with cannabinoid hyperemesis syndrome (CHS) in adults. However, current theories do not necessarily imply cannabis use in patients using hot showers for relief (as children display this without exposure) but rather that CHS patients represent a subset of CVS triggered by excessive and prolonged use [15]. Many are hyperesthetic to light, sound, motion, odor, taste, and even to parental touch and attempt to shut out all external stimuli. Nearly all turn their rooms into a darkened cave in order to avoid any stimuli that can trigger more nausea and vomiting.

Various recurring stressors have been identified by parents to precipitate CVS episodes in 76% of patients. These include psychological (44%), infectious (31%), and physical triggers. Although negative stressors are common, the psychological stress is often of an excitatory nature such as holidays, birthdays, outings, and vacations. Episodes may be triggered by various infections including upper respiratory infections, sinusitis, strep throat, and flu. The largest fraction (32%) has a seasonal clustering of episodes with more during the winter and fewer during the summer. Although this pattern correlates with the school year, we can only speculate that less school-related stress, less exposure to infections, and longer duration of sleep all factor into the improvement during summer months. Dietary triggers include foods rich in amines, aged-cheese, chocolate, monosodium glutamate, and fluctuating caffeine intake (23%). Lack of sleep from excess physical exhaustion due to travel, sports, sleepovers or a sleep disorder (24%), and menses (catamenial CVS 22%) are also common inciting events. Environmental triggers include changes in barometric pressures in weather fronts. One subgroup with a precisely timed interval every 60 days (predictable within a week) and an absence of identifiable triggers is noted to be especially refractory to therapy.

Pathophysiology

In the absence of a defined etiopathogenesis, CVS remains classified as an idiopathic disorder. Investigations support the contributory roles of mitochondrial DNA (mtDNA) mutations and dysfunction, polymorphisms involving the cannabinoid receptor type 1 and μ-opioid receptor genes (adults), dysfunction of hypothalamic-pituitary-adrenal (HPA) axis or endocannabinoid system, and autonomic nervous system (ANS) dysfunction [14]. CVS is a functional disorder of gut-brain interaction perhaps mediated through altered brainstem modulation of effector signals.

Mitochondrial Dysfunction

In two series, a striking maternal inheritance pattern was recognized for migraines in 64% and 54% of probands with CVS [16, 17]. Evidence of mitochondrial dysfunction was first provided using NMR to establish decreased ATP production in peripheral muscle in migraineurs [18]. This mitochondrial pathogenesis gained substantial support following the identification of two tandem mtDNA polymorphisms, 16,519 T and 3010A with impressive odds ratios of 17 and 15 in CVS and migraine in haplotype H, respectively [19]. Because the mutations are found in the control region rather than the enzyme sequence, the structure to function relationship is unclear. However, elevated lactate, ketones, and Krebs cycle intermediates during the early part of the attacks are consistent with mitochondrial dysfunction. In addition, clinical trials and open label experience show some effects of mitochondrial supplements Coenzyme Q10, L-carnitine, and riboflavin in the treatment of migraines and CVS in children [20, 21].

Neuroendocrine

Stressors, both psychological (excitement, panic) and physical (fever, lack of sleep), are common triggers of attacks of CVS. An activated HPA axis during episodes of CVS was first described by Wolfe and Adler and later in greater detail by Sato [22, 23]. These authors documented elevated levels of adrenocorticotropic hormone (ACTH), antidiuretic hormone, cortisol, catecholamines, and prostaglandin E_2. These elevated levels may partially explain the symptoms of hypertension and profound lethargy in this subset of patients. Attenuation of CVS symptoms occurred after use of high-dose dexamethasone by Wolfe and Adler and indomethacin and clonidine by Sato et al. [24]

These findings have focused attention upon the potential role of corticotropin-releasing factor (CRF) as a brain-gut neuroendocrine mediator of foregut motility. Taché et al. have shown that psychological or physiologic stressors induce CRF release from the hypothalamus which stimulates inhibitory motor neurons via CRF-R2 receptors in the dorsal motor nucleus of the vagus that delays gastric emptying, independent of downstream effects of ACTH, and cortisol secretion [25]. Preliminary data demonstrates increased peripheral CRF levels during episodes of CVS but whether this acts to trigger emesis or occurs in response to the stress of the illness is not clear. The new entity of cannabis-induced hyperemesis syndrome (CHS), which probably represents a variant of CVS, suggests that the endocannabinoid system plays a role in CVS. CB1 receptor activation attenuating the stress response, reducing nausea, and increasing appetite are well-known effects of THC. Interestingly, a growing number of case reports suggest that prolonged and frequent high dose use may alter the ligand-receptor relationship and result in a cannabis-triggered type of CVS [26]. This unique response suggests that in some patients, altered endocannabinoid signaling may trigger attacks. Conversely, there may be therapeutic potential in other CB1 receptor agonists.

Autonomic Dysfunction

Most of the prominent symptoms of CVS are expressed through the ANS, strongly suggesting ANS dysregulation during vomiting episodes. The peripheral vasoconstriction, hypersalivation, diaphoresis, tachycardia, and listlessness are prominent manifestations of nausea that persist throughout the episode, typically unrelieved by evacuation of the stomach. A small series of children with CVS identified autonomic dysfunction in the form of postural orthostatic tachycardia syndrome (POTS) [27]. This study noted that treatment of the POTS appeared to help reduce the frequency of CVS episodes. Further, heart rate variability studies have documented autonomic imbalance at baseline in children with CVS, manifested by diminished cardiac parasympathetic modulation [28, 29]. One small study associated state anxiety during a stress test to changes in heart rate variability in children with CVS, suggesting a possible link between anxiety and abnormal ANS reactivity serving as triggers of episodes [29]. Two formal studies of ANS function in adults with CVS revealed a pattern of heightened sympathetic tone with normal parasympathetic tone [30, 31].

We have found an overall prevalence of POTS in 19% of our CVS patients, and when we limited the cohort to adolescents >11 years in whom POTS is known to be more common, the rate was 38% [32]. This rate may be even higher in later adolescence as the disorder is frequently unrecognized and testing not widely available. Further, an evolution into chronic symptoms of ANS imbalance is noted in a subset of CVS children during teenage years. This tends to manifest by severe, daily morning nausea along with dizziness, concentration difficulties, sleep problems, and chronic fatigue. Further data is needed to characterize such subtypes.

Subtypes of CVS and Comorbidities

Migraines

An association with migraines was identified over a century ago [4, 33]. The current association occurs in 83% of those with CVS who have a positive family history of migraines or migraines themselves. In addition, there is a common progression from CVS to migraine headaches with advancing adolescent age. In the absence of definitive diagnostic tests

for migraines and CVS, strong link is further supported by similar symptomatology (e.g., pallor, lethargy, nausea, photophobia, phonophobia), positive responses in both groups to antimigraine therapy, and mtDNA polymorphisms. These migraine-associated CVS patients generally have milder episodes, a greater association with psychological stress, and significantly higher response rates to antimigraine therapy (79% vs. 36%) [34, 35].

Sumatriptan (a selective 1B/1D serotonin agonist) is one antimigraine drug that can abort episodes if administered early on especially via the nasal route (52%) [36]. This action on serotonin receptors with similar rates of response to patients with migraine headaches suggests a central role of action presumably by decreasing cerebrovascular dilatation. Until we have a clearer delineation of mechanisms involved in migraine and CVS, we cannot be certain if the CVS patients who do not fit under the migraine umbrella have dissimilar pathophysiologic cascades.

Neurocognitive Delays

In Boles' series, 25% had coexisting neurological findings of developmental delay, seizures, hypotonia, and skeletal myopathy as well as cognitive and cranial nerve dysfunction [37]. These children, classified as CVS+, were found to have an earlier age of onset for CVS and a 3- to 8-fold higher prevalence of dysautonomic (neurovascular dystrophy) and constitutional (growth retardation) manifestations than CVS patients without neurological findings.

Cannabis

As noted, there is a group of adolescents and young adults with CVS who chronically use marijuana to alleviate nausea and vomiting. However, this instead may aggravate CVS symptoms in susceptible individuals and has been labeled as CHS [15]. This more likely represents cannabis-triggered CVS [26]. Although not pathognomonic, CHS has been associated with compulsive hot water bathing [38]. CHS is now recognized in the adult Rome IV criteria as a separate entity. This is defined as cyclical emetic episodes mimicking CVS, after longstanding cannabis use, and often with associated pathologic bathing behaviors [39]. There are now over 280 case reports described, mostly young males and daily users over 6 years. One series of nine patients reports termination of bouts of emesis after cessation of chronic use of marijuana with exacerbation upon resumption of smoking cannabis, but most case reports do not provide sufficient follow-up to establish whether there is clinical resolution upon cessation of cannabis.

Other Subgroups

As discussed, some have documented ANS abnormalities and comorbid POTS in whom treatment of POTS may help reduce frequency of vomiting episodes. The Sato variant is associated with hypertension during episodes only and an endocrine profile of heightened HPA axis activation including ACTH, cortisol, cathecholamines, and vasopressin. These patients generally have significantly more prolonged episodes (102 hrs vs 50 hrs) and increased vomiting per episode (75 emesis vs 31) (Li, Unpublished data). Those with long-interval, calendar-timed episodes every 60+ days apart appear particularly difficult to treat and usually have no identifiable stress or infectious triggers. A stable periodicity has also been observed in postmenarchal girls with catemenial CVS who may respond to low-estrogen birth control pills or Depo-Provera. Finally, in a group of children, dietary triggers of CVS episodes can be identified. Some are initiated by typical migraine precipitants including cheese, chocolate, and monosodium glutamate, whereas others are triggered by other foods and/or preservatives.

It is unclear whether these groups are distinct or more likely overlapping phenotypes. We hope that delineation of clinical patterns into subgroups may ultimately point us towards more specific treatment approaches for each subgroup. New findings from mitochondrial genome studies and related nuclear genes that affect mitochondrial function may also eventually point to specific treatments.

Comorbidities

We have begun to document numerous comorbidities in affected children most of which affect them during the episode-free intervals when well. We find that they contribute to symptoms of fatigue, abdominal pain, and dizziness that impair the daily quality of life as documented by Tarbell and Li [40]. Comorbidities in non-neurologically impaired children include anxiety (47%), depression (14%) [41], chronic fatigue (52%), sleep disturbances (48%), irritable bowel syndrome (41%) [42], gastro-esophageal reflux disease (39%), colonic dysmotility (20%) [37], postural orthostatic tachycardia syndrome (19%), daily nausea (coalescent 12%), and complex regional pain syndrome (10%) [15, 43]. It is possible that several of these comorbidities are manifestations of underlying ANS dysregulation. Often, these complaints contribute to the poor quality of life with an average of 3.1 comorbid symptoms per child and have to be treated concomitantly to help restore the child to functionality.

Differential Diagnosis

Differentiating a cyclic versus a chronic pattern of vomiting is the first step in narrowing the differential diagnosis. Although the majority of patients (88%) with a cyclical pattern ultimately are diagnosed with CVS, the remaining 12% have other specific causes for vomiting found on diagnostic testing. The majority of disorders that can mimic CVS include nongastrointestinal as well as GI disorders.

Of the gastrointestinal disorders, the most serious are anatomic anomalies of the GI tract including malrotation with intermittent volvulus which can cause devastating bowel necrosis. Although not typically cyclical, we have found children with eosinophilic esophagitis related to significant food allergies to mimic CVS. Lucarelli et al. have described seven children with positive RAST to foods (milk, egg white, and soy) whose episodes diminished after specific food elimination [44].

The most common extraintestinal surgical cause is acute hydronephrosis resulting from ureteral pelvic junction obstruction. Metabolic causes include mitochondrial disorders (disorders of fatty acid oxidation, mitochondrial encephalopathy, lactic acid, and stroke-like syndrome), urea cycle defects (partial ornithine transcarbamylase deficiency), organic acidurias (proprionic acidemia), aminoacidurias, and porphyrin degradation disorders (acute intermittent porphyria) [45, 46]. Neurosurgical causes include various lesions of the subtentorial region including cerebellar medulloblastoma, brain stem glioma, and Chiari malformation, likely precipitating vomiting through increased intracranial pressure. Endocrine causes include Addison disease, pheochromocytoma, and carcinoid. Munchausen by proxy (ipecac poisoning) should also be included in the differential diagnosis of a cyclic pattern of vomiting.

Gastroparesis must be considered in the differential diagnosis. Patients with gastroparesis generally have chronic postprandial symptoms as opposed to the severe, episodic emesis of CVS within a cycle. However, a subset may have a cyclic exacerbation of upper GI tract dysmotility that can mimic CVS. Gastric emptying scans may not be helpful, as no pediatric norms are available and emptying rates may differ if assessed at baseline compared to during the prodromal or emetic episode when autonomic reactivity is high. It may also confuse the diagnosis as CVS patients are found to have various patterns of gastric emptying [47]. Instead of hypomotility, the majority of adult patients with CVS were found to have rapid gastric emptying (59%) [48], while 27% were normal and only 14% were actually delayed. This hypomotility is less pronounced in children as the respective numbers for rapid, normal, and delayed were more even [47]. This hypermotility may be a surrogate marker for autonomic dysfunction that is present in many of these patients [30, 31]. It is important to consider the limitations of these data given the absence of pediatric gastric emptying norms and the retrospective study design.

Diagnostic Evaluation

At present, there are no specific biomarkers or tests to diagnose CVS, and the diagnosis rests primarily upon fulfilling clinical criteria in the NASPGHAN Consensus Statement or Rome IV (less rigorous) [2, 3]. The key first step requires recognizing a cyclic pattern (high intensity, low frequency) of vomiting because 88% will eventually turn out to be diagnosed with CVS [9]. There are still one in eight who will have an organic underlying cause, often extra-intestinal. Underlying disorders that may require surgical intervention include anatomic anomalies of the GI tract, especially malrotation with the risk of volvulus, renal hydronephrosis, and subtentorial Chiari malformation or neoplasm. These can be excluded by upper GI series (to ligament of Treitz) renal ultrasound performed during/soon after illness (acute calyceal dilation can resolve in 10 days) and brain MRI (CT may not adequately visualize the brainstem), respectively. The challenge to the clinician is to determine which and how much testing should be performed, as the traditional 'shotgun' approach is costly, time-consuming, and invasive.

The recent NASPGHAN Consensus Statement (2008) guidelines recommend against the traditional shotgun approach and a minimal amount of screening to include an upper gastrointestinal series to exclude malrotation and anatomic obstructions and a basic metabolic profile (electrolytes, glucose, BUN, creatinine) [2]. This is supported by a recent study showing minimal yield of extensive diagnostic testing that only changes approach in 4% in pediatric CVS [49]. Similarly, our cost-decision analysis found an UGI x-ray to be the most cost-effective test followed by empiric treatment for 2 months [50]. Further testing beyond that should be based upon specific red flags or warning signs (Table 25.4). In those who present with bilious vomiting and abdominal tenderness, abdominal imaging should be performed to exclude hydronephrosis, pancreatitis, and cholecystitis. In those in whom episodes are triggered by intercurrent illnesses, fasting, or high protein meals, metabolic screening should be performed for urea cycle, fatty acid oxidation, disorders of organic and amino acid metabolism, and mitochondrial disorders. This screening has an improved diagnostic yield during the early part of an episode of CVS before intravenous glucose and fluids are administered. Those presenting with abnormal neurological findings including altered mental status, papilledema, ataxia, or sei-

Table 25.4 Evaluation of cyclic vomiting

Patient meets consensus criteria for CVS > UGI series to evaluate for malrotation + serum electrolytes, BUN, creatinine. If no warning signs or findings to suggest an organic disorder > two-month trial of empiric therapy to treat CVS.
If warning signs are present:
Severe abdominal pain, bilious, and/or hematemesis > serum chemistries, liver and pancreatic assessment, abdominal ultrasound (vs CT or MRI), esophagogastroduodenoscopy.
Fasting, high-protein meal, intercurrent illness precipitating episodes of vomiting > serum and urine metabolic evaluation (lactate, ammonia, carnitine profile, amino acids, and organic acids) *prior to intravenous fluid treatment during episode* as well as metabolic consult.
Abnormal neurological findings (altered mental status, papilledema) > brain MRI, neurology consult.

Table 25.5 Rescue and abortive pharmacotherapy

Antimigraine
Sumatriptan 20 mg intranasal at episode onset and may repeat once vs. 25 mg po once vs. 3–6 mg s.c. once SE: Chest and neck burning, coronary vasospasm, headache
Alternatives: *Rizatriptan*, *zolmitriptan, frovatriptan (longer half-life)*
Antiemetic
Ondansetron 0.2–0.3 mg/kg per dose (≤12 mg) q 4–6 h iv/po/rectal/topical. SE: Headache, drowsiness, dry mouth
Alternatives: *Granisetron*
Aprepitant 3 day regimen: 125, 80, 80 mg one q.d. prior to anticipated episode
Fosprepitant 3–4 mg/kg (max 150 mg) IV day one (aprepitant days 2–3)
Sedative
Lorazepam 0.05–0.1 mg/kg per dose q 6 h iv/po: Useful adjunct to ondansetron. SE: Sedation, respiratory depression
Chlorpromazine 0.5–1 mg/kg per dose q 6 h iv/po. SE: Drowsiness, hypotension, seizures, dystonic reaction
Diphenhydramine 1.25 mg/kg per dose q 6 h iv/po: Useful adjunct to chlorpromazine. SE: Hypotension, sedation, dizziness
Dexmedetomidine bolus 0.5mcg/kg over 15 min > 0.5mcg/kg/h (up to 1.5 mcg/kg/h) continuous infusion
Analgesic
Ketorolac 0.5–1 mg/kg per dose q 6 h iv/po. SE: Gastrointestinal bleeding, dyspepsia

zure should have a neurological evaluation and brain MRI. Presentation of CVS under the age of 2 should also prompt further metabolic or neurological testing [2].

Treatment

Current treatment for CVS can be divided into supportive or rescue therapy (during episodes), lifestyle modifications and prophylactic (daily treatment to prevent episodes), and abortive therapy (prodromal intervention to abort episodes). The goals of treatment are to reduce the frequency and severity of episodes, enhance functionality, and improve quality of life. Treatment of nausea, vomiting, abdominal pain, and dehydration during acute episodes requires a protocol for use at home, in emergency departments, and on hospital wards. Other strategies for management of CVS include avoidance of identified triggers (e.g., dietary cheese), psychological interventions (e.g., stress management), and treatment of comorbid symptoms.

The NASPGHAN Consensus Statement recommendations on treatment are based upon therapeutic responses from case series and expert opinion of the task force [2]. The main recommendations include first line prophylactic use of cyproheptadine and amitriptyline in children under and over age 5 years, respectively, with propranolol serving as the second line. Sumatriptan was recommended as an abortive agent for those >12 years. For rescue therapy during acute episodes, IV rehydration with higher dose antiemetic ondansetron (0.3–0.4 mg/kg/dose) and sedation from diphenhydramine or lorazepam was recommended.

Supportive or Rescue Therapy

Supportive or rescue care is used when the vomiting becomes well established in an episode and at that point usually fails to respond to any abortive strategies. The goal is to correct energy, fluid, and electrolyte deficits and render the child more comfortable through antiemetic therapy, analgesics, and sedation for relief from intractable nausea, vomiting, and abdominal pain. The recommendation is for an IV bolus of saline for rapid correction of fluid deficits and concurrent 10% dextrose 0.45 normal saline at 1.5 X maintenance rates to provide sufficient cellular energy to terminate ketosis. One may have to reduce IV rates and increase Na^+ content when hyponatremia and diminished urine output ensues from elevated antidiuretic hormone release present in Sato-variant CVS. Ondansetron has been the most widely used $5HT_3$ antagonist given safely at higher than standard doses (up to 0.3 mg/kg/dose) but can prolong the QTc interval [16]. It generally reduces both nausea and vomiting but usually does not stop the episode or the misery from nausea (Table 25.5). A recent systematic review found greatest evidence for ondansetron as rescue therapy in the emergency department for pediatric CVS with promising support for sumatriptan and aprepitant [51].

Diphenhydramine, lorazepam, diazepam, or chlorpromazine combined with diphenhydramine is used to induce sedation because sedation is often the only means of providing relief from the unrelenting nausea and abdominal pain. The analgesic ketorolac is recommended as first line as narcotics should be avoided and are felt to have a sensitizing effect in migraine analgesia. A nonstimulating environment including quiet, dark single room may be helpful. When all else fails

and episodes are prolonged and debilitating (>1 week), we have occasionally used a dexmedetomidine infusion to achieve deep sedation in a PICU setting for 18 hours as described by Khasinwah [52].

Lifestyle Modifications

Lifestyle modifications are used during the interictal phase of CVS when the child is not in an episode in order to keep the child properly conditioned and to avoid exposure to known and potential precipitants of episodes. The lack of sleep resulting from disturbed sleep patterns, sleepovers, or travel sports tournaments are often cited as triggers of episodes. Good sleep hygiene (e.g., turning off all phones, computers, music, TV) with a regimented sleep time can reduce the frequency of episodes. Providing at least maintenance volumes of fluids is widely used to prevent migraines and postural orthostatic tachycardia syndrome. Providing low glycemic energy sources before strenuous activity, sources may prevent an exercise-induced energy deficit. Routine exercise can help reverse the deconditioned state and improve mitochondrial function. Finally, avoiding identified triggers specific to the individual (e.g., sleepovers) or including those generally found in migraines (monosodium glutamate and fluctuations in caffeine intake) may help reduce the frequency of episodes. Fleisher reported that consultation and lifestyle modifications alone reduced the frequency of episodes in 70% of patients even before beginning standard prophylactic therapy [42].

Prophylactic Therapy

For those with more frequent or severe episodes (e.g., more than once a month), prophylactic therapy daily (or twice weekly with aprepitant) is recommended during the interictal phase with the goal of preventing the next episode or to at least reduce the frequency, duration, or intensity (# emeses) of episodes. These *prophylactic medications* are traditionally used to treat other disorders including migraines. The NASPGHAN consensus recommendations for the initial treatment were for cyproheptadine for the younger (<5 years) and amitriptyline for the older children and adolescents (≥5 years) (Table 25.6) [2]. Despite its pharmacokinetics, cyproheptadine (0.25–0.5 mg/kg) appears to be effective given as a single night time dose as opposed to the usual two or three divided doses [53]. Amitriptyline causes side effects in 50%, the most common being morning sedation (like a hangover), and is stopped in 21% [54]. Beginning at a low dose of 0.2 to 0.3 mg/kg at bedtime and titrating it gradually in 10 mg increments every week or two to the target dose of 1.0–1.5 mg/kg allows the child to gradually adapt to the side effects. Switching to other tricyclic antidepressants such as nortriptyline, desipramine, or doxepin may lessen specific side effects. An EKG to measure the QTc interval is recommended before starting amitriptyline. At higher doses (>1.0 mg), we monitor the ECG and/or amitriptyline levels [55]. Propranolol is second line therapy and can be monitored for efficacy and toxicity by a desired drop in pulse rate of 15–20 beats per minute not to fall below 55 bpm, respectively.

Table 25.6 Prophylactic pharmacotherapy

Antimigraine
Amitriptyline start and 0.2–0.3 mg/kg and advance to 1–1.5 mg/kg/day q.h.s.: Monitor EKG QTc interval prior to starting and with higher dose titrations. First choice ≥5 years old. Side effects: Sedation, anticholinergic
Propranolol 0.25–1 mg/kg/day divided b.i.d or t.i.d: Monitor resting heart rate. SE: Hypotension, bradycardia, fatigue
Cyproheptadine 0.25–0.5 mg/kg/day divided b.i.d. or q.h.s.: First choice <5 years old. SE: Sedation, weight gain, anticholinergic
Alternatives: *Nortriptyline*, *desipramine, doxepin*
Anticonvulsants
Topiramate titrate to 1.5–2.0 mg/kg/day divided b.i.d. SE: Appetite suppression, cognitive dysfunction, renal stones
Phenobarbital 2–3 mg/kg/day q.h.s. SE: Sedation, cognitive impairment
Alternatives: *Gabapentin, levetiracetam, zonisamide, valproate, carbamazepine*
NK-1 receptor antagonist
Aprepitant 125 mg PO twice weekly (>60 kg); 80 mg (40–60 kg); 40 mg (<40 kg)
Mitochondrial supplements
l-*carnitine* 50–100 mg/kg ≤ 2 g/day divided b.i.d. SE: Diarrhea, fishy body odor
Coenzyme Q_{10} 10 mg/kg/divided b.i.d. ≤600 mg/day
Riboflavin 10 mg/kg/day divided b.i.d. ≤400 mg/day

Sunku and Li [11], with kind permission from Springer Science + Business Media

If standard prophylactic therapy fails, aprepitant, anticonvulsants, and Ca^{++}-channel antagonists have been used. In a series of children and adolescents, 81% receiving Aprepitant achieved a partial (62%) or complete (19%) response when administered twice weekly [56]. Topiramate (1–2 mg/kg/day) and phenobarbital at low (2–3 mg/kg) nighttime doses have been reported to be effective, the former having a strong evidence based in migraines [57, 58]. Unfortunately, cognitive dysfunction is a well-known side effect of both. A retrospective review of 38 pediatric CVS patients documented efficacy in 81% of patients treated with topiramate vs 59% treated with propranolol [59]. A recent randomized trial from Iran found amitriptyline (1 mg/kg/d) superior to topiramate (1–2 mg/kg/d) in 70 children with CVS, documenting short-term efficacy in 68% vs. 39% of patients, respectively [60]. Other effective anticonvulsants, zonisamide and levitiracetam, have been effective in adults with CVS [61]. Another group of agents includes Ca^{++}-channel antagonists with the

main side effect of hypotension. Other antidepressants may also be considered when there is strong psychiatric comorbidity. A pediatric case series documented efficacy of the tetracyclic antidepressant mirtazapine in CVS patients with anxiety and depression [62]. Mirtazapine also facilitates both sleep and appetite and may thus be considered in specific patients with sleep disturbances and poor weight gain.

Treatment may vary by clinical subgroup. Children that have a migraine connection with either a positive family history or migraines themselves are much more likely to respond to antimigraine agents such as cyproheptadine, amitriptyline, and propranolol (79 vs. 36%) than those children without one [34]. Postmenarchal girls with catamenial CVS often respond to low estrogen birth control pills or Depo-Provera. Sato-variant CVS associated with hypertension may require intra-episodic short-acting antihypertensives as well as prophylactic tricyclic antidepressants in the USA and divalproex sodium in Japan [23].

Prophylactic use of mitochondrial supplements as adjunctive prophylactic therapy in CVS is quite common based upon evidence in migraines and preliminary evidence in children with CVS. These supplements have demonstrated efficacy in the prevention of migraines in adults (randomized controlled trials) and preliminary evidence of efficacy in pediatric migraine and CVS in children [54, 63–65]. Interestingly, in some children with CVS, the accompanying chronic fatigue may respond to these supplements. The doses used include CoQ10 10 mg/kg divided b.i.d. up to 600 mg/day, riboflavin at 10 mg/kg divided b.i.d. to up to 400 mg/day, and L-carnitine at 50–75 mg/kg up to 3 g/day divided b.i.d. The dose and duration of these supplements has not been established in children with CVS.

Abortive Therapy

Abortive therapy should be considered for those who have sporadic or milder episodes that occur less than once per month and who prefer not taking prophylaxis or those who have breakthrough episodes while on prophylaxis. Abortive therapy is administered during the prodrome or at the beginning of the vomiting episode in the hope of stopping it. The novel NK-1 receptor antagonist aprepitant is a highly effective antiemetic when administered as an abortive agent in the prodromal phase at least 30 min before vomiting begins (only oral formulations available). This may be particularly effective in calendar-timed CVS if administrated prior (e.g., a day before) to the anticipated episode. One retrospective pediatric study documented efficacy of aprepitant 3-day regimen for abortive use (Table 25.5) [56]. Subtype-specific abortive therapy includes antimigraine triptans for those with migraine features. The nasal (sumatriptan or zolmitriptan) or subcutaneous (sumatriptan) forms appear more effective than oral forms that cannot be effectively absorbed due to repeated vomiting (Table 25.6) [2, 66]. The triptans are usually either fully effective or not at all and more effective if administered early in episode or if the duration of episodes is less than 24 hours (Li, unpublished data).

In a few children, ondansetron administered alone aborts episodes in progress. Although the oral forms may not reach the duodenum, ondansetron can be reformulated by individual pharmacies into a rectal suppository or topical (lipodermal) forms. Although not established, we successfully use the same dosages as the oral form.

Comorbidities

Treatment of specific comorbid conditions and symptoms may alleviate the CVS, improve quality of life, and reduce functional disability. Most of important of these is addressing anxiety through stress reduction techniques (e.g., cognitive behavioral therapy) as well as anxiolytics. This approach has anecdotally reduced the number of episodes in anxious children whose attacks are triggered by stressors and/or panic anxiety. Chelimsky has shown in a small series that treatment of the POTS with fluids, salt, fludrocortisone, and/or propranolol helps prevent attacks of CVS [27]. Alleviating other comorbid symptoms – disordered sleep, chronic fatigue, and irritable bowel syndrome – may substantially improve the quality of life and functional disability.

Natural History, QOL Impact, and Complications

There is some data for the natural history of CVS. Our projection analysis estimates that 75% of patients will develop migraine headaches by age 18 (Li Unpublished data). Other long-term studies have shown that up to half of CVS patients continue with CVS or migraine headaches. Several studies have noted the mean duration of illness to be around 6 years, but in our cohort, the younger the age of onset, the longer the duration. Also 5% of patients will progress through all 3 phases of periodic disease from CVS to abdominal migraine and finally to migraine headaches. We are currently encountering a growing group with teenage-onset CVS and it is too early to ascertain if they are at greater risk of carrying CVS into adulthood.

CVS has a significant deleterious impact on the quality of life in affected children. Although well in between episodes approximately 90% of the time, 58% of affected children require intravenous fluids during episodes and average 10 visits to the Emergency Department [67]. School-age children in our cohort missed an average of 24 days of school per year [13]. Medical morbidity is reflected by the high average

annualized total cost of $17,035 in 1999 dollars that includes doctor visits, emergency department visits, inpatient hospitalizations, missed work by parents, as well as biochemical, radiographic, and endoscopic testing [50]. A more recent pediatric study documented a mean cost of screening diagnostic workup per CVS patient at $6125 [49]. This study found that most (96%) patients did not undergo any change in diagnosis or medical management based on the laboratory evaluation. Growing number of comorbid conditions such as anxiety and postural orthostatic tachycardia syndrome also contribute to functional impairment. We have demonstrated significantly lower quality of life scores than in healthy controls, equivalent to those in children with organic GI diseases (e.g., inflammatory bowel disease, gastritis) [40].

Complications and medical morbidity include iatrogenic tests and interventions from the misdiagnoses that are often applied to recurrent vomiting. Most are mislabeled as acute gastroenteritis, gastro-esophageal reflux, and food poisoning and treated in urgent care settings. Some with severe pain, bilious vomiting, and intractability have undergone unnecessary laparotomy, appendectomy, cholecystectomy, and Nissen fundoplication. Others have been labeled with psychiatric disorders including bulimia and psychogenic vomiting and hospitalized on psychiatric wards, while a few parents have been referred for suspicion of Munchausen-by-proxy.

Medical complications can also occur from the frequent and often severe episodes of vomiting that occur with CVS. Dehydration and electrolyte disturbances are common and IV rehydration is required at some point in 58% of patients, which can be compared to less than 1% in rotavirus. Hematemesis can occur towards the end of attacks and is usually related to prolapse gastropathy or Mallory-Weiss tears. Although not common, frequent vomiting can lead to secondary peptic injury.

Summary

CVS is a disorder that now well described and accepted in the literature and increasingly diagnosed by pediatric and family physicians as well as pediatric and adult emergency medicine specialists, neurologists, and gastroenterologists. Recently, there is greater appreciation of comorbid conditions and symptoms that deleteriously affect quality of life and functioning. Although the precise pathophysiology remains unknown, we have growing evidence of involvement of the autonomic nervous system, stress axis, and mitochondrial function. Unfortunately, no robust treatment trials have been completed to date and so therapies remains empiric. Yet, the progress made over the past two decades has been impressive.

Food Allergy

26

Ragha Suresh, So Lim Kim, Scott H. Sicherer, and Christina E. Ciaccio

Introduction

An expert panel convened by the National Institute of Allergy and Infectious Diseases defined food allergy as "an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food" [1]. This description distinguishes food allergy from nonimmune adverse reactions to foods (Table 26.1). Over 170 food allergens have been identified, but nine foods or food groups (milk, egg, peanut, tree nuts, soy, wheat, fish, crustacean shellfish, and sesame) account for 90% of significant allergic reactions [1, 2]. It is important to note that parental perception of food allergy is generally much higher than physician-diagnosed food allergy, particularly in early childhood. Up to one-third of parents report at least one adverse reaction to food [3–8]. The emotional impact of food allergy is considerable, with significant impact on health-related quality of life [9, 10]. This chapter reviews the spectrum of food-allergic disorders with an emphasis on those relevant to the pediatric gastroenterologist. Celiac disease is the result of an immune response to foods, but is not typically categorized as an allergy and is reviewed in a separate chapter.

Epidemiology

The Centers for Disease Control and Prevention reported that the prevalence of food allergy in US children increased from 3.4% in 1997–1999 to 5.1% in 2009–2011 [11]. A study by Gupta et al. examining data from 2009 to 2010 estimated the prevalence of childhood food allergy in US children to be up to 8% [1, 12–15]. Most recently, the same group conducted a population-based survey between October 2015 and September 2016 to reassess the prevalence of food allergy in US children. The study found the prevalence to be 7.6% after excluding 4% of children whose parent-reported food allergy reaction history was inconsistent with IgE-mediated food allergy [16, 17]. The most recent study used more stringent criteria to define "convincing" allergies, thus precluding direct comparison of the estimates. The most prevalent allergens were peanut (2.2%), milk (1.9%), shellfish (1.3%), and tree nut (1.2%) [16]. Among food-allergic children, 42.3% reported ≥1 severe food allergy and 39.9% reported multiple food allergies. Furthermore, 19.0% reported ≥1 food allergy-related emergency department visit in the previous year and 42.0% reported ≥1 lifetime food allergy-related emergency department visit. Prevalence rates of food allergy were higher among African American children and children with atopic comorbidities [16].

A population-based survey study from 2015 to 2016 of US adults found that an estimated 10.8% had a convincing food allergy, confirming that many children do not outgrow their food allergies [18]. Among food-allergic adults, 51.1% experienced a severe food allergic reaction, 45.3% were allergic to multiple foods, and 48.0% developed food allergies as an adult [18]. The most common allergies were shellfish (2.9%), milk (1.9%), peanut (1.8%), tree nut (1.2%), and fin fish (0.9%) [18].

Adverse Food Reactions

Adverse food reaction is a broad term that describes an abnormal response of the body to ingestion of a particular food. This encompasses both immune-mediated and nonimmune-mediated processes.

https://doi.org/10.1007/978-3-030-80068-0_26

Food allergy is defined as an adverse specific immune response that occurs reproducibly on exposure to a given food. On the other hand, *food intolerance* is a type of nonallergic adverse reaction, defined as difficulty digesting or metabolizing a particular food. Food intolerance can arise from properties of the food itself (e.g., toxic contaminants or pharmacologic properties) or host characteristics (e.g., metabolic disorders that lead to poor digestion of food). Some well-defined examples of food intolerances are listed in Table 26.1.

Distinguishing true food allergy from food intolerance is important. In general, food intolerance presents with prominent gastrointestinal symptoms, symptom severity correlates with the amount of food ingested, and each exposure results in similar symptoms. On the other hand, IgE-mediated food allergy reactions are less predictable, and even small amounts of food have the potential to cause severe or life-threatening reactions.

Table 26.1 Nonimmune-mediated reactions or food intolerance/adverse reactions to food

Type	Example(s)
Metabolic	Lactose intolerance, galactosemia, alcohol dehydrogenase deficiency
Pharmacologic	Caffeine (jitteriness), tyramine in aged cheeses (migraine), alcohol, histamine
Toxic	Bacterial food poisoning, scombroid fish poisoning (histamine)
Undefined mechanisms	Reactions to sulfites, tartrazine

Immunopathogenesis and Specific Disorders

Tolerance is the normal immune response to food [19]. The immune system recognizes food proteins, and IgG and IgA antibodies may be generated, but there are no adverse reactions. Food allergy results from a disruption of normal tolerance mechanisms. Food allergies may be immunoglobulin E (IgE)-mediated, cell-mediated, or "mixed" adverse immune responses. The distinction of pathophysiology is important in diagnosis and management. For example, IgE-mediated reactions are typically sudden in onset following exposure to a food allergen, whereas cell-mediated responses may result in chronic inflammation or delayed symptoms. Table 26.2 highlights gastrointestinal manifestations of food allergy according to pathophysiology.

IgE-Mediated Reactions

Natural History of IgE-Mediated Reactions

IgE-mediated food allergy often appears during the first 2 years of a child's life. The sensitivity to some allergenic foods (egg, milk) self-resolves in 85% of children during childhood [20]. Sensitivity to peanuts, tree nuts, fin fish, and shellfish persists into adulthood in the large majority of affected children. Approximately, 20% of peanut-allergic children under the age of 2 years and 10% of children with tree nut allergy will become tolerant to those foods by the time they are of school age [21]. Though shellfish, tree nut,

Table 26.2 Gastrointestinal food allergies

Disorder	Mechanism	Symptoms	Diagnosis
Pollen-food allergy syndrome (oral allergy syndrome)	IgE mediated	Mild pruritus, tingling, and/or angioedema of the lips, tongue, or oropharynx	Clinical history and positive sensitization to pollens
Gastrointestinal "anaphylaxis"	IgE mediated	Rapid onset of nausea, abdominal pain, cramps, vomiting, and/or diarrhea; other target organ responses (i.e., skin, respiratory tract) often involved	Clinical history and positive tests for food-specific IgE; ± oral challenge
Eosinophilic esophagitis	IgE mediated and/or cell mediated	Gastroesophageal reflux or excessive spitting-up or emesis, dysphagia, intermittent abdominal pain, irritability, sleep disturbance, failure to respond to conventional reflux medications	Clinical history, endoscopy and biopsy, elimination diet, and oral food challenge (possible test directed)
Eosinophilic gastroenteritis	IgE mediated and/or cell mediated	Recurrent abdominal pain, irritability, early satiety, intermittent vomiting, FTT and/or weight loss, peripheral blood eosinophilia (in 50%)	Clinical history, endoscopy and biopsy, elimination diet, and challenge (possibly test directed)
Food-protein-induced proctocolitis	Cell mediated	Gross or occult blood in stool; typically thriving; usually presents in the first few months of life	Negative SPT responses; elimination of food protein → clearing of most bleeding in 72 h; ± endoscopy and biopsy; challenge induces bleeding within 72 h
Food-protein-induced enterocolitis syndrome	Cell mediated	See Tables 26.6 and 26.7	History, response to elimination/oral food challenge
Food-protein-induced enteropathy	Cell mediated	Diarrhea or steatorrhea, abdominal distention and flatulence, weight loss, FTT, ± nausea and vomiting	Endoscopy and biopsy

FTT failure to thrive, *SPT* skin prick testing, *IgE* immunoglobulin E

and fin fish allergies were the most common adult-onset food allergies, adult-onset food allergies to all major food allergen groups is also possible [22].

Symptoms

Symptoms triggered by IgE-mediated reactions occur rapidly following ingestion of the trigger food. IgE antibodies that are specific for regions (epitopes) of food proteins bind to tissue mast cells and circulating basophils. Cross-linking of the IgE antibodies by the food proteins leads to release of preformed mediators (such as histamine and platelet-activating factor) from cytoplasmic granules and transcription of inflammatory cytokines. The target organs(s) involved in the reaction define the type of food allergy. The symptoms occurring during an acute reaction can be classified as cutaneous, ocular, gastrointestinal, respiratory, cardiovascular, or neurologic. A combination of these symptoms may occur.

Cutaneous manifestations of an acute food allergy reaction include erythema, hives, pruritus, flaring of eczematous lesions, and angioedema. Food allergy may account for up to 20% of new-onset urticaria [23, 24]. Food allergies rarely cause chronic urticaria (e.g., episodes occurring regularly for 6 weeks or longer). Eczema (atopic dermatitis) can be chronically exacerbated by specific IgE-mediated food allergy, with improvement upon removal of the suspect food [25–27]. Overall, skin symptoms are the most common manifestation of IgE-mediated food allergies. Food can also induce skin symptoms by direct skin contact (contact urticaria) [28–32].

Ocular symptoms include pruritus, tearing, conjunctival erythema, and periorbital edema.

Gastrointestinal symptoms include nausea, vomiting, diarrhea, and abdominal pain. Isolated acute gastrointestinal reactions are uncommon. In the case of a food-allergic reaction, upper gastrointestinal symptoms usually begin within minutes of ingestion, but may take as long as 2 h to develop. Diarrhea may have a more delayed onset, beginning 2–6 h after ingestion of the allergen.

Respiratory tract symptoms may be acutely induced by IgE-mediated reactions. Symptoms may include pruritus and edema of the larynx, dyspnea, nasal congestion, rhinorrhea, hoarseness, stridor, tachypnea, wheezing, and cough.

Cardiovascular symptoms associated with acute food-allergic reactions include increased vascular permeability, widened pulse pressure, increased heart rate and cardiac output, and flushing. These effects can lead to the decreased organ perfusion that is characteristic of anaphylactic shock.

Neurologic manifestations include a sense of impending doom, dizziness, confusion, incontinence, and loss of consciousness. Neurologic compromise is thought to result from hypotension and hypoxia [33].

Anaphylaxis

Anaphylaxis is traditionally defined as a systemic, rapid-onset, severe, and potentially life-threatening allergic reaction resulting from the sudden release of mast cell mediators. Diagnosis of anaphylaxis is critical as these patients need prompt administration of epinephrine; however, it is not always easy to recognize. Symptoms generally include a combination of the above symptoms (or respiratory or cardiac symptoms alone), with anaphylactic shock referring to signs of poor organ perfusion in addition to anaphylaxis. In children, respiratory, cutaneous, and gastrointestinal symptoms are prominent, and the most common cause of death is respiratory compromise.

A clinical diagnostic criteria for anaphylaxis developed by a multidisciplinary group of experts (Table 26.3) helps clinicians recognize the variability in presentation [34]. This criteria has a sensitivity of >95%. It is also important to recognize that although anaphylaxis represents the most severe form of allergic reaction, there is a spectrum of severity in anaphylaxis itself. Anaphylaxis can range from mild or transient symptoms to hemodynamic compromise/shock. Less than 1% of anaphylaxis cases (including those not due to food ingestion) result in death, indicating fatal anaphylaxis is

Table 26.3 Diagnostic criteria for anaphylaxis

Anaphylaxis is highly likely when any ONE of the following three criteria is fulfilled:
1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, pruritus or flushing, swollen lips-tongue-uvula) AND AT LEAST ONE OF THE FOLLOWING: A. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, hypoxemia) B. Reduced BP* or associated symptoms of end-organ dysfunction (e.g., hypotonia, collapse, syncope, incontinence)
2. TWO OR MORE OF THE FOLLOWING that occur rapidly after exposure to a LIKELY allergen for that patient (minutes to several hours): A. Involvement of the skin mucosal tissue (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula) B. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, hypoxemia) C. Reduced BP* or associated symptoms (e.g., hypotonia, collapse, syncope, incontinence) D. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP* after exposure to a KNOWN allergen for that patient (minutes to several hours): A. Infants and children—Low systolic BP (age-specific)* or greater than 30% decrease in systolic BP B. Adults—Systolic BP of less than 90 mmHg or greater than 30% decrease from that person's baseline
BP: blood pressure. * Low systolic blood pressure for children is defined as: Less than 70 mmHg from 1 month to 1 year Less than (70 mmHg + [2 × age]) from 1 to 10 years Less than 90 mmHg from 11 to 17 years

Reproduced from: Sampson et al. [34]

rare [33–35]. Several grading systems have been used to define reaction severity (Tables 26.4 and 26.5).

In retrospective analyses, several factors appear to be associated with the severity of the allergic response. A larger quantity of food allergen ingested, concomitant alcohol consumption, fever, and concomitant nonsteroidal anti-inflammatory drugs (NSAID) use all appear to increase the rapidity and severity of the reaction [35–39]. Concomitant ingestion of fatty foods appears to slow the rate of absorption and thus delay onset of symptoms.

Risk-taking behaviors among adolescents and young adults, including increased incidents of exposure to the avoided allergen and a lack of a prompt treatment response to symptoms, contribute to the disproportionately higher number of fatal food-induced anaphylaxis in this age group [40]. In one case series of fatal food-induced anaphylactic reactions, accidental ingestion of a known food allergen was present in 87% of cases [35]. In several cases, previous reactions to the known allergen were relatively mild, highlighting the inconsistency in severity of reactions. Having asthma is an additional risk factor for fatal anaphylaxis.

Anaphylaxis is usually characterized by rapid onset and evolution of symptoms, but the time course can be unpredictable. Biphasic anaphylactic reactions occur in up to 20% of cases [41]. In this scenario, a second wave of symptoms occurs 1–4 hours following resolution of the initial anaphylactic reaction. Delayed anaphylaxis is rare and refers to anaphylaxis characterized by a delayed onset of symptoms, from minutes or even hours. Protracted anaphylaxis is an allergic reaction that can last hours or even days [42].

Table 26.4 Criteria for severity grading (Muraro et al., 2007) staging system of severity of anaphylaxis

Stage	Defined By
1. Mild (skin and subcutaneous tissues, GI, and/or mild respiratory)	Flushing, urticaria, periorbital or facial angioedema; mild dyspnea, wheeze or upper respiratory symptoms; mild abdominal pain and/or emesis
2. Moderate (mild symptoms + features suggesting moderate respiratory, cardiovascular or GI symptoms)	Marked dysphagia, hoarseness and/or stridor; shortness of breath, wheezing and retractions; crampy abdominal pain, recurrent vomiting and/or diarrhea; and/or mild dizziness
3. Severe (hypoxia, hypotension, or neurological compromise)	Cyanosis or $SpO_2 < 92\%$ at any stage, hypotension, confusion, collapse, loss of consciousness; or incontinence

Reproduced from Muraro et al. [33]

Food-Dependent, Exercise Induced Anaphylaxis

Food-dependent, exercise-induced anaphylaxis is an IgE-mediated food-induced anaphylactic reaction that occurs when vigorous exercise is performed within a few hours of food allergen ingestion. Neither exercise alone nor ingestion of the food allergen alone is sufficient to cause symptoms. While generally associated with specific causative foods (such as wheat, other grains, celery, seafood, or nuts), in some cases any food can cause the reaction when consumed in close temporal relation to exercise [44].

Alpha-Gal

Another syndrome of anaphylaxis is delayed anaphylaxis occurring several hours after ingestion of mammalian meat or "red meat" including pork, beef, and lamb. This is attributed to an IgE response against a carbohydrate moiety, galactose-α-1,3-galactose (α-gal). Unlike other food allergies, which typically occur within minutes of ingestion,

Table 26.5 The CoFAR grading system for allergic reactions

Grade 1 – Mild	Grade 2 – Moderate	Grade 3 – Severe	Grade 4 - Life Threatening	Grade 5 – Death
Transient or mild discomforts (<48 hrs), no or minimal medical intervention/therapy required. These symptoms may include pruritus, swelling or rash, abdominal discomfort or other transient symptoms.	Symptoms that produce mild to moderate limitation in activity some assistance may be needed; no or minimal intervention/therapy is required. Hospitalization is possible. These symptoms may include persistent hives, wheezing without dyspnea, abdominal discomfort/ increased vomiting or other symptoms	Marked limitation in activity, some assistance usually required; medical intervention/therapy required, hospitalization is possible Symptoms may include Bronchospasm with dyspnea, severe abdominal pain, throat tightness with hoarseness, transient hypotension among others. Parenteral medication(s) are usually indicated.	Extreme limitation in activity, significant assistance required; significant medical/ therapy. Intervention is required; hospitalization is probable. Symptoms may include persistent hypotension and/or hypoxia with resultant decreased level of consciousness associated with collapse and/or incontinence or other life threatening symptoms.	Death

Reproduced from Burks et al. [43]

symptoms from eating red meat may be delayed, occurring 3–8 hours after eating [45]. Most food allergies are directed against a protein molecule, but alpha-gal is unusual because it is a carbohydrate, and a delay in its absorption may explain the delay in symptoms. The etiology is presumed to be related to exposure to this allergen via tick bites [46–49]. Alpha-gal is a molecule carried in the saliva of the Lone Star tick and other potential arthropods typically after feeding on mammalian blood. People that are bitten by the tick, especially those that are bitten repeatedly, are at risk of becoming sensitized and producing the IgE necessary to then cause allergic reactions. As might be expected, the incidence of tick bites is much higher in the southern and eastern United States, the traditional habitat for the tick. However, cases are now increasingly reported in the northern and western states. This phenomenon has also been observed worldwide, with different ticks responsible for similar cases of red meat allergy in many other countries including Sweden, South Africa, and Australia [50]. Immediate symptoms such as hives or shortness of breath are treated with antihistamines and epinephrine depending on the severity of the reaction. Prevention long-term involves avoidance of all red meat in sensitized individuals. Of note, poultry and fish can still be consumed without reaction.

Pollen Food Allergy Syndrome (Oral Allergy Syndrome)

Pollen food allergy syndrome is a relatively common form of food allergy that occurs in people who have pollen allergy, although not all patients have obvious seasonal allergy symptoms. Sensitization initially occurs from inhalation of pollens, but results in symptoms when fresh fruits or vegetables with proteins that are homologous to the pollens are ingested. The symptoms are IgE-mediated and result from contact urticaria in the oropharynx caused by pollen-related proteins in these foods. For example, birch pollen contains proteins homologous with Rosaceae fruits (e.g., apple, peach, carrot). Pruritus and mild swelling of the lips, tongue, and throat occur when specific uncooked fruits and vegetables are ingested, but heated forms are tolerated [48]. Symptoms typically last several minutes before self-resolving. While anaphylaxis associated with oral allergy has been reported, it is relatively rare [49]. This type of allergy has also been called oral allergy syndrome (OAS); however, OAS has been imprecisely applied in the literature to describe oropharyngeal reactions due to a variety of non-plant foods as well as both oropharyngeal and systemic symptoms due to plant foods in subjects with pollen allergy. Therefore, pollen food allergy syndrome (PFAS) is now increasingly used and the preferred term both to emphasize the pathogenesis of these reactions, and to describe the full range of oropharyngeal and systemic symptoms that can occur in response to pollen-related foods [1].

Management of Acute IgE-Mediated Reactions

Patients with food allergy should have an up-to-date food allergy action plan to guideline emergency treatment. Mild IgE-mediated reactions that only involve one organ system may subside with antihistamines. However, progressive, multisystem, or severe reactions should be treated promptly with intramuscular epinephrine. Given the inability to predict severe reactions and evidence that early epinephrine may help reduce risk, all anaphylactic reactions (irrespective of severity) demand appropriate treatment with intramuscular epinephrine [51]. Severe reactions may require multiple doses of epinephrine, intravenous fluids, oxygen, vasopressors, additional treatments, and monitoring in an acute care setting. Oral corticosteroids may prevent development of a biphasic reaction, although data is limited.

Cell-Mediated Food-Allergic Disorders

Cell-mediated food-allergic reactions include food-induced pulmonary hemosiderosis, food-protein-induced enterocolitis syndrome (FPIES), food-protein-induced enteropathy, food-protein-induced proctitis and proctocolitis, and celiac disease. Celiac disease is discussed in Chap. 40.

Pulmonary hemosiderosis is a rare condition characterized by pulmonary infiltrates, iron-deficiency anemia, hemosiderosis, hemoptysis, cough, wheezing, nasal congestion, recurrent otitis media, dyspnea, colic, diarrhea, vomiting, hematochezia, and failure to thrive attributed to cow's milk. While the immunologic mechanisms underlying this illness are not understood, peripheral eosinophilia and IgG to cow's milk are generally present. Symptoms remit with elimination of the causative allergen [52, 53].

Non-IgE-mediated gastrointestinal disorders are highlighted as follows.

Food Protein Induced Enterocolitis Syndrome

Background

Food-protein-induced enterocolitis syndrome (FPIES) is a cell-mediated gastrointestinal food allergy that typically manifests in infancy and often resolves by 3 years of age, although current evidence indicates that only 20% of children with FPIES to cow's milk and soy resolved by 3 years of age. In the acute form, 1–3 h after ingestion of the caus-

Table 26.6 Food-protein-induced enterocolitis syndrome (FPIES)

Clinical findings	*Acute:*
	Profuse, repetitive vomiting occurring 1–3 h after food ingestion
	Diarrhea occurring 5–8 h after ingestion
	Dehydration
	Lethargy
	Pallor
	Abdominal distention
	Bloody diarrhea
	Hypotension
	Hypothermia
	Chronic:
	Weight loss
	Failure to thrive
	Diarrhea
	Lethargy
	Abdominal distention
	Bloody diarrhea
	Dehydration
Laboratory/ imaging findings	Anemia
	Thrombocytosis
	Hypoalbuminemia
	Elevated white blood cell count with a left shift
	Eosinophilia
	Transient methemoglobinemia
Triggers	Milk/soy (most common)
	Solid food: rice, oats, barley, chicken, turkey, egg white, green peas, peanuts, sweet potatoes, white potatoes, fruits, fish, mollusks
Management	Elimination of food trigger
	Oral food challenge to evaluate for resolution

Table 26.7 Diagnostic criteria for patients presenting with possible FPIES

Acute FPIES	
Major criterion: Vomiting in the 1- to 4-h period after ingestion of the suspect food and absence of classic IgE-mediated allergic skin or respiratory symptoms	Minor criteria: 1. A second (or more) episode of repetitive vomiting after eating the same suspect food 2. Repetitive vomiting episode 1–4 h after eating a different food 3. Extreme lethargy with any suspected reaction 4. Marked pallor with any suspected reaction 5. Need for emergency department visit with any suspected reaction 6. Need for intravenous fluid support with any suspected reaction 7. Diarrhea in 24 h (usually 5–10 h) 8. Hypotension 9. Hypothermia
The diagnosis of FPIES requires that a patient meets the major criterion and ≥3 minor criteria. If only a single episode has occurred, a diagnostic OFC should be strongly considered to confirm the diagnosis, especially because viral gastroenteritis is so common in this age group. Furthermore, although not a criteria for diagnosis, it is important to recognize that acute FPIES reactions will typically completely resolve over a matter of hours compared with the usual several-day time course of gastroenteritis. The patient should be asymptomatic and growing normally when the offending food is eliminated from the diet.	
Chronic FPIES	
Severe presentation: When the offending food is ingested on a regular basis (e.g., infant formula); intermittent but progressive vomiting and diarrhea (occasionally with blood) develop, sometimes with dehydration and metabolic acidosis. Milder presentation: Lower doses of the problem food (e.g., solid foods or food allergens in breast milk) lead to intermittent vomiting and/or diarrhea, usually with poor weight gain/FTT but without dehydration or metabolic acidosis.	The most important criterion for chronic FPIES diagnosis is resolution of the symptoms within days after elimination of the offending food(s) and acute recurrence of symptoms when the food is reintroduced, onset of vomiting in 1–4 h, diarrhea in 24 h (usually 5–10 h). Without confirmatory challenge, the diagnosis of chronic FPIES remains presumptive.

Reproduced from Nowak-Węgrzyn et al. [54]

ative food, infants present with profuse, repetitive vomiting and may experience dehydration and lethargy. Diarrhea may occur several hours following the vomiting. In the chronic form, with continued ingestion of the allergen, infants develop weight loss and failure to thrive. Cow's milk and soy are the most common triggers in formula-fed infants. Symptoms begin 1–4 weeks after introduction of cow's milk or soy. Solid food FPIES is less common than milk/soy FPIES, and presents later, usually at 4–7 months of age, most often when weaning a breast-fed infant. Solid food FPIES triggers include most often rice and oat, but many foods have been implicated including barley, chicken, turkey, egg white, green peas, peanuts, sweet potatoes, white potatoes, fruits, fish, and mollusks. Of those infants diagnosed with solid food FPIES, 65% carried a prior diagnosis of milk/soy FPIES and 80% reacted to more than one food. Overall, 75% of infants presenting with FPIES appear acutely ill, and 15% become hypotensive, requiring hospitalization. Laboratory findings may include anemia, thrombocytosis, hypoalbuminemia, and an elevated white blood cell count with a left shift and eosinophilia. Transient methemoglobinemia and intramural gas have also been reported [54]. Table 26.6 shows key features of FPIES and Table 26.7 describes diagnostic criteria for acute and chronic FPIES. While the exact pathophysiologic mechanism for FPIES has yet to be elucidated, it is thought to be a cell-mediated disorder. Studies have shown increased levels of tumor necrosis factor-α, increased numbers of circulating blood mononuclear cells, and decreased intestinal mucosal expression of transforming growth factor-β receptors in association with FPIES [54].

Natural Course

Resolution of FPIES appears to be population dependent, particularly for cow's milk and soy. A study by Caubet et al. conducted in the United States found that 20% of patients with cow's milk FPIES resolved by 3 years of age [55]. Interestingly, a Korean cohort showed more than 60% resolution by 10 months of age and an Israeli birth cohort showed 90% resolution by 30 months [56–58]. Caubet et al. also found that 20% of cases of soy FPIES resolved by 3 years of age, whereas in the Korean cohort more than 90% of children showed resolution of soy FPIES by 10 months of age [55, 57]. These differences are likely explained by the higher proportion of subjects with detectable food-specific IgE levels and atopic dermatitis among the subjects who were referred to a major allergy center and the differences in methodology compared with the Israeli and Korean studies. Caubet et al. found that 65.5% of children with FPIES to grains resolved by 5 years of age, whereas resolution of FPIES to meat and fish/shellfish took more time (50% and 0% at 5 years of age, respectively) [55].

Diagnosis

History, clinical presentation, and at times oral food challenges are useful in the diagnosis of FPIES. A positive oral food challenge is considered the gold standard of diagnosis. However, if infants demonstrate a fitting history and presentation, an oral food challenge can be avoided if the symptoms resolve after removal of the suspected causative food. While >90% of patients do not have detectable serum-specific IgE to foods at the time of diagnosis, those that do have such antibodies are more likely to experience a protracted course of FPIES or develop acute allergic reactions [56, 59, 60].

Differential Diagnosis

In its acute form, FPIES is frequently mistaken for viral gastroenteritis, sepsis, or food poisoning. The intramural gas sometimes seen on abdominal radiographs mimics that seen in necrotizing enterocolitis. Methemoglobinemia often raises concern for a metabolic disorder.

Management

In acute cases, aggressive intravenous fluid administration is the mainstay of management. Other therapies for acute symptoms may include steroids and ondansetron [56, 61]. Methemoglobinemia may be treated with methylene blue. Chronic symptoms usually improve within 3–10 days after eliminating cow's milk from the diet and beginning a casein hydrolysate-based formula [59]. See Table 26.8 for further management recommendations for mild, moderate, and severe cases of FPIES.

Food Protein Induced Enteropathy

Food-protein-induced enteropathy is a disorder described decades ago and was characterized by vomiting, diarrhea, malabsorption, failure to thrive, and anemia in an infant [52]. Cow's milk protein was the most likely causative agent, particularly in infants fed intact cow's milk prior to 9 months of age. This syndrome has also been described in infants following an episode of gastroenteritis and in response to other foods, including eggs, rice, fish, shellfish, and poultry [53, 62]. Endoscopy with biopsy was required for diagnosis. Small bowel biopsies reveal patchy villous atrophy with a cellular infiltrate [63]. Affected infants would abstain from the causative food to bring about symptom resolution. Spontaneous resolution occurs typically by 2 years of age. This presentation has not been noted in the literature for decades. The diagnosis may have been subsumed by newer categorization of chronic FPIES or eosinophilic gastrointestinal disease.

Food Protein Induced Allergic Proctocolitis

Food-protein-induced allergic proctocolitis is characterized by blood and mucus in the stool of an otherwise healthy infant. Infants may be fussy or have increased frequency of bowel movements. The causative agent is usually milk in the maternal diet of a breast-fed infant, although egg, soy, and corn have been implicated as well [64]. The diagnosis is clinical, but rectal biopsy can be performed to confirm eosinophilic inflammation. The bleeding does not typically result in anemia. Maternal dietary elimination of the causal agent leads to resolution of symptoms within 72 h. The problem generally resolves by 1 year of age. The benign nature of the symptoms can allow re-trial of the potential trigger food protein weeks or a few months after resolution. The primary alternative explanation for these symptoms is infection. This diagnosis may be quite commonly made by primary care physicians and overdiagnosis is a concern because of benign causes of mild rectal bleeding in infants [65]. Inappropriate prolonged dietary elimination might be associated with onset of typical IgE-mediated food allergy [66].

Table 26.8 Management of acute FPIES episode at the medical facility

Presenting Symptoms		
Mild	Moderate	Severe
Symptoms		
1–2 Episodes of emesis No lethargy	>3 Episodes of emesis and mild lethargy	>3 Episodes of emesis, with severe lethargy, hypotonia, ashen or cyanotic appearance
Management		
1. Attempt oral rehydration (e.g., breastfeeding or clear fluids) 2. If age 6 mo and older: consider ondansetron intramuscular, 0.15 mg/kg/dose; maximum, 16 mg/dose 3. Monitor for resolution about 4–6 h from the onset of a reaction	1. If age greater than 6 mo: administer ondansetron intramuscular 0.15 mg/kg/dose; maximum, 16 mg/dose 2. Consider placing a peripheral intravenous line for normal saline bolus 20 mL/kg, repeat as needed 3. Transfer the patient to the emergency department or intensive care unit in case of persistent or severe hypotension, shock, extreme lethargy, or respiratory distress 4. Monitor vital signs 5. Monitor for resolution at least 4–6 h from the onset of a reaction 6. Discharge home if patient is able to tolerate clear liquids	1. Place a peripheral intravenous line and administer normal saline bolus, 20 mL/kg rapidly; repeat as needed to correct hypotension 2. If age 6 mo and older: administer intravenous ondansetron, 0.15 mg/kg/dose; maximum, 16 mg/dose 3. If placement of intravenous line is delayed because of difficult access and age is 6 mo or older, administer ondansetron intramuscular, 0.15 mg/kg/dose; maximum, 16 mg/dose 4. Consider administering intravenous methylprednisolone, 1 mg/kg; maximum, 60–80 mg/dose 5. Monitor and correct acid base and electrolyte abnormalities 6. Correct methemoglobinemia, if present 7. Monitor vital signs 8. Discharge after 4–6 h from the onset of a reaction when the patient is back to baseline and is tolerating oral fluids 9. Transfer the patient to the emergency department or intensive care unit for further management in case of persistent or severe hypotension, shock, extreme lethargy, respiratory distress
Strong consideration should be lent to performing food challenges in children with a history of severe FPIES in the hospital or other monitored setting with immediate availability of intravenous resuscitation. Oral challenges in the physician's office can be considered in patients with no history of a severe FPIES reaction, although caution should be urged because there are no data that can predict the future severity of FPIES reactions.		

Reproduced from Nowak-Węgrzyn et al. [54]

Mixed IgE- and Cell-Mediated Disorders

Atopic dermatitis (also referred to as eczema), eosinophilic esophagitis, and eosinophilic gastroenteritis are disorders that have both IgE- and cell-mediated components. In up to 40% of patients with atopic dermatitis, food allergy may lead to increased erythema and pruritus of eczematous lesions [23, 25, 26]. IgE-mediated flares occur within minutes to a few hours, while cell-mediated reactions may take up to several days to manifest themselves [67, 68]. Elimination of the suspected food allergen leads to improvement.

Eosinophilic gastrointestinal disorders are described in detail in other chapters. Briefly, eosinophilic infiltration of the gastrointestinal tract may result in dysphagia, vomiting, abdominal pain, poor growth, and food impaction and are the hallmarks of the eosinophilic gastrointestinal disorders (eosinophilic esophagitis and eosinophilic gastroenteropathy). A significant portion of patients with these disorders have other allergic diseases, and food is a primary trigger. In the case of eosinophilic esophagitis, elimination of foods to which the child has demonstrated sensitivity can result in both clinical and histological improvement. Similarly, elimination diets may show benefit in eosinophilic gastroenteropathy. The role of allergy testing remains controversial, but skin tests (including atopy patch tests) and serum tests may be helpful in guiding elimination diets and the means to reintroduce foods that were excluded from the diet [69, 70].

Diagnostic Evaluation of Food Allergy

Diagnostic evaluation of food allergy includes the history and physical examination, skin prick testing, serum-specific IgE testing, food elimination diets, and oral food challenges. The clinical history is paramount in diagnosing food allergy, as the pretest probability of food allergy determines what further testing is necessary. The history also discloses whether the illness is likely IgE antibody-mediated or not.

History and Physical Examination

The medical history plays a central role in determining which further steps in evaluation need to be performed. The symptoms and their temporal relation to the ingestion of food are particularly important. Acute IgE-mediated food-allergic reactions generally occur within seconds to minutes of ingestion of the food allergen. It is quite uncommon for these reactions to begin more than 2 h after the ingestion of the food. Chronic or delayed reactions may be cell-mediated and simple tests may not help to identify triggers—elimination diets and oral food challenges may be required.

With regard to IgE-mediated reactions, the time to resolution of symptoms should be noted. Particularly in the case of new-onset urticaria, in which 80% of cases are due to causes other than food allergy, [71] hives lingering longer than 24–48 h are unlikely to result from food allergy, unless the suspected allergen has been repeatedly ingested concurrent with the urticaria. Hives lasting more than a day or two should raise suspicion for a viral or other process rather than food allergy.

A food that has never been eaten before or is ingested rarely is much more likely to cause a reaction than foods that have been previously tolerated on a regular basis. Parents or other caregivers may have reached early closure regarding which substance was the causative food. The clinician must attempt to reconstruct an accurate history of all the food and drink ingested within 2 h prior to the reaction as best as possible. Dressings, beverages, side dishes, snacks, and sauces should be included in this evaluation. In addition, a careful review should take into consideration the possible cross-contact with a potential allergen. Cross-contact can be a cause of reactions at restaurants and buffet-style meals. A new allergy to a previously tolerated food is less likely than having a reaction to an ingredient that is not routinely ingested, or having had accidental exposure to a previously diagnosed allergen that was accidentally included in the meal that triggered a reaction.

If the patient has experienced allergic symptoms in the past, it is important to ask whether they had been consistently associated with the same food. Acute IgE-mediated allergic reactions generally occur every time the same quantity and preparation of an allergen is ingested. While trace amounts of protein can result in severe allergic reactions in particularly susceptible individuals, others have a threshold amount of protein that must be ingested before symptoms develop [72–75]. This threshold level can be as high as 10 g of the allergenic protein. In addition, cooking of foods induces conformational changes in certain proteins. For example, patients may react to less-heated forms of a food, such as the egg white in scrambled egg or French toast, but may not react to extensively heated forms of the same food (e.g., eggs baked in breads).

Depending on the patient's age, certain foods are more likely to be causative agents of an acute food-allergic reaction. In young children and infants, the following foods constitute 90% of IgE-mediated allergies: cow's milk, egg, soy, peanut, tree nuts, wheat, fish, shellfish, and sesame [1, 2]. In adolescents and adults, peanuts, tree nuts, fish, and shellfish are more common causes of serious acute reactions [15, 76, 77].

Besides the symptoms listed above that characterize acute reactions, the clinician should also note signs of chronic allergic processes, such as sinus venous congestion (and associated "allergic shiners"), horizontal nasal creases, boggy and pale nasal mucosa, or eczematous skin patches. While these signs of other allergic processes are not indicative of a food allergy in themselves, patients with other forms of atopy are more likely to experience food allergy, and therefore the presence of such signs increases the pretest probability of food allergy.

Tests for Food-Specific IgE

When the history and physical examination raise concern for possible IgE-mediated food allergy, skin prick testing and serum food-specific IgE testing can be helpful in investigating the potential allergens in question. Of paramount importance prior to selecting and interpreting these tests is the accurate medical history to determine pretest probability for IgE-mediated food allergy. A positive test (sensitization) to tolerated food(s) is common; therefore, a positive test cannot be solely used to diagnose food allergy. In addition, occasionally a test is negative despite true allergy. Therefore, negative tests with a compelling history should not be considered sufficient evidence of no allergy [1, 78, 79].

Skin Prick Testing

Skin prick testing is typically performed by allergist–immunologists. The allergen is introduced by scratching the surface of the skin and observing for a wheal and flare response, which is measured. Intradermal tests are not indicated as they are too sensitive and may induce systemic allergic reactions. Larger wheal size correlates with a greater concentration of food-specific IgE and greater likelihood of clinical allergy [80–82]. The size of the wheal does not correlate with severity of reaction. The sensitivity of skin prick testing is about 90%, the specificity is approximately 50% [83]. The skin of infants tends to be less sensitive than that of older children [84]. Given the high sensitivity of skin prick testing, it is a useful test for ruling out individual allergens in patients with a low pretest probability for food allergy to those specific allergens. However, performing skin prick testing to broad arrays of foods without attention to the medical history is not recommended, as the false-positive rate is high.

In Vitro Testing

In vitro testing methods, in contrast to skin tests, are not affected by antihistamine use, are not limited by skin conditions (such as urticaria, dermatographism, or eczema), and do not pose a risk of anaphylaxis. The first in vitro assays, termed "radioallergosorbent tests" (RAST), used radioactive isotopes to characterize relative IgE levels in a patient's serum. These have been replaced by fluorescent enzyme immunoassay (FEIA) tests, which determine serum-specific IgE levels to a variety of foods. Multiple in vitro assays have been developed, but results are not comparable across the various assays [85]. Most studies establishing normative serum-specific IgE cutoff values in children have used the Phadia ImmunoCAP FEIA (CAP-FEIA) system. Using this system, a prospective trial determined 96–100% positive predictive values for reaction during a food challenge for egg (≥7 kU_A/L), milk (≥15 kU_A/L), peanut (≥14 kU_A/L), and fish (≥20 kU_A/L) among 5-year-olds, with reactive thresholds being lower for children less than 2 years of age [86]. A study by Sindher et al. further analyzed biomarker thresholds for other allergens including almond (≥12.2 kU_A/L), hazelnut (≥14.6 kU_A/L), sesame (≥7.5 kU_A/L), walnut (≥ 13.5 kU_A/L), and wheat (≥43.1 kU_A/L) [87]. It is important to note that while skin prick testing and in vitro testing can determine the *likelihood* of a systemic reaction to ingestion of a particular food; they are unable to accurately predict the *severity* of that reaction should it occur. Newer generation tests evaluate specific IgE to specific proteins within a food. Foods are comprised of multiple proteins, of which those that resist degradation from heat or digestion are more likely to cause significant allergic reactions. Taking peanuts as an example, the peanut protein Ara h 8 is a labile protein homologous to a protein in birch tree pollen. When compared with the stable peanut storage protein Ara h 2, Ara h 8 is less likely to cause a significant allergic reaction. Elevated serum IgE levels to whole peanut can represent an allergy to Ara h 8, Ara h 2, or other peanut proteins. In individuals with allergy to whole peanut, performing component testing to determine which specific peanut proteins play a role in their food allergy is important in determining which patients may be appropriate for food challenge testing [78, 88].

Diagnostic Food Elimination Diets

In the case of acute IgE-mediated food allergy, eliminating the causative allergens prevents further reactions—this type of elimination diet represents treatment of the underlying disorder. In the case of chronic food allergy in which no causative food is identified on testing, particularly in cell-mediated and mixed IgE- and cell-mediated food allergy, elimination diets are pursued for both diagnostic and treatment purposes. There are three basic types of diagnostic elimination diets: focused elimination diets, oligoantigenic diets, and elemental formula diets.

In a focused elimination diet, based on clinical history, one or several suspect foods are removed from the child's diet. The child is then monitored for the improvement of symptoms. If the symptoms fail to improve over 2 weeks (in the case of chronic IgE-mediated processes) or over several weeks (in the case of cell-mediated and mixed IgE- and cell-mediated food allergies), the food(s) removed from the diet are unlikely to be the underlying cause of the child's symptoms.

In the case of a child in whom no potential causative foods can be identified, an oligoantigenic diet may be pursued. In this diet, several of the most common causative foods are removed from the child's diet while maintaining a nutritionally complete diet with other foods. One example is a diet consisting of rice, lamb, asparagus, spinach, lettuce, sweet potato, cooked apple, olive oil, sugar, and salt [89].

In rare circumstances, children with multiple suspected food allergy triggers and continued significant disease burden are placed on an elemental diet. In this type of diet, the child's food intake is limited to an extensively hydrolyzed or amino-acid-based formula. Such diets can have significant adverse consequences and should only be pursued under the supervision of an allergist and nutritionist familiar with such diets.

If the child's symptoms abate following introduction of an oligoantigenic or elemental diet, other foods are added one by one into the diet with careful monitoring for the return of symptoms. In addition to the complexity of maintaining nutritional adequacy in a food elimination diet, reintroduction of foods after a long period of elimination poses a risk of increased severity of reaction to foods to which specific IgE is present or develops [90]. Consequently, care should be taken to avoid unnecessary elimination of foods.

Food Challenges

A controlled oral food challenge is the gold standard for the diagnosis of food allergy. A food challenge is a physician-supervised ingestion of a single serving of potential allergen performed to confirm or refute the diagnosis of food allergy to that food. This test is generally used when history and supporting tests fail to confirm or refute an allergy. The test may be used for diagnosis of food allergy from any pathophysiology, IgE mediated or not.

A food challenge is performed for diagnostic purposes in the following scenarios:

- When several foods are being avoided, a food challenge can help determine foods that may be added back into the diet, particularly in the case of foods being avoided based on allergy testing alone (rather than a history of reaction).
- When IgE testing is negative, but a particular food is being avoided based on clinical history alone.
- When a cell-mediated or mixed IgE- and cell-mediated process is present (i.e., FPIES), a food challenge may be the only means of determining if an allergy is present.

- In addition, if serum IgE and skin prick test results appear to indicate that a particular allergy has resolved, a negative (or nonreactive) food challenge confirms allergy resolution [91].

Food Challenge Format

While a double-blind placebo-controlled food challenge is the gold standard for determining food allergy, in practice open food challenges and single-blind challenges tend to be more commonly pursued, as they reduce the amount of time required in clinic and overall cost of evaluation. A single-blind challenge, in which the observer, but not the child, is aware of which substance is placebo and which is the allergen, is useful in cases where a strong anxiety component is present. In an open food challenge, the child consumes the food in question in progressively increasing portion sizes every 10–15 min until the cumulative total of food given equals approximately one standard serving of the food. The patient is then observed for a predetermined period of time for delayed reactions prior to discharge home. If a reaction occurs, the challenge is halted, and the child treated for symptoms [91]. The physician performing the test, typically an allergist–immunologist, must be prepared to treat anaphylaxis.

Unproven Tests That Are Not Recommended

Food-specific IgG/IgG4, lymphocyte activation tests, kinesiology, sublingual or intradermal provocation tests, cytotoxic tests, or vega testing are not supported by scientific validation and should not be performed as part of food allergy evaluation [1].

Prevention of Food Allergy

A small body of evidence gathered at the beginning of the food allergy epidemic led to the recommendation to delay introduction of highly allergenic foods in order to try to prevent the development of food allergy. In 2008, due to lack of evidence and a continued increase in prevalence of food allergy, these recommendations were modified to acknowledge that data was insufficient to determine how timing of introduction of food allergens influenced the development of food allergy [92]. Finally, the LEAP (Learning Early About Peanut Allergy) study published in 2015 found that the early introduction of peanuts significantly decreased the frequency of the development of peanut allergy among children at high risk [93]. High-risk children were defined as those with severe eczema, egg allergy, or both. In this study, introduction of peanut was between 4 months and 11 months. Following this landmark trial, a consensus group recommended introducing peanut-containing products into the diets of "high-risk" infants early on in life (between 4 and 11 months of age) in countries where peanut allergy is prevalent because delaying the introduction of peanut can be associated with an increased risk of peanut allergy [94]. More recent guidelines for prevention encourage early incorporation of allergens in the infant diet [92, 95].

Dietary Treatment of Food Allergies

Avoidance

Food avoidance education is the cornerstone of food allergy management. Once it has been determined that a particular food must be eliminated from the diet, the child's family and all caregivers must undertake what amounts to a complete readjustment of one of the most basic daily habits—that of partaking in meals and snacks. Food elimination entails a careful evaluation of food packaging labels, safety in food preparation both in the restaurant and at home, and working with everyone from restaurant chefs, other children's parents, bakers, camp counselors, school cafeteria workers, and anyone else involved in the preparation of food to ensure that the allergen is not incorporated into any food consumed by the food-allergic child. Medications, vaccines, and cosmetics can also include food allergens. In highly sensitive individuals, less than a milligram of peanut, milk, or egg can cause a reaction [72–75].

Maternal Diet and Allergies in Breastfeeding

Food proteins can be detected in breast milk, and several cases have been reported of children experiencing reactions ranging from chronic atopic dermatitis to anaphylaxis due to maternal transfer of allergens through breast milk [96–99]. However, a tolerizing effect has been hypothesized in at least one study [100]. For infants with a history of reacting to a protein in the breast milk, strict maternal avoidance of the allergen is recommended. Many children with food allergy will be able to continue consumption of breast milk without removal of the allergen from the maternal diet.

Nutritional Issues in Food Allergy

When foods are being avoided due to allergy or potential allergy, care should be taken to assure that the nutritional needs of the affected child are addressed initially and revisited on a regular basis, as lower caloric intake and increased macro/micronutrient deficiency are more common in children with food allergy when compared with their age-matched peers without food allergy [101, 102]. The greater the number of allergens being avoided, the

greater the chance of a nutritional deficiency developing: Thus, greater diligence must be exercised to tailor food choices to ensure a well-balanced diet. In certain circumstances, this cannot be attained by incorporation of regularly available foods alone, and commercially prepared formulas may be necessary beyond the first year of life, particularly in children with cow's milk and/or soy allergies. As children with food allergies are more likely to suffer from inadequate growth and poor nutrition than their peers, a consult with a dietitian well versed in food allergy elimination diets is necessary in most children with food allergies that significantly affect protein, fat, or carbohydrate intake [1, 101–104].

Recent Advances in Food Allergy Management

Immunotherapy is an emerging management approach to patients with IgE-mediated food allergy. An allergic individual is administered very small amounts of allergen (e.g., peanuts) below the threshold of reaction and the dose is incrementally increased over months. The goal of therapy is to raise the reaction threshold to protect the individual from accidental ingestion or make an individual "bite-safe." These approaches have not been shown to be curative.

Different routes of administration are being studied and developed, including oral (OIT), sublingual (SLIT), subcutaneous (SCIT), and epicutaneous (EPIT, or a skin patch) immunotherapy. Although most studies have focused on single antigen desensitization, multi-food oral immunotherapy, where multiple food items are combined into a single oral immunotherapy course, is also being investigated for its safety and efficacy [105]. Most of these approaches are still in their investigational stages [106–108]. Other approaches under investigation also include vaccines, microbiome modulating agents, and biologics, each used either in conjunction with immunotherapy or as a single treatment. Currently the only FDA-approved treatment for food allergy is a standardized OIT product for peanut allergy.

Summary

- A food allergy is "an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food" [1].
- The nine major food allergens (milk, egg, peanut, tree nuts, soy, wheat, sesame, fish, and crustacean shellfish) account for 90% of allergic reactions.
- Food allergies may be IgE-mediated, cell-mediated, or "mixed" adverse immune responses.
- IgE-mediated reactions are typically sudden in onset following exposure to a food allergen, whereas cell-mediated responses may result in chronic inflammation or delayed symptoms.
- Acute IgE-mediated reactions can have cutaneous, ocular, gastrointestinal, respiratory, and/or cardiovascular symptoms.
- Anaphylaxis is defined as a serious allergic reaction that is rapid in onset and may cause death.
- Cell-mediated food-allergic reactions include FPIES, food-protein-induced enteropathy, food protein-induced proctitis and proctocolitis, and food-induced pulmonary hemosiderosis.
- FPIES is a cell-mediated gastrointestinal food allergy that typically manifests in infancy and generally resolves by 3 years of age. In the acute form, 1–3 h after ingestion of the causative food, infants present with profuse, repetitive vomiting and may experience dehydration and lethargy. Aggressive intravenous fluid administration, steroids, and ondansetron may be used to treat acute cases. Elimination of the causative food leads to chronic symptom resolution within 3–10 days.
- Food-protein-induced enteropathy is characterized by vomiting, diarrhea, malabsorption, failure to thrive, and anemia in an infant. Cow's milk protein is the most likely causative agent, and symptoms usually spontaneously resolve by 2 years of age.
- Food-protein-induced allergic proctocolitis is characterized by blood and mucus in the stool of an otherwise healthy infant. Maternal dietary elimination of the causal agent (usually cow's milk) leads to resolution of symptoms within 72 h. The problem generally resolves by 1 year of age.
- Atopic dermatitis, eosinophilic esophagitis, and eosinophilic gastroenteritis are disorders that can have both IgE- and cell-mediated components. Elimination diets may be helpful in these disorders.
- Diagnostic evaluation of food allergy includes the history and physical examination, skin prick testing, serum-specific IgE testing, food elimination diets, and food challenges. The clinical history is paramount in diagnosing food allergy, as the pretest probability of food allergy determines what further testing is necessary. The history also discloses whether the illness is likely to be IgE antibody-mediated or not.
- Skin prick testing and in vitro testing can determine the likelihood of an IgE-mediated systemic reaction to ingestion of a particular food, but they are unable to accurately predict the severity of that reaction should it occur. Positive predictive values for reaction during a food challenge have been established for in vitro testing to certain foods within certain age groups using a particular testing system.
- Food elimination diets play a treatment role in acute IgE-mediated food allergy and fulfill both diagnostic and

treatment roles in cell-mediated and mixed IgE- and cell-mediated food allergy.

- A food challenge is a physician-supervised ingestion of a single serving of potential allergen performed to confirm or refute the diagnosis of food allergy to that food.
- Immunotherapy is an emerging management approach to patients with IgE-mediated food allergy.

Eosinophilic Gastrointestinal Disorders Beyond Eosinophilic Esophagitis

27

Eleni Koutri and Alexandra Papadopoulou

Introduction

Eosinophilic gastrointestinal disorders (EGIDs) are chronic inflammatory disorders of the gastrointestinal (GI) tract characterized clinically by symptoms related to the dysfunction of the affected segment(s) of the GI tract and histologically, by dense eosinophilic infiltration, in the absence of an identifiable secondary cause [1]. EGIDs are classified according to the affected segment(s) of the GI tract to eosinophilic esophagitis (EoE), eosinophilic gastritis (EG), eosinophilic gastroenteritis, and eosinophilic colitis (EC) [1, 2]. It should be noted, however, that it is not uncommon that multiple parts of the GI tract are involved in the inflammatory process, either simultaneously or sequentially [3, 4]. Furthermore, EGIDs beyond EoE are subclassified according to the depth of the eosinophilic inflammation through the wall of the GI tract to mucosal, muscular, or subserosal disease.

Due to the absence of biological markers, the diagnosis of EGIDs is based on clinical symptoms and on histological findings of eosinophilic inflammation, after the exclusion of a secondary cause of inflammation or a systemic disorder, which may be a challenging issue given the absence of strict histological criteria for EGIDs diagnosis (beyond EoE).

Currently, the European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN), and invited experts in the field have been working jointly on consensus guidelines on diagnostic criteria of EGIDs beyond the esophagus.

Epidemiology

EGIDs are rare diseases. An electronic survey conducted by Spergel et al. to 10,874 US pediatric and adult allergists, immunologists, and gastroenterologists including a total of 1836 responses (17%) revealed a prevalence of EGE or EC in 28/100,000 population based on patients assessed by gastroenterologists and 2/100,000 by allergists and immunologists [5]. Later, Jensen et al. [6] estimated that there are less than 50,000 total patients with EGIDs in the United States, with the prevalence of EG estimated about 6.3/100,000 population, of EGE 8.4/100,000 and of EC 3.3/100,000 persons, while in children, the prevalence was 4.4, 10.7, and 4.3/100,000, respectively. More recently, a population-based database, established by Mansoor et al. extracting information from electronic health records from 26 major healthcare systems in United States between 1999 and 2017, estimated a prevalence of EGE in 5.1 per 100,000 individuals and of EC in 2.1 per 100,000 individuals [7].

EGIDs are reported to be more prevalent in Caucasians compared to African-Americans and Asians [7]. With regard to sex, Mansoor et al. [7] reported an increased prevalence of all EGIDs in females, Jensen et al. [6] of only EG, but not of EGE or EC, while Mark et al., reported that EC had a higher incidence in males [8].

According to early reports, EGE can affect patients of any age, from infancy through the seventh decade, but typically presents with a peak age of onset in the third decade of life [9–11]. Newer studies [7] reported EGE be more prevalent in children and adolescents (under 18 years of age) than in adults, with the highest prevalence compared to the other EGIDs, among children below the age of 5 years [6]. With regard to EC, some studies report greater prevalence in adults (older than 18 years of age) [7] than in children and adolescents, while others showed no age or gender differences [6].

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_27

Esophageal involvement is not uncommon occurring in 10.6%, 12%, and 10.9% of patients with EG, EGE, and EC, respectively [6]. Furthermore, Jensen et al. [6] reported a high frequency of atopic comorbidities in patients (particularly in children), occurring in 38.5%, 45.6%, and 41.8% of patients with EG, EGE, and EC, respectively [6].

Pathophysiology

The eosinophils are present in all segments of the GI tract with the exception of esophagus [12], playing an important role in the immune homeostasis, while their absence is suggested to cause dysregulation of the mucosal barrier [13, 14]. The contribution of eosinophils to host defense is primarily based on the release of cationic proteins from cytoplasmic granules and various cytokines [12, 15]. However, the infiltration of the GI mucosa by an excessive amount of eosinophils, especially in association with changes in architecture and/or the presence of eosinophils in the deeper layers of the GI tract, is almost always pathologic.

The eosinophilic infiltration of the GI mucosa may be enhanced by the exposure to a food or other antigen [16], possibly through a Th_2 immune response [17]. Parasitic infections and other immune responses are also, likely to induce eosinophilic inflammation of the GI tract throughout important mediators like interleukin (IL)-5 [12]. In EGE, the recruitment and activation of eosinophils in the GI tract wall have been attributed to cytokine interleukins (IL)-3, IL-5 and granulocyte macrophage colony-stimulating factor [18], while the eotaxin family of chemokines has been reported to play a central role in regulating the accumulation of eosinophils in the lamina propria of the stomach and the small intestine, in response to antigen stimulation [19, 20].

The existing evidence suggests that a hypersensitivity reaction is involved in the pathogenesis of the disease [9, 21, 22], which is supported by the presence of peripheral eosinophilia, the elevated serum immunoglobulin E (IgE) levels [21, 23–25], and the prompt response to steroids [26, 27].

A study conducted at Mayo clinic revealed that 20 to 40% of patients with EGE had a history of an allergic diseases such as asthma, rhinitis, food allergy, drug allergy, and eczema [9]. Although the role of food allergy in the pathogenesis of EGE has not been well defined, the reports on improvement with an elemental or elimination diet [3, 28–30] support an atopic component in some patients.

Recently, Sato et al. [31] performed transcriptome analysis studies in children undergoing upper GI endoscopy for clinical symptoms suggestive of EGID between 2011 and 2016. The histological diagnosis of EG was based on finding of gastric mucosa eosinophilia ≥30 eosinophils per high power field (eos/hpf). The authors reported 1999 differentially expressed genes between patients with EG and the controls, including significant upregulation of eotaxin-3 (C-C *chemokine* ligand 26). More recently, Shoda et al. [32] showed in blood-based platforms from children with EG, increased eotaxin-3, thymus and activation-regulated chemokine, IL-5, and thymic stromal lymphopoietin levels. Upregulated gene cadherin 26 (CDH26), which is expressed by gastric epithelial cells, seems to play an important role in the pathogenesis of EG, as shown by other transcriptome analysis studies [33]. CDH26 binds to a4 and aE integrins regulating the adhesion and activation of the leukocytes, while, in vitro, it has been shown to inhibit CD4+ T cells, suggesting an important role as downregulating factor of inflammation [33]. Furthermore, other than eosinophils cells, such as mast cells and FOXP3-positive lymphocytes, seem to play also an important role in the disease's pathogenesis as their counts in the gastric mucosa of patients with EG have been increased to be excessive compared to the controls [4].

The pathogenesis of EC is even less clear. Several studies have shown similarly increased eosinophilic infiltration of the colonic mucosa of patients with IBD [34–37], that was much greater compared to patients with allergic conditions [38], while children with ulcerative colitis showed in their colonic biopsies from the recto sigmoid segment elevated levels of eotaxin-1 [37]. Torrente [39] et al. reported that patients with EC, but with IBD, had higher density of CD3+ T cells, eotaxin-2+ intraepithelial lymphocytes, and IgE+ cells in the lamina propria. The copresence in the colonic biopsies of inflammatory cell populations indicating chronic inflammation process in the absence of sheets of eosinophils is indicative of IBD, whereas the finding of degranulating eosinophils and mast cells in combination with IgE and tryptase deposits in perineural locations raise the suspicion for EC [39]. However, in some cases, the differential diagnosis of EC from IBD is challenging.

Clinical Manifestations (Table 27.1)

The clinical presentation of EGIDs varies depending on the location of the arising inflammation in the GI tract and the specific layer of the GI tract (mucosal, muscular, serosal) that is involved. Gastrointestinal mucosa is most commonly affected by the eosinophilic inflammation, but muscular and/or serosal layers can also be involved with different symptomatology and diagnostic approach [1, 17, 23, 40].

Table 27.1 Clinical manifestations of eosinophilic gastrointestinal disorders beyond eosinophilic esophagitis depending on the depth of inflammation through the GI tract wall

	Clinical symptoms and signs
Mucosal involvement	EG: Nausea, vomiting, retrosternal or epigastric pain, dyspepsia, gastrointestinal bleeding (hematemesis and/or melena) EGE: Nausea, vomiting, abdominal pain, diarrhea, failure to thrive/weight loss, protein loss, gastrointestinal bleeding (hematemesis and/or melena) EC: Abdominal pain, tenesmus, diarrhea with mucus, and/or blood
Muscular involvement	EG: Outlet obstruction mimicking pyloric stenosis EGE/EC: obstructive symptoms, intussusception, perforation
Subserosal involvement	EGE/EC: abdominal distention, ascites

EG Eosinophilic Gastritis, *EGE* Eosinophilic Gastroenteritis, *EC* Eosinophilic Colitis

Mucosal Disease (Figs. 27.1, 27.2, 27.3, 27.4, and 27.5) [2, 41, 42]

Mucosal EG presents with a variety of symptoms such as epigastric pain, nausea, vomiting, and early satiety [40], hematemesis and/or melena from gastric/duodenal erosions (Figs. 27.1 and 27.2) [2] or gastric/duodenal ulcers (Fig. 27.3) [2], while the laboratory findings include hypoalbuminemia, anemia, and peripheral blood eosinophilia [3, 4, 40, 43]. The presence of an isolated ulcer, not responding in proton pump inhibitor treatment, has also been described in adolescents [41, 44] (Fig. 27.4) [41] with possible perforation (Fig. 27.5) [42]. Jensen et al. reported as most common symptoms of EG in 774 patients, abdominal pain, chest pain/throat pain, and nausea/vomiting, while 10.2% of these patients had concomitant EoE, which possibly explained the presence of throat pain [6].

Mucosal EGE presents with nonspecific symptoms. In a retrospective study of 40 patients with mucosal subtype of EGE, the most common symptoms appeared to be abdominal pain, nausea, vomiting, early satiety, diarrhea, and occasionally bleeding and weight loss [9, 17, 26, 45, 46]. Patients with diffuse small intestine mucosal disease can develop malabsorption, malnutrition, anemia, protein-losing enteropathy, and failure to thrive [1, 23, 40, 47–49]. In a study of 44 patients with EGE, conducted by Reed et al., the most common symptoms were vomiting (71%) and abdominal

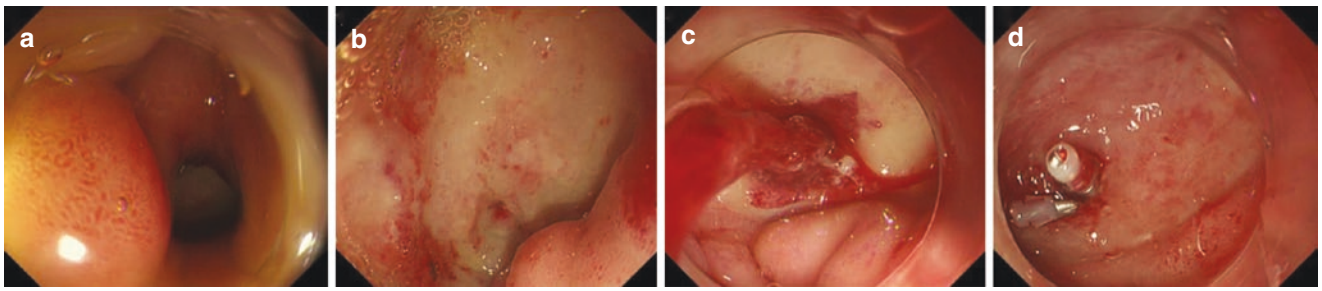

Fig. 27.4 (**a**–**d**) Hemorrhagic duodenal ulcer on an adolescent with eosinophilic gastroenteritis [41]. (**a**) Marked mucosal edema was observed in the duodenal bulb. An ulcer with a thickened, deep, white, moss-like appearance, and marked edema at its edge was present at the superior duodenal angulus. (**b**) Upper gastrointestinal endoscopic findings (approximately 1 week after the initial endoscopy). (**c**) Bleeding from an exposed vessel was noted. (**d**) Hemostasis was performed using a clip. (From Yamazaki et al. [41]. Reproduced with permission from Springer Nature)

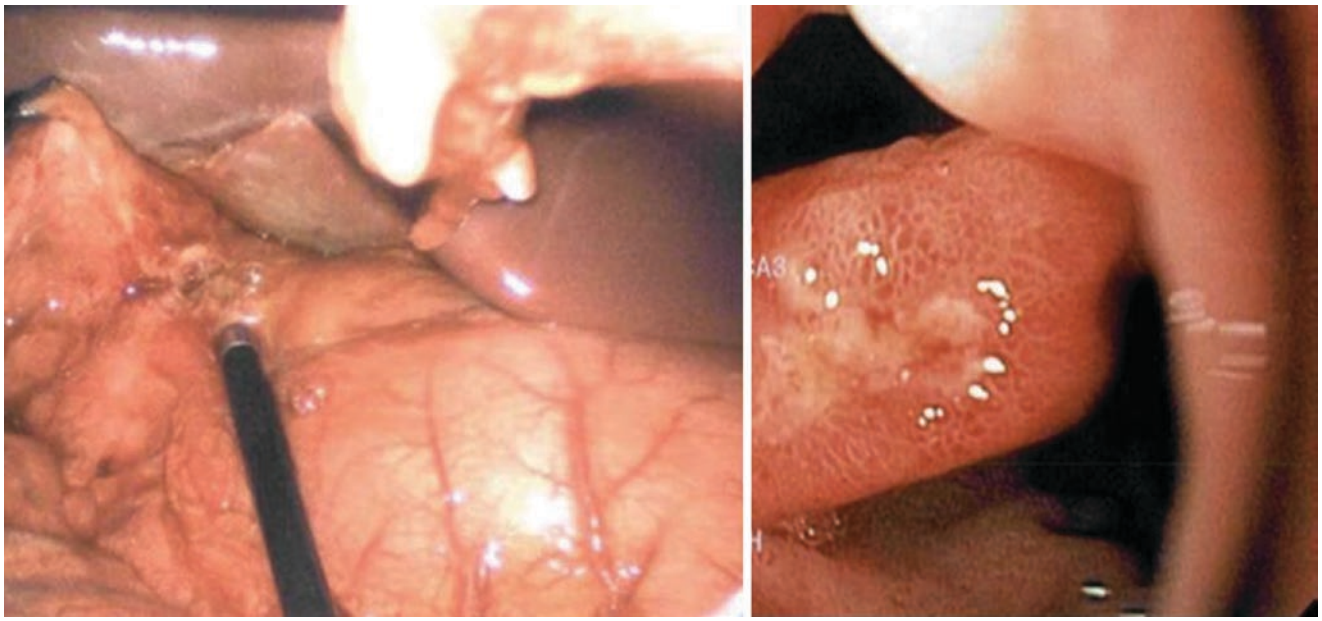

Fig. 27.5 (**a**–**b**) Perforated duodenal ulcer in a 16-year-old boy [42]. (**a**) Intraoperative photo depicting the perforated duodenal ulcer in the first portion of the duodenum. (**b**) Initial endoscopy showing residual duodenal ulceration after repair. (From Riggle et al. [42])

pain (62%) [48]. Jensen et al. reported abdominal pain, diarrhea, and nausea/vomiting as the most common symptoms among 954 patients with EGE [6]. Furthermore, it has been shown that approximately 80% of patients have symptoms for several years [50].

Mucosal EC manifests with abdominal pain, diarrhea, and even hematochezia although, in some circumstances, patients may be totally asymptomatic [6, 8, 34, 40].

Muscular Disease (Figs. 27.6, 27.7, 27.8, 27.9 and 27.10) [51–53]

The eosinophilic infiltration of the muscle layer of the GI tract may cause wall thickening and impaired motility with symptoms suggestive of obstruction such as nausea, vomiting, and abdominal distention [9, 23, 47, 52, 54, 55]. Eosinophilic infiltration of the muscular layer may cause

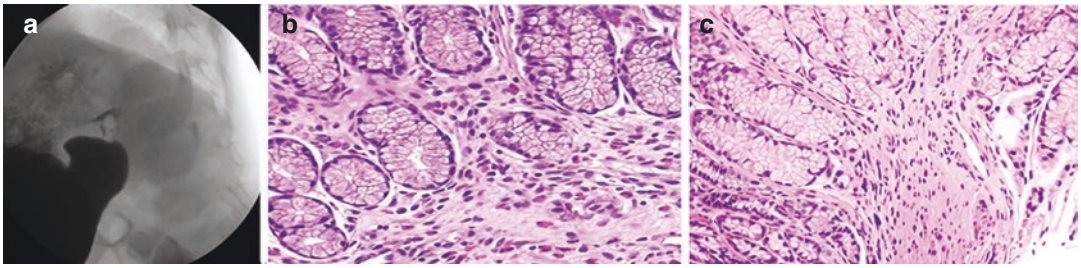

Fig. 27.6 Upper gastrointestinal follow through and gastric mucosal biopsy histology. (**a**) Minimal advancement of the contrast material through the pylorus (arrow). (**b–c**) Histologic images before and 5 d after steroid therapy. (**b**) Peripyloric antral sections showed prominent eosinophilic infiltration of the lamina propria (up to 30 eosinophils per single high-power field), with occasional degranulation (arrow) of eosinophilic content and infiltration of the muscularis mucosae. (**c**) Biopsies 5 d after intravenous steroid therapy demonstrated only a few eosinophils with a peak count of 2 eosinophils per high-power field (HE, ×40). (From Kellermayer et al. [52] Reproduced with permission by Baishideng Publishing Group Inc)

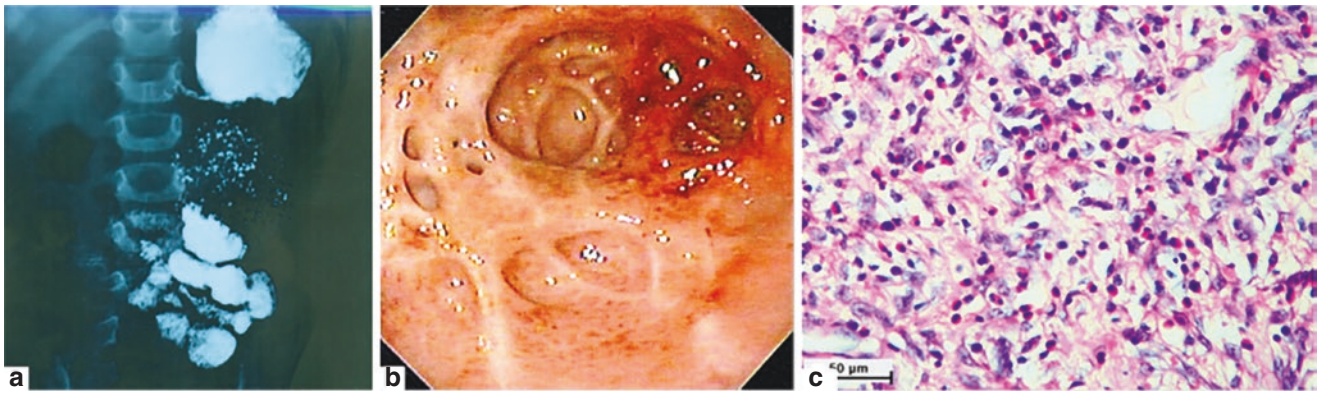

Fig. 27.7 (**a–c**) Gastric outlet obstruction on a 3-year-old girl with eosinophilic gastritis. (**a**) Barium meal X-ray showing absence of the duodenal bulb and the C-loop. Note that the distal stomach is also not visible. (**b**) Endoscopic visualization of the gastric mucosa showing formation of multiple diverticuli, erosion, and ulceration. dilatation of the bile ducts [51] or result in obstruction (and even perforation) of the gastric outlet, small bowel, and rarely the colon [9, 21–23, 25, 47, 56–58]. It should be noted, however, that in EGIDs beyond the esophagus, the presence of strictures is not that common as in EoE [44, 59].

Serosal/Subserosal Disease (Figs. 27.11 and 27.12) [60, 61]

In serosal/subserosal disease, patients may present with isolated ascites or ascites combined with symptoms of mucosal or muscular involvement [9, 60, 61]. An eosinophilic pleural effusion can also be present [47]. Features like cholangitis, pancreatitis [62], acute appendicitis, and eosinophilic splenitis have also been reported in literature.

Laboratory Findings

Peripheral blood eosinophilia occurs in 20–80% of patients [9] with eosinophil counts ranging from 5% to 35% with an average absolute eosinophil count of 1000 cells/μL [63]. Mucosal and serosal/subserosal EGE are usually associated with higher eosinophil counts compared to muscular EGE. EGE is often associated with iron deficiency anemia due to impaired iron absorption and/or occult gastrointestinal bleeding, especially in the mucosal subtype of the disease [23, 24, 47]. Hypoalbuminemia may occur due to the

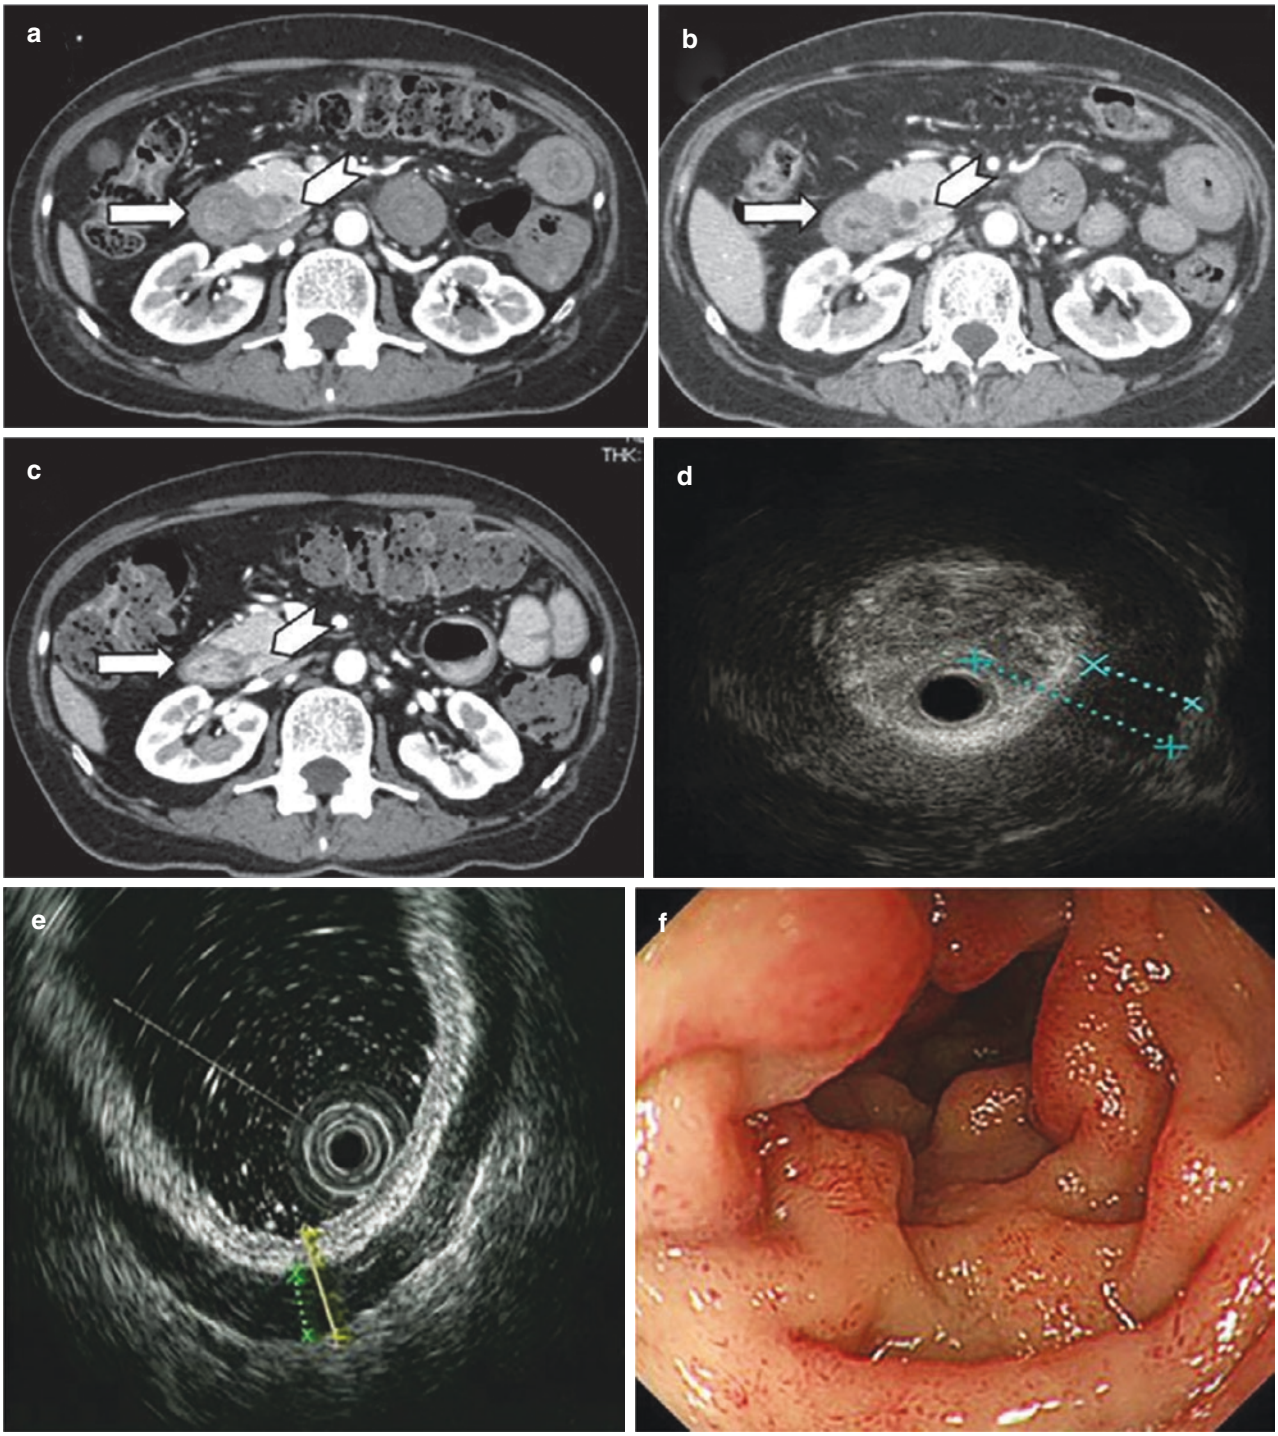

Fig. 27.8 (**a**–**h**) Contrast-enhanced computed tomography (CT) findings (**a**–**c**) and endoscopic ultrasound (EUS) findings of the duodenum (**d**–**e**). Upper gastrointestinal endoscopic examination findings (**f**–**h**). (**a**, **b**) CT revealed the thickening of the gastroduodenal mucosal wall (arrow). (**d**) EUS of the duodenum revealed extreme thickening of the mucosal and muscular walls. (**c**, **e**) Both findings were improved after steroid therapy. In contrast, (**b**) dilation of the bile duct (arrow head) and (**g**) narrowing of the lumen of the second part of duodenum diminished before steroid therapy. (**a**, **d**, **f**) On admission, (**b**, **g**) 5 days before steroid administration and (**c**, **e**, **h**) 2 weeks after steroid administration. (From Hamamoto et al. [51]. Fig. 27.10 Changes in the invagination of the duodenal wall during the clinical course. The changes were observed by magnetic resonance cholangiopancreatography. Before steroid therapy (**a**); after half a year of steroid therapy (**b**). (From Hamamoto et al. [51]. Reproduced with permission from The Japanese Society of Internal Medicine)

increased mucosal permeability and protein-losing enteropathy that can be assessed measuring fecal alpha 1-antitrypsin in a 24-h feces collection. Low levels of immunoglobulins can present consequently to the protein loss [9, 21, 23]. The erythrocyte sedimentation rate is usually normal or modesty elevated in approximately 25% of patients [9, 47].

Gastrointestinal Endoscopy (Figs. 27.1, 27.2, 27.3, 27.4, and 27.5) [2, 41, 42]

The endoscopy findings in EG or EGE may include nodular or polypoid appearance of the gastric mucosa, erythema, friability, and occasional ulcerative or erosive changes of either gastric (Fig. 27.1) [2] or duodenal mucosa (Fig. 27.2) [2], although not rare is the development of a giant ulcer that may cause severe abdominal bleeding and even perforation (Figs. 27.3, 27.4, and 27.5) [2, 41, 42], while in some circumstances, the mucosa may appear completely normal [2, 3, 4, 29, 43]. Newer reports in patients with EGE using wireless capsule endoscopy have shown salmon patch colored lesions with noticeable eosinophilic infiltration throughout their intestinal mucosa [65]. In patients with EC, the endoscopy findings include erythema, aphthous ulcers, erosions, whitish elevated lesions, or pale granular mucosa.

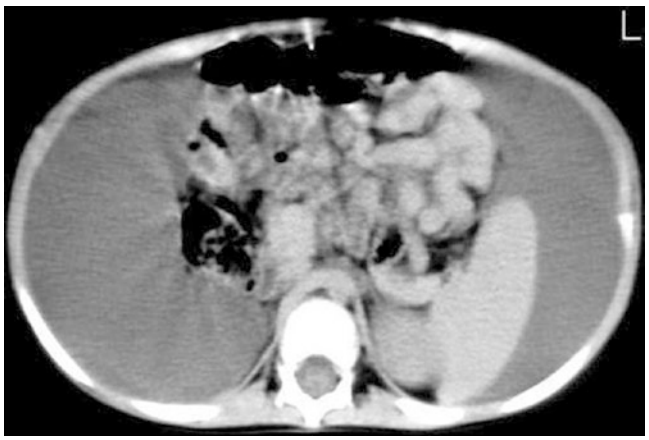

Fig. 27.11 CT scan findings on a 3-year-old boy with subserosal EGE [60]. CT scan shows a massive ascites displacing the intestine in the center of the abdomen in a 3-year-old patient with serosal subtype of EGE. (From Barabino et al. [60]. Reproduced with permission from Springer Nature)

It should be noted, however, that none of the above findings are specific for EGIDs.

In patients with subserosal involvement, abdominal ultrasound (US), abdominal computed axial tomography (CT), or magnetic resonance imaging (MRI) may reveal the presence of ascites (Figs. 27.11 and 27.12) [60, 61].

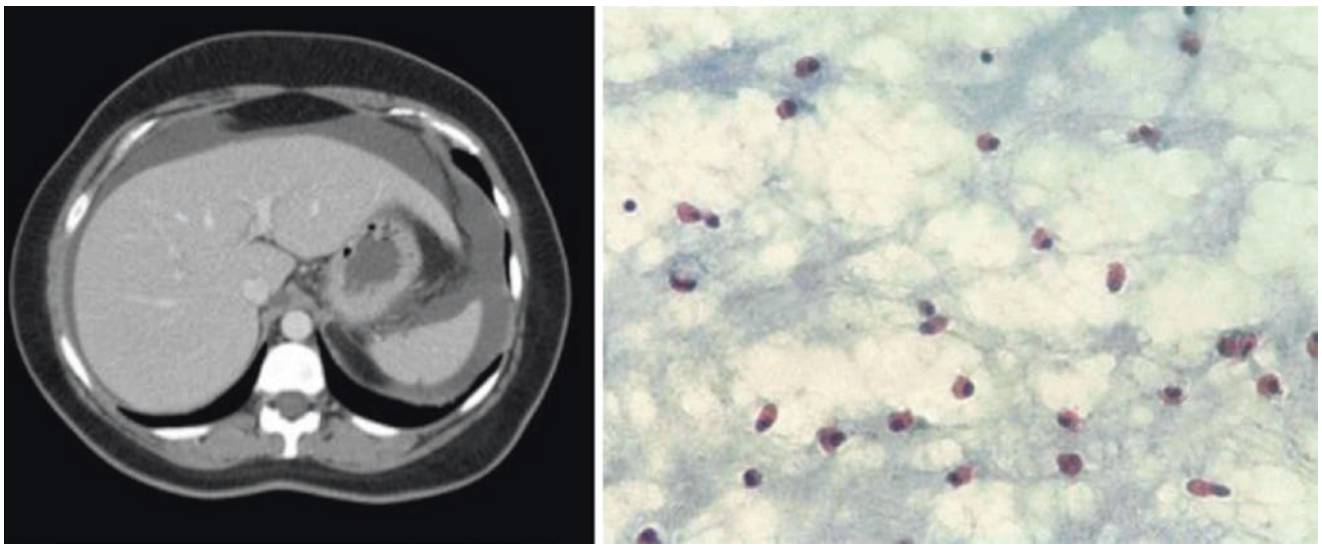

Fig. 27.12 (**a**–**b**) Abdominal computed axial tomography on an adult patient with subserosal EGE and histological examination of the ascitic fluid [61]. (**a**) Abdominal computed axial tomography showing ascites and gastric wall thickening. (**b**) Histological examination of ascitic fluid showing abundant cellularity with inflammatory characteristics with a predominance of eosinophils (40× magnification). (From Ferreira et al. [61]. Reproduced with permission from SMC media Srl)

Histology (Figs. 27.13, 27.14, 27.15, 27.16, 27.17, and 27.18) [2, 66]

In contrast to EoE, consensus diagnostic histological criteria for EGIDs beyond the esophagus are lacking [17, 40]. Various studies have defined differently pathological eosinophilic infiltration of different parts of the GI mucosa to justify the diagnosis of EGIDs in the clinical context [35, 43, 67, 68]. With regard to eosinophilic infiltration of the mucosa of different segments of the GI tract, the following counts were considered by several authors to justify the diagnosis of EGIDs in the clinical context: ≥30 eosinophils per high power field (eos/hpf) in ≥5 hpfs or ≥70eos/hpf in ≥3 hpfs in the gastric mucosa, for the diagnosis of EG [3, 43, 69, 70]; ≥52 eos/hpf in duodenal mucosa and ≥56 eos/hpf in ileum for the diagnosis of EGE [17, 59, 69, 70]; ≥100 eos/hpf in cecum and ascending colon, ≥84 eos/hpf in transverse and descending colon, and ≥64 eos/hpf in the mucosa of rectosigmoid area, for the diagnosis of EC [70]. Debrosse et al., however, assessed the amount and location of eosinophils in the GI tract of healthy children and reported much lower peak numbers of eosinophils in the "healthy" GI mucosa: ≤26 eos/hpf in the duodenum; ≤50 eos/hpf in the ascending colon; and ≤30 eos/hpf more distally [69].

It is not easy to explain the discrepancies in the eosinophilic counts in the GI mucosa reported by different authors. An important issue is the calculation of eosinophil counts per high power field the size of which depends on the technical parameters of the microscope such as the magnification of the objective lens and the diameter of the ocular. The diversity of the technical parameters of the commercially available microscopes may cause up to fivefold discrepancies in the eosinophil counts of the same biopsy sample. In our recent study [71] carried out in three major pediatric centers (Athens, Madrid, and Rome), histology slides (n = 1014) from GI biopsies taken from 155 children who had no organic disease (based on an extensive work up due to GI symptoms and the GI endoscopy) were reviewed and the eosinophilic counts were expressed per different sizes of hpfs (0.196 mm^2 and 0.306 mm^2) and as eos/mm^2 [71]. The study showed discrepancies in the peak counts of eosinophils in the same segments of the GI tract depending on the size of the hpf that was used for the calculation (Figs. 27.13 and 27.14) [71]. The above discrepancies highlight the importance of using eosinophil density (eos/m^2) instead of eos/hpf, that is a universally accepted tool, independent of the size of hpf [71]. Furthermore, in the above study, we found a significant geographical distribution in eosinophilic counts of the GI mucosa of children with no organic disease, but not differences among children with and those without the diagnosis of functional GI disorders based on Rome IV criteria [71].

Other histological abnormalities found in patients with EGIDs (Figs. 27.15 and 27.16) [2] may include the findings of eosinophilic sheets in expanded lamina propria, abundant intraepithelial eosinophils, eosinophil cryptitis/pititis or abscesses, or the presence of eosinophils in the muscularis mucosa and submucosa. In some circumstances, complete loss of intestinal villi (Fig. 27.17) [66], multiple layers involvement, submucosal edema, and fibrosis may develop consequently to diffuse intestinal inflammation [24, 66, 72].

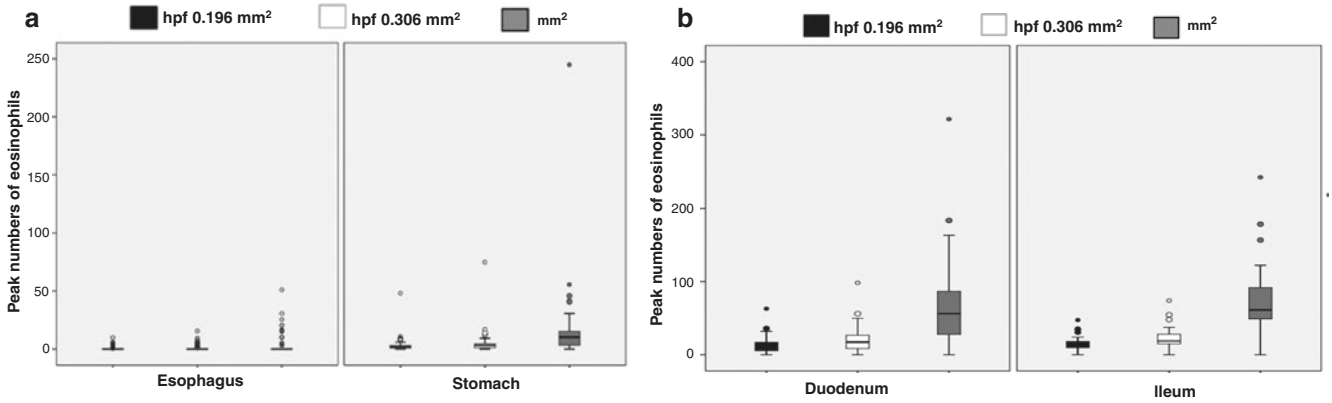

Fig. 27.13 (**a**, **b**) Peak numbers of eosinophils in the esophageal, gastric, duodenal, and ileal biopsies in children with no organic diseases [72]. (**a**) Median (IQR) of peak counts of eosinophils/high power field 0.196 mm^2 and 0.306 mm^2, and /mm^2 in the esophagus (111 biopsies) and the stomach (111 biopsies) was as follows: esophagus: 0 (0–0), 0 (0–0), and 0 (0–0), respectively; stomach: 2 (0.6–3.0), 3.1 (1.0–4.7), and 10.2 (3.3–15.3), respectively. (**b**) Median (IQR) of peak counts of eosinophils /high power field 0.196 mm^2 and 0.306 mm^2, and /mm^2 in the duodenum (111 biopsies) and ileum (44 biopsies) was as follows: duodenum: 11.0 (5.1–17.0), 17.2 (8.0–26.5), and 56.1 (26.1–86.7), respectively; ileum: 12.0 (9.6–18.0), 18.7 (15.0–28.1), and 61.2 (49.0–91.8), respectively (From Koutri et al. [71]. Reproduced with permission from Annals of Gastroenterology)

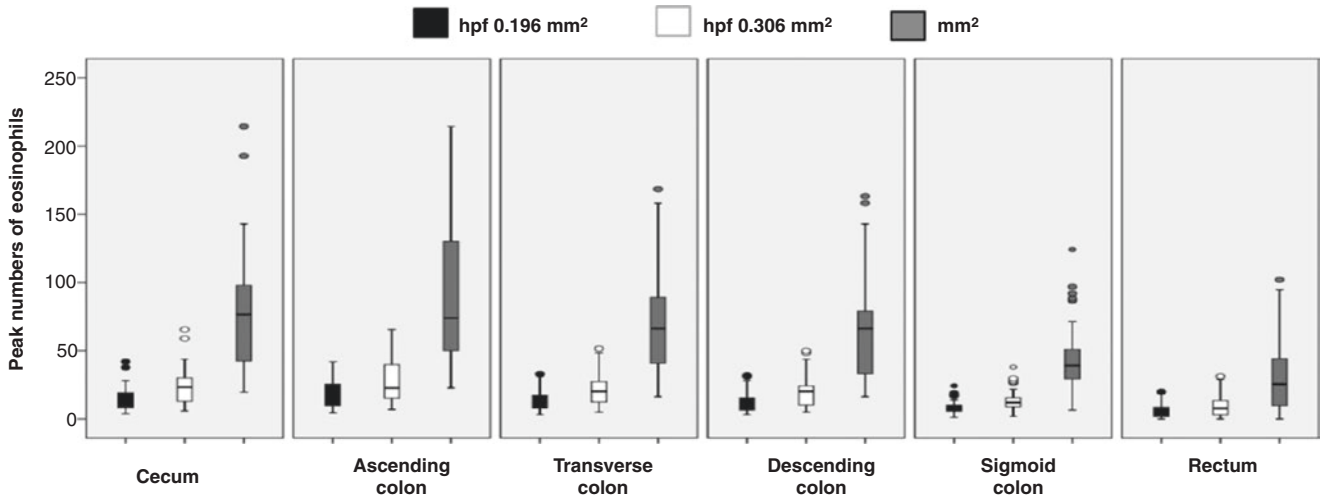

Fig. 27.14 Peak numbers of eosinophils in the colonic biopsies in the whole cohort of children. Median (IQR) of peak counts of eosinophils / high power field 0.196 mm^2 and 0.306 mm^2, and /mm^2 in the cecum (37 biopsies), ascending colon (28 biopsies), transverse colon (44 biopsies), descending colon (31 biopsies), sigmoid colon (37 biopsies), and rectum (41 biopsies) was as follows: cecum: 15.0 (8.0–19.5), 23.4 (12.5–30.5), and 76.5 (40.9–99.7), respectively; ascending colon: 14.5 (9.7–25.8), 22.8 (15.2–40.2), and 73.9 (49.5–131.4), respectively; transverse colon: 13.0 (8.0–17.9), 20.3 (12.5–28.0), and 66.3 (40.8–91.5), respectively; descending colon: 13.0 (6.0–16.0), 20.3 (9.4–24.9), and 66.3 (30.6–81.6), respectively; sigmoid colon: 7.6 (5.4–10.0), 12.0 (8.5–15.6), and 39.2 (27.8–51.0), respectively; rectum: 5.0 (1.9–8.9), 7.8 (3.0–14.0), and 25.5 (9.8–45.8), respectively (From Koutri et al. [71]. Reproduced with permission from Annals of Gastroenterology)

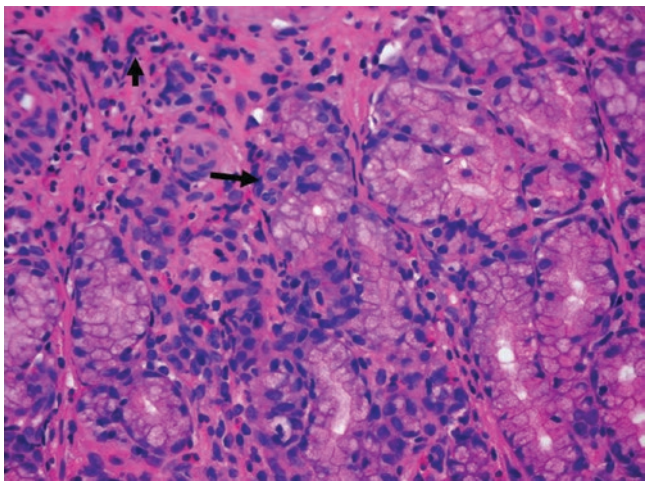

Fig. 27.15 Histological features of eosinophilic gastritis [2]. Aggregates of eosinophils near the muscularis mucosa [small arrow]. Eosinophilic infiltration of pyloric glands [long arrow]. (From Koutri and Papadopoulou [2]. Adapted with permission from Kurger AG Basel)

In patients with EC, the findings in colonic biopsies (Fig. 27.18) [2] may include apart from increased eosinophilic density, eosinophilic cryptitis/crypt abscesses, abnormalities in the architecture of the crypts, increased intraepithelial eosinophils, and the presence of eosinophils in the muscularis mucosa and submucosa [66].

In order not to miss the diagnosis, multiple biopsies should be taken from both normal- and abnormal-appearing mucosa since even a normal-appearing mucosa can be infiltrated by eosinophils and demonstrate inflammation [73].

In patients with muscular or subserosal type of EGE, mucosal biopsies can be normal [9, 73]. Thus, negative endoscopic mucosal biopsies do not definitively exclude muscular or subserosal disease. In that case, laparoscopic full-thickness biopsy should be performed to establish the diagnosis of EGID. In patients with intestinal wall thickening and/or obstruction, laparoscopic full-thickness biopsy is important to exclude a possible underlying malignancy.

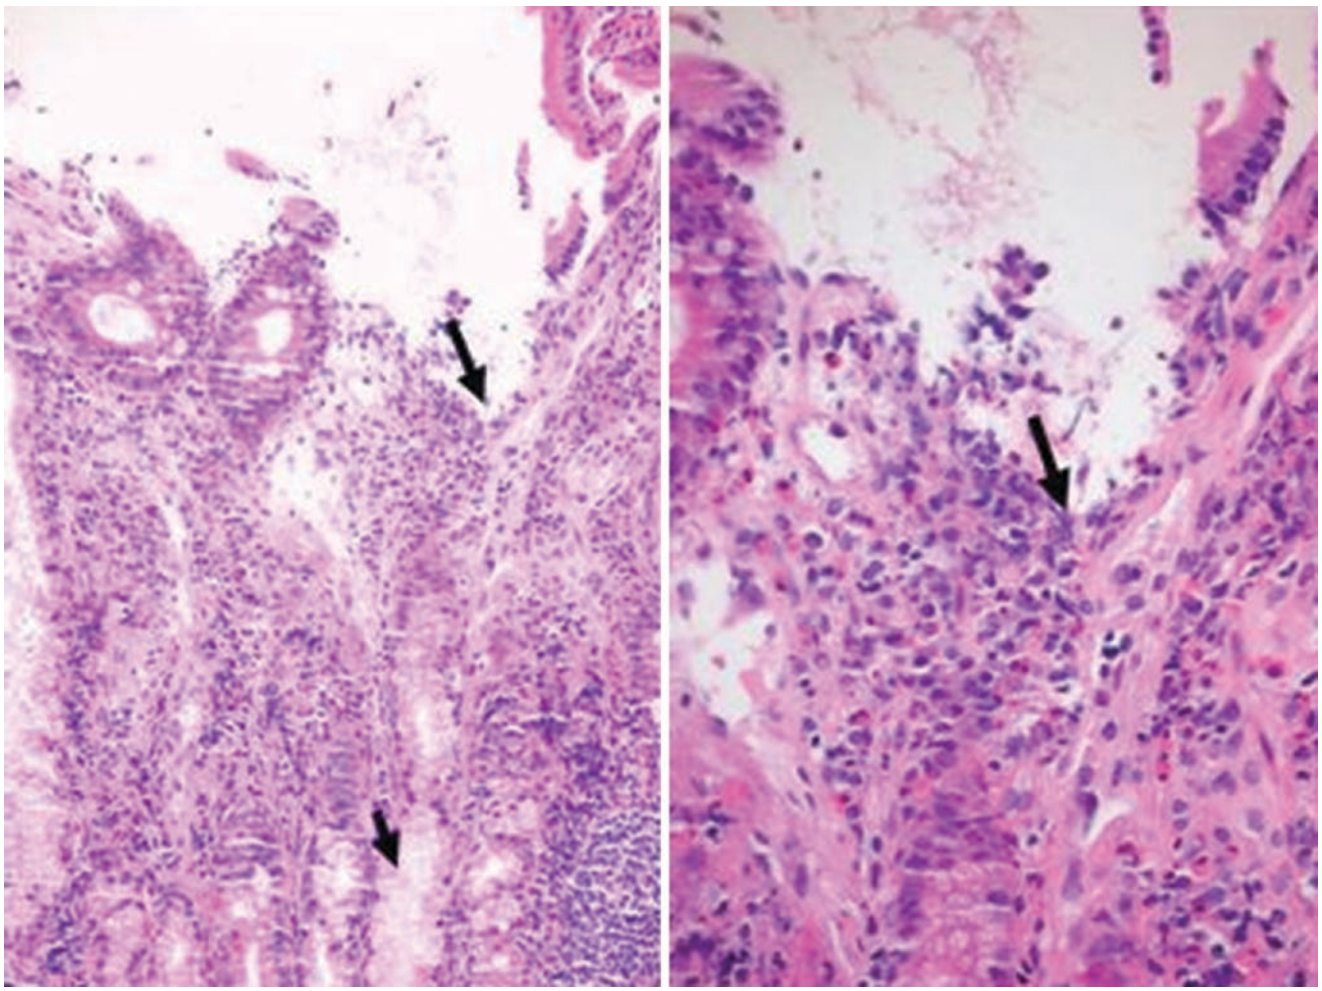

Fig. 27.16 (**a**, **b**) Histological features of eosinophilic gastroenteritis (duodenal biopsies) [2]. (**a**) Erosion and aggregates of eosinophils [long arrow]. Eosinophilic infiltration of colonic crypts [small arrow]. (From Koutri and Papadopoulou [2]. Adapted with permission from Kurger AG Basel)

In conclusion, the location and depth of the obtained GI biopsies, the technical parameters of the microscope, and the analyses used for the examination of the histological samples, as well as the knowledge of the geographic variation in the normal amount of eosinophils in healthy GI tract, are all important factors to consider when interpreting the histological findings [1, 71]. Taking into account that there are no well-determined histological criteria for the diagnosis of EGIDs beyond EoE and until the consensus recommendations on diagnostic criteria of EGIDs by the ESPGHAN and NASPGHAN become available, the contribution of an expert gastrointestinal pathologist is extremely important.

Imaging Studies (Figs. 27.6, 27.7, 27.8, 27.9, 27.10, 27.11, and 27.12) [52, 53]

In patients with mucosal disease, imaging studies of the GI tract may reveal thickening or nodularity in the antrum and thickening or "saw-tooth" appearance of the mucosa of the small bowel [56]. It should be noted, however, that the above findings lack of sensitivity and specificity regarding EGE.

Imaging studies are particularly important tools for the diagnostic approach of muscular and subserosal subtype of EGIDs. Barium follow through (Figs. 27.6 and 27.7) [52, 53], abdominal ultrasound, abdominal computed tomography scan (Figs. 27.8 and 27.9) [51], or magnetic resonance imaging (Figs. 27.9 and 27.10) [51] may reveal in patients with muscular involvement, irregular narrowing of the lumen, especially in the area of the distal antrum and proximal small bowel [52, 53, 74].

Other Tests

In patients with subserosal disease and ascites, increased eosinophil counts have been reported in the ascitic fluid analysis (Fig. 27.12) [61]. The analysis of the ascitic fluid apart from cytology, it should also include Gram stain, acid-fast bacillus stain, fungal cultures, and mycobacterial cultures. Studies have documented a marked elevation of the eosinophil counts up to 88% in patients with subserosal subtype of EGE [23]. It should be noted, however, that no strict criteria to evaluate the eosinophilia of the ascitic fluid are available.

Differential Diagnosis (Table 27.2)

The differential diagnosis of EGIDs includes infections, allergic conditions (such as drug allergy), hypereosinophilic syndrome, inflammatory bowel diseases, autoimmune diseases, connective tissue disorders, malignancy, chronic graft versus host disease, immunodysregulation, etc. [17, 35, 40, 59], while the differential diagnosis of EC should also include mastocytic enterocolitis [75, 76] or systemic mastocytosis [77, 78].

To exclude parasitic infections, it is necessary to check stool microscopy for ova and parasites and serology for *Strongyloides* and *Toxocara* species, while patients with a recent history of travel to (or residence in) endemic areas should be tested also, for antibodies to fungi and parasites such as *Coccidioides, Echinococcus, Schistosoma,* and *Trichinella spiralis.*

Allergic colitis of infancy may also be associated with >20 eos/hpf in rectal biopsies [79], with patchy distribution [80], but the disease resolves clinically and histologically following the removal of the offending antigens (typically

cow's milk) from the diet of the affecting infant. Tissue eosinophilia can also be found in colon biopsies of patients in immunosuppression following transplantation, especially in those receiving tacrolimus [81–83].

Shoda et al. [32] tried recently to uncover likely molecular pathogenesis that accounts for the distinct endoscopic and histologic features of EG and developed tissue- and blood-based platforms for its diagnosing and monitoring. They enrolled 185 patients (74 patients with EG and 111 without) across nine Consortium of Eosinophilic Gastrointestinal Disease Researchers–associated sites. The researchers analyzed an EG Diagnostic Panel (EGDP; gastric transcript subset) and an EG blood biomarker panel (protein multiplex array). EGDP scores were derived from the expression of 18 highly dysregulated genes, while blood EG scores were derived from dysregulated cytokine/chemokine levels. The authors reported that the EGDP18 scores were inversely correlated with gastric peak eosinophil counts, periglandular circumferential collars, and endoscopic nodularity. With regard to blood-based platforms, the authors [32] reported significant increases in eotaxin-3, thymus, and activation-regulated chemokine, IL-5 levels, as well as thymic stromal lymphopoietin levels. Blood EG scores were able to distinguish patients with EG from control subjects: They positively correlated with gastric eosinophil levels and inversely correlated with plasma and serum EGDP18 scores. The authors concluded that EGDP scoring based on tissue- and blood-based platforms is an important diagnostic tool for assessing EG. Further studies are required for the validation of the above platforms, assessment of their efficacy, and optimization for disease stratification.

Treatment

Due to the rarity of EGIDs beyond the esophagus, there are no randomized controlled studies regarding standardized treatment options in children [17, 40]. Most evidence is based on case reports and case series and few randomized trials in adults. Corticosteroids are a mainstay of treatment for inducing remission, but there may be a subset of patients in whom elimination diet can be effective. In some occasions, the disease is not easily controlled [40, 48], while maintenance therapy is often required [29, 48, 67]. Additional therapies have been reported in case reports or small series of patients [84] with conflicting results, while novel drugs [85, 86] for treating refractory disease are currently under investigation.

Table 27.2 Differential diagnosis of eosinophilic gastrointestinal disorders beyond eosinophilic esophagitis

(i) *Dietary Treatment*

In some pediatric patients with EGIDs beyond the esophagus, symptoms and tissue accumulation of eosinophils may be reduced by antigen restriction [3]. Ko et al. evaluated, retrospectively, the response to dietary treatment of 30 children with EG, 43% of whom had concomitant EoE and 21% EGE [3]. The dietary therapy included elemental diet, seven food elimination diet (milk, egg, wheat, soy, peanut/tree nuts, fish/shellfish, and red meet) or empiric avoidance of one to three foods. Overall, 82% of patients achieved clinical remission. However, histological assessment was available in only up to five children per each dietary treatment group, 78% of whom achieved histological remission, making difficult to draw conclusions on efficacy [3]. Patients with concomitant esophageal eosinophilia appeared to be more resistant to dietary therapy since 6 of 16 patients were noted to have persistent esophageal eosinophilia despite resolution of findings in gastric biopsies. The above study showed also no correlation between response to dietary therapy and food sensitization, despite the fact that 86% of patients were found to be sensitized to several foods using skin prick tests or serum analyses [3].

In patients with EGE and symptoms of malabsorption, an initial therapeutic approach could involve an empiric six-food elimination diet or an elemental diet. Elemental diet eliminates all potential food allergens and has been reported to be beneficial in selected patients [28, 87]. Six-food elimination diet, excluding soy, wheat, egg, milk, peanut/tree nuts, and fish/shellfish, foods that most commonly cause hypersensitivity reaction in the general population, is the most commonly used diet, empirically, in such patients [88]. Reed et al. [48] reported that in 21 of 44 patients with EGE (13 being placed on an elemental formula, seven on a testing directed diet, and one not specified) 12 patients (57%) had resolution of symptoms. However, 15 of them received concomitant corticosteroids while histological response was not assessed [48]. Gonsalves et al. carried out a prospective study published recently as Conference abstract [30], assessing the efficacy of elemental diet in 15 adults with EG/EGE, 87% of whom atopic comorbidities. The authors reported that elemental diet for 6 weeks was associated with histological remission in all patients, significant improvements in clinical symptoms, endoscopic findings, in depression and fatigue domains of the patient reported outcomes' information measurement scores and also of the EGDP score [30]. A

systematic review carried out by Lucendo et al. [88] assessed the efficacy of dietary interventions in children and adults with EGE. The review included 30 studies, most of which were of low quality. Elemental diets were associated with clinical improvement in 75% of patients, but histological assessment was carried out in only six patients, five of which had achieved histological remission. Empiric elimination diets (6FED or 7FED that included the elimination also of red meat) were introduced to 34 patients and were associated with clinical improvement in 85% of them (histological response was not assessed), while single food (cow's milk) elimination diet was introduced to 16 patients, 62% of whom improved clinically, without though, assessing histological response. In patients who were assessed for histological response, a significant reduction in gastric (but not duodenal) eosinophilic infiltration was reported [88]. More recently, a retrospective multicenter study [89] reported on treatment response of 109 patients with EGIDs beyond EoE who had a 6-month follow-up from the start of treatment. The authors reported that all types of elimination diets (6FED, elemental and targeted diet) were associated with clinical improvement. Furthermore, patients with EG showed a significant reduction in eosinophilic gastric infiltration, while those with EGE showed a significant decrease in gastric and a nonsignificant in duodenal eosinophilic infiltration [89].

Dietary therapy should be under the guidance and supervision of a dietician trained in EGIDs in order to assure the patient's compliance and to avoid nutritional compromise. In patients with EGE and peripheral eosinophilia, a reduction of >50% could be considered as a response to dietary therapy. In all cases of uncertainty regarding the response to treatment and/or the degree of activity of the ongoing disease, a repeat endoscopy with biopsies should be performed. Once the dietary intervention is successful at reducing symptoms, peripheral and/or tissue eosinophilia, foods are reintroduced slowly, starting from the least allergenic to most allergenic.

To conclude, some studies suggest that dietary treatment may be an alternative for inducing remission in patients with EGIDs beyond EoE, but data on histological response and on the long-term disease outcome are scarce, the possible food triggers have not been identified and the process of food reintroduction is not clear. Furthermore, although food allergens' hypersensitivity plays an important role in the pathogenesis of EGIDs, there is no evidence to support the routine use of food allergy testing, in making clinical decision.

(ii) *Drug Treatment*

Corticosteroids

Oral Corticosteroids

Corticosteroids are known to decrease the recruitment of inflammatory cells including eosinophils, to decrease the release of eotaxins and other inflammatory mediators, and to reduce capillary permeability. Pineton et al. demonstrated efficacy of oral corticosteroids in 18 out of 19 (95%) patients with EGE in whom it was used among a total number of 43 patients [67].

As fibrosis in EGE is much less common in EGE compared to EoE, the minimum dose of oral corticosteroids can improve EGE symptoms and control peripheral eosinophilia, avoiding the systemic side effects associated with high doses. Improvement in symptoms with the use of corticosteroids usually occurs within 2 weeks regardless of the layer which is involved [46, 47]. Prednisone is introduced at a dose of 1–1.5 mg/kg for 2 weeks, and subsequently, it is tapered rapidly over the next 2 to 4 weeks.

Topical Corticosteroids

Case reports have indicated that fluticasone improves gastric eosinophilia when used primarily to treat EoE [90], while others reported that the off-label use of formulations of budesonide in form of capsules, dissolved in water, may target the upper GI tract [59]. Treatment with topical steroids in the form of budesonide, as a budesonide capsule, has also been reported to be occasionally effective in patients with EGE involving the antrum and the small intestine [91–94].

In some circumstances, more prolonged therapy with glucocorticoids is needed in order to succeed complete resolution of symptoms [46, 95]. Patients who do not respond to oral glucocorticoids should undergo a course of equivalent intravenous glucocorticoids and in case of failure, a thorough reevaluation is needed in order to rule out other possible underlying conditions.

Cromolyn, Ketotifen, and Montelukast

Cromolyn is expected to prevent the release of mast cell mediators such as histamine, platelet-activating factor, and leukotrienes and reduce antigen absorption by the small intestine. Some case reports have documented its effectiveness for short- and long-term management of EGE, while others not [9, 96, 97]. Ketotifen is an H1-antihistamine and mast cell stabilizer which has been reported to improve clinical symptoms and tissue eosinophilia in small series of patients [98–100]. Montelukast is a leukotriene antagonist which has been reported to be effective in some case reports but not in others [64, 101–104].

Reed et al. assessed the efficacy of various treatment options including dietary therapy, corticosteroids, mast cell inhibitors, H_2 antagonists, and leukotriene receptor antagonists in 44 patients with EGE, including pediatric patients, for an average of 26.2 months, 76% of whom needing more than one treatment option [48]. None of the patients treated only with mast cells inhibitors, leukotriene receptor antagonists, or H_2 antagonists achieved clinical or histological remission [48]. When all treatment modalities were considered, 60% of patients presented resolution of symptoms and

51%, histological remission. Corticosteroids appeared to be the most effective treatment achieving resolution of symptoms in 22/36 (61%) patients, while dietary therapy in 12/21 (57%) patients, 71% of whom received also treatment with corticosteroids. Twenty-eight patients were assessed for histological response, 19 of whom demonstrated remission after treatment: 9/19 had received corticosteroids, 6/19 combination treatment with corticosteroids and dietary therapy, and 4/19 only dietary therapy [48].

In summary, although studies to date do not advocate the use of leukotriene receptor antagonists, cromolyn, or ketotifen as monotherapy in patients with EGIDs, in case of existing comorbidities for which they are indicated, evidence suggests that they are unlikely to be harmful.

Biological Agents and Immunosuppressive Drugs

Humanized anti-IL-5 antibody has been reported in a preliminary report of a small number of patients to reduce peripheral and tissue eosinophilia without improving symptoms [105, 106], while after the discontinuation of the treatment eosinophilia reappeared. Omalizumab, an anti-IgE monoclonal antibody, was reported in nine patients to be associated with improvement in symptoms and measures of IgE-mediated allergy, decrease in peripheral eosinophilia but no reduction in tissue eosinophilia [10], thus has no place in the treatment of EGIDs. In a recent study [107] on mouse model of food allergen induced GI eosinophilic inflammation, anti-CCR3 antibody significantly reduced the severity of eosinophilic inflammation, mucosal injury, and diarrhea. CCR3 may be a novel therapeutic target for treatment of EGE and other GI eosinophil-mediated diseases, but further studies are necessary to determine whether the above results can be extrapolated to humans. Suplatast tosilate, a novel antiallergic drug that seems to suppress the production of cytokines, including interleukin (IL)-4 and IL-5 from T helper 2 (Th2) cells, was reported to be effective in a single patient [108]. Thiopurines, such as azathioprine, have been reported to be effective in refractory cases [109]. A recent study [85] using an anti-integrin agent (Vedolizumab) in adult patients with steroid refractory EGE reported clinical and histological improvement in three-fourths of steroid-refractory patients receiving Vedolizumab, which is quite promising but more studies in children are necessary.

Another agent that also seems promising is Siglec-8 blocker that was assessed recently in a double-blind, placebo-controlled trial [86] in 65 patients with refractory EGE (AK002: 43, placebo: 22). The mean percentage change in gastrointestinal eosinophil count was -86% in the combined AK002 group, as compared with 9% in the placebo group. Treatment response occurred in 63% of the patients who received AK002 and in 5% of the patients who received placebo. The mean change in total symptom score was -48% with AK002 and -22% with placebo. Adverse events associated with AK002 were similar to those with placebo, with the exception of higher percentages of patients having mild-to-moderate infusion-related reactions with AK002 (60% in the combined AK002 group and 23% in the placebo group) [86].

In conclusion, although several novel drugs seem quite promising in treating EGIDs, more trials are required in adults and in children with EGIDs to assess their efficacy and safety. Due to limited number of randomized controlled trials on the efficacy of the above drugs, they cannot be recommended for routine use in pediatric patients with EGIDs, but they can be used in EGID centers either as part of research studies or for selected patients with refractory disease. Well-designed randomized controlled trials are urgently needed to establish the best drug treatment option for refractory disease.

(iii) *Surgical Treatment*

Surgical treatment is limited only to highly selected cases of persistent pyloric or small bowel obstruction with increased percentage of recurrence [110, 111].

Natural History of EGIDs Beyond EoE

Unfortunately, only few patients with EGE present complete long-term remission with treatment. In most patients, the disease is chronic, relapsing, with periodic flares months to years after the initial episode if long-term maintenance treatment is not applied.

Chen et al. noted that among 15 patients with EGE, 13 patients treated with oral corticosteroids, followed by a rapid tapering, manifested symptom remission within 2 weeks but five of them relapsed within 12 months from drug discontinuation [29]. Patients who have recurrent symptoms with periodic flares months to years after the first episode may undergo another short course of oral glucocorticoids, typically prednisone, followed by a rapid taper [46]. Pineton et al. assessed the long-term outcomes of 43 patients with EGIDs and noted that 18 of them (42%) had an initial flare without a relapse, 17 (37%) presented recurrent disease with multiple flares among periods of full remission and 9 (21%) had chronic disease. Among patients with recurring disease, an important variability of the intervals between flares was observed, ranging from months to years [67]. Similarly, Reed et al. noted that only one-third of the pediatric and adult EGE patients, enrolled in their study, underwent long-term remission [48].

More studies are needed to better understand the pathogenesis and the natural history of various disease subtypes, their impact on patient's growth, development and quality of life, and the effectiveness of various therapeutic approaches. Understanding this variance appears to be very important in educating patients and analyzing the outcomes of different

therapeutic options, especially in patients who present refractory disease [32]. With all subtypes of EGIDs increasing more and more, emerging phenotypic data may facilitate the understanding of the complex pathogenetic mechanisms behind the disease, leading to an individualized short- and long-term management. Furthermore, international, consensus recommendations on diagnostic criteria for the diagnosis of the EGIDs beyond EoE are urgently needed to facilitate well-designed, randomized trials assessing the efficacy of various treatment modalities. ESPGHAN and NASPGHAN are about to produce such document to encourage high quality research, and to guide clinicians dealing with these disorders, decreasing variations in clinical practice and improving effectiveness and quality of care.

Crohn's Disease

28

Marina Aloi and Salvatore Cucchiara

Introduction

Crohn's disease (CD) is a chronic, relapsing disorder of the gastrointestinal tract, belonging to the inflammatory bowel diseases (IBDs). Approximately 25% of IBD is present in childhood and adolescence, with recent studies suggesting that the prevalence is rising in both developed and developing countries [1–4]. The precise cause of IBD is still unsettled, but there is evidence that they develop as a consequence of an abnormal immune response to the intestinal microbiota in a genetically susceptible host [5, 6]. Although pediatric- and adult-onset IBD seem to share many clinical aspects and pathogenetic pathways, however, some features characterize the pediatric form, such as the potential for linear growth impairment and pubertal delay, as complications of undertreated inflammation and malnutrition, the influence of nutritional treatment on the course, and the different phenotype expressions of the disease [7]. Finally, evidences from animal models of IBD and preliminary observations in children support the concept that IBD develops in distinct phases and that key mediators of the inflammation may play different roles, depending on the stage of the disease [8, 9]. These observations highlight the importance of taking into consideration the disease course when studying pediatric IBD and targeting appropriate treatments.

Epidemiology

Although IBD can occur at any age, up to 25% of patients develop symptoms during childhood and adolescence [1–3]. Some epidemiological studies from the United States and Europe have shown a steady increase in the overall mean annual incidence of IBD around the world: the rising rate of pediatric IBD seems to be primarily due to an increase of the incidence of CD [1, 3, 10]. CD is unequally distributed all over the world, with highest rates occurring in Western and Northern countries, and with a decreasing gradient from North to South and from West to East [4]. The worldwide highest prevalence of pediatric IBD is reported from the Canadian Ontario region, with approximately 50 IBD patients per 100,000 inhabitants [3]. Recent epidemiological observations from two large claims databases in the United States reported an increased prevalence of IBD overall by 133%, from 33/100,000 in 2007 to 77/100,000 in 2016. Among children, CD was twice as prevalent as UC (45.9 vs 21.6). Prevalence was higher in boys than girls for all forms of IBD, in contrast to the adult population where the prevalence was higher in women than men [1]. In Europe, a recent study based on the Epidemiology of Inflammatory Bowel Diseases (EPIMAD) data of Northern France indicated a dramatic increase of both CD and UC in adolescents from 1988–1990 to 2009–2011: for CD, from 4.2 to 9.5/105 (+126%) and for UC, from 1.6 to 4.1/105 (+156%) [10]. Factors contributing to the evident increase in the global incidence could be a greater case ascertainment, the widening case definition, earlier onset in predisposed individuals, and greater access to health care; however, it is widely agreed that the rising incidence of pediatric IBD is due to a real increase in the number of affected children [11]. It has been postulated that the "Westernization" of different societies accounts for the progressive rise in the incidence of the disease also in previously low-incidence areas, including Japan [12], other Asian countries [13, 14], and some Eastern European countries [15].

Pediatric IBD present specific phenotypic and demographic differences when compared with the adult-onset disease. While CD and UC occur with an equal distribution in adults [4], it has been reported that in childhood CD is more frequently diagnosed than UC [1]; moreover, while in adults there is an equal male-to-female ratio (or a mild female

predominance), all pediatric IBD cohort studies or registries indicate a male predominance [16]. In pediatric CD, most patients have an extensive disease, ileocolonic or colonic, and distinction of UC from colonic CD may not be uncommonly challenging [17]. Moreover, children with CD are more likely to have upper gastrointestinal involvement than their adult peers [18]. Pediatric CD also seems to have a different behavior than the adult-onset disease: children often present with an inflammatory or nonstricturing, nonpenetrating disease, while complicated disease is fairly unusual at presentation. However, even with treatment, many data demonstrate that inflammatory CD progresses to stricturing and penetrating disease in several children [18, 19]. Adult disease begins more often with a complicated behavior (stricturing or penetrating), with a lower trend of disease progression [20].

Etiopathogenesis

The most accepted hypothesis for the pathogenesis of CD is that the interaction between luminal contents (i.e., the intestinal microbiota) and the mucosa leads to a dysregulated inflammation in a genetically predisposed host. Several microorganisms have been historically considered as potential causative agents for CD, including *Mycobacterium paratuberculosis*, *Listeria monocytogenes*, novel Burkholderiales, and *Escherichia coli* [21, 22]. Interestingly, strains of adherent-invasive *Escherichia coli* (AIEC), capable of adhering to and invading epithelium, and to replicate in macrophages, have been described in adults and children with CD [23–25]. Nevertheless, there are no strong data to support a role for any of these microorganisms as the causative factor in the etiology of IBD. Some interesting findings in the pathogenesis of IBD come from genetics. The importance of genetics in CD was suggested by family, twin, and phenotype concordance studies. Monozygotic twins exhibit phenotypic concordance in 50–70% of CD patients, and their relative risk of developing CD is 800-fold greater compared to the general population [26–28]. Recently, the discovery of several susceptibility genes has further secured the importance of genetic predisposition in CD and UC [26]. After the pivotal study of Hugot et al., in 2001, who discovered the association of variants of the NOD2 gene with ileal CD [29], and the discovery of the correlation between variants of IL23 receptor (IL23R) gene and both CD and UC in 2006 [30], the number of IBD genetic associations is dramatically increased. More susceptibility loci have been quickly identified, such as autophagy genes, ATG16L1 and IRGM [31, 32]. In the last decade, the implementation of genome-wide association studies (GWAS) has significantly advanced our knowledge on the importance of genetic susceptibility in IBD [33]. To date, GWAS have identified more than 200 risk-conferring loci for IBD [34], most of them shared by CD and UC. However, some genes are quite different for CD or UC, clearly denoting the genetic heterogeneity of the two forms of IBD, each one of them showing distinctive and shared genetic associations. For instance, NOD2 and autophagy genes, and ITLN1 (Intelectin 1) are unique for CD [34]. Despite the discovery of a massive number of susceptibility genes for IBD, we are still far from understanding the mechanism by which such genetic variants cause the uncontrolled intestinal inflammation. The challenge for basic IBD researchers is now to identify how genetic abnormalities influence pro-inflammatory pathways, providing information directly improving the clinical management. Some pro-inflammatory pathways have been partially or totally understood, in some cases this knowledge has enabled the development of specific interventions. For instance, NOD2 gene defected patients have an impaired ability to recognize and process bacterial products, and this may lead to an inappropriately innate immune response. Some CD patients with variants of the autophagy genes (ATG16L1 and IRGM) have a defective capacity to process cell degradation products, as well as bacteria, and therefore an insufficient ability to eliminate pro-inflammatory factors [23]. One of the most important discoveries in the field of genetics of pediatric IBD is the identification of impaired interleukin 10 (IL-10) signaling in some forms of very early onset (within the first months of life) CD [35]. The common characteristics of these patients are a very early onset of a severe form of CD (infantile colitis), with colonic involvement and presence of fistulae, in some patients associated with growth failure, resistant to conventional therapies. Allogeneic hematopoietic stem cell transplantation is effective in most patients [36]. This form of CD is due to homozygous mutations in either IL10RA or IL10RB, which encode subunits of the IL10 receptor, or for IL10 itself [37]. One could speculate that this form of IBD with a monogenetic inheritance could identify a subset of patients with a "more" Mendelian transmission, opening new horizons for research and also expectations to understand the definite mechanisms underlying these diseases. Since then, several other forms of monogenic chronic inflammatory conditions with an IBD phenotype have been discovered, sharing a disturbance of the intestinal epithelial barrier function or a dysfunction of the innate and adaptive immune system, with a wide spectrum of disease presentations and with different courses and medical and surgical treatments, although allogeneic hematopoietic stem cell transplantation is often the only effective therapy [36, 38, 39]. A correct diagnostic approach, including genetic analysis, is mandatory in children who develop a very early onset IBD, and possibly in general in those patients with a severe CD course [36].

Beyond the genetics, in the last two decades epidemiological and pathogenetic studies have been mainly focused on the role of environmental factors in the etiology of IBD. Indeed, the epidemiology of both CD and UC clearly

addresses environment as the main factor that can determine such rapid changes. Moreover, the increasing incidence and prevalence of pediatric IBD worldwide, both in developed and in developing countries, seem to follow changes in the diet and lifestyle, with the adoption of a "Westernized" lifestyle [5]. Even though a causative role for a single factor has not been proven, several potential environmental influences have been studied so far. Smoking has been widely demonstrated to negatively affect the risk of developing CD and to exacerbate its disease course. The extensive use of antibiotics and gastrointestinal infections, particularly in the early ages of life, seem to increase the risk of developing IBD. Personal stress is recognized as a risk factor for disease exacerbations as well [40]. Among all, the spread of the "Western" diet, high in fat and protein but low in fruits and vegetables, is regarded by many researchers as a strong candidate, and its influence on gut inflammation is highly hypothesized [41].

Clinical Presentation

CD is characterized by transmural inflammation that can be found everywhere in the gastrointestinal tract, from mouth to anus. The terminal ileum is the most common site of CD, however about 60% of children have an extensive ileocolonic involvement, and 20–30% an isolated colonic disease [17]. CD typically presents in any age group with a constellation of abdominal pain, diarrhea, weight loss, and poor appetite, however, short stature and predominant perianal disease are further significant features of presentation of pediatric CD. Impairment of linear growth and associated delay in sexual development can present before the onset of intestinal symptoms and can dominate the clinical presentation [42]. Growth failure is a unique characteristic of pediatric-onset CD: it is defined as linear growth at or <2 SD below the mean for age, or decreased growth velocity, and can occur in 15–20% of children with CD. The onset of growth failure is usually insidious, and any child or adolescent with impairment of linear growth should have an appropriate initial diagnostic evaluation for IBD. The assessment of growth and pubertal delay is a key factor in the management of pediatric IBD. Maintaining adequate nutrition, minimizing inflammation, and maximizing corticosteroid-free treatment remain a crucial part of managing the potential growth stunting effects of active IBD, most specifically of small bowel CD. During the clinical course of CD, growth failure has been reported in up to 40% of children with CD and a final height below the fifth centile is reported in 7–30% of patients with pediatric-onset CD [43]. Growth failure in CD originates from different factors, such as malnutrition with decreased intake, increased gastrointestinal losses, malabsorption, and medication effects. All these components might certainly impact an individual's nutritional state. Nevertheless, it is widely agreed that the inflammation process per se may directly inhibit linear growth and play a major role in the etiology of growth retardation. Inflammatory mediators, such as interleukin 6 (IL-6) and tumor necrosis factor (TNF)-alpha, are key factors in reducing plasma levels of insulin-like growth factor 1 (IGF-1), the peripheral mediator of the growth hormone [44]. Impressive catch-up growth can be observed as soon as remission of the intestinal inflammation is achieved. It is essential that height, weight, puberty staging, and bone age are accurately and regularly measured and recorded in young patients with CD. Nutritional supplementation and need for "catch-up" growth should be part of the evaluation of a CD pediatric patient. Delay of pubertal onset is also common in active pediatric CD, and the duration of puberty can be impaired too. Active or relapsing disease during the years following the onset of puberty may slow or even arrest the progression of puberty. Moreover, pubertal delay affects estrogen and androgen levels, which are critical for normal bone mineralization, contributing to the development of osteoporosis and osteopenia. Inducing and maintaining disease remission before and during the pubertal years is crucial in order to ensure the attainment of final predicted height, avoiding a missed pubertal growth spurt.

Diagnosis

There is no gold standard single test allowing a definite diagnosis of CD; however, the combination of family and clinical history, physical examination, and subsequent laboratory, imaging, and endoscopic assessment usually leads to the correct diagnosis. Nevertheless, 10–15% of children with IBD confined to the colon receive an initial diagnosis of inflammatory bowel disease-unclassified (IBD-U) and they will be subcategorized as CD or UC only during follow-up [45]. The first diagnostic issue is whether the presenting symptoms are related to CD. When the classic clinical presentation is evident, differentiating CD from other diseases with initially similar symptoms may be relatively simple [46]. However, in a child with bloody diarrhea, infectious etiologies by invasive agents, like *Salmonella*, *Yersinia*, *Shigella*, *E. coli*, etc., must be excluded. It is also important to evaluate and rule out vasculitides (such as Henoch–Schonlein purpura and hemolytic–uremic syndrome) or allergic colitis. An abdominal pain mimicking CD pain may be determined by other conditions, such as lymphoma, ovarian cyst, appendicitis, or intussusceptions. Figure 28.1 shows the suggested diagnostic work-up of children or adolescents with suspected IBD.

Noninvasive Tests

Serologic Tests

Serologic tests are the first diagnostic tool for suspected CD. They mainly include complete blood count and acute phase reactants (i.e., C-reactive protein, erythrocyte sedimentation rate, ferritin, platelet count). C-reactive protein (CRP) is a marker of inflammation, and its concentration reflects disease activity in patients with CD. However, CRP is nonspecific, particularly in children, since its serum levels can raise because of other inflammatory conditions beyond the gut, while genetic factors, along with age, sex, and body mass index (BMI), may influence CRP production. Nevertheless, there are no alternative biomarkers for use in routine clinical practice [47, 48]. Due to the transmural inflammation, CRP plays a major role in CD monitoring: indeed, previous studies have shown that patients treated with infliximab and early normalization of CRP levels were more likely to maintain response to treatment, while persistently abnormal CRP levels correlated with higher relapse risk [49, 50]. The optimal CRP cut-off level for monitoring disease activity is unclear: in a large multicenter study, CRP > 5 mg/L (CRP > 0.5 mg/dL) was a criterion for treatment failure [51].

Several antibodies to microbial antigens have been identified in patients with IBD. The most extensively studied and commonly used are anti-*Saccharomyces cerevisiae* antibodies (ASCA) and perinuclear antineutrophil cytoplasmic autoantibodies (pANCA). ASCAs have initially been suggested as a marker for CD with a prevalence of 50–60%, compared with 10–15% in UC and 0–5% in healthy controls [52, 53]. Conversely, pANCAs have been proposed as a marker for UC or colonic CD [54]. However, between 30% and 50% of the IBD patients did not screen positively for either of these markers, so they could not be used for diagnostic purpose, except in the context of an IBD-U, where ASCA or pANCA positivity might help labeling the patient as a CD or UC, respectively [55, 56]. The attention of researchers has been recently focused on the possible relationship between serologic markers and distinct subgroups of patients and prognosis of the disease [57]. In CD, positive ASCA titers have been correlated to younger age at onset, ileal disease, severe behavior, and increased risk of early surgery [57]. Because of these promising data, other markers useful for prognostic purposes have been identified. Reactivity to *Pseudomonas fluorescens*-related protein was independently related to stenosing disease and need for surgery, whereas anti-*Escherichia coli* outer membrane porin C (OmpC) has been associated with penetrating disease [57]. Both the presence and magnitude of the immune response seem to be correlated with more aggressive disease courses. Recently, a large, multicenter, prospective study tried to derive a risk-stratification model of a complicated behavior based on clinical and serologic factors defined at diagnosis in pediatric CD. Stricturing disease was associated with ASCA, antibody reactivity to bacterial flagellin (CBir1), and neutralizing auto-antibodies (Ab) against granulocyte-macrophage colony-stimulating factor antibody (GM-CSF Ab), penetrating disease was associated with older age, African American race, and ASCA and CBir1 seropositivity in univariate analyses. The authors also found that *Ruminococcus* was implicated in stricturing behavior and *Veillonella* in penetrating complications. Moreover, ileal genes controlling extracellular matrix production were associated with stricturing complications [8].

Fecal Markers of Inflammation

The neutrophil-derived marker calprotectin is a noninvasive tool for the diagnosis and monitoring of the activity of IBD. Calprotectin is a calcium-binding protein that is excreted in the feces and can be readily measured using an ELISA (enzyme-linked immunosorbent assay). The protein is stable in stool specimens for up to a week at room temperature, allowing patients to collect a specimen at home without special precautions. Calprotectin is commonly used in the initial diagnostic approach to suspected IBD: a fecal calprotectin concentration of less than 40 μg/g in the presence of abdominal symptoms, suggestive of irritable bowel syndrome, is associated with only 1% chance of IBD, therefore reducing the number of negative endoscopies in both children and adults. Conversely, higher fecal calprotectin values (a cut-off of 100 μg/g has a good sensitivity for discriminating patients with suspected inflammation) help in identifying those patients who need investigation (i.e., endoscopy) and are most likely to have IBD [58].

Fecal calprotectin is, moreover, equally useful in the context of disease monitoring, due to its ability to confirm tissue healing and predict disease relapses. A few studies have evaluated this outcome, demonstrating a sensitivity of 89–90% and specificity of 82–83% for predicting disease relapse during a 12-month period, with a sensitivity and specificity to predict the absence of mucosal healing of 70–100% and 44–100%, respectively, depending on the calprotectin concentration threshold used [59]. Other fecal biomarkers, such as lactoferrin, neutrophil-derived S100A12 and High-Motility Group Box 1 (HMGB1), have shown promises as potential biomarkers for CD, but have been studied far less extensively [60, 61].

Ileocolonoscopy and Esophagogastroduodenoscopy (EGD)

Traditional endoscopy has a pivotal role in the diagnosis of suspected CD. According to the last European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) guidelines on the diagnosis of IBD, ileocolonoscopy and EGD should be recommended as the initial work-up for all children with suspected disease. Multiple biopsies should be obtained from all sections of the examined gastrointestinal tract, even in the absence of macroscopic lesions [46]. Beyond diagnostic aims, traditional endoscopy has an important role in staging disease severity, evaluating and treating strictures, detecting postoperative recurrences, surveilling neoplasms, and preoperative assessment. Moreover, endoscopy allows the monitoring of response to therapies, by evaluating mucosal healing (MH). In the last decade, MH has become the most rigorous endpoint in both adult and pediatric therapeutic trials. The so-called treat-to-target strategy for disease management and the importance of reaching MH will be further discussed at the end of this chapter. Tables 28.1 and 28.2 show the typical endoscopic and histologic findings differentiating CD and UC.

Table 28.1 Endoscopic differentiation between typical CD and UC

CD	UC
Throughout the entire GI tract	Confined to colon
Discontinuous lesions	Usually continuous lesions
Rectal sparing or segmental inflammation	Rectal involvement (in children may be absent)
Aphthous ulcers (may occur in normal mucosa)	Mucosal granularity/friability
Linear ulcers common	Erosions/microulcers
Cobblestoning	Loss of vascular pattern
Ileocecal valve stenotic and ulcerated	Ileocecal valve patulous and free from ulcerations (possible backwash ileitis)

Table 28.2 Histologic findings in CD and UC

CD	UC
Focal crypt distortion Ulcers and/or aphthoid ulcers Mucin depletion absent or weak Pseudopyloric metaplasia Focal cryptitis Focal lympho-plasmacellular infiltration in the lamina propria Granulation tissue-like inflammation Epithelioid granulomas	Mucosal surface alteration Crypt distortion Atrophy Mucin depletion Cryptitis and/or crypt abscesses. Diffuse lympho-plasmacellular infiltration in the lamina propria Basal plasma cell infiltration

Small Bowel Evaluation

Imaging

Most CD patients, particularly those with a childhood-onset disease, present with a small bowel involvement. The revised PORTO criteria state the need of small bowel assessment at the diagnosis in all suspected CD cases, through magnetic resonance enterography (MRE) or wireless capsule endoscopy [62]. Furthermore, children with CD need frequent evaluations during the course of their disease, so noninvasive, radiation-free imaging tests, could be a valuable alternative to endoscopy for the definition of activity and complications of the disease. In the past, small bowel follow through (SBFT) was the "gold standard" for small bowel disease, but it no longer plays any role both in CD diagnosis and follow-up. In the last decade, due to considerable advances in technologies, other modalities, such as MRE, ultrasound (US), and computed tomography (CT), have taken its place [63, 64]. Computed tomography has the major disadvantage of the large radiation exposure, therefore limiting its use only to the

emergency setting, when magnetic resonance (MR) is not available. Magnetic resonance with the administration of oral contrast (MRE) results in luminal distension, facilitating evaluation of bowel wall thickness, profile, and structure; MR enteroclysis (with contrast administered through a nasojejunal tube) seems to have the same sensitivity (88%) of MRE but a superior patient discomfort [63], and therefore it is not recommended in children with CD. In comparison with endoscopy, MRE has a sensitivity of 84–96% and a specificity of 92–100% for the diagnosis of IBD [65]. MRE can also allow a detailed assessment of perianal fistulae, and it should be preferred as the imaging tool for perianal disease [66]. The last European Crohn's and Colitis Organization (ECCO) and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) guidelines on the management of pediatric CD recommend MRE as the imaging tool of choice for the diagnosis and follow-up of CD [67]. Abdominal US is a widely used technique in the evaluation of patients with CD because of its excellent safety profile, low cost, and recent advances in the equipment (Doppler and use of oral contrast) that allow high-resolution images [64, 68]. Recently, small intestine contrast ultrasonography (SICUS), performed after ingestion of an oral contrast material filling the small bowel lumen with anechoic fluid, has been developed for the study of the small bowel [68]. SICUS provides the opportunity to visualize and assess the entire small bowel by measuring the intestinal wall thickness and lumen diameter at different levels [63]. Ultrasound techniques have several advantages: they are cheap, noninvasive, well-tolerated and have a good correlation with MRE [69]. Their use is limited by local expertise and lack of validated score for grading inflammation [70].

Small Bowel Capsule Endoscopy

When there is a strong suspicion for small bowel inflammatory lesions, with normal features at ileocolonoscopy and imaging, small bowel capsule endoscopy (SBCE) represents a valuable and well-tolerated tool. It allows the evaluation of CD small bowel lesions, with no radiation. It is very sensitive for determining mucosal lesions: in comparison to traditional endoscopy, SBCE can evaluate the entire small bowel and is better tolerated from children. Regardless of its many advantages, SBCE also has some weaknesses: biopsy or intervention is not possible, it cannot detect extraluminal processes and there is no way to guide the capsule, so significant lesions may be missed because of a bad orientation of the camera, obscured visualization due to luminal bubbles or debris, or delayed intestinal transit resulting in an inaccurate examination. SBCE is contraindicated in patients with strictures because of the risk of capsule retention. Furthermore, there are no established diagnostic criteria for CD, although most studies have defined the presence of more than three ulcerations in the absence of nonsteroidal anti-inflammatory drug ingestion as a diagnostic criterion, this has not been prospectively validated. Given the concerns about the specificity of SBCE in the diagnosis of IBD, but recognizing its good sensitivity, its utility is greater for monitoring established CD rather than for initial approach [71].

Balloon Enteroscopy

Given the availability of the abovementioned noninvasive tools, the role of enteroscopy, especially balloon-assisted enteroscopy (BAE), remains limited to symptomatic patients in whom ileocolonoscopy, SBCE, and/or cross-sectional imaging are inconclusive for active disease, as well as to obtain mucosal samples to exclude potential malignancies and for therapeutic purposes [72]. Balloon-assisted enteroscopy was first introduced in 2001 as a device offering the possibility of a complete diagnostic and therapeutic access to the entire small bowel with an endoscope [73]. A single-balloon device has also been developed with a similar intention. The enteroscope can be inserted via the oral or anal route and, using the combination of these approaches, a complete examination of the entire small bowel can be achieved in many patients [74]. Several studies support the utility of BAE in established adult and pediatric CD with the potential to affect management in select populations of patients (small bowel disease) [75]. The main limitations of BAE are the invasive nature with the risk of bleeding and perforation (complication rate for diagnostic procedures is around 0.8% but can be as much as 4% for therapeutic interventions), prolonged duration, limited evaluation of the entire small bowel in a one-step approach, and requirement for specialized personnel [75].

Therapy

The traditional management of CD based on achieving prolonged clinical remission has experienced a dramatic evolution in the last years, since the recognized paramount importance of MH, as the main outcome, and, possibly, transmural healing. The so-called treat-to-target (T2T) approach, adapted from rheumatoid arthritis and other chronic diseases, is now a consolidated strategy in the management of IBD: it is focused on an objective measure and monitoring of the intestinal damage at predefined timepoints, and includes therapeutic adjustments in case of failure [76]. The introduction of these targets might be the best way to alter the natural course of IBD by preventing disability and bowel damage [77]. This may be of clinical relevance in children with CD, given the long-term consequences of an early-onset aggressive disease presentation. Pediatric CD therapy employs many of the same treatment regimens as its adult counterpart. There are only a few well-designed clinical trials performed in children, therefore much of the

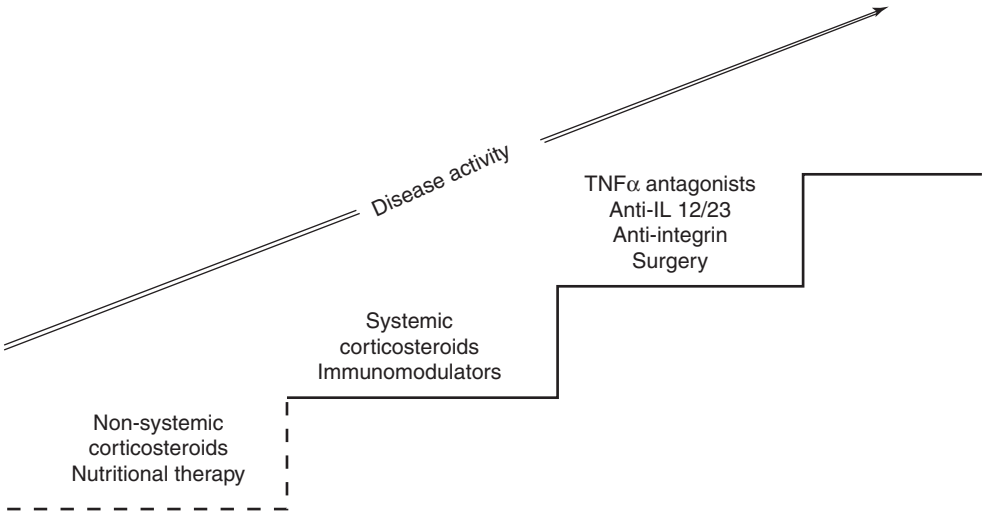

Fig. 28.2 Step-up approach in pediatric Crohn's disease

evidence given is based on adult data. Conventional therapy is based on the escalation of drugs, from those with a better safety profile but a lower efficacy to those with improved efficacy but a greater risk of side effects (steroids, immunomodulators, biologicals, surgery). This "step up" approach is applied in some cases of pediatric IBD. The advantages of "step up" management are mainly to reserve more toxic drugs for those patients with a demonstrable "need" for more intensive therapy [78] (Fig. 28.2). However, potential disadvantages include the observation that conventional therapies have not altered the disease course toward disease complications (strictures and fistulae) or the need for surgical procedures. Hence, an "early aggressive" treatment ("top-down" approach) through the introduction of an early biologic therapy at the diagnosis is now a consolidated treatment strategy for CD patients at high risk of an aggressive disease course [79]. Several risk factors, which prompt this "top-down" treatment, have been identified and include the presence of deep colonic ulcerations on endoscopy, persistent severe disease despite adequate induction therapy, extensive (panenteric) disease, marked growth retardation, severe osteoporosis, stricturing and/or penetrating disease [80]. Increasing the knowledge of these markers (genetic, biochemical, or clinical) of poor prognosis or response to treatment will be the challenge in pediatric IBD research. Figure 28.3 shows the therapeutic pyramid applied in the management of pediatric CD.

Conventional Therapy

Aminosalicylates

There are no randomized controlled trials evaluating aminosalicylate (5-ASA) efficacy for the induction and maintenance of remission in children. Current data in adults do not support their use in ileal CD, showing any (or a slight) improvement compared to placebo, thus their use in CD should not be supported.

Steroids

Conventional corticosteroids (CS) are used for the induction of remission in moderate-to-severe CD. CS are usually quickly weaned after the induction, due to their known adverse effects. Budesonide, an oral steroid preparation that is released in the distal ileum and proximal colon, can be used in patients with mild-to-moderate disease of those segments. It has less systemic side effects than conventional steroids but it is not completely without them, and a quick withdrawal can lead to an adrenal insufficiency [81].

Immunomodulators (Azathioprine, 6-Mercaptopurine, Methotrexate)

Thiopurines, comprising azathioprine (AZA) and its active metabolite, 6-mercaptopurine (6-MP), are widely used maintenance agents in pediatric CD [67]. Their efficacy has been demonstrated in several trials both for induction and maintenance of remission in CD, however, due to their well-known slow onset of action (about 3 months), they are not used for induction of remission. Although the only pediatric prospective, multicenter, double-blind, placebo-controlled trial conducted in children, reported 91% of children receiving thiopurines to be in remission after 18 months of therapy [82], in routine clinical practice, a complete remission can be achieved in about 60% of patients 1 year after beginning the therapy [83]. Myelosuppression is a dose-dependent adverse event that can occur during AZA treatment. Complete blood count and liver tests should be monitored frequently during the therapy. Acute pancreatitis is a rare drug-related adverse event, typically occurring in the first month of treatment [84]. Genetic analysis for thiopurine S-methyltransferase (TPMT) deficiency can help to identify those patients at high risk for hematopoietic toxicity, although normal TPMT

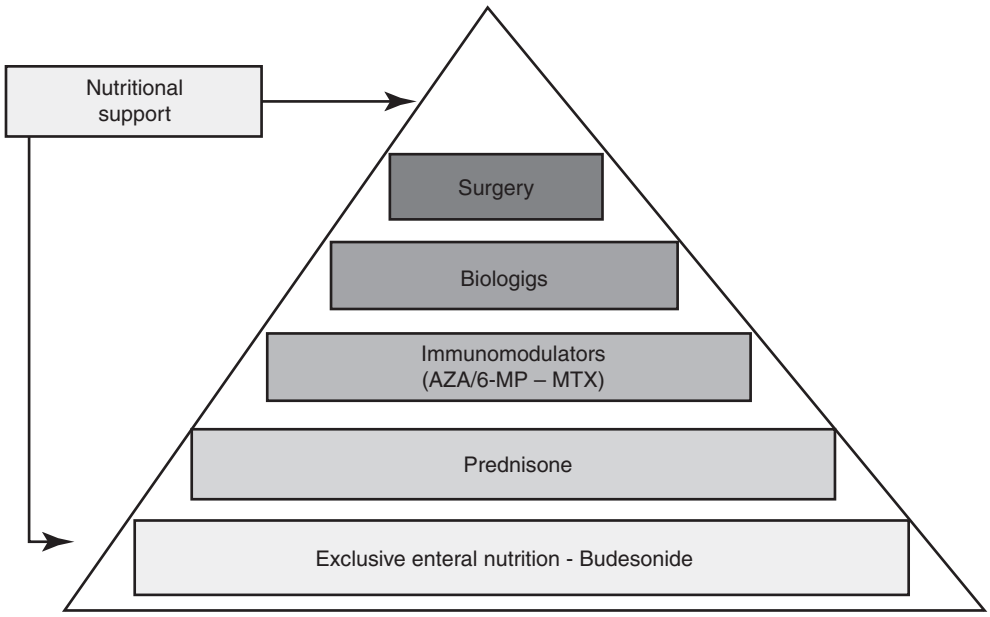

Fig. 28.3 The therapeutic pyramid of pediatric Crohn's disease. (Figure modified from Aloi et al. [78])

testing does not exclude the possibility of leukopenia. Assays for 6-thioguanine (6-TGN) and 6-methylmercaptopurine (6-MMP) levels are commercially available and are related to therapeutic response and hepatotoxicity, respectively. While chronic thiopurine administration has been linked to a potential risk of developing non-Hodgkin (roughly, a four-fold increase in this risk compared to nontreated patients and the general population), AZA may have a role in the risk of developing the hepatosplenic T-cell lymphoma (HSTCL), an aggressive form of non-Hodgkin lymphoma, rapidly evolving and with a poor response and high mortality, mainly occurring in young male patients with IBD, who have received a long-lasting combination of AZA and anti-TNF alpha agents. Methotrexate is often regarded as a second-line immunomodulator in CD patients not responding or intolerant to thiopurines. Some data in adults have demonstrated its efficacy in inducing and maintaining remission [85]. To date, there have been no controlled trials of its use in pediatric CD, but reports from retrospective reviews and uncontrolled trials have shown good remission rates [86, 87].

Biologic Agents

Monoclonal anti-TNF antibodies have revolutionized the treatment and management of IBD since their introduction more than 20 years ago. Infliximab (IFX), the first in this class to be approved in pediatric IBD, is a chimeric monoclonal immunoglobulin G1 (IgG1) antibody (part mouse and part human) that is given intravenously. Infliximab is effective in both inducing and maintaining remission in pediatric CD [88]. It reduces the need for corticosteroid, hospitalization, and surgery, is effective in perianal CD, and induces mucosal healing [89]. In the main pediatric clinical trial, the Realizing Effectiveness Across Continents with Hydroxyurea (REACH) study, children with moderate-to-severe CD received a 3-dose induction of 5 mg/kg IFX at 0, 2, and 6 weeks, followed by 5 mg/kg maintenance infusions every 8 weeks. Remission rates were 60% at week 30 and 56% at week 54 [88]. Moreover, several studies have demonstrated that IFX is able to induce MH [90, 91] and its efficacy seems to be improved when used in combination with AZA, as clearly shown by the Study of Biologic and Immunomodulator Naive Patients in Crohn's Disease (SONIC) trial, in which the combined therapy with IFX and AZA led to a 44% MH rate at week 26, compared to 30% in the IFX group and 17% in those patients treated with AZA monotherapy [59, 92]. In the last decade, therapeutic drug monitoring (TDM), based on the assessment of serum drug concentration and antidrug antibodies, has become an indispensable tool to optimize the use of anti-TNFs. Performed in the setting of active disease ("reactive" TDM) is helpful in elucidating the mechanism underlying the loss of response: an immune-mediated failure (which may benefit a "within-class" switch) is suggested in the presence of high titer of antidrug antibodies with low drug levels, while low drug concentrations in the absence of antibodies indicate nonimmune-mediated pharmacokinetic failure. In this case, treatment optimization through a dose increase or reduced intervals is likely successful. A mechanistic failure, and the need of switching to a non-anti-TNF agent, is implicated in the setting of adequate drug concentrations during active disease [93, 94]. "Proactive" TDM, performed in patients with quiescent disease, to maintain a target trough concen-

tration was recently associated with favorable therapeutic outcomes [95–97]. Whether it should always be preferred to "reactive" TDM is still a matter of debate since the only prospective trials conducted in adults with the aim of evaluating the efficacy of a proactive approach in CD did not confirm its superiority [95, 98].

While it is clear that higher drug levels are associated with better response, IFX optimal serum drug concentration has not been clearly defined. It is suggested that postinduction concentrations greater than 7 μg/mL are more likely to be associated with MH, while during the maintenance phase, through concentrations should not be lower than 3 μg/mL when in remission [93].

Adalimumab is a humanized anti-TNF therapy that has been shown to be effective for induction and maintenance of remission for children with CD [99]. Its efficacy in luminal CD is comparable to that of IFX [100]. Its superiority over placebo in inducing and maintaining remission in patients with moderate-to-severe CD has been largely proven both in adults [101–103] and children [99, 104]. European guidelines on the medical management of pediatric CD recommend its use as an alternative to IFX (according to the availability, route of delivery, patient preference, cost, and local regulations) as the first treatment options for penetrating fistulizing CD, and in children with high risk for poor outcome [67]. TDM applies also to adalimumab: as for IFX, during maintenance therapy, at least 5 μg/mL is recognized as the optimal trough concentration threshold to target, but higher levels (>10 μg/mL) seem to be associated with better therapeutic outcomes [105].

Vedolizumab, an anti-α4β7-integrin humanized immunoglobulin G1 monoclonal antibody and ustekinumab, an anti-interleukin (IL)12/23p40 monoclonal antibody, are emerging as important rescue therapy for patients with moderate-to-severe CD, who fail to respond or lose response to anti-TNF (40% of cases) or, more recently, are biologic naïve. GEMINI 2 and 3 trials of vedolizumab in moderately to severely active CD demonstrated only a partial benefit of vedolizumab on clinical outcomes with approximately 14% of 6-week clinical remission rate [106].

For ustekinumab, the UNITI study reported up to 30% of 6-week clinical remission rate, showing superiority to placebo, with percentage reaching 50% in those patients who were biologic naïve [107].

Nutrition

Exclusive enteral nutrition (EEN) is used as a therapy to achieve remission in children presenting with acute CD [67]. Nutritional therapy consists of using different milk formulas (elemental, semi-elemental, and polymeric) as the primary therapy to induce and maintain remission in CD, as a supplement to improve growth, or to replenish micronutrient deficiency. Although several evidence support the use of enteral nutrition as primary therapy, it has found favor in some parts of the world (mainly Europe and Canada), while it is less widely utilized in others (United States), and can be difficult to administer for long periods of time, mainly because of poor compliance by the patients. Several studies have shown the effectiveness of EEN in achieving clinical remission and mucosal healing in active CD [108–111]. Despite these data, there still remain a multitude of theories explicating the mechanisms of action of EEN. The most frequently advanced theory is that the microbiota of the gut lumen, or more probably products deriving from microbiota, are modified by enteral nutrition [112]; furthermore, the reduction in antigenic load associated with an exclusive enteral nutrition may also contribute to bowel rest [113]. The main drawback of enteral feeding is the poor compliance, most parents are reluctant to commit total enteral nutrition for their children for 6 to 8 weeks as required, and few children are able to consume adequate formula volume by mouth, thus requiring the insertion of a nasogastric tube.

In the last years, new data have emerged about the efficacy of partial enteral nutrition with specific diets for both the induction and maintenance of remission of pediatric CD [114, 115]. Specifically, a few diets from different parts of the world have been evaluated in small prospective and retrospective studies with promising results [115, 116].

Surgery

Up to 30% of children with CD require surgery within 10 years from the diagnosis [117]. The main indications are complications of the disease (especially strictures and fistulae), intestinal perforation or bleeding, failure of medical therapy, and complications of medical therapy (e.g., growth failure). Terminal ileal and colonic disease account for most of surgical interventions in children with CD. Primary goals of surgical treatment in CD are to preserve as much bowel as possible, relieve complications, and to help the patient to achieve the best possible quality of life. In children, the potential for bowel loss due to surgical resections must be weighed against the risk of poorly controlled disease, long-term steroid therapy, and growth failure. The surgical procedure depends on the clinical situation (urgent vs. elective) and the disease extent. Most of the procedures are bowel resections due to strictures, commonly located at the terminal ileum. Stricturoplasty can be an alternative to bowel resection in the case of multiple short segments or longer segments up to 20 cm in length [118, 119].

Another setting of surgical intervention is perianal CD. Several studies have shown that infliximab therapy combined with surgical treatment of fistulizing perineal disease results in significant improvement of perineal disease, which is superior to medical treatment alone [120, 121].

29 Inflammatory Bowel Disease Unclassified (IBD-U)/Indeterminate Colitis

Barbara S. Kirschner

Introduction

The majority of patients with chronic IBD are diagnosed with either ulcerative colitis (UC) or Crohn's disease (CD) on the basis of established clinical, endoscopic, histologic, and radiologic criteria [1–2]. However, in 5–23% of patients with chronic colitis, a definitive diagnosis of UC or CD cannot be established because the initial macroscopic appearance (either during ileo-colonoscopy or following colectomy) and histologic features overlap between UC and CD [1–9]. In this case, the diagnosis should be IBD-U if made prior to colectomy or indeterminate colitis (IC) if the pathology of the resected colon is not consistent with either UC or CD involving the colon [1–2, 8].

While many of these patients eventually evolve into patterns consistent with UC or CD, approximately 20–60% retain the diagnosis of IBD-U, over 5–10 years or longer post diagnosis [6–13]. This observation is increasingly suggestive that IBD-U represents a separate unique subtype within the spectrum of IBD [1–5, 8]. Updated information describing clinical, histologic, serologic, and newly described genetic features of IBD-U in pediatric patients has been added to this revised chapter.

Inflammatory Bowel Disease Unclassified (IBD-U)

Clinical Presentation

Several studies have estimated the percentage of patients with IBD-U among the patients with chronic IBD (See Table 29.1). A concurrent retrospective/prospective analysis of 1576 children and adolescents from the Italian Pediatric National IBD Register showed that 8% of their study population were diagnosed with IBD-U compared with 52% UC and 40% CD [14]. Presenting symptoms in IBD-U were more similar to UC (bloody diarrhea and abdominal pain) than CD (abdominal pain and diarrhea). Fever and weight loss occurred more frequently in CD than IBD-U and UC: fever in 40.5% CD, 12.9% in IBD-U, and 12.6% in UC; weight loss 50.1% in CD, 17.4% in IBD-U, and 20.6% in UC. The locations within the colon were also similar between IBD-U and UC (pancolitis 34% versus 39%; left colon 27% v. 23%; and rectum only 9% v. 7%). The male to female ratio was lowest in UC (0.82), intermediate in CD (1.18), and highest in IBD-U (1.42). Heyman et al. [15], using the PediIBD Consortium Registry, reported that the prevalence of IBD-U in children with IBD-U was highest in those aged 0–2 years (33%) and decreased to 18% at 3–5 years, 12% at 6–12 years, and 9% in those aged 13–18 [15]. In young chil-

Table 29.1 Proportion of IBD-unclassified (IBD-U) cases in pediatric IBD reported studies

	Total no. IBD Pts	Age group	IBD-U		Mean age at diagnosis (years)		
			No. Pts	(Percent)	IBD-U	v	UC
Everhov [31]	4663	Pediatric	839	18.0%

dren (less than 5 years of age), failure to thrive is more prominent than seen in UC [16].

Jose et al. [17] compared IBD disease type with the prevalence of extraintestinal manifestations (EIMs) at the time of diagnosis and during follow-up in pediatric patients with IBD [17]. That study, also from the PediIBD Registry, included 1649 patients:

IBD-U ($n = 171$), UC ($n = 471$), and CD ($n = 1007$). With the exception of primary sclerosing cholangitis (PSC) being more prevalent in UC, the frequencies of the other EIMs did not differ between these disease types.

Epidemiologic Aspects

Sykora et al. [18] noted a broad worldwide variation in the incidence of pediatric IBD with detailed numbers for many countries. For North America, it was highest for CD (0.7–13.9/100,000 person years, 0.5–10.6 for UC, and lowest for IBD-U (0.2–2.1/100,000). A meta-analysis of 14 studies of pediatric patients with IBD and 18 studies in adult patients with IBD showed a higher frequency of IBD-U in children (12.7%) versus adults (6.0%) [19].

Gupta et al. [7] reviewed the medical records of 428 children with IBD followed at the University Chicago. Of those, 49 (11.4%) were diagnosed with IBD-U. Within the IBD-U group, 42.9% had histology "favored ulcerative colitis" (UC) but these patients also had features of CD including areas of focal colitis, focal gastric or duodenal inflammation, anal fissures or isolated granulomas adjacent to ruptured crypts. Features "favoring Crohn's disease" (CD) were present in 20.4% of children with IBD-U, none of whom had granulomas, radiologic evidence of small bowel CD, or perianal findings. In the remaining 36.7%, there were no endoscopic and histologic findings favoring UC or CD. IBD-U was diagnosed after an X-ray study of the upper gastrointestinal tract with small bowel follow-through to exclude the possibility of Crohn's disease.

Heikenen et al. reported a prevalence of IBD-U (10%) in a pediatric population of IBD [9]. As a group, children with IBD-U were diagnosed at a younger age (7.8 years) than those with either UC (9.7 years) or CD (11.4 years).

Criteria for Histologic Diagnosis

In establishing a diagnosis of IBD-U, it is essential to exclude other causes of colitis such as infections (*Clostridium difficile*, Yersinia, *Mycobacterium tuberculosis*, *Entamoeba histolytica*, *E. coli* 0157:B7 or other verocytotoxin-producing strains), drugs (NSAIDS), Behçet's, malignancy, vasculitis, and certain immunologic disorders. Immune deficiency disorders which may include chronic intestinal inflammation are: chronic granulomatous disease, Wiskott-Aldrich syndrome, common variable immunodeficiency disease (CVID), immunodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX), and glycogen storage disease type 1b [1–2, 8, 20].

Geboes and Van Eyken [8] published an in-depth description of the histologic features observed in normal intestinal mucosa as well as the changes seen in patients with IBD. Focal or diffuse plasmacytosis at the base of the mucosa and crypt architectural changes are strong predictors of IBD. However, it is important to recognize that these findings develop during the course of IBD. Thus, while basal plasmacytosis was seen within 15 days of the onset of IBD, crypt distortion was observed at 16–30 days in only 25% of patients but increased to 75% after 4 months. By comparison with adults, children <10 years of age with new-onset UC show less crypt architectural changes and more rectal sparing than older patients. In addition, 4–8% the initial biopsies were within the normal range. The authors suggested that the presence of basal lympho-plasmacytosis, seen in 58% of cases, should lead to suspicion of underlying IBD. It in this group of children and adults with short history of disease onset, mild basal lympho-plasmacytosis, and no or minimal crypt architecture abnormalities the authors concurred with using the term "inflammatory bowel disease unclassified (IBD-U)."

Patients with IBD-U clearly have IBD but definitive features of UC or CD are absent. IBD-U may also be appropriate for cases of primary sclerosing cholangitis where rectal sparing and patchy or focal inflammation are also more frequently observed [2]. Guindi and Riddell [20] stated that to differentiate indeterminate colitis from Crohn's disease in *resected* specimens, submucosal and subserosal lymphoid aggregates away from areas of ulceration, non-necrotizing granulomas, and skip areas should be absent. This is particularly true where there is nonspecific ileal involvement or gastritis with negative stains for *H. pylori*.

In cases of fulminant colitis, overlapping features between UC and CD (relative rectal sparing, focal inflammation or deep fissuring ulceration) result in a diagnosis of IBD-U in approximately 10–15% of patients [8, 20]. It is also important to recognize that some medications, such as corticosteroids or aminosalicylic acid preparations, may change the diffuse histologic appearance in UC to a more focal appearance [1–2, 8, 20]. Thus, slides from the original or pretreatment colonoscopy should be reviewed when considering a diagnosis of IBD-U [1, 20, 21].

Although histologic criteria would appear to allow differentiation between CD and UC, Farmer et al. (2000) documented disparity among pathologists reviewing cases of colonic IBD [21]. The diagnosis of gastrointestinal pathologists differed from that of the referring institution in 45% of surgical specimens and 54% of biopsy specimens. Of 70

cases initially diagnosed with UC, 30 (43%) were changed to CD or IBD-U or IC, in contrast, 17% of cases initially diagnosed with CD were changed to UC or IBD-U or IC.

The performance of upper gastrointestinal endoscopy with biopsies (EGD) identifies some patients with Crohn's disease whose colonoscopy biopsies are not, by themselves, typical for CD [1–2, 22–24]. McHugh et al. [22] observed that while focal enhancing gastritis (FEG) was highly associated with IBD, 61% in IBD v 11.6 in non-IBD patients, it did not reliably distinguish between UC and CD [22]. Kundhal et al. showed that granulomas in the stomach or duodenum provide evidence confirming the diagnosis of CD even in endoscopically normal-appearing mucosa [23]. Hence, performing an EGD should be part of the initial evaluation of pediatric patients for IBD.

Winter et al. [24] used the EUROKIDS Registry to assess the frequency of change in diagnosis from IBD-U in children provisionally diagnosed with IBD-U. After undergoing repeat endoscopic and/or radiologic re-evaluations, mean 5.7 years after the IBD-U diagnosis, 20% children were diagnosed with UC and 10% CD. The authors noted that an initial incomplete diagnostic workup likely contributed to this change in diagnosis, since only 73% of the CD group had undergone small bowel imaging. They emphasized the importance of endoscopic or small bowel imaging in patients with active disease attributed to IBD-U.

Serologic Markers and Defining IBD Categories

Gupta et al. [7] evaluated the role of p-ANCA and anti-*Saccharomyces cerevesiae* (ASCA) to determine whether serology could identify UC and CD in pediatric patients previously diagnosed as IBD-U [7]. While p-ANCA was positive in 68% of those favoring UC, and ASCA positive in 37% of those favoring CD, 86% of patients with IBD-U were negative to both p-ANCA and ASCA.

Joossens et al. [10] correlated serologic markers in 97 adult patients initially diagnosed with IBD-U. After a mean follow-up of 6 years, 32% of adult patients with IBD-U were reclassified as having UC or CD, half of whom were positive for p-ANCA or ASCA. However, almost half of the patients with IBD-U (48.5%) remained p-ANCA/ASCA negative and continued with that diagnosis 10 years after the initial diagnosis.

Birimberg-Schwartz et al. [25] analyzed IBD serology patterns in 146 pediatric patients with IBD-U followed in the IBD Porto Group of ESPGHAN. As reported in adults, the most common pattern was p-ANCA−/ASCA− in 41% but other patterns were present as well including p-ANCA+/ASCA− in 34% and p-ANCA−/ASCA+ in 17%. The authors concluded that IBD serology was a poor discriminator to identify patients with IBD-U.

Radiologic Imaging

The most frequently used diagnostic studies (after ileocolonoscopy and EGD) for distinguishing among the various forms of pediatric IBD are those which image the small intestine such as magnetic resonance enterography (MRE) or small bowel follow-through (SBFT). Because of the ionizing radiation associated with SBFT, utilization of MRE is favored in children with IBD-U, UC, and CD [26]. MRE in combination with oral contrast, used to distend the small bowel, demonstrates increased wall thickness in children with CD while those with IBD-U and UC showed mild parietal contrast enhancement but not bowel wall thickening.

Capsule Endoscopy (CE)

Small intestinal capsule endoscopy (SBCE) has the potential to identify lesions in the upper GI tract, jejunum, and ileum which would allow differentiation between IBD-U and CD after conventional diagnostic modalities. Gralnek et al. [27] used SBCE to determine whether ulcers could be observed in four pediatric patients previously diagnosed UC or IBD-U, who were experiencing disease exacerbation. Based on abnormal mucosal findings, two of the four patients were reclassified with CD. In addition, 8 of 10 patients with "suspected IBD" were also found to have ulcerations and diagnosed with CD.

Goldstein et al. [28] performed SBCE in adult postcolectomy patients with IC (n = 20) and UC (n = 49) and were unable to identify patients who would be reclassified as de novo CD following IPAA. These authors cautioned that since SBCE may identify lesions in healthy individuals, as well as those who take NSAIDS, the specificity of mucosal these lesions is unclear.

Kopylov and Seidman [29] reported that the most common cause of lesions which mimic pediatric small bowel CD is NSAID medication. The authors noted that the lesions were indistinguishable from CD, occur as early as two weeks of use, and may be seen in up to 70% of chronic NSAID users. They advised instructing patients who will undergo CE to avoid NSAIDs for at least one month before the examination.

Another confounding variable is that small bowel inflammation was observed in a significant number of patients with established UC compared with non-IBD patients [30]. Of 23 UC patients, 13 (57%) showed small-bowel lesions and 8 (35%) had erosions, as opposed to 2/23 (7%) and 1/23 (4%)

in the control group. These findings emphasize the potential risk of misdiagnosis in IBD patients.

Natural History

With time, 50–72% of adult patients and up to 64% of pediatric patients with IBD-U are reclassified as definite UC or CD during subsequent observation [1–6, 14, 19, 25]. Moum et al. observed that of 36 patients initially diagnosed as IBD-U, 33% were reclassified as UC and 17% as CD after a follow-up period averaging 14 months [11]. Meucci et al. [12] reported that 37/50 patients (72.5%) changed from IBD-U to a definite diagnosis of UC or CD during follow-up with a cumulative probability of 80% within 8 years of diagnosis [12]. In contrast, Wells et al. followed 16 patients with IBD-U for a mean of 10 years and observed 3 were reclassified with UC, 1 with CD but 75% remained IBD-U [13].

The course of IBD-U in 36 Swedish children after a mean follow-up of 4.6 years was analyzed by Hildebrand et al. [6] Their findings were similar to those as described above in adults: 21/36 (58%) were subsequently categorized as UC, 2/36 (6%) CD, and 13/36 (36%) remained as IBD-U. Everhov et al. [31] in a later study of Swedish children reported that they were more likely to change their IBD subtype than adults over 3.8 years (29% v 17%): CD 43–44%, UC decreased 45–38%, and IBD-U increased from 12% to 18%.

In our series of 49 children with IBD-U, nine had undergone colectomy at a mean of 24 months after diagnosis of IBD-U [7]. After a mean follow-up of 42 months, 6/9 with postsurgical diagnosis of IC had repeat endoscopic examinations resulting in reclassification consistent with UC in 3/9 (33%), IC in 2/9 (22%), and CD in 1/9 (11%). Malaty et al. [32] described a 12-year telephone follow-up of 20/60 pediatric patients who had been previously diagnosed with IBD-U The range of outcomes was broad: 30% remained IBD-U, 10% reclassified as CD, 5% as eosinophilic colitis but 55% reported a complete resolution of their symptoms.

Medical Therapy

The observation that many patients with IBD-U are reclassified as UC or CD has made it difficult to establish whether IBD-U represents a separate form of IBD. Perhaps because of the smaller number of patients with IBD-U and the variability of their histologic findings, the response to various drug regimens in this population has not been specifically addressed.

In our program, the choice of therapeutic intervention (see Table 29.2) is selected depending on the severity of symptoms, extent, and severity of endoscopic and histologic findings and laboratory parameters. Given the current state of knowledge of IBD-U, most pediatric patients receive drug therapy which is similar to that indicated for UC with comparable extent and severity. These include 5'aminosalicylic acid (5'ASA, mesalamine) preparations for mild disease and corticosteroids and immunomodulatory and/or biologic therapy for moderate and severe disease. In the past, immunomodulatory agents, such as azathioprine or 6-mercaptopurine, were used in approximately 60% of our pediatric population with IBD due to the presence of steroid dependency, resistance, or toxicity. More recently, there has been a trend among pediatric gastroenterologists to use methotrexate for immunomodulation when concomitant therapy is indicated. The expectation is that there may be a lower risk of malignancy, especially hepatosplenal T-cell lymphoma, than with the combination of thiopurine and anti-TNF therapy.

Table 29.2. A medical approach to the pediatric patients with IBD-U

5'Aminosalicylic acid preparations (5'ASA, mesalamine) for mild disease
Corticosteroids (moderate to severe disease severity)
Immunomodulators, if indicated
Azathioprine (AZA) or 6-mercaptopurine (6-MP)
[Measure thiopurine methyltransferase (TPMT) prior to use to exclude deficiency
Monitor RBC 6-thioguanine (6-TG) levels, CBC, ALT to reduce risk of toxicity
Methotrexate for combined therapy
Biologics: Anti-TNFα preparations for moderate to severe disease.
No published studies for anti-α4β7 integrin, anti- IL-12/23 in pediatric IBD-U.

*Note: There are no published pediatric trials which have specifically addressed the response to these medications in patients with IBD-U. These recommendations are based on the limited clinical reports of use in pediatric patients with IBD-U [4–5] and published guidelines for ulcerative colitis in pediatric patients

Some clinical trials of adult patients with IBD have included small numbers of patients with IBD-U although not specifically addressing therapeutic response in this group. Clinical response to infliximab in 20 adult patients with refractory IBD-U was reported [33]. In that study, 14/20 (70%) showed a "complete clinical response" and 2/20 (10%) "partial response."

In the absence of clinical trials in pediatric IBD-U patients, Aloi et al. [4] reviewed various treatments and outcomes of 797 pediatric patients with isolated colonic IBD and compared results between groups of patients with IBD-U, UC, and CD after mean follow-up of 2.8 years. Patients with IBD-U were more likely to have received 5-ASA than those with UC (88% v 71%) and less likely to be treated with corticosteroids than UC (59% v 71%) or immunomodulators than CD (26% v 52%). At follow-up, remission or mild disease (PGA < 1) in IBD-U was similar to UC (69% v

64%) but significantly more frequent than CD (46%, $P = 0.0001$). Biologics were also similar between IBD-U and UC (17%, 14%) but used less often than CD (34%, $P = <0.001$). The authors concluded that IBD-U tends to have a milder course than UC and CD with less requirement for corticosteroids, immunomodulators, and biologics and suggested that mesalamine could be considered for the initial therapy of pediatric patients with IBD-U. Favorable outcomes in pediatric patients with UC and CD suggest that anti-TNF agents will also be effective in some patients with IBD-U who are not responding to conventional medications.

Surgical Treatment

Conflicting data has been published regarding medical failure and complication rates following medical and surgical intervention in patients with IBD-U versus UC. Some centers report that IBD-U is more refractory to medical intervention than UC resulting in a greater relapse rate and subsequent need for colectomy. In contrast, Witte et al. [34] described similar response rates to medical intervention in IBD-U and UC for patients enrolled in the European Collaborative Study on Inflammatory Bowel Disease (EC-IBD). "Complete relief of complaints" was noted in 48% of UC patients versus 50% of those with IBD-U. Partial response was also similar in both groups: 37% of patients with UC "improved" versus 33% with IBD-U.

One of the most important reasons for distinguishing IBD-U from UC and CD is for counseling the patient and family about the potential increased risk for complications and possible subsequent change in diagnosis following IPAA. Higher rates of pelvic sepsis, fistula formation, and pouch failure after ileal pouch-anal anastomosis (IPAA) occur in patients diagnosed with IC after surgery versus UC [35]. A potential positive finding is that patients diagnosed with IC after surgery who are p-ANCA and ASCA negative have lower risk for pouchitis, pouch complications, and the development of Crohn's disease [36]. Thus, obtaining these serologic tests in patients being evaluated for IPAA may provide useful predictive information [37].

It is our practice to repeat colonoscopy, usually with concurrent EGD, during selected periods of relapse, if a higher level of therapy is being considered to assess whether histologic changes consistent with UC or CD have developed in patients with IBD-U. This is especially the case if colectomy and ileal pouch anal anastomosis (IPAA) are being advised because of refractory disease. Part of the reassessment should include repeat small bowel x-ray imaging so that patients with ileal CD would be excluded from IPAA. Patients with persistent IBD-U are counseled regarding the potentially greater risk of pouch complications. Patients diagnosed with IC after reviewing the colon pathology undergo a multistaged operative course consisting of a total abdominal colectomy with temporary ileostomy and Hartmann pouch. In this way, the entire resected colon can be assessed to exclude Crohn's disease prior to creating the IPAA.

Multicenter Collaborative Studies Supporting IBD-U as a Separate IBD Subtype

Two recent large multicenter pediatric studies have further advanced the concept of IBD-U as a separate and intermediate subtype between Crohn's disease and typical ulcerative colitis. Birimberg-Schwartz et al. [38] using the Porto Group Registry published criteria with a goal of standardizing the classification of the different subtypes of IBD (small bowel CD, isolated Crohn's colitis, IBD-U, atypical UC, and typical UC), but focusing on those with the isolated colon phenotype [38]. The authors proposed a list of 23 features based on the presence or absence of perianal findings, macroscopic appearance on endoscopy, histology of mucosal biopsies, and abnormal radiologic findings such as thickened bowel loops or fistulae which were placed into one of three classes. Class 1 contained features consistent with Crohn's disease and these patients were excluded from further analysis. Class 2 also had features suggestive of Crohn's, such as rectal sparing, ileitis which could be backlash, positive ASCA with negative p-ANCA, but which could occur in up to 5% of UC cases. Class 3 included focal colitis on histology and <5 aphthous ulcers in the stomach or colon which can occur in 5–10% of UC cases.

At follow-up, mean 2.8 years, 79% of pediatric patients diagnosed as IBD-U maintained their diagnosis and 21% changed to UC or CD. The major feature associated with a change in diagnosis to CD was the presence of ileitis with only mild inflammation in the ascending colon. This is in contrast to the backwash ileitis seen in ulcerative colitis win association with severe pancolitis with cecal involvement.

Macroscopic upper gastrointestinal involvement on endoscopy was statistically different between the three groups with IBD-U being intermediate between CD and UC: CD 53%, IBD-U 41%, and 28% in UC. Although the follow-up was of short duration, the authors concluded that their low reclassification rate supported the concept that IBD-U is a "true intermediate phenotype." IBD serology did not improve the accuracy of the algorithm.

Recently, Dhaliwal et al. [39] compared the clinical IBD diagnosis with that predicted using the PIBD classes algorithm in a group of 62 pediatric patients with colonic IBD (UC, CD, or IBD-U) prior to colectomy with the postcolectomy histologic diagnosis. Clinical diagnosis was more con-

cordant with the postcolectomy diagnosis in 58/62 patients (94%) compared with the IBD classes algorithm concordance in 51/62 patients (82%).

In 2018, Chandradevan et al., using data from the RISK study population, compared IBD serology and RNASeq gene expression profiles in terminal ileal and rectal biopsies from an inception cohort of pediatric patients with IBD-U, CD, and UC [5]. In this population of 1411 subjects, 136 were initially diagnosed with IBD-U. After 2 years of follow-up, 60% of subjects remained IBD-U, 26% were reclassified as UC, and 14% as CD. Both serology profiles and mucosal gene expression profiles in the IBD-U group were very similar to UC and dissimilar to CD. With regard to serology, the only difference between the IBD-U and UC groups was a higher percentage of ANCA+ in the UC group (64.9% v 43.5%). In contrast, three serologies (ASCA, CBir1, and OmpC) were statistically different between CD and IBD-U ($P < 0.0001$).

Gene expression profiles between IBD-U and UC in both ileal and rectal biopsies were similar with a small number of differences between them 15/5084 (TI) and 26/16,408 (rectum). In contrast, differences in gene expression profiles were much greater between IBD-U and CD, 5084/5094 (TI) and 2645/16,408 (rectum). These results suggest that IBD-U is more like UC than CD on a molecular basis. Clinically, anti-TNFα was required by significantly more patients with CD (50.3%) compared with UC (27.8%) and IBD-U (24.2), $P = <0.0001$. In this short follow-up period, no disease-modifying effects were noted in patients with IBD-U or UC who received anti-TNFα compared with reduction in penetrating disease observed in the RISK CD population which was published in 2017 [40].

Conclusions

IBD-U is being increasingly recognized as a separate subtype in the classification of chronic IBD, remaining separate from UC and CD in many cases after long-term follow-up. In young patients or those with recent-onset symptoms, the histologic features are less likely to have developed typical features [1, 8]. Patients and families should understand that IBD-U is not indefinite colitis but rather a form of chronic inflammatory bowel disease which may either remain as IBD-U or become more consistent with UC or CD over time. The clinical observations from many groups, as described above, conclude that the course of IBD-U is more like UC than CD and therapies favored for UC should be considered in the treatment strategies for IBD-U. The results emanating of the RISK study by Chandradevan et al. provide mucosal gene expression profile and IBD serology associations to support IBD-U as a separate form of IBD [5].

Ulcerative Colitis

30

Anita Rao and Ranjana Gokhale

Introduction

Chronic inflammatory bowel diseases (IBD), which include Crohn's disease (CD), inflammatory bowel disease unclassified (IBDU) and ulcerative colitis (UC), are important causes of gastrointestinal disease in children and adolescents. The early age of disease onset in some children, variable clinical presentations, therapeutic challenges, as well as emotional needs of children and their parents pose difficult challenges to the gastroenterologist.

Epidemiology

UC has an increasing incidence and prevalence worldwide, especially in adolescents and young adults. The incidence of UC may vary from 0.5 to 31.5 per 100,000 people each year, depending on the studied population. In general, the disease has a high occurrence in Western countries such as those in North America and Northern/Western Europe compared to Asian countries. However, incidence rates have plateaued or even decreased in Western countries over time, and in contrast incidence has been steadily increasing in more developed countries in Asia as well as in Central and South America. In Asia in particular, the incidence of IBD is 1.4 cases per 100,000 people and climbing [1].

There is also a geographical gradient for the incidence of IBD, with higher rates in the north as compared to the south [2]. Additionally, pediatric-onset IBD continues to increase steadily. As IBD is a chronic disease with relatively low mortality that is diagnosed primarily in young people, the prevalence of IBD increases over time such that new diagnoses add to the base population at a rate significantly higher than the loss of patients from a clinical practice [1].

According to a single-center prospective study by Capone et al. there was an increase in the prevalence of IBD for first-degree relatives and all relatives at 20 years from the time of diagnosis by 12.9% and 13.7%, respectively. Additionally, positive family history at diagnosis was associated with a 2-fold greater likelihood of subsequent positive family history at 20 years. This suggests an increased role of environmental factors and lifestyle effects on the pathogenesis of UC [3].

The female to male ratio for UC differs between 0.51 and 1.58, indicating that UC is not sex specific. Any age group from infants to the elderly can be affected, but the peak age of onset is between 15 and 30 years with a second but smaller peak between 50 and 70 years. About 20 to 30% of patients with UC and CD have the onset of their symptoms below the age of 18 years, and about 5% of cases occur before age 10 years [4].

Pathogenesis

UC can be considered an immune-mediated disorder that develops in genetically predisposed individuals because of dysregulated immune responses against environmental and intraluminal antigens [5]. More recently the focus of research has shifted to examining the interplay between the environment (mainly the intestinal flora) and the defense mechanisms of the intestinal barrier (mainly the mucosal layer and the mucosal immune system). These aberrant immune responses to commensal microbes likely result in lesions of the intestinal mucosal layer involving extensive epithelial damage, immune infiltration, crypt abscesses, and chronic inflammation, which are hallmarks of UC [6].

Genetics

In a recent meta-analysis of genome-wide association studies (GWAS) for CD and UC, more than 200 IBD-associated loci were identified. Many of them are associated with both UC and CD. These regions contain candidate genes for a variety of functions like autophagy, microbe recognition, lymphocyte signaling, response to endoplasmic reticulum stress, and cytokine signaling, among others. While GWAS has uncovered many new pathogenesis pathways, each locus only has a very small to modest effect size, with the exception of a strong association for the human leukocyte antigen (HLA) loci on chromosome 6 that has consistently shown a large effect on UC susceptibility [7].

UC is more common in the Jewish population. The lower concordance rate in monozygotic twins of 15% and in dizygotic twins of 5% in UC, compared with 50% in monozygotic twins and 20% in dizygotic twins in CD, indicates that genetic contribution in UC is weaker than in CD [8]. In the case of "very early onset" or VEO-IBD, mutations of the genes *IL-10RA*, *MSH5*, and *CD19* are associated with disease development [9].

Environmental Factors

Increasing incidence particularly in industrialized countries indicates environmental influences in the development of UC. In fact, cesarean delivery, lack of exposure to breast milk [10], increased dietary fat intake (i.e. a "western diet"), and early exposure to antibiotics have all been implicated as risk factors for IBD. Patients with newly diagnosed UC are more likely than age-matched controls to have a history of gastroenteritis [11]. Interestingly, early appendectomy prior to the age of 20 years is associated with decreased risk of UC [12]. In a meta-analysis of 13 studies examining the relationship between UC and smoking, there was an association between former smoking and the development of UC, with current smoking having a protective effect on the development of UC compared to controls [13, 14].

Children of persons who emigrated from an area of low prevalence to one of high prevalence show an increased risk of UC than the immigrants themselves, suggesting that environmental factors in early life that affect the developing immune system and microbiome are essential to UC pathogenesis [5, 15]. The natural geographic distribution of IBD, with higher rates seen in the north and lower rates seen in the south, introduces the question of whether vitamin D and sunlight are protective factors.

UC and the Microbiome

The IBD gut is characterized by reduced microbiome diversity and a depletion of protective bacteria such as short-chain fatty acid (SCFA)-producing Ruminococcaceae and Lachnospiracaea that coincides with an expansion of pro-inflammatory microbes such as Enterobacteriaceae, including *Escherichia coli* and Fusobacteriaceae [6]. SCFAs including butyrate are a major fuel source for colonic epithelium and are associated with better gut health; notably, oxidation of butyrate is impaired in UC patients [16]. Blooms of *Ruminococcus gnavus* strains and an increase in facultative anaerobes co-occur with more severe IBD activity. Microbes also show protective effects in mouse models, and *Bacteroides fragilis* mono-colonization has been shown to protect against induced colitis. Depletion of butyrate-producing *Faecalibacterium prausnitzii* in IBD has been reported previously in the literature, and animal studies have shown that *F. prausnitzii* inhibits IL-17 and suppresses Th17 activity, suggesting an association between this bacterium and reduced mucosal inflammation. Topical butyrate is effective as an adjunct therapy for UC, and butyrate enemas have been shown to reduce mucosal inflammation in distal UC, indicating a benefit of increased butyrate levels. The anti-inflammatory activity of butyrate in UC has been associated with inhibition of NF-kB activation in lamina propria macrophages, reducing cytokine secretion and inflammation [6]. Early onset dysbiosis may cause immune disruptions that result in microbiome intolerance by the host. Factors that cause early-life dysbiosis, including antibiotic usage, have gained more attention as the incidence of pediatric IBD has increased dramatically [17].

Clinical Manifestations

UC always affects the rectum and extends proximally in a symmetric fashion involving variable lengths of the colon. Involvement could be limited to the rectum (proctitis), or can extend to the distal colon (up to splenic flexure or left-sided colitis) or the entire colon (pancolitis). Children tend to have a higher likelihood of pancolitis at presentation as well as proximal extension of disease over time compared to adults [18]. In fact, 60–90% of pediatric UC presents with pancolitis, which is twice as often as adult UC. Additionally, pediatric UC carries a 30–40% colectomy rate at 10 years, compared to 20% in adult UC. Childhood-onset disease is also characterized by a higher risk of corticosteroid dependency and earlier immunosuppressive therapy introduction [19].

Intestinal Manifestations UC is usually diagnosed earlier after the onset of symptoms than CD, as rectal involvement leads to the presence of gross blood in the stools alerting parents and physicians to a gastrointestinal problem. The most consistent feature of UC is the presence of blood and mucus mixed with stool, accompanied with lower abdominal cramping that is most intense during the passage of bowel movements. Patients may also experience tenesmus, which a sensation of needing to evacuate stool. The location of abdominal pain depends on the extent of colonic involvement. Pain in the left lower quadrant is associated with distal disease and extends to the entire abdomen with pancolitis. Systemic symptoms including fever, anorexia, weight loss, and anemia may occur with fulminant colitis [11].

Nevertheless, the diagnosis of pediatric-onset UC may be more challenging due to the existence of atypical phenotypes. "Atypical UC" is suggested when features not characteristic of classic UC are present, but common enough in UC to preclude the diagnosis of CD. In particular, six different atypical phenotypes have been recently identified in the revised criteria from the Pediatric IBD Porto Group of the European Society of Pediatric Gastroenterology, Hepatology, & Nutrition (ESPGHAN) for the diagnosis of pediatric UC: rectal sparing, short segment disease, cecal patch, upper gastrointestinal (UGI) findings, acute severe colitis (ASC), and "backwash ileitis" [19]. The presence of ileitis may complicate the potential diagnosis of UC, and although UC is restricted to the colon by definition, nonspecific mucosal inflammation in the terminal ileum (called "backwash ileitis") may be found in up to 20% of UC patients [20]. According to the Porto criteria, backwash ileitis should entail a "short segment of nonstenotic erythema or edema in the presence of pancolitis including the ileocecal valve, without granulomata or deep ulcers" which would suggest CD [21].

Extraintestinal Manifestations
