Bacterial, Fungal and Parasitic Infections of the Liver

64

Anita Verma

Introduction

Primary nonviral infections of the liver parenchyma itself are uncommon; presumably the phagocytic Kupffer cells play a key role in preventing the infection. The liver's dual blood supply renders it uniquely susceptible to infection, receives blood from the intestinal tract via the hepatic portal system and is sustained by systemic circulation via the hepatic artery. Because of this unique perfusion, the liver is frequently exposed to systemic or intestinal infections or the mediators of toxaemia. The biliary tree provides a further conduit for gut bacteria or parasites to access the liver parenchyma.

Infections of the liver with a wide range of organisms present variously from asymptomatic biochemical abnormalities to symptomatic hepatitis or space-occupying lesions, for example, abscesses or granulomata producing biochemical changes of cholestasis but rarely significant jaundice. Some of these infections have a high mortality if not treated promptly. We describe nonviral infectious diseases affecting the liver caused by bacteria, mycobacteria, spirochaetes, rickettsia, fungi and parasites.

Bacterial, Spirochaetal and Rickettsial Infections

Bacterial Sepsis

Bacterial sepsis precipitating jaundice is a well-recognized phenomenon particularly in the newborn and young infants [1]. The exact pathogenesis of hepatic insult is not known but may be multifactorial, including direct invasion of liver parenchyma by blood-borne pathogens and nonspecific injury due to hypoxia or endotoxin-mediated paralysis of biliary canaliculi inducing cholestasis. Implicated bacteria include 'coliforms', pseudomonads, *Salmonella* spp., anaerobes, *Haemophilus influenzae*, streptococci and *Staphylococcus aureus.* In patients with jaundice, serum bilirubin is usually between 5 and 10 mg/dl. Hepatomegaly is found in 50% of cases, and liver enzymes are usually mildly elevated. Clinical evaluation and microbiological investigation may identify the source of sepsis, and antimicrobial therapy usually results in complete resolution.

Liver Abscess

Pyogenic liver abscess (PLA) in infancy and childhood is uncommon, with incidence ranging from 25 to 400 per 100,000, but carries a high mortality [2–4]. PLA is uncommon in developed countries, but higher prevalence has been reported from developing countries [2–5]. Though PLA in healthy children is a rare entity, up to 40–50% has occurred among immunocompromised children [2]. Pyogenic bacteria can reach the liver through various routes: (i) portal, secondary to gut pathologies such as appendicitis, inflammatory bowel disease or diverticulitis, sometimes complicated by portal pyelophlebitis and portal vein system thrombosis; (ii) biliary, caused by extrahepatic biliary tract disease such as stricture, calculus or malignancy; (iii) blood-borne from an infected focus anywhere in the body via hepatic artery; (iv) contiguous extension from gallbladder or perinephric abscess; (v) following penetrating wounds of liver; and (vi) cryptogenic [2, 5].

PLA may present as single large lesion or multiple abscesses, the latter are often secondary to biliary tract infection. The importance of the portal venous route has fallen with better diagnosis and management of appendicitis. In most reviews, more than 60% abscesses are in the right lobe, 20–25% bilateral and less than 15% in the left lobe [4, 5]. Predisposing factors include immunosuppression, quantitative or qualitative granulocyte abnormalities like

chronic granulomatous disease, trauma, umbilical vein catheterization, omphalitis, sickle-cell disease, biliary tract surgery, hepatic artery thrombosis (post-liver transplantation), liver biopsy, percutaneous or endoscopic biliary drainage, diabetes, worm infestation and protein-energy malnutrition especially in developing countries [4, 5].

Multiple abscesses complicate biliary diseases such as bacterial cholangitis, sclerosing cholangitis, congenital biliary anomalies (Caroli's disease) and gallstones with higher mortality. The aetiology of PLA is variable. *S. aureus* is the most common isolate reported in children from developed world and mostly associated with underlying condition of chronic granulomatous disease [5]. Gram-negative aerobes (*Klebsiella* spp., *E. coli*) were the most common organisms reported from developing countries [2, 4, 5]. Less frequent causes include, e.g. anaerobes, microaerophilic streptococci, *Pseudomonas* spp., *Clostridium* spp., *Salmonella typhi, Yersinia enterocolitica* and *Pasteurella multocida*.

The classic presentation is pyrexia, chills, right upper quadrant (RUQ) tenderness, abdominal pain, hepatomegaly and leucocytosis but may be nonspecific. The diagnosis must be entertained in any pyrexia of unknown origin (PUO). Unusual presentations include an abdominal mass or acute abdomen secondary to rupture into the peritoneal cavity or portal hypertension secondary to portal pyaemia and portal vein thrombosis. Liver function tests may be unhelpful with nonspecific changes. Ultrasonography (USS), computerized tomography (CT) and magnetic resonance imaging (MRI) are all sensitive but cannot always differentiate abscesses from other lesions such as cysts, tumours or haemorrhage. USS- or CT-guided drainage of as much pus as possible (from as many abscesses as possible) confirms diagnosis and is central to the management. Initial treatment is conservative with broad-spectrum antibiotics (e.g. cefotaxime plus metronidazole or clindamycin) and should be adjusted when culture results are available [5, 6]. Duration of treatment is usually 3–6 weeks. Patients with multiple abscesses have to be on conservative treatment after a diagnostic tap, and up to 3–4 months of antibiotic therapy has been recommended to prevent relapses [5]. Prognosis is worse in multiple abscesses. Most reports emphasize the good outcome after percutaneous drainage, which should be USS or CT guided [6, 7]. Contraindications to drainage include ascites and inaccessible lesions. Complications of aspiration include haemorrhage, hepatic laceration, fistula formation, peritonitis and additional abscess formation. Indications for open drainage procedure are biliary obstruction, loculated or highly viscous abscesses, persistence of fever for more than 2 weeks despite percutaneous catheter drainage and appropriate antimicrobial therapy [7]. Predisposing immunodeficiency conditions should be managed with appropriate expert opinion from immunologists or infectious disease experts.

Cholangitis

The normal biliary tract is sterile, and, in children, acute cholangitis rarely occurs in the absence of congenital abnormalities or interventions to the biliary tract [8]. The children at highest risk include those with portoenterostomy or choledochal cyst, those with underlying condition of primary sclerosing cholangitis and those who have nonoperative biliary manipulations such as transhepatic cholangiography or endoscopic retrograde cholangiography with stent placement. Risk of cholangitis in children after Kasai operation has been reported to be 40–50% [8]. Partial biliary obstruction encourages bacterial growth, with increased intraductal pressure and reflux of bacteria into blood vessels and perihepatic lymphatics leading to bacteraemia. Infection may ascend from the duodenum or an infected gallbladder or via lymphatics or bloodstream [9].

Cholangitis is a clinical diagnosis based on fever, abdominal pain, jaundice, pale stools or hepatic tenderness. However, the spectrum encompasses mild disease to severe sepsis, or shock, with bacteraemia [8]. Although *Escherichia coli, Klebsiella* spp., *Enterobacter* spp. and *Pseudomonas* spp. are usually implicated, infection may be polymicrobial and include anaerobes [8]. Leucocytosis is common, but changes in liver function tests are nonspecific; the serum bilirubin may be normal. In recurrent cholangitis, liver biopsy may be indicated for confirmation and microbiological examination. Treatment requires supportive care, and an urgent USS or CT will help establish whether obstruction requires drainage. Broad-spectrum antibiotics should be administered—such as an acylureidopenicillin (piperacillin, mezlocillin or piperacillin-tazobactam) or a late-generation cephalosporin (e.g. ceftazidime), plus an aminoglycoside [10]. Single agents, such as piperacillin-tazobactam, ciprofloxacin and imipenem or meropenem, appear safe and effective if an aminoglycoside is contraindicated. Duration of treatment is generally 3 weeks for acute cholangitis, but prolonged therapy may be necessary for recurrent cholangitis and multiple resistant bacteria [11]. Three months of intravenous antibiotics through central line has been helpful in treating recurrent cholangitis in biliary atresia children with portoenterostomy. Prolonged antimicrobial therapy in recurrent cholangitis only helps in preventing the bacteraemia by preventing bacterial overgrowth in biliary tract. With prolonged antibiotic therapy, there is always risk of development of resistant organisms and therefore more serious infection.

Tuberculosis

Tuberculosis (TB) of the liver is almost invariably a complication of miliary disease and occurs in 50% and 75% of patients with pulmonary or extrapulmonary TB, respectively.

The site of primary focus usually dictates presentation. Rarely the liver appears to be the sole site of infection such as in congenital TB acquired via the ductus venosus [12, 13]. Congenital TB may present in first few weeks of life with failure to thrive, hepatosplenomegaly and jaundice. In older children, hepatic TB presents with PUO, weight loss, abdominal discomfort and hepatomegaly [12, 13]. In areas of low incidence, a positive tuberculin skin test and quantiferon blood test (interferon-gamma release assay) is diagnostically useful. However, confirmation requires liver biopsy, histology and culture confirmation. Caseating granulomata on liver biopsy are highly suggestive of TB but may be absent; a granulomatous hepatitis can complicate bacillus Calmette–Guerin (BCG) administration. The diagnosis of TB should be sought by specific staining and culture of material from other sites, including bronchoalveolar lavage, lymph node or pleural biopsy, marrow aspirate, lumbar puncture or early morning gastric aspirates, as clinically indicated. Polymerase chain reaction (PCR)-based tests may be helpful but require further evaluation. Standard antituberculous therapy is effective, but expert advice should be sought in areas with a high incidence of drug-resistant TB or in compromised patients, including those with concurrent HIV infection.

Brucellosis

It is a multisystem infection caused by *Brucella melitensis, B. suis, B. abortus* and *B. canis; B. melitensis* causes more severe disease with a higher risk of chronicity. In endemic areas, transmission is often by ingestion of unpasteurized dairy products or raw meat. Granulomatous hepatitis may occur in acute or chronic disease and manifests as nonspecific changes in liver function tests [14]. Diagnosis requires clinical suspicion, blood and bone marrow cultures, serology and histopathological examination. PCR-based tests for brucellosis are available. The recommended treatment for children under 9 years of age with uncomplicated brucellosis is trimethoprim–sulphamethoxazole. For the treatment of serious infection, the addition of gentamicin or streptomycin is recommended for the first 1–2 weeks. Older children should receive doxycycline (6 weeks) plus rifampicin or streptomycin (2 weeks).

Listeriosis

Listeria monocytogenes may cause liver disease as part of systemic intrauterine infection of the foetus—granulomatosis infantiseptica at birth or later in the neonatal period—and in older immunocompromised children after ingestion of contaminated food or water. The major hepatic manifestation is granuloma; jaundice is rare. Diagnosis is achieved by recovering the bacterium from blood culture, cerebrospinal fluid or liver aspirates. Treatment is with high-dose ampicillin, with or without gentamicin.

Tularemia

Francisella tularensis has been isolated from many wild mammals, domestic animals and birds. Human infection usually follows bites from parasites of these animals or direct contact with animals. In some cases, a hepatitis-like picture follows with raised aminotransferases. Hepatomegaly is rare and biopsy may show necrosis. Diagnosis is usually serological as the bacterium is difficult to recover in culture. Treatment with streptomycin or gentamicin is effective; the fluoroquinolones appear promising but require further evaluation.

Leptospirosis

Human infection follows exposure to leptospires excreted in the urine of chronically infected animals—including rats, cattle and dogs—or water contaminated with urine. Children are usually infected when swimming in contaminated rivers, ponds or lakes or by canine exposure [15]. Leptospires gain entry via skin abrasions, conjunctivae or mucosae, and an initial leptospiremia presages a multisystem infection. The incubation period is 5–15 days, and in 90% of patients there is a self-limiting anicteric disease, but 5–10% develop jaundice (Weil's disease) [16]. Classically, the anicteric leptospirosis runs a biphasic course, with a leptospiremic phase lasting for 3–7 days and a second phase associated with leptospiruria and rising antibody titres lasting for 4–30 days. Predominant manifestations are fever, headache, myalgia, abdominal pain, nausea, vomiting, meningism, conjunctival suffusion, maculopapular rash, impaired renal function, lymphadenopathy and hepatosplenomegaly. Weil's disease is characterized by hepatic, renal and vascular dysfunction with persistent fever, profound jaundice, abdominal pain, renal failure, confusion, epistaxis, haematuria, gastrointestinal bleeding and other haemorrhagic phenomenon. Death may follow cardiovascular collapse, renal failure and gastrointestinal or pulmonary haemorrhage, though with supportive therapy mortality should be less than 10%. Liver histology reveals swollen perivenular hepatocytes with increased mitoses indicative of regeneration and disorganized liver cell plates. Leptospires may be recovered from blood, urine or cerebrospinal fluid (CSF) during the first week of illness, and from urine thereafter, and may be seen by dark ground microscopy of blood in the early stage of disease and in urine thereafter. Diagnosis, however, is usually serological using complement fixation tests (CFTs), enzyme-linked immunosorbent assay (ELISA)

or a microagglutination test. PCR can detect leptospiral DNA in blood, serum, CSF, urine or aqueous humour. Penicillin or doxycycline is recommended and most beneficial if started early in the disease: The benefits of commencing antimicrobials later in Weil's disease are less clear.

Borreliosis

Borrelia burgdorferi is a tick-borne spirochaete which causes systemic infection in humans (Lyme disease) following exposure to these vectors in forest or parkland. Predominant manifestations of acute disease are fever, malaise, extending erythematous rash, meningism, arthralgia, hepatitis and lymphadenopathy. Abnormal liver function tests occur in up to 20% of patients and, rarely, hepatomegaly and RUQ tenderness [17]. Diagnosis requires clinical suspicion, positive serology and histopathology. Spirochaetes may be seen in liver biopsy with a mixed inflammatory infiltrates in sinusoids, mitotic activity and ballooning degeneration of hepatocytes with hyperplastic Kupffer cells. Ampicillin or amoxicillin is administered for 3 weeks in early disease in children less than 9 years of age and tetracycline for older children. In late disease, intravenous cefotaxime or ceftriaxone for 2–4 weeks is recommended followed by oral ampicillin plus probenecid for a further 4–8 weeks.

Syphilis

Treponema pallidum may infect the foetus at any stage of maternal syphilis, causing disseminated infection. Congenital syphilis may result in mucocutaneous lesions, a diffuse rash, pneumonitis, myocarditis, hepatosplenomegaly, jaundice, lymphadenopathy, haemolytic anaemia, thrombocytopoenia, perichondritis and osteochondritis; the infant is usually small for age. Late stigmata include arthropathy with bilateral knee effusions, notched upper incisors and frontal bossing of the skull and poorly developed maxillae. Neonatal death usually results from liver failure, severe pneumonia or pulmonary haemorrhage. Diagnosis requires detection of spirochaetes by darkfield examination (skin rash, nasal secretions) or serology, including detection of specific IgM antibodies; long bone radiography at 1–3 months of age may contribute to diagnosis. Benzylpenicillin (10–14 days) remains the drug of choice.

Q Fever

Q fever is a systemic infection caused by the rickettsia *Coxiella burnetii* following exposure to infectious dust or aerosols from farm or domestic animals or consumption of raw milk. Illness is usually a self-limiting 'flu-like illness' with an incubation period of 1–2 weeks. However, acute Q fever can present with atypical pneumonia and hepatitis with jaundice, hepatomegaly and abnormal liver function tests [18]. The characteristic histopathological finding is granulomata with dense fibrin rings around central lipid vacuoles. Diagnosis is by detecting immunoglobulin G (IgG) and immunoglobulin M (IgM) to phase II antigens of *C. burnetii*, usually by indirect fluorescent antibody test or ELISA. Seroconversion occurs at 7–15 days after the onset of symptoms with 90% patients having detectable antibodies by the third week. Titres of antibodies to phase I antigens exceed those to phase II antigens in chronic disease. Treatment is recommended for all cases to prevent chronicity; doxycycline or chloramphenicol is effective. Treatment duration depends on if it is acute or chronic Q fever. For acute infection, it is 2–3 weeks. But in case of chronic infection it can be as long as 12–18 months.

Parasitic Infections

Amoebiasis

Entamoeba histolytica is most commonly encountered in the tropics and subtropics. Hepatic abscess is a major complication of invasive amoebiasis and seen in 3–9% of adult cases but is less common in children [19]. Amoebic trophozoites reach the liver via the portal vein and induce hepatocyte apoptosis and a leucocyte response resulting in abscesses containing viscous brown pus. Hepatic abscesses can be demonstrated by USS or CT scanning and are usually single and most frequent in the right lobe. Multiple abscesses may be associated with more severe disease. A typical presentation is with pyrexia (75%) and RUQ pain radiating to the right shoulder. In left lobe disease, there may be epigastric or left shoulder pain. Tenderness in the hypochondrium (85%), tender hepatomegaly (80%) and localized swelling over the liver (10%) may be elicited [20]. Less specific symptoms include nausea, vomiting, concurrent diarrhoea or dysentery (10%) and loss of weight. Jaundice is present in up to 8% of cases. The white blood cell count is usually elevated. Demonstrating cysts in stool may contribute to diagnosis, but serum antibodies are present in more than 95% of patients. Aspiration under USS guidance may yield 'anchovy sauce' pus; rarely amoebas are seen in necrotic abscess wall or adjacent parenchyma. Abscesses may rupture into the peritoneal cavity, pleural cavity or lungs, pericardium, portal vein or biliary tract, intraperitoneal rupture being more common than intrathoracic. Extraintestinal amoebiasis should be treated with metronidazole or dehydroemetine for at least 2 weeks [21]. The cure rate with both the drugs are same, but metronidazole has the advantage of being less toxic and being effective for both hepatic and intestinal phases of the

disease. To prevent continued intraluminal infection, luminal amoebicide, such as paromomycin or diloxanide furoate, should be given. Occasionally, amoebic abscesses do not respond to metronidazole, and addition of daily chloroquine may be considered for 2–3 weeks. Chloroquine has an additive effect to metronidazole and better penetration of the abscess wall. Percutaneous needle aspiration is recommended for large abscesses, failure to respond or if there is imminent risk of rupture, particularly in to the pericardium.

Schistosomiasis

Schistosomiasis affects 200 million people worldwide, the majority of children aged 5–15 years [22]. Transmission occurs in endemic areas (Middle East, Brazil, West Indies, Far East and Southeast Asia) after exposure to water inhabited by infected snails. The intermediate hosts larvae (cercariae) released from snails can penetrate intact skin and disseminate. *S. japonicum, S. mansoni* and *S. mekongi* cause hepatosplenic disease subsequent upon portal venous system obstruction by a granulomatous response to eggs and subsequent periportal fibrosis and portal hypertension. Granulomata consist of eosinophils, epithelioid cells, plasma cells and lymphocytes encircling an ovum. Patients present with pyrexia, urticaria, eosinophilia, hepatosplenomegaly or upper gastrointestinal tract bleeding from oesophageal varices. Dilated abdominal wall veins and ascites reflect portal venous hypertension, and USS may reveal thickening of the portal vein. Ova should be sought in stool and urine and may be identified in liver or rectal mucosal biopsy. Serological tests cannot distinguish past from active infection, but a negative ELISA excludes the diagnosis. Praziquantel is the drug of choice; oxamniquine an alternative for *S. mansoni*.

Hydatid Disease

Echinococcus granulosus is the dog tapeworm. Typically, dogs are infected by being fed offal from infected livestock—such as sheep—which contain hydatid cysts. Humans become infected by close exposure to domestic dogs and the eggs passed in their faeces. The liver is most frequent site for cyst formation, usually in the right lobe (60–80%). Presentation is with hepatic enlargement, with or without palpable mass, epigastric pain, nausea and vomiting; secondary cyst pressure effects include portal hypertension, inferior vena cava compression or thrombosis and biliary cirrhosis. USS of the liver reveals round solitary or multiple cysts of variable size with multiple internal daughter cysts; calcification may be noted. Diagnosis requires demonstration of specific antibody by ELISA, CFT, indirect agglutination or latex agglutination tests. Closed aspiration should not be undertaken: definitive therapy requires surgical removal which may be complicated by spillage of contents, anaphylaxis and seeding of new cysts. To avoid this, cysts can be injected with chlorhexidine or hydrogen peroxide prior to surgery. Both mebendazole and albendazole may successfully treat small uncomplicated cysts.

Ascariasis

Adult *Ascaris lumbricoides* worms cause disease by migrating into the pancreatic ducts, gallbladder and biliary tract. Biliary ascariasis is more common in children than in adults. Children with a heavy worm burden may be malnourished. Presentation of biliary involvement includes fever, RUQ pain, vomiting and passing of worms in stool or vomitus. Mechanical obstruction by worms can cause acute cholecystitis, cholangitis and biliary colic. Adult worms in the biliary tract may be demonstrated by USS, cholangiography or endoscopic retrograde cholangiography (ERCP); eggs should be sought in the faeces [23]. Treatment is usually with mebendazole or albendazole—though endoscopic removal of adult worms may be necessary if there are persisting biliary symptoms.

Toxocariasis

Toxocariasis is caused by infection with the dog roundworm *Toxocara canis.* Ingested eggs hatch in the small intestine, and larvae penetrate the mucosa before migrating to the liver, lungs and many other tissues. Visceral larva migrans (VLM) refers to a syndrome of eosinophilia, pyrexia, leucocytosis, hepatosplenomegaly, lymphadenopathy and hyperglobulinemia as the larva migrates. Ocular disease may also occur. A history of exposure to puppies should be sought. Humans are a 'dead-end' host: adult worms do not develop so eggs are not passed. Serodiagnosis is with an ELISA. In massive infection, liver biopsy may reveal eosinophils surrounding larvae or granulomata formation with epithelioid giant cells and lymphocytes. VLM is treated with thiabendazole. Severe disseminated disease or occular infection may warrant concomitant steroids.

Liver Fluke Infestation

Fasciola hepatica infection follows ingestion of aquatic plants—such as watercress—contaminated with eggs passed by infected sheep or cattle. After hatching, larvae penetrate the gut wall, enter the peritoneum and having breached the liver capsule pass through the parenchyma to the bile ducts. The flukes mature and lay eggs in the biliary tract, causing cholangitis and hepatomegaly. Diagnosis is made by demon-

strating ova in stool and positive serology. ERCP may show filling defects due to inflammation, and worms can be aspirated. Liver biopsy shows infiltration with eosinophils, histiocytes and polymorphs; granulomas may or may not be present. Treatment is with bithionol.

Clonorchis sinensis is endemic in the Far East. Infection follows ingestion of cysts in uncooked freshwater fish or crabs. Metacercariae excyst in the small intestine and invade the bile ducts in which the flukes mature, producing eggs which may be demonstrated in the faeces. Infection is usually asymptomatic, but bile duct fibrosis with liver impairment, strictures and pancreatitis may ensue. Praziquantel is the treatment of choice.

Toxoplasmosis

In the immunocompetent patient, acute acquired *Toxoplasma gondii* infection usually presents as self-limiting lymphadenopathy, though hepatosplenomegaly and hepatitis can occur. The risk and severity of congenital toxoplasmosis vary according to the trimester in which maternal infection with the protozoan occurs. The likelihood of foetal infection increases through pregnancy, whilst disease severity decreases. The spectrum of disease in infected neonates includes retinochoroiditis, meningoencephalitis, hydrocephalus, intracranial calcification, pneumonitis, myocarditis, purpura, hepatitis, hepatosplenomegaly and hydrops fetalis. Congenital toxoplasmosis must be differentiated from the other major causes of congenital infection: rubella virus, cytomegalovirus, herpes simplex virus, *T. pallidum* and *L. monocytogenes*.

Diagnosis of congenital infection requires full clinical evaluation and exclusion of other infections, with recovery of *T. gondii*, histology or serological investigation. Reference laboratory tests include culture (blood, body fluids, placenta), the dye test (for serum and CSF) and ELISAs for IgG, IgM, IgA and IgE detection in both neonate and mother. *T. gondii* DNA may be detected in body fluids (blood, urine and CSF) by PCR.

Treatment is with pyrimethamine plus sulphadiazine, though expert advice should be sought. Toxoplasmosis in the immunocompromised may follow reactivation or new acquisition and usually presents as central nervous system disease though other organs, including the liver, may be affected. *T. gondii* may be transmitted in the graft at liver transplantation and cause liver and severe systemic disease thereafter.

Fungal Infections

Fungal infections of the liver are usually seen in the immunocompromised—including those with acute liver failure. Although *Candida albicans* predominates, other *Candida* spp. and *Aspergillus* spp. infections are increasingly reported.

Hepatic Candidiasis

Severely immunocompromised patients are prone to disseminated candida infections with the liver (and often spleen) affected in 50–70%. Typically, hepatosplenic candidiasis presents in haemato-oncology patients rendered neutropenic at the time of recovery of the neutrophil count. The other risk factor for hepatic candidiasis is hepatic artery thrombosis in liver transplant patients. The hallmark is multiple small lesions in the liver and spleen on USS or CT scan with raised alkaline phosphatase. Yeasts or pseudohyphae may be visible on fine needle aspiration or in liver biopsy, and cultures may be positive; blood cultures are usually negative. Serology test such as detection of circulating cell wall antigen beta-D-glucan by ELISA and PCR-based tests can be used an adjunct for diagnosis of hepatic candidiasis. Hepatic or hepatosplenic candidiasis is treated with amphotericin B or micafungin or fluconazole. Although prolonged therapy may be required, the immune status of the patient is the key determinant of outcome.

Aspergillosis

Disseminated aspergillosis is an increasingly recognized problem in the severely immunocompromised. Increased incidence is seen in hospital with building constructions. Hepatic aspergillosis may manifest as an aspergilloma or granulomata formation, with hepatomegaly, elevated bilirubin, alkaline phosphatase and aminotransferases. Confident diagnosis requires both histopathological demonstration of invading hyphae and isolation of *Aspergillus* spp. (usually *A. fumigatus*) from liver biopsy. To date, serology has been unhelpful, but detection of circulating cell wall galactomannan by ELISA- and PCR-based tests shows promise. Treatment with voriconazole and liposomal amphotericin B should be commenced immediately—on clinical suspicion alone—in immunocompromised patients.

Other Rare Fungal Infections

Other rare fungal infections of the liver include histoplasmosis, blastomycosis, coccidioidomycosis and paracoccidioidomycosis.

Liver Disease in Primary Immunodeficiencies

65

Nedim Hadzic

Introduction

Primary immunodeficiencies (PIDs) are heritable disorders of innate and/or acquired immunity, often complicated by severe, recurrent or unusual infections, chronic diarrhoea with failure to thrive and malignancies of lymphoid tissue in long-term survivors [1, 2].

Many of the problems children with these conditions face have been successfully addressed; for the early-presenting, life-threatening PIDs such as variants of severe combined immune deficiency (SCID) or hyper-immunoglobulin E (IgE) syndrome, elective hematopoietic stem cell transplantation (HSCT), preferably from haploidentical donors, has become a treatment of choice [3]. In contrast, many milder forms of PIDs can be successfully managed for short-to-medium term by regular anti-infectious prophylaxis with antibiotics and/or antifungals and replacement immunoglobulins. Next-generation sequencing has dramatically improved the diagnostic pathways by development of targeted molecular genetics panel but also introduced additional queries about relevance of heterozygous states and variants of unknown significance [4].

Liver disease occurs in approximately 25% of children with PIDs [5]. The proportion of adult patients developing this complication is unknown but likely to be underdiagnosed and overall higher. Their number and liver pathology potentially could be affected by exposure to alcohol and propensity to develop diabetes mellitus and obesity-related liver problems such as nonalcoholic fatty liver disease later in life.

Pathophysiology

Many of the liver-related problems in PIDs stem from the fact that compromised first-line anti-infectious barrier in gastrointestinal tract allows low-grade chronic infection which could ascend proximally into the biliary system and the liver. The infections are frequently caused by unusual pathogens, escaping routine anti-infectious strategies, such as *Cryptosporidium* (CS) or *Microsporidium* [5]. The main form of liver disease in PIDs is chronic cholangiopathy, seen in around 65% of affected children [5]. This condition has a well-documented potential to develop biliary cirrhosis and full-blown clinical features of end-stage chronic liver disease, such as portal hypertension, bleeding from oesophageal varices and hypoalbuminaemia with jaundice. In a small proportion of PID patients with the liver involvement, milder and more nonspecific histological features, such as fatty change, mild portal inflammation or development of small non-caseating intrahepatic granulomas, could be observed [5].

A considerable role in the chronic cholangiopathy of PIDs is attributed to protozoal infections, unaffected by the standard anti-infectious regimens. Chronic cryptosporidial infection has been implicated in chronic inflammatory and dysplastic biliary changes in the context of chronic cholangiopathy and superimposed complications such as biliary cirrhosis and cholangiocarcinoma. The pathogenic role of CS in immune deficiency is likely, albeit incompletely understood. Animal models of the CS-related cholangiopathy have been described. For example, interferon-gamma knockout mice appear to be particularly susceptible to CS infection, suggesting important role for this cytokine in pathogenesis of the cholangiopathy in PIDs [6]. The biliary injury in humans appears to be caused by direct cytopathic effects of this protozoan, mediated by apoptosis [7]. In addition, CS is known to cause cholangiopathy in human immunodeficiency virus (HIV) infection [8] and after organ transplantation [9]. Several additional intracellular parasites such as

Microsporidium, *Mycobacterium avium intracellulare* and cytomegalovirus (CMV) have also been implicated in development of the chronic cholangiopathies in adult HIV-positive patients [8]. The accelerated evolution of the cholangiopathy in this setting is often interpreted by probable synergistic effects of multiple biliary infections [8].

A classical paradigm for development of the cholangiopathy of PIDs is hyper-IgM syndrome. This condition is caused by mutations in cluster of differentiation (CD)40 ligand (CD154) gene, known to control interaction between CD40 molecules from B-cells and CD40 ligand on activated lymphocytes in its X-linked form (CD40 ligand deficiency). Alternative mechanism for hyper-IgM syndrome is defective expression of immune activation-induced cytidine deaminase (AID) on B cells in the autosomal recessive form of the disease [10]. As a consequence, in both forms, B cells could not facilitate physiologic IgM class switching to other immunoglobulin types, which renders total serum IgM levels high and distal components of the immune response arm ineffective. However, the IgM levels may not always be elevated, and chronic neutropenia is often observed [11, 12]. Several series have described development of chronic biliary disease occasionally complicated by cholangiocarcinoma in older patients with hyper-igM syndrome. Another condition, recently described to predispose patients to develop chronic cholangiopathy, is dedicator of cytokinesis (DOCK)-8 deficiency, previously known as hyper-IgE syndrome [13].

Although there are hundreds of described PIDs, a majority now characterised by mutations in different genes encoding various molecular mediators of the immune response, frequent lack of genotype/phenotype correlation makes general recommendations for detecting liver disease difficult. On occasion, an adult patient could be diagnosed with PIDs, and exceptionally some children with conditions known to confer susceptibility for chronic cholangiopathy, such as hyper-IgM syndrome, could remain completely asymptomatic, on anti-infectious prophylaxis, well into the adulthood. However, the lifelong risk of the liver disease and its complications remains undisputable.

Diagnosis

Increased awareness of immunologists is a key to early detection of liver involvement. Routine biochemical blood tests and regular expert ultrasonography with stool screening for CS are recommended. Of note, standard stool microscopy could often miss protozoan infections, and therefore PCR-based techniques are preferable.

When CS is detected with whatever technique available, aggressive treatment is required. In immunodeficient patients, therapeutic options include nitazoxanide, paromomycin and azithromycin, often required in combination, in repeated courses or indefinitely [9, 14]. This clearly indicates that neither is very effective and that primary avoidance of this ubiquitous pathogen is recommended if possible. Thus, preventative measures such as drinking boiled water or azithromycin three times a week may be more appropriate in children diagnosed with conditions known to confer susceptibility to cholangiopathies such as hyper-IgM syndrome or DOCK-8 deficiency.

Fig. 65.1 Endoscopic retrograde cholangio-pancreatogram showing diffuse bilateral intra- and extrahepatic cholangiopathy in a child with a form of hyper-IgE syndrome (DOCK8 deficiency)

If prominence or dilatation of bile ducts is noted on ultrasound scan (USS), further imaging with magnetic resonance cholangiopancreatography (MRCP) is required. If MRCP is suggestive of dominant biliary stricture, endoscopic retrograde cholangiopancreatography (ERCP) could be indicated in order to attempt balloon dilatation, sample the bile for microbiology and biopsy the suspected lesion to rule out cholangiocarcinoma. Percutaneous liver biopsy under intravenous antibiotic cover is justified in the presence of consistent biochemical abnormality in patients with PIDs (see Fig. 65.1).

Management

Liver replacement will not work for the patients with PIDs until their immune defect is also rectified. There are many reports describing recurrence of cholangiopathy in the liver grafts within months after successful liver transplantation. Patients with less advanced liver disease can survive iso-

lated reduced-intensity conditioning (RIC) HSCT, but generally children with established cholangiopathies secondary to hyper-IgM syndrome, DOCK-8 deficiency or any other PIDs should be identified and screened early for a matched HSCT donor [15]. When the liver injury becomes clinically more severe, the children with PIDs are unlikely to tolerate conventional HSCT protocols, which often include potentially hepatotoxic medications. Thus, they should be transplanted while their liver involvement remains minimal, mild or absent if a good donor is available [16]. A sequential approach with combined liver and non-myeloablative RIC HSCT may be required for the ones with decompensated biliary cirrhosis and complications of advanced liver disease [17].

Effective HSCT not only prevents progression of established cholangiopathy but also could revert the histological abnormalities. We have observed four children with significant improvement of their histological features of cholangiopathy within couple of years after HSCT. However, there was no short-term change in the calibre of their bile ducts on ultrasonography [16].

Over the past decade, we have observed a reducing number of patients with PIDs and advanced chronic liver disease. There are two possible explanations for that: (1) these patients are referred earlier due to increased awareness of possible liver problems among immunologists, and (2) they receive their HSCT earlier, before serious liver disease develops. It is hoped that this strategy will continue to work and that the hepatologists would only exceptionally be required to see the patients with PIDs.

Haemophagocytic Lymphohistiocytosis

Haemophagocytic lymphohistiocytosis (HLH) is a condition which probably still remains underdiagnosed due to a relatively specialised diagnostic pathway and the clinical features mimicking acute septicaemia of early infancy. Majority of primary or familial HLH cases are a form of PID. Secondary or nonfamilial forms can be associated with any infectious trigger or presence of malignancy. In rheumatology, the term macrophage activation syndrome is used to highlight ubiquitous nature of this immune overreaction. A subgroup of patients with primary perforin deficiency presents acutely, often in infancy, with acute liver failure, but also in respiratory distress, fever, pancytopenia, rash and renal impairment, all indicative of systemic involvement. Perforin is a 60-kDa polypeptide, produced by cytoplasmic granules of activated natural killer (NK) cells and cytotoxic lymphocytes. Perforin physiologically assists in primary immune response by forming perforations/"pores" on membrane of the invading cells, facilitating entry of mediators such as granzyme, which lead to osmotic cell lysis and consequent cell death [18]. There are at least five different loci where mutations in perforin production pathway, leading to familial forms of HLH, can be detected [18].

The liver involvement at presentation is frequently so severe to warrant consideration for liver transplantation. In addition to classical signs of acute liver failure such as hyperbilirubinemia, coagulopathy and hypoalbuminaemia with ascites, those patients have hyperferritinaemia, hypertriglyceridaemia, hypofibrinogenaemia and signs of activated T lymphocytes, in particular interleukin (IL)-2R-positive cells in circulation. Patients often exhibit fever, splenomegaly and pancytopenia. Bone marrow aspirate reveals haemophygocytosis—a phenomenon defined by macrophages engulfing other cells and cellular debris. This urgent situation requires prompt identification of immune defect if it underlies the clinical situation, as liver transplantation would then only be a palliative measure; the underlying ongoing immune overactivity continues. Potential cure is control of the immune reaction by combination of steroids and chemotherapy (HLH protocol) [20]. One recently described novel option includes a selective blockage of proinflammatory cytokine pathway by using interferon-gamma blocking monoclonal antibody—emapalumab—for control of HLH-induced "cytokine storm" and its clinical consequences [21]. The overall mortality is high, and surviving patients should be worked up for HSCT as each new exposure to an infectious agent could trigger another life-threatening episode of haemophagocytosis [19].

Therefore, any young child who presents in indetermined acute liver failure with fever, splenomegaly and pancytopenia should, in addition to standard treatment of this condition, be urgently investigated for primary immunodeficiency by performing bone marrow aspirate and flow cytometry for expression of IL-2R and perforin on activated lymphocytes. Suggestion that the child could be immune deficient may indicate that consideration for emergency liver transplantation may not be justified as it could potentially result in a loss of precious liver graft.

Autoimmune Liver Disease

66

Giorgina Mieli-Vergani and Diego Vergani

Autoimmune liver disorders are inflammatory diseases characterized histologically by a dense mononuclear cell infiltrate in the portal tract that invades the surrounding parenchyma (interface hepatitis, Fig. 66.1a), biochemically by increased levels of transaminases, and serologically by the presence of circulating autoantibodies and high levels of immunoglobulin G (IgG) [1]. These disorders usually respond to immunosuppressive treatment and can present insidiously or with a picture of acute hepatitis. Best results are obtained with early institution of immunosuppression [1–3].

There are three liver disorders in which liver damage is likely to arise from an autoimmune attack: autoimmune hepatitis (AIH), autoimmune sclerosing cholangitis (ASC), and de novo autoimmune hepatitis after liver transplant.

Hitherto considered rare, juvenile autoimmune liver diseases are reported more frequently than in the past, because of enhanced awareness, a real increase in their prevalence, and/or the decrease in viral hepatitis-related diseases.

Autoimmune Hepatitis

Clinical Features (Table 66.1)

Two forms of AIH are recognized according to the type of autoantibodies present in the serum. Type 1 AIH (AIH-1) is positive for smooth muscle antibody (SMA) and/or antinuclear antibody (ANA), while type 2 AIH (AIH-2) for anti-liver/kidney microsomal type 1 (anti LKM-1) and/or anti-liver cytosol type 1 (anti-LC-1) antibody (Fig. 66.2).

AIH-1 accounts for three-quarters of the cases and presents often around puberty, while AIH-2 tends to present at a younger age and also during infancy. IgG levels are usually raised at disease onset in both types, though 15% of children with AIH-1 and 25% of those with AIH-2 have normal values at presentation, particularly when the disease presents acutely [4, 5]. Partial IgA deficiency is common in AIH-2, affecting some 40% of patients [4, 6].

In children and adolescents, AIH has a more aggressive phenotype than in adult patients. For long, it was believed that children and adolescents of non-European origin were rarely affected by AIH and the clinical course of juvenile AIH has been mainly described in Caucasoid patients [3, 4, 7–13]. More recently, however, juvenile autoimmune liver diseases have been reported in several countries [14–24].

The mode of AIH presentation includes [3, 4, 7, 21, 25–27]:

- Acute presentation resembling that of viral hepatitis, with nonspecific symptoms of malaise, nausea/vomiting, anorexia, and joint and abdominal pain, accompanied by jaundice, dark urine, and pale stools (40–50% of patients with AIH-1 or AIH-2)
- Fulminant hepatic failure with grade II to IV hepatic encephalopathy developing 2 weeks to 2 months after the onset of symptoms (~3% of patients with AIH-1 and ~25% of patients with AIH-2)
- Insidious onset, characterized by nonspecific symptoms (progressive fatigue, amenorrhea, headache, anorexia, joint and abdominal pain, diarrhea, weight loss), lasting from 6 months to a few years before diagnosis (~40% of patients with AIH-1 and ~25% of patients with AIH-2)
- Late presentation with complications of cirrhosis and portal hypertension (hematemesis from esophageal/gastric varices, bleeding diathesis, splenomegaly), without previous history of jaundice or liver disease (~10 of both AIH types).
- Incidental finding of abnormal transaminase levels, without hepatic symptoms or signs (rare in older series but reported in some 30% of patients in a recent report [3]).

(**a**) Portal and periportal lymphocyte and plasma cell infiltrate, extending to and disrupting the parenchymal limiting plate (interface hepatitis). Swollen hepatocytes, pyknotic necroses, and acinar inflammation are present. Hematoxylin and eosin staining. (**b**) Reticulin staining of the same biopsy showing connective tissue collapse resulting from hepatocyte death and expanding from the portal area into the lobule ("bridging collapse")

The mode of presentation of AIH in childhood is therefore variable, and the disease should be suspected and excluded in all children presenting with symptoms and signs of liver disease not ascribable to more common pathologies. The course of the disease can be fluctuating, with flares and spontaneous remissions, a pattern that may result in delayed referral and diagnosis. Often, however, on physical examination, the patients have clinical signs of an underlying chronic liver disease, including cutaneous stigmata (spider nevi, palmar erythema, leukonychia, striae), firm liver, and splenomegaly. At ultrasound, the liver parenchyma of these patients is often nodular and heterogeneous.

About one-third of patients with AIH have cirrhosis at the time of diagnosis, irrespective of the mode of presentation [3–5], indicating that the disease process is long-standing. AIH patients presenting acutely have often advanced fibrosis or cirrhosis on liver biopsy.

Severity of disease is similar in the two AIH types [3, 4, 28], but children with AIH-2 have higher levels of bilirubin and transaminases at onset than those who are ANA/SMA-positive, present more frequently with fulminant hepatic failure, and are more refractory to eventual treatment withdrawal [4, 20, 23]. Excluding children with the fulminant presentation, a severely impaired hepatic synthetic function, as indicated by the presence of prolonged prothrombin time and hypoalbuminemia, is more common in AIH-1 than in AIH-2. The severity of interface hepatitis at diagnosis is similar in both types, but cirrhosis on initial biopsy is more frequent in AIH-1 than in AIH-2, suggesting a more chronic course of disease in the former. Progression to cirrhosis during treatment is more frequent in AIH-1. In both types of AIH, a more severe disease course and a higher tendency to relapse are associated with the possession of antibodies to soluble liver antigen (SLA) [29, 30]. In both types, some 40% of patients have a family history of autoimmune disease [3, 4], and some 20–40% have themselves associated autoimmune disorders—including thyroiditis, type 1 diabetes, inflammatory bowel disease (IBD), hemolytic anemia, vitiligo, coeliac disease, Behçet disease, Sjögren syndrome, glomerulonephritis, idiopathic thrombocytopenia, urticaria pigmentosa, hypoparathyroidism, and Addison's disease (mainly in AIH-2) [3, 4, 31, 32] (Table 66.1). These associated conditions should be actively sought for prompt treatment [33]. In this context, diagnoses of particular importance are thyroiditis with hypothyroidism that affects 8–23% of patients [4, 31], coeliac disease that affects between 5% and 10% of patients [34–37], and IBD that is reported in 18% of patients [7]. Interestingly, patients with AIH and coeliac disease have been reported to achieve treatment-free sustained remission in a significantly higher proportion of cases than patients with AIH without coeliac disease, suggesting a possible long-term adjuvant effect of the gluten-free diet [38].

AIH-2 responsive to immunosuppressive treatment can be part of the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome, an autosomal recessive genetic disorder characterized by the triad of chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease, in which AIH-2 is also present in some 20–30% of cases [39–41]. Autoimmune and immunodeficiency diseases reflect a dysfunctional immune system: multiple single-gene defects have been identified, resulting in rare diseases with features of both immunodeficiency and autoimmunity, including AIH [42–44].

As mentioned above, AIH is being increasingly reported in children and adolescents of non-Caucasoid descent, probably because the diagnosis of autoimmune liver disease was previously overlooked in view of the presence of epidemic

Table 66.1 Clinical presentation, histological features, and HLA association of childhood autoimmune liver disease: King's College Hospital experience [4, 7, 47]

Parameter	AIH-1	AIH-2	ASC
Median age in years	11	7	12

viral hepatitis B and/or C. Reports from India [16, 21], Malaysia [17], Pakistan [15, 24], Bahrain [18], Iran [14], Egypt [23], Jamaica [22], and Mexico [20] indicate a clinical presentation and response to immunosuppressive treatment similar to those described in Caucasoid patients but an overall worse response to treatment and outcome, possibly related to delay in referral to specialized centers and diagnosis.

Epidemiology and Genetic Predisposition

The epidemiology of childhood autoimmune liver disease has not been studied in depth. Data collected at the King's College Hospital Pediatric Hepatology Tertiary Referral Center show a steady increase in the yearly incidence of juvenile autoimmune liver disease, only partially explained

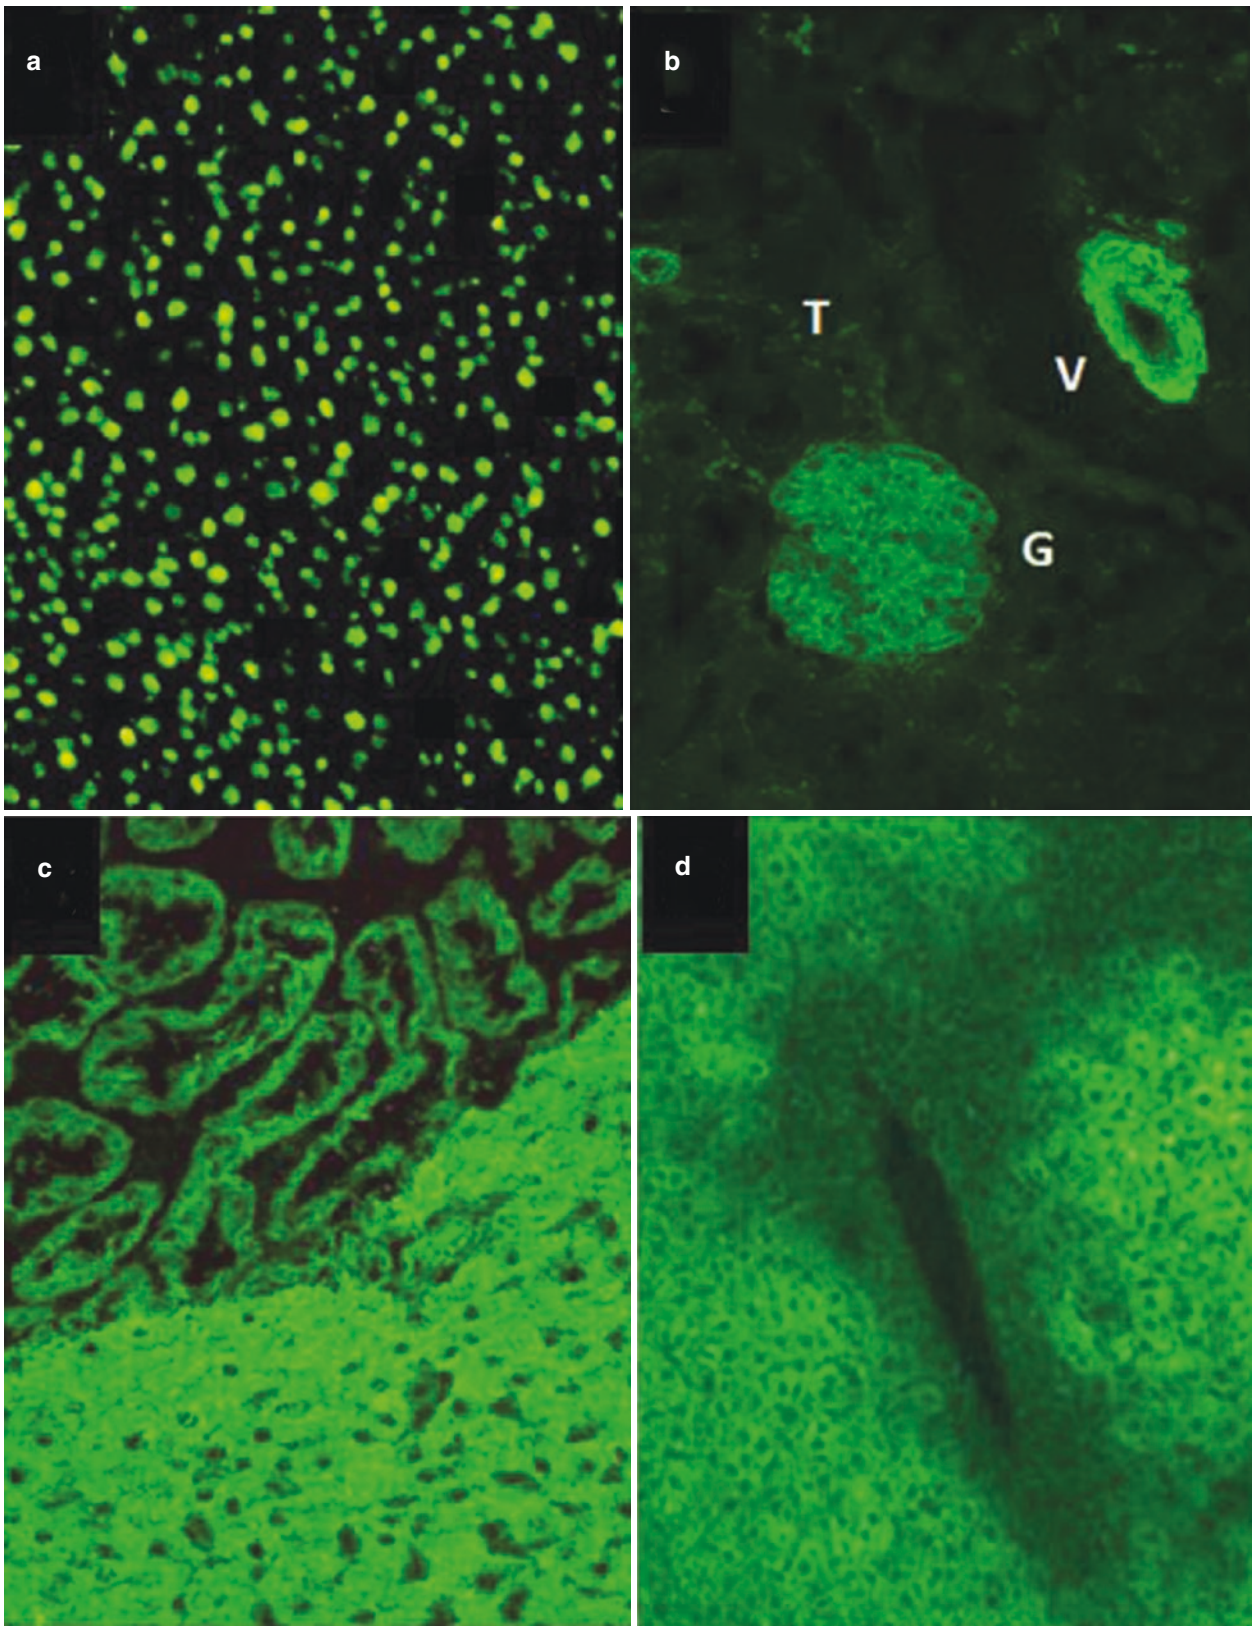

Fig. 66.2 Autoantibody immunofluorescence pattern on rodent tissue substrates. Panel (**a**) Antinuclear antibody (ANA) (liver): the homogeneous pattern is the most common in autoimmune hepatitis. Panel (**b**) smooth muscle antibody (SMA) (kidney): SMA stains the smooth muscle of arterial vessels (V), glomeruli (G), and tubules (T) (picture courtesy of Dr Luigi Muratori). Panel (**c**) anti-liver kidney microsomal type 1 antibody (LKM-1) (kidney and liver): anti-LKM-1 stains the cytoplasm of hepatocytes and proximal renal tubules. Panel (**d**) anti-liver cytosol type 1 (anti-LC-1) (liver): anti-LC-1 stains the cytoplasm of hepatocytes with a weakening of the stain around the central vein

by a referral bias: over the last 4 decades, the incidence has increased from 3.6 cases/year in the 1990s [4] to 5.4 cases/year in the 2000s [7] to 16.6 cases/year currently [3].

In Northern Europe, pediatric AIH-1, similar to adult AIH, is associated with the possession of the human leukocyte antigen (HLA) DRB1*03 (Table 66.1) [4, 45]. In contrast to adult patients, possession of DRB1*04 does not predispose to AIH in childhood and can even exert a protective role [4]. AIH-2 is associated with possession of DRB1*07 and, in DR7 negative patients, with possession of DRB1*03 (Table 66.1) [46, 47]. In Egypt, AIH-2 has also been associated with possession of HLA-DRB1*15 [48]. In Brazil and in Egypt, the primary susceptibility allele for AIH-1 is DRB1*1301, but a secondary association with DRB1*0301 has also been identified [48, 49]. Interestingly, in South America, possession of the HLA DRB1*1301 allele not only predisposes to pediatric AIH-1 but is also associated with persistent infection with the endemic hepatitis A virus [50, 51]. Pediatric patients with AIH, whether anti-LKM-1- or ANA/SMA-positive, have isolated partial deficiency of the HLA class III complement component C4, which is genetically determined [52].

As mentioned above, AIH-2 can be part of the APECED syndrome, in which the liver disease is reportedly present in some 20–30% of cases [39, 40].

Diagnosis

The diagnosis of AIH is based on a combination of clinical (see above), biochemical (raised serum transaminase levels), immunological (raised IgG levels, presence of autoantibodies), and histological indices and the exclusion of other known causes of liver disease that may share serological and histological features with AIH (e.g., hepatitis B, C, and E, Wilson's disease, nonalcoholic steatohepatitis, and drug-induced liver disease) [2, 53, 54].

Histology Liver biopsy is necessary to establish the diagnosis; the typical histological picture includes a dense mononuclear and plasma cell infiltration of the portal areas, which expands into the liver lobule leading to damage of the hepatocytes at the periphery of the lobule with erosion of the limiting plate ("interface hepatitis") (Fig. 66.1a). Hepatocytes surrounded by inflammatory cells become swollen and undergo pyknotic necrosis. Plasma cells are usually abundant at the interface and within the lobule, but their presence in low number does not exclude the diagnosis of AIH. When AIH presents acutely or at the time of relapse, panlobular hepatitis with connective tissue collapse resulting from hepatocyte death and expanding from the portal area into the lobule ("bridging collapse") is often observed (Fig. 66.1b). Nonspecific features that may point to the diagnosis of AIH are emperipolesis and hepatocyte rosetting [55]. The typical histological picture, however, is not always present at diagnosis as it varies according to disease stage or previous immunosuppressive treatment for associated conditions [56]. It has been suggested that in pediatric AIH hyaline droplets in Kupffer cells might be a useful diagnostic marker to distinguish AIH from other forms of chronic hepatitis, the hyaline droplets being positive for IgG by immunohistochemistry and correlating with a >twofold increase in serum level of IgG [57].

Histology also allows evaluating the extent of fibrosis and helps in identifying overlap syndromes or possible presence of concomitant diseases, such as nonalcoholic fatty liver disease [58]. Though inflammatory changes surrounding the bile ducts have been reported also in a proportion of patients with classical AIH [59], when conspicuous they suggest an overlap with sclerosing cholangitis.

Autoantibodies A key diagnostic criterion for all AIH scoring systems is the detection of autoantibodies (ANA, SMA, anti-LKM-1 and anti-LC-1) [60, 61], which not only assists in the diagnosis but also allows differentiation of AIH types. ANA and SMA characterize AIH-1, while anti-LKM-1 and anti-LC-1define AIH-2, though occasionally ANA or SMA can coexist with anti-LKM-1 or anti-LC-1, the clinical course in these cases being similar to that of AIH-2. A major target of SMA is the actin of smooth muscle, whereas the molecular target of LKM-1 is cytochrome P-4502D6 (CYP2D6) [62] and of anti-LC-1 is formiminotransferase cyclodeaminase [63]. ANA, SMA, anti-LKM-1, and anti-LC-1 should be sought by indirect immunofluorescence using rodent stomach, kidney, and liver as substrate, as other techniques, e.g., commercially available enzyme linked immunosorbent assays (ELISAs), remain to be fully validated (Fig. 66.2) [60]. In contrast to adults, in healthy children, autoantibody reactivity is infrequent, so that titers of 1:20 for ANA and SMA and 1:10 for anti-LKM-1 are clinically relevant. Anti-LC-1, also detectable by indirect immunofluorescence, can be present on its own but frequently occurs in association with anti-LKM-1. This co-occurrence can go unnoticed because anti-LKM-1 obscures the anti-LC-1 pattern. Anti-LC-1 can also be detected by commercial available tests (ELISAs, line blots, and immunoblots). Positivity for autoantibodies is not sufficient for the diagnosis of AIH since they can be present, usually at low titer, in other liver disorders such as viral hepatitides [64, 65], Wilson's disease [66], and nonalcoholic steatohepatitis [67].

Other autoantibodies less commonly tested but of diagnostic importance include peripheral antinuclear neutrophil antibody (atypical pANCA or pANNA) and anti-SLA. pANNA is frequently found in AIH-1 and in ASC and is also common in IBD, while it is virtually absent in AIH-2. Anti-SLA, originally described as the hallmark of a third type of AIH [68], is also found in up to 50% of patients with AIH-1,

AIH-2, or ASC, where it defines a more severe course [29, 30]. Anti-SLA is not detectable by conventional immunofluorescence, but the definition of its molecular target as UGA transfer RNA (tRNA) suppressor-associated antigenic protein (SepSecS) [69, 70] has enabled the establishment of molecularly based diagnostic assays. However, it should be noted that ELISAs are less sensitive than radioligand assays available in research laboratories.

There are a small proportion of patients with AIH without detectable autoantibodies. This condition, which responds to immunosuppression like the seropositive form, represents seronegative AIH [71], a rare type of AIH in adults, whose prevalence and clinical characteristics remain to be defined in children.

Diagnostic Criteria The diagnosis of AIH has been advanced by the scoring systems developed by the International Autoimmune Hepatitis Group (IAIHG) for adult patients [53, 54] where negative criteria such as evidence of infection with hepatitis B or C virus, Wilson's disease, or alcoholic liver disease, among others, are taken into account in addition to the positive criteria mentioned above. The IAIHG scoring system was devised mainly for research purposes to allow ready comparison between series from different centers but has also been used clinically, including in pediatric series. More recently, the IAIHG have published a simplified scoring system based on autoantibodies, IgG, histology, and exclusion of viral hepatitis that is better suited to clinical application [72]. However, neither scoring system is suitable to the juvenile form of the disease, where diagnostically relevant autoantibodies often have titers lower than the cutoff value considered positive in adults [73–75]. In addition, neither system can distinguish between AIH and ASC (see below) [7, 76], which can only be differentiated if a cholangiogram is performed at presentation. For this reason, the European Society of Pediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) has published in 2018 a position paper for the diagnosis and management of pediatric autoimmune liver disease, which includes a diagnostic scoring system that should be evaluated in a large number of patients with juvenile AIH or ASC for validation [2]. Not included in the ESPGHAN criteria, but useful in the differentiation between AIH and ASC, is the alkaline phosphatase/aspartate aminotransferase ratio, which is significantly higher in ASC than in AIH, a ratio ≥ 3 being strongly suggestive of ASC [3, 7].

Pathophysiology

The typical histological picture of AIH, which is characterized by a dense mononuclear cell infiltrate eroding the limiting plate and invading the parenchyma (interface hepatitis, Fig. 66.1a), first suggested that autoaggressive cellular immunity might be involved in its causation [77]. Immunocytochemical studies have identified the phenotype of the infiltrating cells. T lymphocytes mounting the alpha/beta T-cell receptor predominate. Among the T-cells, a majority is positive for the CD4 helper/inducer phenotype, and a sizable minority is positive for the CD8 cytotoxic phenotype. Lymphocytes of non-T-cell lineage are fewer and include (in decreasing order of frequency) natural killer cells (CD16/CD56-positive), macrophages, and B lymphocytes [78, 79]. Natural killer T-cells, which express simultaneously markers of both natural killer (CD56) and T-cells (CD3), are involved in liver damage in an animal model of autoimmune hepatitis [79].

A powerful stimulus must be promoting the formation of the massive inflammatory cell infiltrate present at diagnosis. Whatever the initial trigger, it is most probable that such a high number of activated inflammatory cells cause liver damage. There are different possible pathways that an immune attack can follow to inflict damage on the hepatocyte (Fig. 66.3). Liver damage is believed to be orchestrated by CD4-positive T lymphocytes recognizing a self-antigenic peptide. To trigger an autoimmune response, the peptide must be embraced by an HLA class II molecule and presented to uncommitted T helper (Th0) cells by professional antigen-presenting cells (APCs), with the co-stimulation of ligand–ligand (CD28 on Th0, CD80 on APC) interaction between the two cells. The Th0 cells become activated, differentiate into functional phenotypes according to the cytokines prevailing in the microenvironment and the nature of the antigen, and initiate a cascade of immune reactions determined by the cytokines they produce. Arising in the presence of the macrophage-produced interleukin-12, Th1 cells secrete mainly interleukin-2 and interferon-gamma, which activate macrophages, enhance expression of HLA class I (increasing the vulnerability of liver cells to cytotoxic attack), and induce expression of HLA class II molecules on hepatocytes, which then become able to present the autoantigenic peptide to Th cells, thus perpetuating the immune recognition cycle. Th2 cells, which differentiate from Th0 if the microenvironment is rich in interleukin-4, produce mainly interleukin-4, interleukin-5, and interleukin-10, which induce autoantibody production by B lymphocytes. Physiologically, Th1 and Th2 cells antagonize each other. The process of autoantigen recognition is strictly controlled by regulatory mechanisms. If these regulatory mechanisms fail, the autoimmune attack is perpetuated. Over the past four decades, different aspects of the above pathogenic scenario have been investigated.

An impairment of immunoregulatory mechanisms has been described in AIH. Both children and young adults with this condition have low levels of T-cells expressing the CD8 marker and impaired suppressor cell function [80, 81] which

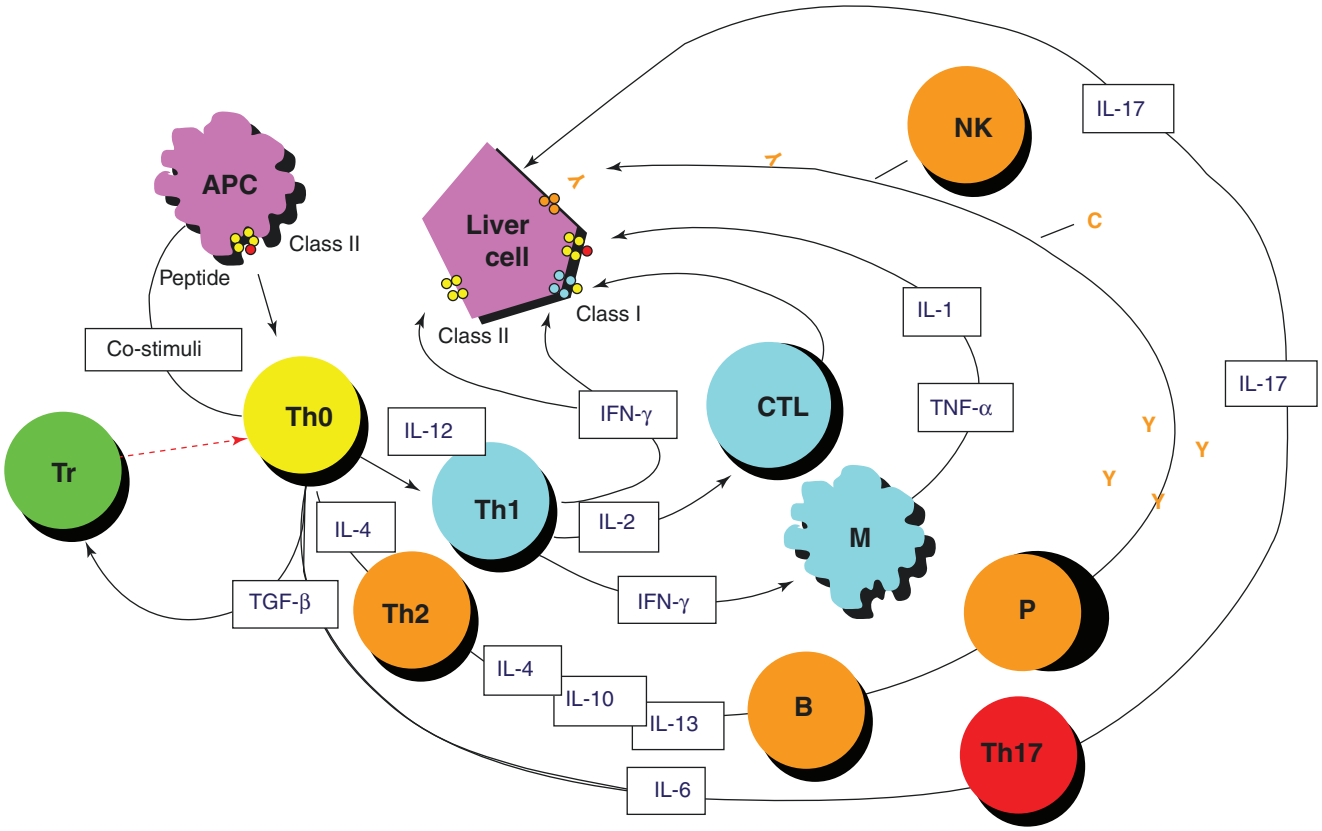

Fig. 66.3 An autoantigen is presented to uncommitted T helper (TH0) lymphocytes within the HLA class II molecule of an antigen-presenting cell (APC) either in the regional lymph nodes or within the liver itself. Activated TH0 cells differentiate into TH1 or TH2 cells in the presence of interleukin (IL)-12 or IL-4 and according to the nature of the antigen and trigger a series of immune reactions determined by the cytokines they produce: TH1 cells secrete IL-2 and interferon-gamma (IFN-γ), cytokines that stimulate cytotoxic T lymphocytes (CTL), enhance expression of class I and induce expression of class II HLA molecules on the liver cells, and activate macrophages. The latter release IL-1 and tumor necrosis factor alpha (TNF-α). TH2 cells secrete mainly IL-4, IL-10, and IL-13 and stimulate autoantibody production by B lymphocytes. In the presence of defective regulatory T-cells (Treg), hepatocyte destruction ensues from the engagement of damaging effector mechanisms, including CTL, cytokines released by TH1 and activated macrophages, complement activation, as well as adhesion of natural killer (NK) cells to autoantibodycoated hepatocytes through their Fc receptors. TH17 cells, a recently described proinflammatory population that derives from TH0 cells in the presence of transforming growth factor beta (TGF-β) and IL-6, are focus of current investigation

segregates with the possession of the HLA haplotype B*08/DRB1*03 (formerly B8/DR3) and can be corrected by therapeutic doses of corticosteroids [82]. Moreover, patients with AIH have been reported to have a specific defect in a subpopulation of T-cells controlling the immune response to liver-specific membrane antigens [83]. Further evidence for an impairment of immunoregulatory function in AIH has been obtained in the last two decades [84–86]. Among T-cell subsets with potential immunosuppressive function, CD4+ T-cells constitutively expressing the interleukin 2 receptor (IL-2R) alpha chain (CD25) (regulatory T-cells, Tregs) have emerged as the dominant immunoregulatory population [87]. These cells, which represent 5–10% of the total population of peripheral CD4+ T lymphocytes, control the innate and the adaptive immune responses by preventing the proliferation and effector function of autoreactive T-cells. Their mechanism of action involves mainly a direct contact with the target cells and to a lesser extent the release of immunoregulatory cytokines, such as interleukin 10 and tissue growth factor beta 1.

A numerical Treg impairment affects both children and adults with AIH. This defect is more evident at diagnosis than during drug induced remission, although even then circulating Treg frequencies fail to reach the levels seen in health [84, 88, 89]. The percentage of Tregs inversely correlates with biomarkers of disease severity, suggesting that a reduction in regulatory T-cells favors autoimmune liver disease and its severity. Importantly, Tregs from AIH patients at diagnosis are impaired in their ability to control the proliferation of CD4 and CD8 effector cells compared to Tregs isolated from AIH patients at remission or from healthy subjects [88].

Effector CD4 T-cells isolated from patients with AIH are less susceptible to the regulatory control exerted by Tregs. This defect is linked to reduced expression of the inhibitory receptor T-cell-immunoglobulin- and-mucin-

domain-containing molecule-3 (Tim-3), which upon ligation of galectin-9 expressed by Tregs induces effector cell death [90].

Hepatocytes from patients with AIH, in contrast to normal hepatocytes, express HLA class II molecules [91], and, although lacking the antigen-processing machinery typical of APCs, they may present peptides through a bystander mechanism. Given the impaired regulatory function and the inappropriate expression of HLA class II antigens on the hepatocytes, it is conceivable that an autoantigenic peptide is presented to the helper/inducer cells, leading to their activation. Although there is no direct evidence as yet that an autoantigenic peptide is presented and recognized, activation of helper cells has been documented in AIH [78, 92]. These activated cells possess the CD4 phenotype, and their numbers are highest when the disease is most active.

Most advances in the study of T-cells have occurred in AIH-2, since the knowledge that CYP2D6 is the main autoantigen has enabled the characterization of both CD4 and CD8 T-cells targeting this cytochrome. One study has shown that CD4 T-cells from patients with AIH-2 positive for the predisposing HLA allele DRB1*0701 recognize seven regions of CYP2D6 [46], five of which have later been shown to be also recognized by CD8 T-cells [93]. High numbers of interferon-gamma-producing CD4 T-cells and CD8 T-cells are associated with biochemical evidence of liver damage, suggesting a combined cellular immune attack.

What triggers the immune system to react to an autoantigen is unknown. A lesson may be learned by the study of humoral autoimmune responses during viral infections. Thus, studies aimed at determining the specificity of the LKM-1 antibody, present in both the juvenile form of AIH and in some patients with chronic HCV infection, have shown a high amino acid sequence homology between the HCV polyprotein and CYP2D6, the molecular target of anti-LKM-1, thus implicating a mechanism of molecular mimicry as a trigger for the production of anti LKM-1 in HCV infection [62, 94, 95]. It is therefore conceivable that an as yet unknown virus infection may be at the origin of the autoimmune attack in AIH.

Titers of antibodies to liver-specific lipoprotein, a macromolecular complex present on the hepatocyte membrane, and to its well-characterized component asialoglycoprotein receptor correlate with the biochemical and histologic severity of AIH [96, 97]. Antibodies to alcohol dehydrogenase, a second well-defined component of liver-specific lipoprotein, have been described in patients with AIH [98]. Immunofluorescence studies on monodispersed suspensions of liver cells obtained from patients with AIH showed that these cells are coated with antibodies in vivo [99]. A pathogenic role for these autoantibodies has been indicated by cytotoxicity assays showing that autoantibody-coated hepatocytes from patients with AIH are killed when incubated with autologous lymphocytes. The effector cell was identified as an Fc receptor-positive mononuclear cell [100]. T-cell clones obtained from liver biopsies of children with AIH and expressing the gamma/delta T-cell receptor have been shown to be cytotoxic to a variety of targets but to preferentially kill liver-derived cells as opposed to cell lines derived from other organs [101].

The establishment of cell lines and clones has shown that the majority of T-cell clones obtained from the peripheral blood and a proportion of those from the liver of patients with AIH are CD4-positive and use the conventional alpha/beta T-cell receptor [101–104]. Some of these CD4-positive clones were further characterized and were found to react with partially purified antigens, such as crude preparations of liver cell membrane or liver-specific lipoprotein [102], and with purified asialoglycoprotein receptor [102, 104], or recombinant CYP2D6 [103] and to be restricted by HLA class II molecules in their response. Because CD4 is the phenotype of Th cells, T-cell clones were investigated for their ability to help autologous B lymphocytes in the production of immunoglobulin in vitro [102, 104]. Indeed, their coculture with B lymphocytes resulted in a dramatic increase in autoantibody production.

The possible role of Th17 cells in the pathogenesis of AIH is under investigation. Th17 cells contribute to autoimmunity by producing the proinflammatory cytokines IL-17, IL-22, and TNF-α and inducing hepatocytes to secrete IL-6 [105], which further enhances Th17 activation. Th17 cells have been shown to be elevated in the circulation and liver of patients with AIH [105].

Treatment

The aim of treatment is to obtain a complete biochemical, immunological, and clinical remission in order to halt the progression of the disease.

Definition of Remission/Relapse For juvenile autoimmune liver disease, remission is defined as complete clinical recovery with transaminase levels within the normal range. It is obtained in 60–90% of patients [4, 14, 16, 23, 26], the rapidity and degree of treatment response depending on disease severity. More recently, three more remission criteria have been added: normalization of IgG levels, negative or very low titer autoantibodies, and histological resolution of inflammation [2, 5]. Histological improvement, however, lags behind clinical, biochemical, and immunological response [106–108], though after a mean duration of 4 years of effective treatment, some 95% of patients show marked histological amelioration [107]. As liver biopsy cannot be repeated frequently, for clinical pur-

poses, remission is considered complete when transaminase and IgG levels are normal, ANA and SMA are negative or low titer (<1:20), and anti-LKM1 and anti-LC1 are <1:10 or negative [2].

Relapse is characterized by increase of serum transaminase levels after remission has been achieved. Relapse during treatment occurs in some 40% of patients and requires a temporary increase of the steroid dose. An important cause of relapse is nonadherence, which is common, particularly in adolescents [3, 17, 109]. In more aggressive cases, the risk of relapse is higher if steroids are administered on an alternate-day schedule, which is often instituted in the assumption that may have a less negative effect on the child's growth. Small daily doses, however, are more effective in maintaining disease control, avoiding adverse effects, and minimizing the need for high-dose steroid pulses during relapses (with attendant more severe side effects).

Standard Treatment When AIH presents with fulminant hepatic failure (i.e., acute liver failure and encephalopathy), it usually requires urgent transplantation, though patients may respond to a trial of steroids, avoiding transplantation [25]. With all other modes of presentation, AIH responds satisfactorily to immunosuppression, even in the presence of poor synthetic function and/or established cirrhosis [3, 4, 7]. Treatment should be started with prednisolone 2 mg/g/d (maximum 60 mg/d), which is gradually decreased over a period of 4–8 weeks if there is progressive normalization of the transaminases, and then the patient is maintained on the minimal dose able to sustain normal transaminase levels, usually 5 mg/d. During the first 6–8 weeks of treatment, liver function tests should be checked weekly to allow a frequent fine-tuning of the treatment, avoiding severe steroid side effects. The initial goal is to obtain at least 80% reduction of the transaminase levels by 8 weeks of treatment. During this period of time, if progressive normalization of the liver function is not observed at weekly blood tests, azathioprine is added at a starting dose of 0.5 mg/g/d, which, in the absence of signs of toxicity, is gradually increased up to a maximum of 2–2.5 mg/g/d until remission (i.e., normal transaminase levels) is achieved [2]. Azathioprine is not recommended as first-line treatment because of its potential hepatotoxicity, particularly in severely jaundiced patients. Interestingly, it has been shown that neither thiopurine methyltransferase genotype nor activity predicts azathioprine hepatotoxicity in AIH, which appears instead to be related to the degree of liver fibrosis [110]. Measurement of the azathioprine metabolites 6-thioguanine (6-TGN) and 6-methylmercaptopurine has been reported to help in identifying drug toxicity and nonadherence and in achieving a level of 6-thioguanine considered therapeutic for inflammatory bowel disease [111], though an ideal therapeutic level for AIH has not been determined. In a retrospective review, 87% of 66 children with AIH were reported to maintain sustained biochemical remission (normal transaminase levels) in association with low 6-TGN levels ranging from 50 to 250 pmol on an azathioprine dose of 1.2–1.6 mg/kg/day [112]. Although an 80% decrease of initial transaminase levels is usually obtained within 6–8 weeks from starting treatment in most patients, complete normalization of liver function may take several months [3, 4]. Using the above schedule, steroid side effects are usually mild, the only serious complication being psychosis during induction of remission in 4%, which resolves after prednisolone withdrawal [4]. All patients develop a transient increase in appetite and mild cushingoid features during the first few weeks of treatment. After 5 years of treatment, 56% of our patients maintained their baseline centile for height or went up across a centile line, 38% dropped across one centile line, and only 6% dropped across two centile lines [113]. Moreover, all patients achieved their expected final height after a median steroid treatment of 8.9 years [113].

Treatment should be continued for at least 2–3 years before considering its cessation, after which period stopping treatment can be attempted but only if liver function tests and IgG levels have been persistently normal, and autoantibodies are either undetectable or detectable at very low titer (ANA/SMA <1:10; anti-LKM-1 should be negative) over at least 12 months, and a liver biopsy shows no inflammatory changes [2]. However, it is advisable not to attempt treatment withdrawal during or immediately before puberty, when relapses are more common. Treatment withdrawal is reportedly successful in 20% of children with AIH-1 but is rarely achieved in AIH-2 [3, 4, 9]. An important role in monitoring the response to treatment is the measurement of IgG levels and autoantibody titers, the fluctuation of which is correlated with disease activity [114].

A few studies using quality of life questionnaires report a decreased health-related score in young patients with AIH compared to healthy controls, advanced disease, active symptoms, extrahepatic autoimmune diseases, and a dislike of taking medications being associated with the worse scores [115–117]. However, a recent series of 83 patients with AIH or ASC followed up long term shows an excellent real-life clinical, educational, and social outcome in those who respond to immunosuppressive treatment [3]. Development of end-stage liver disease requiring liver transplantation 3–14 years after diagnosis, despite treatment, has been reported in 8–16% of children with AIH, the need for transplant being correlated to poor response to treatment, episodes of relapse, length of follow-up, and a diagnosis of ASC [3, 4, 7].

Maintenance with azathioprine monotherapy has been advocated once remission is achieved [112, 118], but whether this is effective long term and whether it offers any benefit on possible side effects compared to low-dose prednisolone/azathioprine maintenance is unclear.

Alternative Treatments

Induction of Remission Budesonide would appear to be an attractive drug for the induction and maintenance of remission in AIH, as its hepatic first-pass clearance is >90% of the oral dose and it has fewer side effects than predniso(lo)ne [119]. Budesonide, however, cannot be used in the presence of cirrhosis, which affects at least a third of AIH patients. In a large European study including adults and children with AIH, a combination of budesonide and azathioprine was reported to have fewer adverse effects compared to medium-dose standard prednisone and azathioprine [120]. In that study, budesonide at a dose of 3 mg three times daily, decreased upon response, was compared with prednisone 40 mg once daily reduced per protocol irrespective of response. After 6 months of treatment, remission was achieved in 60% of the budesonide group but in only 39% of the prednisone group, both percentages being worse than those achieved with standard treatment [3, 4, 7]. The results among the children recruited into that study were particularly disappointing, with a similarly low remission rate of 16% for budesonide and 15% for prednisone after 6 months of treatment and of 50% and 42%, respectively, after 12 months of treatment, with similar steroid side effects in both groups, apart from higher frequency of weight gain in children on prednisone [121]. Large controlled studies are needed to establish the appropriate dose for children and to evaluate whether budesonide has any advantage over predniso(lo)ne [122].

Induction of remission has been obtained in 72% treatment-naïve children with AIH-1 using cyclosporine A alone for six months, followed by maintenance with low-dose prednisone and azathioprine [123]. A 5-year follow-up of this study shows that 94% of the patients eventually achieved remission, with minor side effects [124]. Whether this mode of induction has any advantage over the standard treatment remains to be evaluated in controlled studies in specialized centers.

Tacrolimus is a more potent immunosuppressive agent than cyclosporine, but it also has significant toxicity. There is limited evidence supporting its role as treatment of AIH. Its use in the juvenile form of the disease is limited to one report, where tacrolimus was administered to 17 children with newly diagnosed AIH with or without the addition of prednisolone and/or azathioprine and to 3 children who had failed conventional therapy. Target tacrolimus trough levels were relatively low (2.5–5 ng/ml) and similar to those used in the maintenance of successful liver transplant. The study shows that monotherapy with tacrolimus was not sufficient to achieve complete remission in most cases, but the calcineurin inhibitor allowed reduction of the dose of prednisolone and azathioprine. On the other hand, tacrolimus-related side effects were noted in half of the patients [125].

Difficult-to-Treat Patients In those patients (up to 10%) in whom standard immunosuppression is unable to induce stable remission or who are intolerant to azathioprine, mycophenolate mofetil at a dose of 20 mg/kg twice daily together with prednisolone has been successfully used [126]. A meta-analysis, including data from several small studies of second-line treatments in children with AIH refractory to standard therapy, suggests that calcineurin inhibitors might have the highest response rate at 6 months but also the highest rate of adverse events; MMF was the second most effective drug with a low side effect profile, indicating that MMF is currently the best choice for second-line therapy [127]. If the absence of response persists or if there is intolerance to MMF (headache, diarrhea, nausea, dizziness, hair loss, and neutropenia), calcineurin inhibitors should be considered.

There is anecdotal experience with the successful use of the anti-B lymphocyte monoclonal antibody rituximab in two children with refractory AIH [128]. However, despite the relatively low adverse event profile of the drug, its use has been associated with a 2.4% rate of sepsis in children with autoimmune diseases [129].

Infliximab has been reported to be effective in the treatment of refractory AIH, including in a pediatric case [130–132], though it has potential serious side effects, including infections and hepatotoxicity [132]. In addition, anti-TNF-α-induced AIH has been described both in adults and children treated for IBD or other autoimmune conditions [133–135]. A better understanding of the role of TNF-α in the pathogenesis of AIH is needed before recommending its use in AIH.

As patients with AIH have a defect in immunoregulation affecting regulatory T-cells, sirolimus, a drug that expands selectively Tregs in vivo and in vitro [136], was used in four patients with refractory AIH, with short-term beneficial effect in two [137].

Of note, a survey on the management of juvenile AIH commissioned by the IAIHG [138] has shown that within the pediatric IAIHG members, there is considerable more experience with second-line therapeutic agents than among the IAIHG adult hepatologist members [139].

As mentioned above, children who present with fulminant hepatic failure, i.e., with grade 3–4 encephalopathy and INR ≥2, pose a particularly difficult therapeutic problem.

Although it has been reported that they may benefit from conventional immunosuppressive therapy [25, 140, 141], most require liver transplantation [4]. Encouraging results have been reported using cyclosporine A in anti-LKM-1-positive patients presenting with fulminant hepatitis [140]. These treatments should be evaluated on a larger number of patients because our own experience has not confirmed the value of this therapeutic approach.

Autoimmune Polyendocrinopathy-Candidiasis-Ectodermal Dystrophy (APECED)

APECED is a monogenic disorder due to mutations of the *AIRE* gene [142, 143]. Its phenotype is variable and includes AIH in about 20–30% of the cases [39, 40]. This resembles AIH-2 and responds to standard immunosuppressive treatment [39], though the anti-LKM-1-like antibody detected by immunofluorescence targets cytochromes P450-2A1 and P450-2A6 [40], besides P450-2D6 [144]. APECED, also known as autoimmune polyendocrine syndrome 1, is usually an autosomal recessive disorder caused by homozygous mutations in the *AIRE* gene and characterized by a variety of organ-specific autoimmune diseases, the most common of which are hypoparathyroidism and primary adrenocortical failure, accompanied by chronic mucocutaneous candidiasis. The presence of two of these conditions is deemed to be diagnostic, though more recently diagnosis has been based on a combination of genetic and immunological tests [145]. Occasionally, depending on the genetic abnormality, the condition has been reported to be inherited in a dominant fashion [146].

To date, over 115 *AIRE* mutations have been identified in the APECED syndrome [147], present both in coding and noncoding regions and generating truncated protein sequences or single amino acid missense variants. These variants include single-nucleotide substitutions, insertions, and deletions with protein splicing effects [148, 149].

The protein encoded by *AIRE* is a transcription factor. *AIRE* is highly expressed in medullary epithelial cells and other stromal cells in the thymus involved in clonal deletion of self-reactive T-cells. Studies in a murine model indicate that the gene inhibits organ-specific autoimmunity by inducing thymic expression of peripheral antigens in the medulla leading to central deletion of autoreactive T-cells. Though the inheritance pattern of APECED indicates a recessive disorder, there are anecdotal data of mutations in a single copy of *AIRE* being associated with autoimmune disease of a less severe form than classically defined APECED [142, 143]. The role of *AIRE* heterozygote state in the development of AIH remains to be established. *AIRE* mutations have been reported in three children with severe AIH type 2 and extrahepatic autoimmune manifestations [150].

Autoimmune Sclerosing Cholangitis

Clinical Features

Sclerosing cholangitis is an uncommon disorder, characterized by chronic inflammation and fibrosis of the intrahepatic and/or extrahepatic bile ducts. When bile duct damage is detectable histologically, but cholangiography is normal, a diagnosis of "small duct disease" is made. In childhood, sclerosing cholangitis may occur as an individual disease or may develop in association with a wide variety of disorders. The term primary sclerosing cholangitis (PSC), used in adult patients, is not accurate to describe pediatric sclerosing cholangitis: "primary" denotes ignorance about etiology and pathogenesis, while in pediatrics there are etiologically well-defined forms of sclerosing cholangitis [7, 10, 151–154]. In the neonatal period, pathological features of severe sclerosing cholangitis characterize biliary atresia as well as neonatal sclerosing cholangitis, a condition inherited in an autosomal recessive manner [155]. Some other inherited diseases and immunological defects may produce a clinical picture similar to adult PSC. For example, mild to moderate defects in the *ABCB4* (MDR3) gene are a likely cause of a number of cases of small duct PSC in children and adults [156, 157], and sclerosing cholangitis may complicate a wide variety of disorders, including primary and secondary immunodeficiencies, Langerhans cell histiocytosis, psoriasis, cystic fibrosis, reticulum cell sarcoma, and sickle cell anemia. Moreover, an overlap syndrome between AIH and sclerosing cholangitis (autoimmune sclerosing cholangitis, ASC) is significantly more common in children than in adults [158]. In only a relatively small number of pediatric patients, sclerosing cholangitis occurs without any of the above defining features. The term of PSC would be better confined to the latter, as different types of sclerosing cholangitis respond to different therapeutic managements.

ASC is characterized by florid autoimmune features, positive autoantibodies, especially ANA and SMA, hypergammaglobulinemia, and interface hepatitis on liver biopsy [7, 158, 159].

Since these features are shared with AIH, and alkaline phosphatase (AP) or gamma-glutamyl transpeptidase (GGT) levels are often not elevated at disease onset, the diagnosis of ASC relies on the findings of bile duct damage on cholangiographic studies. In a 16-year prospective study, during which all children with serological and histological features of AILD underwent liver biopsy, sigmoidoscopy, and cholangiography at presentation [7], approximately half were found to have bile duct changes characteristic of sclerosing cholangitis (Fig. 66.4) and were therefore diagnosed with ASC. Importantly, a quarter of children with ASC had no histological features pointing to bile duct involvement, despite

Fig. 66.4 Magnetic resonance cholangiography of a child with autoimmune sclerosing cholangitis showing a diffuse cholangiopathy with strictures and dilatations affecting the intrahepatic bile ducts

abnormal cholangiograms. Virtually all ASC patients were seropositive for ANA and/or SMA. In contrast to AIH, which is a predominantly a disease of females, ASC affects similarly boys and girls [3, 7].

The mode of presentation of ASC is similar to that of AIH-1, although an association with IBD is more common in ASC (45–73%) than AIH-1 (11–20%) [3, 7]. Of note, in the King's prospective study [7], only one-third of the children with autoimmune liver disease and IBD had bowel symptoms, while the others were diagnosed because of surveillance sigmoidoscopy. At presentation, liver function tests—including GGT levels, which are a more reliable indicator of cholestasis than AP in growing children/adolescents, in whom AP often reflects bone growth—do not discriminate between AIH and ASC, though the AP/AST ratio is significantly higher in ASC (Table 66.2). Notably, pANNA positivity is present in 74% of children with ASC but only 45% of those with AIH-1 and 11% of those with AIH-2 [7]. Anti-SLA by a sensitive radioligand assay was found in some 50% of patients with ASC, and also in this condition it defines a more severe disease course [29]. HLA studies have shown that in the UK susceptibility to ASC is conferred by the possession of HLA DRB1*1301 and DRB1*0301 [47].

Evolution from AIH to ASC was documented in one patient during the published prospective series [7] and has been observed in two further patients during follow-up [160]. This was also documented in a recent retrospective review of the long-term outcome of juvenile AIH and ASC [3], suggesting that AIH and ASC may be part of the same pathologic process. Clinical, laboratory, and histological features of type 1 and 2 AIH and ASC are compared in Tables 66.1 and 66.2.

Table 66.2 Biochemical findings at presentation in childhood autoimmune liver disease: King's College Hospital experience [4, 7]. Results expressed as median (range)

	AIH	ASC
Bilirubin (nv <20 μmol/L)	35 (4–306)	20 (4–179)
Albumin (nv >35 g/L)	35 (25–47)	39 (27–54)
AST (nv <50 IU/L)	333 (24–4830)	102 (18–1215)
INR (nv <1.2)	1.2 (0.96–2.5)	1.1 (0.9–1.6)
GGT (nv <50 IU/L)	76 (29–383)	129 (13–948)
AP (nv <350 IU/L)	356 (131–878)	303 (104–1710)
AP/AST ratio	1.14 (0.05–14.75)	3.96 (0.20–14.20)

AIH autoimmune hepatitis, *ASC* autoimmune sclerosing cholangitis, *AST* aspartate aminotransferase, *INR* international normalized ratio, *GGT* gamma-glutamyl transpeptidase, *AP* alkaline phosphatase, *nv* normal values

Though "small duct disease" is reported rarely in pediatric series, in a study [153], where cholangiography was mainly performed by magnetic resonance (MRCP), no radiological biliary involvement was detected despite histological evidence of sclerosing cholangitis in a high proportion (36%) of patients, some of whom had autoimmune features. Whether this finding is due to a lower sensitivity of the MRCP compared to retrograde cholangiopancreatography in detecting biliary changes remains to be verified.

Currently, in our center imaging of the biliary system by MRCP, followed by ERCP if MRCP is not informative, as well as colonoscopy are part of the evaluation of all children with liver disease associated with autoimmune features.

The adult IAIHG scoring systems for the diagnosis of AIH, as currently formulated, do not allow distinguishing AIH from ASC [7, 76], as they do not include cholangiographic investigations at presentation. The ESPGHAN diagnostic scoring system should be used [2] (Table 66.3).

Treatment

Children with ASC respond usually well to the same immunosuppressive treatment described above for AIH [3, 7, 153] with resolution of liver test abnormalities within a few months in most patients. Response to immunosuppressive drugs is less satisfactory if the disease is long-standing before starting treatment [152, 154].

The medium- to long-term prognosis of ASC is worse than that of AIH because of progression of bile duct disease despite treatment in some 50% of patients, with some 20% of them eventually requiring liver transplantation [3, 7, 153, 160].

Table 66.3 Proposed scoring criteria for the diagnosis of juvenile autoimmune liver disease [2]

Variable	Cut-off	Points	
		AIH	ASC
ANA and/or SMA[a]	≥ 1:20[b]	1	1
	≥ 1:80	2	2
Anti-LKM-1[a] or	≥ 1:10[b]	1	1
	≥ 1:80	2	1
Anti-LC-1	Positive[b]	2	1
Anti-SLA	Positive[b]	2	2
pANNA	Positive	1	2
IgG	> ULN	1	1
	> 1.20 ULN	2	2
Liver histology	Compatible with AIH	1	1
	Typical of AIH	2	2
Absence of viral hepatitis (A,B,E,EBV), NASH, Wilson disease & drug exposure	Yes	2	2
Presence of extrahepatic autoimmunity	Yes	1	1
Family history of autoimmune disease	Yes	1	1
Cholangiography	Normal	2	-2
	Abnormal	-2	2

Score ≥7: probable AIH; ≥8: definite AIH
Score ≥7: probable ASC; ≥8: definite ASC
AIH autoimmune hepatitis, *ASC* autoimmune sclerosing cholangitis, *ANA* antinuclear antibody, *SMA* anti-smooth muscle antibody, *anti-LKM-1* anti-liver kidney microsomal antibody type 1, *anti-LC-1* anti-liver cytosol type 1, *anti-SLA* anti-soluble liver antigen, *IgG* immunoglobulin G, *EBV* Epstein-Barr virus, *NASH* nonalcoholic steatohepatitis, *ULN* upper limit of normal
[a]Antibodies measured by indirect immunofluorescence on a composite rodent substrate (kidney, liver, stomach)
[b]Addition of points achieved for ANA, SMA, anti-LKM-1, anti-LC-1, and anti-SLA autoantibodies cannot exceed a maximum of 2 points
From Mieli-Vergani et al. [2]

Based on a reported beneficial effect in adult primary sclerosing cholangitis, ursodeoxycholic acid (UDCA) is added to immunosuppression in the treatment of ASC, but whether it is helpful in arresting the progression of the bile duct disease remains to be established. In adults with primary sclerosing cholangitis, high-dose UDCA was reported as more beneficial than standard doses [161], but a randomized double-blind controlled study from the Mayo Clinic shows that high-dose (30–40 mg/kg) UDCA has a severe negative effect and was discontinued [162]. It is prudent, therefore, to use doses not higher than 15–20 mg/kg/day.

Reactivation of the liver disease often follows flares of the intestinal disease in sclerosing cholangitis patients with IBD. It is therefore essential to control the bowel pathology to avoid progression of liver disease. It has been suggested that the chronic IBD associated with ASC may represent a distinct nosologic entity, different from classic ulcerative colitis and Crohn's disease, being characterized by right-sided colitis with frequent rectal sparing and small bowel mucosal breaks on capsule enteroscopy [163]. A beneficial effect of oral vancomycin has been reported in a small number of children with sclerosing cholangitis and IBD by the same group [164, 165]. Each report includes 14 pediatric patients, six of whom were described in both series. Vancomycin was given at 50 mg/kg/day (maximum 1500 mg daily), in three divided doses. In the first paper, after 1–2 months of therapy, all 14 patients had a decrease in GGT levels, and nine (64%) normalized them, but five (36%) did not, including the four patients who were cirrhotic before treatment. Bilirubin levels did not improve, and the decrease of GGT levels was dependent on continuation of treatment, as they increased again when oral vancomycin was discontinued. In the second series, nonspecific histological and cholangiographic improvements were reported in all patients after at least 3 months of therapy. Most patients were treated continuously and indefinitely, and none of them developed end-stage liver disease or dominant strictures, but the mean follow-up was less than a year and a half, too short to draw

any conclusion, as only 6% of a large cohort of children with sclerosing cholangitis were shown to progress to end-stage liver disease or dominant strictures within a year and a half of follow-up [166]. Whether vancomycin would have beneficial effects through its antibiotic or immunomodulatory [165] properties remains to be elucidated.

Pathophysiology

It is unclear if the juvenile autoimmune form of sclerosing cholangitis and AIH are two distinct entities or different aspects of the same condition. Akin to AIH, in addition to positivity for ANA and/or SMA, liver-specific autoantibodies, including antibodies to liver-specific lipoprotein, asialoglycoprotein receptor, alcohol dehydrogenase, and soluble liver antigen, can be found in ASC [29, 98, 167]. Susceptibility to ASC in children is conferred by the possession of HLA DRB1*0301 and HLA DRB1*1301, while possession of HLA DRB1*0401 appears to be protective. HLA DRB1*1301 has also been associated with susceptibility to primary sclerosing cholangitis in adults [168]. An association with HLA DRB1*1301 has been reported in children with ANA/SMA-positive AIH in Argentina, but no cholangiographic studies were performed, therefore not excluding the possibility that the cohort comprised also children with ASC [169].

Liver Transplant and Autoimmune Liver Disease

Liver transplantation is indicated in patients with AIH who present with fulminant hepatic failure (with encephalopathy) unresponsive to steroids and in patients with AIH or sclerosing cholangitis who develop end-stage liver disease despite treatment. The latter is more likely when established cirrhosis is present at diagnosis or if there is a long history of liver disease before the start of treatment. Approximately 10% of children with AIH and 20% of those with sclerosing cholangitis require liver transplantation. After transplantation, recurrent AIH has been described in about 20% of cases [170] and recurrent sclerosing cholangitis in 27–67% of transplanted patients [152, 160, 171]. Diagnosis of recurrence is based on biochemical abnormalities, presence of autoantibodies, interface hepatitis on liver histology, steroid dependence, and, for sclerosing cholangitis, presence of cholangiopathy. Recurrence may occur even years after transplantation, and consequently maintenance of steroid-based immunosuppression at a higher dose than that used for patients not transplanted for autoimmune liver disease is recommended. While recurrence of AIH does not usually affect posttransplant outcome, recurrence of ASC leads to re-transplantation in a high proportion of patients [160]. Recurrence of sclerosing cholangitis after transplantation is often associated with uncontrolled IBD [171, 172]. In this context, it is of interest that primary sclerosing cholangitis recurrence in adults with IBD can be prevented by pre-liver transplant colectomy [173–175].

De Novo Autoimmune Hepatitis After Liver Transplantation

In the late 1990s, it was observed that AIH can arise de novo after liver transplantation in children who were transplanted for non-autoimmune liver conditions. Characteristic of this condition is a histological picture of interface hepatitis and multilobular collapse associated with increased IgG levels and positive autoantibodies. These include ANA, SMA, and classical anti-LKM-1 but also atypical anti-LKM-1, staining the renal tubules but not the liver. After the original report [176], de novo AIH following liver transplant has been confirmed by several studies both in adult and pediatric patients [177–181] and has been reported to be more frequent in steroid-free antirejection regimens [182, 183]. Importantly, treatment with prednisolone and azathioprine using the same schedule for classical AIH, concomitant with reduction of the calcineurin inhibitor dose, is highly effective in de novo AIH, leading to excellent medium-term graft and patient survival, though, if allograft dysfunction persists long term, chronic liver damage may ensue leading to re-transplantation [184]. It is of interest that patients with de novo AIH do not respond satisfactorily to the standard antirejection treatment schedule, making it essential to reach an early diagnosis to avoid graft loss. Rapamycin has been reported to be effective in difficult-to-treat patients [185].

Pathophysiology of De Novo AIH After Liver Transplant

Whether the liver damage observed in these patients is a form of rejection or the consequence of an autoimmune injury, possibly triggered by drugs or viral infection, remains to be established.

Several reports have investigated whether the development of de novo AIH is associated with the possession of specific major histocompatibility complex (MHC) antigens either by the recipient or by the donor. In the original report, five of seven children with de novo AIH received livers from donors who were HLA DR3- or DR4-positive [176]. In adults, Heneghan et al. found HLA DR3 or DR4 in either donors or recipients in all cases [186], and Salcedo et al. noted an overrepresentation of DR3 in recipients [187].

There are several non-mutually exclusive explanations as to why autoimmunity and AIH may arise de novo in patients

transplanted for non-autoimmune conditions. Besides autoantigen release from the damaged tissue, molecular mimicry might be involved, where immune responses to external pathogens become directed toward structurally similar self-components [188]. In Salcedo et al.'s series, all patients developed de novo AIH in relation to infection with cytomegalovirus, Epstein-Barr virus, or parvovirus [187]. Viral infections, which are frequent after liver transplant, may lead to autoimmunity also through other mechanisms, including polyclonal stimulation, enhancement and induction of membrane expression of MHC class I and II antigens, and/or interference with immunoregulatory cells [180, 189].

Moreover, calcineurin inhibitors may interfere with the maturation of T-cells and/or with the function of Tregs, with consequent emergence and activation of autoaggressive T-cell clones [189–194]. In the experimental context, calcineurin inhibitor-associated autoimmunity arises in animals treated during the neonatal period or rendered immunocompromised by irradiation, reinforcing the concept that patients treated with immunosuppressants, like prednisolone, after liver transplant, may be predisposed to developing autoimmunity through the influence of calcineurin inhibitors. Cyclosporine blocks activation-induced cell death of effector T-cells and interferes with tolerance induction by co-stimulation blockade [193]. Calcineurin inhibitors also act by reducing IL-2 production [195]. As IL-2 is an indispensable survival and growth factor for Tregs [196], the absence of IL-2 leads to impaired suppressor function [197]. De novo AIH occurs more frequently in patients who develop repeated episodes of acute cellular rejection [183, 186, 198–202], which is also associated with a decreased number of circulating Tregs [203]. Treg impairment, as a consequence of calcineurin inhibitors and/or acute cellular rejection, may contribute to the perpetuation of an autoreactive immune response and to the development of de novo AIH.

Since children have an immature immune system—therefore an active thymus and an immature T-cell-receptor repertoire—and are exposed to numerous primary infections, they may be more vulnerable to autoimmunity under calcineurin inhibitors' influence [129, 198]. This would account for the reportedly higher incidence of de novo AIH in pediatric age compared to adults.

Liver-Based Inherited Metabolic Disorders

67

Roshni Vara

Introduction

The liver is the central metabolic organ in the body, and there are now more than 400 monogenic disorders described involving the liver [1]. Hepatocytes play a key role in several biochemical pathways including protein synthesis, bile production and metabolism of proteins, fats and carbohydrates. Disorders of mitochondrial, lysosomal and peroxisomal function can also present with liver manifestations. Inherited metabolic diseases (IMD) account for approximately one third of paediatric patients presenting with hepatomegaly, cholestasis, acute liver failure and chronic liver disease [2]. IMDs now account for 15–20% of all paediatric liver transplants in some centres.

Clinical manifestations of liver-based IMDs can be detected in the neonate, infancy, childhood and adulthood. Early diagnosis and intervention is vital and can impact mortality and morbidity in some of these disorders.

The majority of these disorders are inherited in an autosomal recessive manner, and hence genetic counselling for affected families is important.

Clinical Presentation

Liver-based metabolic disorders can present at any age but tend to be more common in the neonatal period and infancy. However, mitochondrial disorders, for example, can present anywhere from birth to adulthood. Clinical manifestations include hepatomegaly, cholestasis, acute liver failure, hepatic steatosis and chronic liver disease (Table 67.1). There is often overlap of more than one clinical manifestation in inherited metabolic diseases, and hence the table is a guide.

Clinical History and Examination

IMDs are rare and heterogeneous with often non-specific presentations, which can overlap with other liver diseases. Diagnostic clues can be sought from the history and examination to indicate an IMD. Many disorders are inherited in an autosomal recessive manner, and their information regarding consanguinity or other affected individuals should be sought. There may be a positive family history, previous miscarriages, sudden infant deaths and early neonatal deaths with or without a previous diagnosis. The mode of inheritance should be considered carefully when taking a family history. Predominantly affected males may indicate an X-linked inheritance pattern, and a matrilineal inheritance pattern may suggest a mitochondrial DNA point mutation. In some babies with fatty acid oxidation defects, there may be a history of acute fatty liver of pregnancy (AFLP) or maternal HELLP syndrome (haemolysis, elevated liver enzymes and low platelets); the association has been previously reported in association with long-chain fatty acid oxidation defects [3, 4].

There is often a symptom-free period in intoxication-type IMDs, and neonates tend to present in the first few days of life. There is often a trigger in the form of fasting, intercurrent infections or surgery. In the past medical history, there may be specific food aversions, e.g. protein in urea cycle defects and specific sugars in hereditary fructose intolerance. There may be a history of developmental delay or intermittent episodes of clinical manifestations. IMDs affecting the liver can also be multisystemic, and hence it is important to identify other clinical signs and symptoms.

Table 67.1 Clinical presentations of metabolic liver disease

Clinical presentation	Differential diagnoses	Associated features
Hepatomegaly		
	GSD I a/b, III, IV and IX	Hypoglycaemia Ketosis Lactic acidosis, hyperuricaemia, hyperlipidaemia (GSD I) Neutropenia (GSD Ib) Short stature
	Fanconi–Bickel syndrome	Hypoglycaemia Renal tubulopathy
	Fructose-1,6-bisphosphatase deficiency	Lactic acidosis Hypoglycaemia
	Lysinuric protein intolerance	Elevated ferritin
	Cholesterol ester storage disorder	Failure to thrive Splenomegaly
	Lysosomal storage disorders	+ / – splenomegaly Coarse facial features
	Niemann–Pick disease	+ / – splenomegaly Cholestasis (NPC)
Cholestasis		
	Galactosaemia	Coagulopathy
	Citrin deficiency	Failure to thrive
	Congenital disorders of glycosylation	Dysmorphic features
	Bile acid synthesis disorders	
	Peroxisomal disorders	Dysmorphic features CNS involvement
	α1-antitrypsin deficiency	
	Progressive familial intrahepatic cholestasis	Low GGT (PFIC1 and BSEP deficiency)
Acute liver failure		
	Tyrosinaemia type 1	Splenomegaly/chronic liver disease Elevated AFP
	Hereditary fructose intolerance	Specific food aversion
	Fatty acid oxidation defects	Elevated CK, hypoketotic hypoglycaemia
	Mitochondrial disorders	Multi-organ involvement
	Urea cycle disorders	Hyperammonaemia Encephalopathy
	Organic acidaemias	Metabolic acidosis Hyperammonaemia
Hepatic steatosis		
	Cholesterol ester storage disorder	Elevated cholesterol/LDL/low HDL
	Glycerol-3-phosphate dehydrogenase 1 deficiency (GPD1)	Hypertriglyceridaemia Hepatomegaly
	Abetalipoproteinaemia	Fat-soluble vitamin malabsorption Failure to thrive
Chronic liver disease/ cirrhosis		
	GSD IV	Hepatomegaly
	Transaldolase deficiency	Dysmorphic features
	Argininosuccinate lyase deficiency	Hyperammonaemia

IMDs do not often have specific findings on clinical examination; however, some manifest with dysmorphic features such as peroxisomal disorders (large anterior fontanelle and forehead, hypotonia), congenital disorders of glycosylation (abnormal fat distribution, inverted nipples) and lysosomal storage disorders (coarse facial features). A full neurological examination is important in establishing any features of central nervous system involvement. Formal ophthalmological examination can reveal classical features in some IMDs such as 'oil drop' cataracts in untreated galactosaemia and cherry red spots in Niemann–Pick disease, and pigmentary retinopathy is a feature of long-chain hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency and some mitochondrial disorders. Eye movement disorders are a feature of Niemann–Pick C disease (supranuclear gaze palsy), Gaucher disease (horizontal gaze palsy) and mitochondrial disorders (nystagmus, external ophthalmoplegia).

Investigations

Investigations can be divided into first and second line, and initial biochemical markers can indicate a defect in a specific pathway, which can be elucidated with further targeted testing (Table 67.2).

Baseline metabolic investigations should include:

- Blood sugar.
- Blood or urine ketones.
- Blood gas and lactate.
- Plasma ammonia.

Table 67.2 Summarises metabolic investigations with specific disorders and aspects of hepatic presentation

Investigation	Condition	Metabolite/finding	Hepatic presentation
Plasma amino acids	Tyrosinaemia type 1 Urea cycle defects Citrin deficiency Lysinuric protein intolerance	↑ tyrosine/methionine ↑ glutamine ↓ arginine (OTC) ↑ citrulline (citrullinaemia) ↑ arginine (arginase deficiency) ↑ citrulline ↑ threonine/serine ratio ↓ lysine, ornithine, arginine (plasma)	ALF, CLD ALF, E C, ALF, HS H, E, HS
Urine organic acids	Organic acidaemia	↑ specific organic acids	ALF, E
	Tyrosinaemia type 1	↑ succinylacetone	ALF, CLD
	Argininosuccinic aciduria	↑ argininosuccinic acid	ALF, CLD, E
Acylcarnitines	Fatty acid oxidation defects Organic acidaemias	↑ specific acylcarnitines ↑ specific acylcarnitines Often low free carnitine	ALF, HS, H, E
Lactate	Mitochondrial disorders GSD 1 a/b GSD III	↑ ↑ with fasting ↑ post prandially	ALF, CLD, HS H, HS H
Creatine kinase	Fatty acid oxidation defects GSD III	↑ ↑	
Lipid profile	Cholesterol ester storage disorder GSD	↑ cholesterol/LDL ↓ HDL ↑ triglycerides	H, CLD, HS H, HS
Urate	GSD 1 a/b	↑	H
α-Fetoprotein	Tyrosinaemia type 1	↑↑	ALF, CLD
Bile acids	Bile acid synthesis defects	Specific abnormal bile acids	C, CLD
Very-long-chain fatty acids (VLCFA)	Peroxisomal disorders	↑	C, ALF, CLD
Transferrin glycoforms	Congenital disorders of glycosylation Hereditary fructosaemia/galactosaemia	Type 1 or 2 pattern Type 1 pattern (untreated)	C, CLD, ALF, H C, ALF, H, HS
α1-antitrypsin phenotype	α1-antitrypsin deficiency	Pi M/Z/S	C, CLD
Galactose-1-phosphate uridyl transferase	Galactosaemia	↓↓ affected | heterozygote	ALF, C
Oxysterols	Niemann–pick type C	↑	C, ALF
Polyols (urine or plasma)	Transaldolase deficiency	↑ sedoheptulose, ribitol, erythritol and arabitol	CLD, H
Vacuolated lymphocytes	Lysosomal storage disorders	Storage cells	H
Urine glycosaminoglycans	Lysosomal storage disorders	Specific patterns	H
White cell enzymology	Lysosomal storage disorders	Specific deficiencies	H
Bone marrow aspirate	Lysosomal storage disorders	Storage cells	H
Skin biopsy	Lysosomal storage disorders Mitochondrial disorders FAODs	Filipin staining abnormal (NPC) Respiratory chain complex (RCC) activity Fatty acid oxidation studies	H ALF, CLD ALF, H
Muscle biopsy	Mitochondrial disorders	RCC activity Abnormal histology	ALF, CLD
Abdominal X-ray	Cholesterol ester storage disease (infantile form)	Adrenal calcification	H, HS

C cholestasis, *H* hepatomegaly, *ALF* acute liver failure, *CLD* chronic liver disease, *E* encephalopathy, *HS* hepatic steatosis

- Plasma amino acids.
- Urine organic acids.
- Acylcarnitines (dried blood spot or plasma).
- Creatine kinase.
- Lipid profile.
- DNA store (EDTA sample).

Urine amino acids are rarely useful in a baseline screen unless a specific transporter defect is suspected, e.g. lysinuric protein intolerance. Urine reducing substances are also rarely used in recent years due to lack of sensitivity and specificity, and if galactosaemia is suspected clinically, formal enzymology should be sent.

Formal investigation of multi-organ involvement may be required and may include renal, cardiac and central nervous system assessment with glomerular filtration rate, renal tubulopathy screen, electrocardiogram, echocardiography, magnetic resonance imaging (MRI) brain, electroencephalogram (EEG) and muscle biopsy.

Liver imaging may be helpful in elucidating the presence of fatty liver or evidence of chronic liver disease. Liver biopsy can often indicate an IMD with the presence of micro- or macrovesicular steatosis, glycogenated hepatocytes and the presence of storage material.

Molecular diagnosis for IMDs is required for confirmation and can be used for prenatal testing or cascade screening. The use of gene panels with next-generation sequencing has revolutionised the diagnosis of IMDs presenting with liver disease and the ability to provide targeted therapy and early intervention [5]. The use of rapid diagnosis, for example, in mitochondrial disorders presenting with neonatal liver failure can avoid liver transplantation in cases with an extremely poor prognosis. In more recent years, whole exome (WES) and whole genome sequencing (WGS) is increasingly used, particularly in complex and undiagnosed cases [6].

Newborn screening programmes identify some IMDs and allow early therapeutic intervention. In the UK, screening is limited to six IMDs: medium-chain acyl CoA dehydrogenase deficiency (MCADD), phenylketonuria (PKU), isovaleric acidaemia (IVA), maple syrup urine disease (MSUD), glutaric aciduria type 1 (GA1) and homocystinuria (HCU). MCADD can present with hypoketotic hypoglycaemia, hepatomegaly and acute liver failure if left undetected. The other disorders do not tend to have hepatic involvement. Galactosaemia can occasionally be detected incidentally when phenylalanine and tyrosine are found to be elevated as a consequence of screening for PKU in which the phenylalanine is elevated in relation to tyrosine; however, with liver dysfunction of any cause, both can be elevated. Worldwide newborn screening programmes are variable and include conditions such as tyrosinaemia type 1, galactosaemia and urea cycle defects [7].

Disorders of Carbohydrate Metabolism

Galactosaemia

Classical galactosaemia is an autosomal recessive disorder due to deficiency of galactose-1-phosphate uridyl transferase (GALIPUT) and typically presents in the first week of life when milk feeds are introduced. The introduction of galactose in the form of lactose leads to the accumulation of toxic metabolites including galactose-1-phosphate and galactitol (Fig. 67.1).

The incidence in the UK is approximately 1 in 45,000 live births, and the *GALT* gene is located on chromosome 9 and inherited in a recessive fashion. There is a common mutation Q188R identified in 72% of cases with classical galactosaemia. Genotype–phenotype correlations are unclear; however, the Duarte variant (N314D) has 50% residual enzyme activity and is a benign variant [8]. The neonate typically presents with poor feeding, failure to thrive, cholestasis, hypoglycaemia, liver dysfunction or acute liver failure with coagulopathy as a prominent feature. Ophthalmological examination may reveal the classical 'oil drop' cataracts, which resolves with treatment. Neonatal sepsis typically with *Escherichia coli* can also accompany the hepatic presentation, and hence the threshold for antibiotic therapy should be low. Raised intracranial pressure due to cerebral oedema has been reported [9]. A more insidious presentation with symptoms beyond the first few weeks of life can occur with failure to thrive, cataracts, renal tubulopathy and very rarely developmental delay. Diagnosis is made by measurement of GALIPUT activity in erythrocytes with a clear distinction between affected (absent or barely detectable), heterozygote carriers and unaffected cases. Care must be taken in neonates who have received a red cell transfusion within 6 weeks of testing as this may lead to false-negative results. In this circumstance, parental enzyme testing is recommended, as there is a well-defined heterozygote range. Galactose-1-phosphate levels can be measured in some laboratories and will be elevated in untreated cases.

Galactose epimerase deficiency is due to uridine diphosphate-galactose-4′-epimerase (GALE) deficiency and can present in a similar fashion to classical galactosaemia. It should be considered when there is a strong clinical suspicion of galactosaemia and the GALIPUT activity is normal. Diagnosis confirmation is made genetically. Galactokinase deficiency is another disorder of galactose metabolism; however, the phenotype is restricted to ophthalmic manifestations without liver involvement.

Prompt exclusion of lactose from the diet results in resolution of clinical manifestations; hence, if the diagnosis is suspected, a lactose-free formula should be used until the diagnosis is excluded. The use of a casein-based protein

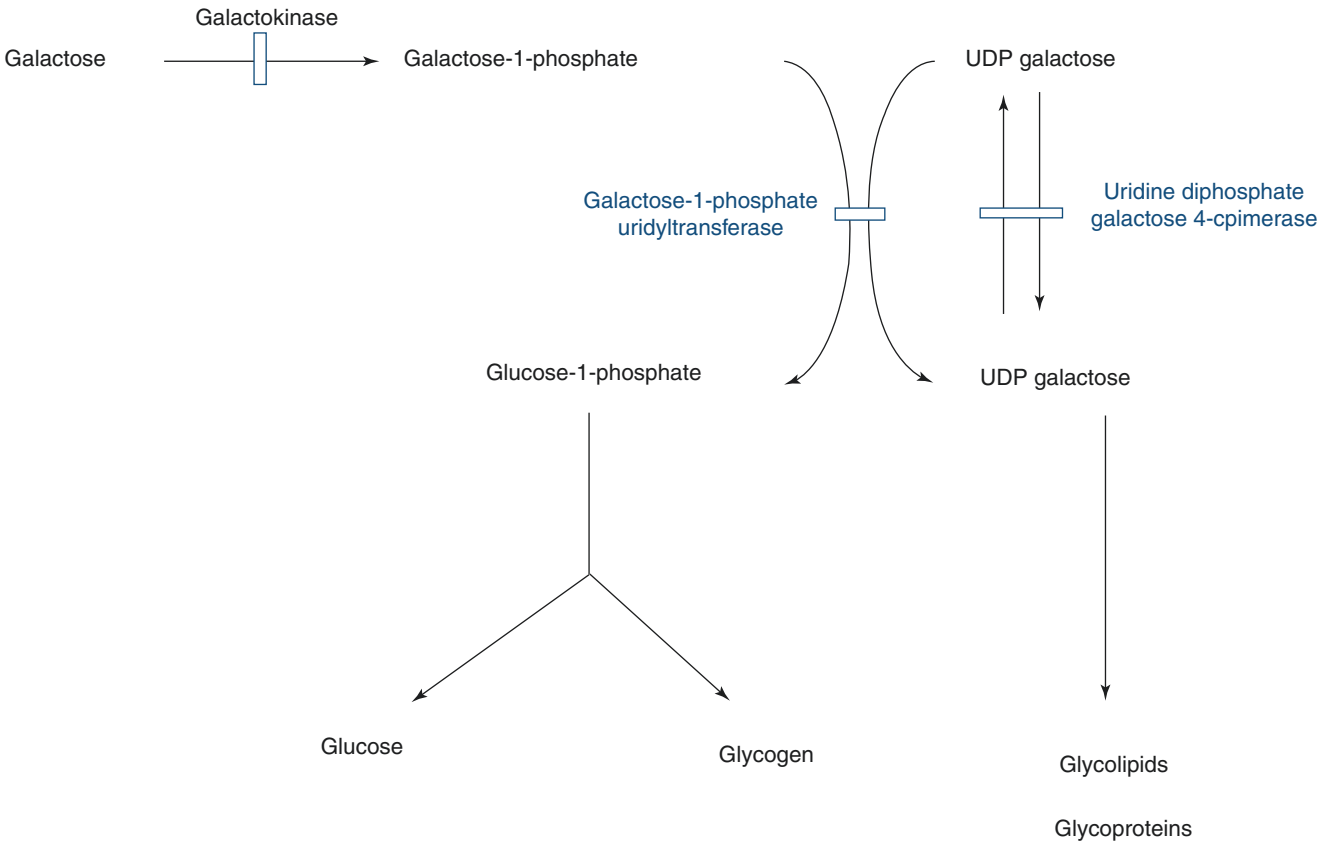

Fig. 67.1 Metabolism of galactose and associated disorders. *UDP* uridine diphosphate

hydrolysate formula (e.g. Pregestimil) is often used when cholestasis and liver dysfunction is prominent with conversion to a soya-based formula once this has resolved. If soya-based formula is not tolerated, an elemental formula (e.g. Neocate) can be used. A lifelong dietary galactose restriction is recommended, and practices are variable worldwide with regard to severity of restriction and necessity in later life [10, 11]. Calcium intake and vitamin D sufficiency need to be regularly assessed at outpatient visits.

Despite treatment, long-term complications of classical galactosaemia are not abolished and include speech and language delay, learning difficulties, neurocognitive issues, movement disorders, osteoporosis and primary ovarian failure in females [12, 13]. In view of these complications, despite even presymptomatic treatment, newborn screening for galactosaemia remains controversial [14].

Hereditary Fructose Intolerance (HFI)

HFI is an autosomal recessive disorder due to deficiency of aldolase B. The key to diagnosis is establishing a clear history of fructose, sucrose or sorbitol intake prior to the onset of symptoms. Fructose is a monosaccharide that is found in many food sources, notably sucrose (glucose–fructose disaccharide), fruits, vegetables and honey. Sorbitol is an artificial sweetener that is metabolised to fructose. The classical presentation is that of a healthy milk-fed infant that develops symptoms when it is first exposed to fructose upon weaning. Occasionally, infants may receive inadvertent fructose prior to weaning as a soother in some cultures. Gastrointestinal upset progresses to persistent vomiting, sweating, lethargy and coma if intake continues. These symptoms are accompanied by liver failure and evidence of renal proximal tubulopathy. Hypoglycaemia and hyperlactatemia are common but can be masked by glucose administration. There is a considerable spectrum of disease severity; infants can present with a chronic course of failure to thrive, hepatomegaly and liver impairment. School-age children may present with avoidance of sweet foods and hepatomegaly, with dentition that is unusually free of caries. Patients may develop self-selected food aversion to avoid sources of fructose that allow them to remain quite well.

Biochemical associations include lactic acidosis, hyperuricaemia, marked liver dysfunction, often without jaundice and renal tubulopathy. The enzyme deficiency results in accumulation of fructose-1-phosphate, an inhibitor of both glycogenolysis and gluconeogenesis that depletes inorganic phosphate, thus restricting adenosine triphosphate (ATP) production. Cellular depletion of ATP is postulated to be a significant mechanism of hepatocellular toxicity [15].

There is no rapid test that can exclude HFI. If it is suspected clinically, then fructose should be immediately excluded. A rapid correction of biochemistry and liver function can be expected over a number of days to weeks. Transferring glycoforms can show a type 1 pattern of glycosylation in the untreated state. Hepatomegaly and transaminasemia may take several months to resolve. Direct enzyme assay is restricted to liver tissue, and liver biopsy may be contraindicated in the acute phase due to coagulopathy. Genotyping of the *ALDOB* gene can often provide a definitive diagnosis; however, if pathogenic variants are not detected, enzymology may need to be performed if clinical suspicion remains high.

Treatment requires specialist dietetic input with a lifelong restriction of fructose, sucrose and sorbitol from the diet and can be a challenge due to its restrictive nature. In addition, medicines and formulas in which fructose/sucrose may not be listed as a primary component need to be avoided. During hospitalisations, special caution is advised to avoid the use of fructose-containing intravenous fluids. Given that reduced fruit and vegetable intake is a dietary requirement, daily supplementation with a 'sugar-free' multivitamin is recommended to prevent micronutrient deficiencies, specifically water-soluble vitamins, vitamin C and folate. No formal guidelines for surveillance exist. Once the diagnosis of HFI has been made, annual assessment of liver function, renal function and growth is recommended, particularly if compliance with the fructose/sucrose/sorbitol-restricted diet is not absolute. Long-term outcomes are good if treatment is adhered to [16].

Glycogen Storage Disorders

Glycogen is a branched polysaccharide structure consisting of glucose units and is the main storage form of glucose primarily in the liver and muscle tissue. During times of need, glycogen is rapidly broken down to form glucose; in the muscle, this provides an immediate source of energy during the first 30 minutes of exercise [17]. Hepatic glycogen is broken down to release free glucose into the bloodstream and is crucial for maintaining blood glucose levels to support the needs of other tissues. Glycogen synthesis and degradation are highly regulated multistep processes involving distinct sets of enzymatic steps (Fig. 67.2).

Glycogen storage disorders result from abnormalities in the function of the enzymes that control the synthesis, regulation and degradation of glycogen.

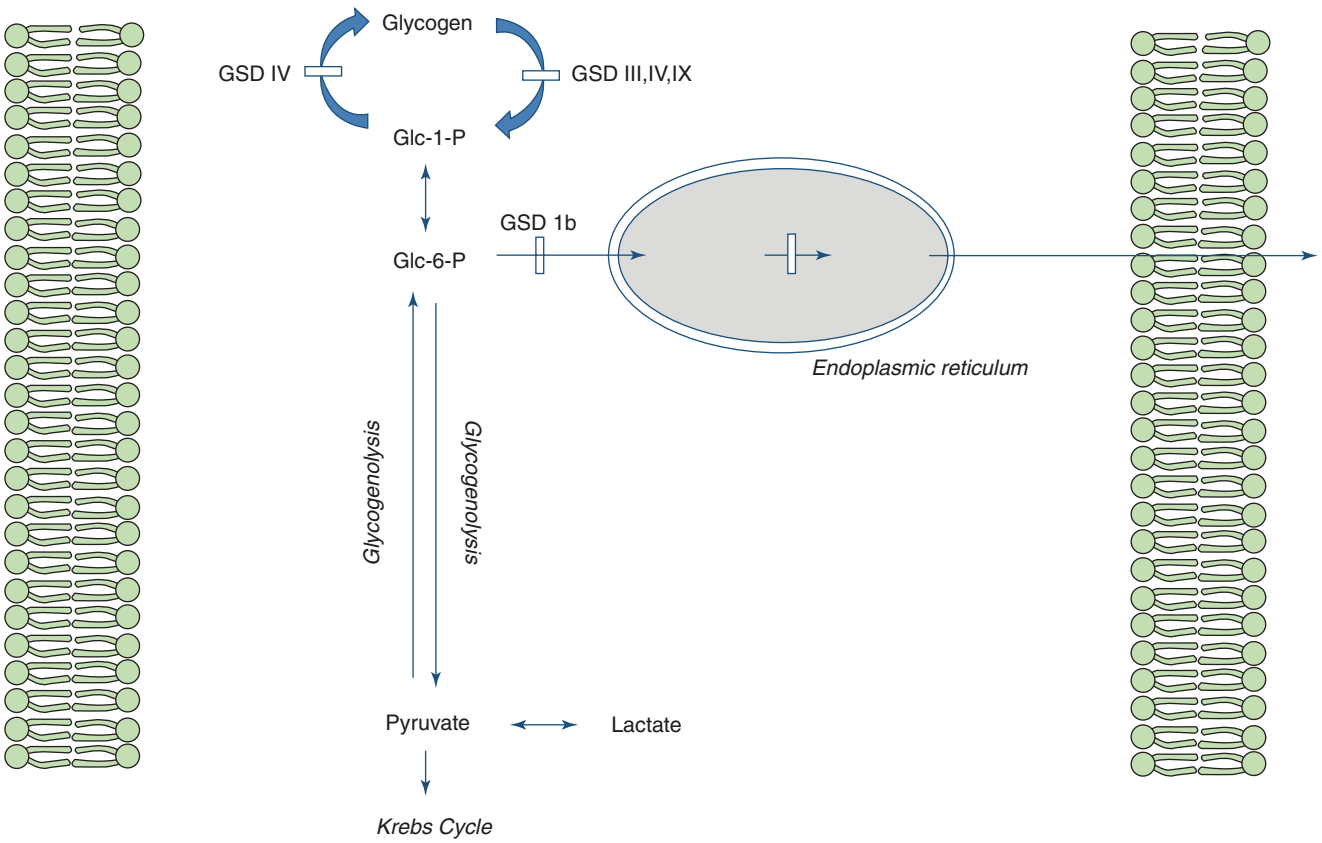

Fig. 67.2 Glycogen metabolism in the hepatocyte. *GSD* glycogen storage disorders, *Glc* glucose, *Glc-6-P* glucose-6-phosphate, *Glc-1-P* glucose-1-phosphate

Cumulatively, the incidence of GSDs is rare (<1:20,000), and all are inherited in an autosomal recessive fashion, with the exception of GSD type IX and Danon disease (X-linked recessive). Although abnormal glycogen storage is a hallmark, there is a large spectrum of phenotypes associated with these disorders, with the age of onset ranging from in utero to adulthood [18]. GSDs are primarily classified according to the affected enzyme, and the focus will be hepatic GSDs (type 1, III, IV, VI and IX) for the purposes of this chapter (Table 67.3).

Common clinical manifestations of GSD are significant hepatomegaly, occasionally splenomegaly, hypoglycaemia (which may be masked by frequent feeding) and short stature. The suspicion of GSD is often raised following investigation of an incidental finding of hepatomegaly or episodes of hypoglycaemia.

GSD 0 is due to glycogen synthase deficiency and causes a block in glycogen synthesis. It typically presents with ketotic hypoglycaemia and short fasting tolerance in the absence of hepatomegaly. There is often postprandial hyperglycaemia and hyperlactatemia [19].

GSD type 1 is the most severe form of GSD and often presents in the first 6 months of life. The abnormal fat distribution gives a 'doll-like' facial appearance, and splenomegaly and nephromegaly may be present. There are two subtypes: 1a and 1b. Glucose-6-phosphatase deficiency or GSD 1a accounts for 80%. G6Pase catalyses the conversion of G6P to glucose and inorganic phosphate. G6Pase is anchored onto the endoplasmic reticulum and requires the G6P transporter (G6PT) to bring G6P into the ER lumen before it is hydrolysed [20]. A defect in this translocase activity is known as GSD 1b. The primary metabolic abnormality of both subtypes is fasting hypoglycaemia because glucose cannot be formed from G6P that is produced from either via gluconeogenesis or glycogenolysis. The elevated G6P leads to associated biochemical abnormalities, i.e. lactic acidosis, hyperuricaemia and hyperlipidaemia. Neutropenia, recurrent infection due to abnormal neutrophil function and inflammatory bowel disease are unique features of GSD 1b. More recently, empagliflozin, a SGLT2 inhibitor, has been shown to improve neutropenia and neutrophil dysfunction in GSD 1b patients [21].

Dietary intervention is the cornerstone of management with regular carbohydrate intake to maintain good metabolic control and avoid long-term complications of disease. Traditional approaches in infants utilise continuous overnight feeding regimens to maintain normoglycaemia and reduction of lactate. In addition, the use of uncooked cornstarch aims to maintain normoglycaemia during the day and night as required. Guidelines for the dietary management of GSD 1 are well published [22, 23]. If treatment is not optimal, long-term complications of GSD 1 can occur, which include osteoporosis, hyperuricaemia, nephrolithiasis, anaemia and liver adenomas [24, 25].

GSD type III is caused by a deficiency of the glycogen debrancher enzyme that results in the accumulation of abnormal glycogen. It may be clinically indistinguishable from type I, but fasting tolerance/tendency for hypoglycaemia is typically not as severe as type I, and nephromegaly is not a feature. Lactate characteristically increases postprandially, and creatine kinase is commonly raised. The mixed hepatic and muscle form is the most common (type IIIa). Muscle weakness is not common in childhood and becomes more prominent in adults, although motor milestones may be delayed and activity can be impaired. Cramps at night are common. Long-term outcome in the purely hepatic form (type IIIb) is good. Hepatic adenoma is rare, and reports of cirrhosis and progression to liver failure are infrequent. In type IIIa complications include progressive myopathy and cardiomyopathy although the latter is rarely clinically symptomatic [26, 27].

GSD type IV is extremely rare and is due to deficiency of the branching enzyme and mutations is *GBE1* gene, resulting in the formation of abnormal glycogen known as amylopectin or polyglucosan. The clinical manifestations range from a severe neonatal neuromuscular form (often fatal), a progressive hepatic form and nonprogressive hepatic form. Cardiomyopathy can be present. Children tend to present with hepatomegaly, evidence of chronic liver disease and classical findings on liver biopsy. The majority have an

Table 67.3 Nomenclature of hepatic glycogen storage disorders

Type	Enzyme	Gene	Inheritance
Ia (von Gierke)	Glucose-6-phosphatase	*G6PC*	Recessive
Ib	Glucose-6-phosphate translocase	*G6PT1/SLC37A4*	Recessive
IIIa (Cori/Forbes)	Glycogen debrancher (liver and muscle)	*AGL*	Recessive
IIIb (Cori/Forbes)	Glycogen debrancher (liver)	*AGL*	Recessive

IXa (XLG)	α-Subunit phosphorylase b kinase (liver)	*PHKA2*	X-linked
IXb	β-Subunit phosphorylase b kinase (liver/muscle)	*PHKB*	Recessive
IXc	γ-Subunit phosphorylase b kinase (liver)	*PHKG2*	X-linked
0a	Liver glycogen synthase	*GYS2*	Recessive

absence of fasting hypoglycaemia. Recently, the clinical spectrum of this disorder has widened considerably [28]. Liver transplantation is the only treatment option for those with the progressive hepatic form who can go on to develop decompensated liver disease. Regular liver and cardiac surveillance is recommended [29].

Phosphorylase (GSD type VI) and its activator phosphorylase b kinase (GSD type IX) are required for the removal of glycosyl molecules from the straight chains of glycogen. GSD VI presents with hepatomegaly and a tendency to ketotic hypoglycaemia in early childhood. Growth failure may be marked, but catch-up growth occurs with treatment, and normal adult height is achieved. The disorder may be so mild that it remains undiagnosed. Long-term outlook is generally excellent, although hepatic adenomas have rarely been described. GSD type IX has a number of subtypes including three that have a hepatic component. Type IXa is by far the most common and has a relatively mild isolated hepatic phenotype similar to type VI. Type IXb is very rare and has a mild mixed liver/muscle phenotype. Type IXc has more severe phenotype often associated with significant hypoglycaemia and progression to cirrhosis [30–33].

Confirmation of a suspected diagnosis of GSD requires assessment of biochemical characteristics (Table 67.4) and ultimately confirmation with molecular diagnosis. The use of enzyme assays for diagnosis has more recently been superseded by genetic panel testing [34]. Liver biopsy may often be performed as part of investigation for hepatomegaly and glycogenated hepatocytes, and occasionally steatosis may be present. Periodic acid–Schiff (PAS) staining reveals cytoplasmic glycogen deposition.

Treatment regimens are tailored for individual patients and necessitate correction of metabolic abnormalities and maintenance of normal growth and development. Regular assessments are required to monitor for complications of individual GSDs and routine follow-up in outpatient clinics with specialist dietary guidance [35].

Liver transplantation is occasionally an option in GSDs with progressive liver disease or hepatocellular carcinoma and in those whom metabolic control is not maintained with medical therapy alone. Liver transplantation for GSD 1b may not correct the neutropenia and inflammatory bowel disease complications and is very rarely required in types VI and IX. The consideration for liver transplantation should be made as part of a multidisciplinary team and on an individual case basis [36, 37].

Fanconi–Bickel Syndrome

The Fanconi–Bickel syndrome, previously classified as type GSD XI, presents with marked hepatomegaly secondary to glycogen storage and fasting hypoglycaemia. Other features include postprandial hyperglycaemia, hypergalactosaemia and renal Fanconi syndrome. The primary defect is a deficiency of the glucose 2 (Glut2) transporter, which is important in the uptake and release of glucose from the liver. Glut 2 is also expressed in the pancreas, gut and kidney. Defects impair glucose sensing within islet β-cells compounding hyperglycaemia in the fed state, due to decreased liver uptake, by blunting the insulin response. Hypoglycaemia, in the fasting state, is secondary to impaired glucose release from the liver. Increased intrahepatic glucose inhibits glycogen degradation facilitating storage, and glycogen deposition may be noted on liver biopsy. Diagnosis relies on recognition of abnormal glucose homeostasis and renal tubulopathy, while transaminitis, hyperlipidaemia and hyperuricaemia may be present. Treatment focuses on dietary support of glucose homeostasis with regular feed and also active replacement of renal losses [38].

Fructose-1,6-Bisphosphatase Deficiency

Fructose-1,6-bisphosphatase (FDP) deficiency is a defect in gluconeogenesis, the pathway that generates endogenous glucose and is a crucial mechanism to maintain glucose homeostasis when dietary glucose is depleted. It is also required for the metabolism of exogenous fructose. The classical features of FDP are hypoglycaemia, lactic acidosis and prominent hepatomegaly. Approximately 50% of cases present within the first 4 days of life and the majority by 6 months of age. Acute acidosis causes hyperventilation and irritability that can progress to coma, apnoea and cardiac arrest. Acute

Table 67.4 Biochemical characteristics of hepatic GSDs

GSD	Hypoglycaemia	Lactate	Ketones	Triglycerides	Cholesterol	CK	ALT/AST

0	+ / ++	+ [a]	+	–	–	–	– /+

[a] Postprandial

hepatomegaly is commonly found, with elevated lactate and ketosis that can be evident (an unusual finding in neonates). Diagnosis relies on clinical suspicion that is confirmed by enzyme analysis of FDP in leucocytes (or liver) or genetic analysis of the *FBP1* gene. It is an autosomal recessive condition, and a family history of neonatal death/acidosis is not uncommon.

Treatment of the acute presentation involves vigorous supplementation of glucose to inhibit gluconeogenesis. The acidosis and hepatomegaly generally respond promptly to this therapy. The acidosis may be severe enough to warrant the use of bicarbonate to correct acid–base balance. Mild hepatomegaly may persist during infancy but is not associated with signs of liver disease. Long-term treatment involves strict avoidance of fasting and adequate supply of carbohydrate during intercurrent illness. Dietary sources containing significant amounts of fructose (including sucrose/sorbitol) should be avoided in the acute situation, but fructose does not have to be rigorously excluded as in HFI. Prognosis is excellent as long as metabolic decompensation is avoided and managed correctly [39].

Transaldolase Deficiency

Transaldolase deficiency is a very rare single enzyme defect of the pentose phosphate pathway. There is a wide phenotype, but some cases described present uniformly in the neonatal period with hepatosplenomegaly and liver impairment. Associated features included dysmorphism (including cutis laxa), cardiac anomalies, oedema, renal abnormalities, haemolytic anaemia and thrombocytopenia. Diagnosis relies on clinical suspicion followed by analysis of urine polyols. Confirmation of diagnosis can be achieved by enzyme assay in lymphocytes, erythrocytes, fibroblasts or liver tissue and more recently by rapidly available analysis of the *TALDO1* gene. Prognosis may be poor with developmental delay and commonly death within the first year of life associated with liver failure. More recently, further cases have been reported and aid family counselling and management of these patients [40, 41].

Congenital Disorders of Glycosylation (CDG)

The CDs are a rare and large group of heterogeneous disorders, which often present a diagnostic challenge. Since their first clinical description in 1980, more than 100 different types of CDG have been described. Glycosylation is the addition and modification of complex carbohydrate molecules (glycans) to proteins and lipids. The majority of extracellular, membrane-bound and some intracellular proteins are glycosylated, and the glycans perform a wide range of functions from structural roles to cell–cell signalling. The process of glycosylation is a highly complex intracellular mechanism, the understanding of which is continuously being updated as new disorders are described [42]. There are mainly two categories of glycosylation: N-glycosylation and O-glycosylation. N-glycans are linked to the amide group of asparagine, while O-glycans are linked to the hydroxyl group of serine or threonine.

The liver is the major site of glycosylation in the body, and disturbances in glycosylation can affect liver development, structure and function. The clinical phenotype of CDGs is extremely broad; often, multisystem and hepatic involvement is described in several types [43, 44].

MPI-CDG results from deficiency of mannose phosphate isomerase and manifests in the first months of life with liver dysfunction and hepatic fibrosis in the majority of patients without neurological involvement. Oral mannose has been shown to be beneficial for the liver disease.

PMM2-CDG (phosphor-aminomutase 2 deficiency) typically presents in the neonatal period with dysmorphism, abnormal fat distribution, inverted nipples, abnormal coagulation factors, hyperinsulinaemic hypoglycaemia and hepatomegaly. Liver histology can show steatosis and fibrosis with myelin-like lysosomal inclusions within hepatocytes on electron microscopy.

Phosphomannose isomerase deficiency (MPI-CDG) presents primarily with a hepatic and gastrointestinal phenotype and has an effective treatment with mannose supplementation. Typical presentation is within the first year of life with vomiting, abdominal distension, protein-losing enteropathy, GI bleeding and liver dysfunction.

TMEM199-CDG is due to a defect in the transmembrane protein 199 and is an example of a purely hepatic CDG. The few reported patients show mild, subclinical hepatic phenotype without liver failure or cholestasis but with elevated LDL-cholesterol and alkaline phosphatase in all patients. There is mild liver copper accumulation and ceruloplasmin are low, and there is some resemblance to Wilson's disease. On transferrin isoelectric focusing (IEF), there is a type 2 pattern.

Diagnostic screening relies on analysis of glycosylated proteins, and the most widely used is transferrin IEF. An abnormal pattern (either type 1 or 2) often precedes further testing with genetic analysis with next-generation sequencing or whole exome sequencing. It should be noted that a type 1 pattern can be seen in untreated galactosaemia or HFI. If the pattern is normal and the clinical suspicion remains high, genetic testing should be pursued in cases with undiagnosed liver disease and other organ involvement. The liver is involved in approximately 22% of CDGs and is highly variable and often not in isolation.

Disorders of Protein Metabolism

Tyrosinaemia Type 1

Tyrosinaemia is an autosomal recessive disorder with an The metabolic defect responsible for tyrosinaemia type 1, fumarylacetoacetase deficiency, arises late in the catabolic pathway of tyrosine (Fig. 67.3). The immediate precursors to the block fumarylacetoacetate and maleylacetoacetate are cytotoxic to the liver and kidney, with their reduced derivatives including succinylacetone [45]. The early-onset form presents with liver failure, coagulopathy, jaundice and ascites in the first 6 months of life. Hypoglycaemia may result from liver dysfunction or hyperinsulinism secondary to islet cell hyperplasia and may require treatment with diazoxide in the acute presentation [46]. Attenuated forms may present with hypophosphatemic rickets secondary to a renal Fanconi syndrome and evidence of chronic liver disease. Occasionally, children can present with neurological crises, which resemble acute porphyria with abdominal pain, hypertension, peripheral neuropathy and muscle weakness.

The management of tyrosinaemia type 1 has been revolutionised by nitisinone, originally developed as a herbicide, with rapid resolution of liver and renal dysfunction [47]. Prior to 1992, liver transplantation was the only treatment option. Treatment with a phenylalanine- and tyrosine-restricted diet is required in addition to home dried blood spot monitoring of tyrosine and phenylalanine levels; the risk of hepatocellular carcinoma is markedly reduced in patients treated early (<6 months). α-Fetoprotein monitoring in clinics should therefore continue with annual imaging of the liver. Current management combines oral nitisinone at 1 mg/kg/day with a tyrosine- and phenylalanine-restricted diet supplemented with a tailored amino acid supplement. Target tyrosine levels are below 400 μmol/l and nitisinone levels 20–40 μM [48]. Non-adherence to nitisinone can result in acute porphyric-like crises with intermittent abdominal pain, muscle weakness and even respiratory failure that could mimic the progressive weakness in Guillain–Barre syndrome. Interruption of treatment leads to inhibition of porphobilinogen synthase by excess succinylacetone.

Indications for liver transplant include failure of response no significant improvement in prothrombin time within 14 days of commencing treatment or a bilirubin >100 mMol/l despite increasing dose to 2 mg/kg/day and suspicion of hepatocellular carcinoma (development of liver nodule or persistently elevated or rising α-fetoprotein) [49]. Patients presenting later may do less well in the longer term as the liver has been subjected to chronic exposure to the toxic metabolites and therefore is more likely to have cirrhotic change. Concerns remain as to the cognitive outcomes of treated patients, and further work is needed to delineate whether this is due to the condition or a long-term nitisinone effect [50].

Urea Cycle Disorders

The urea cycle converts waste nitrogen to urea for excretion via the kidney and is the site of synthesis of the nonessential amino acid arginine. Enzyme defects within the pathway result in hyperammonaemia and encephalopathy (Fig. 67.4). Inheritance is autosomal recessive with the exception of ornithine transcarbamylase (OTC) deficiency, which is

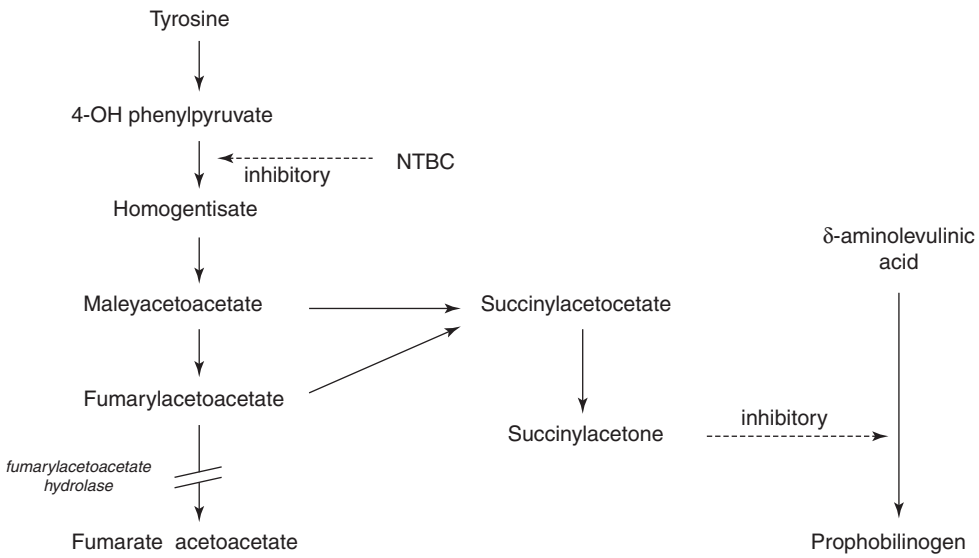

Fig. 67.3 Diagram showing biochemical pathway of tyrosine catabolism, defective step causing tyrosinaemia type I and the action of the substrate reduction therapy nitisinone

NTBC: (2-(2-intro-4-trifluoromethylbenzol)-1,3-cyclohexendiome

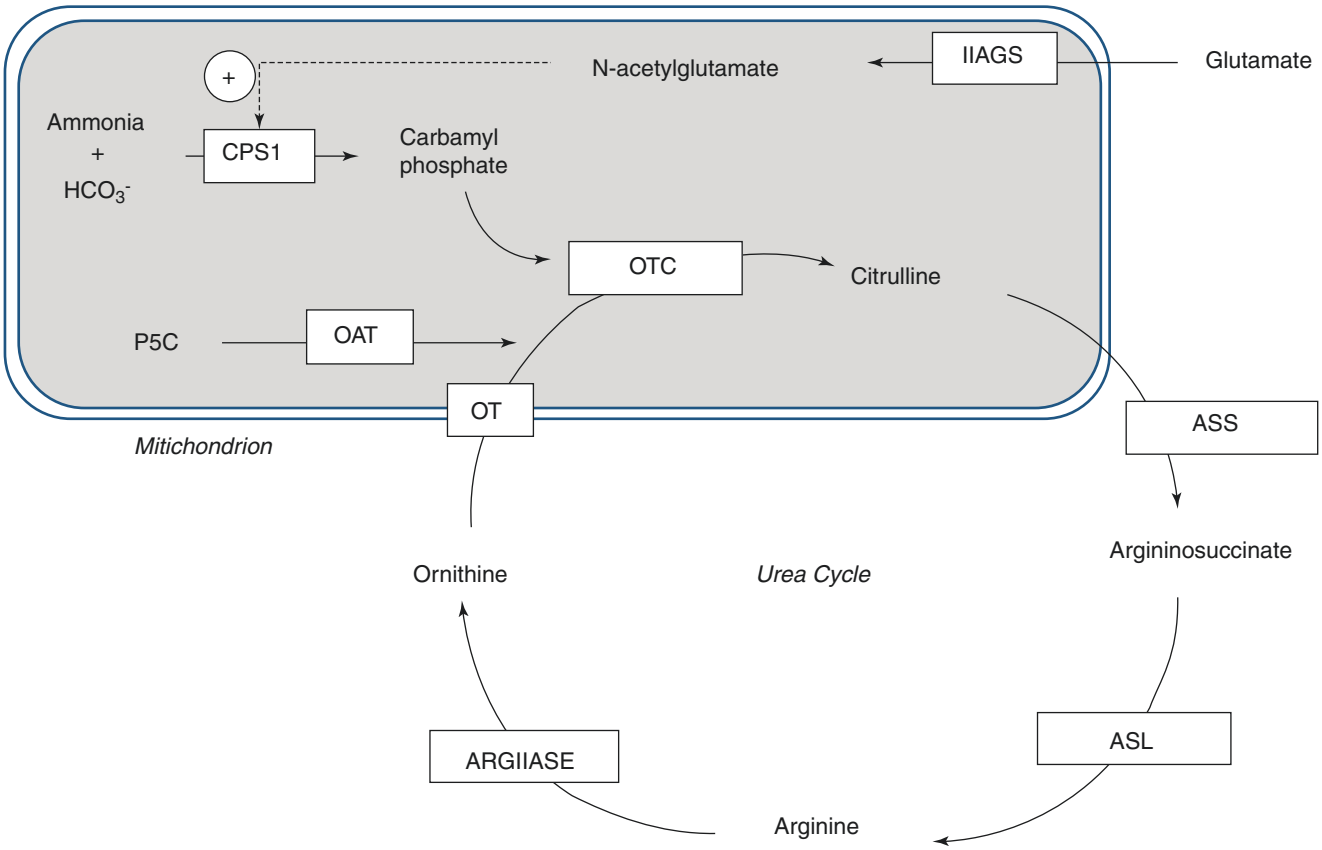

Fig. 67.4 Urea cycle disorders. *CPS* carbamoyl-phosphate synthetase 1, *OAT* ornithine aminotransferase, *OT* ornithine transferase (hyperornithinaemia, hyperammonaemia, homocitrullinuria or HHH syndrome), *OTC* ornithine transcarbamylase, *NAGS N*-acetylglutamate synthase, *ASS* argininosuccinate synthase, *ASL* argininosuccinate lyase, *P5C* pyrroline-5-carboxylate

X-linked recessive. Females can present with symptoms due to the effects of lyonisation if sufficient wild-type OTC genes are inactivated in the liver. OTC is the most common UCD.

Neonatal presentation is a classical intoxication with lethargy/irritability, poor feeding and vomiting progressing to overt encephalopathy. Tachypnoea secondary to the respiratory stimulant effect of ammonia initially produces a mild respiratory alkalosis. Apnoea and fits are also common. First presentation may occur later with a variety of non-specific features including failure to thrive, developmental delay, anorexia and vomiting. Investigation of cyclical vomiting should include assessment of ammonia during at least one of the episodes. Children may appear fussy eaters self-electing a low-protein diet. Episodes of acute metabolic decompensation may be precipitated by intercurrent infections. Long-term neurological sequelae relate to the severity of encephalopathic episodes (peak ammonia and duration), with peak ammonias as low as 360 μmol/l being associated with poorer outcome [51].

Diagnosis is suggested by marked hyperammonaemia and low plasma urea in severe defects. Assessment of amino acids and urinary orotic acid reveals the level of the block (Table 67.5) and can be analysed on a single sample by tandem mass spectrometry. Glutamine tends to be elevated as it forms part of the hepatic nitrogen pool that feeds into the urea cycle, and arginine low as it becomes an essential amino acid in UCDs due to reduced flux through the cycle, with the exception of arginase deficiency. Liver dysfunction and coagulopathy are often featured in the acute stage. The main differential diagnosis for hyperammonaemia includes spurious (poor sampling technique), organic acidaemia, acute liver dysfunction and FAOs. Diagnosis is confirmed by liver enzymology, and more recently mutation analysis as the first-line, prenatal diagnosis can then be made available.

Acute management requires cessation of feeds, promotion of anabolism with 10% dextrose-based fluids with the addition of an insulin infusion if hyperglycaemia persists and removal of ammonia. Initial management of hyperammonaemia includes loading with alternate pathway drugs: sodium benzoate (250 mg/kg) conjugates with glycine from the hepatic nitrogen pool allowing excretion in the urine bypassing the urea cycle and sodium phenylbutyrate (250 mg/kg) conjugates with glutamine. This helps reduce the nitrogen load on the cycle and can be followed by a continuous infusion. Arginine becomes an essential amino acid with the exception of arginase deficiency and should be supplemented

Table 67.5 Diagnosis of urea cycle defects

Condition	Enzyme	Key amino acids	Orotic acid	Tissue enzymology
NAGS deficiency	*N*-acetyl-glutamate synthase	Glutamine ↑ Arginine-normal	Normal	Liver
CPS deficiency	Carbamoyl-phosphate synthase	Glutamine ↑ Arginine ↓	Normal	Liver
OTC deficiency	Ornithine transcarbamylase	Glutamine ↑ Arginine ↓	↑↑↑	Liver
Citrullinaemia	Argininosuccinate synthase	Glutamine ↑ Citrulline ↑↑↑	↑	Liver
Argininosuccinic aciduria	Argininosuccinate lyase	Glutamine ↑ Argininosuccinate ↑	↑	Red blood cell Liver
Arginase deficiency	Arginase	Glutamine ↑ Arginine ↑↑↑	↑↑	Red blood cell Liver

(150 mg/kg load) followed by a continuous infusion. Higher doses are required in citrullinaemia and argininosuccinic aciduria (300–500 mg/kg/day). Carglumic acid, an *N*-acetylglutamate synthetic analogue, is the specific treatment for *N*-acetylglutamate synthase (NAGS) deficiency [52]. A trial of carglumic acid has been proposed for use in all undiagnosed hyperammonaemic crises. If ammonia levels are >300 μmol/l and rising, dialysis is indicated for rapid control and to avoid the long-term neurological sequelae of prolonged hyperammonaemia. The latter can be achieved with hemofiltration but may be limited by the size of the baby (>2.5 kg) where peritoneal dialysis (PD) is used. Crossflow PD using two catheters may be used in the smallest babies to improve ammonia clearance [53].

Long-term management requires dietary protein restriction, titrating growth with ammonia (<50 μmol/l) and glutamine (<1000 μmol/l) concentration. Essential amino acids are monitored to ensure the adequacy of the diet. Essential amino acid supplements can be used as part of the protein intake having the advantage that nitrogen waste will be reduced as nonessential amino acids will need to be synthesised. Sodium benzoate and/or sodium phenylbutyrate and arginine continue as part of long-term management; Carglumic acid is used in NAGS deficiency and sometimes CPS1 deficiency. Citrulline can be added or substituted with arginine in severe OTC and CPS deficiency [54].

Prognosis is related to the peak ammonia and duration; a rapid reversal of hyperammonaemia reduces the risk of neurological injury. Liver fibrosis may develop in argininosuccinic aciduria, and the exact pathophysiology is not known; however, regular liver imaging and AFP monitoring is recommended. Neonatal presenting OTC has the poorest prognosis, and early liver transplantation in the first 6 months is indicated to offer the best long-term outcomes [55]. Liver transplantation in UCDs is well published with successful outcomes and improves quality of life [56]. Hepatocyte transplantation has been used as a bridge to transplant in some cases [57], and more recent trials for gene therapy are underway with potential good outcomes [58].

Citrin Deficiency

Citrin deficiency results from a deficiency of the glutamate–aspartate transporter which has a role in gluconeogenesis from lactate and transporting cytosolic nicotinamide adenine dinucleotide (NADH)-reducing equivalents into mitochondria as part of the malate aspartate shuttle. Citrin deficiency causes three age-specific phenotypes: neonatal intrahepatic cholestasis associated with citrin deficiency (NICCD), in older children as failure to thrive and dyslipidemia caused by citrin deficiency (FTTDCD) and in adults as recurrent hyperammonaemia with neuropsychiatric symptoms in citrullinaemia type II (CTLN2) [59]. The clinical features of NICCD are a transient intrahepatic cholestasis and poor weight gain. Liver dysfunction is variable and usually resolves in the first year of life. Transaminases are modestly elevated with hypoproteinaemia and reduced coagulation factors. Complications include haemolytic anaemia and hypoglycaemia. Ammonia is only mildly elevated, but citrulline and methionine are significantly elevated with milder elevations in threonine, tyrosine, lysine and arginine [60]. Diagnosis is confirmed by SLC25A13 genotyping. Management includes the supplementation of fat-soluble vitamins and the use of lactose-free or formulas containing medium-chain triglyceride (MCT) during the period of liver dysfunction. Many children subsequently develop aversion to carbohydrate-rich food and prefer protein-rich or fat-rich foods developing hyperlipidaemia and the risk of fatty liver and pancreatitis.

CTLN2 is characterised by acute-onset recurrent hyperammonaemia with neuropsychiatric symptoms. Hepatic argininosuccinate synthetase protein is reduced but without any mutations in the argininosuccinate (ASS) gene as seen in citrullinaemia. Precipitants include alcohol, sugar intake, medicines such as anti-inflammatories or analgesics or surgery. Not all patients have a preceding history of NICCD. Liver transplantation is the most effective treatment, preventing hyperammonaemic crises and reversing the

biochemistry [61]. Careful dietary supervision is required to provide appropriate carbohydrate (low) and protein (high) intake as the standard hyperammonaemic treatment. Intercurrent illness and low protein with high carbohydrate can precipitate crises in these patients. This is because carbohydrate suppresses ureagenesis in citrin deficiency. Emergency regimens consist of high protein and low carbohydrate. Sodium pyruvate may have a role in treatment by reducing oxidative stress, reducing NADH and reducing inhibition of ureagenesis [62].

Lysinuric Protein Intolerance (LPI)

LPI is a rare disorder resulting from recessive inherited mutations involving the *SLC7A7* gene. Defects occur in the y^+LAT1 subunit of the cationic amino acid transporter localised at the basolateral membrane of the tubular kidney and small bowel cells, leading to the classical hallmarks of the disease: leakage of cationic amino acids in the urine (arginine, ornithine, lysine) with associated normal to low plasma levels. y^+LAT1 is also expressed in the lung and spleen and in circulating monocytes and macrophages, which would explain the wide spectrum of symptoms that has been described, such as failure to thrive, protein intolerance, hepatosplenomegaly, osteoporosis, lung involvement, kidney failure, immunological disorders with autoimmunity and haemophagocytic lymphohistiocytosis. Plasma lysine, ornithine and arginine are low with corresponding increases in urinary excretion. Plasma glutamine, alanine and glycine can be elevated. Ammonia can be elevated, particularly postprandially due to arginine depletion and secondary urea cycle dysfunction. Lactate dehydrogenase, ferritin and hyperlipidaemia are common. In the acute situation treatment with arginine and ammonia, scavenging agents may be required for hyperammonaemia. Long-term treatment requires protein restriction, citrulline and lysine supplementation and ammonia scavengers. Periodic evaluation of renal function, lung involvement, serum LDH and ferritin and plasma amino acids is recommended [63, 64].

Organic Acidaemias

Organic acidaemias result from inherited blocks in the catabolic pathways of amino acids provoking the accumulation of organic acids prior to the block. There are many disorders, but the most common are propionic acidaemia (PA), methylmalonic acidaemia (MMA) and isovaleric acidaemia (IVA). Acute presentations, either severe neonatal or intermittent late-onset forms, are associated with encephalopathy, marked metabolic acidosis, raised anion gap, ketosis, elevated lactate and variable hyperammonaemia, the latter resulting from secondary inhibition of the urea cycle. Hepatomegaly and liver dysfunction are frequent. Neutropenia, or frank pancytopenia, is a sign of marrow depression and may lag behind the initial presentation and will recover as the decompensation is controlled. Blood glucose may be low, high or normal. Hypocalcaemia is a frequent finding in the acute stage. IVA has an associated pungent odour of sweaty feet.

Diagnosis relies on urinary organic acid analysis to identify the key urinary metabolites and acylcarnitine analysis to identify abnormal plasma metabolites. Free carnitine may be depleted, and glycine is often raised on plasma amino acid analysis. Complications include pancreatitis, cardiomyopathy and renal failure. Amylase should be measured during metabolic crises. Optic neuropathy has more recently been recognised as an association in PA and MMA [65]. Liver histology may show macro- or microvesicular fatty infiltration. Liver tumours have been reported in a few cases of MMA [66]. Definitive diagnosis is with genetic confirmation, *PCCA* and *PCCB* in PA and *Mut*, *CblA* and *CblB* in MMA.

Acute management is focused on promoting anabolism while removing toxic metabolites—intravenous fluids containing 10% dextrose are used in conjunction with protein restriction. Carnitine supplementation is used to facilitate organic acid excretion. Glycine is used in IVA for conjugation and increased clearance. Alternate pathway medication is used to manage acute hyperammonaemia, and recently carglumic acid has been shown to be of use in some patients. Theoretically, the site of urea cycle inhibition is at the level of NAGS, and carglumic acid is a synthetic analogue of *N*-acetylglutamate [67]. Acute toxin removal during crises may require dialysis.

General management consists of protein restriction to a level that prevents overload of the pathway while providing sufficient for growth and repair, with or without amino acid supplementation, and cofactor supplementation. A trial of vitamin B_{12} should be given to assess responsiveness in all patients with MMA. Metronidazole in low dose either continuously or episodically may be used to alter bowel flora to reduce propionate production from the gut. Constipation in itself may precipitate decompensation due to increased gut propionate production [68].

Patients remain at risk of decompensation most commonly precipitated by intercurrent infection, and for patients with neonatal presentations, the outlook is poor [69]. Neurological and cognitive defects are common, and progressive renal impairment is a feature of MMA leading to renal failure in the second to third decade. MMA patients who are B_{12} responsive have a better prognosis, but the poor outcomes for most organic acidaemias have led to serious consideration of transplantation. Liver transplant in PA has been successful with a marked reduction in risk of decompensation, but the risk of metabolic stroke persists, and so a

degree of protein restriction may still be required [70]. The value of liver transplantation in MMA is less certain with significant continued risk of metabolic stroke and renal involvement [71]. Combined liver and renal transplantation has been performed with variable outcomes, and isolated renal transplant may also have a role in MMA patients with chronic kidney disease and may help reduce the frequency of decompensation [72].

Disorders of Lipid Metabolism

Fatty Acid Oxidation Defects (FAOD)

The FAODs for a large group of conditions commonly present with hepatic symptoms. Fatty acids are a major fuel source in the fasted state, the preferred substrate for cardiac muscle and a vital energy source for skeletal muscle during prolonged exercise. Fatty acids are mobilised from stores and are oxidised by most tissues except the brain, which is reliant on hepatic β-oxidation for ketone production that can be utilised within the central nervous system reducing the demand for glucose. Fatty acids are predominantly oxidised within mitochondria (Fig. 67.5 and Table 67.6). The carnitine cycle is required for passage of fatty acyl-coenzyme A (CoA) across the mitochondrial membrane with the exception of medium-chain fatty acids. The fatty acyl-CoAs then enter the β-oxidation cycle with shortening of the fatty acid by two carbons with each passage through the cycle yielding acetyl-CoA for entry into the TCA cycle or ketone production (liver) and reduced cofactors for entry into the respiratory chain for ATP production. The acyl-CoA dehydrogenases central to the β-oxidation cycle are chain length specific, for example, short-chain acyl-CoA dehydrogenase (SCAD), medium-chain acyl-CoA dehydrogenase (MCAD) and very-long-chain acyl-CoA dehydrogenase (VLCAD) for saturated straight chain fatty acids. Unsaturated fatty acids require additional enzymes for oxidation, while branched-chain fatty acids require initial α-oxidation in peroxisomes before they can enter β-oxidation. This is why very-long-chain fatty acids (VLCFA, which include the branched-chain fatty acids) are used as a screening test for peroxisomal disorders. Deficiencies of the electron transfer flavoprotein and its dehydrogenase (multiple acyl-CoA dehydrogenase deficiency, MADD, or glutaric aciduria type 2) block the transfer of electrons from β-oxidation to the respiratory chain and

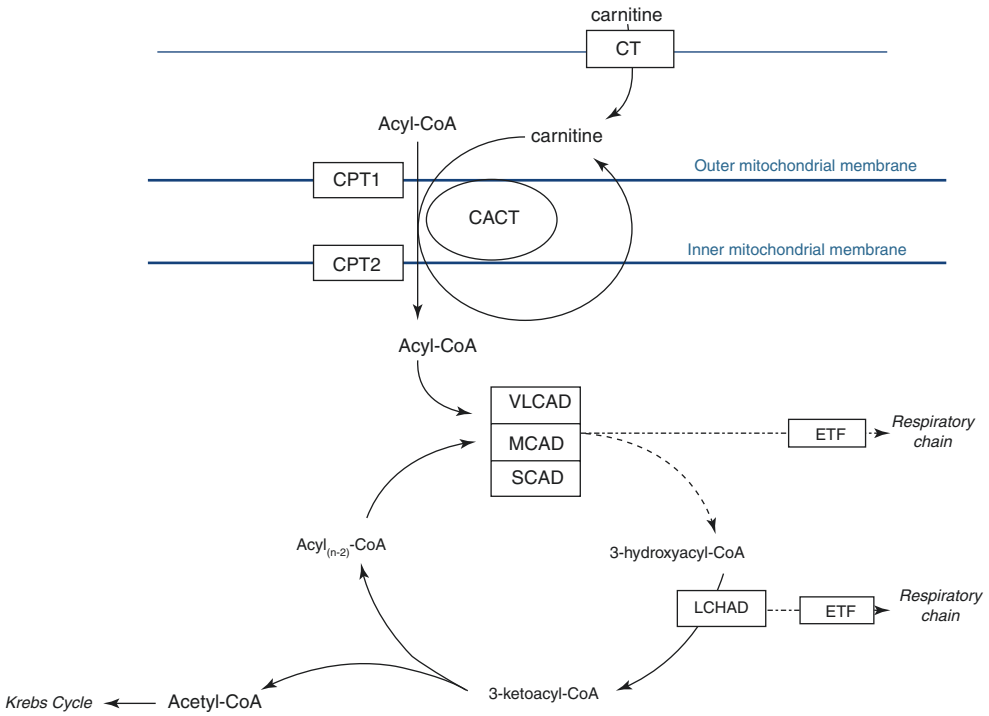

Fig. 67.5 Schematic of mitochondrial fatty acid β-oxidation. The carnitine shuttle facilitates fatty acid entry into the mitochondrial matrix where the β-oxidation spiral chain shortens fatty acids releasing energy in the form of acetyl-CoA that enters the Krebs cycle and electrons that are transferred via electron transfer flavoproteins *(dash-dot line)* to the respiratory chain. Disease-causing enzymes are boxed: *CT* carnitine transporter, *CPT1* carnitine palmitoyltransferase 1, *CPT 2* carnitine palmitoyltransferase 2, *CACT* carnitine acylcarnitine translocase, *VLCAD* very-long-chain acyl-CoA dehydrogenase, *MCAD* medium-chain acyl-CoA dehydrogenase, *SCAD* short-chain acyl-CoA dehydrogenase, *ETF* electron transfer flavoproteins (causing multiple acyl-CoA dehydrogenase deficiency (MADD)), *LCHAD* long-chain hydroxyacyl-CoA dehydrogenase

Table 67.6 Clinical features of fatty acid oxidation defects

Enzyme/transporter defect	Hypoketotic hypoglycaemia/liver dysfunction	Cardiomyopathy	Rhabdomyolysis	Other features
Carnitine cycle				
Carnitine transporter (CTD)	+	+		
Carnitine palmitoyltransferase-1 (CPT1)	+	+	+	Renal tubular acidosis
Carnitine/acylcarnitine translocase (CACT)	+	+		
Carnitine Palmitoyltransferase-2 (CPT2)	+	+ (CPT2 and cardiomyopathy)	+ (CPT2 and rhabdomyolysis)	
β-Oxidation cycle				
Very-long-chain acyl-CoA dehydrogenase (VLCAD)	+	+	+	
Long-chain hydroxyacyl-CoA dehydrogenase (LCHAD) and trifunctional protein (MTP)	+	+	+	Retinopathy, neuropathy
Medium-chain acyl-CoA dehydrogenase (MCAD)	+	+	+	
Short-chain hydroxyacyl-CoA dehydrogenase (SCHAD)	+			
Electron transfer				
Multiple acyl-CoA dehydrogenase (glutaric acidurias type II)	+	+		

also block the oxidation of branched-chain amino acids, lysine and glutaric acid.

Clinical features are predominantly hypoketotic hypoglycaemia, encephalopathy, hepatomegaly, cardiomyopathy and rhabdomyolysis with the majority presenting within the first year, often precipitated by intercurrent infection. Fasting tolerance increases with age as hepatic glycogen stores increase and relative glucose requirement decreases. Hepatic symptoms are common with associated elevated lactate and ammonia. Acute hepatomegaly can occur due to fatty acid mobilisation. Liver failure can occur. Hepatic symptoms may also occur in carrier mothers carrying an affected foetus. Cardiac involvement, either cardiomyopathy or arrhythmias, may be seen in all FAOs except carnitine palmitoyltransferase 1 (CPT 1). Episodic muscle pain, rhabdomyolysis and myoglobinuria may be precipitated by metabolic stress such as exercise or intercurrent infections. Creatine kinase is elevated during muscle crises. Proximal muscle weakness may have a more chronic progressive course. Neuropathy and pigmentary retinopathy are long-term complications of LCHAD deficiency. Neurological deficits may remain following acute encephalopathic insults in many of the FAODs.

Inappropriately low ketones in the presence of hypoglycaemia always raise the possibility of an underlying FAO. Plasma acylcarnitine analysis by tandem mass spectrometry is the investigation of choice to diagnose the specific defect. Plasma free carnitine may be depleted, thereby masking the diagnostic acylcarnitine profile. Very low free carnitine levels are found in a carnitine transport defect and are significantly elevated in CPT I deficiency. Full characterisation may require fat oxidation studies on cultured fibroblasts. Urinary organic acids at the time of decompensation may reveal characteristic dicarboxylic acids; however, they may be normal in between episodes. Further confirmation may be gained from genotype analysis screening for the common A985G mutation in MCADD and G1528C in LCHAD. FAODs are inherited in an autosomal recessive fashion, and therefore siblings should be screened.

The acute management consists of glucose either orally or, if not tolerated, intravenously as 10% dextrose saline in order to halt lipolysis. Hypoglycaemia is a late sign, and so normoglycaemia does not exclude significant decompensation, and therefore management should not be delayed. Resolution of encephalopathy may take some hours. Long-term management consists of avoiding prolonged fasting. An emergency regime consisting of giving frequent high-calorie glucose polymer drinks every 2 hours day and night is adopted during intercurrent infections. Failure to improve or to tolerate the drinks requires admission to hospital for intravenous dextrose.

In the long-chain defects, fat mobilisation is suppressed to avoid the production of toxic long-chain acylcarnitines by frequent feeds, the use of uncooked cornstarch and overnight nasogastric feeds. Long-chain fat in the diet is restricted, and essential fatty acids supplemented as walnut oil. MCT bypasses the carnitine cycle and enters the mid-portion of the β-oxidation cycle and therefore may be of benefit in carnitine cycle and long-chain defects.

Carnitine replacement is essential in the carnitine transport defects (100–200 mg/kg/day). Low levels of carnitine are seen in many FAODs due to accumulation of acylcarni-

tines. The use of carnitine in long-chain FAOs remains controversial with the theoretical risk of compounding mitochondrial toxicity with the accumulation of long-chain acylcarnitines. A trial of riboflavin should be started in all patients with MADD. Triheptanoin is currently under investigation for use in FAOs to help replenish tricarboxylic acid intermediates and therefore increase flux and ATP production [73, 74].

The prognosis in many FAODs depends on the avoidance of acute decompensations. The outcome in MCADD is much improved once the diagnosis is made and future crises avoided. Neonatal screening for detection of MCADD in the UK and other FAOs overseas on blood spot acylcarnitines by tandem mass spectrometry has greatly reduced morbidity and mortality but cannot eliminate early neonatal deaths prior to the screening result being available [75]. Siblings with milder phenotypes with the same genotype have been recognised since screening, particularly with regard to VLCAD.

Acyl-CoA Dehydrogenase 9 (ACAD 9)

Mitochondrial acyl-CoA dehydrogenase family member 9 (ACAD9) is essential for the assembly of mitochondrial respiratory chain complex I. ACAD9 is most homologous to VLCAD. Both ACAD9 and VLCAD function as homodimers associated with the inner mitochondrial membrane and catalyse the initial step of the fatty acid oxidation cycle. The clinical phenotype is dominated by cardiomyopathy but continues to expand and includes liver dysfunction or liver failure, hypoglycaemia, muscle hypotonia, lactic acidosis and neurological symptoms. Most patients present in the first year of life. Muscle biopsy tends to show complex 1 deficiency, and diagnosis is confirmed by genetic analysis. Patients may be responsive to riboflavin supplementation [76].

Glycerol-3-Phosphate Dehydrogenase 1 Deficiency (GPD1)

GPD1 encodes the glycerol-3-phosphate dehydrogenase, a cytosolic protein which catalyses the reversible redox reaction of dihydroxyacetone phosphate (DHAP) and reduces NADH to glycerol-3-phosphate and NAD^+; this plays a critical role in both carbohydrate and lipid metabolism. This rare condition causes transient infantile hypertriglyceridemia, hepatomegaly, hepatic steatosis and fibrosis. Differential diagnoses often include GSDs and LALD. There are very few cases worldwide, and associated hypoglycaemia and hypertriglyceridemia persisting into adulthood have been reported. The phenotype is expanding, and the long-term outcome is unclear. There are no other specific biochemical markers, and the diagnosis is most often made by genetic testing following clinical suspicion or broader testing with WES. GPD1 should be considered in the differential diagnosis of hepatic steatosis [77]. Treatment with fenofibrate has been reported in a single patient [78].

Lysosomal Storage Disorders

The lysosome is an intracellular organelle that is a key component in cellular recycling and homeostasis. The LSDs are a large group comprising over 50 disorders with an estimated combined prevalence of approximately 1 in 8000 [79]. The fundamental pathological mechanism of these disorders is a single enzyme deficiency leading to defective degradation or transport of a complex molecule such as a mucopolysaccharide or sphingolipid. The consequence is a buildup of 'storage' material that impacts on normal cellular function and homeostasis. These conditions are commonly progressive and multisystemic, affecting systems to a highly variable degree. Musculoskeletal involvement can include hypotonia, dysostosis multiplex, cardiomyopathy and the classic course features of the mucopolysaccharidosis. Endothelial reticular involvement can include hepatosplenomegaly and bone marrow dysfunction. Neurological involvement is common and is the most devastating feature of LSDs, causing severe neurological regression. Hepatomegaly, usually associated with splenomegaly, is a common feature of LSDs. A list of LSDs that are associated with hepatosplenomegaly is shown in Table 67.7. Of all the LSDs, the lipid storage diseases (Niemann–Pick disease and cholesterol ester storage disease) are most commonly associated with liver involvement and are considered in more detail below.

Niemann–Pick Type C Disease (NPC)

NPC is a progressive and life-limiting autosomal recessive disorder caused by mutations in either the *NPC1* (accounts for 95%) or *NPC2* gene. Mutations in these genes are associated with abnormal endosomal–lysosomal trafficking, resulting in the accumulation of multiple tissue-specific lipids within lysosomes. The clinical spectrum of NPC ranges from a neonatal rapidly progressive fatal disorder to an adult-onset chronic neurodegenerative disease. In regard to hepatic involvement, the neonate typically presents with cholestasis and persisting hepatosplenomegaly or acute liver failure, hepatosplenomegaly and ascites, which can be fatal early on. Visceral symptoms, if present, usually precede neurological symptoms and occur in about 85% of patients. The age of onset of the first (beyond 3 months of life) neurological symptoms may predict the severity of the

Table 67.7 LSDs commonly associated with hepatosplenomegaly

Disorder	Associated features
GM1/GM2 gangliosidosis	Neurological regression, coarse facies, cherry red spot
Mucopolysaccharidoses	Coarse facial features, +/− skeletal dysplasia, neurological regression, cardiomyopathy
Fucosidosis	Neurological regression, seizures, coarse facies
Mannosidosis	Neurological regression, corneal clouding, coarse facies
Sialidosis type II	Neurological regression, coarse facies, cherry red spot, cardiomyopathy
Galactosialidosis	Coarse facies, neurological regression, skeletal dysplasia, spasticity, corneal clouding, cherry red spot
Niemann–Pick A	Neurological regression, failure to thrive, cherry red spot
Niemann–Pick B	Growth restriction, interstitial lung disease, normal intelligence
Niemann–Pick C	Neonatal liver disease, neurological regression, seizures, cherry red spot
Farber	Contractures, skin nodules, neurodegeneration
Multiple sulphatase deficiency	Coarse facies, skeletal dysplasia, neurodegeneration, spasticity
I-cell disease	Neonatal coarse features, skeletal dysplasia, neurodegeneration, cardiomyopathy
Pompe	Hypotonia, cardiomyopathy, macroglossia
Wolman (infantile CESD)	Failure to thrive, abdominal distension, diarrhoea, calcification of adrenal glands

disease and determine life expectancy. The most characteristic neurological symptoms are cerebellar ataxia, dysarthria, dysphagia and developmental delay or progressive dementia. The majority of patients show a characteristic vertical supranuclear gaze palsy. Pulmonary involvement is well documented in NPC [80].

Diagnosis can be difficult and prolonged. More recently, genetic analysis is the first line, and the NPC genes are included in cholestatic gene panels in some centres. Other biomarkers of disease include elevated chitotriosidase (marker of macrophage activity; however, it can be normal in 5% of the European population) and elevated plasma oxysterols [81]. Filipin staining demonstrates accumulation of unesterified cholesterol in perinuclear vesicles (lysosomes) after staining with filipin in cultured fibroblasts. This requires an invasive procedure and is time-consuming; however, it can be used in the event of finding variants of uncertain clinical significance [82].

There is no effective treatment for NPC and largely consists of supportive therapies [83]. Miglustat has been shown to slow the neurological progression of disease in some patients [84]. There are a number of agents undergoing clinical trials such as cyclodextrin [85].

Niemann–Pick A and B Disease

Acid sphingomyelinase deficiency (ASMD) is also known as Niemann–Pick types A and B. The metabolic defect in ASMD is deficiency of the lysosomal enzyme acid sphingomyelinase due to mutations in the sphingomyelin phosphodiesterase 1 gene (*SMPD1*). ASM catalyses hydrolysis of sphingomyelin to ceramide and phosphocholine, and deficiency results in the progressive accumulation of sphingomyelin and other lipids within tissues that are rich in reticuloendothelial cells, including the spleen, liver, lung, bone marrow and lymph nodes. The disease spectrum ranges from a rapidly progressive neurovisceral neonatal form (NPA), a chronic neurovisceral form (intermediate) and a chronic visceral form without neurological involvement, presenting with hepatosplenomegaly. Pulmonary function may worsen over time, and interstitial lung disease and pulmonary infections are common. A mixed dyslipidemia is seen early in the disease course, and some patients develop coronary artery disease later on in life. Development of hepatic fibrosis ranging from minimal to cirrhosis is common, and progression of liver disease contributes to early mortality in some patients. Progressive splenomegaly may result from deposition of sphingomyelin and progressive portal hypertension [86].

Cholesterol Ester Storage Disease (CESD)

CESD or lysosomal acid lipase deficiency (LALD) is a recessively inherited condition caused by mutations in the gene encoding lysosomal acid lipase, *LIPA*. The resulting reduced or absent enzyme activity leads to a spectrum of disease, from the severe infantile form (also known as the Wolman disease) to a later-onset milder form which can remain asymptomatic and undiagnosed into adulthood. The infantile form is a severe disorder that presents during infancy, resulting in failure to thrive, hepatomegaly, often splenomegaly and hepatic failure, adrenal calcification and an average life expectancy of less than 4 months. Cholesterol ester storage disorder arising later in life is less severe, with a heterozygous phenotype with hepatomegaly and transaminitis, chronic liver disease and cardiovascular disease. The two phenotypes share many common features, including dyslipidaemia and transaminitis. The dyslipidaemia shows an elevated total cholesterol and low-density lipoproteins (LDL) and low high-density lipoproteins (HDL). The diagnosis is confirmed by identification of either biallelic pathogenic variants in *LIPA* or deficient LAL enzyme activity in peripheral blood leucocytes, fibroblasts or dried blood spots [87].

In 2015, regulatory agencies approved the use of a human recombinant LAL for the treatment of LALD. This

long-term enzyme replacement therapy has been associated with significant improvements in the hepatic and lipid profiles of patients with LALD, increasing survival rates markedly in infants with an otherwise rapidly progressive disease [88, 89].

Disorders of Bile Acid Synthesis (BASD)

The synthesis of bile from cholesterol is a complex pathway consisting of at least 14 enzymatic reactions. Defects at specific enzymatic steps cause disease resulting in reduced bile flow and accumulation of abnormal and toxic bile acid intermediates. These disorders broadly tend to present with cholestasis, fat-soluble vitamin malabsorption and, in some subtypes, neurological involvement. They tend to present in infancy but can be diagnosed at any age. The diagnosis is made from the detection of urinary or blood metabolites characterising BASDs via mass spectrometry.

The most common BASD is 3β-hydroxysterol-C_{27}-steroid oxidoreductase (3β-HSD) deficiency, which presents in the neonatal period with a low GGT cholestasis, transaminitis, hepatomegaly and fat-soluble vitamin malabsorption. Liver biopsy shows cholestasis and giant cell transformation. The phenotype is heterogeneous, and some can show resolution of jaundice and present later on with liver dysfunction; the majority however go on to develop progressive cirrhosis without treatment. Treatment with cholic and chenodeoxycholic acid supplementation is successful [90].

Δ4–3-ketosteroid 5β-reductase deficiency is similar in presentation but tends to manifest at a younger age and is characterised by a more severe course with an elevated GGT and often coagulopathy.

Cerebrotendinous xanthomatosis (CTX) or 27-hydroxylase deficiency is a defect at the entry step of the classical bile acid synthetic pathway. It can present with neonatal cholestasis, progression to liver failure or in adulthood with CNS and tendon xanthomas and ataxia. Long-term treatment with chenodeoxycholic acid (750 mg/d) can improve neurological symptoms and contribute to a better prognosis [91].

Bile acid amidation defects are two defects responsible for the lack of bile acid conjugation with amino acids glycine and taurine, respectively. Both can present with low GGT cholestasis and fat-soluble vitamin malabsorption. Treatment with glycocholic acid has been shown to be beneficial.

2-Methylacyl-CoA racemase deficiency has been reported in very few patients who can present with cholestatic liver disease in infancy or fat-soluble vitamin malabsorption in older patients [92]. Treatment of the neuropathy is with a phytanate restricted diet, while the neonatal cholestasis may respond to cholic acid therapy. It should be noted VLCFAs will be normal with elevated pristanic and bile acid intermediates dihydroxy cholestenoic acid (DHCA)/trihydroxy cholestenoic acid (THCA).

Peroxisomal Disorders

Peroxisomes are subcellular organelles present in all cells, except mature erythrocytes, and are especially abundant within the liver. Key functions include β-oxidation of chain fatty acids and fatty acid derivatives, pipecolic acid and glyoxylate degradation, phytanate α-oxidation, plasmalogen, cholesterol and bile acid biosynthesis [93]. Biochemically, peroxisomal disorders are characterised by the extent of peroxisomal dysfunction from complete absence of peroxisomes (biogenesis disorders) to multiple enzyme defects and single enzyme defects. However, there is much overlap within the phenotypes of these groups; hence, a more useful categorisation is made by considering clinical features and age of presentation.

In the most severe peroxisomal phenotype, Zellweger spectrum disorder (ZSD—includes previous classifications of Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease), hepatic involvement is a prominent feature. ZSD presents in the neonatal period or early infancy with severe neurological impairment including marked hypotonia, seizures and neurological impairment, jaundice, hepatomegaly, cholestasis, liver dysfunction and classical dysmorphic features (prominent forehead, large fontanelles). Liver histology can show fibrosis, which may develop into micronodular cirrhosis. Renal cysts are common; however, they may not be easily demonstrable in ultrasonography. Ocular features are common including retinopathy, cataracts and optic nerve dysplasia. Failure to thrive evolves and little developmental progress is made. Death usually occurs within the first 12 months although the more attenuated forms may involve survival well into the first decade.

Defects in a large number of genes have been described as causing ZSD (mostly *PEX* genes). Initial investigations should include plasma VLCFAs. These are typically elevated, but it should be noted that in some peroxisomal phenotypes other than ZSD VLCFAs may be normal. Further delineation of the biochemical block may be gained by measuring plasma bile acid intermediates and erythrocyte plasmalogens. Definition of the precise molecular defect requires skin biopsy and complementation studies followed by enzymology or molecular genetic techniques. Other investigations that may be considered to support a diagnosis of ZSD are electroretinogram (ERG), visual evoked potentials (VEPs) and brain auditory evoked responses (BSAERs) that are abnormal in most cases. Neuroimaging may delineate neuronal migrational defects and demyelination. Plain films of the knees may reveal calcific stippling. More recently, an

increasing number of patients are being diagnosed by WES or WGS as first-line testing followed by more detailed fibroblast studies for confirmation of potentially causative variants.

A newly described peroxisomal disorder involving the liver is peroxisomal *ABCD3* (*PMP70*) deficiency. ABCD3 also known as PMP70 uses one of the three ATP-binding cassette transporters present in the peroxisomal membrane and catalyses the ATP-dependent transport of substrates for metabolic pathways into the peroxisome. The first patient presented with hepatosplenomegaly and severe liver disease with markedly elevated di- and trihydroxy cholestenoic acid [94].

Treatment remains supportive and can be challenging. Seizures are typically difficult to control, and hypotonia often results in a requirement for supportive feeding. Progressive liver impairment often contributes to morbidity and mortality. Vitamin K supplementation to correct coagulopathy and treatment of any associated adrenal insufficiency are recommended. Docosahexaenoic acid (DHA) supplementation has been attempted as it is believed to play an important role in brain development, but most recent evidence does not support therapeutic benefit [95, 96]. Ursodeoxycholic acid is commonly used to improve bile flow in cholestatic patients, but the primary bile acids cholic and chenodeoxycholic acids have also been reported to improve hepatic outcome in those without advanced liver disease. The primary bile acids are postulated to improve bile flow but also inhibit, by negative feedback, the production of abnormal bile acid metabolites formed in the absence of functioning peroxisomes.

Mitochondrial Disorders

Mitochondria are ubiquitous intracellular organelles with complex roles in intermediary metabolism and cell signalling. Functions include ATP generation via oxidative phosphorylation (OXPHOS) system, which consists of five enzyme complexes (I–V), homeostasis of intracellular calcium levels, reactive oxygen species-mediated cell signalling and regulation of apoptosis.

Mitochondrial disease can affect any organ and present at any age with any symptom. Organs with high energy demand tend to produce the majority of symptoms: brain, liver, muscle, heart and kidney. Gastrointestinal and hepatic manifestations are frequent; however, they are rarely isolated symptoms and occur as part of a multisystem disease. Diagnostic clues such as lactic acidaemia may be present but are often absent, and further evidence of mitochondrial dysfunction is often sought by biochemical assay of respiratory chain enzymes that require invasive muscle biopsy. Cerebrospinal fluid lactate can be useful for detecting CNS involvement. Multisystem involvement should be sought if clinical suspicion is raised. Genetic inheritance of mitochondrial disorders is complex and relies on the synergistic relationship of two unique genomes: nuclear DNA (nDNA) defects (usually autosomal recessive) or mitochondrial DNA (mtDNA, matrilineal inheritance) in the form of point mutations or large deletions and rearrangements. Nuclear DNA defects affect the structure and function of mitochondria. The mtDNA depletion syndrome is caused by defects in nDNA, which controls mtDNA replication, stability and maintenance. Hepatocytes contain thousands of molecules of mtDNA, and mostly their sequence is identical, i.e. homoplasmy. However, mutated mtDNA can co-exist with their wild-type counterpart in various proportions, i.e. heteroplasmy, and this has implications for widely diverse phenotypes of mitochondrial disease.

Treatment for the vast majority of mitochondrial disorders remains symptomatic and supportive. Most are progressive disorders, while examples of self-limiting conditions have recently been described. There are a rapidly increasing number of mitochondrial disorders being described whose pathophysiology is becoming clear and that present with well-defined clinical syndromes. Examples of these that include the hepatic/GI system are included in Table 67.8, and the reader is directed to several recent reviews of hepatic/GI mitochondrial disease [97, 98]. Any review of mitochondrial disease warrants a text all to itself, but this section outlines a few of the mitochondrial conditions whose primary features are hepatic/GI in nature.

Hepatic dysfunction is common in mitochondrial DNA depletion syndromes (MDDS). These conditions may present with early-onset liver failure, hepatomegaly and hypoglycaemia and are usually associated with significant neurological symptoms such as seizures, encephalopathy, neuroregression and nystagmus. Alpers (Alpers–Huttenlocher) syndrome typifies this presentation and is caused by mutations in the nuclear gene *POLG* that encodes a DNA polymerase that is responsible for mitochondrial replication. Seizures are often the herald of disease onset, usually before the age of 2 years. Liver failure may then ensue and can be triggered by valproate therapy. Hepatic dysfunction has also been associated with disorders of mitochondrial DNA translation. A particularly interesting example of this is seen in mutations of the *TRMU* gene. These are associated with a syndrome of acute liver failure in early infancy that, if surviving the initial presentation, has spontaneous recovery of liver function and subsequent normal development with favourable prognosis. Identification and intensive support of these patients is paramount. Defects of individual respiratory chain complexes can also give rise to hepatic disease. An example of this is GRACILE syndrome (growth restriction associated with aminoaciduria, cholestasis, iron overload, lactic acidosis

Table 67.8 Mitochondrial syndromes affecting hepatic/gastrointestinal systems

Disorder	Clinical features	Gene(s)
Alpers–Huttenlocher syndrome	Liver failure and seizures	*POLG (PEO1, FARS2)*
Hepatocerebral MDDS	Liver failure, rotatory nystagmus, developmental delay, elevated plasma tyrosine	*DGUOK*
Hepatocerebral MDDS	Liver failure, chronic liver disease, peripheral neuropathy	*MPV17*
Succinyl CoA ligase deficiency	Liver failure, Leigh-like encephalopathy	*SUCLG1*
'Benign reversible' mitochondrial hepatopathy	Liver failure with spontaneous recovery	*TRMU*
Complex III deficiency	Liver failure and renal tubulopathy	*BCS1L*
GRACILE syndrome	Growth restriction, amino aciduria, cholestasis, iron overload, lactic acidosis and early death	*BCS1L*
MEGDEL syndrome	Liver disease with sensorineural hearing loss, Leigh-like encephalopathy and 3-methylglutaconic aciduria	*SERAC1*
Pearson marrow–pancreas syndrome	Exocrine pancreatic insufficiency and sideroblastic anaemia	Large scale mtDNA rearrangement
MNGIE	Pseudo-obstruction and peripheral neuropathy	*TYMP*
Ethylmalonic encephalopathy	Diarrhoea, acrocyanosis and petechiae	*ETHE1*

MDDS mitochondrial DNA depletion syndrome, *mtDNA* mitochondrial DNA, *MMA* methylmalonic acid, *GRACILE* growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis and early death, *MEGDEL* methylglutaconic aciduria with deafness, encephalopathy and Leigh-like syndrome, *MNGIE* mitochondrial neurogastrointestinal encephalomyopathy

and early death) caused by mutations in *BCS1L*, although this has been linked to a variety of other phenotypes, many of which include liver impairment.

Examples of mitochondrial disorders that present with GI features include mitochondrial neurogastrointestinal encephalopathy (MNGIE) and ethylmalonic encephalopathy (EME). MNGIE is caused by an autosomal recessive deficiency of thymidine phosphorylase that classically presents in the first three decades of life. Initial symptoms are often related to GI dysmotility and can present as frank pseudo-obstruction and failure to thrive/cachexia. However, neurological symptoms develop that include peripheral neuropathy, ptosis, ophthalmoplegia, hearing loss and a progressive leukoencephalopathy. Lactic acidaemia may be present. Unusually for a mitochondrial disorder, a diagnostic metabolic profile of raised urinary/plasma thymidine and deoxyuridine will confirm the diagnosis. EME also has a characteristic metabolic profile with large amounts of ethylmalonic acid found in urine (ethylmalonic acid is commonly found in small amounts in urine as a non-specific marker of mitochondrial dysfunction). It is caused by mutations in *ETHE1* that encode a mitochondrial sulphur dioxygenase, which has a role in sulphur detoxification. Accumulation of hydrogen sulphide potently inhibits complex IV of the respiratory chain. Affected infants classically have persistent diarrhoea and the unusual finding of petechiae and acrocyanosis. Associated neurological findings include seizures, encephalopathy and developmental regression. This condition is usually lethal in infancy. Successful liver transplantation has been reported [99].

Investigation of suspected mitochondrial disease includes assessment of potentially affected organ systems; it is important to consider markers of renal tubular dysfunction, echocardiogram/ECG and neuroimaging. Non-specific biochemical evidence of mitochondrial dysfunction can be demonstrated by elevated plasma and CSF lactate levels, but further biochemical evaluation requires invasive testing such as muscle biopsy to assess individual components of the respiratory chain. The approach to genetic testing can be guided by muscle biopsy RCC deficiencies; however, more recently, WES or WGS may be able to identify a pathogenic variant in the nDNA or mtDNA in order to avoid invasive testing. Rapid testing for common nDNA genes causing MDDS is more readily available in some centres and can avoid unnecessary liver transplantation in cases where acute liver failure may require urgent decision-making [100].

Mitochondrial conditions have a vast array of presentations that can include hepatic dysfunction and GI symptoms. These are multisystem disorders and should always be in the differential diagnosis in a child with multisystem disease, especially a child with unexplained neurological symptoms and liver disease.

Conclusions

Inherited disorders of metabolism affecting the liver are individually rare but as a group of conditions are relatively common. The description of liver-based IMDs continues to expand particularly with the advent of novel molecular diagnostics and the availability of rapid metabolite detection. The liver can be predominantly involved or as part of a multisystem disease. The awareness of IMDs in the differential diagnosis of liver disease is vital. Developments in the understanding of the pathophysiology and genetics of these complex disorders will aid research into current and future novel therapies.

Wilson's Disease

68

Piotr Socha and Stuart Tanner

Introduction

In 1912 Samuel Kinnier Wilson described adults with "Progressive lenticular degeneration, a familial nervous disease associated with cirrhosis of the liver." Recognition of the role of copper in Wilson's disease (WD) and the mainly hepatic presentation of WD in childhood came later [1]. After 100 years we know a lot about the disease – its treatment with copper chelators, diagnostic methods, its molecular basis, and the role of liver transplantation. Basic questions remain, such as an explanation for its phenotypic diversity. Moreover, diagnostic and therapeutic practices differ between countries as shown in a large European database of new Wilsonian cases within the "Eurowilson" project. A number of guidelines have appeared [2, 3], and recently a pediatric position statement of ESPGHAN has been published [4].

Definition

Wilson's disease (WD) is an autosomal recessive disorder of copper metabolism, which leads to copper accumulation in the liver and other organs and tissues including the brain. The clinical presentation was first described by Wilson in 1912, who also indicated inheritance of the disease showing familial nature. The disease gene *ATP7B* encodes adenosine triphosphatase 7B (ATPase7B) – a protein responsible for transporting copper into the secretory pathway for incorporation into apoceruloplasmin and excretion into the bile. It is located on chromosome 13. Prevalence of different mutations differs among populations. Clinical presentation is variable – the disease commonly affects the liver and central nervous system. The prevalence of the disease is estimated to be 1:40000 up to 1:30000.

Pathophysiology

Copper is an essential dietary nutrient which is present in most of dietary products. The daily requirement is about 0.9 mg and the excess must be excreted. Copper facilitates electron transfer reactions and is needed for mitochondrial respiration, melanin biosynthesis, dopamine metabolism, iron homeostasis, antioxidant defense, connective tissue formation, and peptide amidation. Still, it can be potentially toxic to the cells which may be explained partly by the Fenton reaction in which Cu^{1+} causes production of the highly reactive hydroxyl radical which may cause lipid peroxidation of macromolecules:

$$H_2O_2 + Cu^{1+} > OH^{\cdot} + Cu^{2+} + H_2O.$$

Biliary excretion is the only mechanism for copper elimination under physiological conditions, and it increases with increasing size of the hepatic copper pool. Trafficking of copper in and through the hepatocytes involves several transport proteins: *Copper transporter 1* (Ctr1) responsible for the copper uptake at the hepatocyte plasma membrane; *metallothioneins* (MT), intracellular proteins capable of binding metal ions, including copper; and *metallochaperones* that mediate the delivery of copper to specific proteins and are responsible for transfer of copper from metallothionein to the site of synthesis of copper-containing proteins. Trafficking of copper is essential for further binding with ATP7B protein.

The Wilson's disease protein, ATP7B, has got several functions that finally allow effective copper excretion from

the hepatocyte and binding with ceruloplasmin which protects from potential copper toxicity. Copper transport into the trans-Golgi is initiated by ATP binding to the "nucleotide-binding domain" of ATP7B. ATP hydrolysis and subsequent dephosphorylation allow the movement of copper associated with two binding sites on one of the transmembrane domains into the lumen of the trans-Golgi. Entering trans-Golgi is essential for further transport of copper – it is incorporated into apoceruloplasmin and other apoproteins and then excreted to sinusoids or after saturation of six copper-binding sites at the N-terminal cytoplasmic tail of ATP7B and phosphorylation of serine residues it migrates in vesicles to the biliary canaliculus [5].

Mutations of the WD gene coding ATP7B protein impair its function and lead to accumulation of copper in the hepatocyte and in other organs. The Human Gene Mutation Database [6] references 858 mutations, including 539 missense/nonsense, 71 splicing, 16 regulatory, and 146 small deletions. Large deletions are rare, in contrast to mutations in ATP7A (Menkes disease). H1069Q (His1069Glu) is the most common mutation in Europe and North America; the majority of WD patients are compound heterozygotes [7]. In central Europe, H1069Q occurs at allele frequencies of 30–60% in series of WD patients from Poland, Romania, Austria, and Saxony [8, 9]. By contrast, H1069Q is rare in Asian, Japanese, and Chinese patients, and in the heterogeneous population of the UK, WD is associated with many mutations, mostly compound heterozygous. Unusual genetic mechanisms such as three ATP7B mutations in a single patient (two in *cis* on the same chromosome) and uniparental disomy (both homologues of a chromosomal region originating from only one parent) emphasize the importance of also genotyping both parents. Several studies have identified families with WD in subsequent generations ("Pseudodominant" inheritance) emphasizing the need to consider the diagnosis of WD in the children of affected parents.

Genotypic incidence considerably exceeds phenotypic incidence. Whether this is due to underdiagnosis or incomplete penetrance is debatable [10].

The functional consequences of most mutations are not well described. H1069Q mutant binds ATP in an incorrect orientation with a reduced affinity, causing instability due to temperature-dependent unfolding and retention of $ATP7B_{H1069Q}$ within the endoplasmic reticulum [3]. For better understanding of the role of different mutation of functionality of ATP7B, a yeast strain that lacks its endogenous copper transporter was used to segregate ATP7B mutants into severe and mild categories based on their ability to restore growth. Studies in mammalian cells have shown decreased protein levels and mislocalization for several mutants, and copper transport has been studied in vesicles derived from cell lines with various ATP7B mutations [11]. The functional studies can help to understand why some mutations are pathogenic and lead to copper accumulation, but do not yet explain the phenotypic variability of Wilson's disease. Liver disease seems to result from a direct copper accumulation in hepatocytes, and consequently mitochondrial damage and disturbance of lipid oxidation. Hepatic steatosis is an early pathologic feature of the disease and may be explained by this mechanism. Injury of other tissues seems to be a consequence of copper accumulation outside the liver and usually appears at later age. Once capacity of the liver to store copper is exhausted, copper is released into the circulation. It can be taken by different organs, but the central nervous system is most vulnerable [12].

Specific pathways that allow the intracellular trafficking and compartmentalization of copper within the hepatocyte showing the role of ATPase7B are shown on Fig. 68.1.

Liver Histology and Ultrastructural Changes

Histological abnormalities observed in liver biopsy are not specific for Wilson's disease and cannot be regarded a valuable diagnostic tool. In the early phase, microvesicular and macrovesicular fatty deposition can be observed (Fig. 68.2), with glycogen-containing vacuoles in the nuclei of periportal hepatocytes. Liver disease may then progress to portal fibrosis and inflammation. It should be noticed that histological changes in WD may resemble those observed in autoimmune hepatitis with interportal fibrous bridging or cirrhosis.

Ultrastructural changes are also not regarded to have a significant diagnostic values – one of the typical features are pleomorphic mitochondria with increased matrix density and widening of intercristal spaces.

While rhodanine or rubeanic acid staining may demonstrate copper, the absence of histochemically demonstrable copper does not exclude a diagnosis of WD. Liver copper content >250 micrograms/g dry weight is a major diagnostic criterion – therefore, in suspected WD, a piece of the liver biopsy should be placed in a dry plastic copper-free container for subsequent analysis by atomic absorption analysis [2].

Clinical Symptoms

Wilson's disease may present with liver, neurological, or psychiatric symptoms. It seems that liver involvement can be observed in most of the neurological presentations, but it is

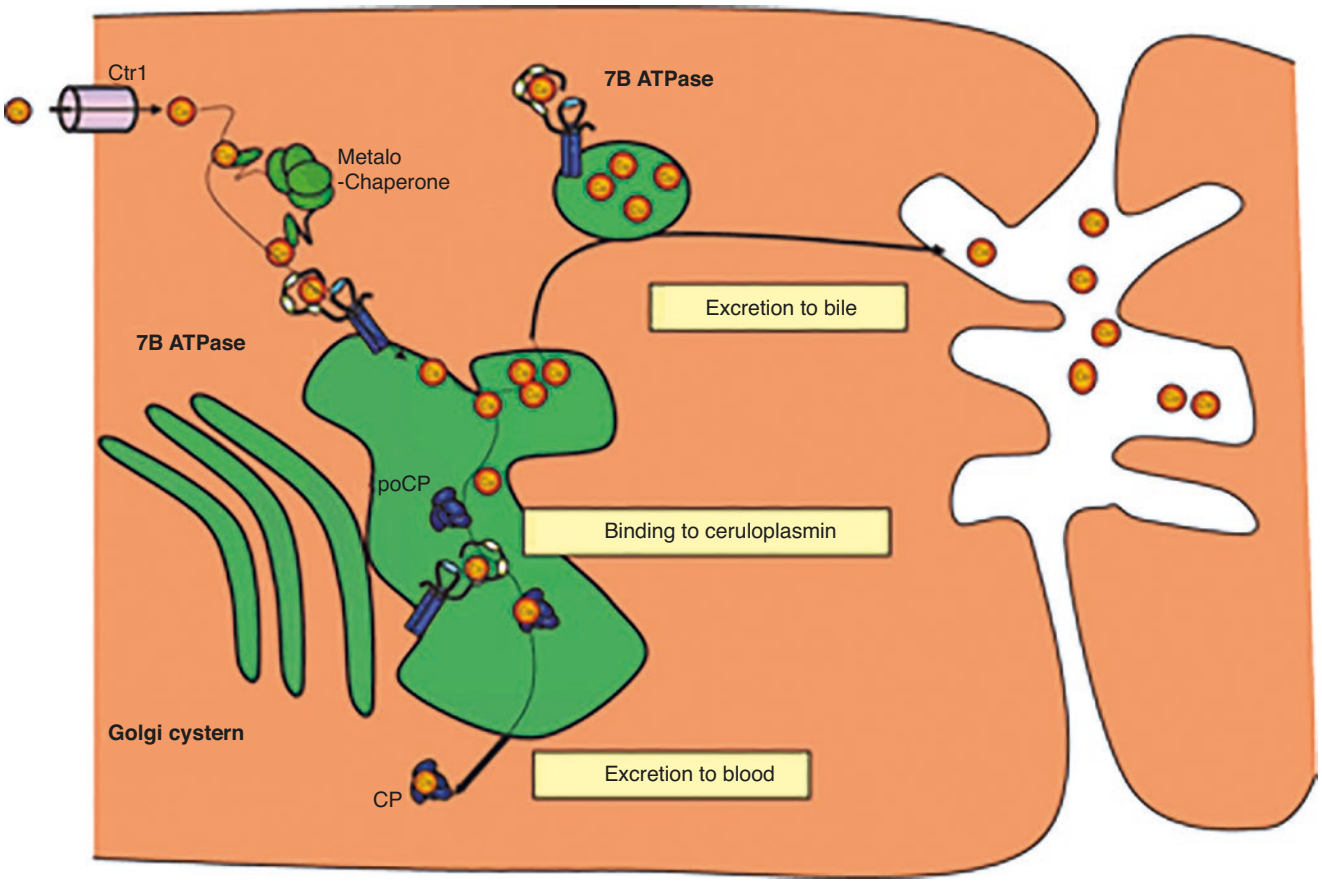

Fig. 68.1 Copper transport within a hepatocyte involving ATPase7B protein

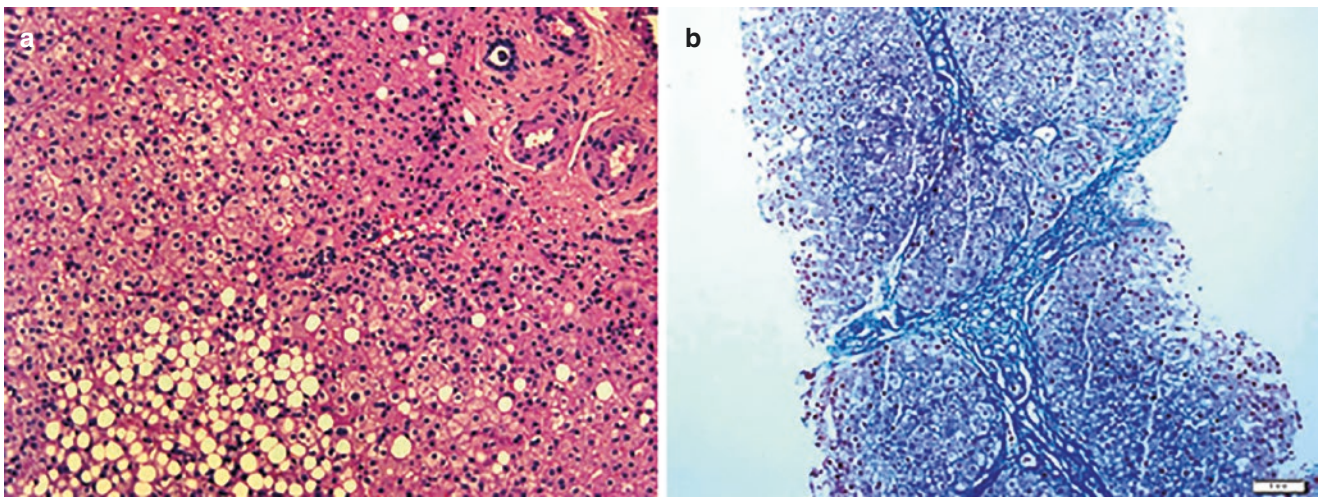

Fig. 68.2 Histopathological findings on liver biopsy from patients with Wilson's disease: (**a**) steatosis (HE staining) and (**b**) advanced fibrosis (Azan staining). (Courtesy of Dr Joanna Kuszyk, Department of Pathology of the Children's Memorial Health Institute, Warsaw)

not always looked for. Due to high index of suspicion in many countries, Wilson's disease is diagnosed very early in the presymptomatic phase. WD may present at any age from early childhood (>1 year of age, with raised transaminases, measured for some unrelated reason) to the eighth decade (often with surprisingly mild neurological features). Still, the clear liver symptoms (like hepatomegaly, clotting disturbances) have not been observed before the age of 2y [2].

Hepatic Symptoms

There is a wide spectrum of hepatic involvement from asymptomatic to hepatomegaly, fatty liver disease, hepatitis, jaundice, cirrhosis, and liver failure at the end. As indicated earlier the liver damage and liver symptoms are not characteristic, and making diagnosis required biochemical and/or molecular tests. Autoimmune hepatitis (AIH) can be easily misdiagnosed as specific for this condition autoantibodies are commonly found in Wilson's disease. Therefore, final diagnosis of AIH required exclusion of WD.

Acute liver failure is a severe presentation of Wilson's disease and requires fast diagnosis which may be difficult to obtain. It is usually found in a previously well child who suddenly presents with jaundice, hepatomegaly, rapidly progressing coagulopathy, and in some cases encephalopathy. The case history of a child may reveal important clinical problems in the past: episodes of jaundice, hemolytic anemia, or increased transaminases. Even if acute liver failure is not a chronic condition, liver biopsies taken at transplantation or post-mortem show cirrhosis which indicates that it is acute or chronic liver disease. Acute liver failure is defined according to the Paediatric Acute Liver Failure (PALF) study group – in a child with biochemical evidence of acute liver injury, international normalized ratio (INR) exceeds/equals 1 and in the presence of clinical hepatic encephalopathy or exceeds/equals 2.0 regardless of hepatic encephalopathy (HE). Wilson's disease makes a significant proportion of ALF etiologies – in 703 ALF patients in the PALF registry, 23 had a diagnosis of WD. However, among 329 patients without a final diagnosis, WD had been tested in only 81%, so there may be some underdiagnosis [13]. WD comprised 4% of the King's College Hospital pediatric ALF series [14].

Some clinical and lab features may indicate WD in acute liver failure like KF ring, family history of WD, neurological features of WD, jaundice and relatively moderately increased transaminases (100–500 IU/l) and alkaline phosphatase (<600 IU/l), hemolysis, and high bilirubin (>300 micromol/l) [15].

Presence of encephalopathy is a bad prognostic feature [16].

Chronic liver disease is more common among Wilsonian patients. Again, AIH may be falsely diagnosed because of the presence of low titer autoantibodies. The differential diagnosis requires also testing for viral hepatitis and alpha-1-antitrypsin deficiency.

Acute hepatitis is not commonly observed though some WD patients give a past history of jaundice and malaise from which they recovered.

Neurological Symptoms

Neurological symptoms are extremely rare in children with WD as they usually develop in the third decade of life and are the presenting symptoms of Wilson's disease in about half of all patients. Some initial symptoms can be difficult to be diagnosed like difficulty with speech. Otherwise, the neurological symptoms seem to be typical and can be described as:

1. A dystonic syndrome with dystonic postures and choreoathetosis.
2. An ataxic syndrome presenting as postural and intentional tremor and ataxia of the limbs.
3. A parkinsonian syndrome with hypokinesia, rigidity, and resting tremor.

To improve diagnostic approach and evaluate therapy, Czlonkowska and coworkers developed a scoring system for neurological symptoms in adult patients with Wilson's disease based on the Eurowilson project [17]. The limited data on neurological presentations in children does not allow to describe the frequency of neurological symptoms at this age. However, dysarthria, salivation, gait disturbances, and postural tremor should be looked for. The presence of Kayser-Fleischer ring is usually associated with neurological involvement [2].

Other Symptoms

Psychiatric symptoms are described to be the predominant presentation of Wilson's disease recognized in adults in later age but usually associate with other clinical symptoms. The most common seems to be depression – which can lead to attempted suicide (also from author's experience in children). Psychiatric problems are not easy to detect as some of them can be attributed to the teenage age like mood change, aggressiveness, and irritability. These symptoms may also be a reason for noncompliance with therapy once Wilson's disease is diagnosed.

Kayser-Fleischer ring is very typical for Wilson's disease and should be always looked for with a slit lamp – it is a gold or gray-brown opacity in the peripheral cornea which represents a deposit of copper and sulfur-rich granules in

Descemet's membrane. Although very characteristic, Kayser-Fleischer ring is uncommon in children.

Hemolysis with negative Coombs test is another typical feature of Wilson's disease even if not commonly described in children with Wilson's disease – usually it is associated with fulminant liver failure [2].

Dermatological findings are also described in children with Wilson's disease – like xerosis, keratosis pilaris, spider angioma, papulopustular lesions, and hyperpigmentation [18].

Fanconi syndrome (renal tubular abnormality presenting as glycosuria, aminoaciduria, renal tubular acidosis, impaired phosphate reabsorption) can be observed in the course of Wilson's disease. Proteinuria may also be detected pointing to glomerular damage in the course of Wilson's disease, but it is usually associated with penicillamine therapy.

Skeletal manifestations appear rarely and include arthritis, rickets, or osteoporosis.

Asymptomatic Wilson's Disease

Asymptomatic liver disease seems to be the most common presentation due to increasing awareness of Wilson's disease manifestation with slightly increased transaminases. Abnormalities at physical examination like hepatomegaly and splenomegaly and abnormal liver tests raise a suspicion of WD. In some countries liver tests are checked at many occasions, and any abnormalities lead to further differential diagnosis of liver problems [19]. Siblings of Wilsonian patients should be also diagnosed as early as possible usually in the preclinical phase.

Diagnostic Approach

Consider WD in any undiagnosed liver disease in childhood. As Wilson's disease can mimic any kind of liver disease in childhood other than neonatal cholestasis, the diagnosis rests upon laboratory findings. Ensure that the lab you are relying upon participates in an external quality assurance scheme. Each of the tests has limitations, and particular tests vary in usefulness in different clinical situations.

Plasma Ceruloplasmin

Plasma ceruloplasmin (CP) may be measured immunologically or by enzymatic activity; the latter is more accurate in WD, where apoceruloplasmin may contribute to the level measured immunologically. Be aware that CP is an acute phase reactant, so may be elevated into the normal range in WD with active liver inflammation, is produced in the liver and so may be reduced in cirrhosis of other causes, may be reduced in WD or aceruloplasminemia heterozygotes, may be low in protein-losing enteropathy, and is a glycoprotein and so may be reduced in some disorders of glycosylation. Twenty percent of WD patients may present with normal ceruloplasmin levels. Values exceeding 30 mg/dl are rare in WD [2].

24-H Urinary Copper Excretion

Accuracy of 24-h urinary copper estimations depends on the collection, the container, and the lab. Values greater than 40 micrograms/24 h raise the suspicion of WD; values greater than 100 micrograms/24 h make it very likely.

In the originally described penicillamine challenge test using a cutoff value of 25 mcmol/24 h (1600 mcg/24 h), the test was abnormal in 15 of 17 Wilsonian patients with active disease and 1 of 58 non-Wilsonian patients. The test was again evaluated by Müller et al. who showed sensitivity to be 76% and specificity 93% in the whole cohort of patients. However, and most importantly, the sensitivity was as high as 92% in symptomatic patients and only 46% in asymptomatic patients [20]. Others have found a cutoff value five times the upper limit of normal gives good differentiation. The test has not been evaluated in adult neurologically presenting cases.

Serum Copper

Serum copper is largely CP bound, so it will be low in mild or presymptomatic disease but sometimes raised (e.g., in acute liver failure) if serum-"free" copper is raised. Calculated free serum copper according to the formula [total copper – 0.3% ceruloplasmin] is in practice a disappointingly inaccurate parameter, but the recently described direct measurement of "relatively exchangeable copper" holds more promise [21]. Other methods to measure non-exchangeable copper are also being developed.

Liver Copper

When a liver biopsy is performed in suspected WD patients, a specimen for measurement of liver copper should always be obtained. Values equal to or higher than 250 μg/gm of dry weight are considered to be typical for Wilson's disease with. In chronic cholestasis conditions, the liver copper content will also be elevated, but this should not be a source of diagnostic confusion. Values less than 250 micrograms/g may be found in WD cirrhosis, where the centers of large

regenerating nodules and tracts of fibrous tissue will both have lower Cu concentrations. Thus, Ferenci et al. assessed the hepatic copper content of 106 patients at the time of diagnosis of Wilson's disease of whom 19 patients had a liver copper concentration below 250. Values equal to or higher than 250 μg/gm of dry weight are considered to be typical for Wilson's disease. In chronic cholestasis weight has a poor sensitivity (82%) and very good specificity. The low range (50 μg/g dry weight) has a higher sensitivity, but lower specificity as well as a positive predictive val [22]. The most comprehensive study analyzed liver samples from 691 patients with various liver diseases, including 178 with WD. Mean liver copper content was significantly higher in patients with WD with liver dysfunction than in asymptomatic patients or patients with neurological dysfunction without signs of liver disease. All patients with WD with liver dysfunction had liver copper levels above 250 mg/g dry weight, but a high proportion (47.8%) of patients with primary biliary cirrhosis or primary sclerosing cholangitis also had liver copper values _ >250 mg/g dry weight [23].

Liver biopsy is rarely performed in adult neurological patients, so the value of liver copper quantification in neurological presentation is not established.

The data from children with WD is scarce. Nicastro et al. reported liver copper >250 μg/g dry weight in 28 of 30 WD children with mild liver. Among WD patients, 2 children (7%) had liver copper level <75 μg/g dry weight, while 4 (6%) of 24 controls had liver copper levels >50 μg/g dry weight [24].

Testing Strategy

Mutations in the Wilson's Disease *ATP7B* Gene, Locus 13q14.3, and Genetic

The WD gene comprises 80,000 base pairs on 21 protein-coding exons and a poorly characterized promoter. As described earlier the Human Gene Mutation Database references 858 mutations, including 539 missense/nonsense, 71 splicing, 16 regulatory, and 146 small deletions. Therefore, genetic testing is challenging but is crucial in making or confirming diagnosis.

Mutation detection by direct sequencing is now widely available, but bear in mind the following. First the testing strategy should be appropriate to the population served. For heterogeneous populations, it may be known which exons have the highest mutation frequency. For the UK, these are exons 14 (24%), 8 (20%), and 2 (12%). Analysis of these three exons would detect 56% of mutations, while analysis of exons 2, 5, 8, 13, 14, 18, and 1920 would detect 82% of the mutations in this population. Second, some patients have been found to have three mutations, two on one chromosome ("in cis"). Therefore, finding two mutations does not necessarily mean the patient has WD; they might be in cis so that he/she is actually a carrier, i.e., has one normal allele on the other chromosome. This mistake is avoided by proving that one of each of the patient's mutations is present in each parent. Third, though large deletions are rare, they can occur and may be missed, and the patient may be wrongly described as just having the one point mutation on the other chromosome. Fourth, apparent parent-to-child transmission of WD occurs, the unaffected parent turning out to be. Therefore, family screening must extend to the children of known parents with WD. Mutation testing for WD should be restricted to laboratories which participate in the European Molecular Quality Network.

Next-generation sequencing (NGS) is very efficient and can identify both mutant alleles in 95% of affected subjects, but there are several pitfalls as indicated earlier. There is also a risk of identifying variants of unknown significance (VUS) which pose diagnostic difficulties, and with the new cell models, molecular characterization of novel ATP7B variants may help to functionally categorize the mutation and to assist in early WD diagnosis [25].

Diagnosis in Different Clinical Scenarios

In central Europe, a rapid H1069Q test may be the most cost-effective first-line test in any suspected WD patient. Otherwise, one is reliant on biochemistry. Tailor your testing to the clinical scenario. In acute liver failure, suspect WD if there is Coombs negative hemolysis, a high bilirubin (>300micromol/l), and relatively low transaminases (100–500 IU/l) and alkaline phosphatase (<600 IU/l) and alkaline phosphatase IU/l/total bilirubin mg/dl ratio <2. Urine copper and a penicillamine challenge are probably the most valuable copper tests. In active but non-fulminant disease, the penicillamine challenge test is useful, whereas in presymptomatic siblings, it will be useless, but ceruloplasmin should be discriminatory and there is of course time to get a mutational analysis.

WD can present as early as 2 years of age, and early presentation can be challenging to establish diagnosis. Biochemical tests including urinary copper excretion may be less sensitive in very young children; therefore, the diagnoses usually require a combination of tests. If molecular tests are inconclusive, liver copper content should be measured [26].

Making diagnosis in infants is also difficult. Healthy neonates and young infants present with naturally low levels of

ceruloplasmin, and liver copper is increased in infancy, so these tests cannot be used directly for making diagnosis of Wilson's disease.

However, the value of biochemical tests for making early diagnosis should not be completely excluded. Early screening for Wilson's disease may be possible if new cutoff values for ceruloplasmin are established as indicated by Kroll and coworkers who analyzed blood spots for ceruloplasmin concentration from 1045 anonymous newborn screening specimens and from 2 Wilsonian patients. Ceruloplasmin levels were extremely low in Wilsonian patients (2.8 and 2.6 mg/dl) compared to healthy infants (6.5 to >60 mg/dl) [27].

Scoring System for Diagnosis of Wilson's Disease

As making diagnosis of Wilson's disease based on clinical symptoms or single biochemical test is difficult, several parameters need to be taken into account all together. In 2001 a scoring system was proposed and further evaluated by Ferenci et al. [28].

The patients with a total score of at least four are diagnosed to have Wilson's disease. The patients with a total score of two to three are considered as "likely to have Wilson's disease, yet more investigations had to be performed." The diagnosis of Wilson's disease was judged to be improbable for scores between zero and one [29].

In order to test this scoring system, Dhawan et al. investigated records of 143 children with chronic liver disease, aged at least 5 years. Among the patients studied, 53 children were diagnosed to have Wilson's disease (median observation time 11 years), and 90 children had other liver diseases. Fifty patients with Wilson's disease had a score >= 4 (true positives). A total of 85 true negatives with a score of either 2–3 (40 children) or <1 (45 children) were observed. Both sensitivity and specificity of this scoring system were higher than 94% [30].

Genotype-Phenotype

It would be prognostically useful if there were a clear mutation/phenotype relationship, but there is not.

It is common to find differing phenotypes among siblings even for identical twins. Two statements may be made. First, patients homozygous for H1069Q tend to present later and with neurological disease. Second, there is a suggestion that fulminant hepatic failure is more likely in patients with truncating mutations [31–33].

Gene Modifiers

Searching for modifier genes differs from searching for disease-causing genes. In searching for genes involved in the disease, individuals are usually defined as affected or unaffected, but in searching for modifier genes, the affected individuals are related to the clinical symptom variability. The modifier gene effect can vary from strong effects, similar to those observed in a monogenic disease, to much milder effects typical for multifactorial, complex diseases. The strong effect relates mostly to highly penetrant mutations, whereas mild-to-moderate effects relate to single nucleotide polymorphisms (SNPs).

Rare allelic variants in ESD and INO80 seem to associate with a neurological phenotype while rare variants in APOE and MBD6 with age of onset [34].

The *HSD17B13*:TA allele modulates the phenotype and outcome of WD. This allele likely ameliorates hepatic fibrosis and reduces the transition from copper-induced hemolysis to fulminant disease in patients with WD [35].

Treatment

The aim of therapy is to decrease copper absorption and accumulation in the liver and central nervous system. For all WD patients, lifelong medical therapy is required. Conventional medical therapies are based on either copper chelators (penicillamine, trientine, tetrathiomolybdate) or zinc. Chelators mobilize intracellular copper into the circulation which is then excreted with the urine. Zinc decreases copper content mainly by reducing intestinal absorption. It induces copper-binding metallothionein both in enterocytes and hepatocytes, reducing the damaging effects of free liver copper.

Definite treatment is liver transplantation which is however indicated only in selected cases where rapidly progressing liver failure cannot be reversed by medical therapy.

Evidence from observational studies shows very good long-term prognosis on medical therapy with a survival comparable to the general population, even if some of them do not normalize completely aminotransferase activity [36, 37]. Poor compliance is regarded to be the major problem and the major reason of poor outcome.

Copper Chelators

Penicillamine and trientine are chelating agents regarded to be the first-line therapy in severe liver disease, but also effectively used in neurological symptoms and in asymptomatic cases. The major limitations for their use (mainly penicilla-

mine) are side effects and toxic reactions reported in almost 10% of adult patients. The major risk of chelating therapy is worsening of neurological symptoms (in neurological presentation) after therapy is started, and for this reason the doses are usually increased gradually (within a few weeks). Penicillamine therapy is more common in Europe (according to data from Eurowilson project – unpublished). Trientine can replace penicillamine in patients presenting with penicillamine intolerance (trientine is regarded to be safer), but sometimes it is used as a first-line therapy. There have been only rare reports of allergic reactions, arthralgias, muscle cramps, and sideroblastic anemia induced by trientine. Similar efficacy of trientine compared to D-penicillamine was shown in one large study in WD adults with liver symptoms, but trientine was also associated with a higher risk of neurologic worsening of symptomatic neurological patients compared to D-penicillamine [38]. In the pediatric study of trientine as a second-line therapy in 16 children with D-penicillamine intolerance or adverse events, liver function normalized in the majority of children, but trientine did not improve accompanying neurological or psychiatric symptoms [39].

Tetrathiomolybdate is another copper chelator which was mainly investigated in neurological presentation of the disease. It seems to be a more powerful decoppering agent than trientine and penicillamine, but there is limited experience in pediatric practice. According to Brewer et al., it showed very strong control of free copper levels over the 8 weeks of treatment in adults, and it was better than trientine in the tetrathiomolybdate/trientine double-blind study [40].

The full dose of penicillamine is 20 mg/kg/day – given in three doses. Adults receive 1 g per day up to 2 g if there is a poor response. Side effects include hypersensitivity reactions (usually transient and at the beginning of therapy), proteinuria, fever, lymphadenopathy, and bone marrow suppression. Patients should be monitored for side effects with blood count, urine analysis, as well as liver and renal tests. In children, the dose of D-penicillamine is also usually increased progressively to 20 mg/kg/day given in two or three doses, even in patients with only liver presentation. The adverse events like hypersensitivity and proteinuria and hematologic toxicity can be observed and require immediate discontinuation and switching to trientine or zinc salts [41].

The recommended dose of trientine in children is up to 20 mg/kg/day in 2–3 divided doses. The drug is best given 1 hour before or 2–3 hours after food for optimal absorption (Table 68.1). Trientine tablets either must be kept refrigerated (2-HCL trientine) or do not require any special storage conditions (4-HCL trientine).

Zinc

Zinc can be alternatively given to the patients with Wilson's disease, but it is not recommended in severe liver disease with abnormal synthetic function as chelating agents are believed to be more effective in producing negative copper balance. Zinc seems to be safe, and it was the reason for its preferential or alternative use in neurological and asymptomatic cases. It is not associated with neurological deterioration which could be the main reason for its common use in neurological patients. Zinc is also used for maintenance therapy after the induction phase with chelators.

Zinc is given in the dose of 25 mg of elemental zinc three times in younger children (<50 kg) a day or 50 mg three times a day in older children. In very young children under 5 years of age, the dose is not well defined. Patients should be fasted, so zinc should not be given between meals.

There are two different chemical zinc preparations used – zinc sulfate and zinc acetate. Zinc acetate is more commonly used and has a better tolerance profile but is also more expensive. Zinc sulfate is also commonly used but may cause more significant side effects – like nausea, vomiting and epigastric pain, mild gastric irritation, decreased blood iron levels, and anemia. We have also recently reported gastric/duodenal mucosal ulceration or erosion [42]. These side effects may lead to discontinuation of the therapy, and it could be the reason for slightly elevated transaminases observed on this treatment.

Different Clinical Presentations and Choice of Medical Therapy

The choice of medical therapy is related to clinical presentation of Wilson's disease, and there is an agreement to use chelators for acute liver failure as first-line treatment. However, there are still many controversies on preferential use of chelators or zinc for other clinical situations. In severe liver insufficiency due to Wilson's disease, penicillamine or trientine therapy should be started immediately after diagnosis is made. Improvement does not appear soon after therapy was started, and usually first after one or several months, liver function tests improve. For other hepatic presentations of Wilson's disease, chelators seem to be more effective as indicated by the review of 288 patients with a median follow-up time of 17.1 years presented by Weiss et al. who showed that increase in activity of liver enzymes occurred more frequently from zinc therapy (14/88 treatments) than from chelator therapy (4/313 treatments; $P < 0.001$). Similarly, the

Table 68.1 Pharmacotherapy in Wilson's disease

Drug	Dose	Comment
D-penicillamine	20–35 mg/kg/day	
Trientine preparations		
2-HCL 250 mg capsules	500–750 mg in 2–3 doses	Keep in refrigerator Give before or 2h after meals
2-HCL 300 mg capsules	1.2–2.4 grams (4–8 capsules) daily 2–doses	Store in refrigerator
4-HCL 300 mg tablets	450–975 mg (3–6.5 tablets) in 2–4 dos	This medicinal product does not require any special storage conditions
Zinc acetate/sulfate	Up to 5y: 2×25 mg[a]or less 6–16 y: 3×25 mg[a] >16y: 3×50 mg[a]	1h before or2h after meals

[a] Elemental zinc

survival without transplantation was better for chelating agents. Patients who did not respond to zinc therapy showed hepatic improvement after reintroduction of a chelating agent [29].

Zinc is commonly used in neurological presentation where it seems to be as effective as chelators [43].

Still, it is difficult to compare both therapies as most of the evidence comes from observational trials. Wiggelinkhuizen et al. performed a systematic review of zinc and penicillamine therapies for Wilson's disease. They found 1 randomized controlled trial and 12 observational trials. Patients with liver presentation seemed to respond better to penicillamine. Zinc appeared to be better option in presymptomatic and neurological cases [44].

It is also difficult to compare trientine and penicillamine; however, trientine appears to be a safer option, but due to high costs, its use is limited in many countries.

For asymptomatic cases it is not clear at what age therapy should be started, but there is an agreement not to start in the first year of life.

Treatment Monitoring

Compliance with treatment, efficacy, and safety monitoring are the most important issues in WD treatment.

During the correct treatment of WD patient with chelators, the recovery of liver function tests (LFT) and clinical symptoms of liver disease (e.g., jaundice, ascites, coagulopathy, etc.) are expected during the first 2–6 months and should continue through the first year of treatment. Zinc may require longer time. In case of neurological symptoms, the expected improvement takes longer time, is slower, and can be observed up to 3 years after treatment start.

Adequacy of D-penicillamine treatment could be measured with daily urinary copper excretion, non-ceruloplasmin-bound copper (NCBC) in serum analysis, as well as test of urinary copper excretion at baseline and 48 hours after D-penicillamine cessation or patient's drug intake diaries, but all these methods were not properly validated. Urinary copper excretion after D-penicillamine introduction shows value in excess of 1000 μg/24 hours, but it settles to to 300–500 μg/24 hours after 1 year of correct treatment. The results below 300 μg/24 hours suggest overtreatment or noncompliance with treatment and need to be immediately explained (decrease the D-penicillamine dose or ask the patient to correct drug intake). Serum NCBC levels (normal range: 5–15 μg/dl) may further help with adequacy of WD treatment assessment but may be not reliable. The results <5 μg/dl suggest overtreatment and copper deficiency and >15 μg/dl lack of compliance with WD treatment. Urinary copper analysis before and after 48 hours of cessation of D-penicillamine could be helpful in treatment monitoring. In patients with effective WD treatment, urinary copper excretion of under 50 μg/24 hours is usually expected after 48 hours of D-penicillamine cessation.

For safety reasons WD patient treated with D-penicillamine should also undergo analysis of liver tests, complete blood count, and urine analysis at least twice annually. 24-hour urinary copper excretion should be performed at least annually [45].

Monitoring of zinc therapy is based on measuring serum zinc levels, 24-hour urinary copper, and zinc excretion. Brewer et al. advise to test zinc serum and urine copper levels during therapy. A zinc serum level less than 125 μg/dL generally indicates poor compliance. Urine copper levels should not exceed 50–75 μg/24 hours [2].

Diet in Therapy of Wilson's Disease

The role of the avoidance of copper-rich food products (nuts, chocolate, liver, shellfish) is not well established, but they are traditionally excluded from the diet. Avoiding copper-rich food (shellfish, nuts, chocolate, mushrooms, and organ meats) is advised until remission of symptoms and biochemical abnormalities.

Liver Transplantation

Liver transplantation is indicated for acute liver failure with fatal prognosis. Acute liver failure with encephalopathy does not respond to medical therapy and requires immediate listing for liver transplantation. The indications for liver transplantation in acute liver failure without encephalopathy are less clear as many patients recover with chelation therapy. It is advised to use the scoring system developed at King's College Hospital, which should be applied daily. A score >=11 indicates the need to list urgently for liver transplantation. A deteriorating score similarly raises the need to list. A stable or improving score is an indication to continue with medical therapy [34].

The indications for liver transplantation are less clear in patients with predominantly neurological symptoms. In general neurological symptoms are not an indication for liver transplantation, but there are some reports of neurological improvement after liver transplantation (however some patients deteriorated).

Therapy in Pregnancy and during Lactation

Treatment should be continued throughout the pregnancy to avoid exacerbation of symptoms. Zinc is commonly used in this period as it appears to be safer, but according to some practices, penicillamine can be used in decreased doses even if safety of this therapy is not well proven. The possible teratogenic effects of D-penicillamine and the influence on wound healing (cesarean section) should be considered, and the dose should be decreased about 25% only during the first trimester (the higher ratio of teratogenic effect possibility). Moreover, all current drugs used in WD pass into the milk, that's why the children of WD mothers treated with anti-copper agents shouldn't be fed by breast (to avoid the copper deficiency syndrome as well as other adverse drug reactions).

Novel Therapies

The present medical therapy is effective but not enough in some clinical situations like acute liver failure and significant neurological impairment. Therefore, new drugs are being tested like bis-choline tetrathiomolybdate [46]. Recent progress in gene therapy may be also used for treatment of Wilson's disease.

Compliance

Lifelong compliance to drug therapy seems to be a major problem in Wilson's disease which decides about prognosis. Stopping medication may lead to severe organ damage, or even death, within a time period that can be as short as a couple of months. There are several reasons for poor compliance: nausea on zinc therapy, fear for numerous side effects of penicillamine, revolting age (teenagers), as well as psychiatric problems seen in Wilsonian patients. Duodenal and gastric ulcerations identified in children under zinc sulfate therapy can explain poor compliance in some patients. Urine copper excretion and free copper concentration are also good indicators of compliance during penicillamine or zinc therapy.

Conclusions

Even if prevalence of Wilson's disease is not high, it should be included into differential diagnosis of chronic liver disease and acute liver failure in children >1y of age. Disease can be diagnosed early in children with increased transaminase activity and/or hepatomegaly. The scoring system for diagnosis of Wilson's disease may be helpful, and it is highly specific. Except for molecular diagnosis, no single test can be used to establish diagnosis or for screening.

It is difficult to compare effectiveness of different therapies, but penicillamine and trientine appear to be drugs of choice for severe liver damage. Zinc is regarded to be safer and is mainly used in mild liver, neurological, or asymptomatic disease.

Nonalcoholic Fatty Liver Disease

69

Emer Fitzpatrick

Nonalcoholic fatty liver disease (NAFLD) was first described in 1980 in obese adults who had a pattern of injury similar to alcoholic hepatitis but who denied alcohol consumption [1]. The disease was subsequently described in children in 1983 [2]. NAFLD is a condition characterised by liver steatosis with or without inflammation and fibrosis, most often in the setting of overweight or obesity. Inflammation implies the diagnosis of nonalcoholic steatohepatitis (NASH) which previously was felt to be a more progressive condition than steatosis without inflammation; however, it is now better understood that inflammation is not a good predictor of disease progression, and the term steatofibrosis may be more applicable [3].

The importance of this disease is borne out by the dramatic increase in its prevalence with an estimated 30% of adults and 10% of children affected in the USA, with similar prevalence in children in the UK and Australia and with a higher prevalence in Central America [4–7].

It is likely that a significant number of those affected by NASH will go onto end-stage liver disease and/or hepatocellular carcinoma within decades [8]. In fact, NAFLD in adults is rapidly becoming the most common indication for liver transplantation and is now the most frequent indication in American women [9]. As NAFLD is likely to continue to increase in prevalence, this will unfortunately put a huge burden on an already overstretched liver transplantation service [4].

This rise in prominence of NAFLD, the liver manifestation of the metabolic syndrome, is not surprising given the close association with obesity. Body mass index does not measure the entire problem however, with reports of patients with 'lean NAFLD' who may not meet criteria for obesity or overweight based on BMI. These patients are most often metabolically unhealthy, with a large waist circumference and other features of the metabolic syndrome. The close association with this phenotype led to the suggestion that NAFLD should be known as metabolically associated steatohepatitis (MASH/MAFLD) [10]. This nomenclature may not be appropriate to apply to children and young people, however, in view of potential confusion with distinct inborn errors of metabolism which may also present as fatty liver [11].

Both genetic predisposition and lifestyle factors influence the development and progression of NAFLD, the pathophysiology of which has not yet been fully elucidated. In view of the startling prevalence of NAFLD and the potential to progress to serious liver disease, the ability to recognise and manage the condition in children is of great importance.

Epidemiology and Predisposing Factors

The increase in prevalence of NAFLD is undoubtedly directly associated with the epidemic rise of obesity. Prevalence of childhood obesity across the globe has increased dramatically over the last three decades. The definition most widely used for obesity in childhood is body mass index (BMI) > 95th percentile and overweight as a BMI between the 85 and 95th centile. The 'normal' BMI varies with age and sex, and different centile charts are available for different populations. More than 370 million children and young people aged 0–19 years are now overweight or obese (http://globalnutritionreport.org) and are likely to remain so in adulthood, and thus more likely to develop NAFLD and type 2 diabetes.

Variation in reports of prevalence of NAFLD is partly due to the different methods of detection and a lack of clarity regarding the definition of the disorder [7, 12, 13]. Liver biopsy is the criterion standard for diagnosis of NAFLD, but clearly this is not feasible as an epidemiological tool and proxy markers such as abnormal transaminases and/or the presence of an echogenic liver on ultrasound are often used

to define the disorder. The true sensitivity, specificity and predictive value of these proxy markers are unknown, and it is well recognised that an elevation of transaminases may only occur in 60% of cases of fibrotic NAFLD [14]. As the reference range for AST and ALT is derived from population data including those with undiagnosed NAFLD, the use of these markers as a proxy for NAFLD is flawed [4, 15]. In addition, there is considerable variation in the normal ranges for laboratory values across different institutions.

Nevertheless, in the absence of a more robust noninvasive diagnostic test, population studies have used an elevated ALT (in the absence of other diagnoses) as definition of the disorder. In one US-based study, an elevated ALT was found in 8% of 5586 adolescents aged 12–19 years [16]. Park et al. reported a prevalence of 3.2% in 1543 Korean teenagers using ALT >40 [17]. In Japan a population-based study found 2.6% of children to have NAFLD based on ultrasound [18]. In a study from Italy of 268 obese children, 44% had NAFLD using ultrasound and elevated ALT [19]. Studies of liver biopsy findings give a more accurate reflection of prevalence as NAFLD is a histological diagnosis. One of the most useful studies reporting prevalence in the general paediatric population is an autopsy study of 800 children and young people who died of accidental injury. Schwimmer et al. reported fatty liver in 9.3% of this cohort, with NASH present in 3% [5].

The prevalence of NAFLD appears to increase with age, and in general, boys are more at risk [5, 20, 21]. Ethnic variations also exist; Hispanic children and adolescents have a greater risk of NAFLD compared to Caucasian children. Black, non-Hispanic children are less susceptible despite a higher incidence of insulin resistance [5, 21, 22]. This mirrors findings in adults [6, 23, 24]. Both genetic and environmental factors are likely to be involved in ethnic distribution. Familial clustering is also seen [25, 26] with a strong heritability in first-degree relatives [27].

The advent of genome-wide association studies (GWAS) and candidate gene studies has significantly advanced our understanding of genetic susceptibility to NAFLD. Though a smaller body of evidence exists in genetic variation in susceptibility of children with NAFLD than in adults with the condition, children are arguably most likely to demonstrate the effects of genetic variation. We now understand that single nucleotide polymorphisms (SNPs) in DNA (resulting in the altered expression of a gene or altered protein function) and other epigenetic modification influence the phenotype of this polygenic disease [28]. In both GWAS and candidate gene studies, variants in certain genes, namely, patatin-like phospholipase domain-containing protein (PNPLA3; adiponutrin) variant I148M, the transmembrane superfamily 2 (TM6SF2) variant E167K and variants in GCKR (glucokinase regulatory protein) and MBOA7 (membrane-bound O-acyltransferase domain containing 7), amongst others, most consistently convey a susceptibility to NAFLD in both adults and children [29–32].

Perhaps best described and most frequently cited is the variant within PNPLA3, where the mutated protein accumulates on the surface of lipid droplets in the hepatocyte, altering lipid remodelling, and also promotes retinol release prompting inflammation and fibrogenesis [33, 34]. The coexistence of obesity amplifies the effect of the variants [35], and the cumulative risk of genetic variants is also of importance. In a study of 450 children, the combination of variants in *PNPLA3*, *TM6SF2*, *GCKR* and *MBOAT7* explained 19% of hepatic fat fraction (HFF%) variance as quantified by MRI. There is amplification of this effect in the presence of obesity and overweight [36]. Understanding the genetic variation contributing to disease in an individual may allow more targeted prevention and reversal of disease.

Epigenetic factors, particularly microRNA, have been implicated in pathogenesis of NAFLD. Epigenetic modification is unrelated to changes in DNA sequence. MicroRNAs are small soluble RNAs which influence the translation of certain genes. The relative underexpression of microRNA-122 has been described in NAFLD [37].

The importance of the antenatal environment on metabolic programming has been well established since the reports of Barker [38, 39]. Antenatal programming of a child's liver to injury due to lipid accumulation, oxidative stress and innate immune dysfunction may play a role in the susceptibility to NAFLD [40].

In rodent models, the effect of a high-fat diet (HFD) in dams can be seen in the predisposition to developing fatty liver in offspring. A cumulative effect can be seen when the pup offspring of HFD dams are fed with a methionine choline-deficient (MCD) diet, a well-established model for NAFLD [41]. An alteration of DNA methylation and a decrease of microbiome diversity in the gut were found possibly to mediate the effect.

In mice, maternal obesity and a postweaning high-fat diet were independent risk factors for steatosis and steatohepatitis and fibrosis at 12 months with a significant increase in liver injury when both risk factors were present [40]. A macaque model of HFD prior to breeding and during pregnancy showed similar findings with increased steatosis in the offspring of treated mothers [42].

The equivalent antenatal priming of the liver in humans, which may then be exposed to decades of excess nutrition and sedentary behaviour, may result in a more severe phenotype or progressive disease.

The early effects of maternal metabolic control on the infant liver have been investigated. Stillborn infants of mothers with gestational diabetes mellitus (GDM) were found to have steatotic livers in 78.8% of cases versus 17% of those born to nondiabetic mothers [43]. Live-born infants to mothers with GDM in another study demonstrated a higher

liver fat content on MRI in those born to mothers with GDM than controls [44]. As adipose tissue deposition does not occur until the third trimester, there is foetal hepatic accumulation of excess substrate together prior to this point with an increase in de novo lipogenesis due to a high transplacental glucose supply in infants of diabetic mothers [38]. This is in the context that up to 60% mothers are now obese at the time of conception and thus at high risk of GDM [45].

Further evidence of the importance of a healthy pregnancy is that birth weight is associated with the development of NAFLD in childhood in a large cohort [46].

Early nutrition is likely also important in modification of the risk of later NAFLD. Nobili and colleagues have studied breast feeding habits in a cohort of children with NAFLD and concluded that breast feeding is protective against progression of the disease from simple steatosis to steatohepatitis and fibrosis [47].

The role of maternal obesity and the method of delivery and of early infant feeding may all be mediated in part via the microbiome and a decrease in diversity conveyed to the infant microbiome which is associated with later obesity. Soderberg et al. demonstrated this effect in mice by colonising germ-free mice with microbiota from 2-week-old pups born to obese mothers or to normal weight mothers. Mice colonised with the microbiota from infants of obese mothers demonstrated increased liver injury with a histological pattern similar to paediatric patients with NAFLD [48].

Nutrition and physical activity are critically important environmental factors determining risk of NAFLD, with lifestyle modification as the primary recommendation in the prevention and management of the disease [49, 50]. Excess food intake and lack of exercise contribute to weight gain and contribute to the progression of liver fibrosis and inflammation in patients with NAFLD [51, 52].

Specific dietary factors either protect against or exacerbate the development and progression of NAFLD. Food-based analyses have suggested that higher meat and fructose [53–55] and higher consumption of low-nutrient, high-calorie, high-salt food [56] are associated with NAFLD. Fructose has been identified as a particular culprit in increasing fat, inflammation and fibrosis [57, 58]. Fewer paediatric studies of dietary composition have been undertaken in NAFLD; however, a large study from Australia compared Western/health diet in 993 14-year-olds to later development of NAFLD on ultrasound and found a significant association of Western diet and development of steatosis at 17 years [59]. A study in 82 obese Greek children revealed that a diet higher in carbohydrates and saturated fatty acids and lower in omega-3 was associated with NAFLD [60].

Dietary chemical composition of fatty acids may be an important factor in lipotoxicity observed in insulin resistance. Palmitic acid rather than oleic acid results in lower steatosis but in higher cell death and impaired insulin signalling [61]. A study of fish intake and omega-3 fatty acid intake in children with NAFLD revealed a dietary deficiency of both was associated with increased portal and lobular inflammation [62].

Vos et al. described an association of dietary vitamin E insufficiency and increased steatosis in children with NAFLD [63].

Pathophysiology

NAFLD can be thought of as the hepatic manifestation of the metabolic syndrome (linking obesity, insulin resistance, hypertension and hyperlipidaemia). The pathogenesis of the condition is still incompletely understood.

Insulin resistance (IR) is a finding in up to 80% of children with NAFLD and has a similarly high prevalence in adults with the condition [22, 24, 64, 65]. It is widely accepted that IR and the resulting hyperinsulinemia seem to play a major role in the development of hepatic steatosis and steatohepatitis. The molecular mechanism leading to the involvement of IR in the development of NAFLD is complex however, and has not yet been fully elucidated.

The 'two-hit hypothesis' proposed in 1998 consisting of a first hit of liver fat accumulation followed by a trigger for inflammation and fibrosis, was first thought of as a model of liver injury in NAFLD. We now know there are likely multiple 'hits' including oxidative stress, intestinal dysbiosis, bile acid dysregulation [66, 67] and adipocytokines from a high visceral fat mass or saturated free fatty acids (FFA) [68–70]. Figure 69.1 demonstrates the interplay of the multiple hits.

Steatosis

Macrovesicular steatosis is characterised by the accumulation of triglycerides (formed of glycerol esterified to three fatty acids) in the hepatocyte. Steatosis is conventionally thought to arise from increased hepatic supply of FFA as a result of obesity and associated extrahepatic insulin resistance.

Normally adipocytes store fat after meals and release fat during fasting by lipolysis. In the liver, carbohydrate is stored as glycogen, and when the liver is saturated, de novo lipogenesis occurs via acetyl coenzyme A and fatty acid synthetase. The third source of fatty acids as a substrate for the liver is dietary.

In the setting of normal insulin sensitivity, fatty acids undergo esterification to triglycerides in the hepatocyte and are then exported from the cell as very low-density lipoproteins (VLDL) via apolipoprotein B enzyme activity

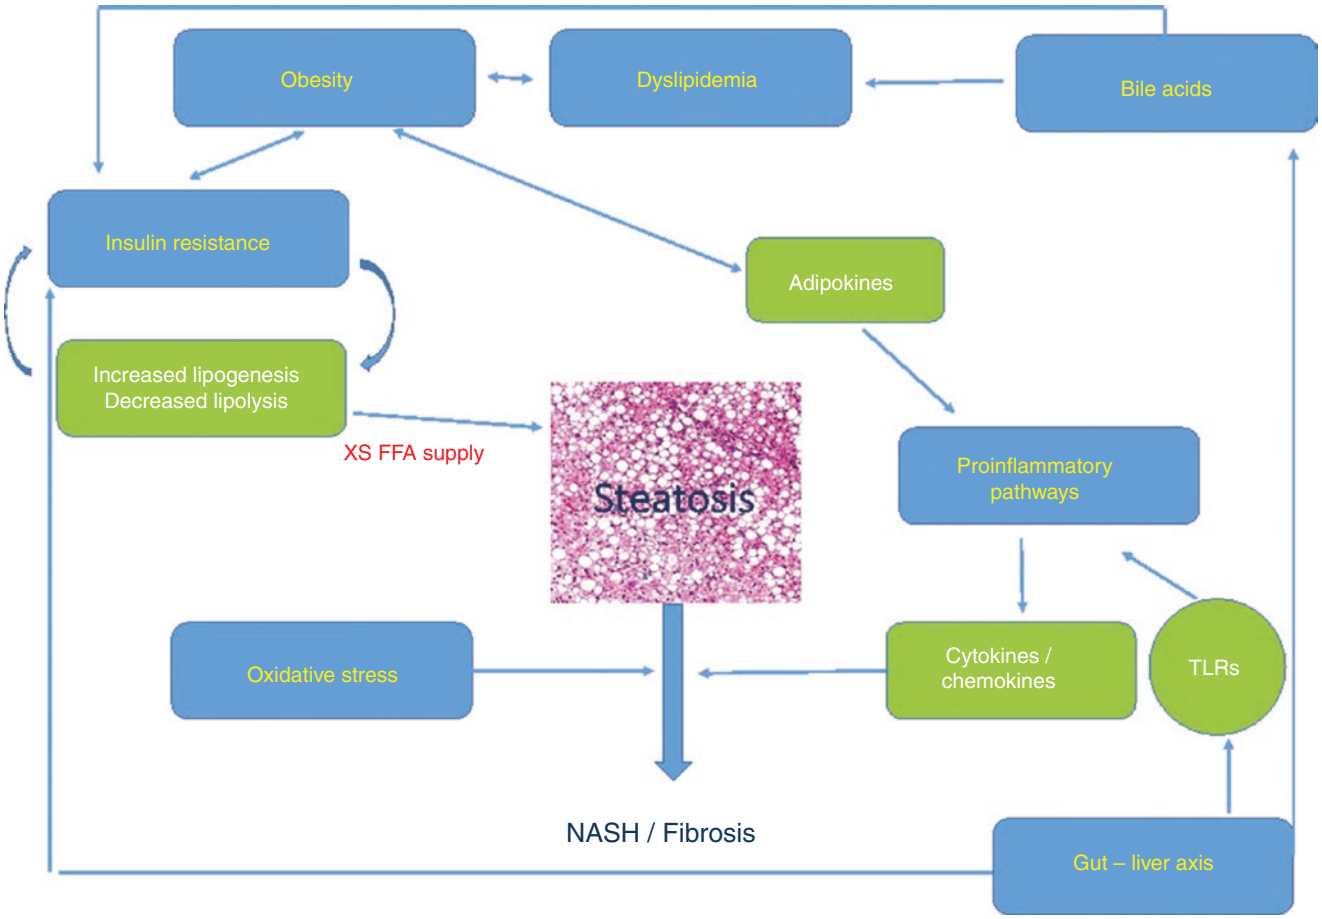

Fig. 69.1 Interplay of multiple hits involved in the pathogenesis NAFLD

[71]. Alternatively they may undergo β-oxidation in the mitochondria or oxidation in the peroxisomes or microsomes. Uptake of FFA into the mitochondria requires carnitine palmitoyl acyl-transferase which is inhibited by insulin and malonyl coenzyme A.

The net retention of lipids is the primary problem in steatosis. The most consistent predisposing factor to hepatic fatty acid accumulation is insulin resistance, though other factors may be involved.

In normal physiological circumstances, the role of insulin includes glycogen synthesis, glycolysis and protein and lipid synthesis. In the postprandial state, insulin promotes lipogenesis and suppresses lipolysis and gluconeogenesis. The normal fall in insulin with the fasting state, which is accompanied by an increase in glucagon and catecholamines, mediates glycogenolysis and gluconeogenesis. These processes are accompanied by lipolysis and increased lipid oxidation. Sensitivity to insulin is increased by adiponectin and decreased by TNFα [72].

In the setting of insulin resistance, fat-laden and insulin-resistant adipocytes continue to release glycerol and FFA into the circulation, and deliver increased free FFA to the liver [73–75]. This in itself may then induce hepatic IR [76]. Hyperinsulinemia and hyperglycaemia promote de novo lipogenesis via upregulation of the transcription factors sterol regulatory element-binding protein 1c (SREBP1c) and peroxisome proliferator-activated receptor γ (PPARγ) [73]. In addition, insulin increases malonyl coenzyme A (an intermediate of FA synthesis) and inhibits carnitine palmitoyl transferase, thereby inhibiting the passage of long-chain fatty acids (LCFA) into mitochondria for β-oxidation [77]. SREBP1c can also be upregulated by glucose and saturated fats, whereas polyunsaturated fatty acids (PUFAs) lead to decreased expression [78]. Increased glucose levels also stimulate lipogenesis through the activation of carbohydrate response element-binding protein (ChREBP), a transcription factor activating the expression of key enzymes of glycolysis and lipogenesis [79, 80].

Hyperinsulinemia also results in decreased triglyceride secretion as VLDL by lowering apolipoprotein B synthesis and stability [81, 82]. Hence, hepatic FFA uptake and lipogenesis outweigh FA oxidation and triglyceride secretion leading to hepatic fat accumulation [83]. In the setting of peripheral insulin resistance, some hepatic insulin sensitivity may be preserved with continuing de novo lipogenesis as a consequence. This is mixed and thought to be medicated

through a functioning insulin receptor substrate 1 (IRS-1) which blocks lipid oxidation, but aberrant IRS-2 serine phosphorylation which fails to suppress gluconeogenesis [71].

Oxidative Stress

Mitochondrial FA oxidation and ketogenesis are increased, and the transcription factor PPARα is activated as a result of fatty acid accumulation [84]. This results in reactive oxygen species (ROS) which lead to oxidative stress and lipid peroxidation. Cell membranes are damaged, and cytochrome c is released from the mitochondrial intermembrane space. In turn, this leads to an imbalance in the flow of electrons over the respiratory chain (RC) creating overreduction of RC complexes which can react with oxygen to form further ROS [85]. ROS may then propagate liver inflammation and injury.

Mitochondrial function has been shown to be impaired in patients with severe steatosis and steatohepatitis [86]. Ultrastructural abnormalities of mitochondria have been demonstrated in patients with NASH [87, 88]. It is not clear if this is a primary or secondary phenomenon however. Mitochondrial abnormalities could be a pre-existing condition enabling the excessive production of ROS in the setting of enhanced FFA ß-oxidation [87]. This could explain why for the same amount of obesity, or for the same degree of IR, certain patients just have steatosis, whilst others develop NASH and cirrhosis. Genetic polymorphisms could also at least partially explain this difference in susceptibility as some could favour mitochondrial dysfunction [89]. Alternatively the overload of the mitochondrial RC, the resulting formation of ROS and subsequent lipid peroxidation products may give rise to mitochondrial damage. There is an inverse correlation of peripheral TNFα levels and measures of insulin resistance with RC enzyme levels suggesting that insulin resistance and cytokine activity may be important in impairment of the mitochondrial RC [90]. Enhanced ROS formation in the vulnerable steatotic liver subsequently triggers lipid peroxidation and the formation of reactive aldehydes such as 4-hydroxynonenal (4-HNE) and malondialdehyde (MDA). These give rise to further mitochondrial damage and ROS formation, resulting in a vicious cycle [85]. Hepatic stellate cells may be activated by these molecules, thus leading to fibrosis [91].

Cytokines and Inflammation

Much of the progression from simple steatosis to steatohepatitis is characterised by an inflammatory response [92]. It is clear from both rodent and human studies that hepatic steatosis is associated with a state of chronic inflammation [93–95]. More specifically, hepatic steatosis in this context is associated with nuclear factor κB (NFκB) activation. FFA can directly activate the pathway via a lysosomal cathepsin B-dependent mechanism [96], as can mitochondrial and ER stress [94, 97]. NFκB is a sequence-specific transcription factor that functions as a pro-inflammatory master switch during inflammation. It upregulates the transcription of a wide range of inflammatory mediators including TNFα, IL6 and IL1β. Increased production of inflammatory cytokines by hepatocytes leads to Kupffer cell activation with subsequent inflammatory mediator release and hepatic and systemic insulin resistance [98].

Animal studies have shown that translocation of bacteria from the gut to the liver via the mesenteric circulation can activate Kupffer cells (via CD14/Toll-like receptor 4 (TLR4) binding) and induce a local and systemic inflammatory response [99]. There has been a great deal of interest in gut microbiota and the innate immune response in the context of obesity and insulin resistance [100]. There is evidence that intestinal bacterial overgrowth exacerbates NAFLD and that the prevalence of bacterial overgrowth is higher in those who are obese [101], the portal circulation providing a direct route from the gut to the liver. Manipulation of gut microbiota and elimination of intestinal bacterial overgrowth may thus be promising ways to halt the progression of steatosis to steatohepatitis and fibrosis.

Finally, visceral fat is a highly inflammatory tissue and the source of many inflammatory mediators known as adipocytokines which have an important role in insulin resistance and, most likely, in NAFLD [102, 103]. These adipocytokines, including leptin, adiponectin, TNFα and IL6, are polypeptides produced by both adipocytes and macrophages which infiltrate adipose tissue [104]. Adipokines are involved in the various injury patterns in NASH such as cell death, inflammation and fibrosis [85].

Leptin is a 16 kDa protein, a product of the ob gene, and has important roles in appetite suppression and regulation of energy metabolism [105], with high levels in obese individuals though this is thought to be a result of leptin resistance. The role of leptin in NAFLD is not yet clear though it is thought to contribute as a pro-inflammatory, profibrogenic mediator [106, 107].

Adiponectin is a polypeptide adipokine with a collagen-like domain and globular domain produced in white adipose tissue. It has an important role in insulin sensitivity; as part of their action, thiazolidinediones are known to increase levels of adiponectin [108]. It is also hepatoprotective with anti-inflammatory and anti-fibrogenic properties [109–111].

Hepatocyte Apoptosis

Hepatocyte apoptosis is recognised as an important event in the development of chronic liver disease and has particular prominence in NAFLD [112]. The initiating event in apoptosis may be extrinsically mediated hepatocyte injury (e.g. in autoimmune liver disease, viral hepatitis and ischaemia per-

fusion injury). This is usually directed through pathways involving Fas ligand, TNFα, and TRAIL. Alternatively, intrinsic injury and death may occur via organelle dysfunction when cells are subjected to excessive oxidative stress (ER or mitochondrial), e.g. with drugs/toxins, fatty acids, and iron. This results in altered membrane permeability and RNA damage with cytochrome C release [113]. The injurious mechanism in NAFLD/NASH appears to be due to a combination of extrinsic and intrinsic insults [114, 115].

Though apoptosis is classically thought to be a silent event without provoking an inflammatory response, this is not the case in the liver [114]. Apoptotic bodies can activate stellate cells and Kupffer cells inducing an inflammatory response and leading to the progression of steatohepatitis and fibrosis [116, 117].

Fibrosis

The final common pathway of inflammation, oxidative stress and hepatocellular damage is the development and progression of fibrosis in NAFLD. The process of fibrosis involves the deposition of extracellular matrix within the parenchyma. Cirrhosis, the end stage of the fibrotic process, is characterised by septae and nodule formation. Several different injurious processes will result in fibrosis. Hepatocyte injury, inflammation, apoptosis and death initiate the process which involves a cascade of inflammatory cells, the release of cytokines and the activation of fibrogenic effector cells (mainly stellate cells) [118].

Thus, a number of different processes and mechanisms are involved in the progression of steatosis to NASH: oxidative stress, inflammation, apoptosis and fibrosis (Fig. 69.2). The exact sequence of development of obesity, fatty liver and NAFLD remains unclear. Whether IR causes hepatic steatosis or whether the accumulation of fat in the liver is the primary event leading to hepatic and peripheral IR is also yet to be elucidated [119].

Diagnosis and Histology

Children with NAFLD are often asymptomatic or may present with vague nonspecific symptoms such as abdominal pain and fatigue. The majority are overweight (gender- and age-specific BMI >85th centile) or obese (>95th centile) [120]. Hepatomegaly may be present, and acanthosis nigricans (a black pigmentation of the skinfolds, axillae and

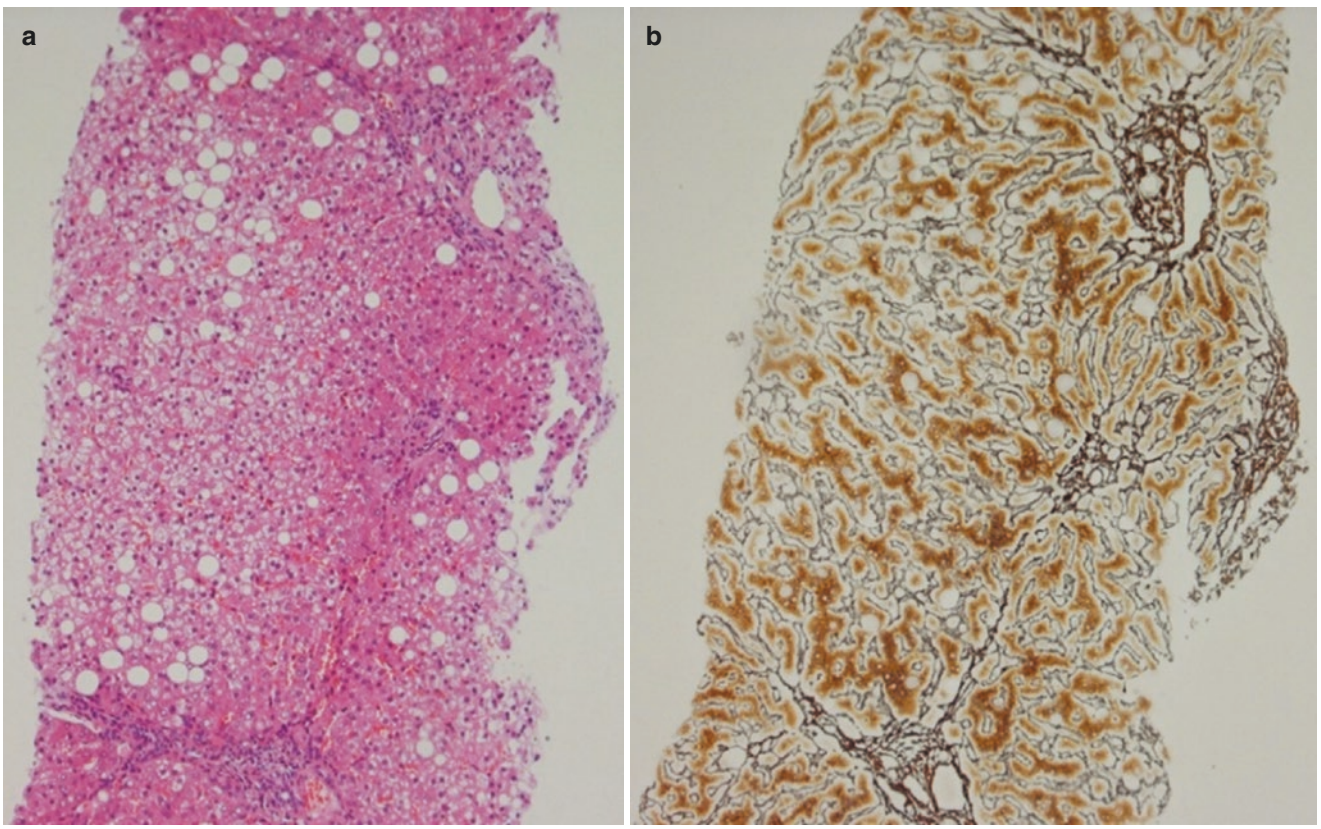

Fig. 69.2 Histology of NAFLD. (**a**) Haematoxylin and eosin staining showing steatosis, inflammation and ballooning. (**b**) Reticulin stain showing fibrosis

neck), often seen in children with insulin resistance (IR), is found in 30–50% of children with NAFLD [22, 121]. The majority of children with NAFLD have insulin resistance as measured by homeostasis model assessment-insulin resistance (HOMA-IR: [fasting glucose (mmol/l) x fasting insulin (IU/l)]/22.5) [22]. A normal HOMA-IR (<90th centile) is generally less than 2.5 but varies with sex and pubertal stage [122]. Children will often have a positive family history for the metabolic syndrome [21].

In the diagnostic work-up of NAFLD, alternative causes of chronic liver disease should be excluded including chronic hepatitis B and C infection, Wilson disease, α1-antitrypsin deficiency, autoimmune hepatitis and drug toxicity (including steroids, amiodarone, oestrogens and antiretroviral treatment). Conditions such as cystic fibrosis, malnutrition and parenteral nutrition-associated liver disease may also present with a fatty liver on ultrasound and can be excluded on clinical or biochemical grounds. In addition, mitochondrial/metabolic disease and cholesterol ester storage disease may also look very similar on liver biopsy and need to be considered. Table 69.1 gives differential diagnoses that must be excluded [11].

Table 69.1 Conditions which need to be excluded before a diagnosis of NAFLD is made

Clinical condition	Clinical features	Biochemical/other features which help distinguish from NAFLD
Wilson disease	May present with chronic liver disease, haemolytic anaemia or more rarely neurological disease in childhood. Look for Kayser Fleischer rings	Low serum caeruloplasmin, high urinary copper pre and post penicillamine, high liver copper, genetics may be positive
α1-antitrypsin deficiency		α1-antitrypsin phenotype ZZ (or ZS) more rarely SS
Drugs – Steroids, amiodarone, alcohol, methotrexate, ecstasy, l-asparaginase, vitamin E, valproate, tamoxifen, antiretrovirals	History of drug ingestion	
Cystic fibrosis-associated liver disease	History/examination	Positive sweat test/genetics positive
Malnutrition	Clinical examination	
Coeliac disease	May have failure to thrive	Tissue transglutaminase positive/positive jejunal biopsies
Hepatitis C		Positive serology
Intestinal failure-associated liver disease	Compatible history	
Mitochondrial disease/fatty acid oxidase deficiency	May be history of neurodevelopmental problems or other system involvement	Abnormal respiratory chain enzymes liver/muscle, abnormal acyl-carnitines/skin fibroblast studies, genetics for mitochondrial disease
Lysosomal; Lysosomal acid lipase deficiency, Niemann Pick C		Positive enzymology or genetics
Galactosaemia	Age of presentation	Abnormal Gal-1-PUT result
Fructosaemia	May be history of avoiding sweets	Enzymology on liver biopsy
Glycogen storage disease	Hepatomegaly, may be short, history of fasting hypoglycaemia	Positive enzymology/genetics glycogen not fat on biopsy
Peroxisomal disorders	May be hypotonic/have wide AF, neurological problems	Abnormal very long-chain fatty acids
Mauriac syndrome	History of type 1 diabetes	Glycogen on liver biopsy
Hypobetalipoproteinaemia/abetalipoproteinaemia	Low serum triglycerides, may have history of fat malabsorption, may be FTT	Low or absent Apo1B levels
Lipodystrophies	Examination	Genetics
Shwachman syndrome	FTT pancreatic insufficiency, bony changes, cyclical neutropenia	Genetics
Inborn errors of bile acid synthesis	Cholestasis in infancy, spasticity later on	Urine bile acids, genetics
Organic aciduria	Neonatal encephalopathy, later developmental delay, mild elevation in transaminases, hyperammonaemia	Enzymology, genetics
Myopathic disorders	Myopathy, elevated CPK	Genetics
Hypothyroidism	Other features hypothyroid	TFTs
Congenital disorders of glycosylation	100 subtypes, can be variable presentation, may have hepatocerebral phenotype	Transferrin isoelectric focusing, genetics
Congenital portosystemic shunts	Presence of focal nodular hyperplasia, high ammonia levels	Imaging
Endoplasmic reticulum function disorders, eg Wolcott-Rallison, NBAS	Recurrent ALF	Genetics
Tyrosinaemia	Jaundice, progressive liver disease, coagulopathy	Urinary succinylacetone, genetics

Recommendations for undertaking biopsy in children with suspected NAFLD are made by a consensus document published by the AASLD, ACG and AGA [123]. These are to perform liver biopsy where the diagnosis is unclear and there is a possibility of multiple diagnoses, before starting therapy with potentially hepatotoxic medications or prior to starting children on pharmacological therapy for NASH. An ESPGHAN guideline was published the same year suggesting that liver biopsy should be performed in children with suspected NASH according to the following criteria to exclude other treatable disease, in cases of clinically suspected advanced disease, as part of an interventional protocol or research trial [124].

Tools commonly used in the work-up and diagnosis of NAFLD in children include ALT, AST and imaging techniques (ultrasound, magnetic resonance imaging/spectroscopy). The sensitivity, specificity and predictive values of these techniques are variable [4]. Franzese et al. studied the incidence of liver involvement in 72 obese children using both ultrasound (US) and transaminases [125]. Fifty-three percent of children had a bright liver on US consistent with liver steatosis, whilst only 25% had elevated transaminases. Molleston and colleagues reported histological abnormalities in 91 children with NAFLD and normal or only mildly elevated ALT. Forty-six percent of the group had some fibrosis with 38% mild to moderate fibrosis and 8% bridging fibrosis [126]. Neither US nor transaminases are good discriminators of histological severity [127]. Ultrasound will detect >20–30% steatosis as increased echogenicity, though this is not specific for fat [128]. Magnetic resonance imaging/magnetic resonance spectroscopy (MRI/MRS) is more sensitive and can detect >5% steatosis [129]. However, neither technique can assess presence of inflammation or fibrosis. Schwimmer et al. used MRI PDFF (proton density fat fraction) to diagnose NAFLD with a cutoff of 5% steatosis. The corresponding cutoff levels for ALT in boys were 42 IU/l and 30 IU/L for girls [130].

Liver biopsy remains the gold standard in differentiation of steatosis from steatohepatitis. The diagnosis of NASH is based on a specific pattern of histopathological findings including macrovesicular steatosis, mixed or polymorphonuclear lobular inflammation, ballooning degeneration with Mallory hyaline and a perivenular distribution of fibrosis in adults (type 1 NASH) [131] (Fig. 69.3). Children often have a different pattern of disease with greater degree of steatosis, less prominent ballooning and portal rather than pericentral accentuation of inflammation and fibrosis (type 2 NASH) [132] (Fig. 69.4). Children and young people may demonstrate type 2 NASH or NAFLD which is a more periportal tract-based pattern [133]. Fifty to seventy percent have a type 2 pattern or a crossover between type 1 and type 2 [127, 134, 135]. Type 2 NASH has been studied in the context of severity, and both adults and children with histology are more likely to have higher stage of fibrosis [136, 137]. It is not clear if this pattern is due to a separate pathophysiological mechanism, though it certainly seems to be a marker of more advanced NASH.

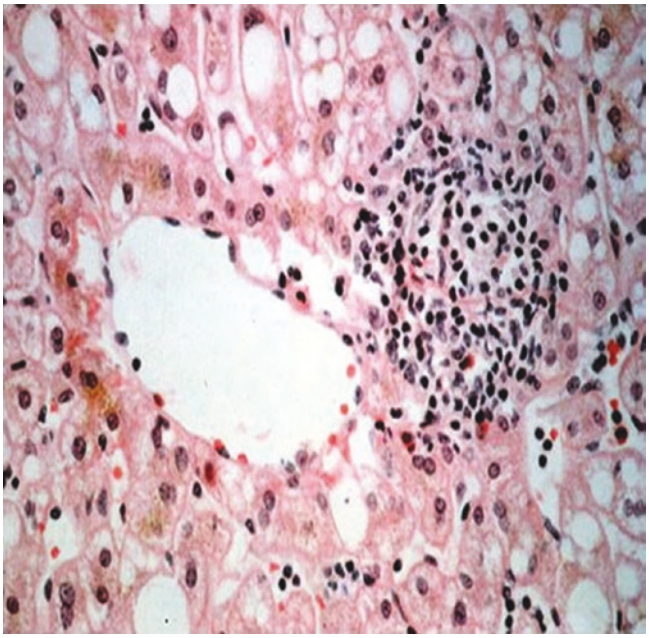

Fig. 69.3 Liver biopsies showing type 1 NASH with pericentral disease. Type 2 NASH is more common in children and type 1 in adults. (Picture kindly provided by Dept. Liver Histopathology, King's College Hospital)

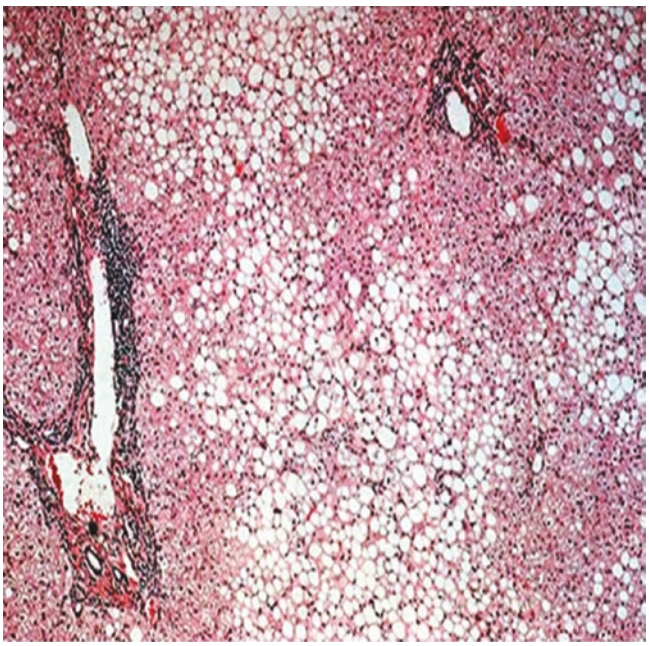

Fig. 69.4 Type 2 NASH with more periportal disease. Type 2 NASH is more common in children and type 1 in adults. (Picture kindly provided by Dept. Liver Histopathology, King's College Hospital)

A possibility which may in part explain the preferential distribution of disease is the concept of zonation. Along the liver lobe, the hepatocytes have different functions depending on their location in the lobule. For example, periportal hepatocytes are functionally specialised in Krebs cycle amongst other tasks, and those in the area of the central vein are rich in cytochrome P450 enzymes. The exposure of the liver to dietary components is more marked in zone 1 than in zone 3 (pericentral) [138].

Africa et al. studied the biopsies of 813 children with NAFLD and found that the presence of periportal (zone 1) steatosis was associated with a younger age and more severe fibrosis. Interestingly, those with zone 3 fibrosis (the more classical adult type 1 pattern) were more likely to have significant inflammation or NASH [137]. The presence of fibrosis in the absence of significant inflammation is now well described leading to the term steatofibrosis as a more accurate reflection of disease stage.

The occurrence of portal inflammation was reviewed as a distinct entity in NASH by the NASH Clinical Research Network (CRN) [136]. A study of biopsies from 728 adults and 205 children found that the presence of portal inflammation in adults was associated with older, female patients with a higher BMI and insulin resistance. There was a clear association with amount and location of steatosis, ballooning and advanced fibrosis. In the paediatric group, portal inflammation was associated with younger age, azonal location of steatosis and more advance fibrosis (bridging). In both groups it was associated with diagnosis of definitive NASH. There was no association with lobular inflammation in either group. It is not clear if this pattern is due to a separate pathophysiological mechanism, though it certainly seems to be a marker of more advanced NASH. The periportal pattern mirrors that of the ductular reaction which has been reported in NAFLD. The possible epithelial-mesenchymal transition of biliary cells in this process may relate to the pattern of fibrosis seen [139].

Though the classic description of fat in NAFLD is macrovesicular, the presence of microvesicular steatosis has been described. In one study approximately 10% biopsies of those in NAFLD revealed microvesicular steatosis [140]. The study found that the presence of microvesicular steatosis was strongly associated with cellular injury and cytoskeletal damage. Microvesicular steatosis has the appearance of distended hepatocytes with foamy cytoplasm; the nucleus is usually central rather than pushed peripherally as in macrovesicular steatosis. Oil red O staining is sometimes needed to identify microvesicular steatosis if it is not visible in haematoxylin and eosin staining. Classically this type of steatosis has been associated with mitochondrial disease, acute fatty liver of pregnancy and some drug effects (e.g. steroids and valproate) which can cause β-oxidation impairment [141]. Taken together, microvesicular steatosis in NAFLD is a likely indicator of mitochondrial damage. It is not yet understood if this is a feature of advanced disease per se or if the pathogenesis of disease in those with microvesicular steatosis is different.

Caldwell et al. reported on the significance of ballooning in NAFLD [142]. These are classically enlarged cells with rarefied cytoplasm. Using ultrastructural analysis this group reported on the multiple small fat lipid droplets seen with degree of ER dilatation and Mallory-Denk bodies and cytoskeletal disarray. Fugii et al. have demonstrated altered expression of FFA-associated protein on the surface of fat droplets which also stain for oxidised phosphatidylcholine (a marker of oxidative damage) [143]. They concluded that oxidative injury to the fat droplet surface may impair its safe disposal and contribute to lipotoxicity.

The Pathology Committee of the NASH CRN proposed a histological scoring system that could be useful in studies of NAFLD [144]. The scoring system includes the evaluation of steatosis (0–3), lobular inflammation (0–2), hepatocellular ballooning (0–2) and fibrosis (0–4). The NAFLD activity score (NAS) is the unweighted sum of steatosis, lobular inflammation and hepatocellular ballooning scores. NAS of 5 or more correlates with the diagnosis of NASH, whilst NAS less than 3 is defined as 'not NASH'. As this system is typically developed for type 1 NASH, the interobserver agreement for type 2 NASH is not as strong (only 18 children were included in the study cohort used for development of the score). The CRN also emphasised that the scoring system was developed as a tool for use in trials and is not a surrogate for a histological diagnosis of NASH [145]. Despite these shortcomings this is the best available tool to standardise the description of the entire spectrum of NAFLD in both adults and children across different centres for research purposes.

It is important, however, to consider the paediatric pattern of disease as a separate entity, particularly when investigating the pathophysiological mechanisms or putative biomarkers of disease severity/progression.

Noninvasive Biomarkers in NAFLD

Though the criterion standard for diagnosis and assessing progression of disease is liver histology, the decision 'if or when' to perform a liver biopsy in children with suspected NAFLD remains controversial. Liver biopsy in children requires admission to hospital and sedation. Risks include bleeding and very rarely death [146]. Repeated biopsy is not a suitable tool for regularly monitoring progression of disease or response to treatment. In addition, biopsy samples only 1/50,000 of the liver, raising the possibility of sampling error [147].

There has been much focus on the development and validation of noninvasive biomarkers of NAFLD in recent years. There is an urgent need for a less invasive method than biopsy of screening the population, stratifying disease severity and following disease progression.

The pathophysiology and evolution of the condition under scrutiny is an important consideration in the development and evaluation of biomarkers. In the case of NAFLD, first is the identification of disease and second the progression. Most longitudinal cohort studies in NAFLD have shown that prognosis is determined by stage and rate of progression of fibrosis rather than the presence of necro-inflammation [52, 148, 149]. Clinical importance lies with being able to differentiate between no/minimal fibrosis (F0/F1), significant fibrosis (F2), severe fibrosis (F3) and cirrhosis (F4).

Serum Biomarkers and NASH

Large adult series have suggested scoring systems using age, BMI, insulin resistance, AST/ALT, platelet count and albumin to differentiate mild from severe disease [150–153]. These simple markers are neither sensitive nor specific enough in isolation [6, 14]. A growing understanding of the pathophysiology of the disease has allowed the investigation of more specific, mechanism-based biomarkers [154–156].

Markers of apoptosis/cell death have been shown to be very useful in differentiating simple steatosis from NASH [112]. CK18-M30 fragments have been shown by a number of studies including paediatric studies to correlate well with severity of NASH [157–160].

Numerous other biomarkers of inflammation, oxidative stress and apoptosis are currently under investigation.

Noninvasive Markers of Fibrosis in NAFLD

Simple tests derived from regression analysis of a large series of patients include the AST to platelet ratio index [161] and the AST to ALT ratio [162], which have been validated in the NAFLD population with AUROC between 0.67 and 0.86 for differentiation of severity of fibrosis [163–165]. Algorithms specifically derived from NAFLD cohorts include the BAAT score (consisting of BMI, ALT, age and triglyceride levels) [166], the BARD score (BMI, AST/ALT ratio, diabetes) [152, 167] and the NAFLD fibrosis score (incorporating age, glucose, AST, ALT, BMI, platelets and albumin) [150, 163, 164, 168, 169]. These markers do not perform particularly well in children however.

In children, Nobili et al. developed and internally validated the paediatric NAFLD fibrosis index (PNFI) in 136 children with NAFLD [170]. Logistic regression analysis of gender, age, BMI, waist circumference, ALT, AST, γGT, albumin, prothrombin time, glucose, insulin, cholesterol and triglycerides gave a predictive model with an AUROC for detection of fibrosis was 0.85. Again this study was limited in view of small numbers in fibrosis groups F2–F4.

The European Liver Fibrosis (ELF) test combining hyaluronic acid, procollagen III N-terminal peptide (P3NP) and TIMP1 was first derived by Rosenberg et al. in a cohort of over 1000 patients with chronic liver disease including NAFLD [171] and has since been validated in other NAFLD cohorts with the addition of several simple markers to improve accuracy [172]. Importantly this test has been shown to correlate well with outcome [173].

The ELF test was evaluated by Nobili et al. in 122 children with NAFLD [174]. Simple markers including age, waist circumference and triglycerides were added to improve diagnostic accuracy. Excellent AUROC for any (0.92), significant (0.98) and advanced (0.99) disease was achieved. In this cohort 37 (30%) had no fibrosis; 58 (48%) scored as F1, 9 (7%) as F2, and 8 (6.5%) as F3–F4. Alkhouri et al. developed this further and validated both the PNFI and ELF in a cohort of 111 children with NAFLD (69% with fibrosis) [175]. The area under the curve for presence of fibrosis was 0.76 for PNFI, 0.92 for ELF and when the two indices were combined: 0.94. The major issue in both studies was the skew towards no or minimal disease, potentially overestimating the accuracy of the test.

Noninvasive Biomarkers and Imaging

Ultrasound, CT and MRI

Ultrasound (US) has a high sensitivity and specificity for diagnosis of steatosis >30%, but is not good at detecting fibrosis. Because of the low cost, the absence of radiation exposure and the wide availability, US is often used in screening for NAFLD. The accumulation of fat causes the liver to appear hyperechoic compared with the kidney. This finding is nonspecific and does not differentiate fat from other substances such as glycogen. When compared with histological findings, the sensitivity of US to detect fat infiltration below 30% of the liver is low [176]. Computed tomography (CT) is rarely used for the assessment of NAFLD in children because of its ionising radiation exposure. Magnetic resonance imaging (MRI) and spectroscopy are the imaging techniques with the greatest accuracy to determine hepatic fat content in studies of both adults and children [129, 177–179]. MRI proton density fat fraction has been validated to liver biopsy with the mean PDFF in those with grade 1 steatosis 9.2%, 15.1% for grade 2 and 26.8% for grade 3 with an acceptable ability to distinguish between stages. Aside from liver fat, however, other features of NASH cannot be assessed. Other methods include MR elastography

which visualises and measures propagating shear waves and has a high sensitivity (>85%) and specificity (>90%) for fibrosis [180]. Cost of this technique may be preclusive however.

For diagnosis of NASH, Iijima et al. have reported on the use of contrast ultrasound with Levovist with an AUC of 1.0 [181]. The decreased accumulation of microbubbles with advancing degree of fibrosis is unique to NAFLD.

There is an emerging literature examining the use of acoustic radiation force-based shear stiffness in NAFLD, an ultrasound-based investigation which uses short bursts of high-intensity acoustic pulses that produce shear waves through the liver tissue, the velocity of which correlates with liver stiffness to correlate well with the stage of fibrosis in the condition [182, 183].

Transient Elastography

Transient elastography (FibroScan) has been shown to be a useful method for detection of liver fibrosis. In NAFLD, a small number of studies have demonstrated the efficacy of TE in distinguishing severity of fibrosis. In a study of 246 adults with NAFLD, TE had an AUROC of 0.84, 0.93 and 0.95 in distinguishing significant fibrosis, severe fibrosis and cirrhosis, respectively [184]. A Japanese study demonstrated similar results [185]. A recent report of 52 children with NAFLD has shown an AUROC of 0.977, 0.992 and 1 for distinguishing any, significant and severe fibrosis [186]. Feasibility and reproducibility of transient elastography is an issue when patients have a BMI > 30 [187]. An XL probe is available for better accuracy in this scenario [188].

Non-hypothesis-Driven Search for Novel Biomarkers Using New Technologies

The use of relatively new techniques such as proteomics [189–192], glycomics [193, 194], lipidomics and metabolomics in the derivation of panels of biomarkers associated with a disease may also give an insight into pathophysiology of the condition.

Natural History and Management

The natural history of paediatric NAFLD has not yet been well described. Case series including one of 20 years describe occasional need for transplantation in young adulthood [195, 196], but the rate of progression is not known [197]. Paired liver biopsies undertaken in 122 children who had enrolled in the placebo arm of two randomised clinical trials in NAFLD were studied. Over time, fibrosis progressed in 23% and improved in 34% [198]. In children who present in the preteenage years with already established with stage 2–3 fibrosis, the rate of progression may be accelerated [199]. The heterogeneity within the population is not yet well understood, but variability in phenotype may be due to underlying genetic susceptibility rather than environmental exposure.

The relative histological severity at presentation in children with this disease and the fact that alcohol is an unlikely confounding factor mean that paediatric NAFLD serves as an excellent disease model in evaluating pathophysiological mechanisms of development and thus targeting intervention in predisposed individuals.

Cirrhosis secondary to NASH has been reported in children as young as 10 years [121, 196]. A recent study by Feldstein et al. describes the long-term outcome of 66 children with NAFLD followed for up to 20 years [200]. Of five children who underwent follow-up biopsy, four showed progression of fibrosis. During the study period, two patients required liver transplantation for decompensated end-stage disease. Both had recurrence of NASH in the allograft and one required retransplantation.

In adult studies, the variables most commonly associated with fibrosis are presence of diabetes, increasing age and high BMI [151]. Similarly in children, severity of obesity and insulin resistance seem to be predictors of advanced fibrosis [22]. The difference between the natural history of type 1 and type 2 NASH has not yet been characterised and is an important subject for future research.

Management of NAFLD encompasses lifestyle modification, medication or both. NAFLD is largely the consequence of imbalanced nutrition and sedentary behaviour on the background of genetic predisposition. Primary prevention is the ideal. In adults, weight reduction of 5–10% body weight often leads to normalisation or improvement of serum transaminases and reduced hepatic steatosis, inflammation and fibrosis [201–203]. In children, weight maintenance as the child crosses the height centiles may achieve the same effect.

In a meta-analysis of adults with NAFLD, weight loss of 5% or more results in improvement in steatosis, whereas ≥7% weight loss resulted in improvement in steatohepatitis, and in those with ≥10% weight loss, all features of NAFLD were reversed or stabilised [204]. In a prospective study again in adults, these outcomes were confirmed [205]. Only 50% of the cohort were able to achieve 7% of weight loss or more though of note in 94% of those who achieved ≥5% weight loss, fibrosis stabilised or reversed.

A small number of trials in children have demonstrated similar outcomes. In a trial of 84 children, weight loss (average 4 kg) over a 12-month period achieved an improvement in ALT and steatosis on ultrasound [135]. Of the cohort, 57 (70%) children completed the 12-month intervention with a mean 8% (SD 4.7%) decrease in weight in the 52 who were overweight or obese. In the remaining five children who

completed the study and had a BMI <85th centile, weight remained unchanged, but ALT levels improved in two and normalised in three patients. Another paediatric study of intensive lifestyle intervention in North America achieved improvement in BMI z-score with a decrease of 0.1 U ($p < 0.05$) baseline to 1 year and decrease in ALT in 69% of the follow-up cohort. There was a 53% dropout rate however [206]. Another study of 53 children comparing lifestyle intervention plus antioxidant or lifestyle intervention plus placebo demonstrated similar improvements in both groups in terms of steatosis, inflammation, ballooning and NAS score [207].

Several case series and uncontrolled trials have demonstrated the effect of weight loss on improvement of transaminases or ultrasound abnormalities [125, 208, 209]. A prospective study carried out in 84 children (3–18.8 years) with NAFLD demonstrated a significant decrease in BMI, levels of fasting glucose, insulin, lipids, transaminases and liver echogenicity on US following a 12-month program of lifestyle advice consisting of diet and physical exercise [135].

Control of both quality and quantity of dietary components may be important. Nutritional data to date has suggested that a high intake of simple carbohydrates such as fructose with a low intake of polyunsaturated fatty acids correlate with pathogenesis and progression of disease [57, 210].

The type of fat consumed is possibly more relevant than quantity with higher saturated fat and lower PUFA intake associated with IR and NAFLD in some studies [56, 210]. Palmitic acid rather than oleic acid results in lower steatosis but in higher cell death and impaired insulin signalling in vitro [61]. Several small studies of PUFAs in adults and one in children have demonstrated improved liver enzymes and histology in the treatment group [211–214].

Insulin resistance is well recognised as an accompanying feature in 70% of those with NAFLD, though not clearly associated with more or less severe disease in terms of inflammation and fibrosis. Insulin sensitisers have been studied frequently in clinical trial but without clear benefit in children. The TONIC trial compared metformin, vitamin E and placebo in 173 children with biopsy-proven NAFLD [215]. There was no statistically significant difference in the outcome measure (improvement in alanine aminotransferase) in those treated with metformin compared to those with placebo. Interestingly a change in HOMA-IR was not seen in those treated with metformin suggesting perhaps that treatment dose may have been insufficient or that selecting out those with insulin resistance may be more appropriate. The likelihood is that as the disease is relatively heterogenous, treatments may need to be individually tailored. Other studies of metformin in children include an open-label pilot study of metformin (500 mg twice daily for 24 weeks) which was conducted in ten nondiabetic children with biopsy-proven NASH and elevated ALT level [216]. Significant improvement was observed in serum ALT and hepatic steatosis as assessed with MR spectroscopy. A subsequent study conducted in children did not show any benefit of metformin compared to lifestyle advice [217]. A third study of metformin in insulin-resistant adolescents resulted in lower severity scores of fatty liver on US and a decrease in prevalence of fatty liver disease in the metformin group [218]. Metformin has the side effect of gastrointestinal intolerance, but weight loss is an advantage of this medication. The thiazolidinediones (TZDs) have the unfortunate side effect of weight gain. There have also been concerns about cardiovascular events and diminished bone mass with their use [219]. There are no available data on the safe use of TZDs in children.

Oxidative stress, most likely mediated by accumulation of fat droplets and the low-grade inflammatory response accompanying visceral adiposity in the setting of genetic predisposition, is known to occur and perpetuate injury in NAFLD. Antioxidants, most commonly vitamin E, have been studied and have been shown in the adult PIVENS trial to reduce steatohepatitis [220] and in TONIC to reduce ballooning. A significant difference in the main outcome measure (ALT) in the paediatric study TONIC was not found however [215].

Current recommendation in adult practice is to use vitamin E in nondiabetic patients with biopsy-proven NASH [221]. The PIVENS study has not yet been validated adequately however, and thus caution is advised generally. There is no consensus on vitamin E use in children with NAFLD.

Ursodeoxycholic acid is another antioxidant which has been used in trial though without consistent effects. Cysteamine bitartrate works by increasing glutathione synthesis. This was used in the CyNCh trial in children with NAFLD in comparison with placebo over 52 weeks. Though there was an improvement in alanine aminotransferase, the primary outcome of histological improvement was not achieved with statistical significance [222].

The gut microbiome and its influence on bile acid metabolism are an exciting area in NAFLD with therapeutic potential. Obesity is associated with a change in the microbiota of the gut and with an increased permeability of the intestinal epithelium [223]. The microbiota influence the development of NAFLD through several different mechanisms amongst which is the production of short-chain fatty acids which stimulate de novo triglyceride synthesis in the liver, modulation of choline metabolism (involved in very low-density lipoprotein synthesis), lipopolysaccharide production and modulation of bile acid metabolism [224].

The change in microbial species leads to a higher concentration of secondary bile acids in the enterohepatic recirculation. In healthy individuals, bile acids play an important role in glucose and lipid metabolism regulating the negative feedback loops. Bile acids act via cellular receptors including

Farnesoid X receptor (FXR) and G protein-coupled bile acid receptor (TGR5) to affect metabolism [224, 225].

Manipulation of gut microbiota with probiotics is a promising way to halt the progression of steatosis to steatohepatitis and fibrosis. Both animal experiments and small human studies have investigated the use of probiotic agents to reverse the progression of steatohepatitis and fibrosis in NAFLD [226, 227]. Two recent double-blind RCTs – one in adults and one in children – were reported [228, 229]. Treatment with probiotics in both studies resulted in improvement in transaminases.

Though probiotics and prebiotics are potentially a way to attempt to re-establish a healthy diversity of flora however, there is no clear guidance on specific formulation nor dose [224]. Weight loss, whether dietary induced or following bariatric surgery, has been found to have a similar effect on the microbiome. Other important ways to disrupt the enterohepatic recirculation of bile thus decreasing the total bile pool is by using FXR agonists [230].

The process of fibrosis is in itself the common end point of several processes: steatosis with oxidative stress, inflammation and apoptosis. Prevention of fibrosis is optimal though antifibrotics are entering the clinical trial arena.

Though there is major interest in the search for a single effective agent for NAFLD, in reality the heterogeneity of the condition means that individualised treatment is required.

Everything considered, the most effective treatment (reversal) of NASH/steatofibrosis is weight loss.

Bariatric Surgery

Bariatric surgery (both Roux-en-Y bypass and gastric band) in management of NAFLD can have beneficial effects in adults showing improvement in AST, ALT, NAFLD fibrosis score and NAFLD activity score post-operatively [231, 232]. In children and young people, Manco et al. described a comparison of sleeve gastrectomy to intragastric balloon and lifestyle advice only and found reversal of NASH at 1-year post surgery in 100% of those who underwent sleeve gastrectomy [214].

New Agents

There are dozens of novel and repurposed therapies currently under investigation for a therapeutic benefit in NAFLD. Amongst these are a peroxisome proliferator-activated receptor alpha and gamma agonist elafibranor that acts as an insulin sensitiser, obeticholic acid a synthetic chenodeoxycholic acid analogue which is an agonist for FXR, losartan (which can decrease PAI1 expression) and antifibrogenic agents.

Why does lifestyle intervention not work for all? Adherence may be the principal challenge, and given that children and young people are almost entirely dependent on family being involved in their goal, this increases the complexity of problem.

Social deprivation, a lack of education about the importance of a healthy lifestyle and cost of fresh, unprocessed foods are all important considerations and not all which can be successfully managed in the context of a clinical lifestyle intervention programme.

An important yet underexplored area in ability to undertake and maintain lifestyle change in this population is the importance of mental health. The prevalence of depression and anxiety in children and young people and adults with obesity is high [233, 234]. Depression is also overrepresented in adults with NAFLD with 53% exhibiting subclinical depression and 14% clinical depression, 45% with subclinical anxiety with 25% clinical anxiety in a large cohort study [235]. A small number of studies have shown that quality of life (QoL) in both adults and children with NAFLD is consistently inferior to normal controls. In a survey of 239 children apart of the NASH CRN, children with NAFLD had worse total physical and psychological quality of life scores as determined by the PedsQL questionnaire. Fatigue, trouble sleeping and sadness accounted for almost half the variance in QoL scores [236]. Though obstructive sleep apnoea (OSA) may contribute to daytime somnolence in obesity, non-OSA sleep problems and the pathogenesis of this fatigue have not yet been systematically studied in NAFLD.

Response to lifestyle intervention in NAFLD is affected adversely in the presence of depression [237]. Though some studies in adults have used a psychological approach to lifestyle change in obesity-related disorders, no trials in children are reported [238–240].

There is a distinct link between poor mental health/depression, inflammation and the coexistence of complications of obesity [241–243]. The effect of visceral, inflammatory obesity leading to exaggerated or prolonged inflammatory responses compounded by sickness behaviours, depressive symptoms and poor lifestyle choices may lead to further inflammation and consequent end-organ damage [241]. Effective treatment options targeting this vicious cycle may halt both the amplified inflammation and depressive symptoms.

Future Areas for Research

The pathophysiology of NAFLD in both adults and children is still incompletely understood. The reason for different patterns of disease in children, particularly with reference to the occurrence of periportal inflammation and fibrosis rather

than the typical type 1 pattern of pericentral disease, remains elusive. Determining susceptibility to the disease using genetic analysis for SNPs may become standard practice, particularly in screening the high number of overweight and obese paediatric patients. Further investigation into specific dietary patterns in children may also yield valuable information in this multifactorial disease.

The determination of the most effective management of the condition – both in terms of achieving lifestyle change and pharmacological treatments – will be a major focus going forwards. Further areas of interest include the role of intestinal microbiota and the possible use of probiotics in the condition and dietary manipulation with PUFA.

Finally the long-term outcome of children with NAFLD remains unknown, and well-designed, long-term prospective studies using networks such as the NASH Clinical Research Network in the US are vital to achieving this.

The recognition of NAFLD in children is important in order to prevent progressive disease through young adulthood. Though closely associated with overweight and obesity, genetic and epigenetic clearly lead to susceptibility to the disease in the setting of an unhealthy lifestyle. At presentation 15% of children will have bridging fibrosis and thus a relatively severe degree of liver injury. Liver injury is reversible however, and lifestyle change which addresses a mismatch in energy balance is fundamental but achievable in less than 50% of those undergoing an intensive programme with dietary advice and support. The reasons for this are as yet unclear but in part may be mediated by the high prevalence of depression and anxiety in those with this disease. There is a growing industry in treatments which target one of more pathophysiological process involved. Stratifying patients with NAFLD according to their susceptibilities and recognising comorbid mental health problems will facilitate individualised therapy and hopefully more successful outcomes.

In conclusion, NAFLD in children is a very real, very prevalent condition and, should current trends continue, is likely to become the most common indication for liver transplantation in coming decades. It is important that the condition is recognised in children as there is the potential to reverse the condition and to avoid the morbidity and mortality associated in later years.

Vascular Disorders of the Liver

70

Ruth De Bruyne and Pauline De Bruyne

Portal Vein Anomalies

The portal vein (PV), originating at the union of the splenic vein (SV) and superior mesenteric vein (SMV), drains the blood from the gastrointestinal tract, the spleen, pancreas, and biliary apparatus [1, 2]. Between the fourth and tenth week of embryonic life, the PV develops from an anastomotic network formed by the vitelline veins around the duodenum [1, 3, 4]. Congenital anomalies of the PV are rare and can often be explained by persistence of portions of the vitelline veins [5].

Congenital Anomalies of the Portal Vein

The most common congenital anomaly of the PV is a *preduodenal portal vein (PDPV)* in which the PV passes anteriorly to the duodenum rather than posteriorly [5–9]. The embryogenesis of this anomaly, described by Gray and Skandalakis [10], consists of the persistence of a preduodenal vitelline communicating vein [11, 12]. Although PDPV can occur as an isolated defect, it is typically associated with other congenital anomalies, including heterotaxia or polysplenia syndrome [13–18], situs inversus [14, 18, 19], cardiac defects [14, 16, 20], malrotation [7, 14, 16–19, 21–24], biliary or duodenal atresia [14, 18, 25], and annular pancreas [14, 17]. Clinically, PDPV can cause a duodenal obstruction by itself or in combination with the coexisting anomalies. Approximately 50% of patients remain asymptomatic, with PDPV being a radiologic or peroperative incidental finding [6, 7, 14, 17, 18]. PDPV is of surgical importance because it may cause difficulties in procedures of the gallbladder, biliary ducts, and duodenum [8, 13, 14, 17, 20, 23, 25].

Congenital PV atresia or hypoplasia can involve the whole length of the PV or can be localized just proximal to its division into its two main branches in the porta hepatis. The foetal umbilical vein and ductus venosus which empty into the left PV undergo a spontaneous obliterative process at birth. If this obliterative process is excessive, the involvement of the PV may lead to PV atresia or hypoplasia [26]. This phenomenon often occurs in patients with biliary atresia [27, 28]. Children with small or hypoplastic PV represent a challenge for liver transplantation with higher risk of complications (such as thrombosis, stenosis, and liver graft ischaemia) [28].

The PV is the most common site of visceral venous aneurysms [29–31]. Nevertheless, *PV aneurysms* (PVAs) are rare, representing fewer than 3% of all venous aneurysms [29, 32–34]. Extrahepatic and intrahepatic locations have been described. The major location of PVA is the main extrahepatic PV at the confluence of the SV and SMV [31–34]. Some PVAs are thought to be congenital: it has been proposed that incomplete regression of the distal right primitive vitelline vein leads to a vascular diverticulum that ultimately develops into an aneurysm [29, 32, 33]. Portal hypertension, related to chronic liver disease, is the most common acquired aetiology of PVA [29–31, 33]. Other acquired causes are inflammatory processes (such as pancreatitis, trauma, invasive malignancy) and previous surgical intervention [30, 35, 36]. The most common clinical presentation is nonspecific abdominal pain, followed by incidental finding and gastrointestinal bleeding [31, 33, 37]. Complications of PVA include PV thrombosis and rupture, biliary tract compression, duodenal compression, and inferior caval vein obstruction [29, 31, 33, 38]. Management ranges from watchful waiting (with serial ultrasound imaging studies) to intervention. Surgical intervention is considered for symptomatic patients, patients

with complications, or patients with enlarging aneurysms [29, 31, 33, 39].

Anomalous pulmonary venous return is a congenital cardiac malformation in which the pulmonary veins fail to connect with the left atrium during cardiac development [40, 41]. In the infradiaphragmatic type of this anomaly, the pulmonary veins drain through a large vessel into the portal venous system or the inferior vena cava [2, 4, 42]. This anomaly is frequently associated with complex cardiac defects [40, 43]. Clinical symptoms of this infradiaphragmatic total anomalous pulmonary venous drainage commonly develop early (within 24–36 h of life) and include respiratory distress with cyanosis, tachypnoea, and tachycardia [41, 44]. No corrective treatment with catheterization exists for infradiaphragmatic anomalous pulmonary venous return. The goal of surgery is to redirect pulmonary venous flow entirely to the left atrium [41, 42].

Abnormal connections between the portal and hepatic veins (portosystemic shunts) and between the hepatic artery with the PV (arterioportal shunts) are discussed in the 'Hepatic Vascular Shunts' section.

Extrahepatic Portal Vein Obstruction

Definition and Aetiology

Extrahepatic PV obstruction (EHPVO) is a major cause of portal hypertension in children and adolescents [45–51]. In EHPVO, the portal inflow is hindered by congenital or acquired obstruction of the PV, commonly by portal vein thrombosis [52–55]. This results in cavernomatous replacement of the PV [32, 53], which consists of formation of venous channels that act as portoportal collateral vessels within and around an occluded PV. The cavernoma consists of dilated biliary (cystic and pericholecystic veins) and gastric branches (left and right gastric veins) of the PV, and the partially recanalized thrombus. These collaterals are usually insufficient to bypass the whole splenomesenteric inflow resulting in signs of prehepatic portal hypertension [32].

Portal vein thrombosis (PVT) is usually associated with the presence of a hypercoagulable state, vascular injury, or stasis [5]. Prothrombotic conditions should be excluded in children presenting with an EHPVO. Genetic abnormalities affecting the physiologic anticoagulant system, such as hereditary deficiency of protein C, protein S, and antithrombin as well as factor V Leiden, methylenetetrahydrofolate reductase C677T, and prothrombin G20210A mutations, are thought to be risk factors of venous thrombosis in adults and should be investigated in children and adolescents with PVT [46, 50, 52, 56, 57].

Direct damage to the PV in about 25% of cases can be linked to a history of umbilical vein catheterization during the neonatal period. Umbilical catheters may cause thrombosis by damage to vessel walls, disruption of blood flow, and damage to endothelial cells by the infusion of substances such as total parenteral nutrition [51, 52, 57]. Portal hypertension appears to be rather uncommon following neonatal PVT. This may be due to the predominant left PV involvement [51, 52].

Clinical Presentation

The presentation of PV thrombosis may be acute or chronic. *Acute PV thrombosis* should be suspected when patients present with symptoms such as abdominal pain, ascites, or fever in the absence of portal cavernoma and portosystemic collaterals. However, patients can also be asymptomatic [56]. Most children with *chronic EHPVO* eventually develop hypersplenism that requires medical assessment. Markedly, one-third to one-half of the children present with acute upper gastrointestinal bleeding with no prior history of gastrointestinal disorders or symptoms of hypersplenism. Morbidity of chronic EHVPO is mainly related to hypersplenism, portal biliopathy, limitations of quality of life (e.g. limited ability to participate in sports because of extreme thrombocytopenia and/or splenomegaly), growth retardation, and neurocognitive impairment (also described as minimal hepatic encephalopathy) [55, 56, 58–63].

Diagnosis

EHPVO is diagnosed by Doppler ultrasound (US), computed tomography (CT), or magnetic resonance (MR) angiography [35, 49, 56, 64] which demonstrate PV obstruction, presence of intraluminal material, or PV cavernoma (Fig. 70.1). CT or MRI imaging enables a good evaluation of the patency of the other abdominal veins facilitating planning of potential future intervention [35, 55]. When patency of the intrahepatic PV remains uncertain, transjugular retrograde or percutaneous transhepatic portal venography should be undertaken. Further diagnostic workup consists of liver biopsy when liver disease is suspected, full hypercoagulability panel, and echocardiography to look for congenital heart disease and for signs of hepatopulmonary syndrome or portopulmonary hypertension [56].

Management

Management of acute PV thrombosis can involve treatment of the causative factor and anticoagulation. Anticoagulation therapy should be considered for patients with a prothrombotic condition. Management of patients with chronic

Voet, Department of Ultrasonography, and Prof. dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

EHPVO focusses on management of oesophageal varices, hypersplenism, and portal biliopathy [55, 60]. Monitoring of growth retardation and neurocognitive impairment is also important in their follow-up [55, 60]. Patients with severe morbidity may need (shunt) surgery [35, 60, 65]. The current shunt technique of choice for children presenting with EHPVO is – if technically and anatomically feasible – mesocaval shunt (Rex shunt) placement, connecting the superior mesenteric vein to the left portal vein in the region of the Rex recess [2, 60].

For the detailed management of portal hypertension caused by EHPVO, refer to Chap. 71 'Portal Hypertension in Children'.

Hepatic Artery Anomalies

Ischaemic Cholangiopathy

Ischaemic cholangiopathy has been defined as focal or extensive damage to bile ducts due to impaired blood supply [66]. Unlike the hepatic parenchyma which has a blood supply from both the hepatic artery and PV, the biliary system only depends on the arterial blood supply [5, 66]. Ischaemic bile duct injury may occur when small hepatic arteries or the peribiliary plexus is injured (by iatrogenic factors or by systemic conditions such as vasculitis), or when all arterial blood supply is interrupted as in the case of hepatic artery thrombosis after liver transplantation [67]. In the acute stage, patients may present with pain, fever, and jaundice. In the further course, focal or diffuse bile duct stenosis can occur with variable presentation: from no symptoms to (fluctuating) jaundice, itch, fatigue, or bacterial cholangitis and eventual portal hypertension [66]. Treatment of ischaemic cholangiopathy must be individualized in relation to symptoms, acute or chronic presentation, and the location of biliary injury [67].

Pseudoaneurysm of the Hepatic Artery

Pseudoaneurysm of an artery is a type of haematoma that develops between the two outer layers of the artery, the tunica media and tunica adventitia; this is in contrast with true aneurysms involving all three layers of the wall of an artery [68, 69]. Hepatic artery pseudoaneurysms (HAPs) are commonly iatrogenic [70] or a result of abdominal trauma [64]. HAPs can be found incidentally. On the other hand, rupture of the pseudoaneurysm can be the first clinical manifestation with abdominal pain, gastrointestinal haemorrhage,

or haemobilia [69, 71]. Although HAPs can resolve spontaneously by thrombosis, the reported risk of rupture ranges from 14% to 80% [72, 73]. Hence, once HAP is diagnosed, the lesion should be treated regardless of symptoms. Treatment consists of embolization or stent placement, or surgical approach [69, 72].

Abnormalities of the Sinusoidal Blood Flow

Pericellular Fibrosis

Pericellular fibrosis is commonly seen in alcoholic liver disease, chronic passive congestion, nonalcoholic fatty liver disease, Gaucher's disease, congenital syphilis, and vitamin A toxicity [5]. The hepatic sinusoids comprise one of the largest-calibre vascular beds in the body. Impairment of blood flow through this vascular bed results in a major loss of physiologic function, with profound influence on homoeostasis for the entire human organism [74]. Endothelial dysfunction occurs early in chronic liver disease even before fibrosis and inflammation take place, and persists in advanced cirrhosis which is the most common cause of sinusoidal blood flow obstruction [75].

Physical Occlusion of the Sinusoids

In sickle cell disease, sinusoids can become packed with sickled red cells and erythrophagocytes leading to parenchymal necrosis [76]. In disseminated intravascular coagulation and eclampsia, fibrin deposits may occlude the sinusoids. When these lesions are severe, widespread infarction might occur. Furthermore, the sinusoids might become infiltrated by mast cells in mastocytosis, Gaucher's cells, metastatic tumour cells, and leukaemia or lymphoma cells [5].

Peliosis Hepatis

Peliosis hepatis is a rare tumour-like condition in which the sinusoidal dilatation is primary [77]. The liver parenchyma contains multiple blood-filled cystic spaces, either nonlined or lined with sinusoidal endothelial cells [78]. The disease is more common in adults, and the exact pathogenesis of peliosis hepatis is unknown [74, 79]. In adults, peliosis hepatis can be associated with the prolonged use of several drugs such as anabolic steroids, azathioprine, and oral contraceptives, [80], or presents in the context of chronic underlying disorders such as malnutrition [81], leukaemia [82], tuberculosis [83], vasculitis [84], cystic fibrosis, malignancy [85], organ transplantation [86], and human immunodeficiency virus (HIV) infection [87]. Peliotic lesions found in acquired immunodeficiency syndrome (AIDS) and other immunosuppressed patients are caused by bacterial organisms (*Bartonella* species) [82, 88]. In 20–50% of patients, peliosis hepatis is idiopathic [89]. In children, peliosis hepatis also occurs most frequently in association with chronic underlying conditions such as cystic fibrosis [90], malnutrition [91], Fanconi anaemia [92], adrenal tumours [93], Marfan syndrome [94], congenital cardiopathy [95], myotubular myopathy [96, 97], and renal transplantation [80]. In paediatric cases without underlying systemic disorder, an association with *Escherichia coli* infection suggesting a direct role of *E. coli* toxins in causing endothelial damage [98–100] has been reported. The definitive diagnosis of peliosis hepatis is based on histological findings but should be suspected when ultrasonography reveals hypoechogenic areas involving the whole liver in association with intraperitoneal fluid and normal Doppler signals [99]. Percutaneous liver biopsy carries a high risk of life-threatening haemorrhage. Therefore, a surgical or transjugular approach appears more appropriate [101].

Hepatic Vein Anomalies

Budd–Chiari Syndrome (BCS)

BCS is defined as hepatic venous outflow obstruction at any level from the small hepatic veins to the junction of the inferior vena cava and the right atrium, regardless of the cause of obstruction. Outflow obstruction caused by hepatic venoocclusive disease and cardiac disorders is excluded from this definition. BCS can be classified as primary due to an endoluminal venous lesion (thrombosis or webs) or secondary due to intraluminal invasion by a parasite or malignant tumour or extraluminal compression by an abscess, cyst, or solid tumour [102]. BCS is very rare in children accounting for approximately 0.1% of paediatric liver disease in Western countries in contrast to 7.4% on the Indian subcontinent [103, 104]. In primary BCS, an underlying prothrombotic disorder or established risk factor for venous thrombosis is often present. In adults, myeloproliferative diseases account for half of the cases of BCS [105, 106]. Children usually have a chronic presentation, and prothrombotic conditions are present in two-thirds of these cases. Table 70.1 gives an overview of predisposing conditions for BCS. The role of hyperhomocysteinaemia and primary protein C, protein S, or antithrombin deficiency is unclear because liver disease or recent thrombus formation and consumption can obscure recognition of these disorders [106]. Hepatic venous outflow tract obstruction results in increased sinusoidal pressure, sinusoidal congestion, hepatomegaly, hepatic pain, portal hypertension, and ascites. Elevated sinusoidal pressure leads to perisinusoidal necrosis of hepatocytes in the centrilobular

region and eventually to irreversible liver damage, cirrhosis, or liver failure [107].

A diagnosis of BCS should be considered in any patient who presents with acute or chronic liver disease as the clinical manifestations can be extremely diverse. The majority of patients present with the typical triad described by George Budd in 1845: right upper quadrant pain, hepatomegaly, and ascites. Oedema of the lower extremities is also a common finding [102]. Asymptomatic BCS accounts for 15–20% of cases [108]. Compared to adults, adolescents more often present with hepatomegaly alone [109]. Jaundice, gastrointestinal bleeding, and hepatic encephalopathy are less common [110]. The diagnosis of BCS is established upon demonstration of obstruction of the hepatic venous outflow tract. US combined with Doppler imaging has a diagnostic sensitivity of more than 75% and should be the first line of investigation [111, 112]. Hepatic veins devoid of flow signal, collateral hepatic venous circulation, a spider web appearance usually located in the vicinity of the hepatic vein ostia and stagnant, reversed, or turbulent flow can all be indicative of BCS [113, 114]. When adequate ultrasonography is technically difficult or when diagnostic features cannot be demonstrated, CT or MRI should be performed. The latter is preferred in children due to absence of radiation exposure. Only in a minority of cases, retrograde cannulation of the hepatic veins for X-ray venography will be ultimately necessary for diagnosis. This technique allows the assessment of the extent of venous outflow obstruction and allows for pressure measurements (Fig. 70.2). Concurrent liver biopsy can contribute in confirming the diagnosis and ruling out other causes such as veno-occlusive disease and cirrhosis of other aetiologies [115]. Once the diagnosis of BCS is established, the patient should be investigated for underlying prothrombotic conditions, and a haematologic workup for myeloproliferative disorder should be performed. The rarity of BCS in children often means that the disease is diagnosed in its later stages by which time irreversible pathology may be present [116].

The management of BCS requires early referral and a multidisciplinary approach consisting of anticoagulation, angioplasty, and thrombolytic therapy, with or without stenting, transjugular intrahepatic portosystemic stent shunting (TIPSS), surgically fashioned portosystemic shunts, and orthotopic liver transplantation [117]. Thrombolytic therapy might be successful in dissolving fresh thrombi and can be

Van Langenhove and Prof. dr. L. Defreyne, Department of Interventional Radiology, Ghent University Hospital, Belgium)

combined by transjugular balloon angioplasty. Maintenance of flow can be ensured by long-term anticoagulation, and if present, the underlying haematologic disorder should be managed medically. TIPSS has been successfully used in children with favourable long-term results [118–120]. Percutaneous stent placement has also played a role in the management of paediatric BCS [121, 122] (Fig. 70.2). Redkar and colleagues published their experience in a case series of 25 paediatric BCS patients. 21 underwent balloon angioplasty of which 17 had good medium- to long-term results, while only 1 out of 4 patients who underwent portocaval shunts survived [123]. The authors encourage early aggressive use of interventional radiological procedures, but further multicentre prospective studies are required to establish diagnostic and therapeutic management protocols for paediatric BCS [124]. In acute liver failure or a late presentation with established hepatic cirrhosis and complications of portal hypertension, liver transplantation is the only option that can offer an excellent chance of long-term survival [103, 125–127].

Veno-Occlusive Disease (VOD)

Hepatic VOD, also known as sinusoidal obstruction syndrome (SOS), is a severe and potentially fatal liver disease originally described in Jamaican drinkers of pyrrolizidine alkaloid-containing bush tea. It is a potentially life-threatening complication following haematopoietic stem cell transplantation (HSCT) or conventional chemotherapy and radiotherapy not associated with HSCT [128].

Many of the cytotoxic agents used in HSCT are metabolized in the liver, including cyclophosphamide and busulfan. It is thought that depletion of glutathione in zone 3 hepatocytes and sinusoidal cells plays an important role in the initiation of the damage [129]. Toxicity from chemotherapy or radiotherapy can lead to sinusoidal endothelial cell activation due to the production of pro-inflammatory cytokines by injured tissues, infection, medications, or the process of bone-marrow engraftment. This can result in damage to the sinusoidal endothelial barrier with obstruction of the sinusoidal flow and ultimately hepatocellular necrosis, fibrosis, vascular occlusion with liver failure, hepatorenal syndrome, multi-organ failure, and death [130, 131].

The prevalence of VOD in children, adolescents, and young adults varies from 20% up to 60%, compared to approximately 10% in adults [128, 132–136]. Children undergoing HSCT for specific diagnoses such as osteopetrosis, high-risk neuroblastoma, thalassaemia, and congenital macrophage activation syndrome are specifically at risk for VOD with a prevalence up to 60% [132–136]. Other risk factors are young age (<1 year), treatment regimens containing busulfan or combination treatments with monoclonal antibodies (e.g. inotuzumab ozogamicin, gemtuzumab ozogamicin), second allogeneic HSCT, etc. [137–143].

The clinical course is typically characterized by rapid weight gain, abdominal pain, hepatomegaly, and ascites. Jaundice, which is an important diagnostic item in the Baltimore and Seattle criteria [144, 145] used in adults, may be absent in 30% of paediatric patients or may appear late in the course of VOD [132]. Early diagnosis and intervention are necessary to prevent multi-organ failure with its very high mortality rate (>80%) [146].

Since the disorder differs significantly between adults and children in terms of incidence, genetic predisposition, clinical presentation, and treatment, the European Society for Blood and Marrow Transplantation (EBMT) proposed new diagnostic guidelines in 2017 [147]. The EBMT paediatric criteria have no limitation for time of onset of VOD and require two or more of the following: unexplained consumptive and transfusion-refractory thrombocytopenia; otherwise unexplained weight gain on three consecutive days despite the use of diuretics, or a weight gain of more than 5% above baseline value within 72 h; bilirubin increasing from baseline on three consecutive days, or bilirubin 2 mg/dL or more within 72 h; hepatomegaly (best if supported by imaging) above baseline value; and ascites (best if supported by imaging) above baseline [147].

In addition to the EBMT diagnostic criteria, an international expert position statement, consensus recommendations were provided for the international implementation of guidelines for the diagnosis, severity grading, and treatment of VOD among children, adolescents, and young adults [128].

In view of its favourable safety profile and promising results in both prospective randomized and retrospective studies, the use of ursodeoxycholic acid in the prophylaxis of VOD is recommended [148, 149]. It is recommended that defibrotide (25 mg/kg per day) is started once diagnostic criteria for VOD are met [128]. The therapeutic results are better than in adults [147]. Guidelines on the use of defibrotide prophylaxis in VOD are awaited, but defibrotide prophylaxis can be considered for high-risk paediatric patients. Supportive treatment of VOD focusses on maintaining intravascular volume and renal perfusion without increasing extravascular fluid accumulation. Avoidance of exposure to hepatotoxic drugs, fluid and sodium restriction, and diuretics are important in the care of a patient with VOD.

Congestive Cardiac Failure

Due to congestive cardiac failure, blood will pile up in the hepatoportal venous system, leading to sinusoidal dilatation, splanchnic congestion, and portal hypertension. The distension of hepatic sinusoids results in parenchymal atrophy,

nodular regenerative hyperplasia (NRH) [150], and stimulation of the fibrotic response which can lead to cirrhosis, liver failure, and increased risk of hepatocellular carcinoma [151].

Hepatic Vascular Shunts

Arteriovenous Malformations

Arterioportal shunts may be congenital (associated with hereditary haemorrhagic telangiectasia, Ehlers–Danlos syndrome, or biliary atresia) or acquired (after blunt or penetrating trauma, after percutaneous liver biopsy, or with cirrhosis) and consist of a communication between the hepatic artery and the portal venous system [2, 5, 32, 41, 152]. Most congenital arterioportal fistulas are symptomatic by the age of 2 years [153, 154]. Hepatofugal flow develops in the arterialized PV that can lead to presinusoidal portal hypertension, hypersplenism, varices, ascites, and hypertensive enteropathy [41, 152–154]. Treatment of arterioportal shunts is either surgical or minimally invasive through interventional embolization techniques [152–155].

Hepatic arteriosystemic shunts are the rarest form of intrahepatic shunts. These shunts connect the hepatic artery (or other systemic arteries) and the hepatic veins. These shunts may be congenital or associated with hereditary haemorrhagic telangiectasia, hepatocellular carcinoma, or large haemangiomas [32]. Hepatic arteriosystemic shunts are usually localized in one lobe of the liver [41]. Arteriovenous fistulas can not only present clinically in neonates with congestive heart failure, anaemia, hepatomegaly, and portal hypertension but also later in childhood in hereditary haemorrhagic telangiectasia with congestive heart failure, hepatic ischaemia, and portal hypertension [41, 156]. Currently, supportive measures, interventional closure (in localized lesions), and surgery (including liver transplantation) are the main treatment methods for hepatic arteriosystemic shunts [41, 156–158].

Portosystemic Shunts

Portosystemic shunts are characterized by abnormal vascular communications between the portal venous system and systemic venous system [2]. The complicated development of the inferior caval vein and the close relationship of its development with that of the vitelline veins may explain the occurrence of congenital portosystemic shunts (CPSS). Incidence of CPSS is estimated to be 1:30,000 [159–161]. CPSS are associated with several congenital anomalies and syndromes. Various forms of congenital heart disease, vascular anomalies, and heterotaxy are clearly linked to CPSS. Associations with Turner syndrome, Down syndrome, and Noonan syndrome and associations with genitourinary, abdominal, and musculoskeletal anomalies have been described [162–164]. Acquired portosystemic shunts occur as a consequence of portal hypertension [165, 166].

Both extrahepatic and intrahepatic portosystemic shunts have been described [41, 167]. Congenital *extrahepatic portosystemic venous shunts* are also known as Abernethy malformations described in 1793 [1, 168–171]. Morgan and Superina classified extrahepatic portosystemic shunts into two types [168, 171]. In type I, there is a complete diversion of the portal blood flow in the caval vein, with congenital absence of the PV. This is further divided into type Ia (the SV and SMV draining separately into a systemic vein) and type Ib (common trunk of PV draining into a systemic vein) [1, 5, 35]. In type II, the PV is intact, but some of the portal flow is diverted into the caval vein through a side-to-side extrahepatic communication [35, 41]. Congenital *intrahepatic portosystemic shunts* are abnormal intrahepatic anastomoses between branches of the PV and the hepatic veins, which develop due to persistence of communication between vitelline veins and sinus venosus [5, 35, 172] (Fig. 70.3). Intrahepatic shunts can occur in one or in both lobes and consist of one or multiple portosystemic connections [163].

Portosystemic shunts allow mesenteric blood to reach the systemic circulation bypassing the liver. This can lead to serious complications such as hepatic encephalopathy, hepatopulmonary syndrome, and pulmonary hypertension, and development of liver tumours. Therefore, screening for asymptomatic complications and close surveillance in CPSS patients are needed [164]. Portosystemic venous shunting causes increased levels of galactose, ammonia, and other nitrogenous substances in the plasma, some of which can negatively affect the brain, with development of encephalopathy [2, 32, 164, 173]. The development of hepatopulmonary syndrome and pulmonary hypertension may be explained by exposure of the pulmonary vascular bed to intestinal vasoactive mediators that have bypassed the liver [163, 164, 174]. Hepatic complications of CPSS include the development of benign and malignant liver tumours, most commonly in patients with extrahepatic CPSS. Reported liver lesions include focal nodular hyperplasia, regenerative nodular hyperplasia, hepatoblastoma, hepatic adenomas, haemangiomas, and hepatocellular carcinoma [162–164, 175–179].

Ultrasonography with Doppler study is usually the first-line exam that shows abnormal communications between the portal and the systemic veins and the consequences on liver morphology. When CPSS is suspected, CT or MRI imaging of the abdomen is indicated to assess the presence of a shunt, the anatomy of the shunt, the patency of the portal vein, and the presence of liver masses [162, 175]. Because of challenging and widely variable portal vein identification in imaging studies (CT or MRI), angiography with occlusion

Fig. 70.3 A 5-month-old child with multiple intrahepatic portosystemic shunts. (**a**) Indirect mesentericography with visualization of multiple intrahepatic portosystemic shunts. (**b**) Direct portography in the same patient with guiding into the right hepatic vein. The child previously presented with acute haematemesis caused by a bleed from a pseudoaneurysm of the gastroduodenal artery which was coiled in a previous procedure. (**c**) Illustration of interconnections in the complex portosystemic shunt. (**d**) Direct portography after occlusion of one connection of the portosystemic shunt with vascular plug. test is essential in most patients and is stated to be the gold standard diagnostic [165, 180–182].

Patients with a CPSS should be followed in a specialized centre. Importantly, therapeutic approach should be individualized: shunt type, patient age, and the presence and severity of symptoms determine treatment strategy [182, 183]. Spontaneous closure of CPSS is mainly described in patients with intrahepatic shunts and occurs mostly within the first year of life. Therapeutic procedures for intrahepatic CPSS should therefore be postponed in asymptomatic infants younger than 1 year [35, 163, 165, 180]. There still remains debate regarding therapeutic strategies for asymptomatic cases of CPSS beyond the age of 1 year. In view of the risk of future complications, several authors state that

preventive treatment may be indicated for asymptomatic CPSS [161, 164, 165, 183]. The choice of a surgical or an interventional radiology shunt closure technique for intrahepatic and extrahepatic CPSS depends on local expertise, the anatomy of the shunt, and the condition of the patient [163, 180, 182]. Liver resection and transplantation is a therapeutic option, especially in patients with specific extrahepatic or large multifocal intrahepatic shunts that are not eligible for embolization or in patients with liver tumours [162, 163, 182, 184].

Hereditary Haemorrhagic Telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) or Rendu–Osler–Weber disease is an autosomal dominant vascular disorder with variable penetrance with an estimated prevalence of 1: 5000–8000 [185]. Clinical manifestations are the result of telangiectasias and arteriovenous malformations involving the mucocutaneous tissues, lung, brain, and liver [2, 186]. The pathophysiological mechanism depends on anomalous angiogenesis with aberrant vascular responses to injury-induced and other angiogenic stimuli [186]. Hepatic vascular malformations have been reported in 47% of paediatric patients with HHT ranging from small telangiectases to large arteriovenous malformations, with various stages of severity [187].

Parenchymal Response to Vascular Injury

Nodular Regenerative Hyperplasia (NRH)

NRH is a major cause of non-cirrhotic portal hypertension in the Western world. It is a benign condition characterized by diffuse transformation of the liver parenchyma into small regenerative nodules distributed evenly throughout the liver with minimal or no fibrosis in the perisinusoidal or periportal areas [150]. The nodules vary in size, from a few millimetres to several centimetres. It is hypothesized that NRH results from disturbances in the intrahepatic venous, arterial, or sinusoidal microcirculation resulting in ischaemic atrophy and compensatory regeneration [188–190]. NRH occurs predominantly in older patients between 25 and 60 years and is rather uncommon in children [191–198]. In a large series of 716 paediatric liver tumours, NRH was demonstrated in 4.5% of the cases [199]. NRH can be idiopathic or can be associated with various multisystem diseases affecting the hepatic blood flow including solid-organ transplantation; haematopoietic stem cell transplantation; vasculitic conditions; autoimmune, inflammatory, and neoplastic diseases; or HIV [74]. Cytotoxic and immunosuppressive drugs such as azathioprine, 6-mercaptopurine, and 6-thioguanine may induce NRH [200–202]. NRH presenting with progressive portal hypertension was described in six children treated with 6-thioguanine as maintenance therapy for childhood acute lymphoblastic leukaemia [203]. The disease is often discovered incidentally during abdominal imaging performed for various reasons [190]. In advanced stages portal hypertension is the most often associated finding. Imaging findings are relatively poor in sensitivity and specificity for NRH. Regenerative nodules are often not visible on ultrasound [189] or can appear as multiple, tiny, well-circumscribed, homogeneous, and hypo-/isoechoic lesions. A diffusely heterogeneous hepatic parenchyma or distortion of the hepatic architecture may be the only imaging abnormality [190]. On CT, regenerative nodules remain isodense or hypodense in both arterial and portal venous phases, distinguishing NRH from FNH and adenomas [191]. The significance of MRI in the diagnosis of NRH is still controversial. Lesions appear slightly hyperintense on T_1-weighted images and iso- or hypointense on T_2-weighted images [204]. The nodules may present gadolinium enhancement preferentially in the portal venous phase, similar to normal liver parenchyma. This is an important feature for distinguishing NRH nodules from other focal liver lesions which may present similar imaging aspects (like FNH, hepatic adenoma, or metastatic disease) and demonstrate arterial phase enhancement, while NRH does not [190]. The gold standard for diagnosis is histopathology demonstrating regenerative nodules consisting of hypertrophied hepatocytes centrally surrounded by atrophic hepatocytes peripherally (Fig. 70.4. There is no or minimal perisinusoidal or portal fibrosis on reticulin staining, and compression of the central veins by the regenerating nodules may be seen [205, 206]. The management of NRH mainly relates to the prevention and treatment of complications of portal hypertension.

Focal Nodular Hyperplasia (FNH)

FNH is a well-circumscribed, non-neoplastic lesion characterized by benign-appearing hepatocytes with vascular anomalies and ductal proliferation of unknown aetiology [190, 207]. Vascular malformations, vascular injuries, and increased flow after paediatric oncologic therapy have all been suggested as underlying mechanisms [190]. The diagnosis of FNH is rarely made in the paediatric population (only 15% of all FNH cases) [208]. It most often affects females between the age of 30 and 50 years [209, 210]. Most cases are found incidentally on abdominal imaging. Large subcapsular lesions might lead to vague abdominal pain. Complications such as rupture and intratumoural haemorrhage are extremely rare. Most lesions remain stable with a likelihood to regress with age, and there is no malignant potential [208]. On imaging, FNH should be differentiated

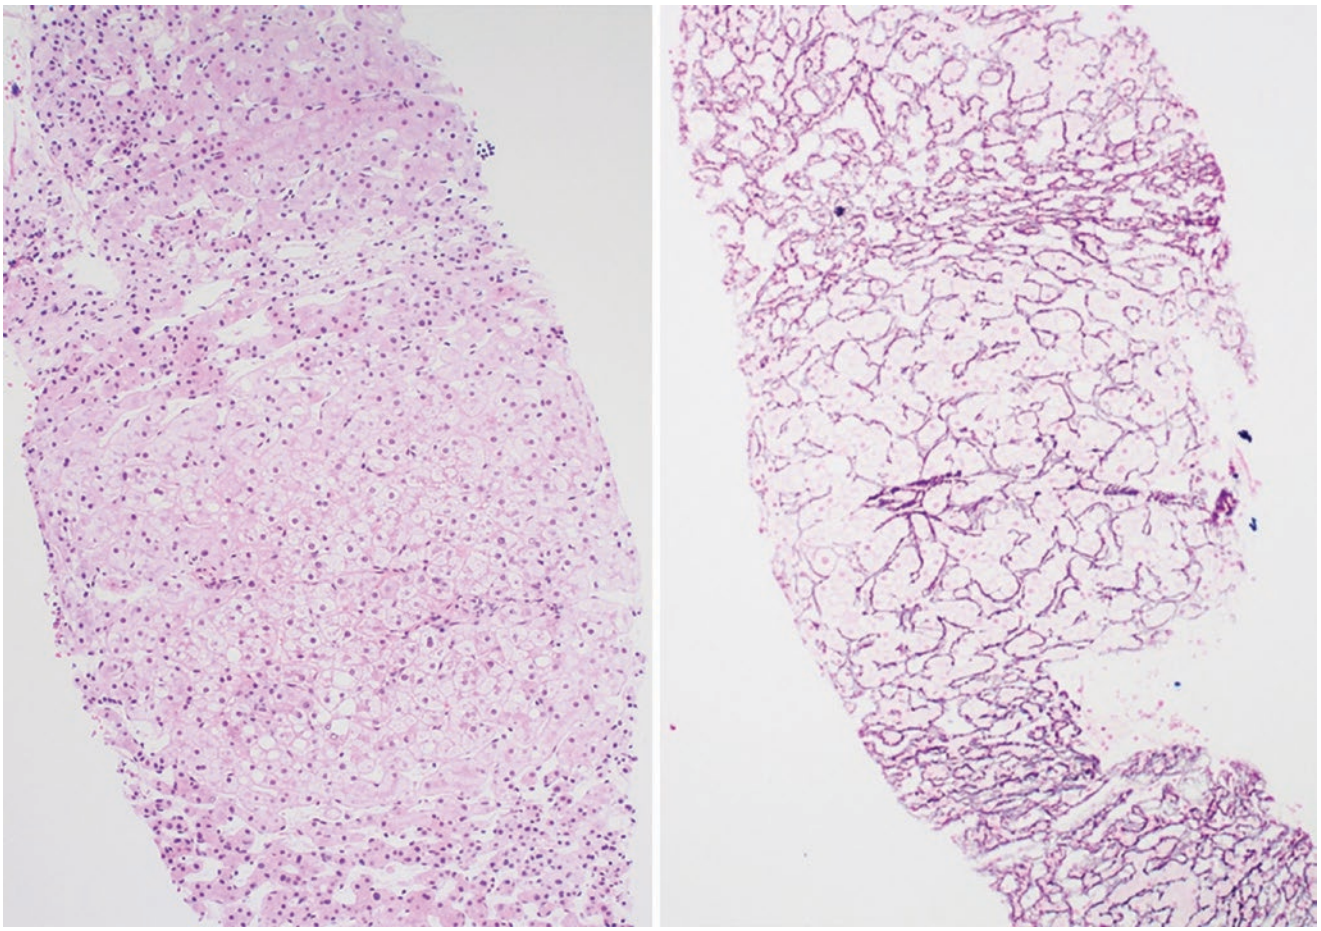

Fig. 70.4 Nodular regenerative hyperplasia (NRH): Liver biopsy of a 16-year-old girl with cystic fibrosis and portal hypertension. H&E staining shows a nodule composed of regenerative hepatocytes surrounded by atrophic hepatocytes forming thinned plates. A reticulin stain clearly outlines the nodule as well as the compressed and atrophic hepatocyte cords surrounding the nodule. There was no fibrosis. (×100) (Courtesy of Prof. dr. A. Hoorens, Department of Pathology, Ghent University Hospital, Belgium)

from liver cell adenoma [211] or hepatocellular carcinoma [212]. The typical ultrasound finding in FNH is a well-demarcated homogeneous hypo- or isoechoic lesion with a central scar which can be seen in less than 20% of cases. On colour Doppler, there is a central arterial structure with a spoke-wheel pattern of radiating smaller aberrant vessels [213]. CT shows typically a well-circumscribed iso- or hypodense lesion with rapid homogeneous intense enhancement in the arterial phase and gradual enhancement of the central scar in the portal venous phase [214]. On MRI, a homogeneous lesion is seen that is isointense or slightly hypointense on T_1- and isointense or slightly hyperintense on T_2-weighted images. During the arterial phase, the typical FNH lesion becomes homogeneously hyperintense apart from the central scar which often exhibits avid enhancement in the delayed phase [215] (Fig. 70.5). In the presence of typical radiological findings, there is usually no indication for liver biopsy. When performed, histopathology (Fig. 70.6) shows a nonencapsulated nodule with a central stellate fibrous region containing large vessels from which there are radiating septa. The parenchyma between the septa exhibits essentially normal hepatocytes but with a thickened plate architecture characteristic of regeneration [209]. Patients with asymptomatic FNH are treated conservatively without need for further imaging if there is a typical radiological appearance of FNH. In case of symptoms, which are usually seen in large subcapsular lesions, or in case of biochemical abnormalities or atypical radiological features which do not allow to rule out malignancy, surgical resection can be indicated [208]. Growth alone should not be considered as an indication for surgery [216].

Benign and Malignant Vascular Tumours

Vascular tumours of the liver comprise a substantial portion (13%) of all hepatic neoplasms in children [217]. Most of these lesions are benign. *Infantile hepatic haemangioma* (IHH) is the most common benign tumour of the liver in infancy [218]. It is recommended to avoid the terminology

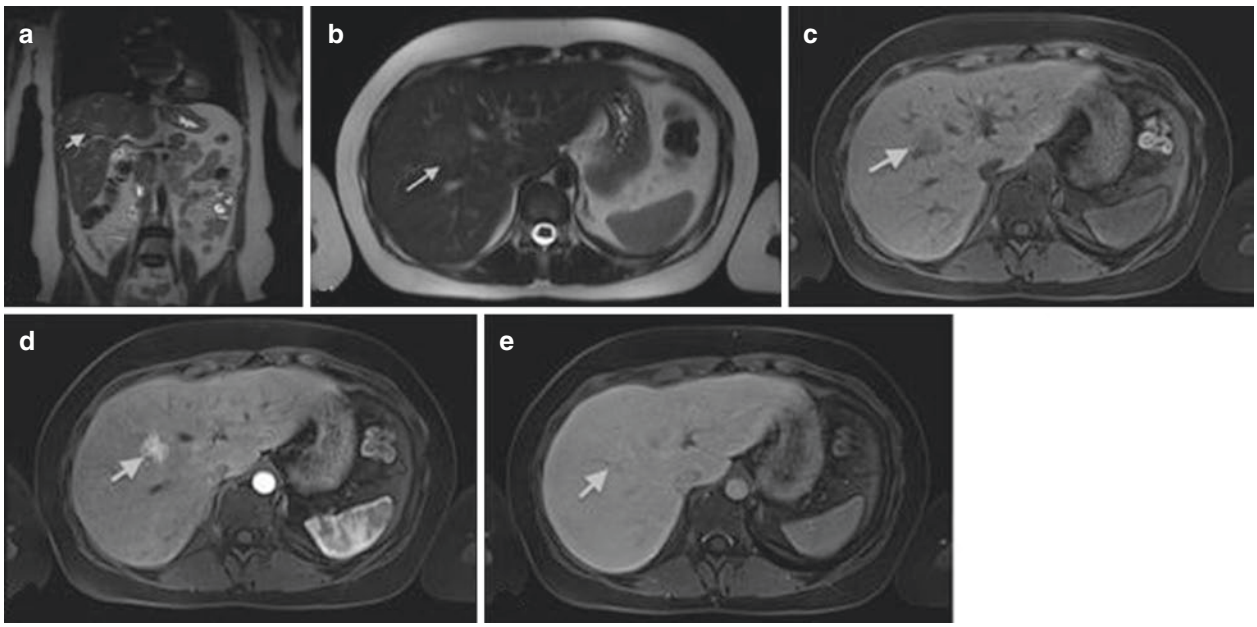

Fig. 70.5 MRI showing focal nodular hyperplasia (FNH) in a 16-year-old girl. This lesion is discretely hyperintense on T2-weighted images (**a**, **b**), hypointense on T1-weighted images (**c**), with intense early arterial phase enhancement (**d**) and isointense aspect compared to normal liver parenchyma in the portovenous phase (**e**). (Courtesy of Prof. dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

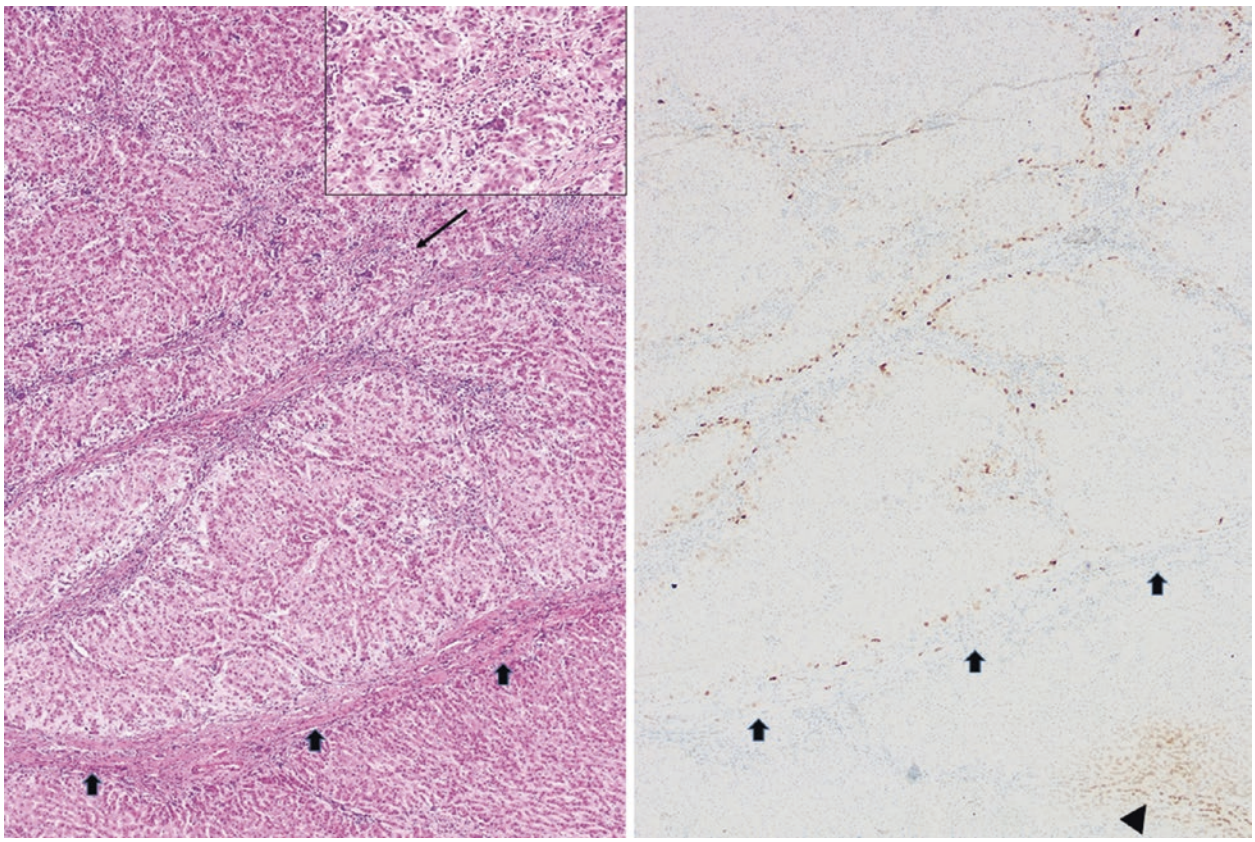

Fig. 70.6 Focal nodular hyperplasia-like lesion (FNH-like lesion) in an 18-year-old boy more than 15 years after bone marrow transplantation. H&E staining shows a nodule with fibrous septa with ductular reaction. Short arrows indicate the limits between FNH-like nodule and non-tumoral liver. (×40) Inset: higher magnification of the area indicated with a long arrow showing the ductular reaction. (×100) These FNH-like lesions may not show the characteristic map-like pattern of glutamine synthetase (GS) staining seen in true FNH, as in shown in this patent. Arrowhead indicates normal GS staining around a central vein in the non-tumoral liver. (×40) (Courtesy of Prof. dr. A. Hoorens, Department of Pathology, Ghent University Hospital, Belgium)

infantile haemangioendothelioma, which is a histological diagnosis (and therefore requires histological evaluation) and might be confused with kaposiform and epithelioid haemangioendothelioma. The majority of IHH presents within the first 6 months after birth and involute until 3–9 years of age [158, 219–223]. The incidence of IHH is unknown as a substantial part remains asymptomatic and often undiagnosed [224]. IHH can manifest as hepatomegaly, palpable abdominal mass, or distension. Life-threatening congestive heart failure can occur due to high cardiac output as well as haemolytic anaemia, thrombocytopenia, and consumption coagulopathy. Infantile HH express type 3 iodothyronine deiodinase that converts thyroid hormone to its inactive form. This can result in acquired hypothyroidism which is often seen in larger multifocal and diffuse IHH and resolves with tumour involution [225–230]. Other symptoms are jaundice, liver failure, intra-abdominal bleeding due to tumour rupture, respiratory distress, and pulmonary hypertension. Approximately half of the cases also have cutaneous haemangiomas. Based on data from the Liver Haemangioma Registry, a division into three principal categories has been proposed: focal, multifocal, and diffuse lesions [224, 227, 231]. Focal lesions could be considered as the hepatic variant of the cutaneous rapidly involuting congenital haemangioma which typically evolves during foetal life and is fully grown at birth. These lesions do not expand postnatally and are less commonly associated with accompanying cutaneous infantile haemangioma [220, 232, 233]. Because they develop antenatally, focal IHH can be diagnosed prenatally [234–236]. Most focal IHH are discovered as an abdominal mass in an otherwise healthy child and involute rapidly by the age of 12–14 months [227]. Ultrasonography reveals a well-circumscribed mass with large feeding and draining vessels. On CT or gadolinium MRI, a well-defined, solitary, spherical tumour with centripetal enhancement and central sparing because of thrombosis, necrosis, or intralesional haemorrhage can be seen [158, 224, 231] (Fig. 70.7). Multifocal and diffuse HH are considered as true IHH [227]. They are associated with cutaneous infantile haemangiomas

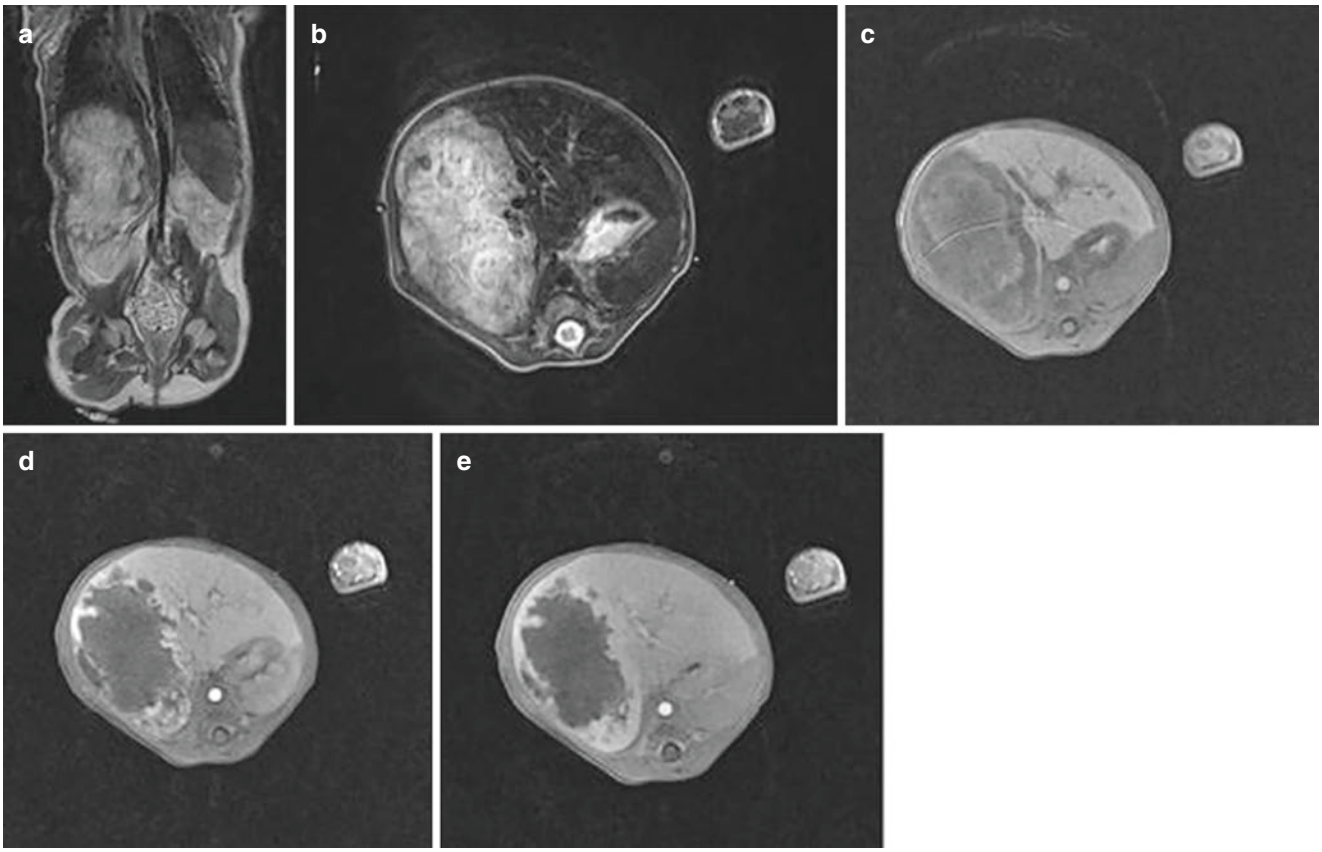

Fig. 70.7 MRI findings in a 2-week-old infant with infantile hepatic haemangioma. Large, relatively well-demarcated exophytic mass in the *right* lobe of the liver (81 × 49 × 87 mm). There is heterogeneous hyperintensity on T_2-weighted images with prominent flow voids (**a**, **b**). On non-contrast-enhanced T_1-weighted images, the spontaneous hyperintense zones in the lesion are compatible with haemorrhagic components (**c**). After intravenous contrast administration, there is peripheral nodular enhancement of the lesion in the arterial phase (**d**) with progressive, centripetal filling in the portovenous phase (**e**). (Courtesy of Prof. dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

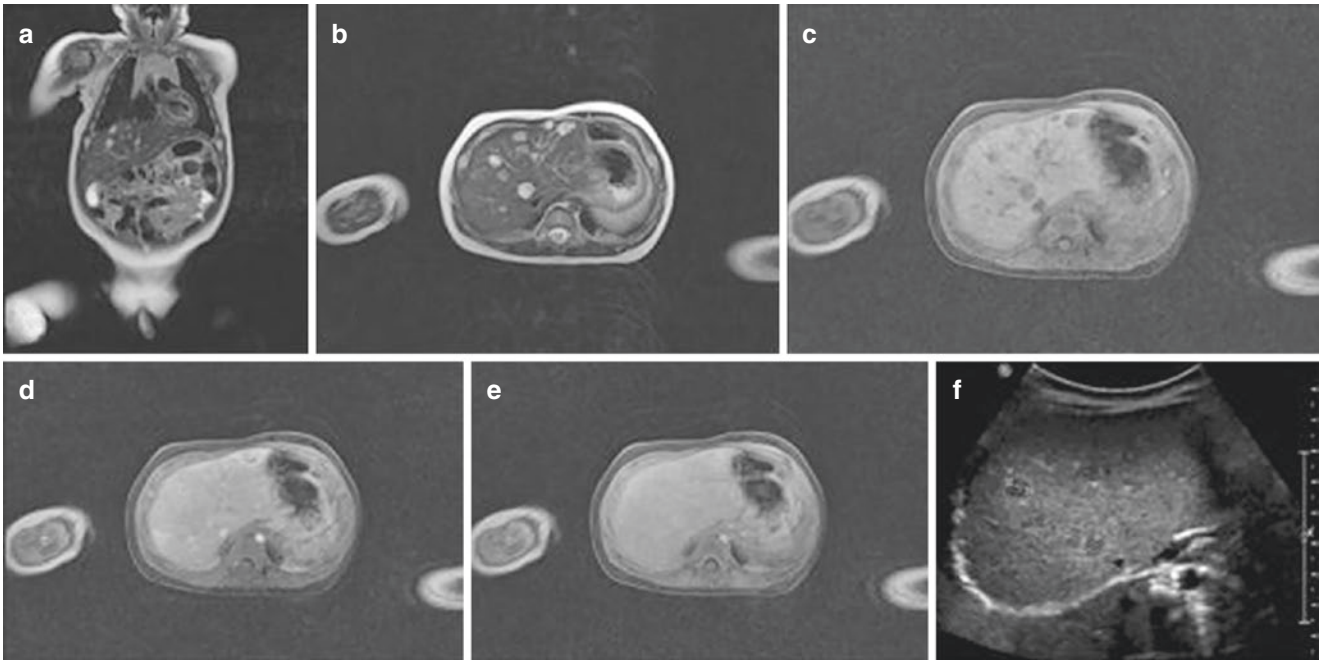

Fig. 70.8 MRI of multifocal infantile hepatic haemangioma in a 3-month-old boy. Multiple well-defined T_2-hyperintense (**a**, **b**), T_1-hypointense (**c**) nodular lesions spread throughout the liver. After intravenous contrast administration, there is nodular enhancement in the arterial phase (**d**) with nearly isointense aspect of the lesions in the portovenous phase compared to unaffected liver (**e**). US findings in the same child (**f**). (Courtesy of Prof. dr. N. Herregods, Department of Radiology, Ghent University Hospital, Belgium)

in the majority of cases and characterized by the immunoexpression of glucose transporter (GLUT)-1 in liver tissue [227]. These lesions appear within the first weeks of life and are therefore not antenatally detected. The typical course in these lesions is one of rapid postnatal growth (0–12 months) followed by slow involution (1–5 years) [227]. Multiple well-defined spherical lesions are observed on CT, MRI, or ultrasound with intervening areas of normal hepatic parenchyma in multifocal IHH, whereas the lesions in diffuse IHH nearly totally replace the liver [227] (Fig. 70.8). The diagnosis of IHH is based on medical history, physical examination, and imaging. Pathological examination is rarely necessary but should not be delayed in the face of diagnostic uncertainty or when children present with vascular tumours after infancy [158, 227]. Two histological subtypes have been described (Fig. 70.9). Type 1 IHH are composed of multiple small vascular channels with an immature endothelial cell lining and a fibrous stromal separation containing bile ductules between the channels. Type 2 IHH have a more disorganized appearing endothelial cell lining and no stromal bile ductules [217, 223, 237]. The treatment of IHH depends on clinical presentation, tumour subtype, size, anatomy, and the severity of complications [222]. Asymptomatic IHH should be observed by serial US follow-up. In case of symptoms, medical treatment, interventional radiology, or surgery is indicated. Corticosteroids were previously considered as the first-line medical treatment. However since 2014, oral propranolol, a nonselective β-blocker, was approved by the European Medicines Agency and became the medical treatment of choice for IHH requiring systemic therapy [238–240]. The dosage ranges from 2 to 3 mg/kg/day in 2 or 3 doses for 6 months. In case of haemodynamic instability and when there is no response to pharmacological treatment, arterial embolization, hepatic artery ligation, or surgical resection should be considered. Hepatic transplantation may be indicated in extremis when other treatment options are impossible or fail [227]. *Congenital hepatic haemangiomas* (CHH) are less common than IHH, proliferate in utero, and are fully formed at birth. They can be either rapidly involuting (by 2 years of age), partially involuting, or non-involuting. Histologically, they are GLUT-1 negative and do not express lymphatic markers [241]. As stated above, some authors pose that focal IHH might represent rapidly involuting CHH as they also stain negative for GLUT-1. *Paediatric angiosarcoma* is a very rare but highly malignant tumour. It usually presents with a rapidly growing hepatic mass. The precise diagnosis may be difficult, even on a biopsy specimen [242]. Open biopsy of the tumour is therefore advisable. Most angiosarcomas develop after the first year of life. Radical resection and even liver transplantation should be attempted but are often impossible due to the extent of the tumour or metastatic disease. Chemotherapy (ifosfamide, doxorubicin, and vincristine or gemcitabine and docetaxel) usually follows resection. Several gene-targeting therapies such as tyrosine kinase inhibitors (sorafenib, sunitinib, pazopanib) and anti-vascular endothelial growth factor monoclonal antibodies

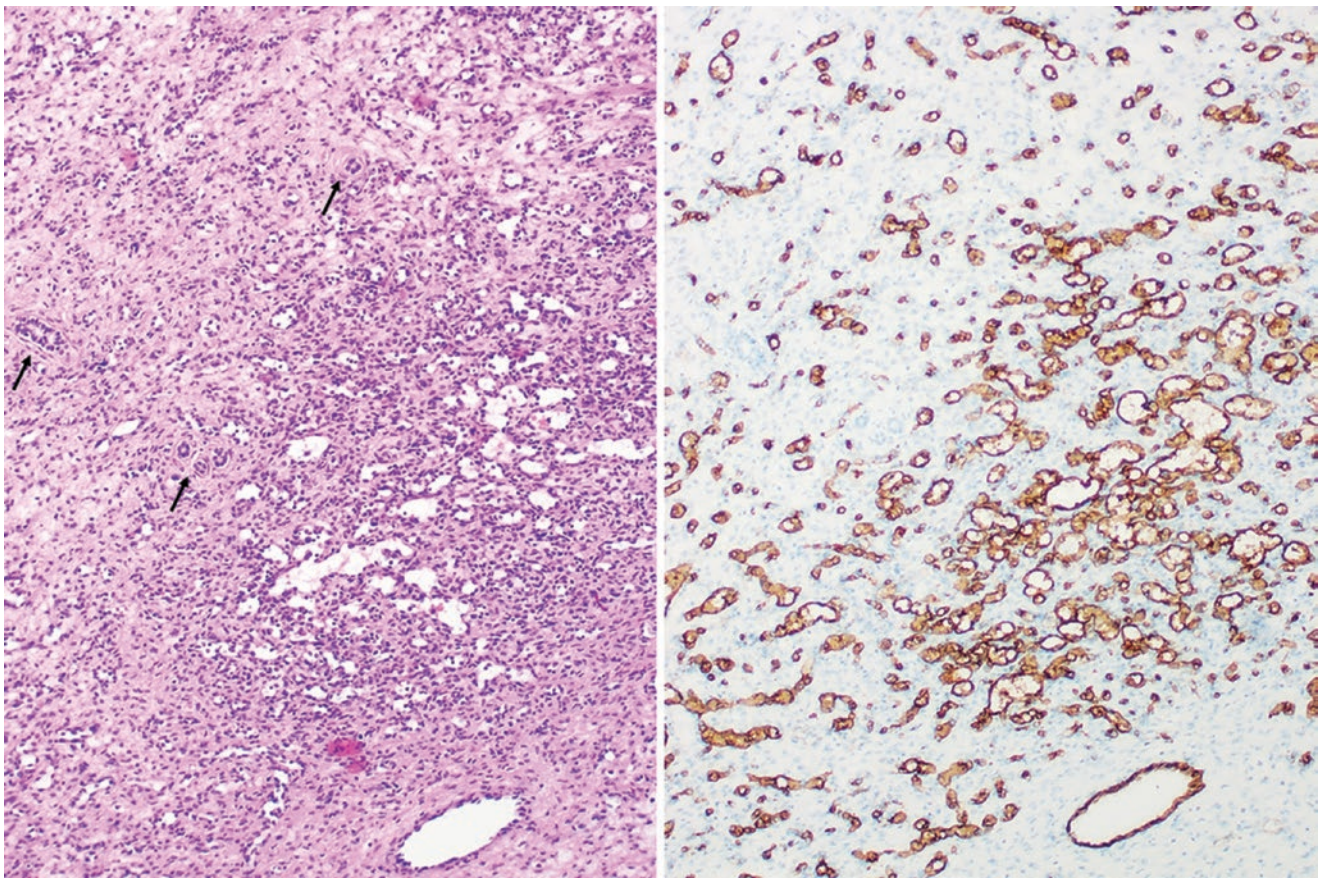

Fig. 70.9 Infantile haemangioma in a 2-month-old boy. H&E staining and immunohistochemistry for the endothelial marker CD34 shows a tumour composed of variable sized vascular structures lined by a single layer of flat to somewhat plump endothelial cells without significant atypia. Arrows indicate entrapped ductular structures. (×100) (Courtesy of Prof. dr. A. Hoorens, Department of Pathology, Ghent University Hospital, Belgium)

(bevacizumab) have been used with some success [243, 244]. The prognosis remains very poor. *Hepatic haemangioendothelioma* is a rare neoplasm of endothelial origin having a clinical behaviour intermediate between haemangioma and angiosarcoma [245, 246]. Patients generally present from the second decade, and the tumour commonly affects the liver, lung, skin, or bone, but also other presentations are reported [247].

Portal Hypertension in Children

71

Angelo Di Giorgio and Lorenzo D'Antiga

Introduction

Portal hypertension (PH) is the commonest complication of chronic liver disease in children as in adults [1]. Patients with PH are at risk of complications including splenomegaly, bleeding from intestinal varices, and ascites. Children with PH and their parents may be frightened by the most severe complication of PH, gastrointestinal hemorrhage (GH), often referred to as a terrifying experience and giving the impression of impending death; gastrointestinal bleeding in children has high morbidity, nevertheless, only few pediatric patients die from variceal bleeding, especially if they have a non-cirrhotic cause of PH [2]. Unfortunately, there are very few robust data published in the past few decades in children with PH [3]. Conversely, in adults, many treatments have been challenged, and a plethora of studies have been carried out and summarized periodically in the Baveno Consensus Conference [4]. A panel of experts sporadically provides a pediatric opinion on the Baveno Conference trying to translate the experience gained from treating adults into children [3–5].

Therefore, most children are treated simply extrapolating the data from adults and applying the same protocols adapted according to body size [6, 7]. Nevertheless, there are several important differences between PH in children and adults. One is represented by the early onset and rapid progression of pediatric liver diseases causing cirrhotic PH, together with a relatively larger availability of split organ donations allowing us to solve most of the severe cases by organ replacement. Thus, the length of the follow-up of children with severe cirrhotic PH is short. Second, a large proportion of children with PH have presinusoidal disease, having different implications as far as management and outcome are concerned [8]. These points explain why most of the children with large varices and bleeding that we manage in the long term usually have non-cirrhotic PH, clearly a different scenario from that seen in adult practice.

Anatomy of the Portal Venous System

The liver receives blood from two main vessels: the proper hepatic artery and the portal vein. The former is a branch of the common hepatic artery, which arises from celiac trunk, and supplies oxygenated blood accounting for 25% of the blood entering the liver. The latter, which drains deoxygenated blood accounting for 75% of the liver blood flow, is the largest vessel of the portal venous system. In adults, the total hepatic blood flow ranges between 800 and 1200 mL/min, which is equivalent to approximately 100 mL/min per 100 g of wet liver. Although the liver mass constitutes only 2.5% of the total body weight, this organ receives nearly 25% of the cardiac output.

This huge portal venous flow is driven through the liver across a minute pressure gradient. The pressure gradient between the portal inflow and the hepatic venous outflow is usually no more than 5 mmHg. The resistance to blood flow through the portal vein is so low because of the unique hepatic vasculature, with conducting blood vessels terminating in each of the microvascular units of the acinus and flowing past only approximately 20 hepatocytes before exiting into the wide hepatic venules. Thus, at least 50% of the entire blood content of the liver can be expelled without significant vascular resistance [9].

The portal venous system extends from the intestinal capillaries to the hepatic sinusoids. It carries the blood from the abdominal gastrointestinal (GI) tract, pancreas, gallbladder, and spleen back to the heart flowing through the liver (Fig. 71.1).

In this system, the central vessel is the portal vein, which is formed by the union of the splenic vein (SV) and the superior mesenteric vein (SMV), but receiving blood also from

the inferior mesenteric vein (IMV), the gastric, and the cystic veins. The SMV is formed by tributaries from the small intestine, colon, and head of the pancreas, and irregularly from the stomach via the right gastroepiploic vein. The SVs originate at the splenic hilum and join near the tail of the pancreas with the short gastric vessels to form the main SV. The IMV carries blood from the left part of the colon and rectum and reaches the SV in its medial third. Anatomical variations include the IMV draining into the confluence of the SMV and the SV, and the IMV draining in the SMV (Fig. 71.1).

Immediately before reaching the liver, the portal vein divides into right and left main branches, and then ramifies further, forming smaller venous branches, and ultimately the portal venules. Each portal venule runs alongside a hepatic arteriole and the two vessels form the vascular components of the portal triad. These vessels ultimately merge into the hepatic sinusoids to supply blood to the liver. Three hepatic veins (right, middle, and left) drain the blood from the liver into the inferior vena cava (IVC) [10].

Pathophysiology of Portal Hypertension

The portal venous pressure is directly proportional to the portal blood flow and the hepatic resistance, according to Ohm's law ($\Delta P = Q \times R$, where ΔP is the variation of pressure along the vessel, Q is the blood flow, and R is the resistance to flow). Since portal vascular resistance is inversely proportional to the fourth power of the radius (Poiseuille's equation), a small decrease in the vessel diameter produces a large increase in the portal vascular resistance and, in turn, in portal blood pressure. In the healthy liver, the intrahepatic resistance changes according to the variation of portal blood flow to keep portal pressure within normal limits. In fact, under physiological conditions, a rise in portal pressure is counteracted by sinusoidal dilatation, even in the presence of increased blood flow as can happen after meal ingestion [10, 11]. Most of the following statements made on PH come from experiments on animal models, such as the rat with a ligated portal vein or bile duct or with carbon tetrachloride-induced cirrhosis, and then confirmed in clinical studies carried out mainly in adults [11–13].

Increased Vascular Resistance

The portal venous system has a baseline portal pressure of 7–10 mmHg, and the hepatic venous pressure gradient (HVPG) ranges from 1 to 4 mmHg. PH is defined as a portal pressure greater than 10 mmHg or a gradient greater than 4 mmHg. In adults, a pressure gradient above 10 mmHg has been associated with esophageal varix (EV) formation, and with ascites and variceal bleeding if above 12 mmHg [14, 15].

The main pathogenetic factor in the development of PH is an increased vascular resistance (Fig. 71.2). Depending

on the site in which it occurs, PH can be classified as extrahepatic (prehepatic and posthepatic) and intrahepatic. The latter may be further subdivided into three forms including presinusoidal (portal venules), sinusoidal (sinusoids), and postsinusoidal (terminal hepatic venules; central veins; Table 71.1).

In patients affected by chronic liver disease, though, increased vascular resistance is located at various intrahepatic levels.

The pathogenetic mechanism explaining the increased resistance in extrahepatic PH, where the blood flow is blocked by a mechanical obstruction, is quite obvious. Conversely, the pathogenesis is more complicated in intrahepatic PH, in which many factors, both mechanical and dynamic, may occur simultaneously [15].

Increased Portal Blood Flow

The second factor contributing to the development of PH is an increase in blood flow, established through splanchnic arteriolar vasodilatation caused by an excessive release of endogenous vasodilators including nitric oxide (NO), glucagon, and endothelin (activated by the vasoactive intestinal peptide), as well as by the activation of the sympathetic and the renin–angiotensin systems. These changes cause sodium and water retention, hypervolemia, renal hypoperfusion, and increase in cardiac output and splanchnic blood inflow, resulting in a hyperdynamic vascular status which characterizes the advanced stages of PH (Fig. 71.2).

Extrahepatic Causes of PH

Prehepatic causes of increased resistance to flow include SV thrombosis, congenital atresia or stenosis of the portal vein, extrinsic compression (tumors), and portal vein thrombosis (PVT). In these disorders, the obstruction in the prehepatic portal venous system leads to an increased portal venous pressure [16].

The isolated obstruction of the SV (mainly due to thrombosis) usually results in left-sided PH (sparing the superior mesenteric district). In this rare clinical condition, the blood flows retrogradely through the short and posterior gastric veins and the gastroepiploic veins, leading to the formation of isolated gastric varices. The most common causes of SV occlusion are pancreatic diseases, such as pancreatic cancer, pancreatitis, or a pseudocyst. Although very rare in children, it should be considered in the presence of isolated gastric bleeding with normal liver function and unexplained splenomegaly. The diagnosis may be difficult, and splenectomy represents the treatment of choice in symptomatic patients [17–19].

PVT is the most prevalent cause of extrahepatic portal vein obstruction (EHPVO), and is the major cause of noncirrhotic PH in children. Conversely, congenital abnormalities, such as portal vein stenosis, atresia, and agenesis, are relatively uncommon.

The etiology of PVT remains obscure in approximately 50% of the cases, whereas known etiologies include umbilical vein catheterization, omphalitis/umbilical sepsis, thrombophilia (acquired, hereditary), myeloproliferative disorders, surgery (splenectomy, liver transplantation), dehydration,

and multiple exchange transfusions in the neonatal period [20–22].

In a multicenter Italian study including 187 pediatric patients diagnosed with EHPVO, it was shown that the condition is strictly associated with a neonatal disorder. The mean age at diagnosis was 4 years; 59% were born preterm; 65% had a history of umbilical catheterization; 82% had associated illnesses, such as complications of prematurity (43.5%), cardiac malformations (7.5%), noncardiac malformations (8.5%), deep infections (7%), and hematological disorders (5.5%). The patients were diagnosed upon detection of splenomegaly (39.5%), after an episode of GI bleeding (36.6%), because of hypersplenism (5.2%), by chance in the context of other investigations (16.3%; personal data, unpublished).

The pathogenesis of PH in EHPVO is closely related to the portal vein obstruction, which causes an increased vascular resistance in the portal venous system. Initially, the occlusion of the portal vein by thrombus formation is followed by compensatory vasodilatation of the hepatic artery buffering the need for blood supply to the liver. Eventually, collateral venous vessels bypassing the thrombus develop and constitute the so-called cavernomatous transformation or portal cavernoma. Part of these collaterals may reperfuse the liver, whereas the majority contributes to the porto-systemic shunting developing at various levels in the portal system. Liver tests are usually normal since there is no parenchymal disease apart from mild vascular changes, such as portal venous dilatation and sclerosis.

The management of EHPVO is mainly directed to the treatment of PH complications through medical and endoscopic means. Despite their efficacy in obliterating esophageal varices (EV), endoscopic methods have no effect on portal pressure. Conversely, surgical procedures may decompress the portal venous system and normalize the portal vein pressure. Possible indications for surgical treatment include acute variceal bleeding that cannot be controlled by endoscopic means, persistent EV formation, massive symptomatic splenomegaly, growth retardation, and symptomatic portal biliopathy [23, 24]. EHPVO is dealt with more extensively in the non-cirrhotic PH section.

Posthepatic causes of increased resistance to flow are those related to vascular and/or cardiac diseases, including thrombosis/stenosis of the hepatic veins or the atrio-caval junction; any condition increasing the right atrial pressure, such as constrictive pericarditis; severe tricuspidal regurgitation; and right-sided cardiac failure. The postsurgical status of some congenital cardiac malformations, such as the Fontan circulation, results in increased central venous pressure and increased resistance to liver outflow [25]. Unlike prehepatic PH, in which liver function remains often normal overtime, in posthepatic PH, the liver blood stagnation may compromise liver function leading to cirrhosis [26].

Budd–Chiari syndrome (BCS) is one of the most common causes of posthepatic PH both in adults and children. BCS is characterized by hepatic venous outflow obstruction at any level from the small hepatic veins to the atrio-caval junction, regardless of the cause of obstruction. The acute increase of vascular resistance secondary to the hepatic venous outflow obstruction causes the sudden appearance of PH, whereas the chronic status may lead to cirrhosis [27].

A wide variety of predisposing causes may determine the onset of the BCS, including congenital or acquired webs of the IVC and thrombotic, inflammatory, or neoplastic processes.

BCS is relatively rare in children. In studies including patients younger than 10 years with PH, the percentage of cases of BCS accounted for 1–7% of all, although in some

areas such as Africa, India, and China, the rate of pediatric BCS may raise up to 16% [28, 29].

The presentation of BCS can be acute, chronic, or fulminant. In the early course of the disease, it may be asymptomatic and accompanied by normal liver tests. Eventually, the hepatic venous outflow obstruction may lead to hepatic dysfunction associated with abdominal pain, ascites, and hepatosplenomegaly.

Due to its rarity, BCS in children is often diagnosed with some delay. The stage of the disease at diagnosis influences the management strategy, and an early diagnosis offers the best chance of cure without major surgery [30].

The management of BCS in pediatric patients may include the use of anticoagulation, thrombolytic therapy and angioplasty with or without stenting, transjugular intrahepatic porto-systemic shunts (TIPS), and, rarely, surgical porto-systemic shunts, the latter carrying high risk of thrombotic obstruction. Some patients may end up with end-stage liver disease and require transplantation.

Intrahepatic Causes of PH

Intrahepatic causes of increased vascular resistance have a more various and complicated pathogenesis compared to the extrahepatic forms, and can be further subdivided, according to the relation with the sinusoidal bed, into three subgroups: presinusoidal, sinusoidal, and postsinusoidal.

Presinusoidal venous block can be caused by many conditions, as detailed in Table 71.1. These disorders cause an elevated portal venous pressure, which cannot be detected by the hepatic vein catheter study, since wedged hepatic venous pressure (WHVP) reflects that of the sinusoids that are distal to the lesion, and therefore have normal blood pressure in this condition. Thus, the only useful technique to gather information on the degree of presinusoidal PH is that of the direct measurement of portal or splenic pulp pressure (Table 71.2).

Schistosomiasis is one of the leading causes of PH in the developing countries. Liver involvement due to schistosomiasis is caused by one of the two trematode flukes *Schistosoma mansoni* and *japonicum*. While the former is seen predominantly in Africa and South America, the latter is common in eastern Asia, especially mainland China [31]. The pathogenesis of liver disease here is secondary to entrapment of eggs in the portal venules that cause granulomatous inflammation leading to fibrosis and, in 4–8% of cases, presinusoidal PH. Portal tract inflammation results from the host response to the parasitic egg in the hepatic venule. The natural history of PH in this condition is closely related to the number of eggs deposited in the liver [32, 33].

Sinusoidal obstruction is mainly due to cirrhosis. It is marked by an increase of HVPG, normal free hepatic venous pressure (FHVP), and raised WHVP (Table 71.2). In sinusoidal PH, WHVP is equal to portal venous pressure because disrupted intersinusoidal communications diminish compressibility and compliance of the sinusoids, allowing direct transmission of portal pressure to the WHVP [34, 35]. In cirrhosis, the increase of vascular resistance occurs at the level of the hepatic microcirculation (sinusoids), and it is secondary to both a *mechanical* and a *dynamic factor*. The *mechanical factor* is represented by the hepatic architectural derangement, and is characterized by hepatocyte swelling, hyperplasia, portal tract inflammation, and fibrosis in response to liver injury. Besides, collagen deposition in the space of Disse may contribute to increased intrahepatic resistance [36]. The *dynamic factor* is represented by the active contraction of myofibroblasts and vascular smooth-muscle cells of the intrahepatic veins, and it may be modified by endogenous molecules and pharmacological agents, which affect the intrahepatic vascular resistance. Factors that increase the hepatic vascular resistance include endothelin-1 (ET-1), the alpha-adrenergic stimulus, and angiotensin II. Those decreasing hepatic vascular resistance include NO, prostacyclin, and vasodilating drugs (e.g., organic nitrates, adrenolytics, calcium channel blockers) [15, 37, 38].

Among these endogenous factors, ET-1 and NO play a key role in regulating the hepatic vascular resistance. ET-1 is a powerful vasoconstrictor synthesized by sinusoidal endothelial cells that has been implicated in the increased hepatic vascular resistance of cirrhosis, and in the development of liver fibrosis. NO is a powerful vasodilator substance that is also synthesized by sinusoidal endothelial cells. In the cirrhotic liver, the production of NO is decreased, whereas that of ET-1, it is increased. The result of these changes is a net vasoconstrictive effect that, in cirrhosis, accounts for

Table 71.2 Hepatic venous pressures according to the pathophysiology of portal hypertension

Etiology of PH		ISP	PVP	RAP	WHVP	FHVP	HVPG
Prehepatic		↑↑	↑↑	N	N	N	N
Intrahepatic	Presinusoidal	↑↑	↑↑	N	N or ↑	N	N or ↑
	Sinusoidal	↑↑	↑↑	N	↑↑	N	↑↑

Posthepatic		↑↑	↑↑	N or ↑	↑↑	↑↑	N or ↑

ISP intrasplenic pressure, *PVP* portal vein pressure, *RAP* right atrial pressure, *WHVP* wedged hepatic venous pressure, *FHVP* free hepatic venous pressure, *HVPG* hepatic venous pressure gradient (difference between WHVP and FHVP), ↑↑ severe increase, ↑ mild increase, *N* normal

approximately 20–30% of the increased intrahepatic resistance [39–41].

Another dynamic factor that can lead to an increase of intrahepatic vascular resistance is mediated by stellate cells. Hepatic stellate cells (HSCs) are located in the perisinusoidal space of Disse, behind the endothelial barrier, resulting in 5–8% of all human liver cells and 13% of sinusoidal cells. HSCs are involved in vitamin A storage and the synthesis of extracellular matrix components, matrix-degrading metalloproteinase, cytokines, and growth factors [42].

HSCs have the capacity to contract or relax in response to vasoactive mediators, such as ET-1 and NO, therefore having a crucial role in controlling intrahepatic vascular resistance and blood flow at sinusoidal level. Indeed, stellate cells become "activated" in response to acute or chronic noxae damaging the liver parenchyma, acquiring a myofibroblast-like phenotype. During HSC activation, their production of extracellular matrix changes qualitatively and quantitatively, leading to an increase of intravascular resistance.

In summary, in cirrhosis, the increased intrahepatic vascular resistance consists of two main components. The "mechanical factor" is fixed and caused by the structural changes, which occur in patients with chronic liver disease mainly in the form of fibrosis and nodule formation [43, 44]. The "dynamic factor" is variable and caused by endogenous mediators (ET-1 and NO) as well as HSC activation. The main target of the management of PH is represented by medical therapy directed against the "dynamic factor" to decrease the intrahepatic vascular resistance [45, 46].

Postsinusoidal obstruction includes right-sided heart failure, IVC obstruction, small venule BCS, and veno-occlusive disease (VOD). In this setting, WHVP is elevated, whereas HVPG and FHVP can be either normal or elevated, depending on the site of obstruction, intrahepatic postsinusoidal or posthepatic, respectively (Table 71.2). Hepatic VOD is a clinical syndrome occurring early after bone marrow transplantation (BMT) as a result of liver damage by pretransplant conditioning, or chemotherapy for solid tumors. Its incidence in the pediatric BMT population is between 22 and 28%, with an associated mortality of up to 47% [47, 48]. The pathologic injury initiates in zone 3 of the liver acinus with subendothelial edema of hepatic venules, fibrin deposition, microthrombosis, venular narrowing, and sclerosis, followed by hepatocyte necrosis [49]. The result is a postsinusoidal increased resistance to hepatic venous outflow resulting in acute PH and, in some cases, multiorgan failure [50–52].

Other Pathogenetic Mechanisms of PH

In some conditions, PH can be caused by the increase of portal venous inflow itself. In patients with an artero-venous communications between the splanchnic arteries and the portal venous system, an *artero-portal fistula* (APF), the portal flow is markedly increased and arterialized, with the consequent development of presinusoidal PH. APF can be acquired or congenital, but the most common causes are hepatic trauma and liver biopsy, and can be asymptomatic or manifest with PH. Long-standing APF can lead to severe PH characterized by arterial Doppler signal in the portal vein, reversal of the portal flow, and thickening/narrowing of the extrahepatic portal vein. In this setting, radiological procedures represent the best treatment option to close the artero-venous fistula and restore a normal portal vein flow, although, in the congenital forms, the fistula often reappears through the development of new spontaneous shunt formation [53].

In 1898 Banti described a disorder characterized by splenomegaly and hypersplenism, resulting in PH and anemia in the absence of hematological and liver disease. The actual existence of the condition has been questioned for a long time due to the lack of explanation for the development of splenomegaly, hypersplenism, and PH in these patients. Nowadays, Banti's syndrome is considered the result of microscopic changes of the portal tract that were not detected at the early stages of its clinical description and corresponding to a group of diseases causing non-cirrhotic PH. *Hepatoportal sclerosis* (HS) is one of the rare disorders characterized by sclerosis of the intrahepatic portal veins resulting in non-cirrhotic PH. HS in children is uncommon but probably underestimated, and only few case reports have been published so far. The cornerstone of the diagnosis of HS is the histology, characterized by portal fibrosis without evidence of either cirrhosis or nodule formation; portal fibrosis is responsible for the increase in the intrahepatic vascular resistance and PH. Nevertheless, the mechanisms leading to portal fibrosis and, in general, the entire phenotype of HS are still not well known [54]. Yilmaz reported on 12 pediatric patients with non-cirrhotic PH. On histology, all patients had HS or intimal fibrous thickening of portal vein and periportal fibrosis, acinar transformation, and regenerative nodules not surrounded by fibrous septa. In some of them, there were also signs compatible with cholestatic disease, including neoductular reaction in seven, mild cholangitis in one, and canalicular bile pigment in one [55].

Systemic Hemodynamic Changes in Portal Hypertension

Increased resistance to portal blood flow is likely to be the *primum movens* in the development of PH; however, a variety of hemodynamic changes contribute to amplify the increased portal venous pressure observed in patients with chronic liver disease.

The hyperdynamic syndrome was first described in the 1950s, when some physicians observed that patients with

cirrhosis often showed "warm extremities, cutaneous vascular spiders, wide pulse pressure and capillary pulsations in the nail beds." In 1953, Kowalski and Abelmann published the first study which demonstrated an increase in cardiac output and a decrease in peripheral vascular resistance in patients with alcohol-induced cirrhosis [56]. The recognition of the dangerous effect of this syndrome on multiple organs, though, was achieved only several years later [57].

Vasodilatation plays a key role in the development of the hemodynamic changes. The hyperdynamic syndrome should be better called "progressive vasodilatatory syndrome," because vasodilatation is the main factor that brings about all the vascular changes and finally the multiorgan involvement seen in cirrhosis [58]. A major step ahead in this field was accomplished in the 1990s, when researchers discovered that NO was responsible for the vasodilatation and, in turn, of the multiple organ malfunctions characterizing the hyperdynamic circulation [59].

Both clinical studies and animal models have demonstrated and explained the hemodynamic events that occur in PH, but, since they have not been performed in children, the findings should be interpreted with caution (Fig. 71.2).

Splanchnic Circulation

Vasodilatation of the splanchnic circulation is a process mediated by humoral vasodilatatory agents, and it is probably the initial signal triggering the hyperdynamic systemic circulation. Splanchnic vasodilatation causes, as a consequence, an increased portal venous blood inflow, contributing to the maintenance and the aggravation of PH [57, 60]. The result of this significant vasodilatation is that a large proportion of circulating blood volume remains confined to the splanchnic system, with a subsequent reduction of central blood volume. This process is called the "forward flow" theory and provides a rationale for the use of vasoconstrictors in adult patients with PH [12].

Systemic Circulation

Splanchnic vasodilatation is associated with changes in the systemic circulation, such as a decrease of arterial pressure, that is, consequence of the decreased central blood volume and peripheral resistance in various organs [61]. Compensatory mechanisms include the activation of baro- and volume receptors as well as the production of neurohormonal substances leading to sodium and water retention, with plasma volume expansion and increase in cardiac output [62].

The cardiac response is directly related to splanchnic vasodilatation and plasma volume expansion, together with an increased venous return that is mostly due to the formation of porto-systemic shunts. Although vasodilatation is essential as the initiating factor, no hyperdynamic circulation occurs without expansion of plasma volume and porto-systemic shunting [63]. The former is due to renal sodium retention, which has been shown to precede the increase in cardiac output, and can be prevented or reversed by sodium restriction and administration of spironolactone. The latter is characterized by the development of new veins (called collateral vessels) bypassing the liver and decompressing the portal venous system. These veins directly connect the portal blood vessels to veins that divert the blood away from the liver into the systemic circulation. The drawback in this compensatory process is that substances (such as ammonia and toxins) that are normally removed from the blood by the liver pass directly into the systemic circulation, and have adverse effects in other organs [64].

Collateral vessels tend to develop at the lower end of the esophagus and at the upper part of the stomach (Fig. 71.1). Here, the vessels enlarge and become full of twists and turns, becoming varicose veins in the esophagus varices (EV) or stomach (gastric varices). Other collateral vessels may develop on the abdominal wall and in the rectum. These vessels are prone to rupture, leading to GI bleeding.

Lung Circulation

PH and liver shunting may also affect the lungs, resulting in the development of hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH); these conditions are characterized by hypoxia due to pulmonary artero-venous shunts and pulmonary hypertension, respectively [65]. Although the intrinsic mechanism triggering these complications is not fully known, the major role seems to be played by molecules active on the pulmonary endothelium (including NO and carbon monoxide) that can cause either condition [66, 67].

Renal Circulation

Renal circulation is affected indirectly by the hyperdynamic state. To balance the progressive systemic vasodilatation, the kidney responds to a perceived hypovolemia by retaining sodium and water. The relative hypovolemia results from an increase of the vascular compartment caused by vasodilatation, leading to the activation of vasoconstrictive and volume-retaining neurohumoral substances that perpetuate sodium and water retention [68]. These compensatory mechanisms

include the activation of renin–angiotensin–aldosterone system and antidiuretic hormone secretion. In the early course of the disease, the intravascular volume and the cardiac output increase to maintain the arterial perfusion pressure [69]. With the progression of the disease, vasodilatation worsens, and the cardiac output continues to increase up to a maximum, and then it is not enough to maintain the perfusion pressure. At this point, the renal blood flow drops and renal failure develops [70, 71].

The hyperdynamic circulation should not be considered a complication of cirrhosis but a complication of PH. In fact, it was observed also in non-cirrhotic subjects and confirmed in different experimental models of PH [57, 59].

Table 71.3 Clinical evaluation and investigations useful to recognize patients with suspected portal hypertension

Step	Aim
Clinical history	Ask for neonatal umbilical catheterization, episodes of gastrointestinal bleeding, results of previous blood tests, investigations for an undefined splenomegaly
Physical examination	Assess liver size and consistency, look for splenomegaly, abdominal venous patterning (site and direction of venous flow), spider nevi and telangiectasias, palmar erythema, ascites, limb edema
Liver function tests	Assess liver function and full blood count for hypersplenism
Ultrasonography and Doppler of the liver	Evaluate liver parenchyma, patency of portal vein and direction of venous blood flow, hepatic vein patency, venous anatomical abnormalities, hepatic artery (patency and abnormalities), porto-systemic shunts, ascites, splenomegaly, renal abnormalities
Upper endoscopy	Assess varices and hypertensive gastropathy
CT scan of the abdomen	Assess liver parenchyma, biliary tree conformation, vascular anatomy, rex recessus patency, and signs of portal hypertensive biliopathy
Measure portal venous pressure (HVPG, WHVP, FHVP)	Evaluate the degree of portal hypertension. Diagnose prehepatic, intrahepatic, posthepatic causes
Liver biopsy	Assess fibrosis/cirrhosis, inflammation, histological pattern

CT computed tomography, *HVPG* hepatic venous pressure gradient, *WHVP* wedged hepatic venous pressure, *FHVP* free hepatic venous pressure

Clinical Manifestation of Portal Hypertension

PH in children has a broad spectrum of clinical manifestations, varying from the occasional finding of splenomegaly discovered during a routine follow-up visit in absence of any symptom to hematemesis and melena due to the rupture of EV (Table 71.3). The main manifestations of PH are GH, ascites, and splenomegaly, but, in a minority of patients, other complications may arise including hepatic encephalopathy (HE), pulmonary vascular disorders, and kidney disease [72].

Gastrointestinal Hemorrhage

GH is defined as bleeding in the digestive tract, and it can be classified as proximal or distal, acute or chronic. Bleeding from the upper digestive tract (esophagus, stomach, and upper portion of the small intestine) causes hematemesis and melena, whereas bleeding from the lower digestive tract (lower portion of the small intestine, large intestine, and rectum) causes dark blood or bright red blood mixed with stool, depending on the proximity to the anal sphincter. GH is mainly related to bleeding from EV and also, in a minority of cases, from portal hypertensive gastropathy, gastric antral vascular ectasia, or gastric, duodenal, peristomal, or rectal varices (Fig. 71.3).

Fig. 71.3 Endoscopic appearance of large esophageal varices with red signs in two children with portal hypertension. (Reprinted from Ref. [73], with permission from Elsevier)

Acute GH is often the first symptom of a long-standing silent liver disease, and therefore it is regarded by patients and carers as a frightening event, giving the impression of imminent death. Although the mortality from GI bleeding in children is lower than in adults, acute GH remains a life-threatening event and requires prompt medical intervention. Chronic bleeding is usually mild and can be discovered since the patient has refractory iron-deficiency anemia and positive fecal occult blood test [73].

The formation of varices and their rupture result from the increased pressure within the vessel as a consequence of PH. When the wall tension exceeds the variceal wall strength, the rupture of the varix occurs, and the patient develops hematemesis and/or melena [74].

Variceal bleeding in children with chronic liver disease often follows an acute upper respiratory tract infection, with the contribution of several factors such as the increased abdominal pressure during coughing or sneezing, the increased cardiac output due to fever, and the erosive effect of nonsteroidal anti-inflammatory drugs used to treat the fever. Gastroesophageal reflux is another factor which may contribute to erosions of varices leading to its rupture and bleeding [75–77].

Hematemesis and melena are the most common presenting symptoms in children with both intrahepatic and extrahepatic PH, and the first episode can be as early as 2 months of age [2, 22, 78–80].

The age at the first bleeding episode is related to the underlying etiology. In children with biliary atresia, the first bleed was described at a mean age of 3 years, while in children with cirrhosis due to cystic fibrosis, it occurred at 11.5 years [74, 81]. In a recent study, 65 children with EHPVO were followed for a median period of time of 8.4 years. Thirty-two (49%) patients presented with bleeding at a median age of 3.8 years (0.5–15.5) and, during the follow-up period, 43 of them (66%) had at least 1 bleeding episode [2]. Triger et al. followed 44 children with EHPVO for a mean follow-up of 8 years. The actuarial probability of bleeding was 49% at age 16 years and 76% at 24 years of age. If the child bled before 12 years of age, the probability of bleeding was higher than in those who had not bled before 12 years of age. Further, there was no evidence of variceal regression over time. These studies do not support the previous hypothesis that variceal bleeding decreased in adolescence due to the development of spontaneous porto-systemic collaterals [2, 82]. In a multicenter Italian study on 187 children with EHPVO, the mean age at diagnosis was 4 years, and the most common symptoms at onset were splenomegaly (40%) and gastrointestinal bleeding (36%). Of 71 patients with an available endoscopy at presentation, 62 (87%) had already developed EV. Development of EHPVO was strictly associated with a neonatal disorder including history of prematurity, neonatal illness, and umbilical venous catheter. Authors concluded that a liver Doppler ultrasound should be performed before discharge from the neonatal unit and at the follow-up to allow an early recognition of the disease and avoid bleeding from EV that are present from the early stages [78]. Since splenomegaly is a very common sign detected in children with PH at the time of GI bleeding, the association between GI bleeding and splenomegaly should be suggestive of PH until proven otherwise [74].

There is no strong evidence supporting the efficacy of any treatment for the prevention of variceal bleeding in children. The administration of nonselective β-blockers (NSBBs), the endoscopic treatment of varices, and the surgical (meso-rex bypass, porto-systemic shunts) and radiological (TIPS) measures to decompress the portal system represent the main therapeutic options for the primary and secondary prophylaxis of bleeding in children with PH [73, 83].

Splenomegaly

Splenomegaly indicates an enlargement of the spleen usually associated with its overactivity, defined hypersplenism, which leads to premature destruction of blood cells. Splenomegaly is due to PH which causes at the beginning only spleen congestion and eventually tissue hyperplasia and fibrosis. The increase in spleen size is followed by an increase in splenic blood flow, which participates in PH actively congesting the portal system [84]. Together with EV, splenomegaly represents the most common finding in children with PH even though, in asymptomatic children, it is often discovered accidentally during a routine physical examination [78].

Despite a big spleen is highly suggestive for PH, many children with liver disease and isolated splenomegaly have often a delayed diagnosis. In clinical practice, splenomegaly accompanied by hypersplenism is considered a sign of hematological disorders, leading to a long hematological follow-up (including bone marrow aspiration and biopsy) before asking consultation to a hepatologist. Due to the large spleen, children with PVT often receive a diagnosis of infectious mononucleosis every time they come to clinical attention because of a viral illness, and PH is disclosed only after a bleeding episode.

Liver function tests and Doppler ultrasound are mandatory in healthy children with splenomegaly and hypersplenism to exclude the presence of EHPVO and avoid worthless procedures [74, 85].

Some studies have tried to identify the best noninvasive method to diagnose the presence of EV in children with PH. Platelet count and splenomegaly are usually considered the most reliable parameter to predict the presence of EV. The clinical prediction rule proposed by Gana has high predictive value (area under the receiver operating characteristic; ROC curve 0.80) and is calculated according to the

following formula: (0.75 × platelets)/(spleen z score + 5) + 2.5 × albumin [86].

Once liver transplantation (LTX) or porto-systemic shunting is performed, splenomegaly and hypersplenism may improve significantly, but sometimes they persist for long, depending on the grade of splenic hyperplasia and fibrosis developed over time [87, 88].

Ascites

Ascites is the accumulation of serous fluid in the peritoneal cavity, and is usually seen in patients with PH due to cirrhosis. Ascites appears when the hydrostatic pressure goes above the osmotic pressure within the hepatic and mesenteric capillaries, and the transfer of fluids from blood vessels to lymphatics overcomes the drainage capacity of the lymphatic system [89].

Ascites should be analyzed to obtain information on its cause and possible complications. The serum ascites albumin gradient (SAAG) is used to classify ascites into portal and non-portal hypertensive etiologies. The SAAG is calculated by subtracting the ascitic fluid albumin level value from the serum albumin value, and the result correlates directly with portal pressure. This phenomenon is the effect of Starling's forces between the fluid of the circulatory system and ascitic fluid, as albumin does not move across membranes easily, because it is a large molecule. Under normal circumstances, the SAAG is ≤1.1 g/dl because serum oncotic pressure (pulling fluid back into circulation) is exactly compensated by the serum hydrostatic pressure (which pushes fluid out of the circulatory system). In presence of PH, there is an increase in the hydrostatic pressure causing more fluid and more albumin to move from the circulation into the peritoneal space with ascites formation. As a consequence, the SAAG increases (≥1.1 g/dl). Thus, a high gradient (SAAG ≥1.1 g/dl) indicates that the ascites is due to PH, whereas a low gradient (SAAG ≤1.1 g/dl) indicates that ascites is not associated with increased portal pressure (Table 71.4). In clinical practice, some conditions may influence the proper value of the SAAG including the sampling of ascites and serum in different states of hydration or the impact of serum globulin concentration [90, 91].

Ascites should also be evaluated for spontaneous bacterial peritonitis (SBP), an ascitic fluid infection without an evident intra-abdominal surgically treatable source. The diagnosis is made by ascitic fluid cell count. The absolute polymorphonuclear cell (PMN) count in the ascitic fluid is calculated by multiplying the total white blood cell count (or total "nucleated cell" count) by the percentage of PMNs in the differential. The diagnosis of SBP is established by an elevated ascitic fluid absolute PMN count (≥250 cells/mm^3), a positive ascitic fluid bacterial culture, and absence of secondary causes of peritonitis [92]. Patients with SBP should receive antibiotic therapy, such as intravenous third-generation cephalosporin, and be considered for liver transplantation.

Table 71.4 Causes of ascites based on serum ascites albumin gradient (*SAAG*)

SAAG ≥1.1 g/dl = portal hypertension	SAAG ≤1.1 g/dl = other causes of ascites
Cirrhosis	Peritoneal lymphoma
Non-cirrhotic liver disease	Serositis
Fulminant hepatic failure	Chronic peritoneal infection
	Tuberculosis
	Other (bacteria, viruses, fungi)
Vascular/heart disease	Low serum colloid osmotic pressure
Portal vein thrombosis	Nephrotic syndrome
Veno-occlusive disease	Protein-losing gastroenteropathy
Budd–Chiari syndrome	Kwashiorkor
IVC obstruction/right heart failure	Hollow organ leak
Benign and malignant neoplasms	Lymphatic
Myxedema	Other (pancreatic, biliary, intestinal)

IVC inferior vena cava, *TBC* tuberculosis

Fig. 71.4 Tense ascites and abdominal venous patterning in a child with biliary atresia, failed Kasai, and end-stage liver disease

Treatment of ascites includes salt and fluid restriction and use of diuretics. Spironolactone is the diuretic of choice as it is an aldosterone antagonist counteracting the endocrine changes of the hyperdynamic circulation, but often there is the need to add a loop diuretic, such as furosemide, which can improve diuresis and counteract hyperkalemia. In children with normal liver synthetic and biliary function, ascites can often be managed with diuretics and occasional paracentesis (Fig. 71.4). If ascites is large and not responding to diuretics, the paracentesis may be utilized safely in children, preferably after albumin infusion [93, 94]. In a prospective

observational study on 32 children with severe ascites, the authors demonstrated that the incidence of post-paracentesis circulatory dysfunction was lower in children who received albumin infusion compared to those who did not (12% vs 67%, $p = 0.003$) [93]. When ascites does not recede and recurs shortly after paracentesis, or when children do not tolerate diuretic therapy due to side effects, the management can take advantage of more aggressive treatment including regular large-volume paracentesis and, if feasible, TIPS. TIPS procedure, although uncommon in children, provided good results in terms of resolution of refractory ascites in both native and transplanted livers [88].

When ascites is accompanied by signs of end-stage liver disease, such as hypoalbuminemia, jaundice, clotting derangement, or SBP, the only effective treatment is liver transplantation. In these cases, albumin infusions can be used along with diuretics, in order to increase the osmotic pressure and facilitate the passage of fluid from the extravascular to the intravascular compartment. In children with end-stage liver disease, ascites can be associated with hyponatremia, which is a risk factor for severe complications and death. Pugliese et al. evaluated the association of pre-transplant variables with the mortality within 90 days following the inclusion on the waiting list of 520 children with cirrhosis. On multivariate analysis, the presence of ascites and serum sodium levels was associated with decreased patient survival while awaiting a liver graft [95].

Chylous ascites is a rare clinical condition marked by an extravasation into the peritoneal cavity of a milky fluid deriving from the mesenteric lymphatic vessels. Usually, it results from major abdominal surgical interventions, such as liver transplantation, during which several lymphatic vessels are inadvertently resected and PH has not yet resolved; nevertheless, chylous ascites can present also in patients with PH due to PVT or congenital portal venous malformation. In this setting, in spite of the absence of strong evidences, the management includes fat-free diet and somatostatin analogues [96].

Pulmonary Complications

Children with PH may develop two rare pulmonary complications: hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH). Their relative frequency and risk factors have not been defined, and only isolated cases or small series have been published so far.

The pathogenesis of HPS and PPH remains unclear, but the two conditions arise only in patients with porto-systemic shunting, and therefore the pathogenesis must be related to it. The proposed theories suggest that these disorders result from a combination of the hyperdynamic circulation, the increased cardiac output, the shear injury to the vascular walls, and an imbalance of circulating vasoactive peptides. Abnormal hepatic synthesis of vasoactive peptides, such as EN-1, or impaired hepatic metabolism of intestinally derived endotoxins, cytokines, and neurohormones may result in these substances reaching the pulmonary vascular bed via porto-systemic shunting, directly altering the vessel tone or leading to pulmonary vascular inflammation and remodeling. The resulting pathology is strikingly different in these two disorders, with vasodilatation of pulmonary arterioles and capillaries causing artero-venous shunting in HPS, and intimal fibrosis with endothelial and smooth-muscle cell proliferation leading to increased pulmonary vascular resistance in PPH [97–99].

HPS is defined as intrapulmonary vascular shunting (IPVS), ventilation–perfusion mismatch, and chronic hypoxemia in a setting of liver disease and/or PH. The mechanisms implicated in the development of HPS are likely to include many of the vasoactive substances involved in the genesis of the hyperdynamic circulation, including NO and EN-1 [100–102]. Porto-systemic shunting plays a key role in the pathogenesis of the HPS; in fact, HPS has been described also in patients with congenital porto-systemic shunting and no liver disease (i.e., the Abernethy malformation).

From the clinical point of view, HPS is characterized by shortness of breath, exercise intolerance, and digital clubbing. Since the disease is often subtle and progresses slowly, in the early stages, it can be easily overlooked and become overt only when advanced. Patients with PH should be screened for HPS by measuring the transcutaneous oxygen saturation and, if <96%, by performing further investigations to assess the real presence of IPVS. The two main procedures to confirm the presence of IPVS are the echocardiography with agitated saline and the macroaggregated albumin scan. The former is simple and sensitive in both symptomatic and asymptomatic children. The latter may be used to quantify the degree of shunting, which can be useful in clinical decision-making and to test the progression of HPS over time [103–105].

Liver transplantation represents the only effective treatment option for children with HPS. Al-Hussaini et al. reported a study on 18 children with HPS over 14 years. Fourteen underwent LTX with resolution of HPS in 13. Six developed vascular or biliary complications and four died (two before transplantation) [106]. Interestingly, the need of oxygen may temporarily persist even many days after LTX. In Warner's study all 15 children (100%) with HPS needed supplementary oxygen after LT for a median of 12 days and with a range of 2–139 days. The authors reported a statistically significant association between a Hb of >130 g/L on the day of LTX with a longer length of supplementary oxygen requirement ($P = 0.005$). Therefore, they concluded that the longer the children with HPS have to wait for a LT, the more polycythemic they will become, and the longer they will need supplementary O2 after LT [103].

PPH is defined as an elevation of the mean pulmonary arterial pressure and increased vascular resistance caused by a pulmonary arteriopathy, in the setting of PH and in the absence of underlying cardiopulmonary disease [105]. The pathophysiology of this disorder is still unclear; however, it seems to be related to a decreased hepatic clearance and porto-systemic shunting of biochemical mediators in the setting of liver dysfunction and PH. PPH produces characteristic histological changes in the pulmonary vasculature that have been well documented on autoptic samples [107]. Although there are scant data in children, it has been shown that PPH can develop in patients with cirrhotic and non-cirrhotic causes of PH such as biliary atresia, PVT, focal nodular hyperplasia, and congenital hepatic fibrosis [108]. From the clinical point of view, PPH presents most commonly with exertional dyspnea, fatigue, palpitations, and syncope or chest pain. The symptoms are often subtle at onset, so that a high index of suspicion is required to diagnose PPH in asymptomatic patients before they develop severe and irreversible pulmonary hypertension [107]. Echocardiography with Doppler flow is considered the most useful screening modality in patients with suspected pulmonary hypertension, although limited by the fact that it relies on the presence of tricuspidal regurgitation, it measures systolic rather than mean pressure in the right ventricle and the measurement is approximate. Chest X-ray and electrocardiogram (ECG) definitely lack sensitivity. If there are indirect signs of pulmonary hypertension at ECG, further evaluation should include a right heart catheter study and, in some cases, high-resolution computed tomography (CT) of the chest and ventilation–perfusion lung scanning [104].

If the diagnosis of PPH is made early before the development of irreversible pulmonary vasculopathy, LTX can be successfully performed and may reverse the process. Conversely, once PPH is advanced (with a mean pulmonary pressure >35 mmHg) and associated with right-sided heart failure, LTX becomes unfeasible because of the functionally obstructed liver outflow that leads to graft failure and death in at least 50% of cases. More recently, it has been shown that the perioperative use of inhaled and intravenous pulmonary vasodilators (NO and epoprostenol) as well as oral drugs (sildenafil and bosentan) can remarkably reduce the pulmonary pressure to a safe level, allowing to perform LTX [108]. The goals of treatment are, therefore, to lower the mean pulmonary arterial pressure and move the patient from high risk to a safer ground for transplantation. However, if there is no response or the pressures remain very high, the only viable option is a combined lung–liver transplant.

Other Major Complications of Portal Hypertension

An abnormal *abdominal venous patterning* can be seen in children with PH, in whom a prominent subcutaneous vascular pattern develops as part of spontaneous porto-collateral shunting (Fig. 71.4). This is the result of the attempt at decompressing the portal venous system through the umbilical vein recanalization that leads to periumbilical collaterals. Although less common than in adults, both umbilical venous shunts and rectal varices can be observed in children with long-standing PH, whereas in children with PH and an intestinal stoma (i.e., in short bowel syndrome associated with liver disease), stomal varices often occur and represent a site of low resistance and bleeding [109].

Hepatorenal syndrome (HRS) is defined as a functional renal failure in patients with liver disease and PH, and it constitutes the climax of the systemic circulatory changes associated with PH [91]. In pediatric patients, HRS is rare, probably due to the relatively short time that cirrhotic children spend on the transplantation waiting list. Two types of HRS have been identified. Type 1 HRS is an acute and rapidly progressive form that often develops after a precipitating factor such as GI bleeding or SBP. Type 2 HRS is a slowly progressive form of renal failure that often occurs without a sudden trigger in the setting of chronic and refractory ascites HRS arises from severe vasoconstriction of the renal circulation to compensate for the characteristic circulatory imbalance of advanced cirrhosis. This leads to an increased renal arterial resistance which in turn causes renal hypoperfusion and arterial hypotension. The small volume of the produced ultrafiltrate is then reabsorbed almost completely in the proximal tubule, whereas no solutes (such as sodium) flow to Henle's loop with nearly no hyperosmolar natriuresis, activation of adiuretin–vasopressin, and reduced urine output. As a result, standard diuretic treatment has little effect on diuresis [110]. The criteria to diagnose HRS are difficult to be applied in young children because of the lack of pediatric data. HRS is a potentially reversible condition, but its natural prognosis is poor. Various vasoconstrictors are useful in the treatment of HRS, and terlipressin is the first choice [111]. In the pediatric setting, the experience is little. In a report, four children with end-stage liver disease received terlipressin treatment for renal failure compatible with HRS type 1 in three and type 2 in one. All four responded well and no side effects were reported [112]. Liver transplantation is the ultimate treatment for HRS, ensuring full recovery and long-term survival, and thus it remains the principal tool both in adults and children.

Hepatic encephalopathy (HE) refers to a variety of reversible neurological abnormalities reported in patients with cirrhosis and PH associated with anatomical and functional porto-systemic shunting. In children, HE can be subtle, and the condition seems to appear at a later stage of liver disease and be difficult to diagnose, especially in ill infants. Disturbed consciousness (including coma), personality changes, intellectual deterioration, and speech and motor dysfunction are common in older children with HE. These symptoms usually have a sudden onset and a rapid reversibility suggesting they are of metabolic origin [113].

Protein diet restriction, cleansing enemas, oral antibiotic, and lactulose are the most effective medical options to prevent and treat HE [114, 115].

Non-cirrhotic Portal Hypertension

Non-cirrhotic PH (NCPH) is a heterogeneous group of liver disorders characterized by PH in absence of cirrhosis and with normal or only mildly elevated HVPG values [116].

They are of crucial importance in pediatric hepatology since, while the majority of children with cirrhotic PH are treated with liver transplantation successfully in the early years of the life, those with NCPH do not have any indication for LTX and are managed and followed up for a long time up to adult age [73].

In relation to the site of increased vascular resistance to blood flow, such disorders may be classified as prehepatic, hepatic, and posthepatic. Among presinusoidal NCPH disorders, non-cirrhotic portal fibrosis (NCPF) and EHPVO represent two different entities in whom features of PH are not associated with significant parenchymal dysfunction [116].

NCPF is mostly a disorder of young adults or middle-aged women, whereas non-cirrhotic EHPVO is reported both in infancy and in older children. Recently, it has been proposed the so-called unifying hypothesis, providing a common explanation to the pathogenesis of both NCPF and EHPVO, and focusing on thrombotic events affecting the portal branches. The authors hypothesize that a major thrombotic event occurring at early ages and involving the portal trunk results in EHPVO, whereas repeated microthrombotic events occurring later in life and affecting the small or medium branches of the portal vein would lead to NCPF [116]. In this session, we focus on such two disorders. NCPF is a rather unknown liver disorder in children, whereas EHPVO represents the most common cause of NCPH in the pediatric population.

Obliterative Portal Venopathy (OPV)

The clinical pattern of presentation of OPV is that of PH in the absence of an evident cause, such as liver fibrosis/cirrhosis or vascular obstruction. Liver disorders named idiopathic PH (IPH), idiopathic non-cirrhotic portal hypertension (INCPH), hepatoportal sclerosis (HS), and non-cirrhotic portal fibrosis (NCPF) are thought to be the common consequences of lesions of the intrahepatic branches of the portal vein and correspond to various stages of the same disease, called OPV [116, 117].

On histology, the main features include phlebosclerosis, fibroelastosis, periportal and perisinusoidal fibrosis, aberrant vessels in portal tract (portal angiomatosis) with preserved lobular architecture, and differential atrophy. The main portal vein branch is dilated, with thick sclerosed walls, along with thrombosis in the medium and small portal vein branches, giving a picture of "obliterative portal venopathy" [118, 119]. However, in children, these features are often subtle and the condition may be overlooked.

The etiology of OPV is undefined, but the attention has been brought to various factors that may trigger autoimmunity or endotoxin-mediated injury leading to vascular abnormalities, which cause presinusoidal block to the portal venous flow. The interest has been pointed particularly on lack of hygienic conditions, which would support the role of infections as trigger of the disease, and prothrombotic disorders, which would support the association with an underlying prothrombotic state [120].

With regard to NCPF, the diagnosis is based on clinical evidence of PH without liver dysfunction and a histology with no significant fibrosis. The Asian Pacific Association for the Study of the Liver (APASL) has proposed some criteria for the diagnosis of NCPF in adults [121]. Recently, Schouten et al. redefined five criteria including:

1. Any one of the following clinical signs of PH: splenomegaly, EV, ascites, raised HVPG, and evidence of porto-systemic collaterals
2. Exclusion of cirrhosis on liver biopsy
3. Exclusion of known causes of chronic liver disease causing cirrhotic or non-cirrhotic PH
4. Exclusion of common conditions causing NCPH
5. Patent portal and hepatic veins

All five criteria must be fulfilled to diagnose NCPF [122].

Of interest, characteristic histological lesions are unevenly distributed, vary greatly in their severity, and are not all necessarily present in an individual case, making the diagnosis of OPV often challenging. In a recent study on idiopathic NCPH, Guido and co-authors proposed a new nomenclature and definition of histological lesions including:

(a) Portal vein stenosis: defined as incomplete or complete obliteration of the portal vein branches with or without thickening of the wall
(b) Herniated portal vein: defined as a portal vein from the portal tract directly abutting periportal parenchyma

(c) Hypervascularized portal tract: defined as multiple thin-walled vascular spaces in the portal tract
(d) Periportal abnormal vessels: defined as single or multiple thin-walled vascular spaces of different caliber outside, but in close contact with, the portal tract

The presence of at least one or more of the above lesions is required to diagnose a patient with OPV [119]. In adults, the most common symptoms at onset include bleeding from varix rupture, splenomegaly with or without hypersplenism, and ascites in 10–34% of the cases. On physical examination, the liver may be normal, enlarged, or slightly shrunken, whereas the clinical signs of chronic liver disease are absent [123]. Liver function tests are usually normal in NCPF, but derangements in liver enzymes, prothrombin time, and albumin are seen in a small proportion of adult patients [124]. Hemodynamic studies showed that the increased vascular resistance in NCPF is pre- and perisinusoidal. HVPG is normal or slightly elevated (median 7 mmHg) in this condition [125]. In adults, the natural history of NCPF seems benign, with an overall good outcome. However, in the long term, 30–33% of the adults develop liver atrophy and possible decompensation, develop PVT and HPS, and, sometimes, need LTX [126, 127].

In childhood, OPV is an uncommon cause of PH, but, since the awareness among pediatric specialists is still low, this condition is probably underdiagnosed. The published experiences in this disease are scarce, and they come mainly from Asiatic regions.

Girard et al. reported a child with Adams–Oliver syndrome and HS. They hypothesized that a vascular anomaly and thrombosis may be the etiology for this condition based on the fact that the patient had PVT and factor V Leiden mutation. However, the same association has not been described in other children so far [128].

Prolonged exposure to several medications and toxins has also been proposed as the possible cause. Indian studies on children with PH showed that, among 134 cases, 29 (22%) were due to NCPF. The authors carried out a sociodemographic study that found a significant association with residency in arsenic-affected areas [129]. Toxins can surely lead to liver injury, but a strong association between arsenic intoxication and development of NCPF has not been proven.

Poddar published the experience on 388 Indian children with PH (median age 11 years). Eleven of them (3%) were diagnosed with NCPF. Variceal bleeding, splenomegaly, and a lump in the left upper abdomen were the most common symptoms at onset [130]. Cantez described 12 children (median age 13.5 years) with a histological diagnosis of HS. Four patients had splenomegaly, three had EV, and one had developed HPS and had been transplanted, whereas the others did not show symptoms of PH [131]. Yilmaz reported on 12 children who had a diagnosis of HS, but some of them had also cholestatic features on histology. The authors concluded that cholestatic features noticed in histopathological evaluation may represent a variant group in the spectrum of this disease [55]. A special mention is needed for HIV-related NCPF. The condition occurs predominantly in males (50–100%) and homosexuals (50–75%), with a prolonged infection (median 11.5 years, range 7–15 years). It is not known whether the development of NCPF is related to the infection or rather to the antiretroviral treatment. A recent study described a 10-year-old HIV-infected girl who was on antiretroviral therapy. She had splenomegaly and presented with a massive bleeding from EV rupture. The liver biopsy showed features compatible with NCPF. HVPG was normal. She was managed successfully by treatment with β-blockers and endoscopic variceal eradication [132].

Of note, symptoms of PH may be absent at onset. In a study on 48 children with OPV, 9/48 (19%) did not have symptoms of PH [117]. Similarly, in a multicenter Italian study on 49 children with OPV, features of PH were recorded in 32 patients (65%, 25 with esophageal varices, 7 with splenomegaly and hypersplenism alone); conversely, no symptoms of PH were reported in 17 patients (35%) (personal, unpublished data). Further studies are warranted to best define the real frequency of OPV in children, and to understand the underlying pathogenetic mechanisms leading to PH, in order to define the best therapeutic strategy.

Extrahepatic Portal Vein Obstruction

EHPVO is defined by the obstruction of the extrahepatic portal vein with or without the involvement of the intrahepatic portal veins. The Baveno VI consensus definition excludes cirrhosis and other liver diseases such as IPH, and emphasizes that EHPVO in these settings is a different entity. Isolated occlusion of the splenic vein or superior mesenteric vein has a different causal spectrum and clinical presentation, and is hence removed from the defining criteria of EHPVO [4]. EHPVO is the most common cause of non-cirrhotic, presinusoidal, and prehepatic PH in children [4]. EHPVO represents also the most common disease on long-term care of PH, since these patients do not progress to end-stage liver disease and have no indication for liver transplantation. As a consequence, they represent the group of pediatric patients in whom there is the largest experience with long-term complications and care of PH [78, 133]. EHPVO is primarily a childhood disorder but can present at any age from few months to adulthood.

The etiology of EHPVO is not yet well defined, but various factors including umbilical vascular catheterization, sepsis, and an underlying hypercoagulable states (or thrombophilia) play a key role in the pathogenesis of the thrombus formation. Due to that a full hypercoagulability

panel, including genetic factors, has to be performed whenever the diagnosis is made [22]. Pathogenetic mechanisms which lead to PH are mainly related to the increased vascular resistance in the portal venous system due to thrombus formation. The formation of the portal cavernoma represents a tentative to bypass the thrombus and replace a physiological portal venous flow.

Studies on adult patients with EHPVO have been performed to assess the role of PH in producing changes in splanchnic and systemic circulation in the absence of liver dysfunction. They demonstrated an increase in the cardiac index and a decrease in the total peripheral resistance in patients with EHPVO compared to control patients, suggesting the presence of a hyperdynamic circulation also in patients with a normal liver function. Systemic and pulmonary hemodynamic changes have been evaluated in adults with EHPVO and compared with a group of controls represented by patients with compensated cirrhosis. The authors considered the measurements of cardiac index (by Fick's oxygen method), and systemic and pulmonary vascular resistance indices. Both patients with EHPVO and cirrhosis had similar values, confirming that patients with EHPVO have a hyperdynamic circulation similarly to cirrhotic compensated patients who have the same degree of PH [78, 134, 135]. These studies suggest a predominant role of PH per se in the genesis of systemic and pulmonary hemodynamic alterations [136].

Expanded plasma volume, development of porto-systemic venous collaterals, and increased venous return to the heart seem to be the main factors which cause and maintain hyperdynamic circulation in patients with EHPVO [133, 137–140].

There are no studies evaluating the presence of a hyperdynamic circulation in children with EHPVO. Radiological procedures to assess hemodynamic changes (i.e., HVPG, right atrial pressure, pulmonary arterial pressure, pulmonary wedge pressure, and mean arterial pressure) are considered too invasive and are not routinely performed in children except in selected cases [125].

Nevertheless, children with EHPVO usually do not show symptoms compatible with the hyperdynamic circulation such as warm extremities, cutaneous vascular spiders, wide pulse pressure, and capillary pulsations in the nail beds. Even major complications of the hyperdynamic circulation of cirrhosis (high cardiac output, HRS, SBP), described in animal models and adult patients, are not common in children with EHPVO. The symptoms at onset are mainly related to the complications of PH and may influence the outcome. In a multicenter Italian study on 187 children, the authors demonstrated that the diagnosis of PVT followed the detection of splenomegaly (40% of cases), gastrointestinal bleeding (36%), and hypersplenism (6%); conversely, the diagnosis was incidental in 18% of cases. Noteworthy, the authors showed that spleen size, variceal bleeding, and hypersplenism at presentation were predictors of surgery or radiological procedure ($p < 0.05$) [78].

Abdominal pain, ascites, or fever in the absence of portal cavernoma and porto-systemic collaterals are suspected for PVT with an acute presentation (pylephlebitis). On physical examination, the liver is normal or shrunken. Liver function tests are usually normal, at least in the early phases, whereas they can be deranged in the long term [141]; in fact, the increase of γ-glutamyl transpeptidase, total bilirubin, and bile salts in this setting should raise the suspicion of the development of portal hypertensive biliopathy (PHB) [142–144].

In clinical practice, EHPVO is considered a less severe form of PH. The patients may be asymptomatic for many years, and the mortality from bleeding appeared to be negligible in this group of patients [145, 146]. The diagnosis is based on Doppler ultrasound, CT scan, or nuclear magnetic resonance (NMR), which demonstrates portal vein obstruction, presence of intraluminal material, or portal vein cavernoma [72, 147].

Invasive procedures, such as transjugular retrograde or percutaneous transhepatic portal venography, should be undertaken when uncertainty persists. Liver biopsy is not essential for the diagnosis unless an underlying chronic liver disease is suspected, but, when performed, has shown a picture similar to what is described in NCPF. Echocardiography may rule out associated congenital heart disease, and look for HPS or PPH. Children with EHPVO are usually diagnosed years after the event. Anticoagulation therapy is not indicated outside of the acute phase, unless a hypercoagulable state has been documented [11].

Growth Retardation

Incidence and natural history of EHPVO in children is not well defined. The morbidity is mainly related to variceal bleeding, hypersplenism, and overall limitation of quality of life. The management of variceal bleeding in non-cirrhotic PH does not differ from what we described in cirrhotic patients. However, other complications, in both the short and the long term, need to be further elucidated. Growth retardation represents an important complication in this setting. Failure to thrive in children with EHPVO depends on duration of PH and declines further with age despite appropriate energy intake. Growth failure in EHPVO is multifactorial and is caused by chronic reduction of hepatic blood flow with concomitant decrease in hepatotropic factors, malabsorptive state caused by portal hypertensive enteropathy, early satiety caused by massive splenomegaly, a state of growth hormone (GH) resistance shown by high levels of GH, and low levels of insulin-like growth factor (IGF)-1 and

IGF-binding protein-3, and lastly caused by anemia and thrombocytopenia. Restoration of portal blood flow to the liver that follows a successful meso-portal bypass (MPB) results in improved growth in these patients [147–150] (Fig. 71.5).

Portal Hypertensive Biliopathy

Patients with EHPVO occurring in infancy almost invariably develop radiological evidence of PHB as young adults; nevertheless, only 20–30% develop clinical signs of cholestasis [151]. The term PHB was coined to describe a disorder characterized by anatomical and functional abnormalities of the intrahepatic, extrahepatic, and pancreatic ducts occurring most commonly in patients with non-cirrhotic PH [142]. The definition needs exclusion of other biliary diseases. Abnormalities of the biliary tree include intrahepatic biliary radicle dilatation, caliber irregularities, displacements, ectasias, strictures, and common bile duct stones [144]. Pathogenesis is related to two mechanisms: compression of the common bile duct by dilated collaterals and neovascularization secondary to long-standing PVT and bile duct ischemia caused by prolonged compression by collaterals, thrombosis of smaller veins draining the duct, or excessive deposition of connective tissue forming a tumorlike cavernoma [143, 147]. Frequency of PHB is highest in patients with EHPVO (80–100%) in contrast with cirrhosis (0–33%) and IPH (9–40%). Most (62–95%) patients are asymptomatic [147–150].When symptomatic, PHB presents with jaundice, biliary colic, abdominal pain, and recurrent cholangitis. Magnetic resonance cholangiopancreatography (MRCP) is the first-choice tool to diagnose PHB in children [152]. The decision to treat biliary obstruction in these patients depends on the presence of symptoms. In asymptomatic patients no intervention is recommended. In symptomatic children, biliary stenting (by endoscopic retrograde cholangiopancreatography, ERCP, or percutaneous transhepatic cholangiography, PTC) may temporarily improve the symptoms restoring a normal bile flow. Natural history of biliopathy is poorly defined, but a slow progression is well known, with development of symptoms over a decade. Overall 4–10% of patients develop complications like choledocholithiasis, cholangitis, and secondary biliary cirrhosis [147–150]. Therefore, some patients may require shunt or bypass surgery to decompress the biliary varices and resolve the obstruction [151].

Fig. 71.5 Twins who were born preterm and had cannulation of the umbilical vein. One developed portal vein thrombosis and shows evident growth retardation

Minimal Hepatic Encephalopathy

HE is a brain dysfunction caused by liver insufficiency and/or porto-systemic shunting; it manifests as a wide spectrum of neurological/psychiatric abnormalities ranging from subclinical alterations to coma. The subclinical manifestation of HE, which is called minimal HE (MHE), is detectable by the alteration of at least two specific psychometric tests or electrophysiological techniques [114]. Nowadays, the term covert HE is also used to refer to all the spectrum of manifestations of HE that do not produce disorientation in time or space [153].

HE can occur not only in patients with liver cirrhosis but also in those with non-cirrhotic PH and porto-systemic shunting [154, 155]. MHE has been reported in about one third of children with EHPVO and normal liver function [156, 157]. The diagnosis is made by psychometric tests, critical flicker frequency, and MR spectroscopy [158]. Hyperammonemia seems to play a key role in the pathogenesis of this complication [159].

According to this research, MHE would compromise attention, processing speed, and psychomotor performance, in some cases affecting the academic performance of the patients. MHE seems solved by restoring blood flow to the liver by the meso-portal bypass (MPB), while surgical porto-systemic shunts may eventually worsen it [114, 156].

Management of EHPVO

Management of children with EHPVO is primarily focused on treatment of PH complications. However, the use of medical therapy, endoscopic procedures, and surgery is still questionable because there are no evidence on efficacy of NSBBs, endoscopic variceal obliteration (EVO), and different types of surgical operations [72]. In clinical practice, EHPVO is managed according to what is proposed for cirrhotic children with PH. As far as surgery is concerned, special attention should be paid to the possibility of curing these patients by a successful MPB. MPB represents a physiologic repair of

EHPVO, restoring the normal hepatic physiology, and therefore it should always be considered in this setting [160]. However, there is no wide agreement on feasibility, indications, timing, and success of this procedure [161, 162]. Due to the absence of standardized guidelines, the management of EHPVO needs to be individualized depending on the age of presentation, site and nature of obstruction, and clinical manifestations. In a retrospective study, we reviewed 65 children with EHPVO (median age at diagnosis 3.5 years) and proposed a stepwise approach to manage such a cohort of patients. After retrograde portogram, MPB resulted to be feasible only in 44% of the cases. Children were treated with endoscopic procedures and NSBB as first-line therapy. Those who had varices not well controlled by medical/endoscopic treatment underwent MPB in 13 (38.2%), a proximal splenorenal shunt in 13 (38.2%), a meso-caval shunt in 3 (8.8%), a TIPS in 2 (5.9%), a distal splenorenal shunt in 2 (5.9%), and a LTX because of HPS in 1 (3%). Such a stepwise approach, consisting of medical, endoscopic, and surgical options, provided excellent survival and bleeding control in more than 90% of the patients [2]. In a large study on children with PVT (n = 187), after a median follow-up of 11.2 years, 124 patients (66%) were treated conservatively, and 63 (34%) had undergone surgical or radiological procedures including meso-portal bypass in 30 (48%), distal splenorenal shunt in 16 (25%), proximal splenorenal shunt in 7 (11%), meso-caval shunt in 4 (6%), isolated splenectomy in 2 (3%), TIPS in 2 (3%), porto-caval shunt in 1 (2%), and LTX in 1, because of development of hepatopulmonary syndrome. At last follow-up the surgical or radiological shunt (total n = 60) was patent in 54 patients (90%) and obstructed in 6 (10%, 4 with proximal splenorenal shunt, 1 with meso-portal bypass, and 1 with meso-caval shunt) [78].

A lively debate is ongoing as to whether MPB should be considered as a preemptive technique or as a second-line option after failure of medical and endoscopic management [162, 163]. Although MPB may turn up not to be feasible in children who developed EHPVO following neonatal umbilical catheterization, it seems reasonable to consider restoring the normal liver flow in the early phase of the disease, whenever possible [2, 164].

Diagnosis of Portal Hypertension

The diagnostic workup in patients with PH includes actions aiming at diagnosing the underlying liver disease, quantifying the degree and severity of PH, and identifying the presence of clinical complications. In the clinical history, it is important to collect information on prematurity, neonatal jaundice, umbilical catheterization, and presence of signs or symptoms highly suspicious for PH (e.g., history of unexplained splenomegaly) (Table 71.3).

Physical examination is directed to assess liver size and consistency, splenomegaly, abdominal venous pattering (site and direction of venous flow), ascites, skin signs of chronic liver disease (e.g., spider nevi, telangiectasias, palmar erythema), bruises, and edema.

Laboratory tests should include liver function, blood cell and platelet count, and clotting.

A variety of radiological and endoscopic procedures are routinely utilized in children to diagnose PH. However, the majority of them have been well studied in adults but not in the pediatric population. Such procedures include abdominal Doppler ultrasound, upper GI endoscopy, CT scan of the abdomen, invasive measurements of portal venous pressure, and liver biopsy.

Doppler Ultrasound

Doppler ultrasound is a noninvasive and inexpensive technique that is widely used in children to study liver vessels and parenchyma. Although operator dependent and related to the experience and skill of the radiologist, Doppler ultrasound is a valuable tool to screen patients with suspected PH both at the time of the diagnosis and during the follow-up. In a few minutes, this test can provide information on liver size and texture, patency of portal and hepatic veins, hepatic artery patency and flow pattern (including the resistance index), porto-systemic shunting, ascites, splenomegaly, and associated intra-abdominal abnormalities [165].

The liver is usually enlarged in the hepatic (e.g., biliary atresia, ciliopathies, genetic cholestasis) and posthepatic forms of PH (e.g., Budd–Chiari syndrome), whereas it is of normal size in prehepatic PH. The echogenicity of the parenchyma may be increased in cirrhosis and in some diseases in which steatosis is a histological feature (i.e., Wilson's disease and α1-antitrypsin deficiency) [166]. Gross abnormalities of the bile ducts, such as biliary dilatation, the presence of gallstones, or other morphological abnormalities, can be easily visualized by ultrasound, whereas small irregularities require more powerful imaging studies to be detected.

In patients with prehepatic PH, it is crucial to detect the presence of a portal cavernoma and rule out a dilatation of the biliary tree possibly due to PHB. The splenic size is easily measured and compared to normal values for age, although it does not correlate strictly with the severity of PH [165]. In children with liver disease, it is important to evaluate also the renal parenchyma to exclude the presence of renal cysts that can accompany several genetic liver disorders and provide a further hint to the diagnosis [166].

Bidimensional ultrasonography can easily detect and confirm the presence of ascites suspected clinically, and the color Doppler technique provides information on blood flow in the portal venous system, the hepatic artery, and the

hepatic veins, where it is possible to calculate the flow velocity, although it is not possible to estimate pressures [167, 168]. When PH worsens, the portal blood flow may become hepatofugal toward the left gastric, paraduodenal, or paraumbilical veins. Reversal of flow in the SMV or SV may be suggestive of spontaneous mesentericocaval or splenorenal shunts, respectively [169].

The hepatic veins are straight, anechoic, tubular structures that converge toward the IVC approximately 1 cm below its confluence with the right atrium. The normal hepatic vein waveform is triphasic as a result of transmitted cardiac activity [170].

Varices are formed in the lower esophagus by portosystemic shunting via the left gastric vein through the lesser omentum (Fig. 71.1). As a consequence, the lesser omentum gets thickened in PH [171, 172]. Patriquin H et al. measured the lesser omental thickness in 150 children without systemic, liver, or renal disease. They suggested that, in the absence of obesity or lymphadenopathy, a lesser omentum measuring more than 1.7 times the aortic diameter should raise the possibility of PH [173].

Although the "gold-standard" method for liver fibrosis assessment is liver biopsy, in the past years, noninvasive methods have increasingly been used in adult hepatology. The best validated tool is transient elastography (TE) [174, 175]. Data on its use in children are still scarce, and the influence of technical aspects such as probe choice and site of measurement on results is not clear. In one study TE was performed in 527 children (229 girls, ages 0.1–17.8 (median 6.0) years, including 400 healthy controls). The feasibility rate was 90%, but it decreased to 83% in children younger than 24 months even in ideal conditions. General anesthesia significantly increased liver stiffness in healthy children. The authors concluded that in one study, TE is feasible even in extremely young children, but confounding influences on test results such as probe choice, sedation, or food intake need to be taken into account when interpreting the results [176].

Endoscopy

Unlike adults, in the pediatric population, there are few reports on the prevalence of varices in children with PH, and it is therefore difficult to predict how many children would benefit from endoscopic screening [177]. In children, the endoscopic procedures to diagnose and treat EV are routinely performed under general anesthesia.

There is no recommendation to routinely undertake tests to screen for the presence of varices in children with PH. Despite that, many pediatric hepatologists prefer their patients to undergo endoscopic surveillance to best define and prevent the risk of bleeding from varix rupture. In fact, when pediatric hepatologists were asked if they would offer screening endoscopy for varices to a child with biliary atresia and evidence of PH, most of them answered they would, both in Europe and in North America [3, 73, 160].

Data on diagnosis and grading of EV in children are scant. The scoring systems adopted in adults have not been validated in children, but such information is mandatory to determine the effectiveness of prophylaxis of variceal bleeding by either NSBBs or endoscopic treatment (Fig. 71.3). Studies on the interobserver agreement on pediatric varices grading suggest that accordance in the recognition of large varices is satisfactory [178].

Another major issue is how to grade varices in this setting. Varices have been defined into three grades according to the size, and red marks have been shown to predict bleeding. Recently, the classification has been simplified, and the proposed description of small or large varices, with or without red marks, appears to be more practical [76]. Large varices, varices of any size but with red marks, and gastric varices are likely at higher risk of bleeding in the short term, but again this has not been proven in children so far [179].

Endoscopy in children with PH has been indicated only for the treatment of acute bleeding and in the secondary prophylaxis of further bleeding episodes. The usefulness of diagnostic endoscopy and primary prophylaxis of bleeding by endoscopic variceal obliteration is still unproven, but may become common practice to prevent the shocking experience and the morbidity of a first bleed in a child with clinical evidence of advanced PH [72, 180].

Measurement of Hepatic Venous Pressure Gradient

PH is defined by an increased pressure in the portal venous system. Such an increased venous pressure may be detected by a direct measurement of the pressure into the portal vein or by the measurement of a portal pressure gradient (PPG) resulting from the difference, in pressure, between the portal vein and the IVC. Direct measurements of portal pressure can be performed through transhepatic or transvenous catheterization of the portal vein, but, since they have high risk of major complications (e.g., intraperitoneal bleeding), these tools are rarely used, apart from those cases in which WHVP is unreliable, such as presinusoidal PH [181].

HVPG measures the PPG as the difference between "wedged" hepatic vein pressure (WHVP) and "free" hepatic vein pressure (FHVP). The WHVP is measured by occluding the hepatic vein by inflating a balloon at the tip of the catheter. The injection of 5 ml of contrast dye into the vein with the balloon inflated can confirm an adequate occlusion of the hepatic vein. The WHVP reflects the portal vein pressure basing on the concept that when the blood flow in a hepatic vein is blocked by a "wedged" catheter, the static column of blood

transmits the pressure from the preceding vascular territory, in this case, the hepatic sinusoids. As in cirrhosis the intersinusoidal communications are lost due to fibrosis, septa, and nodule formation, the sinusoidal pressure equilibrates with portal pressure. Thus, the WHVP correlates closely with portal vein pressure, but, in fact, it is a measurement of the hepatic sinusoidal pressure and not of portal pressure itself [35].

The difference between WHPV and FHPV provides HVPG values (HVPG = WHVP − FHVP).

Normal HVPG ranges from 1 to 5 mmHg in adults. Subclinical PH is defined when HVPG ranges from 6 to 10 mmHg, whereas complications of PH are expected when HVPG is greater than 10 mmHg. An HVPG greater than 12 mmHg correlates with variceal bleeding, rebleeding, and increased mortality [181].

HVPG values allow to classify different forms of PH. Presinusoidal PH is characterized by normal or slightly increased HVPG values, with normal or slightly increased WHVP and normal FHVP. Sinusoidal PH is found in most chronic liver diseases and is characterized by an increase in WHVP with normal FHVP, resulting in high HVPG (cirrhosis is the most common cause). In postsinusoidal PH, HVPG is normal and both WHVP and FHVP are increased, such as in the Budd–Chiari syndrome (Table 71.2).

The HVPG is considered the gold-standard technique to measure portal venous pressure and, in cirrhotic adults, is widely utilized to quantify the severity of PH, predict the outcome, and guide the therapeutic decisions [4, 182, 183].

In children, the diagnosis of PH is essentially based on clinical evidence of PH complications (i.e., splenomegaly, upper varices, ascites) in a setting of an underlying liver disease. Unfortunately, so far the measurement of HVPG in children has been considered an invasive procedure that has to be performed only in limited cases. Due to that, we have only few published data on HVPG measurements in the pediatric setting [184]. Wolfsson reported on 49 children, with acute and chronic liver disease, who underwent 52 HVPG measurements. The procedure resulted feasible in all patients and no complications were documented. HVPG values ranged between 0 and 28 mmHg, and they were greater than 6 mmHg in 30 patients. The authors concluded that, despite the small sample size, HVPG measurements were feasible and safe in their cohort of patients [185]. Further studies on large cohorts of pediatric patients are necessary to obtain strong evidences on the utility of the HVPG measurements in the management of children with PH.

Other Investigations

CT scanning with intravenous contrast and MR angiography may be used to study children with PH. These investigations provide information on focal liver lesions, portal vein and hepatic vein patency, presence of collateral circulation, and arteriovenous shunts. CT has a sensitivity of 85% in the detection of EV compared to endoscopy, but has the advantage of demonstrating splenorenal, gastrorenal, peripancreatic, pericholecystic, retroperitoneal, and omental collaterals, as well as spontaneous large porto-systemic shunts [186]. In a study performed on adult patients, MR angiography proved more reliable than Doppler ultrasound for evaluating the portal venous system in patients with PH caused by cirrhosis [187].

Management of Portal Hypertension

Prophylaxis of Bleeding

Currently there are no data supporting the role of any type of prophylaxis to prevent variceal bleeding in children [3]; nevertheless, many clinicians would consider a cirrhotic child with large varices at risk of mortality from the first bleed, and therefore a definite candidate for primary prophylaxis [73]. Conversely, a reasonable, and somehow evidence-based, consensus on indication to perform endoscopic secondary prophylaxis (prevention of rebleeding) in cirrhotic children appears to be wide [72].

Nonselective β-Blockers

The rationale of NSBBs in PH stands on its ability to decrease the portal flow by reduction of cardiac output (via β1-receptor antagonism) and splanchnic vasodilatation (via β2-receptor antagonism) [188]. Studies in adults have shown that a dose reducing the heart rate by 25% (or the HVPG by 20%) does decrease the bleeding rate in cirrhosis [183]. There are no randomized trials assessing the efficacy of propranolol as prophylaxis of variceal bleeding in children, and the few cohort studies carried out did not include the measurement of HVPG before and after treatment start [6, 189, 190]. Moreover, these studies showed that in children, the evaluation of heart rate at rest is problematic, and the range of drug dosage required to reduce it by 25% is very wide, making achievement of adequate NSBB dosage impractical and time-consuming. Whether pediatric patients with presinusoidal PH, having no classical features of the hyperdynamic circulation, may benefit from treatment with NSBBs has yet to be demonstrated [140].

A further challenge in carrying out trials with NSBBs in this setting is that propranolol is not licensed for use in children [191]. The relative difficulty to dose this drug along with its side effects on physical performance in young and growing subjects may lead to downgrade its benefits in the long term, and reconsider the use of this drug in the prophylaxis of variceal bleeding in children.

Endoscopy for Screening and Management of Esophageal Varices

There are few reports on the prevalence of varices in children with PH, and it is therefore difficult to predict how many would benefit from endoscopic screening. Besides, the uncertainty regarding the impact of any prophylaxis in this setting makes endoscopic screening questionable.

Despite this, in some reports the mortality of cirrhotic children at the time of first bleeding episode was as high as 5–15%, and morbidity was shown to reach 57% of all subjects. This may support the decision to do screening endoscopy in all children with advanced liver disease and clinical signs of PH [80, 180].

Unlike the past decades when endoscopic obliteration of varices was done using sclerosing agents (such as ethanolamine or polidocanol) injected inside or around the varix, currently endoscopic variceal ligation (EVL) has become more popular and has been shown to be superior to sclerotherapy as far as efficacy, safety, and degree of standardization are concerned, in both adults and children [192–193]. Nevertheless, in small children, in whom the banding devices available on the market cannot be used with small pediatric endoscopes, sclerotherapy remains the only feasible treatment option to manage large varices [193].

Endoscopic treatment is usually safe and well tolerated by children, but often it has to be continued for an undefined period of time. Authors reported the results from a single-center study of primary and secondary prophylaxis of bleeding in 66 children with biliary atresia complicated by PH and high-risk varices. Thirty-six children (mean age, 22 months) underwent primary prophylaxis, and 33 (mean age 24 months), who presented with gastrointestinal bleeding, received endoscopic treatment to prevent a relapse of bleeding (secondary prophylaxis). In the primary prophylaxis group, a mean number of 4.2 sessions were needed to eradicate varices; no bleeding from gastroesophageal varices was observed after eradication, and varices reappeared in 37% of cases. In the secondary prophylaxis group, a mean number of 4.6 sessions was needed to eradicate varices, and varices reappeared in 45% of cases. These results showed that endoscopic therapy appeared to be well tolerated and greatly reduced the risk of variceal bleeding. However, the recurrence of varices suggested that the continued endoscopic surveillance was needed [194]. A real challenge in this setting is the presence of large gastric varices; there are no published data on experience of management of gastric varices in children, and probably most centers would treat this scenario according to the experience in adults. Large gastric varices are a threat because they are difficult to obliterate prophylactically, and even more so if actively bleeding; in this situation, balloon tamponade is often ineffective, and the only option is to perform sclerotherapy with tissue glue (such as *N*-butyl-cyanoacrylate). In general, a child with large gastric varices should be considered for TIPS, shunt surgery, or liver transplantation, based on the degree of liver disease.

Management of Acute Variceal Bleeding

The main goal of the management of a child with acute esophageal bleeding is well-balanced blood volume restitution. It is therefore mandatory to monitor vital signs, obtain venous access to perform blood tests (full blood count, international normalized ratio, liver function and electrolytes, C-reactive protein, and a blood crossmatch), and start blood volume correction [195]. Packed red blood cells (PRBC) should be provided with the aim to maintain the hemoglobin >7 g/dl, carefully avoiding a rebound overload of fluids that favor the increase of portal pressure and rebleeding [196]. In the presence of coagulopathy, it might be wise to support the patient with plasma, also in view of the fact that esophageal bleeding implies loss of whole blood that, if large, will not be efficiently replaced by PRC. Children with upper GI bleeding may benefit from nasogastric tube placement, with the primary goal being to monitor persistence of active bleeding. Vasoactive drugs, such as octreotide, are effective in stopping bleeding from varices and should be started immediately to bridge the child to endoscopy, and continued thereafter for a total of 4–5 days [197].

In adults, it has been proven that infectious complications commonly follow an episode of variceal bleeding in cirrhotic patients [198]. Although in children there is no such evidence, it is recommended to monitor them for any sign of infection and, if present, to start antibiotic treatment promptly, especially in cirrhotic children with advanced disease.

After the initial step, the child should be managed according to hemodynamic stability and the control of bleeding. If unstable, the child should be managed in an intensive care setting, possibly with a central venous catheter providing information on circulating blood volume and preload (Fig. 71.6). Usually, bleeding stops spontaneously after the ruptured varix empties. After cessation, it is usually acceptable to schedule an elective endoscopy in the following 24–72 h because rebleeding is uncommon during this time frame. If bleeding does not stop despite appropriate fluid replacement and correction of coagulopathy, the child may require urgent endoscopy and, rarely, the placement of a Sengstaken balloon as a bridge to TIPS or urgent shunt surgery (Fig. 71.7). Endoscopic sclerotherapy around the vessel may be the only option to treat an acutely bleeding varix that is underfilled, and therefore difficult to be strangulated by a rubber band placed by endoscopic variceal ligation devices.

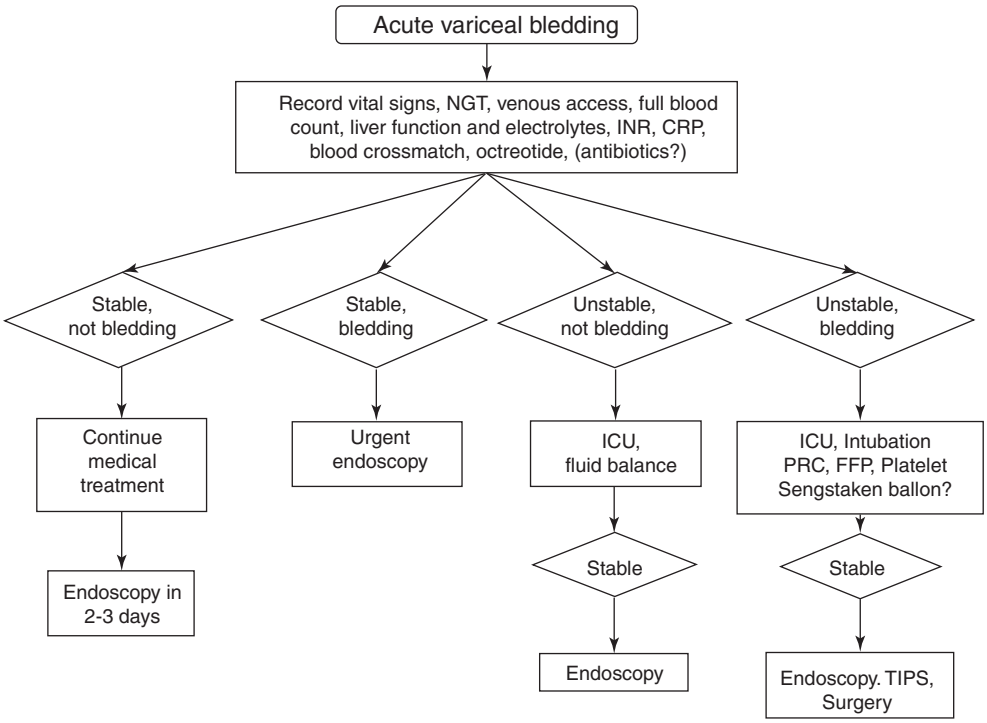

Fig. 71.6 Proposed algorithm for the management of acute variceal bleeding. Surgical Procedures

When medical and endoscopic treatment of bleeding varices fails, the only option is to consider decompression of the portal system by a shunt or a bypass [199]. Children with EHPVO can be managed effectively by MPB (Fig. 71.8) [23]; however, in our experience of children who had an umbilical venous catheter placed at birth, only about half had a patent Rex recessus at retrograde portogram [2]. If the MPB is not feasible, these patients can usually be treated by other forms of shunt surgery [200]. One recently suggested approach is to perform the MPB preemptively, regardless of complications of PH, in view of its beneficial effects on growth and neurocognitive outcome [162, 164, 165]. Other patients with presinusoidal PH, but not amenable to MPB, can be managed by TIPS or by shunt surgery [201].

Nonphysiological porto-systemic shunts are still the commonest surgeries performed for EHPVO worldwide. There is a vast literature on feasibility, patency, and long-term outcomes of these shunt surgeries; however, the long-term

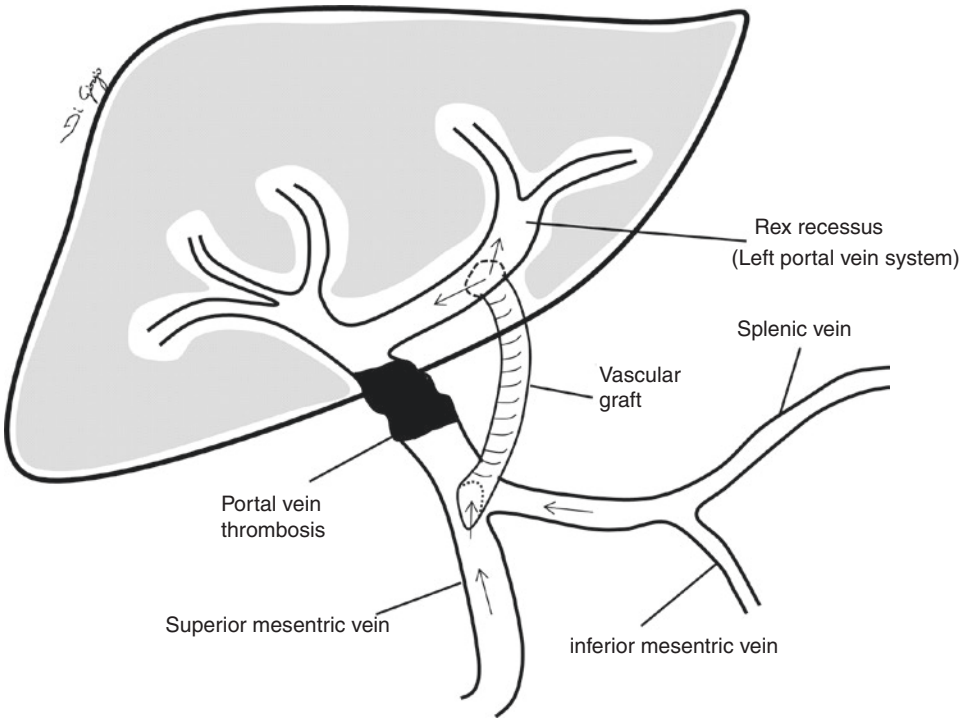

Fig. 71.8 Portal circulation after the operation of meso-portal bypass that reestablishes the hepatopetal flow to the liver

patency has been questioned. While nonselective shunts, like proximal splenorenal shunt, decompress whole system taking care of PHB as well, the distal splenorenal shunt treats the left-sided PH. Furthermore, in younger children there are issues related to technical feasibility and shunt thrombosis, but these have been largely overcome with improvement in surgical expertise [165]. Cirrhotic children with PH usually have a rapidly progressive biliary type of cirrhosis (such as biliary atresia, intrahepatic cholestasis, and Alagille syndrome), are young, and have a short transplant-free survival. In our institution, the median age at transplantation is 1.4 years. Therefore, shunt surgery or TIPS is rarely indicated in this cohort of patients in whom PH is usually accompanied by liver decompensation and is an indication for LT. However, cirrhotic children with a compensated longstanding noncholestatic liver disease complicated by severe PH may be considered for TIPS.

Transjugular Intrahepatic Porto-systemic Shunt

TIPS is a well-established tool to manage severe complications of PH in adults, but its experience in children is limited because it is thought to be associated with high risk of shunt dysfunction, and to offer short-term benefits. As a consequence, in pediatrics TIPS is regarded mainly as a bridge to liver transplantation in children with cirrhotic PH. At our center we performed a study to assess the technical feasibility, clinical efficacy, and shunt patency in a cohort of children with both cirrhotic and NCPH. Twenty-nine children (cirrhotic-PH = 11, NCPH = 18, mean age 10.3 years, ±4.3) underwent TIPS procedure for recurrent variceal bleeding ($n = 18$) and refractory ascites ($n = 11$). The intrahepatic shunt was successfully placed in 27/28 patients, the porto-systemic gradient reduced to δ12 mmHg, and complications of PH were solved in 26/27 cases making the technical success rate, the hemodynamic success rate, and the clinical success rate of 96%. Primary patency rates at 6 months and at 1, 2, and 4 years were 91%, 83%, 60%, and 46%, respectively; remarkably, primary assisted and secondary patency rate were 100% without major differences between the two groups of patients. No patient developed HE. The results from our study clearly demonstrated that TIPS appears to have a high mid-term patency rate. Its high clinical success rate, along with a minimally invasive approach, suggests that TIPS should not be regarded only as a bridge to transplantation but also as an effective and less invasive alternative to surgical vascular shunts in children with NCPH [88]. Therefore, TIPS appears to be feasible and effective in children as it is in adults and should become part of the armamentarium used to manage PH complications in pediatric patients.

A Protocol for Screening, Prophylaxis, and Treatment of Esophageal Varices

The need for large sample sizes, the difficulties in recruiting patients into multicenter studies, and the lack of official approval and knowledge on drug dosing make it quite

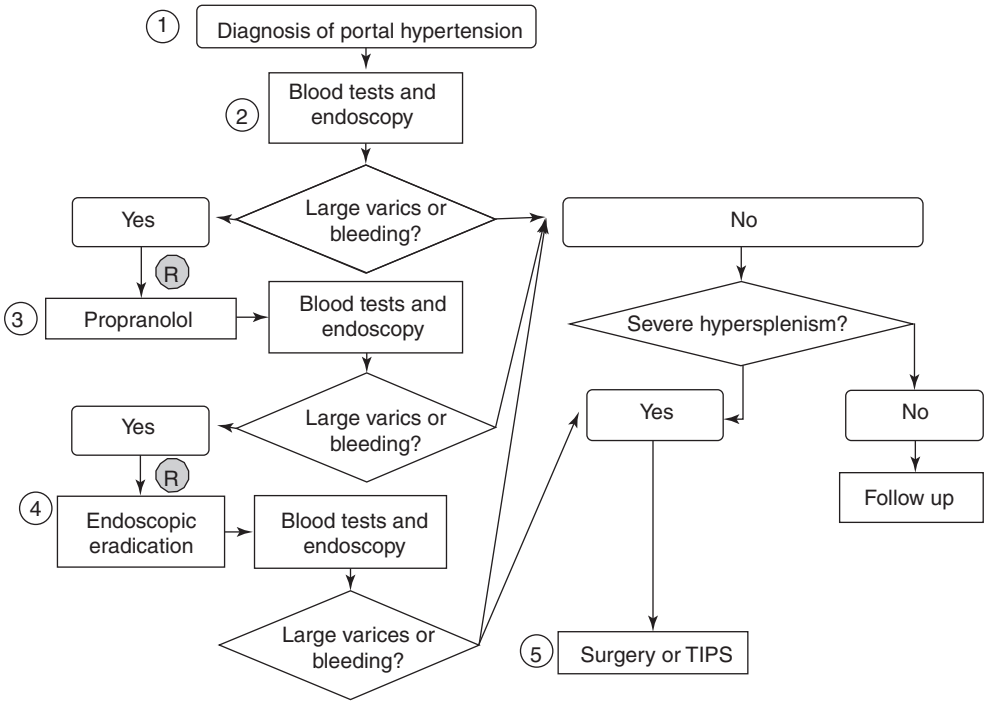

Fig. 71.9 Proposed algorithm for the approach to the child with portal hypertension. TIPS transjugular intrahepatic porto-systemic shunt. The circled "R" represents a step for possible randomization in a clinical trial. (Reprinted from Ref. [73], with permission from Elsevier)

unlikely that there will be robust data on the use of NSBBs in children with PH in the coming years. The same applies to endoscopy because there is no single-center able to recruit enough patients to answer questions regarding screening and primary prophylaxis of varices, and multicenter trials require diagnosis and treatment standardization. Besides, such studies can probably only be carried out in non-cirrhotic children having sufficient follow-up time to test the given hypothesis. Alternatively, many centers are already using these tools empirically in both cirrhotic and non-cirrhotic children, with uncertain and inconsistently measurable results. Is it then possible to gather more information on the utility of NSBBs and endoscopic treatment of varices in children? A proper trial on this matter should be randomized and have variceal bleeding as the primary end point; however, many clinicians and families would consider permitting a GI bleed as unacceptable to test the hypothesis of effectiveness of NSBBs or endoscopic treatment. One possibility to overcome this could come from considering the development of large varices as the end point, because children with large varices or red marks have failed treatment and will eventually bleed. At least two studies have shown that most children with cirrhosis or PVT and grade 2–3 varices will bleed within a few years of follow-up [202, 203]. Therefore, it is possible to hypothesize a randomized, nonblinded multicenter trial of development of large varices in children and their response to treatment. Because of the large sample size needed, such study would first require a solid proof that there is sufficient agreement among endoscopists to recognize large varices in the different pediatric centers involved in the trial [179].

Figure 71.9 illustrates an algorithm of a stepwise approach to manage EV, which considers the formation of large varices as the end point and could offer the chance to test the hypothesis that NSBBs and endoscopy can improve the outcome of children with PH, avoiding the risk of not offering the best of practice currently available. Nevertheless, an extraordinary effort will be required to produce such evidence on the best management of PH in children.

Liver Tumors in Children

72

Mohamed Rela, Ashwin Rammohan, and Mettu Srinivas Reddy

Introduction

Liver tumors are uncommon in the pediatric age group and constitute 1–2% of all solid tumors in children. About 60% of all liver tumors in children are malignant [1]. Hepatoblastoma (HB) is by far the most common constituting over 50–60% of all liver tumors in this age group. Hepatocellular carcinoma (HCC), undifferentiated embryonal carcinoma, and biliary rhabdomyosarcoma are other malignant liver tumors in children. Benign tumors include hemangiomas (HMGs), mesenchymal hamartoma, and focal nodular hyperplasia (FNH). Secondary tumors to the liver can spread from a host of primary tumors including lymphomas, Wilms' tumor, neuroblastoma, osteosarcoma, etc. (Table 72.1). Several congenital and environmental risk factors have been reported to increase the predilection for liver tumors (Table 72.2).

There is a striking age-related variation in the frequency of different tumor types (Table 72.3). Over 90% of liver tumors in children below 5 years are HB, while 87% of tumors in the 15–19-year age group are HCC. A gradual increase in the incidence of liver tumors in children over the past 3–4 decades has been reported. This is particularly evident in the case of HB where the incidence has increased from 0.6 to 1.2 per million population between 1973 and 1977 and 1993 and 1997. On the contrary, incidence of HCC has decreased from 0.45 to 0.29 per million population during the same period [2].

Tumor Markers in Childhood Liver Tumors

Alpha-fetoprotein (AFP) is the most recognized tumor marker in liver tumors. AFP is a glycoprotein similar in physical and chemical characteristics to albumin. It is

Table 72.1 Types of liver tumors in children

Benign	Hemangioma: focal, multiple, diffuse
	Mesenchymal hamartoma
	Hepatic adenoma
	Focal nodular hyperplasia
	Inflammatory myofibroblastic tumor (may be locally invasive)
Malignant	
Primary	Hepatoblastoma
	Hepatocellular carcinoma, fibrolamellar HCC
	Transitional tumors
	Embryonal sarcoma
	Biliary rhabdomyosarcoma
	Calcifying nested stromal–epithelial tumor
	Angiosarcoma
Secondary	Lymphomas, leukemia, Wilms' tumor, neuroblastoma, osteosarcoma, colon cancer

Table 72.2 Risk factors and premalignant conditions for childhood liver tumors

Tumor	Risk factors	Premalignant lesions
Hepatoblastoma	Beckwith–Wiedemann syndrome, familial adenomatous polyposis, Li–Fraumeni syndrome, trisomy 18, preterm birth, and very low birth weight	–
Hepatocellular carcinoma	Glycogen storage disease, hereditary tyrosinemia, Alagille syndrome, biliary atresia, PFIC, ataxia–telangiectasia, hepatitis B infection, hepatitis C infection	Hepatic adenoma
Embryonal sarcoma		Mesenchymal hamartoma
Hepatic angiosarcoma		Multiple/diffuse hepatic hemangioma

PFIC progressive familial intrahepatic cholestasis

Table 72.3 Age-wise distribution of childhood liver tumors

Age group	Benign tumors	Malignant tumors
Neonatal period	Hemangioma, mesenchymal hamartoma	Hepatoblastoma
0–5 years	–	Hepatoblastoma, biliary rhabdomyosarcoma
5–15 years	–	Hepatocellular carcinoma, embryonal sarcoma
>15 years	Hepatic adenoma	Fibrolamellar carcinoma

secreted by the fetal liver and yolk sac until 13 weeks' gestation and then primarily by the fetal liver [3]. AFP levels at birth are very high with Bader et al. reporting a median level of over 40,000 ng/ml in cord blood samples. These levels rapidly drop during the first year of life at a rate primarily dictated by the half-life of AFP of 5–6 days [4]. AFP levels at birth in the preterm babies are higher than full-term babies. Similarly, a decrease in at-birth AFP for every week of prolonged gestation has been reported. The high levels of AFP in the infant should be kept in mind by the clinician when AFP levels are used for the diagnosis and monitoring of pediatric liver tumors.

Several tumors are associated with elevated AFP. HB is the commonest cause in infants though HCCs and germ cell tumors are also associated with elevated AFP. Nonneoplastic conditions, such as tyrosinemia and neonatal hepatitis, can also cause elevated AFP levels.

Malignant Tumors

Hepatoblastoma

HB is the most common liver tumor in children. It is almost always seen in the first 4 years of life with median age at diagnosis of 18 months. It can present at birth and has been diagnosed in the intrauterine period on antenatal scans. Prematurity and very small birth weight have been identified as risk factors. HB developing in these children is also reported to have a worse prognosis [5]. Data from the USA has shown a gradual increase in the incidence of HB over the last 40 years from 0.6 to 2.3 per million children [6].

HB is a tumor of immature hepatocyte progenitor cells. It is an embryonal tumor, which recapitulates various stages of liver development. Histologically, these tumors are heterogeneous and comprise combinations of epithelial, mesenchymal, and occasionally teratoid components in varying proportions (Table 72.4, Fig. 72.1). Majority of tumors have a primarily epithelial component containing hepatoblasts at varying stages of differentiation. The histological type has an impact on behavior with well-differentiated fetal epithelial type having the best prognosis. The small-cell undifferentiated type of HB has the worst prognosis with very poor survival. Mixed tumors contain both epithelial and mesenchymal components, are more resistant to chemotherapy, and have a worse prognosis. Post-chemotherapy residual tumors and metastatic tumors may demonstrate a pleomorphic pattern with pleomorphic nuclei having coarse chromatin and prominent nucleoli. This pattern may resemble HCC.

Table 72.4 Histological types of hepatoblastoma

Histological type	Description
Epithelial	Primarily containing immature hepatocytes
Fetal	Commonest variant of epithelial HB. Composed of polygonal cells resembling fetal hepatocytes arranged in one- to two-cell thick cords, trabeculae, or sheets
Embryonal, well differentiated	Tumor resembles the liver at 6–8 weeks of gestation. It demonstrates organized tubular or acinar formation. Hematopoietic elements are commonly admixed with epithelial component
Cholangioblastic	Tumor cells differentiate as cholangiocytes and form small ducts. This component expresses cholangiocyte lineage markers (cytokeratins 7 and 19)
Macrotrabecular	Cells arranged in thick trabecular pattern (>5 cells thick)
Small cell undifferentiated	Sheets of small cells with large hyperchromatic nuclei similar to neuroblastoma
Mixed epithelial–mesenchymal type	Mixture of epithelial and mesenchymal cell types
Teratoid	Contains heterologous components such as stratified squamous epithelium, mucus-producing cells, neuroectodermal derivatives
Non-teratoid	Contains stromal derivatives including spindle fibroblastic cells, osteoid, skeletal muscle, and cartilage

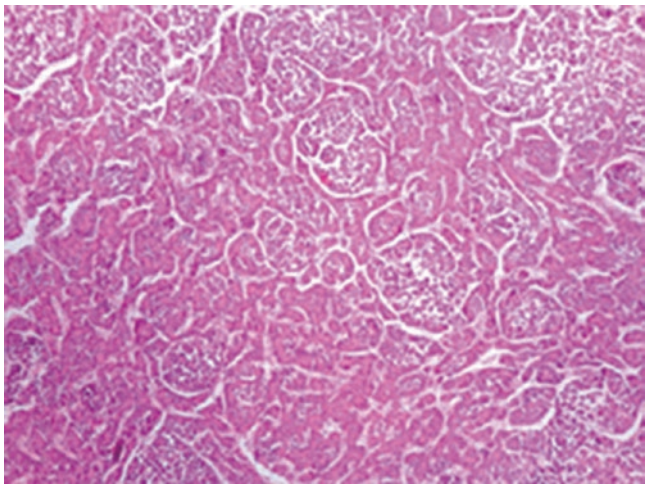

Fig. 72.1 Hepatoblastoma, epithelial type with fetal and embryonal epithelium

Diagnosis

The usual presentation is with an abdominal lump identified by the parent or the clinician. Pain, failure to thrive, and jaundice are uncommon modes of presentation. Investigations reveal an elevated AFP level in over 90% of cases. The AFP levels are extremely high (in the order of 10^5 ng/ml) and are usually a log higher than those seen with HCC. AFP level is a prognostic marker in HB with both very high levels and low levels (<100 ng/ml) predicting poor biology [7]. Thrombocytosis is a recognized laboratory finding in HB and is probably related to production of thrombopoietic cytokines including thrombopoietin in the tumor tissues. Contrast-enhanced computed tomography (CT) of the abdomen and a CT of the chest are necessary to confirm the diagnosis, stage the extent of liver disease, and identify vascular invasion, extrahepatic disease, and lung metastases. HB appears as a heterogeneously enhancing well-circumscribed lesion with occasional calcifications. A biopsy is usually required to confirm diagnosis before start of neoadjuvant chemotherapy and for prognostication.

Staging and Prognostication

The Children's Hepatic tumors International Collaboration (CHIC) included over 1600 children from 4 registries to investigate the predictors of poor outcomes. Age over 8 years at diagnosis, AFP less than 100 ng/ml, multifocal tumor, tumor rupture, portal and hepatic venous involvement, and metastatic disease were identified as poor prognostic markers [8].

Several staging systems have been developed to tailor treatment for HB. The preoperative extent of tumor (PRETEXT) system based on preoperative imaging, which was developed by the International Childhood Liver Tumor Strategy (SIOPEL) Group, is commonly used (Table 72.5, Fig. 72.2). This is an anatomical classification focusing on the extent of tumor and the amount of liver that can be spared during resection [9]. Modifications to the PRETEXT scoring system have included additional subclassifications to identify high-risk factors such as vascular involvement, caudate lobe, lymph node involvement, and metastatic disease (Table 72.6).

SIOPEL also classifies HB into standard-risk, high-risk, and very-high-risk groups based on the PRETEXT staging and additional factors to tailor management (Table 72.7).

Table 72.5 PRETEXT staging and frequency of various PRETEXT stages at initial presentation. Refer to Fig. 72.2

PRETEXT staging	Definition	Frequency at presentation (%)
I	One section is involved and three adjoining sections are free	4.8
II	One or two sections are involved, but two adjoining sections are free	36.6
III	Two or three sections are involved and no two adjoining sections are free	38.8
IV	All four sections are involved	19.8

Management

Early results of HB with surgical resection alone were poor due to the advanced stage at which these tumors usually present. Only 5% of all tumors at presentation can be staged as PRETEXT I, and over 50% are unresectable at initial presentation (Table 72.5). Metastatic disease in the lungs at presentation is not uncommon. However, this should not dissuade the clinician from aiming for cure. Resection of lung metastases along with treatment of primary has resulted in long-term survival [10].

HB are highly chemosensitive tumors and respond well to platinum compound-based chemotherapy. Use of chemotherapy in conjunction with surgery has radically altered the outcomes of these tumors. Today, multimodality treatment with surgery and chemotherapy is the mainstay of treatment for HB.

Ideal treatment strategy for PRETEXT I tumors is controversial. Some authors have suggested complete resection alone without chemotherapy as an option. This holds true for low-risk tumors with fetal histology where complete surgical resection with follow-up has been shown to be effective in providing long-term disease control [11]. Advocates of this approach highlight the fact that these children are spared the adverse effects of chemotherapy such as ototoxicity [12]. The SIOPEL group, however, advocates neoadjuvant chemotherapy for all HB. The purported advantages of this approach are that it shrinks the tumor and clearly demarcates the tumors making resection more straightforward. Tumors also become more fibrotic and hence intraoperative handling is easier.

The current protocol for PRETEXT II and III is to give up to four cycles of neoadjuvant chemotherapy, followed by assessment for resection (Fig. 72.3). If the tumor becomes resectable, then surgery is followed by two more cycles of chemotherapy. If the tumor remains unresectable, two further cycles of chemotherapy may be considered before attempting resection or transplantation. Additional cycle of chemotherapy has not been shown to improve outcomes but is associated with drug toxicity and drug resistance. Monitoring the fall in AFP level after beginning chemotherapy and after surgery is an excellent means of predicting tumor response. The chemotherapy regimen advised by the SIOPEL group varies for the standard-risk and high-risk HB (Table 72.7) [9].

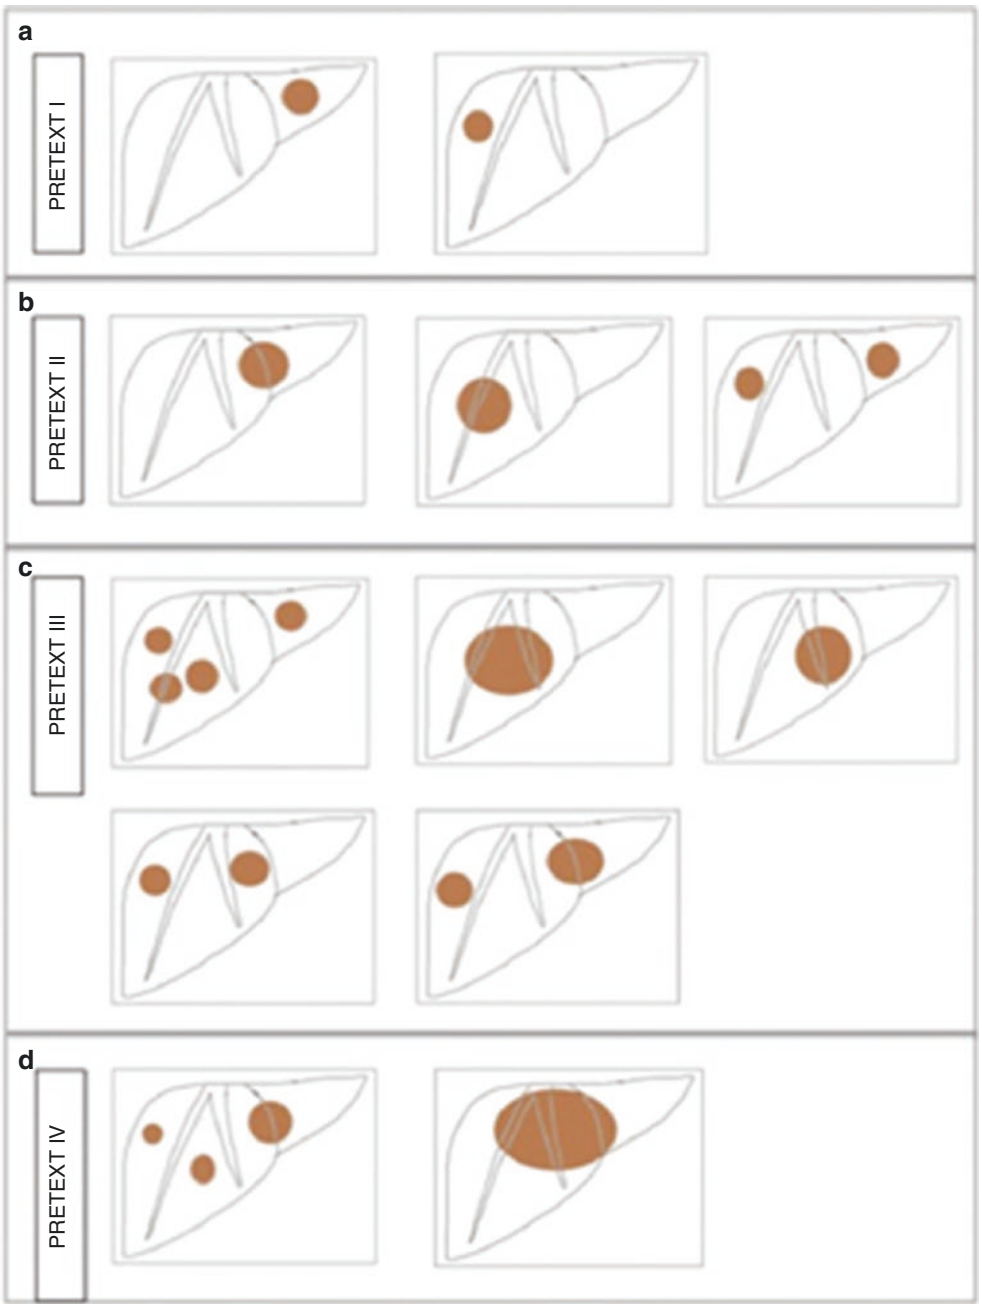

Fig. 72.2 PRETEXT staging: The PRETEXT system is based on the preoperative imaging and is an assessment of the liver that is free of tumor. The liver is divided into four sectors by the right and middle hepatic veins and the falciform ligament. The four sectors are the left lateral, left medial, right medial, and right lateral sectors. The number of contiguous sectors that are free of tumor is the key to the staging. Tumor may be single or multiple. (**a**) PRETEXT 1, three contiguous sectors are tumor-free, (**b**) PRETEXT 2, two contiguous sectors are free of disease, (**c**) PRETEXT 3, only one sector is free, (**d**) PRETEXT 4, all four sectors are involved

Surgical resection for HB should be carefully planned and is best carried out in units with expertise in pediatric hepatobiliary surgery and liver transplantation (LT). This is particularly true in children with large tumors and borderline resectability. Children can tolerate extensive liver resections better than adults, and up to 85% of liver can be resected safely. More aggressive liver resection techniques such as total vascular exclusion and caval resection may be required to achieve complete disease clearance.

LT for unresectable HB is a well-defined indication [13]. These could be PRETEXT IV tumors (solitary or multifocal), centrally located PRETEXT II or III, or tumors with portal or caval involvement (Fig. 72.4). Primary LT in high-risk cases has better outcomes than rescue transplantation after resection, and the latter should be considered a relative contraindication [14]. A recent US study reported that over the past 20 years, the percentage of HB receiving transplantation has increased from 5% to 20%, and the number of transplantations for HB has increased almost 20-fold [15]. This could be a reflection of the increasing confidence among clinicians for this radical modality of treatment.

The options are either split-liver deceased donor LT (DDLT) or living donor LT (LDLT), and both have comparable results. Children planned for DDLT usually complete

Table 72.6 Additional criteria for PRETEXT staging

Caudate lobe involvement	C1—tumor involving caudate lobe	–
	C0—all other patients	
Extrahepatic abdominal disease	E0—no evidence of tumor spread in the abdomen (except M or N)	Add suffix "a" if ascites is present
	E1—direct extension of tumor into adjacent organs or diaphragm	
	E2—peritoneal nodules	
Tumor focality	F0—solitary tumor	–
	F1—two or more discrete tumors	
Tumor rupture	H1	–
Distant metastases	M1	–
Lymph node metastasis	N0—no nodal metastases	–
	N1—abdominal lymph node metastases only	
	N2—extra-abdominal lymph node metastases	
Portal vein involvement	P1—involvement of left or right branch of portal vein	Add suffix "a" if intravascular tumor is present
	P2—involvement of the main portal vein	
IVC or hepatic vein involvement	V1—involvement of one hepatic vein, IVC free	Add suffix "a" if intravascular tumor is present
	V2—involvement of two hepatic veins, IVC free	
	V3—involvement of all three hepatic veins and/or IVC	

IVC inferior vena cava

Table 72.7 Risk stratification and treatment of hepatoblastoma (SIOPEL guidelines)

Risk status	Definition	SIOPEL guideline for treatment
Standard risk	PRETEXT I, II, III without any other risk factors as defined below[a]	*SIOPEL 3, cisplatin-alone arm*
		Cisplatin × four cycles
		Surgical resection
		Cisplatin × two cycles
High risk	PRETEXT IV or any PRETEXT stage with vascular involvement (P2 or V3), extrahepatic disease (E1, E2), tumor rupture (H1)	*SIOPEL 3, SUPERPLADO arm*
		Alternating cycles of cisplatin and carboplatin + doxorubicin × seven cycles
		Resection/transplantation
		Alternating cycles of cisplatin and carboplatin + doxorubicin × three cycles
Very high risk	Any tumor with metastases or very low AFP (<100 ng/ml)	SIOPEL 4, dose-dense cisplatin-based chemotherapy or enrolment in clinical trial

Available at www.siopel.org [9]
AFP alpha-fetoprotein, *PRETEXT* preoperative extent of tumor
[a]PRETEXT I with fetal histology may be considered for surgical resection alone and observation

neoadjuvant chemotherapy and are placed on the waiting list with some form of prioritization to enable timely transplantation. Where LDLT is an option, transplantation can be planned within 4–6 weeks of completing neoadjuvant chemotherapy. Transplantation should be followed by adjuvant chemotherapy. Presence of lung metastases increases the risk of posttransplant recurrence but is not a contraindication for LT as long as they can be completely resected [15]. Close follow-up in the posttransplantation period is essential and usually involves periodic AFP estimation and imaging studies.

Overall disease-free survival has consistently improved for HB with multidisciplinary management using chemotherapy, LT, and radical resection [16]. Low-risk tumors have a 90% 5-year survival, while high-risk tumors have a survival of around 50%. Histological subtype has an impact on survival. Fetal types of HB have the best outcomes, while the small-cell undifferentiated type of tumors have worse prognosis. Relapse after initial complete response occurs in 11% of children. The liver and lungs are the commonest sites of relapse. Positron emission tomography/computed tomography (PET/CT) has been reported to be better at identifying relapse when compared to CT or MRI [17]. A combination of surgery and chemotherapy provides the best chance of achieving a second complete response in these children with reported 3-year overall survival of over 40% [18].

Hepatocellular Carcinoma (HCC)

HCC is the second most common liver tumor in children. The incidence is bimodal, with an early peak that is lower than that of hepatoblastoma. Most of these early cases occur before 5 years of age. A second peak occurs between 13 and 15 years of age. These form 15% of all malignant liver tumors in children and 75% of all liver tumors in adolescents. HCC in children can occur in a background of chronic liver disease secondary to hepatitis B or metabolic disorders, though non-cirrhotic HCC is more common than in adults. Other conditions associated with the development of HCC include cirrhosis, α1-antitrypsin deficiency, tyrosinemia, aflatoxin ingestion, hemochromatosis, hepatic venous obstruction, androgen and estrogen exposure, Alagille syndrome (arteriohepatic dysplasia), and Thorotrast administration. With increasing use of universal hepatitis B immunization, the incidence of HCC in children has decreased [19].

HCC usually presents as an abdominal lump (40%). Occasional presentation may be with abdominal pain or jaundice due to biliary compression or tumor ingrowth into the biliary tree. Rarely, these tumors may present as an emergency due to bleeding or rupture. HCCs are usually associated with an elevated AFP level though the elevation is not as

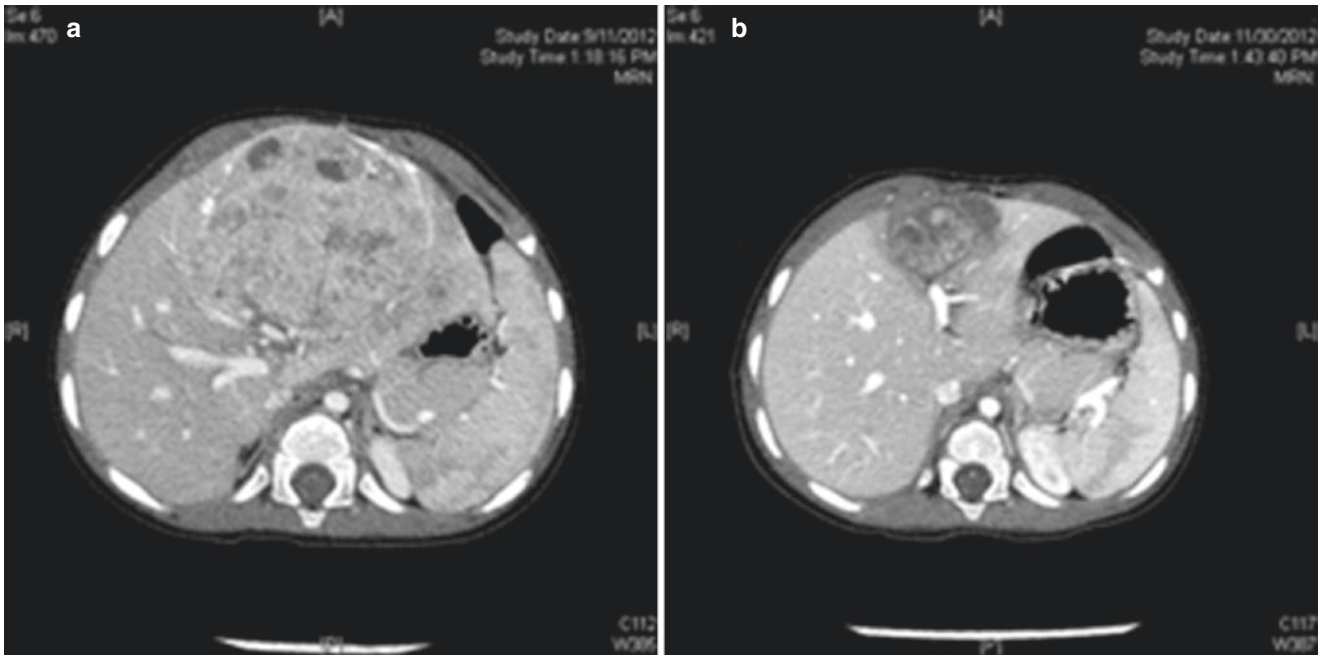

Fig. 72.3 CT images of hepatoblastoma in a 1-year-old child. (**a**) CT at presentation showed a PRETEXT 2 disease with tumor involving the two left sectors. (**b**) CT following four cycles of chemotherapy prior to resection. Note the significant shrinkage in tumor size. The CT appearance of the tumor has also changed, and the demarcation between the tumor and healthy liver tissue is much more clear

Fig. 72.4 CT image of a hepatoblastoma in a 6-year-old child. This child had persistent PRETEXT III tumor after six cycles of chemotherapy. The tumor was closely approximated to the cava. She underwent primary living donor liver transplantation

high as that seen in HB. Liver function tests should be evaluated to assess the severity of any underlying liver disease. Metabolic screen is important to identify underlying liver disease which may impact management. Triphasic CT or MRI with contrast can help in characterizing the lesion, presence of chronic liver disease, any vascular involvement, and the presence of metastases.

HCCs are chemoresistant tumors, and complete resection provides these children with the best chance of long-term cure. However, the feasibility of resection depends on the size and extent of the tumor and the presence of underlying liver disease. In patients with underlying chronic liver disease, LT has the benefit of treating the underlying liver disease and providing adequate tumor clearance. Trans-arterial chemoembolization has been used as a bridge or downstaging therapy in children with HCC awaiting LT [20].

In the adult setting, the option of LT is available only for HCC within strict size and number criteria [21]. It is unclear if these criteria are appropriate in the pediatric setting, as most children will present with large tumors. Studies have shown good results in children transplanted for HCC beyond Milan criteria [22]. Hence, unless there is major vascular invasion or extrahepatic disease, unresectable HCC in children should be considered for LT. Presence of lung metastases is a contraindication for LT in pediatric HCC unlike HB due to the high risk of posttransplant progression of metastatic disease. Use of sorafenib in combination with cisplatin-based chemotherapy has also been reported in the management of pediatric HCC [23]. Outcomes of pediatric HCC are inferior to HB. Recurrent disease is the most common cause of death in these children and usually occurs in the lungs or bones.

Fibrolamellar Hepatocellular Carcinoma

This is an uncommon primary liver tumor seen in older children and young adults. The median age at presentation is 21 years. It is less common than standard HCC and occurs on a background of a non-cirrhotic liver. An elevated AFP is only seen in around 10% of these tumors. They are detected incidentally when they become symptomatic and are hence large at presentation. In a systematic review of available literature of fibrolamellar HCC (FL-HCC), the mean size of tumor at surgery was 12 cm [24]. On CT imaging, they appear as large well-circumscribed lesions which enhance strongly in arterial and portal venous phases becoming isodense in delayed scans. A poorly enhancing central scar may be seen. These tumors spread by both lymph node and blood-borne systemic metastases.

Surgical resection offers the best chance of cure for these tumors with a 5-year survival of 70% in adults [25]. However, within the pediatric age group, results of FL-HCC do not appear to be superior to standard HCC because of late presentation and local recurrence after resection [26]. LT for FL-HCC has been reported though the long-term results are not encouraging possibly because of large tumor size at presentation and presence of lymph nodal metastases.

Transitional Liver Cell Tumors

These are a special group of tumors initially described by Prokurat et al. that share characteristics of both HB and HCC [27]. They are purported to be a subset of liver cell tumors in older children and adolescents that evolve along a transition pathway between blastomatous tumors and adult-type tumors. AFP levels are elevated only in 40–60% of patients, and this elevation is at least one log less than what is observed in HB. Histologically, they have features intermediate between the macrotrabecular variant of HB and trabecular HCC. Most of these tumours are initially diagnosed as HB and treated as such. Liver biopsy may fallaciously allow for a diagnosis of pure HB due to sampling errors which may miss islands of HCC. They have a much poorer outcome which is more in keeping with HCC than HB.

Embryonal Sarcoma (Undifferentiated Sarcoma of the Liver)

This is a rare mesenchymal tumor constituting 5% of all liver tumors in children. The median age of presentation is between 6 and 10 years and is more common in males. There have been several reports of development of embryonal sarcoma from mesenchymal hamartomas [28]. Studies have also shown similar karyotypic abnormalities in both tumors. Presentation is with an abdominal lump or pain. This tumor has characteristic radiological appearance. Ultrasonography (USG) shows a solid isoechoic clearly demarcated tumor. CT shows a well-circumscribed hypoattenuating lesion with multiple enhancing septations. An enhancing pseudocapsule may be present. The tumors are usually large at presentation and may be associated with lung metastases. Histologically, these tumors demonstrate large areas of necrosis with patches of viable tumor. Stellate or spindle-shaped tumor cells are loosely arranged in a myxoid matrix (Fig. 72.5).

Initial reports of this tumor described poor prognosis [29]. However, recent reports have shown that multimodality approach combining resectional surgery, chemotherapy, and transplantation can provide survival rate of up to 90% [30, 31].

Biliary Rhabdomyosarcoma

This is the most common cause of malignant biliary obstruction in the pediatric age group. These tumors arise from any part of the intrahepatic and extrahepatic biliary tree including the gallbladder and ampulla of Vater. The median age at presentation is 3 years, and children commonly present with jaundice and abdominal pain. Preoperative diagnosis is usually a choledochal cyst [32]. CT scan shows a dilated biliary tract with a hypoattenuating tumor in the bile duct. Surgery helps in confirming diagnosis and enables resection of the tumor and biliary drainage in the form of a hepaticojejunostomy. Surgical excision with negative microscopic margins is rarely possible. These tumors have been found to respond

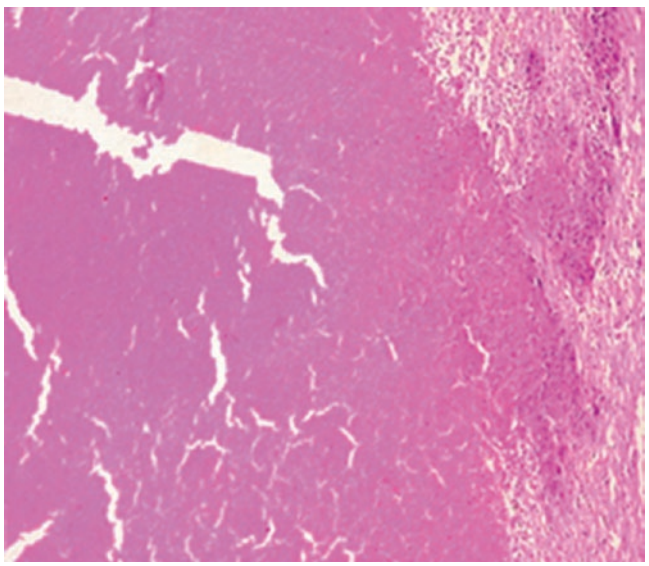

Fig. 72.5 Histology of embryonal sarcoma. Tumor shows large areas of necrosis with islands of spindle-shaped tumor cells in a myxoid matrix

well to adjuvant multi-agent chemotherapy [33]. Spunt et al. reported 25 cases of biliary rhabdomyosarcoma with a 5-year survival of 66% for all cases and 78% for children without systemic metastases. Death was primarily due to recurrent disease or complications of aggressive resection and/or chemotherapy [34].

Calcifying Nested Stromal–Epithelial Tumor

These are rare primary liver tumors of uncertain histogenesis that typically occur in children and young adults. Histologically, they have a characteristic appearance with circumscribed nests and islands of bland-appearing epithelioid cells. Focal psammoma-like calcifications with or without ossification may be present. The tumors typically have an indolent course and are considered as low-grade malignancies. Surgical resection is the treatment of choice. Some of these tumors have been reported to be associated with Cushing's syndrome which improved on resection [35, 36].

Hepatic Angiosarcoma

These are highly malignant vascular tumors with a uniformly poor prognosis. There are reports of malignant transformation of multifocal or diffuse hemangioma into hepatic angiosarcoma [37]. Differentiation from diffuse hepatic hemangioma or hemangioendothelioma may be difficult preoperatively on imaging alone, and clinical presentation can provide clues toward the correct diagnosis. Complete resection is required for cure of angiosarcoma, but recurrence rates are high, and the tumor is often not resectable; it is typically present in both lobes of the liver, and consideration should be given to adjuvant chemotherapy. LT should be avoided due to early development of systemic metastases [38]. Some authors have suggested a waiting time of 6 months in patients with inconclusive preoperative imaging to assess the natural history of these tumors to avoid performing a futile LT [39].

Benign Liver Tumors

Hemangioma

HMGs are the most common benign tumors in the pediatric setting. They constitute over half of all liver tumors in the neonatal period. The Liver Hemangioma Registry of the Vascular Anomalies Center at the Children's Hospital of Boston recognizes three clinical subgroups of infantile hepatic HMG—focal, multifocal, and diffuse [40]. Focal HMGs are usually single and indolent. Their clinical presentation is based entirely on their size and usually present as a large abdominal mass. Smaller focal lesions are diagnosed only on routine imaging studies in the antenatal period or after birth and usually have no clinical relevance. Associated extrahepatic lesions are uncommon with focal HMGs. Multifocal HMGs present as multiple lesions in one or both lobes of the liver or may involve the liver diffusely. Histologically, they may be classified as capillary or cavernous HMG and may rarely show pleomorphism, intravascular spread, necrosis, and hemorrhage. Over half of these children have extrahepatic vascular lesions, most commonly in the skin but also in the brain, eye, etc. Status of the cutaneous lesions has been used as a marker for monitoring the involution of the liver lesions [41].

Abdominal lump is the usual presentation. High-output cardiac failure and consumptive coagulopathy due to intratumoral trapping and destruction of platelets causing a disseminated intravascular coagulopathy like picture are rare but serious complications [42, 43]. Abnormalities in thyroid function have been reported in these children [44]. There appears to be an overlap in clinical behaviors of diffuse hepatic hemangiomas and hepatic angiosarcoma [45]. Multifocal or diffuse hemangiomas may be difficult to differentiate from malignant vascular tumors.

Treatment of these lesions should be tailored to individual presentation [41]. Small, asymptomatic lesions are best left alone. Symptomatic lesions have been treated with a variety of pharmacological and interventional approaches. Steroids, chemotherapeutic agents, β-blockers, hepatic artery ligation, and hepatic artery embolization have all been reported by various authors to be useful. Large symptomatic lesions need liver resection and are best managed in centers with advanced hepatobiliary and LT expertise. LT has been reported in large symptomatic lesions not amenable to resection [41].

Hemangioendothelioma

Hemangioendotheliomas are highly proliferative cellular lesions of variable malignant potential. The incidence is 1%, and it is the most prevalent hepatic vascular tumor in pediatric patients younger than 6 months [44]. Infants with large, actively perfused vascular lesions may come to medical attention with congestive heart failure [42, 43]. Angiosarcomatous transformation in a specific type of these tumors (type 2 hemangioendothelioma) or a coexisting malignant component within a hemangioma-like tumor has also been reported [37]. These lesions may appear very cellular, but they do not metastasize. If a primary lesion produces symptoms, resection is indicated for relief. For lesions which are unresectable, LT may be offered as the treatment of choice [44].

Mesenchymal Hamartomas

These rank second in frequency among benign liver neoplasms in children. They usually present as a large abdominal mass in the first 2 years of life. Some of these tumors may be detected incidentally or because of symptoms of abdominal pain, vomiting, or failure to thrive. Rare presentations are with respiratory distress, high-output cardiac failure in the newborn, and jaundice, hemorrhage, or rupture [46].

Imaging usually shows a single tumor in the right lobe with solid and cystic components. Occasionally, one cyst may be large giving it the appearance of a single cystic lesion. Microscopic examination shows varying proportions of epithelial and loose connective tissue components arranged in a disorganized pattern. The epithelial element consists of bile ducts and hepatic parenchyma without acinar pattern. Numerous arteries and veins are scattered in the loose myxoid stroma. Cystic degeneration and foci of extramedullary hematopoiesis are also identified. Some authors have classified it as a neoplasm rather than a hamartoma. Reports that these tumors are associated with karyotype abnormalities such as aneuploidy and balanced translocations suggest a malignant potential [28].

Treatment is primarily surgical. Complete excision is recommended, and, where not possible, LT has been reported [46].

Hepatic Adenoma

Hepatic adenomas are observed in children with type I glycogen storage disease after the first decade of life and may be multiple. Hepatic adenomas are known to occur in patients undergoing androgen therapy for hematologic disorders [47, 48]. These are diagnosed in older children and adolescents and usually identified on routine screening, though bleeding and rupture of superficial adenomas may lead to a more acute presentation [47, 48]. Hepatic adenomas may show encapsulation on imaging studies, but histologic sections may be difficult to distinguish from HCC. It is best to remove adenomas because of the difficulty of differentiating them from low-grade HCCs. There also remains the uncertainty about future malignant degeneration, and the possibility of rupture and hemorrhage. Small adenomas may however be followed up by serial imaging, but larger adenomas or superficial adenomas presenting with pain should be resected to avoid complications [47, 48].

Focal Nodular Hyperplasia

FNH is uncommon in children and constitutes about 5% of all pediatric liver tumors. An association with previous bone marrow cancers, bone marrow transplantation, or congenital or surgical portosystemic shunts has been reported [48, 49]. A possible response of the liver tissue to the cytotoxic chemotherapy has been postulated. FNH has been reported in an infant antenatally exposed to corticosteroids. Similarly, borderline ischemia of the liver due to the shunting has also been postulated as a possible explanation of their coexistence with shunts. The most common presenting symptom is an incidentally detected mass in the abdomen. FNH is usually diagnosed on routine imaging and is identified as a slightly hypodense, discrete lesion on plain CT. On contrast images, it enhances homogeneously in the arterial phase with the lesion becoming isodense in delayed scans. A central scar is noted in 50% of cases with delayed enhancement of the central scar being a characteristic finding.

Macroscopically, it appears as a well-circumscribed mass with a central depression (Fig. 72.6). Cut surface shows small nodules divided by fibrous septa leading to a central scar. Microscopically, the nodules contain hyperplastic hepatocytes supported by a well-developed reticulin framework. The septa contain abundant vessels, consisting of both arteries and veins [50, 51]. Variable eccentric intimal fibroplasia and disruption of the elastic lamina are noted in the arteries. Inflammatory cells and numerous proliferating ductules are also identified in the septa. Chronic cholestatic features are also identified in the cells adjacent to septa.

These lesions may be small and multiple or may be single and large. If imaging is suggestive of FNH, then close follow-up with serial imaging to detect any increase in size is recommended. Superparamagnetic oxide-enhanced MRI may discriminate between hepatic adenoma and FNH. Biopsy may also be necessary in doubtful cases, but might be prone to sampling errors. Asymptomatic cases of FNH are observed using serial abdominal US, MRI, and clinical examination. Spontaneous regression has been documented. Apart from large, symptomatic lesions, surgery is indicated where there exists a diagnostic dilemma of differentiating the lesion from an adenoma [51, 52].

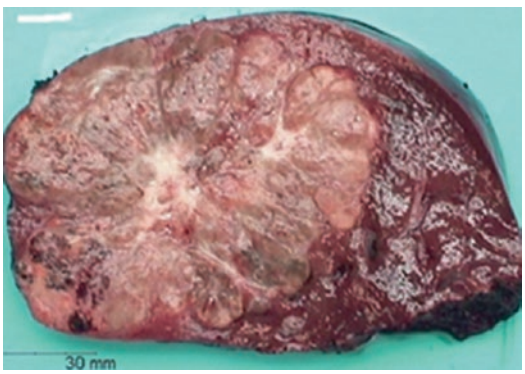

Fig. 72.6 Cut section of focal nodular hyperplasia. Note the well-circumscribed lesion with multiple nodules separated by fibrous septa joining at a central scar

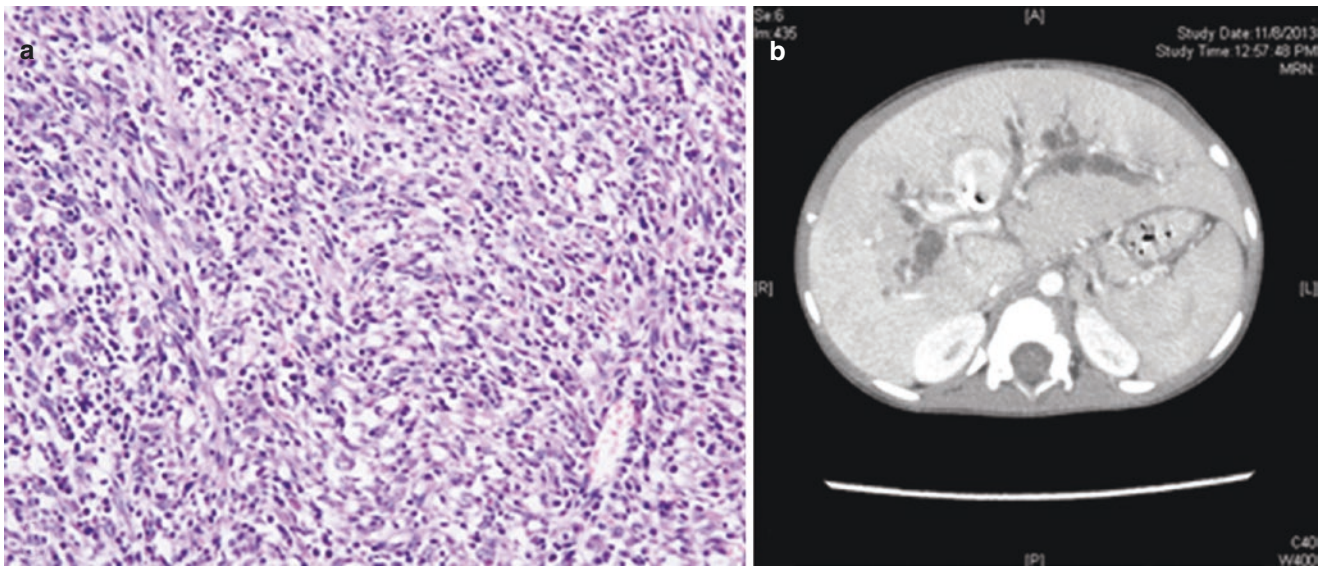

Fig. 72.7 (**a**) Section of an inflammatory myofibroblastic tumor displaying interlacing bundles of fibroblasts admixed with inflammatory cells. (**b**) CT showing an inflammatory myofibroblastic tumor involving the hepatic hilum in a 4-year-old child. The child presented with constitutional symptoms, obstructive jaundice, and recurrent episodes of cholangitis. He underwent endoscopic stenting with no relief of symptoms. Surgical resection (extended right hepatectomy with excision of extrahepatic biliary tract) was carried out

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMFT) are predominantly benign lesions of unknown origin. These tumors can occur anywhere in the body and have occasionally been reported in the liver where they may mimic liver tumors.

These lesions have a characteristic histological picture comprising spindle-cell proliferation admixed with chronic inflammatory cell infiltrate of plasma cells, lymphocytes, and histiocytes (Fig 72.7a). Anaplastic lymphoma kinase gene rearrangements have been noticed in about half of IMFT, further supporting its neoplastic nature. Expression of anaplastic lymphoma kinase is associated with localized disease at presentation and an improved prognosis [53].

Presentation may be with constitutional symptoms such as fever, jaundice, and weight loss. Their natural history is variable with some reports of spontaneous regression, while some children may develop recurrent episodes. Local invasion has been reported in some cases (Fig. 72.7b). Surgical resection is indicated if the lesion persists or progresses after a trial of conservative therapy, or manifests evidence of local infiltration into vital structures, or of malignant transformation. Complete resection is curative in most patients [54].

Secondary Liver Lesions

The liver is a relatively frequent site of metastatic disease in childhood. Non-Hodgkin lymphoma, neuroblastoma, rhabdomyosarcoma, Wilms' tumor, adrenal cortical carcinoma, osteogenic sarcomas, and a host of other malignancies may metastasize to the liver [55–58]. These are usually multiple and are best managed with multimodality therapy. Criteria for surgical removal of hepatic metastases include control of the primary site, a solitary or limited number of metastases, adequate hepatic reserve, good performance status, and a reasonable expectation of prolonged survival or cure [55–58]. Resecting liver metastases from neuroblastoma or Wilms' tumor have the advantage of diminution of treatment and a prolonged survival [57, 58].

Conclusion

Liver tumors in children are uncommon. Most present as an abdominal lump and are usually advanced at initial presentation. HB is the most common childhood liver tumor. Evidence-based multimodality therapy using improved liver resection techniques, LT, and use of effective chemotherapeutic agents has improved outcomes in these tumors.

Acute Liver Failure in Children

73

Naresh P. Shanmugam and Anil Dhawan

Introduction

Acute liver failure (ALF) used synonymously with fulminant hepatic failure is a blanket term used to describe severe and sudden onset of liver cell dysfunction leading to synthetic and detoxification failure across all age groups. Pathogenesis of hepatocyte cell injury is multifactorial (Fig. 73.1) and liver failure is the outcome of a complex equation between hepatocyte death and regeneration, as suggested by the US Acute Liver Failure Study Group [1]. Injured liver cells secrete several bioactive substances and toxins that initiate cascade of events leading to multiorgan failure (Fig. 73.2).

Definition

"Fulminant liver failure" was coined by Trey and Davidson 40 years ago to define onset of hepatic encephalopathy (HE) within 8 weeks of appearance of symptoms of liver dysfunction in an otherwise healthy individual with no prior history of liver disease [2]. O'Grady and colleagues categorized ALF as "hyperacute (1 week), acute (1–4 weeks), and subacute failure (5–12 weeks)" depending on the interval between jaundice and onset of encephalopathy, for prognostication purpose [3]. It is difficult to use adult-based definitions in children, as encephalopathy is a late sign and sometimes ALF has in utero onset and so time quantification would be difficult. Acknowledging the fact that diagnosing encephalopathy in children is difficult and often a late and terminal event, Bhaduri and Vergani proposed the definition of ALF as "A rare multisystem disorder in which severe impairment of liver function with or without encephalopathy, occurs in association with hepatocellular necrosis in a patient with no recognized underlying chronic liver disease" [4]. Even this definition does not seem to be clear as the term "severe impairment of liver function" in the definition did not have any objective quantification values of liver function and so there was a lot of subjective variation in diagnosing ALF.

The Pediatric Acute Liver Failure Study Group (PALFSG) developed a working definition to identify ALF in children without interobserver variation. The PALFSG used international normalized ratio (INR) in the background of acute liver disease as an objective measurement to demarcate acute hepatitis and ALF. As per PALFSG, ALF is defined as (i) hepatic-based coagulopathy defined as a prothrombin time (PT) 15 s or INR 1.5 not corrected by vitamin K in the presence of clinical HE or a PT 20 s or INR 2.0 regardless of the presence or absence of clinical HE, (ii) biochemical evidence of acute liver injury, and (iii) no known evidence of chronic liver disease [5]. Asymptomatic preexisting liver disease, which manifests acutely, should be considered as ALF, if they fulfill the diagnostic criteria, as in acute fulminant Wilson's disease.

Coagulopathy is not only a key criterion in diagnosing pediatric ALF but also acts as a prognostic marker. Due to short half-life of several liver-based clotting factors, PT/INR functions as a dynamic marker of synthetic inadequacy due to loss of liver cells in ALF. Factors II, VII, IX, and X depend on vitamin K to convert them into active form. Correction of coagulopathy by intravenous vitamin K differentiates between vitamin K deficiency due to decreased absorption from liver synthetic failure. Isolated prolonged APTR is not due to liver disease, as factor VII in extrinsic pathway (Fig. 73.3) has the shortest half-life (4–6 h) of the vitamin K-dependent factors, which therefore is the first factor depleted in ALF and invariably affects INR. Coagulopathy secondary to disseminated intravascular coagulation (DIC) precipitated by infection is common in acute liver injury, and so it is essential to rule out DIC before making a diagnosis of ALF based on INR.

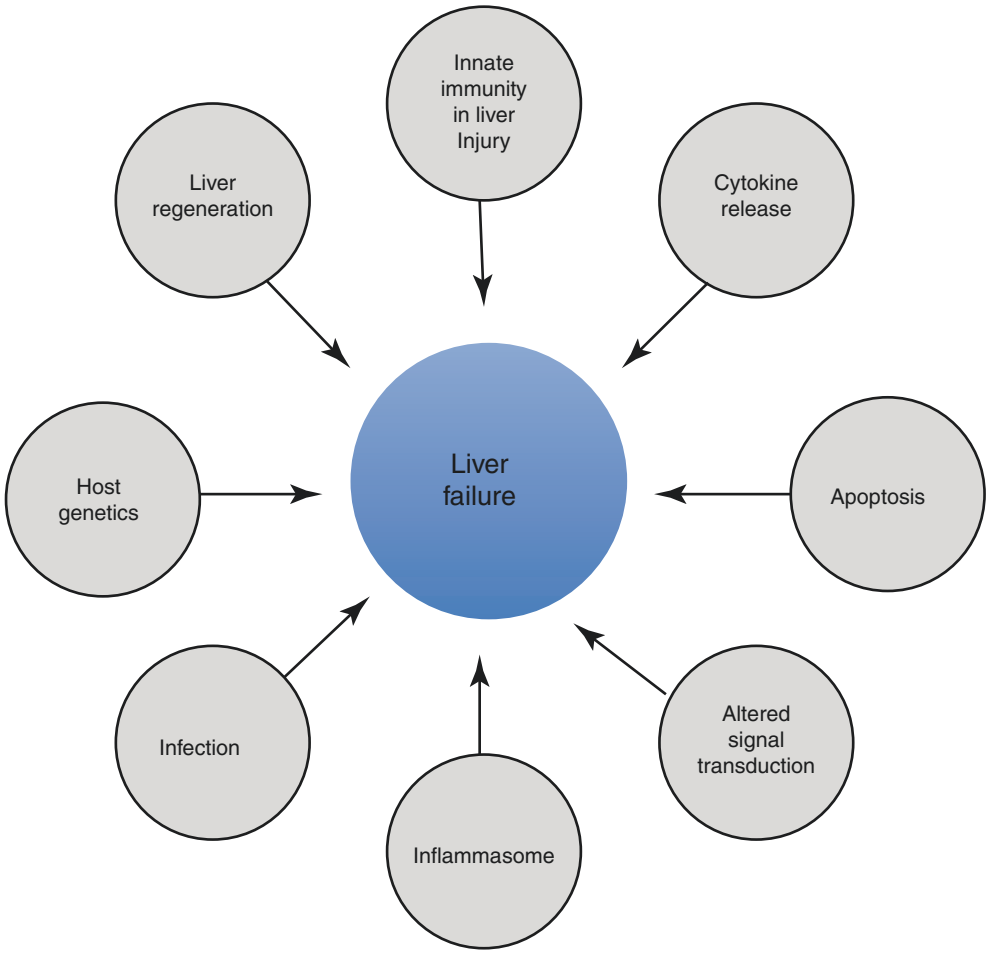

Fig. 73.1 Pathogenesis of liver cell injury is multifactorial with several factors influencing liver cell death and regeneration. When the net result is liver cell loss beyond a critical mass required maintain normal body function, liver failure sets in

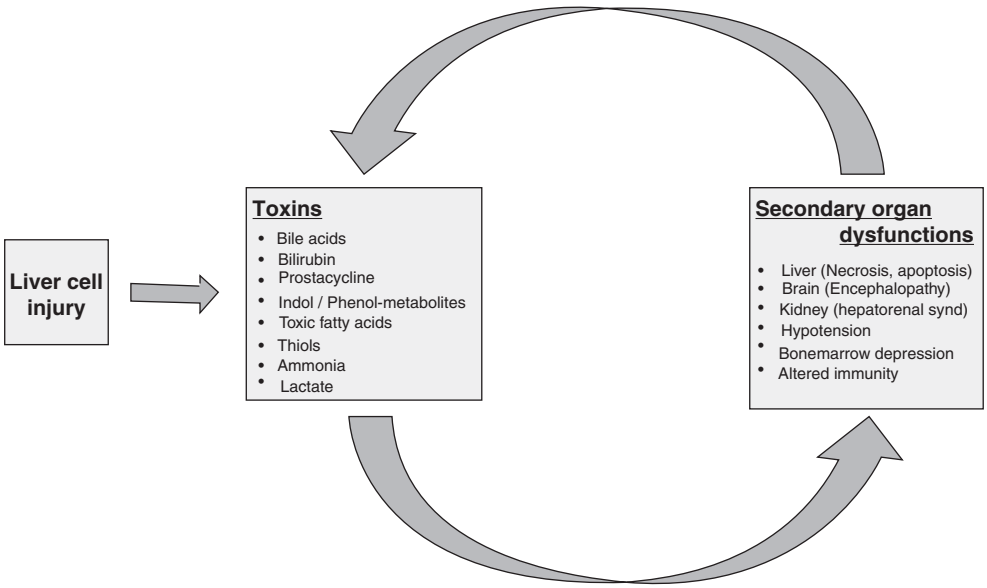

Fig. 73.2 Except for Von Willebrand factor and tissue plasminogen activator, the liver is the major site for synthesis of clotting factors. Factors V synthesis is first to be affected, and factor VII has the shortest half-life and is theoretically more sensitive marker than INR of hepatic synthetic function. *INR* international normalized ratio

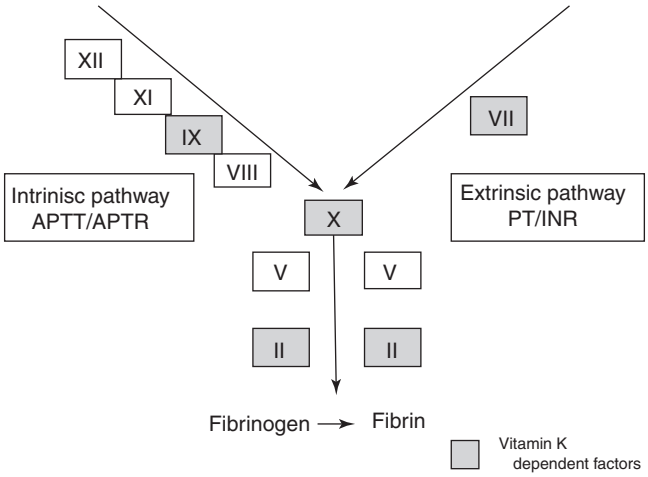

Fig. 73.3 Liver cell injury leads to release several toxic substances that cause secondary organ dysfunction; this leads on to a vicious cycle of autointoxication. APTT, activated partial thromboplastin time, APTR, activated partial thromboplastin ratio, *PT*, prothrombin time, *INR*, international normalized ratio

Etiology

The etiologies of ALF differ within age groups and geographic location. In Southeast Asia and Latin America, viral hepatitis A and E are the most common cause of ALF in children, while in Northern America and Europe, etiology remains elusive (indeterminate) in majority of children [6]. Certain disorders, such as neonatal hemochromatosis, are very unique to pediatric population. The exact incidence of ALF in pediatric age group is not known, but probably the overall annual incidence of ALF in USA is around 5.5/million population among all ages [7].

Infection

Hepatitis A and E viral (HAV and HEV) infections are the common cause of ALF in developing countries with poor sanitation and overcrowding, as these viruses are spread by contaminated water and food. The risk of liver failure is 0.1–0.4% following symptomatic HAV infection, and it increases with a preexisting liver disease. Specific diagnosis is established by detecting HAV immunoglobulin (Ig) M antibodies in the blood at presentation. The infection is most often self-limiting with subsequent recovery and only in few it might be severe enough requiring liver transplantation [8]. The risk of developing ALF in adults following HEV infection is 0.6–2.8%, with higher risk if contracted during pregnancy [9]. Bhatia et al. showed that the case-fatality associated with HEV-induced ALF in pregnancy is similar to that of age-matched general population [10].

The ALF due to hepatitis B virus (HBV) can occur at the time of acute infection, reactivation of chronic HBV infection, or seroconversion from a hepatitis Be antigen-positive to a hepatitis Be antibody (HBeAb)-positive state. Infants born to HBeAb-positive mothers are at special risk and could present with ALF around 6 weeks to 9 months [11]. Super infection or coinfection of hepatitis delta virus (HDV) in HBV-infected patients can cause liver failure. Hepatitis C viral (HCV) infection has not been reported as a cause of ALF.

Herpes simplex viruses 1 and 2 (HSV) are the predominant cause of viral-induced ALF during the first month of life. Neonatal ALF due to HSV carries a high mortality of about 85% and should be suspected in any neonate with or without vesicular rash who is unwell with dramatically high transaminases and coagulopathy. Treatment with high doses of acyclovir should be initiated in all infants with ALF, while awaiting serology results as the associated liver failure is rapidly fatal. Liver transplantation has a good outcome when considered in a hemodynamically stable neonate with ALF due to HSV [12]. Other members of herpes virus family such as cytomegalovirus, Epstein–Barr virus, and varicella-zoster virus can cause ALF. Rarely, viruses such as Dengue, Lassa, Ebola, Marburg, and Toga and bacteria such as *Leptospira* and *Salmonella* are implicated as a cause for ALF.

Drugs and Toxins

In developed countries, drug-induced liver failure is the most common identifiable cause of ALF in adults and children. Drug hepatotoxicity could be an idiosyncratic reaction, a dose-dependent response, or a synergistic reaction due of several drugs. It is essential to include details of complementary therapies and herbal medications as some are potential hepatotoxics [13]. Acetaminophen is the most common drug associated with ALF, probably due to the easy availability without the need for a prescription. It is safe when used in recommended doses and toxicity is usually dose dependent. Acetaminophen is detoxified mainly by glucuronidation (40%), sulfation (20–40%), and *N*-hydroxylation (15%). A small fraction is metabolized via cytochrome P450 to yield *N*-acetyl-para-benzoquinone-imide (NAPQI), a toxic intermediate compound which irreversibly conjugates with the sulfhydryl group of glutathione and causes hepatocyte necrosis [14]. Genetic polymorphism of cytochrome P450 isoenzymes predisposes affected people to acetaminophen toxicity due to increased NAPQI production. Bound NAPQI forms acetaminophen–protein adducts, which act as a specific biomarker for chronic acetaminophen toxicity. Hepatotoxicity of acetaminophen is dose dependent, and liver injury results in either because of acute higher doses of ingestion or cumulative overdoses taken over a few days. In acute acetaminophen

overdose, plotting serum levels after 4 h against time on the Rumack nomogram will guide toward potential toxicity. However, it may not be useful in situations of cumulative over doses. In such cases, bound NAPQI forms of acetaminophen–protein adducts in blood would aid the diagnosis. The mechanism of toxicity of anti-tuberculosis drugs, particularly isoniazid, is similar to acetaminophen; oxidation via cytochrome P450 pathway results in toxic metabolites.

Most common cause of idiosyncratic drug-induced liver injury (DILI) are due to antibiotics and NSAIDs [14]. The reported incidence of idiosyncratic DILI was around 14 new cases/100,000/year, of which 8% would progress to ALF [15, 16]. Genetic susceptibility of an individual and unmasking of underlying mitochondrial cytopathies by certain drugs are some of the proposed causes of DILI [17]. Drugs such as diclofenac, mefenamic acid, valproic acid, amiodarone, isoniazid, etc. can unmask mitochondrial cytopathy and cause ALF. Chemotherapy drugs are known to produce veno-occlusive disease leading to ALF due to endothelial damage.

Council for International Organizations of Medical Sciences/Roussel Uclaf Causality Assessment Method (CIOMS/RUCAM) scale is helpful in establishing causal relationship between offending drug and liver damage. Using the scoring system, suspected drug could be categorized into "definite or highly probable" (score > 8), "probable" (score 6–8), "possible" (score 3–5), "unlikely" (score 1–2), and "excluded" (score 0) [18]. This scale is helpful in identifying drug-induced hepatotoxicity even in newly marketed drugs and for a previously unreported older drug.

Metabolic Disorders

Metabolic disorders presenting as ALF is common in young children. Galactosemia and tyrosinemia 1 are the most common cause of neonatal liver failure, presenting with hepatomegaly, jaundice, and coagulopathy. Classical galactosemia is an autosomal recessive condition resulting in the mutation in galactose-1-phosphate uridyl transferase gene located on chromosome 9p13. Liver failure in this condition is thought to be due to accumulation on galactitol. Neonates presenting with hepatitis or ALF should be started on a galactose-free formula until galactosemia. Galactose-free diet coupled with supportive management helps the liver to recover, but some may still progress and need a liver transplant. Despite strict galactose-free diet, patients could develop complications like developmental delay, motor disorders, and hypergonadotropic hypogonadism due to endogenous galactose production on a long-term follow-up [19]. Tyrosinemia 1 is an autosomal recessive condition due to defect in the enzyme fumarylacetoacetate hydroxylase. This causes accumulation of intermediate compounds, maleylacetoacetic acid, and fumarylacetoacetic acid, which are then converted to succinylacetone, a toxin that damages the liver and kidneys. Tyrosinemia should be suspected when a coagulopathy and modest rise of transaminases is associated with elevated alpha-fetoprotein levels. Fructosemia and inborn errors of bile acid synthesis are a few other rare cause of ALF during infantile period.

Medium-chain acyl-coenzyme A dehydrogenases (MCAD) are group of enzymes involved in β-oxidation of 6–12 carbon chain fatty acids in mitochondria. They help in ketone production from fatty acids when hepatic glycogen stores become depleted during prolonged fasting and periods of higher energy demands. Affected children could present with hypoketotic hypoglycemia, recurrent liver failure, and precipitated by otherwise minor illness. Unless treated with dextrose supplementation, these episodes may quickly progress to coma and death.

Wilson's disease, an autosomal recessive disorder, could present as ALF. The acute hepatic presentation is usually characterized by the presence of liver failure, Coombs-negative hemolytic anemia, and low serum alkaline phosphatase. Diagnosis might be difficult as blood test might show weakly positive autoantibodies, and tissue copper estimation might not be possible due to coagulopathy. Demonstration of Kayser–Fleischer rings is diagnostic of Wilson's disease in a patient who presents with ALF. Wilson's disease presenting with ALF has high mortality without transplantation.

Mitochondrial disorders are group of spontaneous or inherited disorders of mitochondrial proteins resulting in defective oxidative phosphorylation, fatty acid oxidation, urea cycle, and other mitochondrial pathways [20]. This can affect the function of various cell types, such as neurons, myocytes, etc., where the need for energy requirement is high. Deficiencies of complex I, III, and IV, multiple complex deficiencies, and mitochondrial DNA (mtDNA) depletion syndrome are associated with liver failure. Diagnosis might be difficult due to particularly mtDNA depletion syndrome where there is tissue-specific mitochondrial enzyme deficiency. The infants usually presents with hypotonia, hypoglycemia, feeding difficulties, seizures, and deranged liver function. Liver transplantation could be offered in isolated liver-based mitochondrial disorders, while in multisystemic involvement it should be deferred; hence it is of utmost important to perform thorough investigation to rule out neuromuscular involvement [21].

Gestational Alloimmune Liver Disease

Neonatal hemochromatosis (NH) is the single most common cause of ALF during the first month of life, where there is massive iron deposition in the liver and extrahepatic tissues, but with sparing of the reticuloendothelial system. The pattern of iron overloading is similar to hereditary hemochro-

matosis, but NH affects only newborn and so far no specific genetic mutation has been identified. NH was considered to be a primary disease of iron overload of liver leading to liver failure. Under current concept, iron accumulation in NH is considered to be a secondary phenomenon due to immune-related severe fetal liver injury resulting in impaired regulation of maternofetal iron flux [22]. NH is now referred to as gestational alloimmune liver disease (GALD), as maternal antibody is directed toward fetal liver antigen resulting in activation of fetal complement leading to the formation of membrane attack complex (MAC) resulting in hepatocyte loss [23, 24]. This hypothesis is supported by successful prevention of severe disease by antenatal and postnatal treatment with intravenous Ig. GALD presents with jaundice, coagulopathy, moderately elevated alanine aminotransferase, high ferritin, and raised iron saturation levels. High ferritin is seen in other cause of neonatal liver failure, and no single biochemical test is diagnostic of NH. The diagnosis can only be confirmed by demonstration of extrahepatic iron deposits sparing the reticuloendothelial system. Labial salivary gland biopsy is a safe and effective way of demonstrating this [25]. The disease varies in severity; at one end of the spectrum, it is associated with fetal death, while at the other end, spontaneous recovery is reported.

Malignancies

Hemophagocytic lymphohistiocytosis (HLH) is a malignant disorder of the hematopoietic system where there is uncontrolled proliferation of activated lymphocytes and macrophages and could present as ALF, particularly during infancy. HLH could be inherited or acquired following infection due to over activation of natural killer cells and of CD8+ T cell lymphocytes, invariably leading to clinical and hematologic alterations. It is associated with defective apoptosis and reduced cytotoxic activity. Familial HLH is an autosomal recessive disease seen mostly in infancy and early childhood. The mutations result in reduced or defective production of cytoplasmic granules such as perforin in cytotoxic cells resulting in paradoxical over activation. Familial HLH is classified into four types based on mutation analysis. Secondary HLH usually occurs after systemic infection or immunodeficiency, which can affect people at any age and may subside spontaneously. HLH presents with fever, cutaneous rash, hepatosplenomegaly, pancytopenia, and, in severe cases, ALF [26]. ALF might be the presenting feature of hematologic malignancies such as leukemia or lymphoma [27]. Usual associated features would be fever, hepatosplenomegaly, high alkaline phosphatase, high lactate dehydrogenase, and abnormalities on peripheral blood film. Bone marrow examination confirms the diagnosis.

Autoimmune Hepatitis

Autoimmune hepatitis (AIH) can present as ALF, most of these children have positive liver–kidney microsomal (LKM) antibody (type 2 AIH). Diagnosis might be difficult, as some may not show specific antibodies at initial presentation. ALF due to AIH without encephalopathy could be benefited by immunosuppression, while ALF along with encephalopathy do not respond to any form of immunosuppression and need urgent liver transplant [28]. In our experience, of the six AIH children presenting with ALF and encephalopathy, four required liver transplantation, one died while awaiting transplantation, and one recovered with steroids [29]. The steroid responder was antinuclear/smooth muscle antibody positive (type 1 AIH), while the rest were LKM positive (type 2 AIH).

Other Causes

In spite of extensive investigation, the diagnosis could not be found in many children (indeterminate). Indeterminate ALF is probably due to unidentified infectious agent as suggested by presentation with severe hepatitis, liver failure, and bone marrow failure mimicking viral-induced disease or presentation with minimal jaundice and centrilobular necrosis on histology suggesting drug induced. More recent publications hint toward immune dysregulation and an exaggerated response of T cells causing hepatocyte damage but the exact pathways and trigger factors to be eluded [30]. There is wide variation in reporting of indeterminate etiology among various centers. This is probably due to incomplete investigations in ALF, which has been highlighted by Narkewicz et al., and labeling them as indeterminate etiology [31]. Hypoxia, bacterial infections, underlying cardiac problem, and venous outflow obstruction are few other causes of ALF.

Investigations

The etiology of ALF is so diverse that it is practically impossible to do all the tests during initial evaluation. A detailed clinical history and thorough general examination could give valuable clue of underlying problem and could help in directing management while awaiting confirmatory results. The first-line investigations should include complete blood count, liver function tests, serum electrolytes, uric acid, lactate, cholesterol/triglyceride, amylase, coagulation studies (INR), and blood glucose. Surveillance blood and urine cultures should be collected prior to starting antibiotics. The clinical presentation along with the results of first-line investigations will guide further specialized tests. Investigations to establish etiological diagnosis are outlined in Table 73.1. Supportive management along with anticipatory manage-

Table 73.1 Disease-specific investigations in acute liver failure

Infective
Serologic/quantitative tests
Hepatitis A: Anti-HAV IgM antibody
Hepatitis B: HBsAg, HBcAb(IgM), HBcAg
Hepatitis C: Anti-hep C antibody, hep C PCR
Hepatitis D: Anti-hep D antibody
Hepatitis E: Anti-HEV antibody(IgM)
Human immunodeficiency virus (HIV)
Herpes simplex virus (neonates)
Cytomegalovirus, Epstein–Barr virus
If indicated: Measles/varicella/adenovirus/echovirus/leptospirosis/
Cultures
Bacterial cultures: Blood, urine, stool, throat swab, sputum
Skin lesion if present, ascitic fluid if present
Viral culture of urine and skin lesion if present
Metabolic
Galactosemia: Galactose-1-phosphate uridyl transferase
Tyrosinemia: Urinary succinylacetone
Fructose intolerance: Quantitative enzyme assay, q22.3 band mutation in chr 9
Mitochondrial disorders: Quantitative mitochondrial DNA assay, mutation analysis
Congenital disorders of glycosylation: Transferrin isoelectrophoresis
MCAD deficiency: Plasma acylcarnitine
Wilson's disease: Serum copper and ceruloplasmin
24-h urinary copper pre- and post penicillamine
Type 1 and 2 autoimmune hepatitis
Immunoglobulins
Antinuclear antibodies
Smooth muscle antibody
Liver cytosol antibodies
Soluble liver antigen
Liver–kidney microsomal antibody
Antineutrophil cytoplasmic antibodies
Hematological malignancy
Bone marrow examination
Ascitic or cerebrospinal fluid cytospin
Genetics for HLH
Drugs and toxins: Drug levels in serum/urine
Budd–Chiari syndrome: Ultrasound, echocardiography, computed tomography
Neonatal hemochromatosis: Lip biopsy

HAV hepatitis A virus, *HEV* hepatitis E virus, *HBcAg* hepatitis B core antigen, *HBsAg* hepatitis B surface antigen, *HLH* hemophagocytic lymphohistiocytosis, *IgM* immunoglobulin M

ment of possible complications associated with liver failure would help in favorable outcome.

Prognosis

Categorical demarcation between spontaneous liver recovery and irreversible ALF is difficult. In adults with non-acetaminophen-induced ALF, King's College Hospital criteria (KCHC; Table 73.2) is used for prognostication and the need for liver transplantation. Fulfillment of KCHC is usually associated with death unless transplanted [32]. But in children, KCHC does not reliably predict death with a poor positive predictive value of 33% [33]. Of the several prognostic markers that has been proposed to predict outcomes in ALF in children, INR and factor V concentration remains the best indicators. In children with ALF, INR 4, bilirubin 235 μmol/L, age < 2 years, and WBC > 9×10^9/L are associated with poor outcome without liver transplantation [34]. Bhaduri and Mieli-Vergani have shown that the maximum INR reached during the course of illness was the most sensitive predictor of the outcome, with 73% of children with an INR less than 4 surviving compared with only 4 of 24 (16.6%) with an INR greater than 4 [35]. French centers use factor V concentration for prognostication and a value of less than 20% of normal (Clichy criteria) suggests a poor outcome. The new Wilson index proposed by Dhawan et al. based on serum bilirubin, serum albumin, INR, aspartate aminotransferase (AST), and white cell count (WCC) at presentation identified a cutoff score of 11 for death and proved to be 93% sensitive and 98% specific, with a positive predictive value of 88% (Table 73.3) [36]. In acetaminophen overdose, metabolic acidosis with arterial pH less than 7.3, after the second day of overdose in adequately hydrated patients, is associated with 90% mortality. In acetaminophen over-

Table 73.2 King's College Hospital criteria for liver transplantation

Non-acetaminophen acute liver failure
INR greater than 6.5 or
Three of the following five criteria
Patient age <11 or >40
Serum bilirubin >300 μmol/L
Time from onset of jaundice to the development of coma >7 days
INR greater than 3.5
Drug toxicity
Acetaminophen-induced acute liver failure
Arterial pH < 7.3 (after fluid resuscitation) or
All three of the following criteria
INR >6.5
Serum creatinine >300 μmol/L
Encephalopathy (grade III or IV)

INR international normalized ratio

Table 73.3 Wilson's disease index

dose, KCHC could be used in children for selecting candidates requiring liver transplantation (Table 73.2).

Table 73.3 showing Wilson's disease index, which has five parameters, and a score of 11 or more indicates the need for liver transplant.

Management

Due to unpredictable course of liver failure, management has to be carried out alongside of investigation. Early liaison and transfer to a specialist center with transplantation facilities is crucial for better outcome.

General Measures

Children with ALF should be monitored in a quiet setting. Vital parameters, such as pulse, blood pressure, oxygen saturation, and neurologic observations, should be done on regular basis. Prophylactic broad-spectrum antibiotics and antifungals should be started in all children, and acyclovir should be added in infants and neonates. Children with encephalopathy or an INR greater than four should be admitted to an intensive care unit for close monitoring. Hypoglycemia should be avoided by use of intravenous glucose infusion or by ensuring adequate enteral intake. The idea of protein restriction to limit the possibility of HE has now been disregarded and adequate calories should be provided. A plant protein-based diet which has more of branched-chain amino acid (BCAA) is preferred over animal protein which has more of aromatic amino acid (AAA). Oral or nasogastric feeding is usually well tolerated. Prophylactic histamine 2 blockers or proton pump inhibitors should be started to all patients requiring mechanical ventilation as stress ulcers can cause bleed [37].

N-Acetylcysteine (NAC)

N-acetylcysteine (NAC) is being increasingly used in non-acetaminophen-induced ALF as it enhances circulation and improves oxygen delivery. Retrospective study from King's College Hospital has shown that NAC infusion in non-acetaminophen-induced ALF was associated with a shorter length of hospital stay, higher incidence of native liver recovery without transplantation, and better survival after transplantation [38]. In a prospective, double-blind trial in adults with non-acetaminophen ALF, NAC usage is associated with significant improvement in transplant-free survival in patients with early (stage I–II) coma, indicating the necessity for early initiation of treatment [39]. But a more recent prospective study on NAC usage in children with non-acetaminophen ALF failed to show any significant benefit when compared to placebo [40].

Airway and Ventilation

Elective intubation and mechanical ventilation should be considered in patients with grade 1 or 2 encephalopathy that are agitated or planned to transfer and in all patients with grade 3/4 encephalopathy. Apart from providing secure airway, mechanical ventilation helps in reducing sudden variation of intracranial pressure (ICP). Sedation could be maintained with a combination of an opiate such as morphine or fentanyl and a hypnotic such as midazolam. Peak end-expiratory pressure above 8 cm of water should be avoided because it may increase ICP.

Fluid Management and Renal Failure

Intravenous fluids should be restricted to two thirds maintenance, with the idea of decreasing the possibility of development of cerebral edema. Ultrasonic cardiac output monitor (USCOM), which is a noninvasive method to measure cardiac parameters, helps in decision-making regarding appropriate fluid regimens/inotropes even in small infants. In ALF, there would be hyperdynamic circulation with decreased systemic vascular resistance, and in the presence of persistent hypotension, first-line inotropic agent of choice would be noradrenaline followed by vasopressin analogues. Continuous filtration or dialysis should be considered when the urine output is less than 1 mL/kg/h to prevent acidosis and volume overload.

Neurologic Complications

Encephalopathy is not always recognizable in children and usually is a late feature. The most serious complications of ALF are cerebral edema with resultant intracranial hypertension and HE. Encephalopathy that occurs in ALF is categorized as type A, according to the suggested nomenclature by Working Party at the 11th World Congress of Gastroenterology. HE could be clinically graded from 1 to 4 using West Haven criteria (Table 73.4), and consciousness levels could be assessed using Glasgow coma scale, which has lesser interobserver variability [41] (Table 73.5).

Clinical features of raised ICP would include systemic hypertension, bradycardia, hypertonia, and hyperreflexia and in extreme cases decerebrate or decorticate posturing. Electroencephalographic (EEG) changes occur very early in HE, even before the onset of psychological or biochemical disturbances. Ammonia-lowering measures such as dietary

protein restriction, bowel decontamination, or lactulose are of limited or no value in rapidly advancing encephalopathy. Mannitol is an osmotic diuretic commonly used to treat intracranial hypertension. A rapid bolus of 0.5 g/kg as a 20% solution over a 15-min period is recommended, and the dose can be repeated if the serum osmolarity is less than 320 mOsm/L. In ventilated patients, prophylactic hyperventilation provides no role as hypocapnia could decrease cerebral perfusion and $PaCO_2$ should be kept between 4 and 4.5 kPa. In case of clinical features of acute rise in ICP, hyperventilation could be done for a brief period of time until there is symptomatic improvement. Invasive ICP monitoring using special catheters helps in objective measurement of ICP. This helps to maintain optimal cerebral perfusion pressure (mean arterial blood pressure—ICP) of more than 50 mm Hg. Inotropic agents could be used to increase mean arterial blood pressure to achieve the optimal cerebral perfusion pressure. Studies have shown sodium thiopental, mild cerebral hypothermia (32–35 °C), and hypernatremia (serum sodium >145 mmol/L) improve cerebral perfusion. Table 73.6 shows some of the pathophysiological changes that lead on to multiorgan dysfunction associated with ALF.

Table 73.4 West Haven criteria for grading of mental state

Grade 0	Normal
Grade 1	Euphoria or anxiety
	Shortened attention span
	Impaired performance of addition
	Trivial lack of awareness
	Inverted sleep pattern
Grade 2	Subtle personality change
	Minimal disorientation for time or place
	Impaired performance of subtraction
	Lethargy or slow response
	Tremor and hypoactive reflexes
Grade 3	Somnolence to semi stupor, but responds to verbal stimuli
	Confusion, gross disorientation
	Inappropriate behavior
	Brisk reflexes and Babinski's sign
	Muscle rigidity
Grade 4	Deep coma (unresponsive to verbal or noxious stimuli)

Table 73.5 Glasgow coma scale

	Infants	Children	Score
Eye opening	Open spontaneously	Open spontaneously	4
	Open in response to verbal stimuli	Open in response to verbal stimuli	3
	Open in response to pain only	Open in response to pain only	2
	No response	No response	1
Verbal response	Coos and babbles	Oriented, appropriate	5
	Irritable cries	Confused	4
	Cries in response to pain	Inappropriate words	3
	Moans in response to pain	Incomprehensible words or nonspecific sounds	2
	No response	No response	1
Motor response	Moves spontaneously and purposefully	Obeys commands	6
	Withdraws to touch	Localizes painful stimulus	5
	Withdraws in response to pain	Withdraws in response to pain	4
	Responds to pain with decorticate posturing (abnormal flexion)	Responds to pain with flexion	3
	Responds to pain with decerebrate posturing (abnormal extension)	Responds to pain with extension	2
	No response	No response	1

Coagulopathy

As INR is a dynamic indicator of disease progression, coagulopathy should be corrected only if the patient is having a bleed or prior to an invasive procedure. Bleeding manifestation is very unusual in ALF as there would be proportional reduction in plasma levels of both procoagulant and antico-

Table 73.6 Pathophysiology of complications in ALF

Coagulopathy
Decreased levels of coagulation factors, decreased protein C, protein S, and antithrombin associated with dysfunctional platelets and fibrinogen
Encephalopathy and intracranial hypertension
Inhibitory effect of ammonia and gamma-aminobutyric acid on neuronal cell membranes and synapses. The direct toxicity of toxins on neuronal cells and vasogenic imbalance leading to intracellular fluid shifts resulting in cerebral edema
Renal failure
Acute tubular necrosis secondary to complications of ALF such as sepsis, bleeding, and/or hypotension
Hepatorenal syndrome because of renal vasoconstriction probably due to release of vasoactive mediators
Hypotension
Decreased systemic vascular resistance and hypovolemia secondary to shift of fluids into interstitial space. Adrenal insufficiency *due to* decreased liver synthesis of apolipoprotein A-1, the major protein component of HDL leading to decreased HDL and thereby decreased cortisol production
Metabolic derangement
Hypoglycemia due to increased plasma insulin levels owing to reduced hepatic uptake, reduced glycogen stores, and impaired gluconeogenesis. Lactic acidosis is related to inadequate tissue perfusion due to hypotension and also due to decreased detoxification by the liver
Infection
Impaired Kupffer cell and polymorphonuclear function along with reduced levels of factors such as fibronectin, opsonins, chemo attractants, and components of the complement system

HDL high-density lipoprotein

agulant proteins [42]. Thromboelastography would be an appropriate tool in diagnosing risk of bleeding. To correct coagulopathy, fresh frozen plasma could be given at a dose of 10 ml/kg and cryoprecipitate at 5 ml/kg (if fibrinogen is <1 g/l). In resistant cases, factor VII concentrates improve the coagulopathy for a short period. Platelet count should be maintained above 50 × 10^9/dL, as thrombocytopenia is an important risk factor for hemorrhage.

Disease-Specific Management

Antioxidant cocktail (*NAC*, *selenium*, *desferrioxamine*, *prostaglandin E1*, *vitamin E*) has been used in NH, based on the concept that iron chelation and free radical scavenging would prevent liver damage, with no proven benefit. As GALD is the common cause of NH, evidence is accumulating toward the usefulness of high-dose intravenous immunoglobulin (IVIG; 1 g/kg), in combination with exchange transfusion resulting in significant decrease in the need for liver transplantation in NH [43]. IVIG when given as prophylaxis to mothers whose previous pregnancy/child was affected with NH at a dose of 1 g/kg bodyweight, weekly from the 18th week until the end of gestation, has been associated with milder phenotypic expression of the disease and 100% survival of babies [44]. The management of HLH consists of liver supportive therapy, chemotherapy, and hematopoietic stem cell transplantation (for genetically verified/ familial disease and persistent/reactivation of secondary disease) [26]. Dietary intervention with restriction of phenylalanine and tyrosine together with oral medication, 2(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), helps in normalization of liver function in tyrosinemia type 1 but does not prevent long-term risk for development of hepatocellular carcinoma [45]. In *Amanita phalloides* (death cap) poisoning, benzylpenicillin given at a dose of 1,000,000 U/kg/d followed by 500,000 IU/kg for the next 2 days prevents toxin uptake by liver cells. In all the abovementioned conditions (excluding hematological malignancy), liver transplantation has to be considered in case of failed medical management. The beneficial role of corticosteroids in indeterminate ALF has not yet been proven in prospective studies [46].

Liver Assist Devices

Release of toxins and inflammatory mediators from the necrosed hepatocytes initiates cascade of events which could ultimately lead to multiorgan failure, and this elicits a vicious cycle of autointoxication (Fig. 73.3). Liver assist devices are developed to interrupt the cycle of autointoxication by removing toxins there by providing an opportunity for the liver to regenerate. An ideal extracorporeal liver support system has to perform complex synthetic, detoxifying, and biotransformatory functions of hepatocytes and Kupffer cells. Creating such a perfect device with possibility of providing an extracorporeal liver support system for short periods while the native liver regenerates or a liver transplant becomes available is still experimental. Currently available liver support devices could be broadly classified into cell-free cleansing devices and bioartificial liver support system, which contains human or animal liver cells. Cleansing devices perform only the detoxifying function of the liver, whereas bioartificial liver support systems have a theoretic advantage of providing the synthetic and detoxifying properties. These devices have shown to decrease the toxins (ammonia, bilirubin, cytokines, etc.) but have no effect on mortality. Successful use of these devises in ALF as a bridge, supporting liver function while the native liver regenerates, still remains elusive and not recommended outside research setting.

Liver Transplantation

Liver transplant remains the only proven treatment that has improved the outcome of ALF. Improved surgical techniques such as split liver grafts, reduced grafts, and living related donors have increased the timely availability of donor organs. The donor organs are usually blood group matched. In emergency situations ABO-incompatible liver transplantation could be done but is associated with lower graft survival. Careful patient selection is essential, as it would minimize patients from being listed for liver transplantation and then being removed due to spontaneous recovery. Patients, who were removed from the list due to spontaneous recovery, could have potentially ended up with liver transplantation if the organ becomes available before overt clinical improvement is appreciated. Absolute contraindications for liver transplant are fixed and dilated pupils, uncontrolled sepsis, systemic mitochondrial/metabolic disorders, and severe respiratory failure [47, 48]. Relative contraindications are increasing inotropic requirements, infection under treatment, cerebral perfusion pressure of less than 40 mmHg for more than 2 h, and a history of progressive or severe neurologic problems.

Auxiliary Liver Transplantation

Auxiliary liver transplant is a surgical procedure where a healthy donor liver graft is implanted with native liver in situ. Auxiliary liver transplant could be orthotopic (part of the native liver is resected and replaced with a reduced-size graft) or heterotopic (the donor graft is placed alongside the

native liver in the right upper quadrant). Due to higher incidence of complications associated with heterotopic auxiliary liver transplant, it is no more used in clinical practice. Now the standard surgical technique is auxiliary partial orthotopic liver transplantation (APOLT). The rationale behind the use of this technique in ALF is that the allograft supports liver function while the native liver regenerates and then immunosuppression could be weaned and eventually stopped. It has been shown that complete native liver recovery could happen even when there is more than 90% hepatocyte loss [49, 50]. In a series from King's College Hospital, of the 20 children who received auxiliary liver transplantation for ALF, 10-year patient survival was 85% [51]. Among the 17 survivors, 14 (82%) have successfully regenerated their native liver of which immunosuppression was withdrawn successfully in 11 patients at a median time of 23 months after transplantation. This would be an ideal option in ALF due to indeterminate etiology, as spontaneous regeneration of native liver remains a possibility. Caution should be excised while selecting patients with hemodynamic instability and cerebral edema as deterioration might happen during postoperative period due "toxic necrotic liver" left behind.

Hepatocyte Transplantation

Hepatocyte transplantation is a procedure where hepatocytes are infused intraportally into the patient's liver, where a proportion of cells will engraft and would support liver function. This technique has been tried with variable success in certain liver-based metabolic disorders. Its use in ALF still remains experimental. Lack of surrogate markers of rejection poses an important problem, as it is difficult to titrate immunosuppression. Dhawan et al. has recently published the utility of alginate-encapsulated hepatocytes in management of ALF [52]. Alginate-encapsulated hepatocytes were injected intraperitoneally in a cohort of eight children with ALF and has found to avert LT in four and acted as bridge in three. This technique avoids the complications of coagulopathy and portosystemic shunting of infused cells and protects the cells from direct immune attack.

Conclusions

ALF in children is a medical emergency as it leads to multiorgan failure and has to be approached systematically. Newer definition for ALF obviates the need for encephalopathy to make the diagnosis. Expert intensive care facility is essential to stabilize and make these children fit for transplantation. Etiological diagnosis aids in disease-specific management. Acyclovir should be started in all neonates with ALF until results of herpes virology are available. Liver transplantation is the only definitive treatment that improves survival in pediatric ALF, while liver assist devices and hepatocyte transplantation are potential emerging therapies.

Complications of Cirrhosis in Children

74

Naresh P. Shanmugam and Anil Dhawan

Introduction

Cirrhosis is the end result of progressive fibrosis irrespective of the insult to the parenchyma or biliary tree. Unlike adults, there is no time duration of illness that defines chronic liver disease (CLD). All the inherited metabolic and genetic conditions even when diagnosed at birth could have advanced fibrosis or cirrhosis. Cirrhosis is a histological diagnosis but is liberally used in clinical practice without histological evidence. Liver cell death leads to a cascade of immunological reactions leading to activation of stellate cells with subsequent excessive collagen production and ultimately fibrosis. Bridging of the portal tracts (porto-portal) or the central vein to the portal tracts with nodule formation and disruption of the liver architecture is defined as cirrhosis. The disruption of the liver architecture leads to the disturbance in hemodynamics of blood flow into the liver and homeostasis of synthetic and detoxification functions of the liver, resulting in complications such as portal hypertension (PHT), ascites, and encephalopathy. This can lead to a secondary cascade of events affecting the function of several end organs such as the brain, kidney, and lungs [1]. Understanding the pathophysiology of the complications in CLD helps in anticipation and initiation of treatment at appropriate time. This chapter deals with the common complication associated with CLD.

Cirrhosis

The hallmark of CLD is fibrosis of the liver. Cirrhosis is a histopathological term used to describe microscopic and/or macroscopic changes in the liver characterized by aberrant nodule formation, vascular changes, and totally disturbed architecture associated with fibrosis. The degree to which the abovementioned changes progress depends on the nature and duration of the insult. Cirrhosis/fibrosis leads to complications such as PHT, ascites, encephalopathy, hepatorenal syndrome (HRS), hepatopulmonary syndrome (HPS), and eventually resulting in end-stage liver disease.

Etiology of Cirrhosis

Common diseases that cause chronic injury to the liver in children leading to cirrhosis are outlined in Table 74.1. Cell death or injury, as in hepatotropic viral infections or accumulation of toxic by-products such as hydrophobic bile acids in hepatocytes, is associated with release of several proinflammatory mediators (e.g., tumor necrosis factor, TNF) that lead to progressive fibrosis and eventually liver cirrhosis. As with any other multifactorial disease, both genetic and environmental factors play a role in cirrhosis. The pattern and type of proinflammatory mediator released depend on the underlying etiology of hepatocyte death [2]. These mediators act on Kupffer cells, hepatocytes, and cholangiocytes that release secondary mediators, which then activate hepatic stellate cells (HSC) to produce extracellular matrix (ECM). Thus, etiology of liver insult influences the pattern of fibrosis, as fibrosis is first observed in periportal area in viral hepatitis, perivenular region in toxic damage, while in developmental malformations such as biliary atresia fibrosis starts around the bile duct. Liver fibrosis is considered to be a wound-healing process, similar to any injured tissue in body, but when the response is exaggerated and persistent, it progresses to cirrhosis.

Pathogenesis of Liver Fibrosis

Persistent insult to either hepatocytes or cholangiocytes acts as a stimulus for fibrosis to set in. Hepatotropic viruses, toxins, and diseases that cause chronic cholestasis (tyrosinemia,

Table 74.1 Some of the common causes of liver cirrhosis in children

Etiology of liver cirrhosis
Metabolic liver disease
α1-antitrypsin deficiency
Wilson disease
Progressive familial intrahepatic cholestasis
Glycogen storage diseases
(especially types IV, VI, IX, and X)
Lipid abnormalities (e.g., Gaucher disease)
Peroxisomal disorders (e.g., Zellweger syndrome)
Tyrosinemia
Cystic fibrosis
Developmental/genetic
Biliary atresia
Congenital hepatic fibrosis
Alagille syndrome
Infections
Viral (e.g., chronic hepatitis B or C)
Parasitic (e.g., echinococcosis)
Immune related
Autoimmune hepatitis
Sclerosing cholangitis
Vascular
Budd–Chiari syndrome
Hepatic veno-occlusive disease
Portal vein thrombosis
Miscellaneous
Nonalcoholic steatohepatitis (NASH)
Drugs

progressive familial intrahepatic cholestasis, etc.) damage liver cells, either by apoptosis or necrosis leading to activation of a cascade of events causing fibrosis/cirrhosis (Fig. 74.1). The damaged liver cells secrete inflammatory mediators such as transforming growth factor (TGF)-beta1, TNF-α, epidermal growth factor (EGF), insulin-like growth factor (IGF), endothelin (ET), and platelet-derived growth factor (PDGF) that activate HSC. These damaged hepatocytes/cholangiocytes also recruit and activate T cells and Kupffer cells which secrete interleukin 6 (IL-6), interferon (IFN)-alpha, CD40, CCL21, and IGF which in turn activates HSC via a different pathway. The ECM such as type IV collagen, fibrinogen, and urokinase-type plasminogen activator that is secreted during the process of fibrosis could act as a stimulus for further activation of HSC starting a vicious cycle [3].

Under normal condition, HSC are quiescent cells that store lipids and vitamin A in the liver that resides in the space of Disse. When activated, HSC transdifferentiate to myofibroblast-like cells, acquiring fibrogenic and secretory properties. Apart from HSC, myofibroblasts that are derived from small portal blood vessels and bone marrow play a role in ECM formation during fibrosis of the liver [4–6]. The source of fibroblast that is involved in fibrosis of the liver depends on the etiology of insult to the liver [6]. With biliary pathology such as biliary atresia, portal tract fibroblasts, and in hypoxic insults, bone marrow fibroblasts play an important role [7, 8].

The ECM laid during this process of fibrosis differs in structure and composition, when compared to the ECM laid during routine remodeling. Mitogenic stimuli such as TGF-beta upregulate several precollagenous genes and increase the secretion of collagen by myofibroblasts, particularly types 1 and 3. Activated HSC also enhance the secretion of ECM-digesting enzymes like interstitial collagenase, gelatinase A, and stromelysin-1 which degrade specific components of ECM such as type 4 collagen and laminin, paving way for increased composition of type 1 and 3 collagen in fibrosis [9]. Increased tissue inhibitors of matrix metalloproteinases (TIMPs), which inhibit collagenase, result in gross imbalance between production and degradation of ECM. The fibrous tissue thus formed could interconnect portal tracts, portal tracts and central venules, or a mixture of both patterns and progress to cirrhosis. Contrary to the initial belief, it is shown that liver fibrosis even cirrhosis could regress to some extent on successful treatment of underlying cause [10].

Diagnosis of Liver Fibrosis

Fibrosis of the liver covers an entire spectrum of microscopically detectable fibrosis during initial stages to macroscopically gross fibrosis as in advanced stages of CLD. There is no validated biochemical test or scoring system based on biochemical tests that would grade the severity of fibrosis [11]. Synthetic liver function or cholestasis has no correlation with the degree of fibrosis, as these parameters may be normal even in advanced fibrosis as in congenital hepatic fibrosis. Imaging techniques such as ultrasonography, computed tomography, and magnetic resonance imaging (MRI) can identify liver fibrosis though quantification is difficult. Liver biopsy is considered to be the gold standard method for the assessment of liver fibrosis as it provides necroinflammatory and the fibrosis grade. Figure 74.2a shows complete nodule formation, and Fig. 74.2b shows extensive collagen, when stained by trichrome in a cirrhotic liver. Scoring of degree of fibrosis could be done using Metavir (stages I–IV) and Ishak score (stages I–V). Due to invasive nature of the procedure, it is practically difficult to monitor fibrosis progression using liver biopsy. To overcome this problem, transient elastography (FibroScan®), a noninvasive technique, is used in serial monitoring of progress of fibrosis with good accuracy and has been validated even in children [12]. Spleen stiffness measurement using transient elastography has shown to be helpful in predicting clinically significant varices [114].

(**b**) Microscopic image of trichrome-stained liver, where collagen is stained *blue*, while the cytoplasm of hepatocytes is stained *red* and nuclei as black structures within cells

Complications and Management of Cirrhosis

CLD and the term "cirrhosis" have been used interchangeably in literature as cirrhosis is a manifestation of CLD, and most of the complications in CLD are secondary to cirrhosis. With progressive fibrosis, there is distortion of blood vessels and bile leading to increased resistance to blood flow resulting in increased portal pressure on the afferent side and tissue hypoxia due to reduced blood supply on the efferent side. Cirrhosis also leads to increase in hepatic artery resistance, and in the case of hypotension secondary to an infection or variceal bleed, the liver could suffer hypoxic insult and could decompensate. Over a period of time, the fibrous tissue coalesces to form a tight capsule and restricts hepatocyte regeneration and worsens cholestasis. Synthetic/detoxification failure, cholestasis, and fibrosis individually or in combination contribute toward complication of CLD, some of which are highlighted in Table 74.2. There is an increased risk of hepatocellular carcinoma (HCC) in cirrhotic liver, and the generalized nodular transformation of the liver makes it difficult to diagnose HCC at early stages. Ultimately, these patients would succumb either to liver failure or to its complication unless treated appropriately. Fibrosis is a reversible phenomenon, but the extent to which the distorted liver architecture that would revert back to its original state still remains an unanswered question. Disease-specific treatment, for example, chelation for Wilson's disease and steroids for autoimmune liver diseases, halts the progress of fibrosis and could reverse cirrhosis. At present, there is no approved drug that would inhibit or reverse fibrosis.

Table 74.2 Signs and symptoms of cirrhosis and probable mechanism causing it

Complications of cirrhosis		
Symptoms	Signs	Underlying mechanism[a]
Jaundice, pruritus	Elevated bilirubin and bile acids	Detoxification failure of liver
Altered mental status	Encephalopathy	Detoxification failure of liver
Distended abdominal veins, vomiting blood	Caput medusae	Portal hypertension
Abdominal distension swelling of legs	Ascites/edema	Hypoalbuminemia, portal hypertension
Muscle wasting	Malnutrition	Decreased absorption of nutrients due to defective bile flow and increased demand
Telangiectasia	Spider nevi	Detoxification failure of certain hormones
Easy fractures	Osteoporosis and osteomalacia	Hepatic osteodystrophy
Decreased urine output	Oliguria	Hepatorenal syndrome
Bluish discoloration and swelling of fingers	Cyanosis and clubbing	Hepatopulmonary syndrome, portopulmonary hypertension
Difficulty in breathing	Dyspnea	Hepatopulmonary syndrome, portopulmonary hypertension

[a]More than one mechanism could be involved

Complications of Cirrhosis

Portal Hypertension

The liver is a unique organ with dual blood supply, via the hepatic artery and portal vein. The portal vein, formed by the splenic vein and superior mesenteric vein, supplies nutrient-rich blood from the intestine to the liver. The usual pressure is less than 5 mmHg, and this blood traverses hepatic sinusoids reaching hepatic venules having much lower pressures and enters systemic venous circulation. PHT develops when there is increased resistance anywhere along the portal system, and thus PHT could be extrahepatic (portal vein thrombosis), intrahepatic (cirrhosis), or posthepatic (hepatic venous thrombosis). PHT leads to opening up of portosystemic collaterals causing varices, which could rupture and cause bleed.

Direct measurement of portal pressure is difficult, and so hepatic venous pressure gradient (HVPG) is measured via hepatic venous catheterization. HVPG is the pressure difference between wedged hepatic venous pressure (WHVP) and free hepatic venous pressure, which is reflective of portal pressure. HVPG of more than 10 mmHg is associated with the development of varices, and pressures more than 12 mmHg is associated with variceal bleed. In clinical practice, accurate measurement of portal pressure by invasive methods is of little relevance as esophageal varices and splenomegaly hint toward the development of PHT, and this needs to be managed appropriately.

Pathogenesis of PHT in Cirrhosis

Like any other tubular organ, resistance and flow govern the pressure in the portal venous system. In CLD, there is a substantial increase in both flow and resistance of portal vein leading to net increase in portal pressure.

Increased Resistance to Portal Flow

In cirrhosis, dynamic contractile elements within sinusoids and portal venules contribute up to 40% of increased vascular resistance, while the rest is attributed to fibrosis. Wrapping of HSC and myofibroblasts can wrap around sinusoids, and

the portal venular smooth muscle contraction can increase vascular resistance [13]. ETs are a group of peptides, which cause vasoconstriction and stimulation of cell proliferation in tissue. ET-1 and ET-3 are found to be increased in cirrhotics when compared to controls, probably due to increased production [14]. Angiotensin II, norepinephrine, and thromboxane A2 (TXA2) are other vasopressors which are found to be increased in cirrhosis of the liver and cause increased vascular resistance of portal venules [15]. There is an associated endothelial dysfunction, which further increases the vascular resistance instead of decreasing it. This is probably due to increased levels of TXA2 impairing the response to endothelium-dependent vasodilator acetylcholine, and thus the resultant increased vascular resistance is probably due to imbalance between increased vasoconstrictors and decreased vasodilators in CLD [16].

Increased Portal Circulation

Splanchnic vasodilatation combined with hyperdynamic circulation contributes to increased portal circulation. Nitric oxide (NO) [17] increases the production of cyclic guanosine monophosphate, which directly relaxes the smooth muscle. Increased NO due to enhanced endothelial NO synthase (eNOS) activity in splanchnic circulation is suggested to play an important role in splanchnic vasodilatation. Increased levels of glucagon found in cirrhosis cause direct vascular smooth muscle relaxation and decrease the sensitivity of vascular smooth muscle to endogenous vasoconstrictors. Other vasodilators such as capsaicin–calcitonin gene-related peptide, neuropeptides, and adenosine have a doubtful role. Plasma volume expansion due to sodium retention in cirrhosis also plays a role in increased portal flow.

Variceal Bleed in Portal Hypertension

Apart from ascites and hypersplenism, the major complication of PHT is variceal bleed. HVPG of more than 10 mmHg results in opening up of portosystemic collaterals, which are situated at the lower end of the esophagus, rectum, and paraumbilical and retroperitoneal regions. Life-threatening bleeds are usually from esophageal and gastric varices that arise from a collateral network through the coronary and short gastric veins draining into the systemic azygos vein. Miga et al. showed that 20% of children had esophageal variceal hemorrhage (EVH) within 2 years after Kasai portoenterostomy, and the risk of death or need for liver transplantation was 50% at 6 years after the initial episode of EVH in a cohort of children with biliary atresia [18]. Etiology plays an important role in the survival outcome after variceal bleed, with varices due to portal vein thrombosis having better prognosis when compared with those due to intrinsic hepatobiliary disease [19].

Management of Variceal Bleed

Variceal bleed is a life-threatening emergency, and the patient needs to be stabilized before shifting for emergency endoscopy. In the event of hypovolemic shock, fluid resuscitation has to be initiated while awaiting whole blood, and in addition, fresh frozen plasma/platelets/cryoprecipitate/factor VIIa might be required, as these patients would be coagulopathic secondary to liver disease. Nasogastric tube placement and gastric lavage help to quantify the blood loss as well as to remove blood from the stomach that could precipitate encephalopathy. Vasoactive drugs that decrease portal pressure (Table 74.3) should be started along with proton pump inhibitors/H2 blockers and antibiotics. Once stable, endoscopic variceal ligation (EVL) or endoscopic sclerotherapy could be done [20]. In the case of continuous bleed and hemodynamic instability, balloon tamponade with a Minnesota or Sengstaken–Blakemore tube should be attempted. Both these tubes have esophageal and gastric balloon, but Minnesota tube has esophageal aspiration port in addition to gastric aspiration port while Sengstaken–Blakemore tube has only gastric aspiration port. These tubes need to be placed by an experienced person as improper placement or overinflation of the balloon can result in esoph-

Table 74.3 Various drugs used in portal hypertension and its mechanism of action

Medications used in portal hypertension		
Drugs used in acute variceal bleed		
Drug	Dosage	Mechanism of action
Vasopressin	Initial IV bolus 0.3 U/kg (maximum: 20 U) over 20 min followed by infusion: 0.002–0.01 U/kg/min	Acts via V1 receptors, reduces portal blood flow, portal systemic collateral blood flow, and variceal pressure
Octreotide	1 μg/kg/h IV infusion or 2–4 μg/kg/dose/8 h s.c.	Analogue of somatostatin Reduce portal flow and pressures
Terlipressin	8–20 μg/kg of body weight given at intervals of 4–8 h	Terlipressin, a prodrug of vasopressin
Drugs used to prevent rebleed		
Propranolol Atenolol	1–5 mg/kg/day in three divided doses 1 mg/kg/day in two doses (Dose has to be adjusted to decrease heart rate by 25%)	Reduces portal hypertension by decreasing cardiac output and inducing splanchnic vasoconstriction by blocking β-1 and β-2 receptors
Carvedilol	0.3 mg/kg/day	Nonselective β-blocker with additional α-1 blocking action

IV intravenous, *s.c.* subcutaneous

ageal rupture and/or ischemia [21]. Once bleeding is controlled, endoscopic sclerotherapy (ESL) and endoscopic *variceal* ligation (*EVL*) has to be performed, as conservative management (medication and balloon tamponade) without endoscopic intervention was associated with 3.6 times higher risk of rebleed [22].

ESL is a procedure where sclerosant such as ethanolamine oleate or sodium tetradecyl sulfate is injected into a varix under direct vision, thereby obliterating the vessel. Cyanoacrylates are synthetic glues used in gastric varices that rapidly solidify on contact with water and blood. Usually, cyanoacrylates are mixed with ethanolamine oleate at 1:1 ratio to decrease the rate of solidification, as it minimizes the inadvertent adherence of catheters to the endoscope. EVL is a procedure where an elastic O-ring is applied over a small area of esophageal mucosa and submucosa, causing strangulation of the tissue (varix) caught in between the ring, eventually leading to fibrosis and obliteration. Randomized trial of endoscopic sclerotherapy versus variceal band ligation for esophageal varices showed that while both are equally effective in controlling acute bleed, EVL achieved variceal obliteration in fewer treatment sessions along with significantly lower rate of the development of portal gastropathy and rebleeding [23]. Meta-analysis suggests that pharmacotherapy coupled with either EVL or ESL showed better initial bleeding control and 5-day hemostasis but no effect on mortality [24]. Occasionally, bleeding from gastric varices and Roux en Y jejunal loop varices might be difficult to control and might require interventional measures such as transjugular intrahepatic portosystemic shunt (TIPSS), surgical shunts, and esophagogastric devascularization ± splenectomy [25]. Liver transplantation has to be offered to those with CLD, after control of the acute bleeding episode.

Prophylactic Therapy for Variceal Bleed

The American Association for the Study of Liver Diseases (AASLD) practice guidelines recommend β-blockers as first-line therapy in adults with medium/large esophageal varices and EVL for patients in whom β-blockers are contraindicated or poorly tolerated [26]. Trials on children showed that β-blockers and EVL/ESL are relatively safe to be used, but so far, there are no robust data to suggest that its use as primary prophylaxis decreases the incidence of first episode variceal bleed in children [27, 28]. Variceal eradication and nonselective beta-blocker are recommended in adults after an episode of bleed as secondary prophylaxis, while in children, small studies have shown usefulness of EVL/EST to prevent rebleed, but the role of beta-blocker is still unclear [29, 30].

Neurological Complications in Cirrhosis

CLD predisposes to a variety of neurological complications such as intracranial hemorrhage due to the presence of coagulopathy, increased risk of cerebral infection due to decreased immune function, and hepatic encephalopathy (HE) [31].

Hepatic Encephalopathy

HE is defined as a metabolically induced, potentially reversible, functional disturbance of the brain that may occur in acute or CLD [32]. Though HE is considered to be a potentially reversible condition, some patients might not recover to their previous level of cognitive function after a severe episode of HE.

Factors such as infection, trauma, and electrolyte imbalance in the background of CLD could cause sudden liver decompensation and lead to HE. Encephalopathy that occurs in acute liver failure (ALF) is categorized as type A, HE in portosystemic shunt without any intrinsic hepatocellular disease as type B, and in CLD as type C. Type C could be further subclassified into minimal, episodic, or persistent. HE is called minimal hepatic encephalopathy (MHE), when diagnosis could be made only on psychometric analysis in an apparently normal person with CLD. Episodic encephalopathy in CLD coincides with episodes of high protein intake, gastrointestinal bleed, infection, etc. Usually, these episodes resolve with the treatment of the precipitating factors, but sometimes they persist and are termed as persistent HE.

Clinical Features

HE could be clinically graded from 1 to 4 using West Haven criteria, and Glasgow coma scale which has lesser interobserver variability could be used in assessing conscious levels [33]. MHE is associated with mild intellectual impairment, where verbal ability is preserved and apparently normal personality [34]. Worsening of HE leads to asterixis (flapping tremor), hypertonia and hyperreflexia, hypotonia, and areflexia that may be seen with subsequent progression to coma. Features similar to Parkinsonism such as muscular rigidity, bradykinesia, hypokinesia, monotony of speech, and tremors could be seen in HE.

Pathogenesis of Hepatic Encephalopathy

The pathogenesis of HE is thought to be multifactorial, with neurotoxins and altered neurotransmitters acting on the neurons. Ammonia is considered to be an important factor

involved in pathogenesis, while mercaptans, short- and medium-chain fatty acids, phenols, methionine derivatives, etc. play a minor role, altering the ratio of excitatory (↓ dopamine and noradrenaline) and inhibitory (↑ gamma-aminobutyric acid (GABA) and serotonin) neurotransmitters resulting in abnormal cerebral function. Apart from these, there is an increased formation of false neurotransmitters such as octopamine, phenyl methionine from accumulation of phenylalanine, and tyrosine. There are other proposed mechanisms of HE such as an increase in false neurotransmitters (octopamine, phenyl methionine), altered ratios of branched-chain amino acids (BCAA) and aromatic amino acids (AAA), changes in postsynaptic receptor activity, increased permeability of blood–brain barrier, etc.

Role of Ammonia in HE

Ammonia is produced from a variety of sources such as the small intestine enterocytes, gut flora, muscle, and kidney. Under healthy condition, around 80–90% of ammonia is either converted to urea by periportal hepatocytes or glutamine by perivenous hepatocytes. Though ammonia is implicated in HE, the exact mechanism is still elusive. Few of the suggested mechanisms are as follows: (1) Excess ammonia is converted to glutamine by glial cells. This glutamine increases intracellular osmotic pressure, leading to swelling of astrocytes and cerebral edema, and can competitively bind to glutamate receptors and inhibit them. (2) Oxidative stress triggered by ammonia toxicity in the astrocyte resulting in mitochondrial dysfunction. (3) Enhanced cytokine activity and impaired intracellular signaling [35].

It was thought that ammonia in portal circulation was exclusively produced by the gut flora, but current hypothesis suggests that small gut enterocytes produce ammonia in excess of gut flora, and gut decontamination alone has minimal effect on ammonia levels [36]. The kidney is involved in both production and elimination of ammonia. The kidney can metabolize glutamine to produce ammonia and bicarbonate and can excrete ammonia as ammonium ion and urea in urine [35]. Alkalosis can decrease the conversion of ammonia to ammonium, as there is no need to excrete the hydrogen ion resulting in elevated free ammonia that can cross blood–brain barrier and precipitate HE. Myocytes can act as buffer by converting ammonia to nontoxic glutamine via glutamine synthetase, and thus poor muscle mass is an important risk factor for HE [37].

Role of Neurotoxins and Inflammatory Mediators in HE

The ratio of BCAA/AAA phenylalanine, tyrosine, and tryptophan is called the Fischer ratio [38, 39]. There is decrease in Fischer ratio in liver failure, due to preferential usage of BCAA by muscles and decreased clearance of AAA by liver. Elevated serum AAA can cross the blood–brain barrier into the brain and results in synthesis of false neurotransmitter such as octopamine and synephrine [40].

Several short-chain fatty acids such as propionate, butyrate, and valerate are produced in the small intestine through the breakdown of proteins by fecal flora [41]. These short-chain fatty acids competitively inhibit urea cycle enzymes and can bind to albumin and displacing albumin-bound toxins, thus precipitating HE. Indole, oxindole, endozepines, neuronal acetylcholinesterase, TNF-α, and allopregnanolone are few of the other bioactive substances that could play a role in HE [42–46].

Diagnosis

Diagnosis of encephalopathy is mainly based on clinical history and examination [47]. Clinical diagnosis of mild-to-moderate HE is difficult in children as it requires their cooperation to perform psychometric tests. Neuroimaging and electrophysiological studies of the brain would give supportive evidence rather than to confirm the diagnosis of HE. Though arterial ammonia level correlates with the severity of HE, it could not be used to grade encephalopathy [33]. HE could be clinically graded using West Haven criteria, and conscious level is graded using Glasgow coma scale [33].

Neuropsychological Assessment

In children, neuropsychological assessment should be made using tests such as Wechsler intelligence tests and Dutch child intelligence test (Revisie Amsterdamse Kinder Intelligentie test), where validated nomogram exists for the selected age, sex, racial, and ethnical subgroup. The Psychometric Hepatic Encephalopathy score (PHES) and number connect test (NCT) A and B could be used to diagnose MHE in adults while these tests are not validated in children [48, 49].

Critical Flicker Frequency

Critical flicker frequency threshold is a simple and reliable test for the quantification of low-grade HE [50]. The principle of the test is to identify the point of switch over from a steady red light to a flickering light. A normal human eye perceives flicker rate of 60 Hz as a steady light. The frequency of the light is gradually decreased to a point where the patient starts to perceive the light as flicker. Using this technique, it was found that patients with HE can pick up

flickering only when the flicker rate comes below 39 Hz, while cirrhotic counterparts without encephalopathy and normal individual could identify flickering at higher rate [47]. The need for understanding (and being able to follow instructions) the test limits is used only in children more than 8 years [51].

Electroencephalogram

Using electroencephalogram (EEG), HE could be graded into five grades (0–4). Grade 0 is a normal EEG with regular alpha rhythm. Grade 1 encephalopathy is characterized by irregular background alpha rhythm and appearance of theta rhythm. Theta activity becomes continuous with occasional delta wave in grade 2 HE, and theta activity becomes prevalent with transient polyphasic complexes of spikes and slow waves in grade 3. Grade 4 is deep coma, having continuous delta waves with abundant complexes of spikes and slow waves [47]. With the availability of newer complex EEG analytical softwares, EEG can be analyzed in specific regions of the brain.

Neuroimaging in HE

Computed tomography (CT) of the brain is not a useful tool in diagnosis of HE, apart from excluding organic causes such as bleed, tumors, or gross edema that can cause encephalopathy [52]. MRI is a better modality to diagnose cerebral edema and demyelination associated with HE. Conventional MRI lacks sensitivity in diagnosing milder forms of edema, and newer techniques such as magnetization transfer imaging (MTI), fast fluid-attenuated inversion recovery (FLAIR) imaging, and diffusion-weighted imaging are more sensitive in picking up brain tissue water content [53]. Proton MR spectroscopy could measure different levels of metabolites in the brain such as myo-inositol, choline, and glutamine. These specialized neuroimaging is more of research interest and provides little benefit in routine clinical practice.

Management of Hepatic Encephalopathy

Management should be directed toward stabilization of the patient and treating the precipitating factors such as bleeding, electrolyte imbalance, and infection. In HE of grade 3 or 4, elective intubation has to be considered to protect the airways. Despite increased total body water, these patients would be intravascularly fluid depleted. Hydration is best monitored by central venous pressure (CVP) and ideally should be 6–8 cm of H_2O. Though their serum sodium is low, they will have high total body sodium, and any attempt to normalize the sodium will lead to worsening of edema. Supplementation of extra sodium is required if the sodium level falls below 120 mEq/l [54].

Lactulose decreases the colonic pH to around 5, thereby decreasing the bacterial fermentation and production of short-chain fatty acids [55, 56]. In acidic environment, the ammonia produced in the colon is converted to ammonium ion, reducing its diffusibility back into circulation, and thereby removed along with stools. The amount of lactulose dose has to be titrated to produce three soft stools/day. Long-term lactulose in CLD helps to prevent HE but will not change the ultimate requirement of a liver transplantation. Lactitol (B galactosido-sorbitol) is a nonabsorbable sugar which has similar action to lactulose but less sweeter and more palatable [57].

Neomycin, vancomycin, and rifaximin are few of the antibiotics that are used to eliminate ammoniagenic bacteria from the gut, thereby decreasing the ammonia production in the intestine [58]. Of all the antibiotics, rifaximin has been shown to be very effective in decreasing ammonia production and has highest risk–benefit ratio. Rifaximin and lactulose given together were found to be more beneficial than either of them given alone [59]. The use of probiotics has shown to reduce plasma ammonia, but there was no change in final outcome [60].

L-ornithine-L-aspartate (LOLA) enhances the action of ornithine and aspartate transaminases in the brain and peripheral tissues to produce nontoxic glutamate. There is no standard dosing in children; up to 20 g/day could be given at an infusion rate not exceeding 5 g/h as suggested by drug monogram and not recommended in children less than 8 years old [54]. Sodium benzoate (250 mg/kg/day) along with intravenous sodium phenylacetate (250 mg/kg/day) or oral sodium phenylbutyrate (250 mg/kg/day) could be used to eliminate ammonia by alternate pathways, thereby decreasing serum ammonia levels. Water-soluble hippuric acid and phenylacetyl-glutamine are formed by conjugation of benzoate with glycine and phenyl acetate with glutamine, respectively. Hippuric acid and phenylacetyl-glutamine are then excreted by the kidneys, thereby reducing ammonia load [61]. Though all these medications are more useful in hyperammonemia due to urea cycle defects, they are used off-label in hyperammonemia due to liver failure [35].

There has been increasing interest in the possibility of providing an extracorporeal liver support system for short periods while liver allograft becomes available. High cost, nonavailability of small filters, and lack of safety data in children limit the usage of these devises to clinical trial setting. Liver transplantation has shown to be the definitive treatment, which has improved survival outcome both in adults and children. Elective liver transplantation offers 5-year survival of more than 85% in children. Synthetic liver failure with encephalopathy is one of the indications

for liver transplantation in CLD, which has to be done before permanent neurological damage sets in.

Ascites

Fluid retention and low albumin in CLD result in accumulation of fluid in extravascular space leading to edema, ascites, and plural effusion. Presence of ascites is one of the variables that increase the mortality in children with CLD [62]. Onset of ascites indicates decompensation of liver disease and the need for liver transplantation. Ascites increases the risk of bacterial peritonitis and HRS, which potentially adds on to the already increased mortality associated with liver decompensation (see Fig. 74.3).

Fig. 74.3 Image of a child with failed Kasai portoenterostomy showing gross ascites, dilated abdominal veins, and edema of legs

Pathophysiology of Ascites

There are several theories based on the triggering factor of the vicious cycle that leads to fluid retention and ascites. The "overfill" theory suggests hepatorenal reflex to be the primary event that leads to sodium and fluid retention and subsequently ascites. The "underfill" theory suggests that that the increased pressure in portal sinusoids results in increased hydrostatic pressure leading to excessive lymph production. When lymph production exceeds absorption, the net result is ascites and contraction of intravascular volume (underfill). "Peripheral arterial vasodilation hypothesis" which was proposed in 1988 suggests that splanchnic and peripheral arterial vasodilatation secondary to PHT and cirrhosis is the initial triggering event [63]. This causes decreased intravascular volume, leading to baroreceptor-mediated activation of renin–angiotensin–aldosterone system and release of antidiuretic hormone, resulting in hypervolemic stage due to renal sodium and water retention [63–65]. Splanchnic vasodilatation along with hypervolemia results in increased hydrostatic pressure that ultimately results in passage of fluid to the peritoneal space [66]. It is difficult to explain the complex cascade of events leading to ascites based on one theory, and it is possible that mechanisms as suggested by different theories could contribute to various stages of ascites formation.

Biochemical Diagnosis

Ascitic tap should be carried out in any new-onset ascites. Estimating serum–ascites albumin gradient (SAAG) is considered to be superior in making differential diagnosis of probable cause of ascites, compared to quantifying it as exudate or transudate. SAAG $\geq$ 1.1 g/dL is associated with cirrhosis, portal or hepatic venous occlusion, congestive cardiac failure, etc., while SAAG < 1.1 g/dL is associated with nephrotic syndrome, peritoneal infection, or malignancy [67]. Spontaneous bacterial peritonitis is an important complication of ascites and has to be differentiated from surgical cause of peritonitis such as perforation which accounts for 5% of cases [68]. Polymorphonuclear neutrophils (PMNs) of >250 mm^3 in ascitic fluid are suggestive of the presence of bacterial infection while predominant lymphocytic cells in ascites (>20% of the total leukocyte count) along with ascites–blood glucose quotient of <0.7 is suggestive of tuberculous infection. In the case of high PMNs in ascitic fluid with symptoms of fever and abdominal tenderness, antibiotics need to be continued even if the cultures are negative as 34.5% turn culture positive on repeated samples.

Management

Optimizing caloric and protein intake helps improving serum albumin and thus oncotic pressure. Diuretic therapy remains the first line of treatment in ascites. Aldosterone antagonist, spironolactone, is the initial drug of choice. It is usually started at 3 mg/kg/day in three to four divided doses and could be gradually increased to 6 mg/kg/day (maximum dose 400 mg/day). Potent loop diuretics such as furosemide (1–2 mg/kg) could be added if there is no effective diuresis on monotherapy. Spironolactone causes hyperkalemia while furosemide causes hyponatremia and hypokalemia, which has to be monitored on a regular basis. Sometimes duel therapy with these drugs is beneficial as potassium loss by furosemide is counteracted by potassium conservation by spironolactone. The suggested optimal drug dosage ratio to achieve this is 2 (furosemide):5 (spironolactone). Tolvaptan is an oral vasopressin receptor antagonist that helps in free water excretion and corrects hyponatremia, and it has been approved by the US Food and Drug Administration (FDA) for use in adults with cirrhosis. It is currently under phase three trials for its safety in children.

Paracentesis is indicated in the case of tense ascites causing respiratory distress. Usually, 20% albumin at a dose of 5 ml/kg is given slowly over 2 h during the procedure as plasma expander as well as to prevent rapid reaccumulation of ascites. It is shown that children tolerate large-volume paracentesis (>50 ml/kg) well, and the noticed side effect such as reduced urine output responded well to volume expanders [69]. It is advisable to taut the skin at the point of needle entry to create "Z," so that normal skin covers the muscle puncture site, preventing post-procedure leak.

Pulmonary Complications in Cirrhosis

The common pulmonary complications of CLD are HPS, portopulmonary hypertension (PoPH), and pulmonary hydrothorax. Care should be taken to exclude intrinsic lung diseases such as alpha-1-antitrypsin (AIAT) deficiency and cystic fibrosis that could coexist with liver disease and contribute toward hypoxia.

Hepatopulmonary Syndrome

Kennedy and Knudson coined the term "HPS" in 1977 to describe the association of cirrhosis with cyanosis and clubbing. The diagnostic criteria for HPS is the presence of CLD along with $PaO_2 < 70$ mmHg or alveolar-arterial oxygen gradient >15 mmHg and intrapulmonary vascular dilatation [70]. The overall prevalence of HPS ranges from 4% to 30% in cirrhotics. Suggested prevalence of HPS in pediatric population with CLD is around 8–20% [71, 72].

Pathogenesis

Higher prevalence of HPS in disorders where there is intrinsic liver disease along with PHT such as biliary atresia rather than in condition with PHT alone such as portal vein thrombosis led to the hypothesis that PHT along with intrinsic liver disease is essential for the development of HPS [52, 73, 74]. HPS is probably due to the effect of several vasoactive substances such as NO [17], carbon monoxide (CO), prostaglandins, vasoactive intestinal peptide, calcitonin, and glucagon, which escapes liver metabolism due to PHT and acts on pulmonary vasculature. NO is a potent vasodilator, and its nitrates and nitrite metabolites are found to be high in exhaled air of patients with HPS, which normalizes after liver transplantation. NO synthase is an enzyme that helps in production of NO from L-arginine. It has several isoforms of which eNOS was found to be increased in pulmonary small alveolar vessels, in small animal models of HPS. Elevated levels of ET-1 in blood and increased expression of its receptor ET B (ETB) expression in the pulmonary vasculature result in increased eNOS synthesis and thus vasodilatation [75]. Apart from eNOS, TNF-α, IL-1β, carbon monoxide, etc. are some of the other vasoactive substances implicated in pathogenesis of HPS [76–78]. These substances were thought to be involved in angiogenesis and vasodilatation of pulmonary vasculature leading to portopulmonary and hepatopulmonary shunts. In lung areas where there are capillary dilations, there would be more of perfusion compared to ventilation, while in areas with shunting effect, the blood is diverted away from alveoli resulting in less perfusion, leading to ventilation perfusion mismatch. Due to this, 100% oxygen inhalation might improve PaO_2 in cases of HPS with predominant intrapulmonary vascular dilatation, while there won't be any change in those with predominant shunt.

Clinical Manifestation

Dyspnea, clubbing, cyanosis, and spider nevi are some of the clinical manifestations of HPS. In HPS, dyspnea is more on upright position, due to increased congestion because of gravity exaggerating the ventilation—perfusion mismatch. PaO_2 decrease of 5% or more or 4 mmHg or more from the supine to upright position is defined as orthodeoxia, which is the hallmark of HPS [79]. Clubbing, also described as drumstick fingers (Fig. 74.4) seen in HPS, is due to the release of PDGF in nail beds that acts as growth factor and causes bulbous swelling of nail beds [80].

Fig. 74.4 Shows clubbing of fingers in a 10-month-old child with chronic liver disease due to missed biliary atresia

3. AV Shunt
4. Pulmonary vein

Fig. 74.5 Pulmonary angiogram showing AV Shunt

Diagnosis

In cirrhotic patients with hypoxia on arterial blood gas analysis, chest X-ray has to be taken as first line to rule out other causes of hypoxia such as pulmonary atelectasis, pneumonia, pulmonary edema, or hepatic hydrothorax. X-ray would be normal in majority of patients with HPS, but few might show interstitial infiltrate in the lung bases [81]. Based on ABG analysis in room air, severity of HPS could be graded as mild ($PaO_2 \geq 80$ mmHg), moderate ($PaO_2 = 60–79$ mmHg), severe ($PaO_2 = 50–59$ mmHg), and very severe ($PaO_2 < 50$ mmHg) [115].

Contrast-enhanced echocardiography is the preferred screening test for HPS [75]. Saline or indocyanine green is agitated to produce microbubbles at least 15 μm in diameter and then injected intravenously. These microbubbles act as contrast and could be visualized in echocardiography on the right side of the heart. When these microbubbles traverse the lung, they get trapped in alveolar microvasculature and gradually absorbed. In individuals with either intracardiac or intrapulmonary shunts, these microbubbles could be seen in the left heart. Differentiation between intracardiac or intrapulmonary shunts depends on the timing of appearance of microbubbles in the left heart. With intracardiac shunts, the microbubbles appear in three heartbeats, while with intrapulmonary shunts, it takes 4–6 heartbeats for the contrast to appear in the left side of the heart. Though contrast echocardiography is sensitive, it lacks specificity, as some cirrhotic patients with positive results on contrast echocardiography might not fulfill the diagnostic criteria for HPS [75].

If the initial screening raises the possibility of HPS, technetium-99 m macroaggregated albumin (Tc-99 m MAA) lung perfusion scan has to be considered, which is more sensitive and specific [70, 82]. Macroaggregated albumin, which is of 20 μm in size, is tagged with radioisotope technetium. In normal individuals, macroaggregated albumin gets trapped in the lung, and less than 5% of tracer activity can be quantified in the brain. In HPS patients, the fraction is more than 6%. Using this technique, the magnitude of shunt can be quantified which is inversely proportional to arterial oxygen saturation [70]. The drawback of this procedure is that correlation between shunt fraction and response of PaO_2 after 100% oxygen supplement remains unpredictable. High-resolution CT could show increased ratio of segmental arterial diameter to adjacent bronchial diameter, but published data were quite scarce [83]. Selective pulmonary angiography along with possible embolotherapy has to be considered in patients with HPS who fail to respond to 100% oxygen and particularly in those whom liver transplantation has to be considered. Angiography could reveal two types of vascular pattern, diffuse (type 1) and focal (type 2). In type 1 HPS, diffuse speckled, spidery, or sponge-like appearance of vasodilated vessels may be demonstrated. Type 1 was considered to be of better prognosis with liver transplantation as there is high possibility of resolution of HPS [84]. In type 2 HPS, vascular changes resembling arteriovenous (AV) shunts or vascular malformations could be seen. Figure 74.5 shows a discrete arteriovenous shunt in a child with HPS. If amicable, embolization of feeding vessel could be done before considering liver transplantation [85, 86].

Management

Oxygen supplementation remains the mainstay in HPS patients when $PaO_2 < 60$, and it improves the quality of life and exercise tolerance [87], but the usefulness of supplemental oxygen would wane away as HPS is a progressive disease. Several medications such as indomethacin, tamoxifen, somatostatin analogues, sympathomimetics, beta-blockers, methylene blue, and plasma exchange have been tried in HPS with abysmal results. Martinez-Palli et al. showed that decreasing PHT using TIPSS had no effect on pulmonary gas exchange and thus is not recommended [88]. Severity of HPS correlates with mortality, and so it should be combined with the model for end-stage liver disease (MELD) score as to prioritize these patients are in organ allocation [89, 90]. Liver transplantation is considered to be the definitive treatment in HPS patients as it reverts the pulmonary capillary abnormality and normalizes oxygenation [91]. Overall, postoperative complications in patients with HPS are higher than those without HPS. Embolic cerebral hemorrhage, worsening of hypoxia, and failure of AV shunts to resolve (particularly type 2) are a few of the unique complications of HPS [85, 92]. Careful patient selection is essential as severe preoperative hypoxemia ($PaO_2 < 50$ mmHg in room air) and significant intrapulmonary shunting (Tc-99 m MAA shunt fraction >20%) are associated with high mortality after liver transplantation [93]. Practical management protocol of hepatopulmonary syndrome during posttransplant (Tx) period is outlined in Fig. 74.6.

Portopulmonary Hypertension

PoPH is defined as the presence of mean pulmonary artery pressure (MPAP) > 25 mmHg along with pulmonary vascular resistance (PVR) > 240 dynes s cm^{-5} with normal capillary wedge pressure (PCWP) < 15 mmHg, in the presence of PHT [94]. It is postulated that the toxins and bioactive substances that bypasses liver metabolism via varices in PHT could lead to pulmonary vasoconstriction, structural remodeling of the

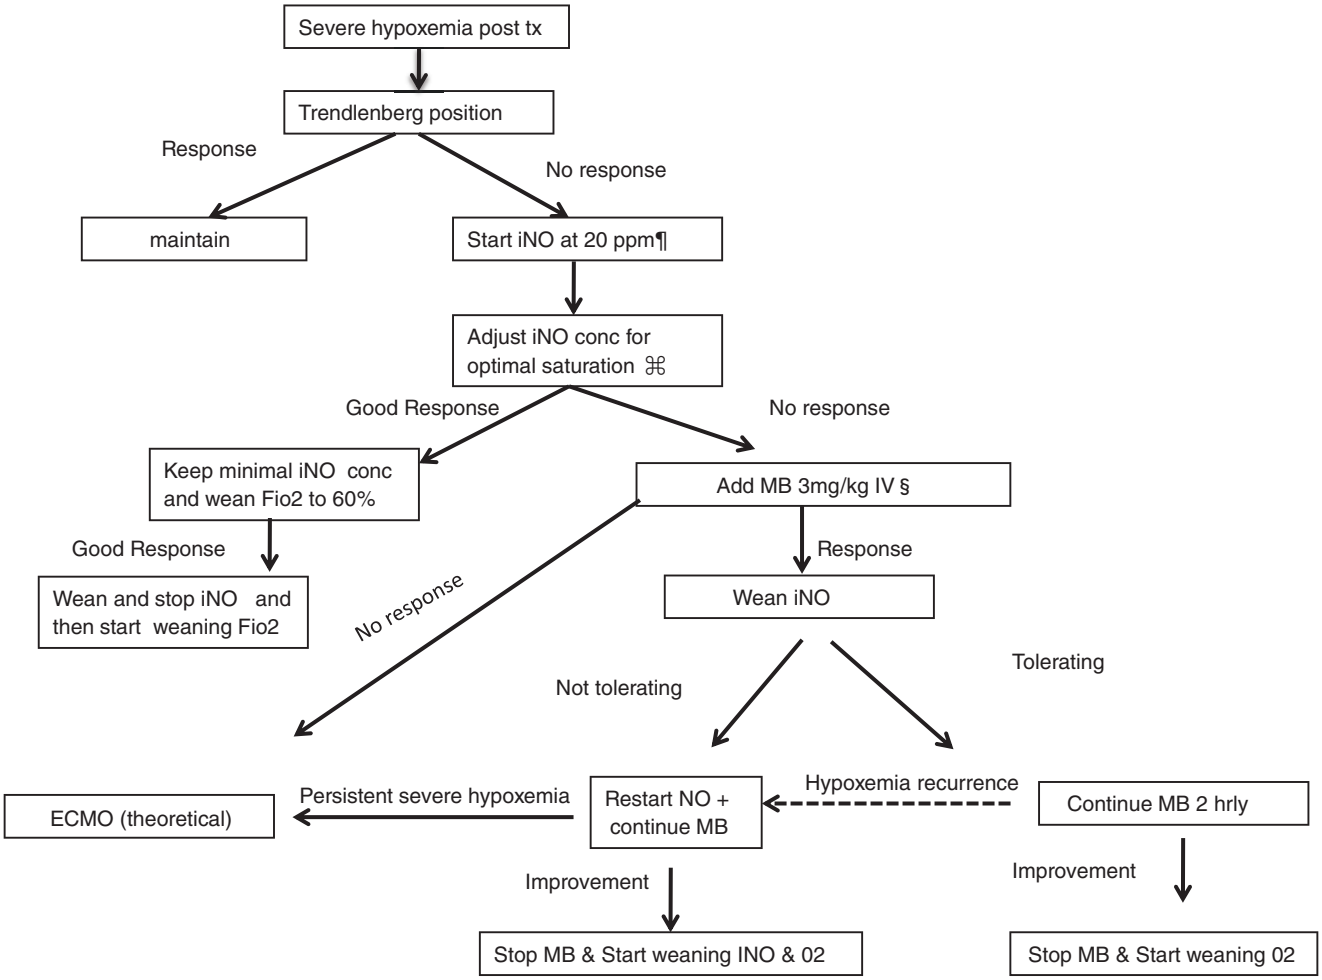

Fig. 74.6 Practical management protocol of hepatopulmonary syndrome during post transplant period. (Image barrowed with permission from Springer – License Number 4902070483558. Sundaram et al. [116])

pulmonary arteries, formation of microthrombi, etc. along with high flow state [95]. PHT seems to be a prerequisite as PoPH is seen in disorders with no intrinsic liver disease such as extrahepatic portal vein thrombosis [96]. The histopathological changes in PoPH consist of medial hypertrophy with nonspecific intimal fibrous thickening along with fibrous mural pads and occlusive fibrous tissue in vascular lumens, which is similar to that of primary pulmonary hypertension [53].

Clinical Features

The most common presenting symptom is dyspnea on excretion followed by syncope, chest pain, and fatigue [97]. Sometimes it is associated with hemoptysis. In mild-to-moderate PoPH, the symptoms are mild or absent. The time interval between diagnosis of PHT and symptoms due to PoPH is around 5 years [98]. Clinical examination would reveal systolic murmur with loud pulmonary component of second heart sound indicating tricuspid regurgitation. Edema and ascites (features of right heart failure) are other clinical features.

Diagnosis

Diagnosis of PoPH is made based on the presence of pulmonary hypertension in the background liver disease. Chest X-ray might show prominent central pulmonary arteries and cardiomegaly, and electrocardiogram might show right ventricular strain pattern. Estimated right ventricular systolic pressure >50 mmHg (normal <30 mmHg) is strongly suggestive of PoPH, when assessed by Doppler echocardiography, but has a false-positive rate of around 15% [94]. Right heart catheterization study remains the gold standard test for accurately diagnosing pulmonary hypertension and could be classified into mild, moderate, and severe based on MPAP, PVR, and cardiac index [94].

Management

Three groups of drugs, namely, prostacyclin analogues (epoprostenol, iloprost), ET receptor antagonists (bosentan), and phosphodiesterase inhibitors (sildenafil), have been used with good response in children with primary pulmonary hypertension, and the data on its usage in children PoPH are sparse [99]. Continuous intravenous infusion of epoprostenol (30–90 ng/kg/min) improves circulatory hemodynamics and exercise capacity in children with PoPH [99]. Treprostinil is another prostacyclin analogue, which could be given either subcutaneously or intravenously [100]. Bosentan is an ET receptor antagonist which when used in children has shown to decrease MPAP and pulmonary vascular resistance index and improve cardiac index [101]. Sildenafil is a phosphodiesterase-5 inhibitors and causes vasodilatation of pulmonary arteries and thereby decreases pulmonary hypertension when given at a dose of 0.5–1 mg/kg/dose given three to four times [99]. Mild-to-moderate PoPH frequently resolves after liver transplantation while severe PoPH is associated with the persistence of pulmonary hypertension and increased mortality [94].

Renal Involvement in Cirrhosis

Renal decompensation in liver disease is an important complication of both acute and CLD. The kidneys could be affected as a part of generalized circulatory changes associated liver disease (e.g., hypovolemia after variceal bleed) or as a specific phenomenon that occurs only in liver disease (e.g., hepatorenal syndrome). Renal involvement in liver disease has to be identified at the earliest and treated appropriately as progressive renal failure in liver disease is an adverse prognostic factor [102].

Hepatorenal Syndrome

HRS is a progressive, reversible functional renal impairment that occurs in patients with advanced liver cirrhosis or those with fulminant hepatic failure. Diagnostic criteria of HRS are outlined in Table 74.4. Type 1 HRS is characterized by rapid progression of renal failure and has a precipitating factor in most cases. It is associated with rapidly declining urine output and increasing creatinine in less than 2 weeks' duration. Type 1 HRS occurs in the setting of an acute deterioration of circulatory function (arterial hypotension and activation of the endogenous vasoconstrictor systems) and is frequently associated with rapid impairment in liver function and encephalopathy, carrying a poor prognosis. Type 2 HRS is characterized by a moderate renal failure, which follows a steady or slowly progressive course. It appears spontaneously in most cases and frequently associated with refractory ascites.

Pathophysiology

The hallmark of HRS is renal vasoconstriction, which progresses with worsening liver disease. The renal cortical blood flow has been documented to be reduced in HRS using selective renal arteriography and xenon-113 studies, but the underlying mechanisms involved in HRS are incompletely understood [103, 104]. Four pathways have been implicated in the pathophysiology of HRS.

Table 74.4 Six major criteria, all of which are necessary for the diagnosis of hepatorenal syndrome, and five additional criteria, which are usually associated with hepatorenal syndrome but are not required for diagnosis

Diagnostic criteria for hepatorenal syndrome[a]
The six major criteria are as follows
1. Presence of cirrhosis and ascites
2. Serum creatinine >1.5 mg/dL (133 μmol/L) or 24 h creatinine clearance of less than 40 mL/min
3. No improvement of serum creatinine (creatinine level £ 1.5 mg/dL or clearance >40 mL/min) after at least 48 h of diuretic withdrawal and volume expansion with albumin
4. Absence of shock, ongoing bacterial infection, fluid loss, or current or recent treatment with nephrotoxic medications
5. Absence of parenchymal kidney disease as indicated by proteinuria >500 mg/day
6. Absence of any evidence of obstructive uropathy on renal ultrasound scanning
The five additional criteria are as follows
Urine volume of less than 500 mL/d
Urine sodium concentration of less than 10 mEq/L
Urine osmolality greater than plasma osmolality
Urine RBC count of less than 50 per high-power field
Serum sodium concentration of less than 130 mEq/L

[a]As defined by the International Ascites Club

1. Peripheral and splanchnic vasodilation secondary to increased production of vasodilatory amines leading to activation of renin–angiotensin system in the kidneys, thereby reducing urine output.
2. Sympathetic nervous system activation leading to possible hepatorenal reflex.
3. Cardiac dysfunction contributing to renal hypoperfusion.
4. Action of cytokines and vasoactive mediators on renal circulation leading to the loss of renal autoregulation mechanisms may also play a role in the development of HRS.

Clinical presentation The incidence of HRS in patients with cirrhosis and ascites is 20% in the 1st year and 39% within 5 years. The rapidity and severity of renal failure at presentation depend on the type of HRS. Type 1 HRS is preceded by a precipitating factor in 70% of cases. The most common precipitating events are spontaneous bacterial peritonitis, large-volume paracentesis without volume replacement, gastrointestinal hemorrhage, and sepsis. These patients have many of the features present with advanced liver disease, in addition to renal dysfunction. These patients may also have underlying ascites, which are refractory to diuretic therapy. The findings in acute azotemia in patients with liver disease are given in Table 74.5.

Table 74.5 Features to differentiate prerenal azotemia, acute tubular necrosis, and hepatorenal syndrome

Differentiating hepatorenal syndrome from other causes of renal failure			
	Hepatorenal syndrome	Prerenal azotemia	Acute tubular necrosis
Urinary sodium concentration	<10 mEq/L	<10 mEq/L	<10 mEq/L
Urine plasma creatinine	>30:1	>30:1	<20:1
Urine osmolality	>Plasma osmolality	>Plasma osmolality	Equal to plasma osmolality
Fractional excretion of sodium	<1%	<1%	>2%
Urinary sediment	Normal	Normal	Casts, debris
Response to volume expansion	Brief or no diuresis	Sustained diuresis	No diuresis

Management

There is no proven effective therapy for HRS except liver transplantation. The general principles include treating precipitating factors and avoiding agents and factors, which can precipitate HRS. In cases of tense ascites, abdominal paracentesis done in conjunction with albumin replacement to avoid circulatory dysfunction has been proved to be safe [105]. Systemic vasoconstrictors including vasopressin analogues (terlipressin and ornipressin), somatostatin analogue (octreotide), and alpha-adrenergic agonists (midodrine and norepinephrine) are helpful in managing HRS. Studies have shown in adults that terlipressin when used alone or with albumin has higher efficacy in reversing the renal function in patients with HRS [106].

Portosystemic shunts such as TIPSS placement in adults have been shown to improve renal function. The mechanism by which TIPSS exerts this effect is still speculative but could be the result of reduction of portal pressure, suppression of a putative hepatorenal reflex, improvement of the circulating volume, or amelioration of cardiac function. Renal replacement therapy is indicated for those who failed to respond to vasoconstrictors, TIPSS, intractable metabolic acidosis, hyperkalemia, and volume overload and those who are waiting for a liver transplant.

Liver transplantation is the definitive treatment for patients with HRS, as it corrects liver dysfunction and eliminates PHT [30, 107]. Shusterman et al. showed that in 77% of those with HRS, serum creatinine levels decreased to less than 1.5 mg/dL after liver transplantation, and at 3 months post liver transplantation, none of the patients required dialysis [30, 107].

Other System Involvement in Cirrhosis

Pruritus is one of the most debilitating complications of CLD that affects the quality of life. Grading of pruritus and medical management is outlined in Table 74.6. Severe pruritus that does not respond to medical management per se is an indication for liver transplantation. Cardiac dysfunction in CLD is a discrete phenomenon called cirrhotic cardiomyopathy, and it is associated with all or some of following changes: (1) baseline increased cardiac output but blunted ventricular response to stimuli, (2) systolic and/or diastolic dysfunction, (3) the absence of overt left ventricular failure at rest, and (4) electrophysiological abnormalities including prolonged QT interval on electrocardiography and chronotropic incompetence [108]. Altered cardiac muscle membrane properties, impairment of stimulatory β-adrenergic receptor signaling pathways, and overactive negative inotropic factors are some of the factors implicated in pathogenesis of cirrhotic cardiomyopathy [109]. In a cohort of 40 children with median age of 8 months awaiting liver transplantation, Desai et al. showed that 27 (74%) had cirrhotic cardiomyopathy [110]. Liver transplantation remains the only curative therapy in most of the patients [110].

Increased caloric needs, decreased absorption due to cholestasis, and poor appetite contribute to undernutrition in CLD. Bone disease with both the components of osteoporosis and osteomalacia in CLD is termed as hepatic osteodystrophy (HO) [111]. The pathogenesis of HO is considered to be multifactorial due to complex interaction of IGF-1 deficiency, vitamin D and K deficiency, hypogonadism, etc., on growth and differentiation of bones in the background of hyperbilirubinemia [112]. The reported prevalence of fractures due to HO in children is around 10–13% [112]. Regular bone mineral density by dual-energy X-ray absorptiometry scan (DEXA) and monitoring serum 25-hydroxy vitamin D (25OHD) levels help in early detection and treatment of deficiency states. Routine supplementation of vitamin D at a dose of 3–10 times the recommended daily allowance has been suggested [60]. The recommended form of vitamin D for both prophylaxis and treatment is either ergocalciferol (vitamin D2) or cholecalciferol (vitamin D3) targeting a 25OHD level of more than 50 nmol/L. Bisphosphonate therapy is indicated only in the presence of low-impact fractures (≥1 vertebral, or ≥1 lower limb, or ≥2 upper limb) along with low bone mineral density (BMD) [113].

Table 74.6 Though grading is very subjective, it helps in comparing the symptomatic improvement to therapy

Grading and medical management of pruritus
Grade 1: no pruritus
Grade 2: mild scratching, but can be distracted
Grade 3: active scratching without abrasion
Grade 4: active scratching with abrasions
Grade 5: taneous mutilation with bleeding/scarring
Ursodeoxycholic acid (10 mg/kg twice a day)
Rifampicin (4–10 mg/kg/day)
Phenobarbitone (15–45 mg/day)
Naltrexone (0.1–0.5 mg/kg)
Ondansetron (0.1 mg/kg/three times a day to max 4 mg/dose)
Cholestyramine (1/3 to 1 sachet three times a day)

Prognosis

MELD is a scoring system developed to predict death within 3 months of surgery in patients who had undergone a TIPSS procedure and was subsequently found to be useful in determining prognosis in patients with CLD due to other etiologies. MELD is calculated using serum bilirubin, serum creatinine, and international normalized ratio (INR). A value of 40 or more is associated with 71% mortality in 3 months, while a value of less than 9 is associated mere 1.9% mortality. MELD is used in the USA and European countries in prioritizing CLD patients for liver transplantation. In children under 12 years of age, pediatric end-stage liver disease (PELD) score is used for prognostication where age less than 1 year and growth failure are also taken into consideration. Though many countries use PELD to prioritize children in waiting list, it has its own limitations. PELD score does not take into consideration complications such as cholangitis, severe PHT, pulmonary hypertension, and HPS and could underestimate the risk of death [17].

Conclusions

Cirrhosis secondarily affects nearly every system in the body, where the correlation might or might not be proportional to the severity of liver disease. Apart from managing complications of cirrhosis, it is essential to take care of the general well-being of these children such as growth monitoring, immunization, vitamin supplementation, and their education. Though the functionality of end organs (brain, kidney, lungs, etc.) could revert back to normal or near normal after liver transplantation, advanced end organ damage might render a patient unfit to undergo liver transplantation. Anticipation of the complication and timely intervention would help in better outcome in these children.

Nutritional Management of Children with Liver Disease

75

Sara Mancell

Introduction

The liver is the key organ in the production and distribution of nutrients, playing a central role in glucose homeostasis, protein synthesis, bile salt production, lipid metabolism and vitamin storage. Chronic liver disease can disrupt these processes leading to malnutrition. Malnutrition is highly prevalent in children with liver disease and is associated with increased morbidity and mortality [1]. Potential causes of malnutrition include insufficient nutrient intake, increased nutritional requirements, impaired nutrient absorption and altered metabolism. Nutrition strategies are centred on managing these factors while promoting normal growth and development. Maintaining optimal nutrition in children with chronic liver disease may prevent further liver damage and improve outcomes post-transplant [2].

In acute liver disease, if the presentation is rapid, children may be well nourished initially. The aim is to preserve nutritional status and manage complications such as hypoglycaemia and hyperammonaemia.

The nutrition management of liver disease caused by inborn errors of metabolism does not form part of this chapter.

Dietary Assessment

The nutritional assessment and monitoring of patients with liver disease is essential, in order to assess requirements as well as to evaluate progress. A dietetic assessment should include the current situation and relevant history. It should be carried out at regular intervals to take account of changes in clinical status, nutrient intake, social factors, activity levels and anthropometry (Table 75.1).

Table 75.1 Anthropometric measurements

Height	Good indicator of long-term nutritional status <2 years = measure using a length board >2 years = measure using a stadiometer
Weight	Good indicator of short-term nutritional status Affected by organomegaly/ascites. Weigh infants naked and older children with no shoes and light clothing
Abdominal girth	Useful adjunct where there is organomegaly/ascites, especially where weights are fluctuating
Head circumference	Good indicator of long-term nutritional status Only used in children under 2 years
Mid upper arm circumference (MUAC)	Good indicator of short-term nutritional status Measure the same arm each time High inter-observer error so use a single observer ideally
Triceps skinfold thickness (TSF)	Good marker of medium- to long-term nutritional status Practically difficult unless the child is cooperative High inter-observer error so use a single observer ideally

Nutritional Management of Chronic Liver Disease

The causes of malnutrition may be multifactorial (Fig. 75.1). Nutrition strategies are focused on each of these areas.

Decreased Nutrient Intake

Poor intake of nutrients may be due to the following:

- Nausea and vomiting
- Pruritis
- Taste changes associated with medications

e-mail: sara.mancell@nhs.net

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_75

- Unpalatable diets/specialist feeds
- Reduced gastric capacity and discomfort from ascites or organomegaly
- Behavioural feeding difficulties
- Fluid and sodium restriction due to ascites
- Investigations and procedures interrupting meals or feeds
- Anorexia

Feeding strategies should take into account the causes of poor nutrient intake which may be multifactorial. When oral intake is significantly reduced because of persistent nausea or vomiting or the discomfort of pruritis or unpalatable feeds, supplemental tube feeding may be required. This can be given during the day as bolus feeds and/or as a continuous overnight infusion. Where there is ascites or organomegaly, high energy, low volume feeds may help with the problem of reduced gastric capacity. With ascites, a rigid sodium restriction is not recommended, but rather a general reduction is salty foods. In hospitals, extended periods of nil by mouth and feeding interruptions due to investigations and procedures should be kept to a minimum, and every effort should be made to make mealtimes enjoyable.

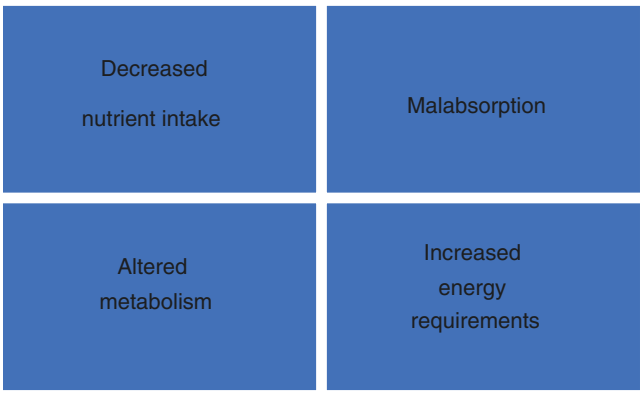

Fig. 75.1 Causes of malnutrition in liver disease

Malabsorption

Malabsorption in chronic liver disease may result in poor growth and fat-soluble vitamin deficiency and may be due to the following:

- Absent or reduced bile flow
- Pancreatic insufficiency
- Portal hypertension causing mucosal oedema

Long-chain triglycerides require emulsification by bile in the intestine, and therefore the absence or reduction of bile flow may lead to fat malabsorption. An energy-dense diet is given combined with medium-chain triglyceride (MCT) supplementation. MCTs do not require emulsification with bile, diffusing easily into the intestinal cells where they are absorbed directly into the bloodstream. There is little evidence regarding how much dietary fat should be MCT with recommendations varying between 30% and 75% [1, 2]. Table 75.2 shows commonly used formulas, feeds and supplements containing MCT.

In some types of liver disease such as Alagille's syndrome, malabsorption may result from pancreatic enzyme

Table 75.2 Formulas, feeds and supplements containing medium-chain triglycerides

Feed per 100 ml	Age (years)/ weight	Dilution (%)	Energy (Kcal)	Protein (g)	Carbohydrate (g)	Fat (g)	Protein type	MCT (%)	Comments
Heparon Junior®	0–3 y	18	86	2	11.6	3.6	Whole	49	Supplemented with BCAA

Liquigen	From birth	n/a	450	0	0	50	n/a	96	Not a complete source of nutrition
MCT Procal (per 100 g)	>3 y	n/a	703	12.2	0	63.5	Whole	96	Not a complete source of nutrition

insufficiency [3] and supplementation with pancreatic enzymes may be required. Inflammation and mucosal oedema in the small bowel due to portal hypertension may cause protein malabsorption [4] necessitating a change to a feed with hydrolysed protein.

Altered Metabolism

As liver failure progresses, the metabolism of carbohydrate, protein and fat may be altered. There is a reduction in glycogen storage and an increased breakdown of fat and protein to meet energy demands alongside inefficient use of the substrates which are available [5]. Mager et al. [6] showed that there is increased oxidation and therefore an increased requirement for branched chain amino acids (BCAA) even in children with relatively mild liver disease. The result of these changes is wasting of fat and lean body mass, hypoglycaemia, hypoproteinaemia and hyperammonaemia [7], and dietary strategies are centred on reversing or preventing these.

Preserving Lean Body Mass

To minimise catabolism, periods of fasting should be limited so that an exogenous supply of nutrients is used in preference to body fat and muscle stores. This can be achieved by giving feeds or meals more frequently or using a feeding pump for continuous feeding. Chin et al. [8] found that supplementation with BCAAs (valine, leucine, isoleucine) may help to improve nutritional status in liver disease, although the evidence for this is limited.

Hypoglycaemia

Where there is hypoglycaemia, the amount of carbohydrates or the times that they are given may need to be adjusted. The carbohydrate content of formulas can be increased by adjusting the concentration of powdered formulas, using a high energy feed or adding glucose polymers (Table 75.4). In older children, the inclusion of starchy carbohydrates and bedtime snacks may be necessary. Intravenous dextrose and close monitoring of blood sugars may be required, especially during periods of fasting or illness.

Hyperammonaemia

A major site of ammonia production is the large intestine, where protein is broken down by bacteria to produce ammonia. Ammonia is converted to urea in the liver, which is then excreted by the kidneys. In liver failure, this process is disrupted resulting in accumulation of ammonia in the blood. Exposure of brain tissue to toxic levels of ammonia leads to hepatic encephalopathy. A dietary protein restriction may be required for the first 24–48 hours [9], but a prolonged protein restriction may worsen catabolism, resulting in reduced muscle mass. This may further worsen hyperammonaemia as muscle is an important site of ammonia uptake.

Increased Energy Requirements

Children with end-stage liver disease may have increased requirements due to the following:

- Stress factors such as infection
- Increased respiratory effort from ascites or organomegaly
- Increased metabolically active cells mass

Greer et al. [10] found that resting energy expenditure (REE) was almost 30% higher than controls and suggested that this was because children with end-stage liver disease have less body fat and a higher relative proportion of metabolically active cells. In contrast, Kyrana et al. [11] found that there was no difference in REE between children with end-stage liver disease and healthy controls and recommended individualised assessments of REE rather than assuming hypermetabolism. Unfortunately, measurements of REE are often impractical in the clinical setting. Given the possibility of an increased REE combined with malabsorption, estimated energy and protein requirements for children with chronic liver disease are high (Table 75.3). Requirements are calculated based on the individual, taking into account age, sex, nutritional status, disease state and growth. Calculated requirements are used only as a guide and are not static; they should be re-calculated as part of the dietary assessment.

There are several methods for increasing the nutrient density of the diet to achieve high energy and protein requirements, including concentrating powder-based feeds, using nutrient-dense feeds and supplements and encouraging high energy/protein meals and snacks (Table 75.4).

Table 75.3 Energy and protein requirements used in practice for children with chronic liver disease

	Infants	Older children
Energy	120–150 kcal/kg	130–150% of the estimated average requirement for age
Protein	3–4 g/kg	130–150% of the recommended nutrient intake

Table 75.4 Strategies to increase energy and protein intake

Concentrating feeds	The concentration of a powder-based formula is increased beyond the recommended dilution, usually in 2% increments e.g. Heparon Junior® 18% = 86 kcal, 22% = 106 kcal/100 ml This also increases micro/macro-nutrients, renal solute load, osmolality, risk of osmotic diarrhoea Explicit instructions needed to avoid preparation errors (usually provided by a registered dietitian)
Nutrient-dense feeds and supplements	Nutrient-dense feeds/supplements orally or via tube Where non-protein energy sources (glucose polymers, fats) are added to the diet, care should be taken to maintain an acceptable protein-energy ratio
Nutrient-dense meals and snacks	High energy/high protein foods e.g. cream, avocado, nuts, nut butters, cheese, butter, oil

Table 75.5 Fat-soluble vitamin supplementation

Vitamins	
Multivitamin (including A and D)	<1 year: Abidec or Dalivit 0.6 ml >1 year: Abidec or Dalivit 1.2 ml >12 years: Forceval 1 capsule
D	1–12 months: Colecalciferol 1000 IU (maximum 3000 IU/day) 1–12 years: Colecalciferol 6000 IU in solution or 6400 IU if able to swallow capsules (maximum 25,000 IU/day) >12 years: Colecalciferol 9600 IU daily (maximum 40,000 IU daily)
E	0–12 years: Alpha tocopheryl 10 mg/kg up to 100 mg/kg (maximum 200 mg/kg per day) >12 years: Alpha tocopheryl 286 mg (maximum 200 mg/kg/day)
K	<1 year: Phytomenadione 1 mg 1–5 years: Phytomenadione 2 mg 5–12 years: Menadiol tablets 5 mg >12 years: Menadiol tablets 10 mg

Fat-Soluble Vitamin Supplementation

Table 75.5 shows how fat-soluble vitamins are supplemented for cholestasis at the author's institution. It should be noted that these are suggested starting doses, and prescribed amounts should be adjusted according to serum levels of fat-soluble vitamins. If serum vitamin levels are particularly low, they may be given intra-muscularly.

Methods of Feeding

Oral Feeding

All children should be encouraged to feed orally where possible. Behavioural feeding difficulties are common in children who have gastrointestinal-related aversive experiences such as abdominal discomfort and vomiting [12] or extended periods with no oral feeding [13], all of which may occur with chronic liver disease. With infants, it is especially important to encourage age-appropriate weaning practices, to avoid missing the 'window of opportunity' to introduce tastes and textures [14]. This can be especially difficult when there is ascites or organomegaly or when the child is being tube fed. The emotional and social benefits of eating and drinking for the child and family are also important, and eating should be encouraged, even if oral intake is minimal.

Tube Feeding

Tube feeding may be required in children who are unable to take sufficient nutrition orally. Nasogastric tube feeding has been associated with improved body composition [15] and growth [16] in children with liver disease. Tube feeding may have a positive impact on quality of life as it can remove the pressure on both the child and family to meet requirements orally. The tube can be used to administer unpalatable feeds and medicines, and continuous or frequent feeds can minimise periods of fasting, thus helping to maintain blood sugars and preserve body stores.

Gastrostomy feeding is preferred in children with long-term feeding problems but is rarely possible in children with chronic liver disease. Portal hypertension and intra-abdominal varices increase the risk of bleeding during placement of the tube, while ascites may prevent adequate tract formation around the gastrostomy [17]. Gastrostomy feeding has been used successfully in children with no portal hypertension, varices or ascites [18].

Parenteral Nutrition

Due to the risks associated with parenteral nutrition (PN), PN should only be used when it is not possible or effective to feed enterally [19]. For example, PN may be used when NG placement is not possible (e.g. due to large, bleeding varices) or where there is significant and persistent malabsorption impacting on growth. Wendel et al. [20] found that there was an improvement in nutritional status in children with end-stage liver disease awaiting transplant who were on PN as they were unable to tolerate enteral nutrition.

The Management of Common Liver Conditions

Conjugated Hyperbilirubinaemia

Infants presenting with conjugated hyperbilirubinaemia will generally require MCT supplementation. If galactosaemia

has not been excluded, breast feeding should be stopped and replaced with an MCT feed containing only trace amounts of galactose (e.g. Pregestimil®). The mother should be encouraged to express breast milk as it is usually possible to restart breast feeding once galactosaemia is excluded. If cholestasis persists with accompanying symptoms of malabsorption and suboptimal growth, MCT supplementation will continue to be required. This can be given as 2–5 ml of a fat emulsion with every breast feed or as an MCT-containing formula (Table 75.2) either exclusively or alongside some breast feeding.

Biliary Atresia

Biliary atresia presents in infancy with jaundice due to biliary duct obstruction and is managed surgically with a Kasai portoenterostomy to restore bile flow [21]. The nutritional intervention is as described for conjugated hyperbilirubinaemia. Close monitoring is important as BA progresses to end-stage liver disease at some point in the majority, with 50% of infants requiring a liver transplant before age two and 75% by age 20 [21]. Standard weaning practices are advised, with age-appropriate solids. MCT supplementation continues until jaundice has cleared or if jaundice does not resolve, MCT supplementation may continue until transplant.

Non-alcoholic Fatty Liver Disease

Non-alcoholic fatty liver disease (NAFLD) exists as a spectrum ranging from benign hepatic steatosis to more aggressive forms that can potentially progress to cirrhosis in childhood [22]. It is the most common liver abnormality in the paediatric population [23]. Weight reduction through dietary modification and physical activity is the cornerstone of management. The aims are to reduce insulin resistance and visceral obesity to decrease oxidative stress [24]. A study of 84 children with NAFLD, who underwent a 12-month diet and lifestyle programme, demonstrated a significant reduction in BMI, fasting glucose levels, insulin, lipids and liver enzyme activity [22]. Evidence for other treatments including vitamin E, metformin and ursodeoxycholic acid have produced equivocal results. Lifestyle changes remain the mainstay of treatment.

Wilson's Disease

Wilson's disease is an autosomal disorder of copper metabolism and may present at almost any age. Copper accumulates in the liver during childhood but may also deposit in other parts of the body such as the brain, eyes, joints and kidneys. Treatment is primarily through chelating agents that bind dietary copper for excretion. Foods with very high concentrations of copper such as offal, shellfish, nuts, dried fruit, chocolate and mushrooms may need to be avoided [25] although this is usually only necessary in patients who are unresponsive or non-compliant with drug therapy [26].

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) refers to a group of autosomal recessive disorders that interfere with the secretion of bile and often present in infancy with cholestasis [27]. The major problem from a nutritional point of view is fat malabsorption, necessitating MCT supplementation. Fat malabsorption may occur without jaundice due to the inability of patients with PFIC to produce bile salts. Poor intake and appetite may also occur as a result of intractable pruritis. Short stature is common, though may improve following liver transplantation [28]. Supplementary nutrition support via nasogastric tube or gastrostomy is often required.

Alagille's Syndrome

Alagille's syndrome can be particularly challenging from a nutrition point of view. It is characterised by cholestasis and malabsorption, poor growth, selective eating, intractable pruritis, renal acidosis [29] and pancreatic insufficiency in some patients [30]. The nutritional management is as described for conjugated hyperbilirubinaemia. Intervention through specialist feeding clinics may be beneficial to address selective eating. Supplementary nutrition support via nasogastric tube or gastrostomy is often required.

Intestinal Failure-Associated Liver Disease

Intestinal failure-associated liver disease (IFALD) is seen in 40–60% of children with intestinal failure on parenteral nutrition [31]. It can progress from cholestasis to fibrosis and cirrhosis and result in the need for liver and/or small bowel transplantation. It may result because of physiological abnormalities associated with intestinal failure or from the toxic effects of PN [32]. Risk factors include prematurity, short bowel syndrome, sepsis, intestinal bacterial overgrowth and a lack of enteral nutrition [33]. Strategies to reduce the risk of IFALD include early implementation of enteral feeding, a specialised, multidisciplinary approach and techniques focused on avoiding sepsis [34]. The use of the lipid formulation SMOF (soybean oil, MCT, olive oil, fish oil) in place of soybean oil has been a significant advancement and has been shown to reduce IFALD-related cholestasis [35].

Liver Transplantation

Feeding post-transplant usually starts within 3–5 days, via nasogastric tube and then progresses fairly quickly to a normal oral diet. High energy feeds are used for patients with poor nutritional status with catch-up growth typically seen in the 2 years following transplant. However, many children may achieve a final height below their genetic potential [36]. Where there are gastrointestinal complications (e.g. bowel perforation) or severe undernutrition at the time of transplant, parenteral nutrition may be required. Pre-existing behavioural feeding difficulties are common and may mean that tube feeding continues for an extended period. In cases where children are likely to continue to require long-term tube feeding post-transplant, the aim will be to keep the current gastrostomy or place a new one during transplant where possible.

Following liver transplant, Seville oranges and grapefruit should be avoided as they may interfere with immunosuppressant medication. It is important to adhere to food safety guidelines and avoid foods that may contain bacteria such as listeria, E. coli or salmonella as there is an increased vulnerability to food poisoning when on high dose immunosuppressant medication.

Chylous Ascites

Chylous ascites is a potential complication post liver transplant. It usually occurs as a result of damage to the lymph vessels during surgery and results in a loss of chyle, a milky, triglyceride-rich fluid, into the peritoneal cavity. This is often evident in the intra-abdominal drain. Treatment for chylous ascites involves the dietary restriction of long-chain triglycerides (LCT) to reduce the flow of lymph in the disrupted lymphatic system. Dietary restriction generally lasts for at least 3 weeks. A feed or formula with high levels of MCT may be used (Table 75.6) alongside low LCT foods. As MCTs are not a source of essential fatty acids (EFAs), supplementation with EFAs may be required (e.g. with walnut oil).

Transplant-Acquired Food Allergy

Transplant-acquired food allergy (TAFA) is present in as many as 17% of transplanted children [37]. The cause of TAFA is not known but may be due to increased permeability of the intestine due to immunosuppressants or the transfer of lymphocytes or IgE as a result of the transplant [38]. Some children may need a long-term dietary restriction, whereas others do appear to develop tolerance over time [39].

The Nutritional Management of Acute Liver Failure

The nutritional consequences of acute liver failure (ALF) include catabolism, hypoglycaemia, hyperammonaemia, hepatic encephalopathy, electrolyte, acid base and fluid disturbance and conjugated hyperbilirubinaemia. Catabolism results from impaired glycogen storage and gluconeogenesis with protein and fat stores broken down to meet energy demands [9]. The catabolic effect is increased by a rise in insulin and glucagon, driving the need for gluconeogenesis to maintain blood sugars [40] and an increase in resting energy expenditure [41]. Hypoglycaemia can worsen the neurological prognosis [42] and is associated with poor outcomes and mortality [43]. Hyperammonaemia occurs due to impaired detoxification of ammonia to urea with increased aromatic and decreased BCAAs in circulation [9]. Management is based on preventing hypoglycaemia, managing metabolic disturbances such as hyperammonaemia, maintaining nutritional status despite fluid restrictions imposed in the critical care setting and supplementing the diet with MCT where there is jaundice (Table 75.2).

Metabolic disorders are a frequent cause of ALF and require specific dietary therapy to prevent accumulation of toxic by-products. The ideal dietary therapy cannot begin until the diagnosis is determined, which can take time.

Table 75.6 MCT feeds which are suitable for chylous ascites

Feed per 100 ml	Age	Standard dilution (%)	Energy (Kcal)	Protein (g)	Carbohydrate (g)	Fat (g)	Protein type	MCT (%)	Comments
Monogen	From birth	17.5	74	2.2	11.6	2.2	Whole	82	
Low Fat Module	From birth	18	67	1.6	14.9	0.14	Whole	100	Contains no essential fatty acids.
Lipistart	0–10 years	15	70	1.8	8.7	3.2	Whole	74	
Emsogen	>1 year	20	88	2.5	12	3.3	Amino acid	83	For cow's milk allergy or when amino acid required

Summary

Optimal nutrition support which is individually tailored and responsive to the changing clinical picture is essential for children with liver disease. Nutrition therapy should focus not only on correcting nutritional deficits and managing the complications of liver disease but also promoting normal growth, development and quality of life.

Paediatric Liver Transplantation

76

Annalisa Dolcet and Nigel Heaton

Introduction

Liver transplantation continues to be the only effective treatment for children with end-stage liver disease. Thomas Starzl performed the first liver transplant in a child in March 1963 [1]; however, it was not until 1967 that he reported the first recipient with significant survival [2]. Following his early series of 7 children aged between 13 months and 16 years [2], more than 15,000 paediatric liver transplants have been carried out in the USA and 10,000 in Europe, with 3- and 5-year survival of 80% and 75%, respectively.

There have been continued improvements in all aspects of care of the child with liver disease coming to liver transplantation including surgical, anaesthetic, intensive care and postoperative management and long-term graft, and patient survivals are now exceptionally good with improved quality of life (QOL) for recipients. The advent of reduced size and split LT in the 1980s led to a significant decrease in waiting list mortality for children. The paediatric overall waiting list mortality is about 10% and appears to be highest in children younger than 6 years. The change in donor demographics over the past 25 years has resulted in a reduction in the number of brain-dead donor livers suitable for splitting, which is the commonest graft for young children in the West. Living donor liver transplantation (LDLT) was first performed in 1989; and subsequently developed as perhaps the most common form of organ donation in the East [3, 4]. Most recently, liver perfusion machine has been utilized to try to improve the condition of marginal donor livers. To date this has not impacted on paediatric liver transplantation, but with increasing experience, this is likely to change.

The large numbers of recipients currently surviving beyond 20 years are informing clinical practice and providing more information for families currently facing transplantation. As the majority of children are transplanted at a young age and have little memory of the events surrounding their transplant, continuing patient and family education is increasingly recognized as important. There has been a change of emphasis in care from a focus on survival to long-term outcomes centred on well-being, psychosocial and physical development and educational attainment. It is clear that adolescence and transition to adulthood and follow-up within an adult environment pose further significant challenges and late death due to non-adherence to medication and follow-up are significant problems. The emergence of models of care to manage these challenges will hopefully help lead to further improvement in long-term outcomes. In addition, the timing of transplant and its influence on subsequent development and outcome is coming under increasing scrutiny.

Pre-transplant

Historically children have been listed for liver transplantation based on criteria adopted from adult experience. However, children present with a different spectrum of diseases, with two-thirds of children coming to liver transplantation in the first 5 years of life, and consideration has to be given to their emotional, social, intellectual and physical development. The timing of liver transplantation has to be considered with the long-term development of the child in mind, and there remains a lack of data regarding this topic.

Indications for Liver Transplantation

Liver transplantation should be considered for any child with end-stage liver disease with a predicted prognosis of less

than 18 months, acute liver failure (ALF), unresectable hepatic tumours and liver-based metabolic defects.

Indications for liver transplantation are in general derived from adult liver transplant experience but are modified for children and include:

- Liver decompensation (prolonged INR, low serum albumin, ascites)
- Disordered metabolism (jaundice, loss of muscle mass, osteoporosis)
- Portal hypertension (variceal bleeding, severe hypersplenism, intractable ascites)
- Encephalopathy
- Spontaneous bacterial peritonitis
- Hepatopulmonary syndrome, hepatorenal syndrome
- Pulmonary hypertension
- Recurrent cholangitis and intractable pruritus
- Quality of life (failure to growth, poor concentration, lethargy)
- Tumours

Extrahepatic biliary atresia is the most common indication for liver transplantation and accounts for 40–50% of cases listed worldwide. Common indications for liver transplantation are listed in Box 76.1. The majority of paediatric recipients under 2 years old have cholestatic diseases, particularly biliary atresia, which accounts for 74% of cases in this age group. Metabolic disorders and ALF are less common indications and account for 9% each of the overall number [5]. However, metabolic diseases, although individually rare, collectively are becoming a more common indication for transplantation.

Box 76.1 Indications for liver transplantation in children

- *Traditional*
  - Cholestatic conditions
    - Biliary atresia
    - Sclerosing cholangitis

Chronic Liver Diseases

Biliary Atresia

Extrahepatic biliary atresia (BA) is a destructive inflammatory obliterative cholangiopathy that affects the intrahepatic and extrahepatic bile tree. Type 3 BA is the most frequent form of the disease accounting for 90% of cases and is the most severe form with a solid porta hepatis, microscopic ductules and a solid gallbladder or mucocele [6]. The majority of children coming to transplant have undergone Kasai porto-enterostomy within the first 3 months of life. Early porto-enterostomy and expertise of the multidisciplinary team have a significant impact on outcome and the need for liver transplantation in early life [7, 8]. The results of concentrating expertise in a small number of centres each performing more than 5 cases per year in the UK have led to a 4-year survival with the native liver intact of 41–51% and an overall survival of 87–89%. More recently survival of 96% at 10 years has been reported for the UK with an integrated programme of Kasai porto-enterostomy and liver transplantation [6]. Mortality is distributed equally between deaths on waiting list for liver transplant and in the post-transplant period. By the age of 18 years, approximately 80% of children with BA will have been treated by liver transplantation. Outcomes have been reported for 5- and 10-year actuarial graft and patient sur-

vival of 76.2% and 72.7% and 87.2% and 85.5% for cadaveric [7] and 84.9% and 76.6% and 86.7% and 80.8% for LDLT [9], respectively.

The majority of young children (under 5 years of age) with BA will come to transplant with jaundice and synthetic failure. In a small number of children (6% of cases), acute decompensation secondary to ischaemic hepatitis may occur following a viral illness or infection. Children at risk of ischaemic hepatitis and liver decompensation are those with a hepatic artery resistance index of greater than 1 on Doppler ultrasound where the liver is dependent on arterial inflow [10]. An episode of systemic hypotension will lead to arterial insufficiency, and the liver will take an ischaemic "hit" and precipitate acute liver decompensation. Urgent liver transplantation will rescue these children if recognized in time. Children older than 5 years of age may present with failure to grow and a falling serum albumin (synthetic failure), but without jaundice. Adolescents coming to transplantation will invariably have portal hypertension as a dominating feature, which in association with adhesions from previous surgery can make for a difficult surgical challenge. The presence of portosystemic collaterals, particularly in the presence of a small or thrombosed portal vein, requires surgical ligation at the time of surgery to maintain PV flow postoperatively.

Congenital anomalies associated with "syndromic" BA (15% of all cases) include polysplenia/asplenia, absent inferior vena cava, portal hypoplasia, preduodenal portal vein, malrotation and situs inversus and may complicate surgery and influence graft choice.

Cholestatic and Metabolic Disorders

Cholestatic liver diseases excluding BA account for 10% of liver transplants in children. These include Alagille syndrome, progressive familial intrahepatic cholestasis and sclerosing cholangitis. Liver transplantation is often used to treat symptoms, such as severe pruritus. Children with Alagille syndrome are at risk of growth failure and morbidity from pruritus, xanthomas and complications of vitamin deficiency. Progressive familial intrahepatic cholestasis (PFIC) defines a group of disorders characterized by chronic, unremitting cholestasis and autosomal recessive inheritance with a shared pattern of biochemical, clinical and histological features. Liver transplantation is reserved for those with severe symptoms including pruritis or progressive liver disease. Earlier transplant may lessen future growth and developmental impairment in some, but not all of these conditions [11]. In Alagille syndrome, the biliary hypoplasia is associated with other congenital malformations, the most important of which is pulmonary artery stenosis. This needs to be assessed preoperatively due to the risk of mortality post reperfusion if cardiac output is limited by the pulmonary stenosis. Dobutamine stress testing has been used to identify at risk children who are unable to increase their cardiac index by 50%.

Inborn errors of metabolism, collectively as a group, form a relatively common indication for LT accounting for 9% and 26% of children under and over 2 years of age at the time of transplant, respectively. Metabolic diseases resulting in cirrhosis include alpha-1-antitrypsin deficiency, tyrosinemia, Wilson's disease, neonatal haemochromatosis, respiratory chain disorders, fatty acid oxidation defect and glycogen storage disease type IV, among many others. Metabolic diseases without structural liver disease include Crigler-Najjar syndrome type 1, glycogen storage disease type 1, propionic acidaemia, primary hyperoxaluria type 1, hereditary tyrosinemia, factor VII deficiency, ornithine transcarbamylase deficiency, familial hypercholesterolemia and protein C deficiency. Two series from the USA from the Scientific Registry of Transplant Recipients of 551 transplants [12] and Europe from King's College Hospital of 112 transplants reported excellent outcomes for this group [11]. Although the presence of cirrhosis did not appear to be a risk factor for worse outcomes, recipient black race, combined organ transplantation, ALF, hospitalization before transplant and age less than or equal to 1 year were predictors. The study from Sze et al. reported 11 ALTs with similar outcomes to whole liver replacement for noncirrhotic liver disease with an absent enzyme/gene product such as Crigler-Najjar type 1 [11].

Tumours

Liver transplantation for liver tumours in children accounts for 2–6% of all cases in European and American series. The most common indication is unresectable hepatoblastoma (following appropriate chemotherapy). Other tumours treated by LT include hepatocellular carcinoma, haemangioma, infantile haemangioendothelioma, rhabdomyosarcoma and epithelioid haemangioendothelioma. Angiosarcomas should not be transplanted as they invariably recur early. However, differentiation from more benign vascular tumours can be difficult even on histological examination of a biopsy. Clinical features such as pain, rapid deterioration or disease progression indicate sarcoma. The outcome of LT for unresectable hepatoblastoma is excellent with long-term patient and graft survival rates for cadaveric transplantation of 91%, 77.6%, and 77.6%, at 1, 5, and 10 years, respectively [13]. Patient and graft survival for children undergoing LDLT is 100%, 83.3%, and 83.3%, at 1, 5, and 10 years, respectively. Two North American series of 25 (HCC, 10 cases and hepatoblastoma, 15 cases) and 12 patients (HCC, 6 cases and hepatoblastoma, 6 cases) reported similar medium- and long-term survival rates for both tumours [14, 15]. Salvage transplantation for recurrent hepatoblastoma after conventional liver resection is less satisfactory with 5-year survival of 40% with a high rate of further recurrence. An analysis of

UNOS data of 336 patients with liver tumours which included 237 hepatoblastomas, 58 HCC and 35 haemangioendotheliomas noted that patient survival for the latter was inferior to that of hepatoblastoma (5-year survival of 72%) and rare liver tumours (5-year survival of 78.9%), but better than HCC (5-year survival of 53.5%) [16]. Tumour recurrence was the major cause of death in hepatoblastoma and HCC patients, but not haemangioendothelioma.

The development of hepatocellular carcinoma has been reported in BA, Alagille syndrome and progressive intrahepatic cholestasis, particularly BSEP (bile salt export pump) caused by a mutation in ACBC II gene. Children with tyrosinemia have a high risk of hepatocellular carcinoma before 2 years of age which appears to be markedly reduced by the use of 2-(2-nitro-4-3 trifluoromethylbenzoyl)-1,3- cyclohexanedione (NBTC) therapy [17]. For HCC, there are no criteria for selection comparable to the Milan criteria in adult patients. Macrovascular invasion of the portal vein trunk and first divisions continues to be a contraindication to transplantation due to the high risk of recurrence.

Acute Liver Failure

Acute liver failure (ALF) is defined by the onset of severe impairment of liver function in the absence of previous liver disease. Coagulopathy is always present, but in young children hepatic encephalopathy may be absent and is a late feature associated with a poor outcome. ALF is an indication for LT in 9% of under and 16% of over 2-year-olds in Europe and 15% of children in America. The cause of ALF cannot be determined in the majority of children (49% of all children and 54% of those aged 1 year) [18]. Potential causes include metabolic, paracetamol intoxication, autoimmune hepatitis, viral hepatitis, drugs, Wilson's disease, vascular disease and *Amanita phalloides* poisoning. The risk of death or liver transplantation is highest in children under 3 years of age. Logistic regression analysis has identified total serum bilirubin >5 mg/dL, INR >2.55 and hepatic encephalopathy as risk factors for death or liver transplantation. Of note, grade IV hepatic encephalopathy on admission was associated with higher rate of spontaneous recovery than those children who progressed to grade IV during the course of admission (50% vs 20%). Indications for LT are different from adults and an INR >4 (in the absence of disseminated intravascular coagulopathy) identifies the at-risk population.

Two recent series reported 5-year patient survival of 70% in children with ALF [19, 20]. Farmer et al. identified 4 factors which predicted graft or patient survival in 122 children with ALF which included cCrCl <60 mL/min/1.73 m (graft and patient), PELD >25 (graft), recipient age <24 months (graft) and time from onset of jaundice to encephalopathy <7 days (patient) [19]. The presence of 2 or more of these factors were associated a significant reduction in graft and patient survival to about 25–40%. Other series have also noted lower graft survival in children aged less than 2 years with ALF possibly reflecting technical challenges in small babies [21]. This population is the most challenging group and further improvements in perioperative surgical and intensive care are needed to make progress.

Acute liver failure in neonates is a rare but often fatal event characterized by a failure of synthetic function with coagulopathy. Hepatic encephalopathy is a late event and difficult to diagnose in infants [22]. Causes of ALF in neonates include metabolic, infectious and haematological disorders, congenital vascular/heart abnormalities and drugs. Congenital haemochromatosis is the commonest indication and the challenge is to provide a graft in time. Neonates and young children with ALF should only be treated in specialized paediatric hepatology centres with facilities for liver transplantation which continues to be the only therapeutic option with a long-term survival of over 60%.

Liver cell (hepatocyte) transplantation is an attractive option, as many patients only require short-term liver support while their own liver recovers. Human hepatocytes encapsulated in alginate beads (HMB) can perform the functions of the liver while alginate coating protects the cells from immune attack. Dhawan et al. reported their King's College Hospital experience and described the transition from animal models to human experience. Intraperitoneal transplantation of HMBs in healthy rats was safe and preserved synthetic and detoxification functions, without the need for immunosuppression. Subsequently, 8 children with ALF received HMBs (4 neonatal haemochromatosis, 2 viral infections and 2 children with unknown cause at time of infusion) at a median age of 14.5 days, range 1 day to 6 years. The procedure was well tolerated without complications. Of the eight children, four avoided LT while three were successfully bridged to LT following the intervention. HMBs retrieved after infusions (at the time of LT) were structurally intact, free of host cell adherence and contained viable hepatocytes with preserved functions. With HMBs 40 patients have been treated in total worldwide and 18 from the USA [23].

Timing of Transplantation

The timing of LT in children has been based on criteria established in adults and thus is focused on graft and patient survival. Optimal timing was viewed as listing for LT when expected survival was less than 18 months. Children with liver disease may not develop physically, intellectually and socially at a time of deteriorating liver function, and timing of transplant needs to take this into account. There is general agreement that Kasai porto-enterostomy should be performed for BA and that LT is reserved for those who develop progressive liver disease (apart from rare cases of late presentation >4 months).

MELD was introduced in 2002 as a response to increasing waiting list mortality for adult recipients. It provides a means of allocating livers based on likelihood of dying while on the waiting list. PELD was a similar mathematical tool based on data derived from the Studies of Pediatric Liver Transplantation (SPLIT) research group using bilirubin, INR, serum albumin, age >1 year and growth [24]. The introduction of MELD (and subsequently PELD) significantly decreased death or removal from the waiting list for being too sick within 2 years for both adults and children [25]. Cowles et al. [26] in reviewing a cohort of 71 children transplanted for BA (61, KP before LT; 10, primary LT) considered that PELD monitoring identified those in need of transplantation. Children with a PELD greater than 12 (n = 47) had a higher rate of post-LT mortality and retransplantation than those with a PELD of 10 or less. The authors suggested that a PELD score approaching 10 should trigger discussion of LT. PELD is the only scoring system currently used in children, and although helpful in advanced liver dysfunction, it is of limited value in the very young (under 1 year of age) and in older recipients, particularly with complications such as recurrent cholangitis, severe portal hypertension, pulmonary hypertension and hepatopulmonary syndrome [27–31]. Because of these limitations, PELD use has been largely restricted to North America. More research is needed to define optimal timing of transplantation in children to gain most benefit in terms of survival, growth and intellectual and social development.

Graft Allocation

Organs from deceased donors are mainly allocated depending on the blood group and organ size. Children will generally receive a liver from donors with the same blood group with certain exceptions. Children below 2 years old have received organs from mismatch blood group donors, but this is usually undertaken in circumstances when it is difficult to find a size match and good quality organ within a limited time such as in very sick patients or in countries where the only source of organs is live donors.

The size of the graft will also be important at the moment of organ allocation; it is generally difficult to have a whole size match organ for a small child; therefore, the main source of livers comes from adult donors, which are reduced or split to provide grafts that fit the children (generally left lateral segment (LLS)).

Graft Type

The type of graft used in children in need of an LT has also been in evolution. In order to match the graft-to-recipient body weight ratio, surgeons have developed techniques to resect segments of the liver from either a live or cadaveric donor. In case of a live donor, this requires estimating the required graft size and the liver remnant volume to ensure both donor and recipient have adequate function post surgery for it to be performed with compatible outcomes to cadaveric liver transplantation. For the youngest and smallest of the recipients, typically a LLS is utilized, while for a larger school-age child one may need the entire left lobe (LL). If the recipient is adult-sized, then a right lobe (RL) graft is required. For deceased adult donor, defined as suitable for routine use in children (<40 years of age, minimal fatty infiltration, ITU stay <5 days, satisfactory liver function tests), the liver can be split into two: extended RL and LLS, either in situ at the donor hospital or ex situ, after the liver has been retrieved on the back table. Long-term graft and patient survival has not been shown to be different between in situ or ex vivo procurement [32].

Criteria for "Split-able" Liver Grafts

Cadaveric donors who met the following criteria are considered to have "split-able" livers: (1) DBD donor <40 years of age, (2) intensive care unit (ICU) stay <5 days, (3) no low-dose vasopressor therapy, (4) estimated cold ischaemia time <10 hours, (5) ideal donor-to-recipient liver volume matching and (6) serum transaminase levels <3 times normal value. If only one of the criteria is missing and the others are well controlled, the graft can be accepted for splitting. However, despite these excellent outcomes, splitting of livers remain very limited with one recent study from the USA finding only 3.8% of the liver grafts that met the criteria for splitting were actually utilized. The number of "split-able" liver grafts was greater than paediatric waitlist deaths, and therefore this procedure has significant unrealized potential which could avoid mortality in young children.

The lack of age- and size-matched grafts and the underused "split-able" liver grafts are the reasons for high mortality in children. Expanding the criteria for SLT by increasing the upper age limit of the donors could help, but mandated splitting of younger donors remains the single most important way of providing sufficient grafts for young children. The lower age limit for "split-able" liver grafts has not been defined, but it is possible to split grafts from 15 kg donors. Gao et al. reported 16 children receiving split liver grafts from 8 paediatric donors <7 years with the youngest donor being 2.7 years old [33, 34].

Intraoperative

The first paediatric LT by Starzl and his team would not have been possible but for the prior experimental preclinical work using large animal models. Once established, however, this

was followed quickly by technological innovations including the development of organ donation and implantation surgical techniques based on the ability to preserve livers in cold storage solutions.

Whole Liver Transplantation

Whole liver replacement is relatively uncommon in children under 5 years of age at the present time. Above the age of 5 years, it becomes more common. The transplant involves excision of the diseased liver, by division of the common bile duct (or Roux loop if there has been previous biliary surgery), hepatic artery, portal vein and IVC above and below the liver. Orthotopic liver replacement is accomplished by anastomosis of the corresponding structures with the donor liver and achieving haemostasis; the alternative technique is the piggy-back technique whereby the donor's suprahepatic IVC is anastomosed to a common orifice of the hepatic veins with the native IVC kept intact. Management of intraoperative coagulopathy is an essential component of the operation. The technique is very similar to adult LT, but the smaller size of the vascular structures demand a more refined surgical technique, especially for arterial reconstruction. The use of optical magnification or the operating microscope appears to reduce the incidence of postoperative vascular and bleeding complications. The use of cell salvage has led to bloodless surgery becoming a practical proposition. Closure of the abdomen should only be performed if there is no risk of graft compression.

Partial Liver Grafts

The use of partial grafts was the solution to both organ shortage due to size mismatch in children. More than 10,000 LT have been performed in Europe in recipients under 16 years old. Of these, approximately 40% have been performed with whole organs. Partial grafts account for 80% and 52% of all LT performed among patients aged 0–2 and 2–15 years old, respectively. Early experience with reduced size grafts, either left lobe or left lateral segment, then led onto to split and living donor LT with both techniques being incorporated into routine clinical practice from 1991 onwards. Roberts et al. analysed data of 6467 LTs performed in patients under 30 years old from the SRTR-OPTN database [35]. It was noted that patient and graft survival during the first year after transplant for each donor graft type varied according to the recipient age group. For children of 2 years and under, living donor grafts had a 51% and 30% lower relative risk (RR) of graft failure than deceased donor split (DD-S) and deceased donor full (DD-F), respectively. A similar difference in mortality risk in the same group of age favoured recipients of LD grafts over DD-S (RR = 0.71, $p = 0.08$). Recipients in the 0–2 year age group had higher risk of mortality and graft failure with DD-S livers than DD-F livers (RR = 1.31, $p = 0.04$ for mortality; RR = 1.42, $p < 0.001$ for graft failure). For patients aged 2–10 years, the relative risks of mortality and graft loss were higher after LD than after DD-F (RR = 1.78, $p = 0.02$ for mortality; RR = 1.53, $p = 0.02$ for graft loss) but not after DD-S. In the 11–16 years age group, a significantly higher relative risk of graft failure was observed after LD than after DD-F transplant (RR = 3.63, $p = 0.0001$) or DD-S transplant (RR = 2.87, $p = 0.02$), although mortality risks were similar for all three donor graft types. Subsequent publications have confirmed the excellent outcomes with living donor LT in young children, but published experience with children over 12 years of age remains limited outside of India and the Far East.

Publications of outcomes of LLS reduced size LT tend to be from the early 1990s, and there are few direct comparisons with those observed after split LT (SLT). SLT has become an established technique to transplant children while preserving the pool of liver grafts for adults. A recent study of 251 LTs which included 138 reduced and 30 split reported 1-year patient and graft survivals that were comparable at 73% and 67%, respectively [36]. In addition, no differences in vascular complications were observed. Of note, biliary complications were significantly more common after split when compared with reduced-size grafts (21% vs 4%, $P < 0.0001$). The most common biliary complication after SLT was late stricture, in contrast to RLT, which was cut surface bile leak. Patients undergoing SLT had a 6.7-fold increased risk of biliary complications compared to those receiving a RLT; however, these complications did not appear to impact on long-term graft or patient survival. A further series from UCLA has compared the outcome of whole and partial grafts in both adult and paediatric recipients [36]. Of 442 LTs, 284 were whole, 109 were split left lateral segment (SL-LLS) and 49 living donor left lateral segment (LD-LLS). The 10-year patient survival was similar for all graft types. Multivariate analysis confirmed that history of previous LT and SL-LLS were independent predictors of reduced survival. Chronic rejection and hepatic artery thrombosis were the most common reasons for graft loss in these children. Hong et al. reported outcomes after partial liver grafting in children analysing data from the SPLIT registry and compared the outcome of each graft variant with that of whole organ transplantation (1183 whole, 261 split, 388 reduced and 360 live donor (LDLT)) [37]. There was a clear difference in outcomes at 1 year (W: 93%; R: 82%; S: 87%; L: 89%) and 4 years (WLT 89%, RLT 79%, SLT 85%, LDLT 85%) post-transplant. However, the groups were not strictly comparable in terms of era of transplant, recipient selection and centre. Children receiving a technical variant waited on average 2.3 months less than those receiving a

whole liver and tended to be younger. Complications were significantly higher after partial grafts: at 24 months the incidence of biliary complications were WLT 17.3%, SLT 28.5%, RLT 25.3% and LDLT 40.1% and vascular complications were WLT 16.5%, SLT 23.8%, RLT 23.5% and LDLT 24.4% [38].

Trying to understand and balance the increased opportunity of being transplanted against the higher incidence of early complications associated with SLT can be difficult. Merion et al. tried to address this issue by comparing the predicted lifetimes for SLT for an adult and child recipient versus WLT for an adult to try to determine the best use of this limited supply of organs [39]. They analysed mortality risk for 48,888 patients on the waiting list, 907 SLT and 21,913 WLT recipients (between 1995 and 2002). Of 23,996 donor livers used for transplantation, 533 grafts were split. Donors aged 10–39 years accounted for 81.6% of split livers and 48.5% of livers used for WLT. Only 11.8% of livers that were split were from donors older than 40 years. They analysed years gained per SLT performed against the waiting list death ratio and concluded that "the potential annual net gain in life years could be as high as 169 patient-years in the first 2 post-transplant years, if all livers meeting accepted criteria were used for splitting". For every 100 donor livers, an extra 11 years of life was predicted over the first 2 years of follow-up if organs were split rather than transplanted whole. In addition they identified a significant survival benefit for paediatric recipients of SLT compared with children continuing on the waiting list and concluded that enough grafts could be provided to satisfy the entire demand for paediatric donor liver grafts.

Living Donor Liver Transplantation

Living donor liver transplantation (LDLT) has become an important source of grafts for children worldwide. Following on from the first description by Raia et al. in 1988 [3], the first long-term survivor from Strong et al. in 1989 [40] and the early series published by Broelsch et al. [41], the technique has become established with excellent short- and long-term survival. Today LDLT is the norm in parts of the world (such India and the Far East) where religious or cultural sentiments or medical infrastructure necessitates this option in response to the lack of robust cadaveric organ-sharing systems, and multiple strong living donor programmes have been established. At present LDLT contributes to 10–20% of LTs performed in the USA and Europe. The work-up time for LDLT varies between 2 days and 3 weeks depending on the urgency of the procedure and the centre volume and experience.

The LLS is the most commonly used graft [42]. Full left or right lobe grafts are used less commonly and tend to be used in young adults. Donation is most commonly from parents although other family members and altruistic donation have been reported. The ethics and understanding of the desire to donate for children are easily understood and the risks appear to be low, but not negligible. Donor mortality for LSS grafts is of the order of 1:1500 or less. The incidence of other significant donor complications which include bile leak (1–2%), bleeding and the need for transfusion (1–2%), deep vein thrombosis and pulmonary embolus (1:1500?) and incisional hernia (5–7%) are considered "acceptable". Risks of donor mortality are similar for left hepatectomy but rise to 0.3% for right lobe donation. The risks of bile leak are also higher for the donor, particularly with the right lobe grafts where the incidence may be as high as 5%. Donor age above 55 years is generally regarded as a contraindication (especially for the right lobe) due to the slower regeneration and the increased risk in this population.

The LLS segment graft accounts for approximately 20–25% of the adult liver but provides a full sized "liver" for the child. Assessment of the donor is designed to ensure that the liver segment is anatomically and functionally suitable for transplantation and to identify additional risk factors such as procoagulant abnormalities, donor smoking and steatosis within the liver. Many centres continue to follow the two-stage assessment and consent model reported by Brolesch et al. which includes psychiatric/psychological assessment of the donor and family with a 2-week cooling off interval before completion of the consent process [41]. Depending on the availability of cadaveric transplantation, suitability for living donation will vary from 50 to 90% when assessing families. The techniques of surgery have been standardized and outcomes are excellent for all liver diseases. The advantages of LRLT include the ability to perform surgery electively with a good quality graft, dry cut surface (minimal blood loss) and excellent outcome. The incidence of early rejection is similar to that of cadaveric transplantation, but in the long term, it is considered, although the supporting evidence is limited, that more of these recipients may be tolerant of their grafts and that immunosuppression may be more likely to be weaned or withdrawn. Lifelong calcineurin inhibitor exposure is considered to be considerably lower.

Morioka et al. reported the long-term outcome of LRLT for metabolic disorders in 46 children [43]. Mean age at diagnosis and LDLT was 48.6 (0–196) and 86.5 (1.4–199) months, respectively, with survival rates of 86.9% and 81.2% at 1 year and 5 years post-transplant. Patient survival was significantly better in children with liver-centred disease which included Wilson disease, ornithine transcarbamylase deficiency, tyrosinemia type 1, Crigler-Najjar syndrome type 1 and bile acid synthetic defect than in those with non-liver-centred disease (glycogen storage disease, propionic acidaemia, methylmalonic acidaemia and erythropoietic protoporphyria) ($P = 0.003$). Further statistical analysis

showed that cumulative patient survival of patients with normal or slightly delayed physical growth at the time of LDLT were significantly better than those with delayed physical growth ($P = 0.012$).

LDLT is an excellent option in the management of ALF in children. The work-up can be performed rapidly if the unit is regularly performing elective LDLT. Ethical concern has been expressed regarding the ability of the donor to appreciate the risk in these circumstances [44]. However the lower risk of LLS donation has led to the use of LDLT as an accepted therapy for children with acute liver failure. Greater debate surrounds the use of right lobe living donation for ALF particularly in countries with effective cadaveric organ donation.

Recent Developments in Transplant Surgery

Over the past 30 years, surgical techniques have become standardized worldwide. Left lateral segment and left and right LT are used to overcome size discrepancy and to engraft the majority of children. Split and living donor LT have been key to sustaining the reduction in deaths on the paediatric waiting list. Auxiliary LT offers scope for native liver regeneration in children presenting with ALF who are able to withdraw from immunosuppression in the majority. Hepatocyte transplants remain experimental and have been used to bridge young children with metabolic liver disease through to transplantation. The current challenge is to minimize technical complications that impact on graft survival, such as hepatic artery thrombosis and biliary strictures, and continue to improve outcomes. New technologies are emerging that are currently under evaluation and will impact on practice of which machine perfusion is perhaps the most promising.

Auxiliary Liver Transplantation

Auxiliary liver transplant (ALT) was first described experimentally by Welch in 1955 [45]. The auxiliary liver was placed in a heterotopic position in the right paravertebral gutter, with portal venous inflow from the iliac vein. The idea of heterotopic ALT was attractive as it avoided the need for native hepatectomy with the aim of improving hemodynamic stability during surgery. The first experience of ALT in a human was reported in 1964, using a heterotopic graft, with the idea of avoiding difficulties presented by whole liver replacement. Chenard-Neu et al. reported long-term survival of 2 out of 47 patients who underwent ALT between 1964 and 1980 [46]. From 1986 onwards, outcomes of ALT began to improve, although only small numbers were performed [47]. The technique of ALT proved to be more difficult than that of LT with a higher rate of technical complications and inferior graft function and outcome. The development of hepatocellular carcinoma in the cirrhotic liver remnant of one long-term survivor led to the abandonment of ALT as a treatment for chronic liver disease.

The technique has become an established indication, however, for acute liver failure especially in children. In addition ALT has also been used to treat noncirrhotic inborn errors of metabolism based in the liver [43], although this has not been accepted as a standard treatment. For ALF the aim is to treat children satisfying established criteria for transplantation, with survival equivalent to that obtained with whole liver replacement with subsequent native liver regeneration and immunosuppression withdrawal. Children have the most to gain from avoiding the complications of lifelong immunosuppression. An early multicentre European experience identified that recipients under 40 years of age and particularly children were most likely to survive, have successful liver regeneration and withdraw from immunosuppression [47]. In addition, patients with hyperacute liver failure were more likely to regenerate than those with subacute liver failure and that orthotopic rather than heterotopic ALT had a better outcome. Immunosuppression withdrawal has been possible in more than 70% of survivors [48–51].

ALT have included the use of whole liver, right lobe, left lobe or left lateral segment grafts implanted into an orthotopic position. A proportion of the native liver is resected to make room for the graft. The graft is piggy-backed onto the cava, portal inflow is established by end to side anastomosis, and arterial inflow is established using either a donor iliac conduit or to a branch of the native hepatic artery. Biliary drainage is achieved with either a short Roux-en-Y hepaticojejunostomy or by anastomosis to the native hepatic bile duct. In children the majority of ALTs are performed using left lateral segment grafts to overcome donor-recipient size discrepancy. Selection criteria include the recipient satisfying existing criteria for LT for ALF, with no neurological or cardiovascular contraindication and a suitable graft. The donor liver should be of excellent quality to ensure that good early function is achieved. Marginal livers are difficult to use as partial grafts and provide inferior function and should be avoided.

Postoperatively patients are managed with conventional immunosuppression. Early graft dysfunction is due to technical complications, particularly inadequate venous inflow or outflow, and poor quality or small-for-size grafts. The serum AST and INR may be slower to settle than with conventional transplantation. Persistent elevation of the serum bilirubin indicates complications with the graft. Postoperative bleeding with the need for relaparotomy is more common due to the presence of two cut surfaces.

Patients are followed with CT or MR imaging and guided biopsies of both graft and native livers in the early postoperative period and at 3-month intervals to assess liver recovery. Dimethyl iminodiacetic acid (HIDA) scintigraphy is also of

value in assessing the differential function of the two livers and documenting native liver recovery. The decision to begin immunosuppression withdrawal is usually made at 6 months or when signs of regeneration are observed on biopsy. Gradual weaning is necessary to avoid severe graft rejection and infarction. The graft will usually atrophy and disappear without the need for resection. Immunosuppression withdrawal may need to be started to stimulate native liver regrowth. Even after massive hepatic necrosis, the liver regenerates fully. However, larger the graft transplanted, slower the regeneration of the native liver is, without a reduction in the level of immunosuppression. In the subacute group, regeneration is less rapid, as observed by sequential imaging. Successful immunosuppression withdrawal has been reported up to 4 years after APOLT.

Histopathological assessment of the native liver at the time of ALT has identified patterns of hepatocyte cell loss that provide insight into the likelihood of regeneration. A diffuse pattern with uniform cell loss throughout was associated with hyperacute liver failure and excellent regeneration with restoration of normal histology in over 70% of patients [52]. A map-like pattern was associated with seronegative hepatitis and in adult patients had a mixed outcome, in contrast to children where the results were excellent. In a small number of cases, no viable hepatocytes could be identified, and this group did not regenerate effectively. Of 5 cases in our series of over 60 adults and children cases with this pattern, 3 died and 2 were retransplanted. ALT should be considered the gold standard for the treatment of children with ALF requiring transplantation.

DCD Donation

Great efforts have been made by the transplant community to expand the donor pool for paediatric LT with the selective use of DCD grafts. In the last few years, an increasing number of DCD grafts have been transplanted into children, with good graft and patient outcomes in the medium and long terms with low incidence of morbidity. The majority of DCD have been from controlled donation (within the hospital intensive care environment) and usually have unrecoverable brain injury. Withdrawal of support occurs and death is pronounced clinically and with ECG. There follows a 5 minute standoff before surgical retrieval is initiated. Warm ischaemia is calculated from the onset of systolic BP <50 mmHg or PaO_2 <70% to cold perfusion of the liver. The organs have been used successfully in children, either as whole or reduced sized grafts. Selection criteria for liver reduction include donor age <40 years, warm ischaemic time of <30 minutes, good liver function and no steatosis with the cold ischaemic time being kept under 8 hours. Several centres including our own have reported RLT DCD paediatric transplants with excellent graft and patient survival with a low incidence of biliary complications such as cholangiopathy [53]. Careful donor selection and short donor WIT and CIT appear to be important for good outcomes. The use of DCD liver grafts in children could potentially be increased by the use of in situ regional normothermic machine perfusion to optimize graft quality. Moreover graft preservation on machine perfusion could permit assessment of organ viability and reduce the impact of ischaemia-reperfusion injury. The new frontier is the technical feasibility of splitting livers during NMP which could increase the number of partial grafts available for children and change the logistics of splitting DCD livers.

Small Infants

Yamamoto et al. reported outcomes despite the surgical challenges of LT in infants 3 months old or younger in a single institution and compared the results with infants 3–6 months old. Acute liver failure was the main indication for LT in the infants under 3 months of age group (XS group $n = 31$, 84%) versus 3–6 months (S group $n = 7$, 26%). The overall incidence of hepatic artery thrombosis and portal vein thrombosis/stricture were 5.4% and 10.8% in the XS group and 7.4% and 11.1% in the S group, respectively (not significant). The overall incidence of biliary stricture and leakage were 5.4% and 2.7% in the XS group and 3.7% and 3.7% in the S group, respectively (not significant). The 1-, 5- and 10-year patient survival rates were 70.3%, 70.3% and 70.3% in the XS group compared with 92.6%, 88.9% and 88.9% in the S group, respectively [54].

On a technical level, the major concern for LT in small infants is the shortage of size-matched or split/reduced livers which contributes to the high waitlist mortality reported in the neonatal age group. The development of technical variants of hyper-reduced or monosegment grafts has proved to be important in ensuring these children are transplanted and has reduced the waiting time and waitlist mortality.

Although the left lateral section (LLS) is used for the paediatric population, this graft may be too large for small infants. Large-for-size grafts can be problematic with microcirculatory hypoperfusion due to a combination of low portal blood flow and external compression of the liver by the small size and depth of the abdominal cavity. The option of monosegment grafts can overcome large-for-size problems. When deciding whether monosegment reduction is necessary, the relationship between the shape (thickness and length), volume, conformation of the graft and the size of the abdominal cavity has to be taken into consideration. For many centres, a GRWR >4.0% combined with a ratio of graft thickness and abdominal depth can be a guide to when reduction is indicated. Reports of monosegments have described the use of a nonanatomical reduced LLS grafts with either segment 3 or segment 2 has shown excellent outcomes [55].

Another option to prevent large-for-size complications is delayed abdominal closure using a silastic mesh or skin closure to avoid graft compression and have no adverse effect on graft/patient survival [56].

The use of ABO-incompatible grafts has been another way to increase graft options for small infants. Both paediatric and adult ABO-incompatible LT survival has improved markedly and has become comparable to ABO-compatible LT on the introduction of rituximab prophylaxis before LT. However, infants under 1 year of age are able to accept ABO-incompatible grafts without desensitization therapy because the immune system is still developing. This can be confirmed by measuring the levels of anti-A and anti-B antibody titres (<1/8) [57].

Post-transplant

Postoperative Immunosuppression

Over the 60 years, paediatric LT has seen serial improvements in morbidity and mortality. These improvements are related to immunosuppression (IS), donor selection and maintenance, surgical technique and complex team working. The focus of IS has been on the prevention of acute rejection and graft loss; however, in children, morbidity and mortality rates from infections exceed those from rejection and can also impair growth and renal function and increase the risk of some cancers. Getting the balance of IS right in the short and long term is key to a successful LT programme. Evidence is also accumulating that children may be more likely to develop graft tolerance and to wean from IS in the long term [58], particularly those with biliary atresia and with the use of LD grafts.

Early post-transplant IS has been the increasing use of induction therapy (26%), with IL-2 receptor antibodies as renal sparing regimen. For maintenance IS, calcineurin inhibitors (CNI) remain the cornerstone, but cyclosporin has been largely replaced by tacrolimus. Children often receive an antiproliferative agent such as azathioprine or mycophenolate mofetil to supplement IS or for CNI/renal sparing. Tacrolimus trough levels of 8–10 ng/l in the first 3 months and 5–8 ng/l thereafter are usually sufficient. In the longer term, tacrolimus levels can be further weaned to low levels, particularly if graft function is normal with no rejection episodes. Moderate to severe acute rejection is treated with steroid boluses, and if unresponsive, antithymocyte globulin can be given.

Over-IS is associated with long-term side effects including renal impairment, hypertension, lymphoproliferative disease and cancer and may hinder the process of immune engagement and the development of immune tolerance. There has been a move towards progressive minimization of IS, including steroid withdrawal which is associated with a growth advantage without any significant rejection-related complications [59, 60]. Many units discontinue steroids during the first or second post-transplant year, and more than 50% of children are on monotherapy tacrolimus by 18 months post-LT [61]. It has been suggested that early steroid withdrawal may be associated with a higher risk of acute and chronic rejection and development of de novo autoimmune hepatitis (AIH) [62]. The pathogenic mechanisms behind de novo AIH remain unclear, but it appears to be related to under immunosuppression and affects 2–5% of paediatric LT recipients [63, 64].

Calcineurin inhibitors share a number of side effects in common including nephrotoxicity, neurotoxicity and hyperlipidaemia [65]. There are, however, some differences between tacrolimus and cyclosporin. Cyclosporin is associated with hirsutism and gum hyperplasia, while tacrolimus is associated with diabetes and hair loss. For teenagers, especially in females, tacrolimus is often the CNI of choice because of the lower incidence of gum hyperplasia and hirsutism. Tacrolimus has greater water solubility and less dependence on bile salt absorption, thus resulting in improved bioavailability over cyclosporin. However, it has larger inter-individual variations. The introduction of once daily preparations of CNI may help reduce variations in drug levels and improve adherence to medication [66]. Tacrolimus may be superior to CsA with regard to steroid withdrawal and the incidence of acute and chronic graft rejection. CNI sparing or substitution with mTOR inhibitors such as sirolimus or everolimus are used for patients with nephrotoxicity, but their efficacy requires validation in long-term studies in large cohorts.

In children surviving more than 1 year post-LT, once daily CNI formulations, particularly taken in the morning, also improve adherence without increasing the incidence of acute rejection, graft loss or death [66]. Non-adherence is one of the commonest causes of late mortality and is the leading cause in adolescents and young adults [67]. Non-adherence has been linked to a number of factors including traumatic stress disorder from the time of transplant, a lack of knowledge and understanding of their medical history and an absence of continuing medical education. Psychological intervention and ongoing education can provide effective intervention and reduce the likelihood of graft and patient loss.

Surgery-Related Complications

Early surgical post-LT complications are primarily related to the vascular and biliary reconstructions. Outcomes and technical complications after paediatric LT are influenced by transplant volume and available expertise. It has been reported that 1-year patient death ratios were significantly lower for high-volume centres (>16 procedures per year) (0.77) than for low-volume centres (<7 procedures per year) (1.23, $P = 0.027$). Colocation of adult and paediatric liver transplantation may also contribute to better outcomes [68].

Primary Graft Non- or Dysfunction

Early failure of the graft is relatively rare (1–2%), and retransplantation is the only lifesaving therapy. Underlying causes of primary nonfunction may be due the mode of death of the donor, problems with retrieval, preservation or implantation. Signs of poor graft function include haemodynamic instability requiring continuing inotrope support, persistent or increasing acidosis and lactataemia and bleeding due to persistent coagulopathy. INR greater than 4 and first day AST levels of greater than 2000 IU/l reflect major cell damage, but even levels of more than 5000 IU/l may settle with good long-term graft function. Early high liver AST levels are seen with DCD donors without impacting on outcome and these settle rapidly after the second postoperative day.

Bleeding

Postoperative intra-abdominal haemorrhage is a common complication in the first 48 hours after transplant occurring in 5–10% of patients. Risk factors include renal failure, perioperative dialysis and acute liver failure. Re-exploration may be necessary, but a definite bleeding point is identified in only half the cases. Bleeding from coagulopathy associated with graft dysfunction needs to be resolved rapidly to avoid hypotension and further graft injury.

Caval Complications

The reported incidence of hepatic vein-inferior vena cava anastomotic complications is low and occurs either as a result of technical failure or as a consequence of graft hypertrophy and remodelling. Caval complications are rare in size matched and full left liver graft with caval replacement LT with an estimated incidence of less than 1%. The use of interrupted anterior sutures in all venous anastomoses may help to avoid stenosis and kinking in the short term. The incidence of hepatic venous obstruction is higher after left lateral segment LT and is of the order of 2–4% and dependent on technique. It is always considered to be hepatic veins outflow associated with caval stenosis at the inferior aspect of the anastomosis or with twisting. It is a risk at retransplantation particularly if the native cava is small. The most important technical development was the triangulation technique for LHV/caval anastomosis which significantly reduced the incidence of complications. Fixing the graft at the end of the procedure also helps to avoid rotation of the liver and kinking of the hepatic vein anastomosis. Clinical manifestations of venous outflow obstruction include hepatomegaly, persistent ascites, unexplained renal impairment and peripheral oedema (if there is caval stenosis) [69]. It may start insidiously two or more weeks after the transplant. The characteristic features of venous outflow can usually be seen on CT angiography and confirmed by pressure measurements across the cava and anastomosis. Balloon angioplasty is usually effective, but occasional hepatic venous and/or caval stents may need to be inserted [70]. Long-term patency rates have not been reported and long-term anticoagulation may help prevent further complications.

Portal Vein Thrombosis and Stenosis

Portal vein thrombosis (PVT) and stenosis occur in up to 4% of LT, with a higher incidence after LLS LT particularly for biliary atresia and when the PV is small or with significant extrahepatic venous collaterals. Early PVT may be asymptomatic for the first day or two but develop gastrointestinal bleeding from the jejuno-jejunal anastomosis, rising INR and increasing ascites (occasionally chylous) if there are few extrahepatic collaterals. If it extends into the liver, hepatic dysfunction may become evident, with rising transaminases which may progress to liver failure. If the extrahepatic PV is involved, collaterals may prevent the development of severe portal hypertension, and normalization of liver function may occur. With clinical stabilization, the INR does not fall below 1.4, the platelet count is low and signs of portal hypertension persist. Risk factors for PVT include discrepancy in calibre between donor and recipient PV (atrophic or pre-duodenal PV associated with biliary atresia), the length of PV, twisting, technical failure and graft rotation [71]. Doppler ultrasound and/or CT angiography will identify the problem. Early diagnosis and surgical correction will rescue the situation. Care must be taken to remove all the clot in the native PV and SMV, and any significant collaterals must be ligated to ensure there is good forward flow in the PV. If PVT is recognized late, when collateralization has developed and liver function is normal, then intervention can be avoided. If there are late complications from persistent portal hypertension, then a Rex or portocaval shunt should be attempted again with ligation of the venous collaterals. Liver biopsy should be performed prior to surgery to identify any changes such as nodular regenerative hyperplasia which may influence the surgical decision. An analysis of 521 paediatric LDLTs identified PV thrombosis or stenosis in 9% with 6 graft losses secondary to early complications [71]. The incidence of PV complications within 3 months of LT was 1.7% and body weight of less than 6 kg was the main risk factor on multivariate analysis. Early recognition and surgical correction was key to avoid graft loss. The platelet count is a valuable indicator of the presence of portal hypertension and the presence of late PV complications.

Porto-mesenteric venous occlusion is a relative contraindication to LT. If there is a large varix or an isolated vein, then a jump graft may be sufficient to revascularize the liver. Many of these patients are young adults with the JAK-2 mutation and the risk of further thrombosis is high and coagulation post-transplant is essential. JAK-2 mutation is a rare cause of venous thrombosis in young children. Portocaval hemitransposition has been utilized in predominantly adult recipients for extensive porto-mesenteric thrombosis; how-

ever, the incidence of primary graft nonfunction and retransplantation are high. Survival of 62% has been reported in 34 cases with relatively modest long-term follow-up [72]. The use of the left renal vein particularly in the presence of a lieno-renal (collateral) shunt has become the preferred way of portal venous revascularization in this difficult group of patients with improved long-term survival.

Arterial Complications

Hepatic artery stenosis (HAS) and thrombosis (HAT) occur in up to 14% and 7% of paediatric LTs, respectively [73], with a mean incidence of 8.3%. A higher incidence of HAT after adult LT has been reported from low-volume centres (5.8% with <30 LT cases/year versus 3.2% with >30 LT cases/year). No data are available for the performance of individual surgeons with respect to the number of LT procedures performed or centre activity.

Early HAT is silent and daily ultrasound for the first 5 days offers the best opportunity for early revascularization and graft salvage in children. HAT should be suspected if there is a fever or a positive blood culture for a gram-negative organism in the first month after LT [74]. If unrecognized, then the subsequent clinical course will depend on the potential for and the efficiency of developing a collateral arterial circulation and supervening infection within the compromised biliary tree. Liver dysfunction may occur with modest transaminitis and subsequent cholestasis. The clinical picture can mimic early rejection. With the development of parenchymal ischaemia, the transaminitis becomes more pronounced. Increasing cholestasis and the onset of cholangitis mark the development of significant biliary ischaemia and cholangiolitic abscesses with associated parenchymal necrosis. Untreated, they can progress to liver failure and death. A more protracted course of recurrent cholangitis and chronic ill health may ensue. The pathognomonic sign of HAT is the development of a nonanastomotic/complex biliary stricture, most commonly at the hilum. The ischaemic biliary tree sheds damaged biliary epithelium, and densely adherent casts form on the ulcerated surfaces. These casts and duct ischaemia predispose the patient to recurrent cholangitis and obstructions with the development of biliary abscesses and liver infarction.

Factors influencing collateralization are poorly understood but include the site of the arterial thrombosis (the closer it is to the hilum, the more likely), the graft type (split/reduced grafts may be more likely to collateralize than whole livers), Roux-en-Y hepatico-jejunostomy, multiple arteries and the timing after LT (patients with a later occurrence are more likely to survive). The overall mortality rate for patients with early HAT has been estimated to be as high as 33%. Just more than half of the recipients with early HAT lose their grafts [75]. The clinical burden of retransplantation and the use of precious grafts to salvage these patients is high and is mirrored by the escalating financial costs.

The surgical causes of early HAT include retrieval injuries (e.g. intimal tears, dissection and hematoma), technical problems with anastomotic stenosis or kinking and small or multiple arteries requiring arterial reconstruction and use of arterial conduits [76]. Other reported risk factors have included split liver grafts, DCD and neonatal donors, CMV-negative recipient, long cold ischaemia, large liver (graft-to-recipient body weight ratio >3–4%), small-for-size liver (graft-to-recipient body weight ratio <0.8%) and ABO incompatibility. Retransplantation is also associated with a higher incidence of HAT from both surgical and nonsurgical complications. Nonsurgical factors contributing to HAT include procoagulant states such as Janus kinase 2, anticardiolipin antibodies, factor V Leiden deficiency and a high haematocrit during the early postoperative course. Procoagulant states may also be associated with particular liver diseases such as autoimmune disease and sclerosing cholangitis, high ascitic drain loss and use of drugs such as aprotinin and tranexamic acid. Vessel fragility with associated alpha-1-antitrypsin deficiency and primary hypercholesterolemia also increase the risk of HAT.

Interventions for early HAT include urgent revascularization with thrombectomy, vascular anastomosis revision and thrombolytic drug therapy. Traditionally, the choice was urgent retransplantation or conservative management. In a comprehensive review of HAT, Bekker et al. looked at outcomes after various interventions in adults and children [73]. Revascularization was attempted in 54% of children with an overall success rate of 56%. A correlation was noted between early intervention and successful outcome. Daily ultrasound examinations for the first week were associated with early recognition and better outcomes (66% versus 45%). Children were more likely than adults to have a successful outcome after early revascularization (61% of adults and 92% of children). Retransplantation was performed for rescue in up to 62% of children with a mortality rate of at least 30%.

Early hepatic artery stenosis (HAS) has also been recognized as a predisposing risk for both HAT and graft ischaemia/loss. Risk factors include clamp injury, intimal trauma caused by perfusion catheters, technical, intimal hyperplasia and severe rejection. In a recent study by Sommerdale et al. in adults, of 37 patients treated by transluminal radiological intervention, hepatic artery patency was 94.6% with 5-year graft and patient survival rates of 82% and 87%, respectively, at median follow-up of 66 months [77] . Repeat interventions were helpful in 20% of treated recipients with an overall incidence of HAT of 11%. The use of Doppler ultrasound to identify HAS with a tardus parvus waveform (defined as a waveform with a resistive index <0.5 and a systolic acceleration time <0.08 seconds) has been associated with a low positive predictive value and a high false-positive rate [78].

When combined with an optimal peak systolic velocity of 48 cm/second, it has an improved specificity of 99% and a positive predictive rate of 88% with a false-positive rate of 1%. The early identification of tardus parvus with appropriate interventions may reduce the incidence of subsequent thrombosis. Further data is needed for children with HAS.

The management of early HAT is based on the appearance of the liver on CT angiography which will confirm thrombosis and reveal the presence of parenchymal ischaemia. If the serum transaminases are normal and there is no parenchymal ischaemia, then revascularization should be attempted with or without accompanying thrombolysis [79]. If there is significant transaminitis or definite parenchymal ischaemia on CT, then revascularization may produce a significant reperfusion injury that may endanger the child. Late recognition should be managed conservatively with rescue retransplantation for those developing ischaemic complications. The routine performance of retransplantation for all cases of early HAT is not indicated in an era of organ shortages.

Biliary Complications

Biliary complications remain a significant problem after LT in children with an incidence of 11–38% [80]. Factors associated with biliary complications include anatomical variations of biliary anatomy, ischaemia, technical failure, DCD grafts, ABO incompatibility and cytomegalovirus (CMV) infection. The commonest early complication is biliary leak which may be anastomotic or nonanastomotic. Anastomotic leaks are usually due to technical failure, but aberrant right posterior sectoral ducts may be missed. Non-anastomotic leaks are only seen with segmental grafts and usually represent missed or anomalous segment IV or segment I ducts. Strictures may be early or late and occur at both anastomotic and nonanastomotic sites [80]. Most anastomotic strictures are secondary to technical failure or scar tissue causing retraction and narrowing of the CBD at the suture site, although covert ischaemia may also be a factor. Anastomotic strictures will require surgical or radiologic intervention. Strictures occurring within the first year after LT will usually respond to percutaneous dilatation. Nonanastomotic strictures are probably caused by bile duct ischaemia due to arterial insufficiency. This ischaemic phenomenon is responsible for the loss of the biliary epithelium, producing multiple focal areas of intrahepatic biliary duct strictures separated by dilatations. These strictures may occur anywhere in the biliary tree and if extensive inevitably lead to retransplantation. A recent report of 126 LT in 108 children identified biliary complications in 30 cases, including leak (14), stricture (14), necrosis (9) and biliary occlusion caused by a drain (1) [80]. 56% of these with complications required surgery. Serum GGT peak value in the first week (358.8 ± 283.7 vs 251.3 ± 194 U/L) was considered a good early non-invasive marker to identify recipients at risk of biliary complications. In contrast, Anderson et al. reported 66 LT, of whom 17 (26%) developed biliary complications that required intervention [81]. The stricture rate was 16% for whole, 27% for split and 43% for LDLT and none after reduced sized grafts. Sixteen patients were treated with radiological percutaneous biliary dilatation, and one was treated with endoscopic stenting with complete resolution in 12 (71%). The remainder underwent surgical correction. Nonanastomotic or diffuse biliary strictures are associated with hepatic artery thrombosis, DCD grafts, preservation injury and transplantation with ABO-incompatible grafts and invariably come to retransplantation.

Other Surgical Complications

Bowel perforation is a rare complication except in children with biliary atresia who have undergone previous surgery when the incidence can be as high as 15%. Division of adhesions, portal hypertension, use of diathermy, cytomegalovirus enteritis, sepsis, use of inotropes, steroids and malnutrition have all been implicated. Paralysis of the right diaphragm due to a phrenic nerve injury at surgery may occasionally be the cause of failure to wean from the ventilator despite excellent gas exchange, and a "normal" chest x-ray and is a particular problem after retransplantation in small babies. Diaphragmatic hernia has been reported in up to 2% of LTs and has been associated with use of LLS grafts, young children, ascites and large-for-size grafts. The hernias may contain small and large bowel and should be repaired promptly to avoid ischaemic complications. Children with a combination of chest and abdominal symptoms should have imaging to exclude diaphragmatic hernia.

Retransplantation

Retransplantation is performed in up to 15% of children, although the incidence has falling consistently over 30 years. Hepatic artery thrombosis accounts for 50% of cases, and patient survival of 82% has been reported with elective versus 46% for emergency retransplantation. Retransplantation for primary nonfunction or in the setting of multi-organ failure has a survival of less than 30%. However, retransplantation makes a significant contribution to overall long-term survival in children undergoing LT [82].

Nonsurgical Complications

Infections

Infection is a common complication of LT. The majority of transplant recipients will have at least one episode of infection in the postoperative recovery period, particularly if transplanted for acute liver failure, if there is persisting graft dysfunction or following steroid therapy for acute

rejection. Bacterial pneumonia is the most common infection in the first week. Gram-positive line infections occur from 5 days onwards and venous access must be changed regularly. Gram-negative sepsis is often associated with biliary leak, bowel perforation or graft ischaemia. Immunosuppressive therapy may minimize clinical signs of sepsis. Late opportunistic bacterial infections including legionellosis, nocardiosis and tuberculosis may also occur particularly in those children who have received higher levels of immunosuppression. Of 2291 children (<18 years) reported by Shepherd et al., infection was the primary cause of death in 3.1% of all recipients, primarily due to bacterial sepsis (56%), with viral and fungal infection accounting for 19% and 10%, respectively, of infection deaths [83]. Infection contributed directly or indirectly to 46% of all deaths from multi-organ and cardiopulmonary failure.

Viral infections tend to occur later than bacterial, and the overall incidence of CMV disease was 6%, EBV disease 8.6% and lymphoproliferative disease (PTLD) 2.7%. Multivariate analysis showed that risk factors for bacterial infection included age (infants vs adolescents), race (black and Hispanic vs white), IS (cyclosporin vs tacrolimus), year of LT (before 2001 vs after 2001), serum bilirubin level and organ donor type (deceased donor split or reduced sized). Risk factors for viral infection were treated acute rejection, era of transplant (before 2001) and organ donor variants (split or reduced sized, i.e. older donors). The risk from infection exceeds that of rejection, particularly in infants, who have three times the rate of bacterial or fungal infection of that seen in adolescents. Infection was the most common cause of death with a tenfold greater risk of death from infection than from rejection (3.1% vs 0.2% of patients; 46% vs 4.7% of deaths, $p < 0.001$).

Fungal infections particularly *Candida* respond to treatment with fluconazole or amphotericin B, but invasive aspergillosis may be fatal. Fungal sepsis is particularly common in children with acute liver failure or bowel perforation, and they must receive appropriate prophylaxis. Atypical pneumonia due to *Pneumocystis carinii* should be considered if hypoxia is present and treated with high-dose septrin. Central nervous system infection with toxoplasmosis is rare and should be treated with pyrimethamine/sulfadiazine or high-dose penicillin.

Herpes viruses form the most important viral pathogens post-transplant. Herpes simplex and Varicella Zoster infections occur within 1 and 3 months, respectively, post-transplant, and both respond to early treatment with acyclovir. Cytomegalovirus infection occurs between 2 and 6 weeks post-transplant and should be treated by a reduction of immunosuppression and ganciclovir. High-risk cases, for example, CMV-positive donor and recipient, are routinely given prophylactic ganciclovir. CMV hepatitis presents with flulike symptoms, high fever and relative neutropenia with a mild rise in serum transaminases. Serology is of limited value and has been replaced by diagnostic tests which monitor levels of antigenaemia or CMV DNA.

Lymphoproliferative Disease and Epstein-Barr Infection

Epstein-Barr virus (EBV) infection may occur as a primary infection from a positive donor or reactivation of a previous infection [84]. It presents with a spectrum ranging from a mononucleosis-like illness to a malignant lymphoma. The presence of unexplained persistent fever, anaemia and positive faecal occult bloods are suggestive of PTLD and should prompt endoscopy and CT examinations. Young, previously EBV-negative children appear to be particularly at risk of developing EBV-related PTLD. The overall incidence is 2% but may be as high as 5–10% in children less than 1 year. It is a life-threatening complication with 35% mortality [85, 86]. Risk factors include primary EBV infection, age at LT, type and intensity of IS and CMV infection [87]. Because most children have not been exposed to EBV, they are particularly susceptible to acute infection, and in combination with IS they are at high risk of developing PTLD. Infants have 10 times the rate of PTLD of adolescents presumably because they are EBV and CMV naïve and have an immature immune system. Some PTLD will regress with immunosuppression reduction and steroid therapy; however, rituximab has become the mainstay of therapy with systemic chemotherapy being reserved for children not responding to this treatment.

An individualized approach to the prevention of EBV disease and PTLD is helpful in infants, given their risk. EBV PCR monitoring identifies children with increasing viral load and allows for IS reduction. The therapeutic value of preventive use of antiviral therapies (e.g. ganciclovir or acyclovir) remains unproven. However, improved EBV monitoring has led to earlier diagnosis of PTLD with less systemic involvement resulting in more favourable outcomes.

Box 76.3 Medical and surgical complications (incidence)

- Post-transplant lymph proliferative disease (1–15%)
  - Renal dysfunction (1–32%)
  - Hypertension (4–50%)
  - Post-transplant metabolic syndrome (18–67%)
  - Hyperlipidaemias (7–26%)
  - Neurocognitive function (15–30%)
  - Disease recurrence: BSEP, PSC (0–33%)
  - Food allergies (5–38%)

Graft and Patient Survival

Over the past 5 decades, there has progressive improvement in outcome after LT. According to data from the UNOS, adjusted graft survival for both deceased and LDLT programmes have achieved excellent survival rates in children. Patient survival at 1 year after elective LT should be in excess of 95% and for ALF approximately 80% and of the order of 80% and 70% at 10 years, respectively. Graft survival has been improving with lower rates of retransplantation due fewer technical complications and a lower incidence of chronic rejection. Concerns over the finding of significant graft fibrosis in many children at 10 years post-LT have raised concerns over the longer-term outlook and question whether IS levels are appropriate [88]. It has been shown that increasing IS in the presence of fibrosis does lead to improvement in the liver fibrosis. Long-term outcomes are similar for all children except for the very young <3 months and young adults. The reasons for the lower outcome of adolescents are not clear and require further research.

Quality of Life

The improved long-term outcomes are turning attention to quality of life of survivors. Quality of life is difficult to measure, especially in children. Studies show that most children surviving more than 1 year post-LT were able to return to school (31). Quality of life is dependent on good graft function and an absence of recurring medical complications requiring repeated hospital admission.

Overall quality of life seems to be satisfactory in children with good graft function. Growth, social and physical developments are normal in the absence of liver diseases such as Alagille. Alonso et al. on behalf of the Studies of Pediatric Liver Transplantation (SPLIT) group studied 873 children surviving at least 12 months, mean age of 8.17 ± 4.43 years (from 22 centres) [89]. Using a 23-item PedsQL 4.0 (Mapi Research Institute, Lyon, France) Generic Core Scales, which encompasses physical, emotional, social and school functioning, they demonstrated that these children had moderately diminished HRQOL as compared with healthy peers. The largest difference was noted in the area of school functioning, with days missed from school being important from the perspective of children and their parents. Comparisons in HRQOL in this study with children with cancer revealed that both populations shared similar struggles in social and school functioning areas.

Some effect has been noted on cognitive function; however, motor developmental delay may be due to chronic illness. Parents often comment that their child is active and plays well and is able to do physical activities. Overall family interaction and school behaviour also improve. Parents may view themselves as more relaxed and being able to be more balance and consistent in applying discipline. Siblings behave more appropriately but may remain resentful towards the recipient. For many families, there is difficulty in adjusting to the new situation of having a well rather than ill child. There remain long-term anxieties about the child's prognosis and well-being. The child is used to taking a disproportionate amount of the parents' time and attention at the expense of other siblings and trying to restore "fairness" can cause problems. Behavioural immaturity may persist, and acts of defiance or aggression are sometimes seen particularly in teenage years. There is continuing parental concern over rejection, side effects of IS, of being overprotective, continuing medical and "social" expenses and changes to family dynamics. Parents who have devoted their energies into the care of a chronically ill child sometimes interrupting their professional life may find it difficult to adjust to their new role within the family [90]. Anxieties about children going to school and being separated from their parents after many years of dependence can also be stressful [91]. However, these challenges can be addressed with continuing follow-up and support from healthcare professionals within the transplant network.

A recent study examined the change in health-related quality of life (HRQOL) and cognitive functioning from early childhood to adolescence in liver transplantation recipients. In 8 North American centres through the Studies of Pediatric Liver Transplantation consortium, a total of 79 participants, aged 11–18 years, previously tested at age 5–6 years in the Functional Outcomes Group study were identified as surviving most recent LT by 2 years and in stable medical follow-up. According to parents, adolescents had worse HRQOL and cognitive functioning compared with healthy children in all domains. Adolescents reported HRQOL similar to healthy children in all domains except psychosocial, school and cognitive functioning ($P = 0.02$; $P < 0.001$; $P = 0.04$). Participants showed no improvement in HRQOL or cognitive functioning over time. For cognitive and school functioning, 60.0% and 50.8% of parents reported "poor" functioning, respectively (>1 standard deviation below the healthy mean). Deficits in HRQOL seemed to persist in adolescence with one half of adolescent LT recipients at risk of poor school and cognitive functioning, likely reflecting attention and executive function deficits [92].

Transition to Adolescence and Young Adult Life-Adulthood

The most difficult step in long-term follow-up is the transition from childhood, and LT recipients require specific care, attention and support. Life cannot be considered to be normal because of the need to take IS and lifestyle restrictions regarding alcohol. The appearance of conflict between recipient and their parents may become problematic. Maintaining a healthy relationship will improve adherence and the quality of life of the recipient. Adolescent and young adults are concerned about their appearance, and

complications such as acne, hirsutism and gum hypertrophy may lead to non-adherence unless IS is changed to help. Nephrotoxicity is a significant problem, and by 10 years post-LT, up to 5% of recipients may have developed end-stage renal failure which has a major bearing on long-term follow-up [93].

An increased incidence of graft loss in adolescence has consistently been linked to non-adherence and has become a leading cause of late death in this population. Annunziato at el [94]. examined adherence during transition and compared it with paediatric and adult cohorts. Adherence was significantly poorer in the adolescent cohort vs paediatric and adult cohorts. The increase in non-adherence was due to a number of factors: paediatric clinics have a more "hands-on" approach to treatment; changes in insurance status may be associated with a lapse attendance and IS usage; and the stress of transitioning to less familiar providers may exacerbate existing individual and familial risk factors that compromise adherence. Subsequently, the same group tested a pilot intervention of facilitating transition [95]. Twenty-two patients were enrolled in a two-session educational programme providing details of their underlying liver disease and treatment. A second component focused on educating families regarding the transition of healthcare responsibility to the recipient facilitated by a clinical psychologist. This structured intervention significantly improved adherence with improvement in liver function and greater consistency of tacrolimus trough levels. Fredericks et al. also confirmed in a review that rates of non-adherence among adolescents are high, and adherence to IS is a critical factor in transition with an increased risk of poor long-term health outcomes [96]. Further research is needed to identify factors and interventions that affect long-term health outcomes in this population.

Long-Term Outlooks and Trends

Long-term survival is now achieved by large numbers of children following LT. The initial obstacles to survival, such as getting to transplant and managing immunosuppression, are being tackled, but the challenges raised by psychological, social and mental health problems produced by successful transplantation are belatedly being addressed by specialist transition and young adult services. The overall life expectancy is still to be determined for a child undergoing liver transplantation. The goal remains transplantation without long-term immunosuppression, but until donor-specific tolerance can be safely induced, there will continue to be complications from IS therapy. As the majority of children are under 5 years of age at the time of transplant, continuing specialist care and education must be provided, particularly during transition to young adult life, when life's challenges may threaten well-being and non-adherence to medication. Ensuring that they complete their education, have employment and are able to have families of their own is important and in the future may have a bearing on the timing of transplantation. The challenge is to ensure children undergoing liver transplantation can be restored to a normal life expectancy with the potential to enjoy life to the full.

Growing Up with Liver Disease

77

Marianne Samyn, Jemma Day, and Anna Hames

Introduction

As the survival of children with liver disease has significantly changed over the last few decades, pediatric liver transplantation and improved medical and nutritional management have changed the outcome for children with liver disease and a large cohort of patients is now moving into adolescence and adulthood with a liver condition. Unfortunately, young people with liver disease have inferior health outcomes compared to younger and older age groups [1]. They face challenges inherent to their adolescent development, now known to carry on into the mid-20s, but also in particular adult healthcare professionals might not be familiar with childhood liver diseases and their management [2, 3]. The current setup of healthcare systems sees young people looked after by either pediatric or adult services, irrespective of whether this is developmentally appropriate and the current provision of support during the transition from one service to the other is limited [4].

In this chapter we, as physician and clinical psychologist, will give an overview of the interaction of physical development during puberty and liver disease, as well as the psychosocial and health behavior aspects of adolescence. We will share our experience of running an integrated multidisciplinary care model for young people with liver disease aged 16–25 years.

Young People

The World Health Organization recognizes that "young people" aged between 10 and 24 years are a population who require dedicated care [5]. Having a chronic condition or disability has multiple effects on adolescent development including biological, psychosocial, and social effects that can in turn contribute to poor adherence and risk-taking behaviors [6]. Non-adherence to medication is a particular challenge in the adolescent population as it is difficult to measure, often multifactorial however relatively developmentally appropriate. Its prevalence is reported to exceed 50% in the post-transplant population and effects long-term outcome in this patient population [7]. Adolescence coincides with transfer of medical care from pediatric to adult-centered services hence the importance of defining a dedicated, individualized transition care pathway for young people. This will be discussed in more detail further in the chapter.

Medical Aspects of Growing Up with Liver Disease

Within pediatrics, liver disease is a relatively new specialty within which the last few decades have seen a significant change in the diagnosis and management of conditions. Patients tend to present in infancy or later childhood with a variety of genetic and incidental conditions, either in an acute, often life threatening, or more chronic setting. Lifelong specialist follow-up and treatment are usually required. The development of pediatric liver transplantation has had a significant impact on the outcome and prognosis of children developing end-stage liver disease or presenting with acute liver failure, and the majority of the patients are now moving into adolescence and adulthood. This emerging population is a challenge for both pediatric and adult hepatology teams.

Information on the long-term outcome of patients with liver disease presenting in infancy, such as biliary atresia (BA) and Alagille syndrome, is becoming available but is still scarce and more focused on survival data. It is estimated that 14–44% of patients with biliary atresia survive into adulthood without needing liver transplantation. In our experience 28%

of BA patients survived with their native liver up to 16 years with a quarter requiring liver transplantation during adulthood. Abnormal serum bilirubin levels, evidence of portal hypertension with varices on endoscopy, and having an episode of cholangitis during adolescence were associated with the need for liver transplantation in adulthood [8]. Of note is that listing criteria vary significantly between pediatrics and adults, and the use of mathematical models based on adult liver diseases disadvantages young people. We found that when comparing a group of young people with BA (median age 15.5 (range 13.8–18.6) years) either listed by the pediatric ($n = 22$) or adult team ($n = 14$), those listed by the adult team waited significantly longer on the waitlist and more likely to require intensive care support at time of listing (29% vs 5%; $P < 0.05$), and this was independently associated with poorer patient and graft survival. The mathematical models used by adult teams as listing criteria did not correlate with waiting times or outcomes. What did improve survival was the support from the multidisciplinary young people's liver service with all young people in this group ($n = 11$) surviving compared to 88% in the rest of the group [9].

In Alagille syndrome, extrahepatic aspects of the syndrome related to vascular or renal involvement are becoming more relevant and can impact the long-term prognosis [10, 11].

The advances in molecular genetics are now enabling us to diagnose genetic liver conditions such as familial intrahepatic cholestasis and other rarer metabolic conditions such as mitochondrial cytopathies, etc. The implications of dealing with a genetically based condition can have further long-term implications on adult life and prognosis [4].

Other conditions such as autoimmune liver disease, Wilson disease, and nonalcoholic fatty liver disease tend to present more frequently during adolescence, and patients will have to come to terms with their condition and management during an already challenging time in their life.

Finally, some young people will present to adult services with liver-related complications related to conditions such as complex congenital heart disease or childhood cancers and will require specialized care. In a series of 95 patients who had underwent a Fontan operation during infancy, 23% developed Fontan-associated liver disease which has shown to be linked with morbidity and premature mortality [12]. Regular screening for adolescents and adults has now been recommended.

Outcome Data

Whereas long-term outcome following pediatric liver transplantation is significantly better compared to adult cohorts (21–52%) with up to 20-year patient and graft survival of 79% and 64%, respectively, those transplanted between the ages of 12 and 17 years have inferior patient and graft survival, and this is similar for other solid organ transplants as heart, kidney, and lung transplants [13, 14]. Young adults, aged 18–24 years, experience disparities both while waiting for transplantation and with regard to outcome [15].

Young people (12–25 years) hence constitute a unique and vulnerable cohort who deserves special attention by health professionals in order to improve survival.

In the non-transplant setting, a recent report on predictors of poor outcome in a cohort of 133 patients with autoimmune hepatitis aged 14 and over found that presentation between the ages of 14 and 20 years was a significant independent predictor of liver-related death or requirement for liver transplantation, suggesting that their condition was more challenging to manage compared to the older population [16].

Impact of Liver Disease on Physical Development

Growth retardation is common in children with chronic liver conditions and more common in cholestatic liver disease, where some degree of catch-up growth is noted after liver transplantation. In an analysis of growth following liver transplantation, risk factors for poor linear growth were prolonged steroid exposure, lower weight percentiles at time of transplantation, linear growth impairment pre-transplantation, and metabolic disease as primary diagnosis [17]. More recently, out of a total of 892 liver transplant patients between 8 and 18 years, 20% had linear growth impairment at their last follow-up and, where available, height z-scores were significantly lower than the calculated mid-parental height z-scores. Linear growth impairment at transplant, re-transplantation, non-white race, and primary diagnosis other than biliary atresia were found to be independent predictors of growth impairment. In the same study, the authors reported that on the pubertal development of 353 children, 61% of girls and 58% of boys aged 16–18 years reached Tanner 5 compared to 100% of a normative population with growth impairment occurring in 11% of Tanner 5 subjects [18]. Growth impairment has also been described in genetic conditions such as Alagille syndrome and can also be associated with the treatment. Further data is needed to establish the prevalence of growth failure and pubertal delay in chronic liver disease but is available in other chronic conditions such as inflammatory bowel disease, nephrotic syndrome, asthma, and cystic fibrosis. Growth failure and pubertal delay can have a significant psychosocial effect on quality of life and long-term outcomes; hence treatment of recombinant human growth hormone in this population has been reported to be associated with improvement in psychosocial functioning as well as linear growth [19]. Larger studies are needed to assess its safety in this patient population.

In girls with chronic liver disease, menstrual cycles can be irregular, and amenorrhea and anovulation are common. Menorrhagia can occur in patients with advanced liver disease with portal hypertension. Estrogens, and typically the synthetically produced ethinylestradiol used in the combined hormonal preparations, are more potent and have a potential effect on the liver irrespective of the route of administration. Progestogens do not have receptors on the liver cells and are commonly given at a lower dose and well tolerated.

Although not contraindicated in patients with compensated cirrhosis, both in pre- and post-liver transplant setting, current contraceptive recommendation is with progesterone-only preparations such as minipill (e.g., Cerazette), medroxyprogesterone injection or etonogestrel implants, and, if sexually active, levonorgestrel releasing intra-uterine system [20]. Successful pregnancy outcomes have been reported both in chronic liver disease and liver transplantation settings, although there is an increased risk both for mother and baby. Treatment with calcineurin inhibitors, steroids, and azathioprine is recommended to be continued during pregnancy to avoid graft dysfunction or relapse in autoimmune liver disease; however, mycophenolic acid and rapamycin are contraindicated because of the increased risk of birth defects. In patients with portal hypertension, an upper GI endoscopy during the second half of the second trimester is indicated to assess the degree of portal hypertension and the need for further management to avoid GI bleeding during the course of pregnancy [21]. Obstetric follow-up by an experienced team in a hospital setting is required. Adolescent girls should be informed timely of the various contraceptive options, the potential complications of pregnancy and childbirth, as well as the possible genetic implications of their underlying condition.

Cosmetic side effects of medical treatment such as steroids and currently less commonly use, cyclosporine, can have an impact on body image and adherence to treatment in the adolescent population (see later), and health professionals should keep this in mind when prescribing treatment.

In order to effectively manage young people's care, it is crucial to successfully address their wider "medical, psychosocial and educational/vocational needs" [22]. In order to do this, professionals need to be familiar with the unique developmental stage of adolescence and recognize that young people are neither just "big children" nor "small adults." This developmental perceptive is discussed in the next section, along with the psychosocial elements of growing up with liver disease.

Adolescent Development and Its Interaction with Liver Disease

The biopsychosocial changes associated with adolescence interact with how young people manage their illness and treatments and accordingly with how their healthcare should be approached. For an excellent review of this area, please see Suris, Michaud, and Viner [6].

Although most of the literature focuses on adolescence, research demonstrates that structural and functional changes continue to take place in the brain into young adulthood [23]. This is mirrored by changing societal norms with young people increasingly delaying many of the traditional "tasks" of adulthood, such as financial independence and starting a family. Furthermore, health outcomes are poorer for young adults into their mid-twenties, so it is more helpful to think about young adult development more broadly [24].

Adolescence is traditionally defined by the onset of puberty. Delayed puberty, reported in young people with liver disease, can impact on how the young person views themselves, their illness, and their wider world. For example, an adolescent who looks younger may be treated differently by people and have reduced social opportunities. Common stories from patients include being asked by adult clinic staff whether they are there with their mum, being stopped by the police when driving to check their age, and being refused entry to 18-rated films or pubs.

Alongside the physical changes are changes in how young people think and feel and in the nature and importance of their social world. In order to become an independent adult, the adolescent needs to separate from their parents. They start to develop a more independent sense of identity, and their peer group typically takes over from family as being their main social world [25]. Peer acceptance becomes key, with a strong desire to feel normal. Self-consciousness increases. The typical adolescent has an increased sense of invincibility, poorer abstract thinking, and reduced thoughts of the future [26]. An increasing body of research demonstrates ways in which the structure and function of the adolescent's social brain is distinctly different from that of children or adults [27].

As part of this adolescent profile, risk-taking behaviors peak, with high levels of alcohol and drug use, smoking, and unsafe sex [28]. In the UK, "binge-drinking" is widespread and synonymous with certain rites of passage for young people, such as the introductory "freshers' week" at university. Young people growing up with liver disease have the same needs as other young people, with the additional challenge of trying to balance their health needs against their social and psychological needs. The way to meet these can often seem to be opposition. Indeed, research suggests that alcohol and drug use is similarly prevalent in young people with chronic illnesses as compared to their healthy peers [29] and they are equally as likely to be sexually active [30]. This adolescent profile and tendency to take risks helps young people to develop independence but can present significant challenges for successfully managing a chronic illness. This is discussed further below under adherence.

Impact of Family

All of the above changes happen within a family context. To enable the young person to develop into an adult, their family also need to adapt their roles, for example, by giving their child more freedom and privacy [31]. Parents/carers of children with chronic illness have often dedicated much of their lives to caring for their sick child and have their own relationships with the illness and hospital teams. Young people's relationships with their family may be impacted by their liver disease, for example, having less independence. Parents/carers might also have had to change other roles in their lives, such as giving up work, in order to successfully care for them. This can result in some parents seeming to be more overprotective, for example, worrying about their adolescent taking their medication, abstaining from alcohol at parties, monitoring for symptoms, or appropriately seeking help [32].

There are also significant challenges for families of young people who are diagnosed with a liver disease during their adolescent years, as is common, for example, in autoimmune liver disease or Wilson disease. At a time when adolescents should be becoming more independent, the acute stage of illness forces them into a state of dependence on others. This can present challenges for the whole family that may not be expected at this stage of development [33], such as parents needing to take time off work, physically caring for their child and spending concentrated time together that might not otherwise have been expected from being the parent of a teenager or be normal among their peers.

Wider Influences

The above processes occur within a wider set of systems still, such as schools, workplaces, friendships, and other relationships; how the liver disease is managed in any of these contexts will interact with the young person's adjustment and management of it. Furthermore, this is within a societal context in which the general public hold certain beliefs, assumptions, and prejudices. As public perception of people with liver disease and transplant is most commonly associated with drug and alcohol use, young people struggle to develop a positive self-identity if they associate (or other people associate them) with this stigmatized group. Our patients often grapple with the dilemmas about who to tell about their condition and how to tell, as many have experienced bullying or prejudiced comments in the past. It can be beneficial to discuss these dilemmas with patients and help support them in communicating their needs to schools and workplaces.

Given the importance of peer relationships during this period, it is worrying that peer networks are often disrupted in young people with chronic illness [34]. Among young people, post-transplant peer support has been found to be an effective means of engaging young people in services and improving their health outcomes and well-being [35]. In a small recent study in which young people were trained to act as mentors for younger post-transplant patients, the mentors themselves benefited from improved adherence as well as the mentees (measured by lowed mean tacrolimus standard deviation levels) [36]. The authors suggested that this may be attributable to the increased emotional support from attending the mentor training workshop. As part of the liver transition service at King's College Hospital, we run peer support days and peer mentoring for young people with chronic liver disease and post-transplant. Preliminary feedback suggests numerous benefits of this for both young people and their mentors, including feeling more positive about having a liver condition due to increased hope and feeling less alone, feeling more prepared for transition, and several comments akin to "I wish I had something like this when I was younger" [37].

Most of the developmental models are based upon Western notions of adolescence. It is unclear how this may differ in other cultures, for example, where adolescence may not exist as a construct or notions such as independence from family are not expected or endorsed. How culture interacts with chronic illness management and transition is an under-researched area that demands further attention [38]. It is important for professionals to be curious about what the adolescence and their family expect at this stage of development rather than making assumptions about how these constructs may or may not apply.

Psychological Aspects of Growing Up with Liver Disease

Adolescence is a period of rapid change, full of opportunities and challenges. Young people growing up with chronic liver disease have the same aspirations in life as their healthy peers but have additional stresses and restrictions to manage, including hospital visits, time off school, medication, and lifestyle restrictions. Rather than focusing purely on the presence of psychological distress, it is important to consider how all young people and families adapt to their changing health needs at different stages of development. Most young people, with or without liver disease, strive to be normal [39]. Those who have difficulties adjusting to their illness/treatment and integrating it into a positive self-identity are at increased risk of developing psychological difficulties and are less likely to manage their physical health needs effectively. Routine questions about the adolescent's wider world are crucial for engagement and in order to assess how they

are adjusting to the demands of their condition and areas that may require intervention [40].

There has been relatively little research into the psychological needs of young people growing up with liver disease, and most of this limited research has focused on those post-transplant. Research conducted with adults with liver disease is unlikely to be generalizable as the populations are different on multiple levels, including age and developmental stage, age at diagnosis, type of liver disease, and/or reason for transplant. A brief overview of some key areas is given below, citing research specific to liver disease where it exists and otherwise extrapolating from other chronic childhood diseases.

Quality of Life

Quality of life is a broad term that encompasses a range of physical, psychological, and social factors. Most studies investigating quality of life in young people with CLD report only on those post-liver transplant, rather than adolescents with CLD as a group. Health-related quality of life is found to be poorer in children and young people post-liver transplant as compared with the general population, but similar to young people with other chronic conditions, including other solid organ transplants [41, 42]. Across studies, Ohnemus identified predictors of poor QoL included transplantation in adolescence (as well as sleep problems and medication adherence) [43]. A study of children and adolescents with autoimmune liver disease found a similar trend, with poorer quality of life being associated with the presence of symptoms such as ascites, abdominal pain, and fatigue [44].

In a qualitative study aiming to understand how liver transplant affects young people's quality of life, adolescent participants spoke about the impact of transplant on their relationships, schooling, fatigue, burden of medication, communication with healthcare professionals, and thinking about the future [41]. These are key areas to explore when working with young people and demonstrate the importance of fostering good collaborative relationships with young people, in which they feel listened to and valued and their wider needs and hopes are respected.

School Achievement

A young person growing up with a chronic liver disease or transplant is more likely than healthy peers to take time off school for hospital appointments and ill health. This can have a significant impact on their school attainment and subsequent employment opportunities in adulthood. There is also some evidence that a portion of the poorer QoL documented in this population relates to poorer cognition and school performance. For example, Ohnemus and colleagues [43] found adolescent liver transplant recipients reported QoL similar to healthy peers in all domains except psychosocial, school, and cognitive functioning. Furthermore, these results indicated no reported improvement in cognitive functioning over time, suggesting transplant does not "fix" this problem.

Data available on cognitive development in the context of pediatric liver conditions, and mainly in the post-liver transplantation setting, confirms an increased incidence of learning disability in this population. Out of 144 patients from the SPLIT registry children aged between 5 and 7 years and more than 2 years post-transplant, 26% were found to have a mild to moderate, and 4% a serious, learning disability with 25% having impaired performance with reading and math skills and a relevant executive functioning deficit which would potentially affect independent management of their health condition in adult life [45]. Further research identified height centile at transplantation and genetic-metabolic conditions as having a high impact on long-term cognitive functioning [46].

The literature relating to cognition in our young people is in its infancy. The limited evidence so far does indicate that cognition is poorer in children and young people with CLD [47] but there is insufficient data to determine whether cognitive development differs between young people surviving with their native livers and young people undergoing liver transplantation. Studies tend to focus on early childhood rather than adolescence or young adulthood and disproportionately on those already post-transplant and not those surviving with their native liver [48–50]. Studies are also heterogeneous due to sample size, age, condition, areas examined, and tests used.

A recent systematic review of the available literature identified a total of 25 studies which have investigated cognition in children and young people with liver conditions (n = 1913) [47]. The majority of these (19/25 studies examined) described individuals post-transplant (n = 1372 children). Of those surviving with their native livers, four out of six studies found low average or impaired scores on cognitive and behavioral measures [51–53]. These studies did collectively indicate that the poorer cognition observed persisted into adolescence, with approximately 50% of young people scoring below 85 for IQ tests (compared to expected rates of around 15% in the general population) [54]. There is also evidence of poorer educational attainment, which is likely to be related to lower cognition, and at levels over and above those with comparable school absence due to hospitalization for other forms of chronic illness [55]. With poor quality of life and job performance seen into adulthood, the importance of interventions to target these impairments becomes increasingly clear.

The longer-term impact of these childhood difficulties also needs to be further researched, as in clinical practice we frequently see the long-term consequences such as in Case Study 77.1.

Case Study 77.1 Harry was diagnosed with biliary atresia shortly after he was born. Following a Kasai procedure, he required regular visits to hospital for appointments and sometimes needed admission for treatment with antibiotics or endoscopy procedures as he developed portal hypertension. He was a bright, sociable child who was well liked by patients and staff. Aged 11, his health deteriorated and the decision was made to list him for liver transplantation. A year later Harry was transplanted and he recovered well after surgery. Due to time spent in hospital, he missed most of his formal education and left school without any qualifications. Harry is now 22 years old. He lives with his parents and is unemployed. He has held a number of causal jobs, but struggles to find permanent employment due to his lack of qualifications and relevant experience. Harry feels left behind by his friends, most of whom who have now been to university and started good jobs.

Mood Difficulties

Research investigating psychological well-being in adolescents with chronic illness more broadly suggest that there are higher rates of depressive and anxiety symptoms relative to healthy controls, but the rates vary across studies and illness group (see meta-analysis by Pinquart & Shen [56]) and were particularly common in young people with conditions impacting upon energy levels, those with severe symptoms, and those resulting in a visible difference, all of which can apply to young people with CLD. Symptoms of chronic illness, restrictions on functioning, and the need for complicated treatment regimens are likely to interfere with many aspects of adolescent life and to cause frustration.

Post-traumatic Stress Disorder

Young people with chronic liver disease are likely to have had some unpleasant experiences in hospital and times which may have been felt confusing, scary, or upsetting. High rates of post-traumatic stress disorder (PTSD) have been found in adolescents who have had transplants. For example, in 104 adolescents (aged 12–20 years) post solid organ transplant, 16% met full criteria for PTSD, with an additional 14% reporting 2 of the 3 necessary symptom clusters at a level that was causing them clinically significant distress [57, 58] reported similar prevalence rates of PTSD (13%) in 76 children post-transplant; these PTSD symptoms were significantly under-reported by parents.

In addition to the distress associated with PTSD, in a small study of 19 adolescents post-liver transplant [59], a significant association was found between presence of PTSD symptoms and non-adherence (as measured by blood levels and clinician judgment). This is likely to be due to medication serving as a reminder of the transplant and non-adherence therefore being a form of avoidance. Functional outcomes are also found to be lower, for example, adult survivors of childhood cancer who had PTSD were found to have lower functioning in areas such as school, work, and personal relationship [60].

Failure to identify PTSD compromises the young person's well-being, impacts on their functioning as adults, and is associated with non-adherence. As parents tend to underestimate rates of PTSD and there is no relationship between the objective characteristics of the trauma and the risk of PTSD [61], it is impossible to predict who will have difficulties. Detection therefore relies upon directly asking the young person. Research has not addressed rates of PTSD in young people with chronic liver disease more generally, but as these young people also encounter situations where they perceive their life to be threatened, then it is reasonable to assume that their rates of PTSD may also be elevated.

One of the most significant challenges of caring for adolescents is the high rates of non-adherence. This is outlined below.

Adherence

As highlighted earlier, rates of non-adherence to medication are found to be as high as 50% in adolescents post-transplant, with significant negative implications for their health. Although non-adherence to treatment, medical advice, and clinic appointments is considered developmentally appropriate in this population, it is a concern for clinicians working with young people and is often challenging to manage.

It is easy to see that a typically developing adolescent as described in the earlier section might not take all their medications or attend appointments correctly. Increases in impulsivity, delay discounting (the extent to which consequences decrease in effectiveness to control behavior as a function of there being a delay to their occurrence), reward-seeking, and emotional reactivity are noted in adolescence, which make this period a time of heightened vulnerability to taking risks with their health. Adherence in liver disease or transplant requires the patient to trust their doctor that the treatment is

required, buy into the notion that the status of their liver disease may not correspond with symptoms, be motivated by a long-term outcome of improved health, and be able to plan and organize themselves to maintain a good routine. This directly contrasts with the developmental profile of young people, as illustrated in Case Study 77.2.

A full review of the factors associated with non-adherence is outside the scope of this chapter, but a number of comprehensive reviews exist (e.g., Drotar, 2009; Shemesh et al., 2008, Kyngas, Kroll & Duffy 2000) [62–64]. Many of the characteristics known to make adherence more difficult are present for young people with liver disease; for example, the treatment is seemingly preventative rather than curative, does not have any immediate tangible benefits, and needs to be taken for life. Knowledge is generally necessary, but not sufficient for adherence (e.g., Macquaid, Kopel, Klein & Fritz, 2003 [65]), and requires particular attention as young people grow up and each with different understandings.

Case Study 77.2 Jake is 18 years old. He was well throughout his childhood until being diagnosed with autoimmune liver disease when he was 14 years old. When he was first diagnosed, Jake felt quite unwell and spent a week in hospital, but since then he has been well and only has to go to an outpatient clinic appointment every few months. Jake does not think of himself as being sick and doesn't really think about it except for when he goes to hospital. He is most bothered about the way he looks, in particular about his acne, which started when he was commenced on steroid treatment and lack of muscle tone. He feels very self-conscious around other people his age and often feels quite down about his appearance. Jake is told to take daily medications to prevent him from getting ill again in the future - but when he stops taking his medications, nothing bad happens; he actually feels better because he isn't bothered by side-effects, his skin gets better and his face looks more defined. Jake feels happier because he feels more similar to his friends, and doesn't feel so self-conscious about having to remember to take his meds or risk having to explain his condition to others. Jake's been told he shouldn't drink alcohol, but all of his friends do and it's really hard to explain why he can't. When he started drinking recently at a party it was really fun and nothing bad happened, so he thinks it must be alright. Jake doesn't really get on very well with his parents and teachers at the moment, so doesn't tell them because he knows they will nag him about it. When he goes to hospital his mum does most of the talking. His doctor tells her about some blood tests numbers that he doesn't really understand, and then he gets to go home.

Exploring non-adherence should be part of the routine management of all patients (irrespective of age) and approached in a non-judgmental fashion to encourage disclosure and engagement. Health professionals should know that in young people non-adherence is considered to be relatively developmentally appropriate and not suggestive of distrust in healthcare professionals or equally rejection on the part of the adolescent. Individual education, which is tailored to the young person's needs and repeated and checked regularly, is important, to ensure the young person has a good understanding of their condition and rationale for treatment recommendations. It is important to understand the young person's priorities and encourage them to have open conversations about the barriers to adherence for them; for example, discussions may enable medication regimes to be simplified or altered to fit in with the person's routine, encouraging use of alarms and reminders, taking medication on sleepovers, and more broadly how to manage the handing over of responsibility from parents to their child. Simplifying medical treatment and conversion to once daily preparations of immunosuppression have been reported to improve adherence and treatment satisfaction [66]. An overview of strategies for improving adherence can be found in Table 77.1.

Non-adherence has also been found to be associated with psychosocial distress, such as PTSD [59] and other psychosocial stressors [67]. Given poor mental health is linked to worse physical health via increased non-adherence to medication and disengagement from services, it is important that mood and emotional well-being in young people post-liver transplant is considered routinely, as part of good clinical care [68, 69]. Social difficulties such as financial restrictions should also not be overlooked. For example, in the UK at the age of 18 years, young people have to start pay-

Table 77.1 Adherence management strategies

Barrier to adherence	Strategies
Naive about the risks of non-adherence	Individualized education about illness and medication
Burden of medication regime: too many tablets or too many times a day	Simplify medication regimes Ensure young person understands rationale for each medication and anticipated course
Non-intentional non-adherence: forgetting or organizational difficulties	Pill boxes, blister packs Medication charts and apps Alarm reminders Visual reminders
Intentional adherence: choosing not to take it due to the meaning of the medication	Explore beliefs about illness and medication, including the benefits of non-adherence for the young person. Assess mood Referral to psychologist
Intentional adherence: practical barriers	Assess barriers such as housing, finances, parental support Referral to social worker

Table 77.2 Routine assessment and management of adherence

Task	Rationale	Example questions
Engage the young person	Young people are more likely to be actively involved in their healthcare and more adherent if they have a good relationship with their healthcare provider Screen for psychosocial difficulties Gather information about how the illness and treatment fit into the young person's life	See HEADSS (Goldenring and Cohen [40]): ask about home, school/college, friendships, activities, and interests
Assess who is responsible for medication	Responsibility needs to be handed over from parents to young person: difficulties often arise during this transition	"Who is in charge of medication at home? How long have you been taking charge of your medication? Who organizes the prescriptions?"
Assume non-adherence and routinely assess with every patient	Rates of non-adherence exceed 50% – most young people will be non-adherent some of the time Impossible to predict who will be non-adherent so need to ask everyone Asking questions in a non-judgmental way that assumed some non-adherence is more likely to increase disclosure	"In a normal week, how often do you tend to miss your medication? How often do you take it at a different time?"
Normalize: full adherence is difficult; very few people are adherent all of the time	More likely to increase honest disclosure and willingness to discuss the barriers to their adherence Trying to scare or tell off your patient is unlikely to improve their adherence but will ensure that they don't disclose it to you again!	"Most young people we see struggle to take all of their medication all of the time. We know that it can be a really hard thing to have to take medication every day."
Check understanding of illness and risks of non-adherence	Knowledge is necessary (but not sufficient) for adherence Need to ensure that the young person understands why they need to take medication and fully understand the risks of not taking it	"How would you explain your condition to someone who hadn't heard of it before? What do you think the medications do? What do you think would happen if you didn't take your medication? How many doses of medication do you think you could get away without taking?"
Assess intentionality of non-adherence	Different determinants of non-adherence require different interventions	"Are there times that you remember your medication, but choose not to take it for some other reason? How often do you forget your medication compared to choosing not to take it? When you miss it, do you always miss all of your medication or just some of them?"
Identify barriers	Different determinants of non-adherence require different interventions.	"What gets in the way of taking medication? What is the worst/hardest thing about (having to take) medication?"

ing for their prescriptions and travel to hospital; when money is limited, these can be very real barriers to adherence for which support is available. Within our service, we adopt a multidisciplinary approach to identifying and managing adherence, which begins with a stance of assumed non-adherence, and reinforcing disclosures as rates are known to be around 50%, we normalize that most young people will struggle to take all of their medication all of their time. Please see Table 77.2 for details of our approach for routinely assessing in this age group. From conducting a case note review of the more complex cases seen by our Clinical Psychologist and Specialist Social Worker, we found that a significant minority had entrenched relational difficulties and had experienced childhood abuse [70]. We hypothesized that non-adherence can be related to attachment difficulties and in some cases can require long-term specialist input to treat. Effective identification of non-adherence and the factors contributing to it are essential to ensure access to the appropriate services.

Self-Management

As described earlier, adolescence and young adulthood for young people with liver conditions can be associated with poor health outcomes related to non-adherence and graft loss. Self-management relies on the engagement of individuals in order to manage their health effectively, in a pediatric setting implying support from the parents/carers. From a behavioral perspective, one of the simplest explanations for difficulties during transition is that some young people are just not yet good at managing their own healthcare [71]. Annunziato et al. demonstrated that in a cohort of young adult pediatric liver transplant recipients, self-management skills appeared to develop with age with lower scores for those transplanted before the age of 10 years compared to older age at liver transplant. Further work from the same authors raised some concerns that young adults post-liver transplant reporting greater self- management were being less adherent to treatment, and this impacted on their medical condition as it was

found to be associated with rejection. They concluded that universal promotion of self-management in young adult patients was inadvisable and that acquiring self-management skills should be viewed as a gradual process. Input from a multidisciplinary team lasting well into the mid-twenties was recommended [72–74].

With the delayed timing of role transitions in today's society, such as completion of education, marriage, and parenthood, many of our young people may continue to rely on parental support well into the period of "young adulthood." This may be especially true in our population, considering almost 50% of children post-liver transplantation require special educational support [47]. Our young patients may be more likely to struggle with the development of the appropriate skills to manage their condition during adolescence and may continue to rely on carer support. Indeed, most young people with childhood liver disease have a long history with the pediatric care providers, with many relationships starting in infancy. Transition of healthcare to adult services can therefore be just as challenging for carers themselves, who have their own relationships with clinicians and healthcare providers. In practice, many patients may physically transfer from receiving services at pediatric to adult-oriented facilities before they manage the requirements of their particular medical illness. It is important that self-management is viewed as a process rather than a one-off conversation, especially in patients with additional learning needs (found at an elevated rate in our patients). It is recommended that clinicians periodically assess developmentally appropriate skills of health management in order to understand patient education needs and their skill acquisition over time.

Also of relevance here is the evidence that almost 50% of children after liver transplantation and with chronic liver disease require specialist educational support hence one can expect this to impact on the development of the skills expected when moving on to adult services [62]. In addition, with evidence that adolescent development is continuing into the mid-twenties, expectations that 16- and 18-year-olds might be capable of managing their condition independently could be unrealistic (Lancet adolescence). We recently explored the self-management skills and adherence patterns in a cohort of 156 patients attending our multidisciplinary young adult clinic. Results: There was a trend toward increased mastery of self-management skills over time, with those ≥19 years reporting being more confident in behaviors related to arranging appointments and organizing medications compared to those ≤18 years.

Non-adherence is thought to be related to both the adolescent stage of development [6] and the process of transitioning into adult services at this risky period [67]. It is therefore crucial for every center to carefully consider how to transition their young people. This is reviewed below.

Transition from Pediatric to Adult-Centered Health Services

The adolescent health society defined transition in 1993 as a "Purposeful, planned process that addresses the medical, psychosocial and educational/vocational needs of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-orientated healthcare systems."

In 2002 American Academy of Pediatrics published the following consensus: "The goal of transition in health care for young adults with special health care needs is to maximise lifelong functioning and potential through the provision of high-quality developmentally appropriate health care services that continue uninterrupted as the individual moves from adolescence to adulthood" [75]. Several reports, mainly in the transplant setting, have since been published, with worse outcomes for patients transplanted during adolescence and a decrease in 12-month mortality in renal transplant recipients as patients age from 20 to 30 years. This supports the concept that maturation and complete development occur after the age of 18 years [2]. It seems that to date the development of dedicated programs to optimize transition from pediatric to adult-centered care has mainly been driven by pediatric specialists, with currently no consensus as to how to implement or measure this or even define what a successful outcome is. A national survey of adult transplant hepatologists on transitional care after liver transplantation in the USA in 2015 provided interesting information on the perception of adult healthcare providers [76]. We subsequently carried out a similar survey in the UK, and the results are summarized in Table 77.3 [3]. Thirty-two percent of respondents did not have a transition strategy at their center and only 16% had a formal transition program. Not having ade-

Table 77.3 Comparison of survey of transition service in the USA and UK

Comparison of USA and UK Survey results	USA (%)	UK (%)
Formal transition programme	16	61
No transition strategy	32	22
Characteristics of YP attending clinic appointment		
Have adequate knowledge about their condition	70	62
Arrived to the appointment with parent/guardian	66	76
Barriers to transition		
Inadequate communication with paediatric provider	61	11
Patient/family dependence on paediatric provider	46	67
Poor adherence	72	56
Patients lack the capability to discuss the impact of their condition independently without the help of their parent/guardian	54	28
Parents/guardians manage their child's condition without engaging their child	49	44

quate knowledge about their condition was found to be present in a third of the patients. The majority of adult transplant hepatologists were confident with their own skills to manage young people but were concerned about the lack of ability of the young people to independently manage their condition and their poor adherence to treatment with similar observations in the UK. Both in the USA and UK, concerns were raised about dependence of families on the pediatric provider and their interference with the patient's management as a barrier to transition and were concerned as well as the prevalence of non-adherence to treatment.

The care for young people with liver disease should focus on providing appropriate care for young people with liver disease irrespective of whether they are looked after in pediatric or adult services.

Different models of transition programs have been described and will need to be developed depending on the setup and needs of the individual centers. Pediatric teams should focus on developing strategies to overcome barriers to an adequate transition including learning difficulties, social factors, patients in care, and patients with mental health problems and aim for an integrative process. With regard to congenital and rare conditions typically presenting in childhood, where adult teams might be less familiar in managing these conditions, management in specialized centers with pediatric expertise is recommended.

What about the success of adequate young people care? Experience in the renal transplant setting demonstrated that the introduction of an integrated pediatric/young adult joint transition clinic and care pathway improved outcome over a 4-year period, with no episodes of late acute rejection or graft loss compared to 35% graft loss in a group of patients who did not benefit from this service [35]. In our UK survey, we found that those centers with formal transition programs perceived young people to have better knowledge of their condition, have better adherence, and rely less on the pediatric providers (Table 77.4) [3]. It is relevant to include parents and carers in the process, to give them realistic expectations of adult healthcare services and help them to transition from care provider to a more supportive role for the young person. This entails nourishing the development of self-management skills which are essential to navigate within an adult healthcare setting. [77]. In this respect, it is important to use transition readiness tools to define a patient's individual needs and for a multi-professional team to address these.

A recent small pilot study in a group of 20 liver transplant recipients whose care was coordinated by a transition coordinator showed, compared to a historic group of 14 patients, improved adherence to treatment during the year before transfer to adult services. After transfer, tacrolimus standard deviation scores (SD) remained stable in the group supported by the transition coordinator compared to the historic group where the tacrolimus SD increased, suggesting poorer adherence [78].

Table 77.4 Comparison between centers with and without transition services

Comparison between centres with and without transition service	Transition service *N* = 9 (%)	No transition service *N* = 9 (%)
YP has adequate knowledge about their condition	76	50
Poor adherence	44	67
Patient/family dependence on paediatric provider	56	78

Ideally the timing of the transition process should be flexible and aimed at the patient's needs and readiness; however in practice, lack of age-appropriate inpatient facilities or pediatric and adult setting being on different sites often means that patients over 18 years cannot be admitted to pediatric inpatient facilities, raising the importance of starting the transition process early enough. This is particularly relevant in patients with special healthcare needs where the transition process becomes more complicated as the patient might not be able to advocate for their care, consent for procedures, and manage an inpatient stay on an adult ward independently. In these cases, the multiprofessional team should ensure a well-documented care pathway is discussed prior to transition to adult services [79, 80].

Summary and Conclusions

- With advances in medicine, more patients with liver conditions are growing into adulthood.
- Adolescence is a period of biological, psychological, and social changes, and the impact of a chronic condition on this process can be significant.
- Outcome data suggest that young people are a unique and vulnerable cohort who deserves special attention by health professionals, focusing on better outcome and survival.
- Growth failure and pubertal delay are prevalent, and sexual health advice should be offered standard during the consultation with the young person.
- Psychological aspects of growing up with liver disease are increasingly being recognized and identified and require management by specialized healthcare professionals.
- Non-adherence to all aspects of care is common, multifactorial, and often underestimated however impacts on outcome and survival. A non-judgmental approach aimed at identifying barriers to adherence and developing an individualized strategy is recommended.

- Successful transition programs have shown improvement in outcome and quality of life and should be developed according to the facilities of the individual center and focus on self-management, keeping in mind the special needs patients might have.

New Horizons in Paediatric Hepatology: A Glimpse of the Future

78

Emer Fitzpatrick and Anil Dhawan

Introduction

Over the last 30 years, considerable advances have been made in the field of paediatric hepatology as a distinct subspecialty. Paediatric hepatology is now poised on the brink of a hugely exciting era with the potential of advances in technology particularly in genetics, bioengineering and small molecules bringing real advantages to diagnostics and therapeutics. In addition, there is a renewed focus not just on survival and medical outcomes but on improving the quality of life for patients and minimising the side effects of each treatment.

As a speciality of rare diseases in general, much of the research and development to date comes adapted from adult practice. In the mid-twenty-first century however, with focus on genetics and metabolic disease, paediatric hepatology research is set to take the lead as regards innovative practice.

Genes, cells and molecules are cross-cutting themes across diagnostics, the better understanding of pathophysiology and thus therapeutic options. In addition, there is a renewed emphasis on the importance of psychosocial outcomes and quality of life. New challenges face us in the twenty-first century, particularly the massive increase in the prevalence of obesity across both the adult and paediatric population. This has consequences in terms of both lifestyle-related liver disease and the decline in healthy livers suitable for transplantation due to the frequent occurrence of steatosis.

Genetics

Diagnostics

Our understanding of single gene and polygenetic/multifactorial disorders has undergone major advances over the last number of years and continues to do so. Many of the rare disorders described in paediatric hepatology have found explanation in genetic alteration thanks to collaboration of paediatric hepatologists and geneticists internationally. The major technological advances of next-generation sequencing, whether in whole genome analysis or targeted studies, have allowed analysis and elucidation of huge amounts of data. Over the last decades, the genetics of Wilson disease [1, 2]; Alagille disease [3, 4]; arthrogryposis, renal dysplasia and cholestasis (ARC); microvillus inclusion disorder; FIC1 disease; BSEP deficiency; MDR3 deficiency; TJP2 disease; and DCDC2 have been described [5–8]. In addition to this, the genetic basis of many metabolic diseases affecting the liver such as glycogen storage disease and mitochondrial depletion disorders [9, 10] has been discovered leading to more rapid and less invasive diagnostic measures. The previous 'black box' of conditions leading to acute liver failure has in part been opened with the discovery of genetic mutations such as LARS, NBAS, SCYL1 and EIF2SK3 [11, 12], and the panel of such mutations is continually expanding.

Gene 'chips' now exist for the diagnosis of cholestatic conditions in neonates, immunological and haematological disorders relevant to hepatology, acute liver failure and certain metabolic diseases. These 'chips' can detect the presence of mutations consistent with liver diseases and as they can usually be processed rapidly may be more useful than biochemical or other means of diagnosis and in some cases, may reduce the need for liver biopsy.

The interaction of genetic susceptibility and the environment has also come to the fore with an understanding of genetic variation in man due to epigenetics. Single-nucleotide polymorphisms can explain variation in susceptibility to disease processes, for example, PNPLA3 in NAFLD [13], auto-

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_78

immune liver disease [14] but also in hepatocellular carcinoma and response to treatment in hepatitis C. Next on the agenda are determining the genetic modifiers for multifactorial conditions – for example, biliary atresia and idiopathic acute liver failure. Cystic fibrosis-associated liver disease and liver disease in those with alpha 1 antitrypsin deficiency will also benefit from this approach.

Gene Therapy

Genetic modification has still promise as a therapy. Liver-based metabolic disease has the particular advantage of the liver as a target organ for gene therapy. Preclinical studies and clinical trials to date have yet to overcome safety concerns.

The delivery of gene therapy involves use of a vector at present which may be viral or nonviral. This in addition to the major issue of introducing genomic instability is the major safety concerns limiting the current clinical applicability of the therapy.

Clinical trials for gene therapy in Crigler-Najjar syndrome and urea cycle defects have commenced, and those for organic acidemias (methylmalonic acidemia and propionic acidemia) are in development. Wilson disease is another potential target as are several others of the monogenic liver diseases of childhood.

Other approaches to genetic therapy targeting liver disease include using interfering RNA. Though this research has largely been abandoned by big companies, smaller biotech companies have reported some success including the use of the technique to treat transthyretin-mediated amyloidosis, a liver-centric disease [15]. Small interfering RNAs bound to the RNA-induced silencing complex mediate cleavage of target messenger RNA. This has been exploited by developing tools to enable delivery to target organ in stable formulation, for example, lipid nanoparticles which are stable and robust. When delivered intravenously, they home to the liver.

MicroRNAs (miRNAs) are small noncoding RNAs, 18–24 nucleotides in length, that regulate gene expression by binding to mRNAs to interfere with the process of translation. They are regulated during or after transcription, and SNPSs in miRNA genes may also modify their activity and function. Approximately 1400 mammalian miRNAs are known and each can influence 100 s of gene transcripts. These molecules are involved in all biological processes in all cell types. In the liver, there has been much interest in the role of miRNA in glucose and lipid metabolism, inflammation, apoptosis and cell death, cell cycle and proliferation and fibrosis. miRNA have been investigated as both biomarkers of disease processes in the liver and as potential therapeutic targets by both inhibition and overexpression.

Regenerative Medicine and Cell Therapy of Liver Disease

Liver transplantation is undoubtedly the standard of care for end-stage liver disease and many liver-based metabolic conditions and developments in surgical technique, peritransplant care, and immunosuppressive medication means that outcomes are improving. However the unfortunate fact is that organs are in short supply and the growing tendency towards obesity in the general population means that fewer and fewer non-steatotic, healthy livers are available through donation and are particularly unsuitable for split organ transplantation (which is the main source of transplanted livers in children). Thus, deaths inevitably occur while awaiting a suitable organ. Hepatocyte transplantation is becoming more established as an alternative to orthotopic or auxiliary liver transplantation in the management of liver-based metabolic conditions and in acute liver failure [16–22]. As with auxiliary transplantation, the native liver remains in place; in the case of acute liver failure, this allows the possibility of native liver regeneration over time; in metabolic liver disease, the native liver serves as a back-up in case of graft failure and remains available for the future possibility of gene therapy. The procedure is significantly less invasive than organ transplantation and previously isolated and cryopreserved cells are available on demand.

Hepatocytes are derived from organs that would otherwise be rejected for transplantation. In general, these often compromised livers may be steatotic, from non-heart-beating donors [23] or unused segments [24]. Innovative methods to improve cell quality from these poor grafts and cryopreservation methods have been a focus of research. Challenges also remain in the effective engraftment of hepatocytes into the host liver including optimal immunosuppression and loss of function after 6–9 months.

In acute liver failure, hepatocyte transplantation may act as a bridge to recovery and regeneration of the injured native liver or alternatively to orthotopic liver transplantation once an organ becomes available. The procedure may also be used in patients who are not candidates for organ transplantation. A major advantage of hepatocyte transplantation is the immediate availability of cryopreserved cells. Sufficient cell mass (approximately 10–15% of liver cell mass) is needed to provide enough function to sustain metabolic function [25]. In chronic liver disease, or acute on chronic dysfunction, the aim of hepatocyte transplantation is both to replace function and to allow the cells engraft and repopulate the liver. As the liver architecture is disrupted in chronically damaged liver, there are difficulties with engraftment however. Attempts at improving engraftment include temporary embolisation of the portal vein [26], liver irradiation [27] and the administration of growth factors [28]. The single most important obstacle to the

widespread application of hepatocyte transplantation is the limited availability of hepatocytes. This has encouraged investigation into alternative sources of cell including stem cells, immortalised cells and xenotransplantation each with its own challenges. Stem or progenitor cells have many advantages as an alternative source of cell for hepatocyte transplantation. They are readily available and may be effectively expanded in vitro or in vivo. Autologous cells (induced pluripotent cells) eliminate the need for immunosuppression and, however, may need to undergo corrective genetic manipulation prior to use to correct the underlying defect [29–32].

Proof of true functionality of these cells has been less frequent. It is not clear as yet whether transdifferentiation or fusion is responsible for change in phenotype of the cells. The tumorigenic potential of modifications to the genome needs to be considered.

Mesenchymal Stromal Cells

Mesenchymal stromal cells have also been shown to have promise in the cell therapy of liver disease [33]. These are multipotent, adherently growing cells which provide support for haematopoietic cells within the bone marrow [34]. They are a readily available source of stem cell also isolated from umbilical cord blood and matrix, placental tissue and adipose tissue [35–37]. Mesenchymal stem cells (MSCs) have beneficial effects in animal models of acute liver failure. They can transdifferentiate into hepatocyte-like cells both in vitro and in vivo [38, 39]. MSCs play a major role in tissue repair both through localised immune-suppressive effects and through the release of soluble trophic factors to affect neighbouring cells, properties which make them excellent candidates for improving the survival of transplanted cells [40]. Improved survival has been shown in animal models of liver disease and in pilot clinical studies of liver failure [41–43]. It is not clear, however, whether it is the transdifferentiation of MSCs into hepatocyte-like cells or an anti-inflammatory, anti-apoptotic effect induced by the MSCs results in the desired outcome. Soluble factors such as growth factors, cytokines, extracellular matrix glycoproteins and other small molecules produced by MSCs likely mediate these effects in acute liver failure rather than transdifferentiation [40]. This anti-apoptotic, pro-regenerative effect of MSCs has also been seen in the setting of myocardial infarction [44] and stroke [45]. In addition to the beneficial effects on liver inflammation and regeneration, other studies have recognised the supportive effects of bone marrow-derived cells in co-culture with hepatocytes [46]. Co-encapsulated hepatocytes and bone marrow stem cells resulted in prolonged maintenance of function in the co-encapsulated group in vitro and in vivo in a rodent model of acute liver failure [47–49]. Thus not only are MSCs are anticipated to improve the viability and functionality of co-transplanted hepatocytes. In addition, transplanted mesenchymal stem cells may also be a source of anti-inflammatory/anti-apoptotic mediators in the setting of the failing liver and the subsequent cytokine storm. MSCs are already used clinically in the treatment of graft versus host disease and have safety and logistical advantages over embryonic stem cells and adult-derived hepatocyte-like stem cells. A recent report of alginate encapsulated primary human hepatocytes together with mesenchymal stromal cells infused into the peritoneal cavity of children with acute liver failure demonstrated encouraging results [50]. A clinical trial is currently set up to explore the safety and efficacy of this approach further.

Induced Pluripotent Stem Cells

The description by Takahashi and Yamanaka [51, 52] of the induction of somatic cells back to their pluripotent state by overexpressing certain transcription factors and the subsequent differentiation of the cells along alternative lineages has opened massive possibilities for cell therapy in liver disease. The differentiation of autologous dermal cells into hepatocytes following induction of pluripotency may have significant advantages, avoiding the need for immunosuppression in cell transplantation and providing an accurate model of disease to investigate pathophysiological mechanisms and test therapies. Of course, the transplantation of autologous cells in a disease state would require the need for genetic manipulation to correct that defect in the first instance. Thus potential genomic instability may be a problem; however, new techniques are emerging which may minimise this risk and allow genomic stability. One such approach is using a piggyBac technique which enables removal of transgenes without residual sequences. This technique was used to good effect in a study by Yusa et al. which differentiated iPS cells from dermal cells of a patient with alpha 1 antitrypsin deficiency, corrected the genetic abnormality and demonstrated the function of the hepatocyte-like cells when transplanted into a mouse [53]. iPS-derived hepatocyte cells have also been used in the successful formation of ‘liver buds’ together with endothelial cells from umbilical cord and mesenchymal stromal cells. When transplanted into a mouse, this human liver bud rapidly vascularised and demonstrated liver-specific function [54].

Immortalisation

In order to establish a sustainable source of cells for transplantation, immortalisation of hepatocytes has also been described. Clonal cell lines of human and rat hepatocytes

have been transduced with retroviral vector expressing the immortalising simian virus 40 large T antigen gene [55]. Despite control mechanisms for switching immortalisation on and off, concerns regarding safety remain. The use of these cells in an extracorporeal device remains attractive.

Thus, the potential of cell therapy for liver disease is promising, though cell source is an issue and the emergence of mesenchymal stromal cells and iPS cells into the clinical field is particularly relevant and may provide an alternative source for successful translation. Paediatric liver disease, especially liver-based metabolic disease, remains a priority for this approach.

Small Molecules and Chaperones

A reduction in protein stability is often a common outcome of monogenic disease, for example, alpha 1 antitrypsin deficiency or cystic fibrosis; thus, focus on the stabilisation of such proteins and provision of an increase in intracellular function are the remit of pharmacological chaperones and other small molecules.

The work of Lomas group and others has focused on the use of small molecules to block the abnormal polymerisation of alpha 1 antitrypsin in the Z state [56]. At present, however, this work is proof of principle and not yet at translation point, though in the future may offer real therapeutic promise. A paediatric group in Pittsburgh investigated the use of carbamazepine as an autophagy enhancer to clear the intracellular load of abnormally formed alpha 1 antitrypsin in the disease state and reduce liver fibrosis in mice [57], using a well-established pharmacological substance as a molecular manipulator. Similarly lysosomal storage disease and phenylketonuria have also been a focus for the development of protein chaperones [58, 59].

Targeting other nuclear receptors with pharmacological agents is a focus for polygenic or multifactorial disease such as NAFLD and primary biliary cirrhosis. FXR is a nuclear receptor that binds extensively to genomic DNA. FXR undergoes conformational change and alters gene expression following binding by bile acids or other pharmacological compounds. This results in the regulation of bile acid levels in the liver and in addition glucose and lipid homeostasis. Thus modulation of FXR binding and function using a semi-synthetic bile acid may be a useful approach to therapy of NASH [60] and certain cholestatic liver diseases for which there are early clinical studies ongoing at present [61]. The apical sodium-dependent bile acid transporter (ASBT) is also a target for inhibitors in clinical trial for the treatment of severe pruritus in cholestatic liver conditions [62].

Liver Transplantation

Now that survival following liver transplant is greater than 90%, the focus has become more about improving long-term quality of life and minimising side effects of immunosuppressive medications. Though short and medium survival is very high, longer-term graft loss and renal dysfunction, post-transplant lymphoproliferative disease and other side effects of immunosuppressive medication are the major issues that must be addressed. A better understanding of late graft loss and the agents involved should contribute to achieving tolerance for a lucky few. True tolerance is a rare occurrence in paediatrics, but individual immunological 'signature' detected with new technology may identify those who are candidates. These areas will be of interest in both paediatric and adult settings but the anticipated longevity of children make this even more relevant for paediatrics.

The Microbiome and Liver Disease

The microbiome and its role in many paediatric liver disease are a major area of interest currently, and should the ongoing studies prove the concept, this is set to be a major area of development over the next 5 years. The role of microbiota in metabolism and in immunity/inflammation is becoming clearer. The relationship between the gut microbiome, bile acids and liver disease is the subject of current study, and exciting new therapies may arise from this understanding. The hypothesis is that a decrease in delivery of bile acids to the small intestine as may occur in cirrhosis or in cholestasis results in dysbiosis which via metabolism of pathogenic bacteria, lipopolysaccharide (cell wall) and translocation exacerbates liver inflammation and thus promotes fibrosis. Hepatic encephalopathy has also been associated with dysbiosis. Modification of this dysbiosis using pre- or probiotics may be effective as therapy and is under investigation in NAFLD in particular in addition to the modification of hepatic encephalopathy in cirrhosis. Vancomycin is also under trial in both sclerosing cholangitis and biliary atresia. In addition to bacteria and antibiotics, TLR54 antagonists may have a role as an anti-fibrotic therapy. Microbial genomics and computational biology has a significant role to play in understanding the gut-liver axis. Considering 99% of genes in the human body are bacterial, there is a huge amount of data to collate and analyse in understanding the contribution of these genes to diversity.

Non-alcoholic Liver Disease

NAFLD in children is now a major public health issue with serious concerns about the burden that this will place on the adult service. It is not known what proportion of children

with NAFLD will go on to develop end-stage liver disease and/or hepatocellular carcinoma in early adulthood, but with early-onset progressive disease, there is a risk that end-stage liver disease secondary to NAFLD will overwhelm the transplant capacity. Though multiple clinical trials are underway investigating potentially disease-modifying medications, the mainstay of management in children is lifestyle change with healthy eating and exercise. Lifestyle and environmental factors are not the only culprits however, and genetic susceptibility has been demonstrated by genome-wide studies. In utero and early infancy exposures are also thought to prime an individual to metabolic risk. Well-designed randomised controlled trials (such as the TONIC trial in children with NAFLD) are needed to evaluate the role of other drugs such as anti-fibrotics, antioxidants and drugs which modify the metabolism and other newer therapies for this condition, but likely it is only a public health approach starting prior to pregnancy that will result in significantly improved outcomes.

Noninvasive Biomarkers of Disease

Though the role of liver biopsy in paediatric hepatology remains important, noninvasive methods of detecting and assessing progression of disease are becoming more accessible. Algorithms of simple biochemical and clinical markers such as paediatric fatty liver index for NAFLD and APRI for detection of varices in chronic liver disease have demonstrated their utility. Ultrasound-based techniques such as transient elastography and shear wave elastography are now well established as surrogates for liver biopsy to determine severity of fibrosis. Contrast ultrasound can distinguish different types of tumour and assist in assessing liver trauma.

Recent MRI protocols can evaluate not only fibrosis (MR elastography) but also inflammation, fat and iron with multiparametric imaging.

Quality of Life

Finally, there is a need to acknowledge the ethical framework around management of children with liver disease. With a renewed focus on best quality of life, liver transplantation is now no longer a lifesaving measure alone. The timing around transplantation is a critical issue and no longer reserved for those with decompensated end-stage liver disease. In certain scenarios, the availability of a donor will have a major influence on this decision – once a child reaches a certain weight, a left lateral segment is insufficient and a right lobe will be required which obviously conveys further risk to living donor. School achievement and the presence of minimal encephalopathy are likely to become even more important in decision-making. There is a need to develop tools to accurately assess these criteria in children so as to time transplant in order to give them the best chance of educational attainment. Chronic pruritus and in the case of liver-based metabolic disease, frequent (even mild) decompensations leading to school absence are becoming accepted criteria for transplantation. In an era where organs are scarce, the complexity of meeting demand with supply is an ever-growing challenge.

Conclusion

This is an exciting and dynamic era in paediatric hepatology. Dramatic advances in genetic analysis, computational biology, understanding the microbiome and the gut-liver axis will lead to decoding many of the elusive concepts in paediatric hepatology. Regenerative medicine and cell therapies together with small molecules as chaperones have real potential for development and clinical application over the next decade. Finally, the recognition that quality of life in children with chronic liver disease and those post-transplant is often compromised will lead to a renewed focus on minimising side effects of medications and promoting early and effective intervention.
