As IBD is a systemic disease that can involve multiple organs, patients with IBD often exhibit extraintestinal manifestations (EIM). In up to 28% of pediatric patients, EIMs are present at diagnosis [18]. In fact, rates of EIM at IBD onset are higher in children compared to adults [22]. EIMs are more commonly seen in CD compared to UC (30–71% vs. 21–22%). EIM's are usually related to disease activity but may precede, develop concurrently, or may also occur after a colectomy [18]. Data from the PediIBD Consortium Registry including 1649 children with IBD show a cumulative incidence of EIMs of 9% at 1 year, 19% at 5 years, and 29% at 15 years after diagnosis. Thus, in 29% of pediatric IBD patients who do not have EIMs at the time of diagnosis, at least one EIM will develop within 15 years [23]. Since up to 35% of pediatric IBD patients may manifest EIM prior to intestinal symptoms, IBD should be suspected in children with EIMs to prevent delays in diagnosis and treatment [18]. EIMs predominantly involve four organ systems: skin, joints, biliary tract, and eyes. Skin-related EIMs include erythema nodosum, pyoderma gangrenosum, psoriasis, and aphthous stomatitis. Eye-related EIMs include episcleritis and uveitis. Other EIMs include peripheral arthritis, axial arthropathy, osteoporosis, primary sclerosing cholangitis, and chronic active hepatitis [5].

Arthralgia and Arthritis

Arthralgia and arthritis occur frequently in about 5–20% of children with UC and may occasionally precede intestinal manifestations of IBD [24]. They usually coincide with disease activity and improve with medical treatment of underlying intestinal inflammation. They can be classified into two forms: peripheral arthropathy and axial arthropathy (AS) [25]. Peripheral arthropathy or arthralgia is usually pauciarticular affecting large joints, such as knees, ankles, hips, wrists, and elbows in decreasing order of frequency. Joint deformities are usually not seen.

Ankylosing spondylitis (AS) is more common with UC and is associated with HLA B27 in 50 to 80% of cases. Progression is variable and does not appear to correlate with severity of bowel symptoms. Colectomy does not affect the course of AS. Sacroileitis is usually asymptomatic and may be detected on bone scans.

Chronic recurrent multifocal osteomyelitis (aseptic inflammation of the long bones and clavicles) and hypertrophic osteoarthropathy (digital clubbing, painful swelling of limbs, arthralgia, joint effusions) are uncommon but have been described. Both of these conditions are managed by treating the underlying colitis [26].

Mucocutaneous Lesions

Oral aphthous ulcers occur less commonly with UC (5%) as compared to CD. Ulcers usually cause minimal discomfort although they may occasionally cause debilitating pain. They tend to parallel disease activity and treatment is directed towards the underlying disease.

Pyoderma gangrenosum (PG) is a deep severe ulceration of the skin and is an unusual manifestation with UC (<1%). Lesions can be multiple in number and are typically located below the knees. Biopsy of the lesion shows neutrophilic infiltration with abscess surrounded by a lymphocytic vasculitis. PG usually parallels active colonic disease but on occasion may be refractory to treatment and may require intensive

local therapy, corticosteroids (CS), minocycline, dapsone, clofazimine, cyclosporine, or infliximab.

Erythema nodosum is characterized by the development of painful, indurated, purplish red, ovoid nodules 1 to 3 cm in diameter, most commonly seen over extensor surfaces. Erythema nodosum is less common in UC, and improvement coincides with the treatment of the bowel disease [27].

Ophthalmologic Disease

Eye abnormalities are described in approximately 1.6 to 4.6% of children with UC [28]. Iritis and uveitis are associated with the presence of the human leukocyte antigen HLA-B27 and typically run a course independent of the bowel disease. They present with eye pain, headache, and blurred vision or may be asymptomatic and detected by slit lamp examination. Treatment consists of pupillary dilatation, covering the eye to decrease pain and photophobia and local or systemic corticosteroids. Episcleritis usually is related to disease activity and presents with scleral and conjunctival erythema with a burning sensation and photophobia. Local corticosteroid drops are usually effective.

Hepatobiliary Disease

Primary sclerosing cholangitis (PSC) is usually seen in association with UC. PSC is a chronic progressive cholestatic disease characterized by inflammation and fibrosis of the intrahepatic and extrahepatic biliary tree resulting in multifocal strictures. It is diagnosed based on a cholestatic biochemical pattern and a characteristic "beaded" appearance on cholangiography, which defines large duct, or "classic" PSC. In contrast, "small duct" PSC is only identifiable by liver biopsy without the presence of cholangiographic abnormalities. It is a less common variant with a more benign course. PSC may be asymptomatic and is detected because of elevated alkaline phosphatase and γ-glutamyltransferase (GGT) during routine blood screening. Patients may occasionally present with pruritis and PSC prior to the development of UC. The course of PSC appears to be unrelated to underlying bowel disease and may progress even after a colectomy. Peripheral antineutrophilic cytoplasmic antibodies (pANCA) are positive in most patients with PSC and may be a marker for genetic susceptibility for this disease.

Colorectal cancer (CRC) has been associated with concomitant PSC and IBD, with patients having a higher risk of CRC at a younger age when compared to non-IBD PSC patients [29, 30].

Autoimmune hepatitis (AIH) is also seen in association with UC. Diagnosis is made following a liver biopsy, which shows lobular inflammation with piecemeal necrosis. Treatment includes CS and immunosuppressive medications. As with PSC the course of AIH can be independent of UC.

Diagnostic Criteria

The diagnosis of UC is based on clinical presentation and then confirmed by laboratory screening tests, radiologic examination, endoscopic appearance, histopathology, and serological findings. Additionally, it is extremely important to exclude the presence of enteric pathogens before confirming the diagnosis of UC. Lennard-Jones suggested the following criteria for the diagnosis of UC: contiguous mucosal inflammation without granulomata, always involving the rectum and extending continuously in various degrees to a part or the whole colon [31]. However, universally accepted well-defined criteria or a point score for classification of UC do not exist. Abnormalities like complex or fistulizing anal lesions, involvement of the upper gastrointestinal (UGI) tract, skip lesions, or granulomata are highly suggestive of CD [5].

Endoscopic and Histological Features

All patients should undergo endoscopic evaluation (colonoscopy and esophagogastroduodenoscopy) with biopsies taken from all segments of the intestine as part of medical workup. Endoscopic features of UC include continuous mucosal ulcerations starting from the rectum with erythema, friability, and loss of typical mucosal vascular pattern. The Ulcerative Colitis Endoscopic Index of Severity (UCEIS) is a method in which to grade endoscopic severity of disease that includes three descriptors: vascular pattern, bleeding, and erosions or ulcerations. The final UCEIS score ranges from 0 to 8, with higher scores denoting increasing disease activity (See Fig. 30.3) [32].

Histological, UC is characterized by diffuse inflammatory cell infiltration of the mucosa with basal plasmacytosis, crypt architectural distortion, cryptitis/crypt abscesses, and a reduction of mucus-secreting goblet cells (See Figs. 30.1 and 30.2) [5, 33] (Figs. 30.3 and 30.4).

Laboratory and Serological Markers

Laboratory findings are important screening tests in the diagnosis and monitoring of UC; however, there are no disease-specific markers yet identified. Common laboratory findings include an elevated white blood cell count, thrombocytosis, elevated inflammatory markers (CRP, ESR, and fecal calprotectin), and measures of deficiencies due to

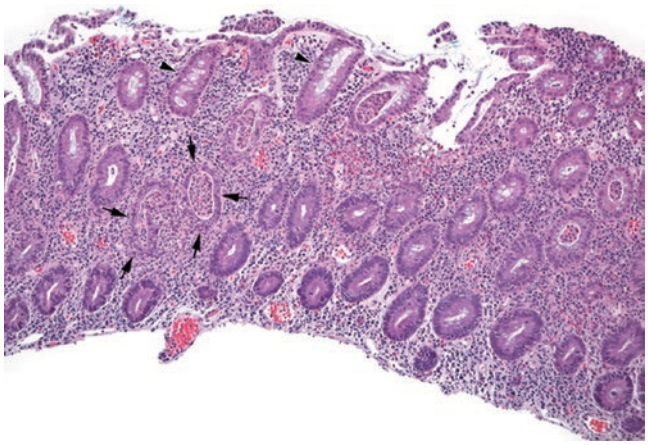

Fig. 30.1 Representative acute inflammatory features. In contrast to relatively well-preserved crypts (arrowheads), crypt abscesses (arrows) are dilated, lined by attenuated damaged epithelium, and contain acute inflammatory cells in the epithelium and the lumen of the crypt (hematoxylin and eosin). Fig. 30.2 Representative architectural and nonarchitectural features. Surface villiform changes are evident (arrows), elongated crypts are easily identified, crypts with abnormal shapes are seen (asterisk), as are subcryptal lymphoid aggregates (arrowheads) (hematoxylin and eosin). (Reprinted with permission from Boyle et al., "Histologic Correlates of Clinical and Endoscopic Severity in Children Newly Diagnosed With Ulcerative Colitis")

increased losses from diarrhea (iron deficiency anemia, hypoalbuminemia) [34].

On presentation, serum inflammatory markers (CRP, ESR) are usually higher in CD compared to UC. In a cohort of 512 children with the new diagnosis of UC, 54% of those with mild disease had normal results on four common laboratory assays (hemoglobin, albumin, platelet count, and ESR), compared with 21% of children with mild CD [35]. ESR and CRP are fairly correlated with colonic inflammation, with a slight superiority of CRP [34]. Fecal calprotectin levels above the cutoff of 100 μg/g have been shown to correlate with mucosal inflammation in UC and are considered to be superior to inflammatory markers in the blood, which may be nonspecific. Fecal calprotectin is also useful for long-term follow-up and in differentiating IBD from functional causes [34].

Generally, serological antibodies related to IBD encompass either autoantibodies or antibodies targeting microbial antigens. Particular microbial antibodies include antibodies directed against the yeast *Saccharomyces cerevisiae* (ASCA), *Escherichia coli* outer membrane porin C (Omp-C), and flagellin (cBir1), which suggests that commensal flora may be triggering a deleterious immune response in patients with IBD [36].

The most frequently studied serological markers in IBD are perinuclear antineutrophil-cytoplasmic antibodies (pANCA) and antibodies against *Saccharomyces cerevisiae* (ASCA). pANCA can be found in 50–70% of UC patients and in less than 10% of CD patients, mainly in those that have a "UC-like" phenotype. pANCA positivity and a negative test for CD-specific ASCA indicate that UC is more likely than CD. In patients with IBD-U, the results of both pANCA and ASCA can aid in making a definitive diagnosis [37].

Previous studies have shown that pANCA titers can be used to stratify patients into distinct subgroups. In a pediatric study from 1998, Ruemmele et al. observed differences in pANCA titers within subgroups of IBD, with equally high titers in both UC-like CD with pancolitis (median of 68.2 EU/mL) and in UC (median of 57.7 EU/mL) [38]. In adults, a preoperative pANCA titer greater than 100 was shown to be a risk factor for the development of chronic pouchitis after ileal pouch-anal anastomosis [39]. An association between high pANCA titers and both pancolitis and backwash ileitis has also been reported [40].

Beyond phenotypic predictions, pANCA titers have been linked to response to therapy. A retrospective study of 56 UC patients with left-sided disease showed that patients who were pANCA-positive were more likely to have treatment-refractory disease than patients with negative pANCA (90% vs 62%) [41]. In a 2007 study of 100 IBD patients starting infliximab, patients who were pANCA+ and ASCA− had lower early clinical response to infliximab (55% vs 76%). In a pediatric study from 2010, Dubinsky et al. reported that pANCA positivity was independently associated with a primary nonresponse to anti-TNF-α therapy in both CD and UC [42].

Another serological marker specific for UC are antigoblet cell antibodies (GAB) occurring in 15–28% of UC patients. Using appropriate assays, GAB are highly specific (and may be pathognomonic) for UC [5]. Recently PR3-ANCA, which is a marker for granulomatosis with polyangiitis, was found in certain subsets of UC patients and appeared to be associated with liver involvement, PSC, and more extensive disease. However, further studies are needed to confirm these findings [43].

In the multicenter pediatric PROTECT study, anti-CBir1 positivity was found in 19% of patients with UC. Additionally, anti-CBir1 positivity was associated with rectal sparing,

more limited disease extent, less plasma cell infiltrate on rectal biopsy, and lower fecal calprotectin [44].

Activity Indices

There are several UC activity indices for classification and prognosis of UC. For clinical practice, it is sufficient to describe disease activity as mild (up to four bloody stools per day), moderate (four to six bloody stools per day and minimal toxicity), or severe (more than six stools per day and signs of toxicity, such as fever, tachycardia). Fulminant colitis is defined when there are more than 10 bloody stools per day with anemia requiring blood transfusion and colonic dilation on plain abdominal radiographs as a sign of toxic megacolon [5].

A commonly used classification for pediatric UC was developed by the Montreal Working Group. In the "Montreal Classification," disease extent for UC was divided into three categories. The first category (E1) describes patients with proctitis, the second category (E2) describes patients with left-sided disease distal to the splenic flexure, and the last category (E3) describes patients with extensive disease proximal to the splenic flexure. Disease extent was defined using macroscopic appearance rather than histopathologic or radiographic evidence. In 2008, Van Limbergen et al. compared a cohort of children with UC to an adult population with UC, demonstrating that 74.5% of pediatric patients had extensive colitis (E3) based on the Montreal classification, compared to 47% of adult patients [19, 45].

The Montreal classification was further adapted into the "Paris classification for pediatric IBD" in 2011, with greater subdivisions for disease location and age of diagnosis. Using the Paris classification, age groupings are subdivided to distinguish children under age 10 from adolescents between 10 to 17 years of age. The Paris classification includes additional subcategories for disease extent, including E3 (extensive disease distal to the hepatic flexure) and E4 (pancolitis proximal to the hepatic flexure) (See Table 30.1) [46]. E4 pancolitis is the most common phenotype in pediatric UC (57–75%), followed by E2 left-sided UC (10–59%), E1 ulcerative proctitis (5–18%), and E3 extensive disease distal to hepatic flexure (4–13%) [18].

Table 30.1 Differences between Montreal and Paris Classifications for pediatric ulcerative colitis

	Montreal	Paris
Extent	*E1:* Ulcerative proctitis	*E1:* Ulcerative proctitis
	E2: Left-sided UC (distal to splenic flexure)	*E2:* Left-sided UC (distal to splenic flexure)
	E3: Extensive (proximal to splenic flexure)	*E3:* Extensive (hepatic flexure distally)
		E4: Pancolitis (proximal to hepatic flexure)

Table 30.2 Pediatric Ulcerative Colitis Activity Index (PUCAI)

Item	Points
(1) Abdominal pain	
No pain	0
Pain can be ignored	5
Pain cannot be ignored	10
(2) Rectal bleeding	
None	0
Small amount only, in less than 50% of stools	10
Small amount with most stools	20
Large amount (>50% of the stool content)	30
(3) Stool consistency of most stools	
Formed	0
Partially formed	5
Completely unformed	10
(4) Number of stools per 24 hours	
0–2	0
3–5	5
6–8	10
>8	15
(5) Nocturnal stools (any episode causing wakening)	
No	0
Yes	10
(6) Activity level	
No limitation of activity	0
Occasional limitation of activity	5
Severe restricted activity	10
Sum of PULAI (0–85)	

Generally, a PUCAI score < 10 indicates remission, 10–34 mild disease, 35–64 moderate disease and ≥65 severe disease
Reprinted with permission from Siow et al. "*Management of acute severe ulcerative colitis in children*"

The Pediatric Ulcerative Colitis Activity Index (PUCAI) as developed by Turner et al. is a tool that is widely used in children, in part due to its feasibility, validity, and its potential use as a primary outcome measure to reflect disease activity (See Table 30.2). The PUCAI is a noninvasive tool for assessment of UC disease severity consisting of six clinical items: daily abdominal pain, rectal bleeding, stool consistency, number of stools, nocturnal stools, and activity level for a maximum score of 85. Scores under 10 represent remission while a score ≥65 signifies severe disease activity. Cut-off scores for remission, mild, moderate, and severe disease have been shown to have sensitivity and specificity of >90%. PUCAI is furthermore useful for assessing clinical response to treatment as a fall of >20 points signifies improvement due to medical therapy [47].

Cross-Sectional Imaging

Imaging modalities are of limited utility in the setting of acute colitis when a firm diagnosis of UC has been previously established (unless complications such as toxic megacolon are suspected). However, if the diagnosis of CD has yet to be ruled out, imaging of the entire GI tract should be performed to help distinguish between UC and CD [48]. This is also relevant for future surgical planning in children undergoing an elective colectomy to effectively rule out CD [49].

Small bowel follow-through (SBFT) was previously considered the standard of care in evaluation of the small bowel in IBD, but has fallen out of favor because of its limitations, including the length of time required to complete the test and increased radiation exposure. Furthermore, SBFT has been shown to have limited sensitivity for detecting small bowel disease when compared to newer radiographic methods. Enterography, which uses enteral contrast to optimally view the small bowel, is becoming more widely used and has proven to be highly sensitive for identifying inflammation and strictures. It encompasses computed tomography enterography (CTE) and magnetic resonance enterography (MRE). CTE is more commonly used in the adult population; however, given the high dose of radiation associated with this modality, its use has been limited in pediatrics. MRE is therefore replacing other imaging modalities as the preferred method in identifying small bowel disease in children [49].

Infectious Etiologies

Clostridium difficile (*C. difficile*)

Patients with IBD are more susceptible to *C. difficile* infection compared to the general population. Nylund et al. found that children with IBD were 11 times more likely to have a diagnosis of *C. difficile* compared to patients without IBD [50]. *Clostridium difficile* infection has been shown to worsen disease severity, prolong hospital stay, increase the need for parenteral nutrition and blood transfusions, as well as increase colectomy rates and colitis relapses.

Nucleic acid amplification tests (NAATs) such as PCR for *C. difficile* toxin genes have surpassed toxin A and toxin B enzyme immunoassays (EIA) as the preferred method for diagnosing *C. difficile,* having both high sensitivity and specificity [51].

In the setting of acute severe UC (ASUC), treatment with oral vancomycin (40 mg/kg per day orally divided into four doses for 10 days) is preferred due to several adult studies showing greater response rates to vancomycin compared to metronidazole in the setting of ASUC. However, if the patient has a coexisting ileus or toxic megacolon, intravenous metronidazole (30 mg/kg in four divided doses for 10 days) with Vancomycin delivered via enema is the recommended treatment [52].

Cytomegalovirus (CMV) Colitis

Several investigators have demonstrated that CMV infection is detected more often in patients with steroid-refractory UC and is associated with increased rates of colectomy. A CMV infection rate as high as 67% is seen in steroid-refractory UC compared to 33% in patients with steroid-responsive disease [53]. It is unclear whether CMV positivity is a causative factor contributing to disease severity or simply a marker of more severe disease. Serologic testing for CMV is not reliable and the diagnosis is usually made via polymerase chain reaction (PCR) or immunohistochemistry (IHC) of intestinal tissue biopsies. A consensus study recommends that children with steroid-resistant disease undergo flexible sigmoidoscopy and biopsy to exclude CMV infection. The decision to initiate antiviral therapy if CMV is detected should be made in conjunction with infectious disease specialists [52]. Recommended treatment is IV ganciclovir 5 mg/kg twice daily for 14 days, with remission rates as high as 67–100% with treatment [54]. A meta-analysis showed that the risk of colectomy was significantly lower in patients with corticosteroid-refractory UC treated with antivirals as compared to those who did not receive antivirals [55].

In a multicenter retrospective case-controlled study of 56 children with ASUC, CMV-positive patients were found to be more resistant to intravenous corticosteroids compared to CMV negative patients. There was also an increased 12-month risk of colectomy that was statistically significant ($p = 0.045$) in the CMV-positive patients [5, 56].

Complications

Toxic Megacolon

Toxic megacolon (TMC) is characterized by total or segmental nonobstructive colonic dilation with signs and symptoms of systemic toxicity. Although the exact incidence of toxic megacolon in pediatric IBD is not known, previous data reports the incidence around 1–5%. Mortality has been reported as 19–50% in adult patients with TMC; however, data is lacking in children. The most common diagnostic criteria for TMC in adults were introduced by Jalan et al. in 1969, which includes the presence of fever, dehydration, hypotension, an altered level of consciousness, hematologic and biochemical abnormalities, as well as radiographic evidence of a dilated colon [57].

Although radiographic evidence of colonic dilation alone is insufficient to diagnose TMC, one retrospective study noted that a transverse colon diameter of ≥56 mm (>40 mm in children less than 11 years old) was highly suggestive of TMC [58]. Importantly corticosteroids, which are commonly used in the treatment of acute colitis, may mask clinical signs of TMC or intestinal perforation. TMC should be treated quickly with intravenous broad-spectrum antibiotics (i.e., ampicillin, gentamicin, and metronidazole), correction of fluid and electrolyte imbalances, *nil* per os (NPO) status, and avoidance of gut-motility slowing agents (i.e., opioids and antidiarrheal medications). Children with toxic megacolon should be evaluated promptly by surgeons and conservative management should only be considered in stable clinical conditions and in highly specialized centers; urgent colectomy is recommended if there is no clinical improvement within 24 to 72 hours [52, 59].

Acute Severe Colitis

Approximately 25–35% of children with UC will require hospitalization for acute severe ulcerative colitis (ASUC) during a period of 3 years after the initial diagnosis, roughly double the rate seen in adult-onset disease [60]. An acute exacerbation of UC may manifest with clinical relapse accompanied by local or systemic complications such as massive hemorrhage, toxic megacolon, and multiorgan failure; in some cases, this condition is defined as "fulminant colitis."

The best validated and most widely used index for the diagnosis of adult ASUC is the European Crohn's and Colitis Organization (ECCO) adaptation of the 1955 Truelove and Witts' classification, which defines ASUC as an exacerbation of disease with at least six bloody stools daily and one of the following: tachycardia (>90 beats per minute), temperature >37.8 °C, anemia (hemoglobin <10.5 g/dL), or an elevated ESR (>30 mm/h) [61]. However, the use of these criteria has never been validated in children with severe colitis. Instead, PUCAI scoring is more widely used for children, with severe disease defined as a score of at least 65 points. Unlike the Truelove and Witts' classification, which is only useful in diagnosing the acute presentation of disease, the PUCAI can be used to monitor disease severity over time as well as response to treatment [48].

ASUC carries a mortality rate of around 1% primarily from perforation, TMC, and infectious complications. Emergent colectomy is now performed infrequently, with medical therapies being used as first-line therapy in ASUC [48].

With few exceptions, children with ASUC should be admitted to the hospital for immediate evaluation and intensive medical treatment. Intravenous methylprednisolone 1 mg/kg/day (up to 40 mg/day) once daily is recommended as the initial treatment on admission; a higher dose of 1.5 mg/kg/day (up to 60 mg/day) in 1 or 2 divided doses should be reserved in children with more severe presentations or who have failed oral steroids before admission. According to a

recent prospective study of pediatric patients with ASUC, higher doses of IVCS > 1.5 mg/kg/day were not associated with better outcomes [62]. Approximately 65% of patients will respond to IVCS alone.

Intravenous fluid for rehydration and correction of electrolyte imbalances should be provided. Blood transfusions and albumin infusions may also be required. Although traditionally patients were restricted from taking food orally, there is no data to support NPO status in UC. In general, patients should be allowed an oral diet if tolerated, and enteral or parenteral nutrition should be provided if an oral diet is not tolerated or in patients with malnutrition. However, enteral feeding is contraindicated if there is concern for toxic megacolon [59].

Bacterial causes for ASUC should be excluded by stool PCR, including *C. difficile*. In the case of *C. difficile* colitis, oral Vancomycin should be considered as first-line therapy in a patient with ASUC. Given the risk of toxic megacolon, an abdominal X-ray (AXR) should be performed upon admission with a low threshold in patients with abdominal tenderness, abdominal distension, significant pain, and systemic toxicity.

In patients who are not clinically improving after 2–3 days of IVCS therapy, surgical consultation should be pursued for potential colectomy. Additionally, CMV colitis should be excluded in children not responding to 3 days of IVCS with a flexible sigmoidoscopy and mucosal biopsies. Second-line therapy, also known as "rescue therapy" or "salvage therapy," should be initiated on the fifth day of IVCS treatment in children with a PUCAI > 65, as this indicates a nonresponse to steroid therapy. Infliximab is recommended as the second-line medical therapy of choice for anti-TNF-α naïve children failing IVCS, with infliximab continuing as a maintenance treatment after discharge from the hospital. Calcineurin inhibitors such as Cyclosporine and Tacrolimus are alternative second-line medical therapies, but if commenced should be weaned within several months as a "bridge" to thiopurines or another maintenance medication such as vedolizumab.

In general, prompt referral for urgent colectomy is recommended following failure of one second-line medical therapy. Children should not be discharged from the hospital unless the disease is at most mild (PUCAI < 35 points) but preferably closer to remission (PUCAI < 10 points) [59].

In a systematic review, the pooled steroid-refractory rate in ASUC across all pediatric studies was 34%, slightly higher than the pooled 29% rate found in adult studies. Additionally, a child who has ever developed an episode of ASUC is at a higher risk for more refractory disease and future colectomy. The advent of calcineurin inhibitors and infliximab has reduced the short-term colectomy rate from 40–70% to approximately 10–20% in children and the 1-year colectomy rate from ~60% to 18–22%. Among those who fail IVCS treatment, roughly 50–60% of responders to rescue therapy will require colectomy within 1 to 2 years [52, 59].

Antibiotics are not routinely recommended in children with ASUC; however, they may provide clinical efficacy likely through modulation of the microbiome. According to the recent PRASCO randomized controlled trial based in Israel, hospitalized children with ASUC defined by a PUCAI ≥ 65 were randomized to receive antibiotics in addition to IVCS (amoxicillin, vancomycin, metronidazole, and doxycycline/ciprofloxacin) or IVCS alone for 14 days, with the antibiotic arm achieving lower mean PUCAI scores compared to the IVCS only arm. However, long-term outcomes are unknown [63, 64].

Medications

5-Aminosalicylic Acid Agents (5-ASA)

Aminosalicylates or 5-ASAs are the first-line treatment for induction and maintenance of remission, of mild-to-moderate UC. They have a wide range of anti-inflammatory and immunomodulatory properties, including inhibition of 5-lipoxygenase, scavenging of reactive oxygen metabolites, and inhibition of interleukin-1 synthesis. Free 5-ASA is almost completely absorbed from the stomach and proximal small intestine, so sustained-release preparations have been developed to deliver the medication to more distal sites of inflammation.

Sulfasalazine has traditionally been used in UC and is composed of 5-ASA linked to sulfapyridine via a diazo bond that is cleaved by colonic bacteria. Sulfasalazine can be formulated as a liquid and is useful in young children with UC. However, sulfasalazine has several dose-limiting side effects, including headaches, nausea, anorexia, and reversible oligospermia that limit its use. Newer formulations, including mesalamine, olsalazine, and balsalazide, utilize pH- or time-dependent delivery systems to release higher concentrations of 5-ASA at various sites of the small intestine and colon with fewer side effects, thus allowing treatment to be tailored to the location of disease [11, 65].

5-ASA can also be effectively administered in the form of an enema or a suppository for management of distal colonic inflammation [66, 67]. According to a multicenter nonrandomized study of 49 children with ulcerative proctitis treated with a 5-ASA, 500 mg suppository daily for 6 weeks, there were significant reductions in disease activity index scores at weeks 3 and 6 with treatment [68].

The landmark Predicting Response to Standardized Pediatric Colitis Therapy (PROTECT) study was initiated in 2012 to systematically examine the responses of children and adolescents newly diagnosed with mild-moderate UC, who were placed on treatment regimens of mesalamine and

corticosteroids to determine when escalation to additional therapy was required. Interestingly, only 48% of patients treated with mesalamine achieved steroid-free clinical remission at week 12 without the need for treatment escalation with immunomodulators, anti-TNF-α agents, or colectomy [69]. According to the results from the North American pediatric IBD registry, only about 40% (86/213) of children with UC who were treated with 5-ASA within 1 month of diagnosis were in steroid-free clinical remission at one year [70].

Corticosteroids

The use of corticosteroids for the induction of remission in UC was first described in 1955 and since then has been the mainstay for induction of remission in moderate to severe UC. Methylprednisolone or prednisone is used more frequently than hydrocortisone with a suggested dosage of 1–2 mg/kg up to a maximum of 60 mg/day [54]. Response should be seen within 2 weeks at which point the steroids can be tapered. No defined tapering schedule exists, but a common approach is to taper by 5–10 mg per week until reaching 20 mg, then decreasing by 2.5–5 mg per week until completed [11] (Table 30.3).

Children on long-term steroids may have more steroid-related complications than adults (even when adjusted for weight), including delay of linear growth and puberty, osteopenia, acne, glaucoma, and cataracts. Steroid dependency has also been reported to be higher in children than in adults (45% vs 8%, respectively). Strategies to avoid steroid dependency include optimization of 5-ASA, adjuvant therapy with enemas, and escalation to immunosuppressants or biologic agents. Steroid treatment is not advised for maintenance of remission [65].

Oral steroids with minimal systemic activity (due to high first-pass liver metabolism) such as budesonide-multimatrix (MMX) are effective at inducing remission in mild to moderate UC. Given the lower risk for systemic side effects, these drugs may be considered as alternative first-line induction drugs in those failing 5-ASA [11].

Rectal corticosteroids can be tried as a second-line add-on therapy to induce remission in proctitis or left-sided ulcerative colitis. Rectal corticosteroids can be administered as foam formulations that are often better tolerated than enemas by patients with active distal UC [11].

Table 30.3 Medication dosages in pediatric ulcerative colitis

Agent	Dosage .
Corticosteroids	1.0–2.0 mg/kg/day prednisone equivalent
	IV or PO in divided doses (max 40–60 mg)
Sulfasalazine	25–75 mg/kg/day (max 4 g)
Mesalamine	30–60 mg/kg/day (max 4.8 g/day)
Azathioprine	1–2 mg/kg/day
	Adjust dose based on 6-MP metabolite levels
6-Mercaptopurine	1–1.5 mg/kg/day
	Adjust dose based on 6-MP metabolite levels
Cyclosporine	4–8 mg/kg/day IV or PO
	Trough blood levels 200–250 mcg/ml
Tacrolimus	0.15 mg/kg/day PO
	Trough blood levels 10–15 ng/ml
Infliximab	5 mg/kg intravenous infusion at week 0, 2, and 6 for induction dosing, 5 mg/kg every 8 weeks for maintenance dosing
Vedolizumab	300 mg (adult dosing) at week 0, 2, and 6 for induction dosing, 300 mg every 8 weeks for maintenance dosing
Ustekinumab	Induction IV (adult dosing): ≤55 kg–260 mg as single dose, >55 kg to 85 kg–390 mg as single dose
	Maintenance subcutaneous: 90 mg every 8 weeks
Tofacitinib	10 mg twice daily (adult dosing) for induction and 5 mg twice daily for maintenance

Immunosuppressive Therapy

Thiopurines

6-Mercaptopurine (6-MP) and its prodrug azathioprine are purine analogs commonly used in the treatment of steroid-dependent UC or in children with frequent relapses (>2 a year) who have failed aminosalicylates [71]. The therapeutic effect of thiopurines may take up to 10–14 weeks after the start of treatment. The recommended dose is 2.5 mg/kg of azathioprine and 1–1.5 mg/kg of 6-MP in a single daily dose [72]. Previous meta-analyses of adult data concluded that azathioprine is not more effective than placebo for induction of remission in UC but is superior to placebo in preventing relapse [71, 73]. Prospective pediatric studies reported steroid-free remission rates of 49% at 1 year and 72% at 2 years in thiopurine-treated children [74, 75].

Thiopurines are associated with a less favorable safety profile than 5-ASA. TPMT assay (either phenotype or genotype) should be used before starting thiopurines to identify patients who are at risk for dose-dependent myelosuppression, and in whom this drug should either not be used (if homozygous for variant alleles or having very low TPMT activity) or administered at lower doses (if heterozygous for variant alleles or having low TPMT activity). TPMT testing does not, however, replace the need for mandatory monitoring of complete blood counts (CBCs) especially when starting treatment.

Dose-independent adverse reactions include fever, pancreatitis, rashes, arthralgias, nausea, vomiting, and diarrhea, while dose-dependent toxicities included leukopenia (up to 5%), thrombocytopenia, infections, and hepatitis [65]. Hepatosplenic T-cell lymphoma (HSTCL) is a rare but fatal

complication of thiopurine therapy. Of over 40 reported cases of IBD-related HSTCL, the majority of patients received thiopurines, with or without anti-TNF-a, and almost all were males; there are only extremely rare and anecdotal case reports of children with HSTCL who were treated solely with an anti-TNF-α medication [65].

Therapeutic drug monitoring, which involves measuring thiopurine metabolites 6-TGN and 6-MMP, is a way of optimizing drug efficacy and avoiding myelosuppression. Dose adjustments following measurement of metabolites have been shown to increase disease remission rates and prevent relapse [65].

Thiopurines may also be used in "combination therapy" with the biologic infliximab. In a prospective trial of combination therapy with azathioprine and infliximab for UC, combination therapy was found to be more effective than either azathioprine or infliximab therapy alone for induction of steroid-free clinical remission and clinical response. Combination therapy results in lower rates of antibodies to infliximab and results higher infliximab concentrations, which are associated with greater efficacy. However, there was no statistically significant difference in mucosal healing at 16 weeks between combination therapy and infliximab therapy alone [76].

Methotrexate

Methotrexate (MTX) is a potent folic acid antagonist that decreases purine production at the cellular level. At high doses, MTX has antiproliferative and cytotoxic effects by inhibiting the enzyme Dihydrofolate reductase leading to defective DNA synthesis and cell death. At low doses that are commonly used in the treatment for IBD, it functions as an immunomodulator.

The immunomodulatory effect of MTX is poorly understood, but involves increased concentrations of adenosine, inhibition of cellular proliferation and induction of apoptosis, and decreased production of inflammatory mediators such as interleukins and eicosanoids [77].

A previous Cochrane meta-analysis of methotrexate for induction and maintenance therapy in adult UC concluded that there is no evidence supporting its use; however, this conclusion relied on low-quality evidence. In the METEOR double-blind placebo-controlled trial of 111 steroid-dependent adults with UC, although clinical remission was significantly higher in the methotrexate-treated group vs. placebo (42% vs. 24%, respectively), there was no statistically significant difference in steroid-free remission at week 16 between methotrexate and placebo [65, 78], which calls into question its potential efficacy in UC.

Tacrolimus

Tacrolimus, a calcineurin inhibitor, is a macrolide antibiotic isolated from the soil bacterium *Streptomyces tsukubaensis* that blocks IL-2 synthesis and thus inhibits the proliferation of T-cells, clonal expansion, and the production of cytokines involved in the immunological response [79]. It possesses potent immunosuppressive properties and has been used to prevent organ rejection after allogeneic organ transplantation or graft-versus-host disease after hematopoietic stem cell transplantation [80]. Tacrolimus is commonly used in inducing remission in patients with steroid-resistant UC due to its fast onset of action, in order to prevent or delay colectomy. Tacrolimus is also useful as a temporary treatment "bridge" for steroid-dependent patients until a new maintenance therapy takes effect. Long-term use is not recommended due to adverse effects such as nephrotoxicity [79, 81].

Rectal tacrolimus has been reported in children and adults as a successful third-line treatment of ulcerative proctitis. In a recent double-blind placebo-controlled trial, 8/11 adult patients receiving rectal tacrolimus ointment (1.5 mg twice daily) achieved mucosal healing by week 8, compared with 1/10 receiving placebo. Although usually well tolerated, rare toxicity episodes have been reported [65].

Biologics

Infliximab

Since the advent of biologics for the treatment of pediatric UC, there has been a significant reduction in overall 2-year colectomy rates [82]. Tumor necrosis factor alpha (TNF-α) is a potent proinflammatory cytokine found in the serum and inflamed intestinal tissue in IBD and is involved in the pathogenesis of disease. TNF-α is a cofactor in the production of inflammatory cytokines such as IFN-y and IL-2. Infliximab (IFX) is a chimeric monoclonal antibody (75% human, 25% murine) against TNF-α. IFX has been shown to induce clinical, endoscopic, and histologic remission, to reduce hospitalizations and surgery rates, and is a leading therapy for moderate-to-severe pediatric IBD. The efficacy of anti-TNF-α therapies has been widely demonstrated in adult and pediatric patients with UC. The Active Ulcerative Colitis Trial I (ACT I) and ACT II trials clearly showed the efficacy of IFX in achieving clinical remission, clinical response, and mucosal healing. IFX is effective for the induction and maintenance of clinical remission for pediatric UC. The standard regimen for this therapy is 5 mg/kg at weeks 0, 2, and 6, followed by maintenance doses every 8 weeks [83, 84].

Studies in children have shown a pooled long-term success rate of infliximab in UC of 64% and a steroid-free

remission rate of 38% and 21% at 12 and 24 months, respectively, with a likelihood of avoiding colectomy at 2 years of 61% [85].

There has been an increasing interest in more intensified dosing regimens of IFX with greater emphasis on maintaining therapeutic drug levels to improve remission rates. Patients with severe disease often have lower serum albumin and IFX loss in the stool, which are factors known to affect IFX pharmacokinetics [86]. Therapeutic drug monitoring (TDM) is based on measurement of IFX trough serum levels and antibodies to IFX for assistance in clinical decision-making. Reactive TDM has been shown to improve outcomes, with trough levels between 3 and 7 μg/mL being correlated with clinical and endoscopic remission. Conversely, given the chimeric nature of this medication, the development of antibodies to IFX is possible. Positive antibodies to IFX have been associated with immunogenic loss-of-response to therapy, which may require a switch to a different agent or combination therapy with a thiopurine [87].

Adalimumab

Adalimumab (ADA), a fully human monoclonal antibody against TNF-α, is less immunogenic than the chimeric antibody IFX and has been initially proven to be as effective as IFX in CD. The pivotal Ulcerative colitis Long-Term Remission and maintenance with ADA (ULTRA) 1 and 2 clinical trials showed the effectiveness and safety of ADA compared to placebo in inducing and maintaining remission at week 8 and 52 weeks in patients with moderate to severe UC who had failed conventional treatment [88]. The open-label extension study, ULTRA 3, confirmed a favorable long-term safety profile of ADA [89]. ADA is commonly used in clinical practice as an off-label treatment for children with UC. According to a retrospective study by Aloi et al., of 32 children who received ADA after prior IFX treatment (either due to nonresponse or the presence of anti-IFX antibodies), 41% were in steroid-free remission and 28% achieved mucosal healing after 52 weeks [90].

Vedolizumab

Vedolizumab is a humanized α4-β7 integrin antagonist, characterized by a gut-selective mechanism of action and less risk of systemic immunosuppression. By binding to surface-expressed α4-β7 integrin, it inhibits T-cell migration into inflamed intestinal tissue. Its efficacy and safety have been evaluated in numerous studies, mostly in adult patients with moderate to severe UC and CD [91]. In two integrated randomized double-blind placebo-controlled trials of vedolizumab in patients with active UC (GEMINI I), vedolizumab was found to be more effective than placebo for both induction and maintenance of remission. Response rates at week 6 (induction) were 47.1% in the vedolizumab group and 25.5% in the placebo group. At week 52 (maintenance), 41.8% of patients who received vedolizumab every 8 weeks and 44.8% of patients who received vedolizumab every 4 weeks maintained clinical remission, compared to 15.9% in the placebo group [92].

In a phase 3b double-blind randomized trial conducted at 245 centers in 34 countries, vedolizumab was found to be superior to adalimumab in achieving clinical remission and endoscopic improvement, but not in achieving steroid-free remission at week 52 [93]. In a retrospective study of pediatric IBD patients receiving vedolizumab (of which 42% had UC), week 14 remission rates were 76% in patients with UC versus 42% in patients with CD. Additionally, anti-TNF-a naïve patients experienced higher remission rates compared to those with previous anti-TNF-α exposure [94]. The clinical response with vedolizumab is slow compared to anti-TNF-α therapies. While the clinical response compared to placebo may be seen at week 6, peak effect of vedolizumab may not be expected until weeks 10–14 [95], which sometimes necessitates the addition of a treatment "bridge" such as Tacrolimus.

Ustekinumab

Ustekinumab is a monoclonal antibody to the p40 subunit of interleukin-12 (IL-12) and interleukin-23 (IL-23) and has been approved for the treatment of psoriasis, psoriatic arthritis, moderate to severe CD in adults, and more recently in moderate to severe UC in adults. In a phase 3 clinical trial of Ustekinumab in adult patients with moderate-to-severe UC, Ustekinumab was more effective than placebo in achieving induction of clinical remission at 8 weeks and maintenance of remission at 44 weeks. This effect was observed in both biologic-naïve patients and patients who had failed a previous biologic [96]. In a recent single-center retrospective study on the use of Ustekinumab in pediatric IBD in which 8% of the study patients had UC, 90% of patients who were biologic-naïve and 50% of patients who failed a previous biologic achieved steroid-free clinical remission at 52 weeks, indicating the efficacy of this medication in the treatment of IBD [97].

Tofacitinib

Tofacitinib is a newer oral small-molecule Janus Kinase (JAK) inhibitor that is approved in multiple countries for the treatment of moderate to severe biologic-refractory UC. The JAK family comprises four intracellular tyrosine kinases—

JAK1, JAK2, JAK3, and nonreceptor tyrosine-protein kinase 2—that regulate signaling for multiple immune mediators implicated in IBD, including IFN-y and interleukins 2, 4, 6, 7, 9, 12, 15, 21, 23, and 27. Tofacitinib inhibits all JAKs but preferentially inhibits JAK1 and JAK3 [98]. In 2018, tofacitinib was approved for the treatment of adults with moderate to severe UC. It has not yet been approved in pediatric populations [99].

Three phase 3 trials known as OCTAVE investigated the use of tofacitinib in induction and maintenance of remission for UC. In two identical phase 3 trials of induction therapy with tofacitinib in patients with moderate to severe UC (OCTAVE induction 1 and 2), the rates of clinical response, clinical remission, and mucosal healing at 8 weeks were significantly higher in patients who received oral tofacitinib 10 mg twice daily than in patients who received placebo. Tofacitinib was shown to have a rapid onset of action, with significant improvement in partial Mayo score observed as early as 2 weeks into treatment. In a third phase 3 trial (OCTAVE Sustain) which evaluated maintenance therapy with tofacitinib, clinical response, clinical remission, and mucosal healing were maintained at 52 weeks with tofacitinib at a dose of either 5 mg or 10 mg twice daily [98].

Tofacitinib has a similar safety profile compared to biologic agents; however, it is associated with an increased risk of herpes zoster infection. This infection risk is dose-dependent, with 10 mg twice daily being more associated with herpes zoster than 5 mg twice daily [100].

Probiotics and Dietary Therapy

Nutritional therapies for IBD have garnered significant interest due to their limited side effect profile, bowel-sparing nature, and naturalistic approach. An individual's diet is thought to play a key role in IBD development as certain foods have been found to increase proinflammatory cytokines, change intestinal permeability, and affect the composition of the intestinal microbiome. Examples of "pro-inflammatory foods" include animal fats and nondigestible dietary carbohydrates as is typical in "Western diets." Conversely, diets high in fruits, vegetables, and fiber have been shown to be associated with a decreased risk of developing IBD [101]. However, the benefit of nutrition as primary therapy for the treatment of UC has not been proven, and enteral or parenteral nutritional supplementation does not appear to increase remission rates or reduce the need for colectomy in UC [102].

Limited studies have explored the relationship between specialized diets and UC. Gearry et al. retrospectively evaluated low fermentable, oligo-, di-, monosaccharides and polyols (FODMAP) diets in 72 patients with IBD (52 CD and 20 UC) for 3 months. Based on self-report, 70% of patients remained adherent to the diet after 3 months, and symptoms of pain, bloating, and diarrhea improved among those who were adherent to the diet. However, there was no significant reduction in disease activity [103, 104].

One of the more commonly used dietary therapies for IBD is the specific carbohydrate diet (SCD), developed by Dr. Sydney Haas, a pediatrician, in the 1930s to treat patients with celiac disease. The SCD was popularized in the late twentieth century by Elaine Gottschall, after her daughter with UC was successfully treated with SCD by Dr Haas. The SCD diet excludes all grains, sugars (except for honey), processed foods, and dairy, except for specific fermented yogurt and some hard cheeses. It is hypothesized that this diet decreases intestinal inflammation by changing the intestinal microbiome from a proinflammatory state to an anti-inflammatory state [105]. There are currently limited studies formally evaluating SCD and its effectiveness for the treatment of IBD. Patient perception seems to support the use of SCD, with 33% reporting remission 2 months after initiation of SCD and 42% achieving clinical remission at 6 and 12 months. A small retrospective study of pediatric patients demonstrated persistent mucosal disease in patients on a modified SCD (rice, oats, quinoa, and potatoes added to diet), who were otherwise asymptomatic with normal or mildly abnormal labs (including fecal calprotectin). Therefore, despite the positive clinical response seen on a strict SCD, the diet is difficult for many patients to maintain long term, and its efficacy in both serological and histological improvement of disease is unclear [101].

Probiotics have been suggested to be beneficial for induction and maintenance of remission in pediatric UC. Specifically, the probiotic preparation VSL #3 has been shown in a small randomized placebo-controlled trial of 29 patients to be efficacious in active pediatric UC, with 92.8% of patients achieving remission with VSL #3 as well as standard IBD therapy compared to only 36.4% of patients achieving remission with standard IBD therapy alone [106]. In a meta-analysis of 12 randomized controlled trials on UC evaluating the effect of different bacterial strains (VSL #3, Bifidobacteria, and *E. Coli* Nissle) on induction of remission, only VSL #3 showed a significantly increased response rate. However, probiotics had no beneficial effect compared to placebo on maintenance of remission [107].

The ECCO/ESPGHAN consensus guidelines on the management of pediatric UC assert that there is insufficient evidence to recommend routine probiotic use for induction or maintenance of remission. As for pediatric pouchitis, there was a 100% consensus for the usefulness of probiotics in the maintenance of an antibiotic-induced remission in subjects with recurrent or chronic pouchitis [108].

Fecal Microbiota Transplantation

"Dysbiosis," which is characterized by alterations in the composition of the commensal microbiome in a host compared to healthy individuals, is thought to play a major role in the pathogenesis of both UC and CD. There is increasing evidence that the composition of gut microbes in a patient with IBD is different and possibly abnormal and that correction of this abnormality might help control the inflammation seen in patients with IBD. While there have been several controlled studies investigating the efficacy of FMT for adults with UC, relatively few trials have taken place testing FMT in children with UC. These small, uncontrolled studies and case reports have had mixed results [16]. The first published study involved five enemas administered daily to nine UC patients aged 7–21, with 6 of the 9 patients maintaining clinical response at one-month follow-up [109]. In a 2015 case series, a single FMT infusion was administered via nasogastric tube (NGT) to four UC patients, with no clinical response seen [110].

The pediatric literature for FMT remains limited, and conclusions are difficult to draw from such small sample sizes. Yet these studies illustrate several key observations. The failure of FMT delivered via NGT suggests that tailoring modes of FMT delivery to individual patients' disease location and targeting specific "hot spots" may influence patient response rates. Also, microbial material may be degraded from gastric acid exposure during proximal delivery techniques. These studies also demonstrated that UC is best treated by targeting the colon directly with *per rectal* therapy [111]. The translation of this practice to the clinical setting is challenging in most pediatric centers where general anesthesia is required for colonoscopy. This is particularly challenging if multiple FMT administrations are required to maximize efficacy. Lastly, these studies suggest that serial treatment may be required to achieve an appreciable response in IBD patients, in contrast to single or short-course FMT administrations in the treatment of recurrent *C. difficile* infections [16, 111, 112].

Psychosocial Barriers

The chronic nature of UC along with the waxing and waning nature of clinical symptoms can be especially disruptive to children's physical, social, and academic development. Young people with IBD are at an increased risk for behavioral and emotional difficulties compared to healthy children, with depression rates as high as 25% [113, 114]. In pediatric IBD, poorer psychosocial functioning including depression is associated with nonadherence to medical management, risk of relapse, worsened disease activity, and higher healthcare costs. Depressive and anxiety symptoms correlate with disease activity, possibly due in part to the effect of proinflammatory cytokines on the brain, sleep disturbance, and side effects from corticosteroid use [113]. According to a recent study, pediatric patients with UC had significantly more sleep disturbance compared to patients with CD, even without significant differences in nocturnal bowel movements or nocturnal pain [115].

Annual depression screening should be a routine part of IBD care, and clinicians should refer patients for treatment when indicated [113].

Psychotherapy has been shown to be effective in young patients with IBD, including cognitive behavioral therapy (CBT) and supportive nondirective therapy (SNDT). Pharmacotherapy may be helpful as an adjunct to therapy [113, 114].

Nutrition, Growth, and Vitamin D

Malnutrition and growth failure are less common in children with UC compared with patients with CD, but nutritional deficiencies can develop quickly during periods of active disease. In newly diagnosed IBD, short stature has been noted only in CD, and for the most part, children with UC are able to reach their expected adult height. It has been documented that bowel rest with total parenteral nutrition (TPN) or exclusive enteral nutrition (EEN) does not have any therapeutic role in acute UC, although bowel rest can alleviate abdominal pain when severe [34, 116].

Children with IBD are particularly prone to disturbed bone health because of increased circulating inflammatory cytokines, malnutrition, delayed puberty, decreased physical activity, treatment with corticosteroids, and in girls, primary or secondary amenorrhea. Severe osteopenia was present in 3% to 6% of patients with UC compared to 12% to 18% of those with CD. DEXA is the preferred screening tool for bone density measurement in children and adolescents, provided that age- and sex-matched z scores are used. It has been suggested that DEXA be performed in all children newly diagnosed with IBD and repeated in cases of severe disease course, including suboptimal growth velocity, prolonged malnutrition, amenorrhea, delayed puberty, and long or repeated treatments with steroids [34, 117].

Children with IBD are particularly at risk for vitamin D deficiency, and emerging data over the past decade have suggested that vitamin D plays a significant role in both epithelial and immune system dysregulation contributing to IBD pathogenesis. According to the multicenter PROTECT study, vitamin D insufficiency was highly prevalent in children with newly diagnosed UC. Also, free and bioavailable vitamin D, but not total 25(OH) vitamin D, was associated with mean PUCAI scores, indicating that bioavailable vitamin D

may contribute to UC clinical activity. It is widely accepted that vitamin D levels be routinely measured and deficiency treated with vitamin D supplementation, especially in children with decreased BMD. Nutrition support, weight-bearing exercise, and disease control using steroid-sparing strategies are also advocated to improve bone formation [118].

Surgical Therapy

In the majority of cases, medical therapy remains the first-line treatment for UC. However, colectomy may be required for patients with severe or medically refractory disease or in those with colonic dysplasia to prevent the development of colorectal cancer (CRC). Timely surgical intervention in the appropriate setting is imperative to avoid complications of UC. Indications for emergent colectomy in a patient with UC include fulminant colitis or a complication of colitis such as massive hemorrhage, perforation, or toxic megacolon. It is also important to consider colectomy in patients with ASUC who have PUCAI scores > 65 at 11 to 14 days after the start of rescue therapy, as surgery is often unavoidable in these situations. In emergency conditions, the primary surgical strategy is to address the complications of disease by removing the diseased colon and constructing an ileostomy. Elective colectomy should be considered in children with active or steroid-dependent UC despite optimized medical therapy and in those with colonic dysplasia [119].

Except in the setting of emergent colectomy, a complete evaluation should be performed to ensure that there is no evidence of CD prior to colectomy, with small bowel imaging or video capsule endoscopy (VCE), upper endoscopy, and colonoscopy unless there is a contraindication.

Total restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) is the procedure of choice in patients with adequate anal sphincter function, as it avoids a permanent ileostomy and allows for a preserved body image with a near-normal life for the patient. An IPAA involves a total proctocolectomy with construction of an ileal reservoir anastomosed to the anus. Surgery restores intestinal continuity, preserves sphincter function, and maintains continence. Several types of ileal pouches can be constructed including the J-shaped, S-shaped, W-shaped, and the lateral-lateral pouch. The J-pouch design is the most commonly used for IPAA [120].

The IPAA may be performed in two or three stages, with the use of a one-stage procedure being extremely rare. However, the choice of a two-stage vs. three-stage procedure is more variable [121]. In general, a three-stage procedure (1st stage: subtotal colectomy with ileostomy creation, 2nd stage: proctectomy and IPAA creation, and 3rd stage: stoma closure) [122] is recommended for patients with ASUC, in those treated with high-dose steroids or recent anti-TNF-α therapy, severe malnutrition, or IBD-U. The most common complication of IPAA is pouchitis, which may clinically manifest as diarrhea, tenesmus, and/or constitutional symptoms [121].

Pediatric patients tend to have a higher rate of pouch-related complications than adult patients after IPAA, including pouch stricture and an eventual diagnosis of CD of the pouch. Postoperative pouch-associated hospitalizations and a requirement of postoperative anti-TNF-a biologics were also more frequent among pediatric patients [123]. According to a previous systematic review, there was no association found between number of surgical stages and the following outcomes: pouch failure rates, complication rates, and quality of life [121].

Pouchitis

Nonspecific inflammation of the ileal pouch reservoir, called pouchitis, is the most common complication following IPAA. The symptoms and severity of pouchitis vary from patient to patient, but typically include increased stool frequency and urgency, loose watery stools, abdominal pain, and hematochezia. Duration of pouchitis can be categorized as acute (<4 weeks), chronic (>4 weeks), or recurrent (≥3 episodes of acute pouchitis a year). The reported prevalence of pouchitis in children with UC after IPAA is variable, and data on predictive factors for the development of pouchitis in children are scarce.

A recent multicenter retrospective cohort study from the Pediatric IBD Porto Group of ESPGHAN that included 129 children who underwent IPAA showed that 67% of children developed pouchitis during a median follow-up of 10.5 months from creation of the pouch, including 26% who developed chronic pouchitis. In an older cohort of 399 UC children with a mean age of 18 ± 3 years at colectomy, 36% had at least one episode of acute pouchitis and 9% had pouch failure [124].

Several reports have identified the risk factors of pouchitis as younger age at the time of UC onset, extensive colonic disease or pancolitis, presence of EIMs, preoperative pANCA positivity, and preoperative steroid use. Endoscopic features of pouchitis may include hyperemia, diminished vascular pattern, friability, hemorrhage, and ulcers. Abnormalities may be focal or diffuse and are often more severe in the distal compared to the proximal pouch. Mucosal biopsies typically demonstrate partial to complete villous blunting with crypt hyperplasia and increased mononuclear inflammatory cells and eosinophils in the lamina propria, crypt abscesses, and ulcerations. Mucosal biopsies should be obtained from the pouch and from the afferent ileal loop, but not from the staple line, as erosions and/or ulcers along the staple line do not necessarily indicate pouchitis.

Antibiotic treatment is considered first-line therapy for pouchitis. Only small placebo-controlled trials have been conducted in adult patients to support this practice, and none in children. A 14-day course of ciprofloxacin and/or metronidazole is recommended, with ciprofloxacin possibly being slightly more effective than metronidazole and with fewer adverse events. Chronic and recurrent pouchitis are less responsive to antibiotic therapy. Oral or topical budesonide can be used in refractory cases. Infliximab and adalimumab have also shown efficacy in refractory pouchitis. The probiotic VSL#3 was additionally effective in maintaining remission in adult patients with chronic pouchitis as shown in two double-blind placebo-controlled trials from Italy [124–126].

Cuffitis may cause symptoms similar to those of pouchitis, especially bleeding. The cuff is the remaining rectal mucosa, referred to as a rectal cuff, at the anastomosis between the ileum and anal canal. This area can become inflamed leading to cuffitis, which, in contrast with pouchitis, typically presents with bleeding and can usually be successfully treated with 5-ASA suppositories [11].

Long-Term Prognosis, Colorectal Cancer, and UC

The association between UC and colorectal cancer (CRC) has been a focus of study for many years. IBD-associated CRC (IBD CRC) affects patients at a younger age than sporadic cancer, but the prognosis is similar, with a 5-year survival of approximately 50%.

Chronic inflammation is believed to promote carcinogenesis. The genetic features that lead to sporadic CRC chromosome instability and DNA hypermethylation also occur in colitis-associated CRC. Unlike normal colonic mucosa, cells of the inflamed colonic mucosa have genetic alterations before there is any histological evidence of dysplasia or cancer. Oxidative stress is likely to be involved in carcinogenesis through reactive oxygen and nitrogen species.

In a meta-analysis, UC increased the risk of CRC by 2.4-fold, accounting for an overall occurrence of 1.6% (including sporadic cases) during the first 14 years of follow-up. Male sex, diagnosis at a young age, extensive colitis, presence of PSC, and family history of CRC are all risk factors for the development of CRC [127].

Evidence-based guidelines advise that patients with colitis receive a surveillance colonoscopy 8–10 years after diagnosis, with the interval for further surveillance guided by risk factors. For a subset of patients, annual CRC screening from the onset of disease has been recommended. This includes patients with coexisting PSC and with a first-degree relative diagnosed with CRC before the age of 50. Because CRC lesions in IBD may be harder to detect as they are often flat and multifocal, it has long been advised to take random biopsies every 10 cm throughout the length of the colon, but this approach represents less than 1% of the colonic mucosa and has been shown to miss many dysplasia-associated lesions. Chromoendoscopy is a method in which the colonic mucosa is colored with a dye to enhance mucosal patterns, therefore making it easier to detect dysplastic lesions. Narrow-band imaging, which is now available on most endoscopes, is thought to help visualize dysplastic/neoplastic lesions through enhancing vessels, pit patterns, and soft tissue structures, but it has not been shown to increase identification of dysplastic lesions compared to standard colonoscopy [127, 128].

Microscopic Colitis

31

Anita Rao and Ranjana Gokhale

Introduction

Microscopic colitis (MC) is an inflammatory condition of the colon marked by chronic or intermittent watery diarrhea with a normal endoscopic appearance but with histological abnormalities [1]. Microscopic colitis is an umbrella term that encompasses two main subtypes: collagenous colitis (CC) and lymphocytic colitis (LC). These subtypes have very similar clinical and epidemiologic features, and the main distinction is made on the basis of histology [2]. Whereas LC is characterized by >20 intraepithelial lymphocytes per 100 colonocytes with mixed inflammation of the lamina propria and normal crypt architecture, CC features a thickened subepithelial collagen band in addition to the inflammatory changes seen in LC. MC affects patients of any age, including children, but most commonly presents in older adults and the elderly with a mean age of 60.7 years [1].

Epidemiology

The reported prevalence of microscopic colitis ranges from 48 to 219 per 100,000 [3], and population-based studies in adults suggest a prevalence of 4–13% in patients investigated for chronic diarrhea [1]. Annual incidence of MC is estimated to be 2.6 to 10.0 per 100,000 person-years, with evidence for an increased incidence over time [4, 5]. The pediatric prevalence of MC remains unknown; however, the youngest reported case is a child 2 years of age [1].

In a pediatric retrospective study by Narla et al, LC was found to be more common than CC, which has also been reported in several adult population-based studies. Also, there was a slight female predominance of MC in this study with a ratio of 3:2, which is lower than what is described for both CC (7:1) and LC (2.4–2.7:1) in most adult reports [1].

Previous epidemiological studies have shown a marked age-dependent rise in the prevalence of MC, especially after the sixth decade of life. Additionally, there is a striking predilection of the disease for female patients [6, 7]. MC typically affects Caucasians, with patients of Indian, East Asian, and Hispanic ethnicity being significantly less affected. Jewish patients tend to be more affected than other ethnic groups [6].

Clinical Findings

MC is characterized by chronic or intermittent watery diarrhea. The severity of diarrhea can range from mild to severe with dehydration and electrolyte abnormalities. Other common symptoms include vomiting, abdominal pain, fecal incontinence, anorexia, abdominal distension, weight loss, and arthralgias [8]. Unlike in adults, MC may manifest in children with atypical symptoms including constipation or alternating constipation and diarrhea [2].

Weight loss is typically mild but can be significant in some cases. MC is not associated with increased mortality, although symptoms can lead to impaired quality of life mostly due to abdominal pain, urgency, and incontinence [3].

Importantly, the symptoms of MC are nonspecific, and many patients with MC actually meet the diagnostic criteria for IBS. Therefore, histologic analysis of colonic biopsies is necessary to distinguish MC from IBS, which is a much more common disorder [9].

Associated Conditions

Although the etiology of MC remains unknown, an autoimmune mechanism is a commonly proposed theory. This rationale is based on the female predominance, frequently

reported co-occurrence of other autoimmune diseases, possible autoimmune marker positivity, and response to steroid therapy [10, 11].

Concomitant autoimmune conditions, such as Type I diabetes mellitus, thyroid dysfunction, connective tissue disorders, and psoriasis, occur commonly in patients with MC. However, the association between MC and celiac disease is clinically particularly important. In fact, as many as 33% of patients with celiac disease have colonic histologic changes that are consistent with MC. In a large cohort study of patients with celiac disease, 4.3% were diagnosed with MC, 72-fold greater than for patients without celiac disease. MC should therefore be considered in celiac patients who have continued or recurrent diarrhea despite a strict gluten-free diet [9, 10, 12]. Alternatively, celiac disease should be considered in patients with MC who have features of malabsorption, such as significant weight loss, steatorrhea, and unexplained iron deficiency anemia, as well as in those who do not respond to usual therapies. In children, additional associations with MC include collagenous gastritis, immunodeficiency, juvenile scleroderma, eosinophilic gastritis, Crohn's disease, autism, and *Aeromonas hydrophila* infection [10].

There have been reports of patients with MC later developing inflammatory bowel diseases (IBDs) and of patients with IBD developing CC. In a population-based study in Sweden by Khalili et al, there was a significant increase in the risk of incident IBD among adult patients with MC [13]. However, given the small number of cases, these reports could represent random associations of two different diseases [14]. Additionally, many of the histologic features of IBD such as Paneth cell metaplasia and crypt architecture distortion may occur in patients with MC who otherwise have no evidence of IBD [9].

According to two studies of women enrolled in the Nurses' Health Study (NHS) and NHS II, certain lifestyle factors were associated with MC risk. Smoking has been identified as a risk factor for MC, with MC risk increasing with higher pack-years and diminishing following smoking cessation [15]. Surprisingly, unlike many other immune- and metabolic-related disorders, obesity and weight gain since early adulthood were associated with a lower risk of MC based on the results of NHS and NHS II [16].

Pathophysiology

The pathophysiology of MC is not well understood. Several proposed etiologies include autoimmunity/immune dysregulation, reactions to luminal antigens, medications, or infectious insults. It may be that multiple different mechanisms result in similar clinical and histologic features that are labeled as MC [9]. Unfortunately, there is no established animal model available for MC and the current data on pathogenesis are mostly obtained from descriptive studies on patients [17]. Causes and associations of MC in the pediatric population are less clear, in part because of the relative paucity of cases in this age group [1].

Reactions to Luminal Antigens and Dysbiosis

As noted previously, MC is strongly associated with autoimmune disorders such as celiac disease, polyarthritis, and thyroid disorders. In fact, up to 20–60% of patients with LC and 17%–40% of patients with CC have concomitant autoimmune disease [18]. LC-like changes can be induced in patients with celiac disease by a gluten enema [19].

One of the most plausible hypotheses for MC pathogenesis is on the basis of autoimmunity: MC is a chronic inflammatory process against self-antigens unleashed by an initial stimulation (infectious, chemical, or others) in a predisposed individual.

Interestingly, symptoms and histologic changes of MC may resolve with diversion of the fecal stream, which also suggests abnormal immune responses to luminal antigens as well as dysbiosis playing a key role in MC [20]. According to a study by Morgan et al, dysbiosis is the defining feature of the gut microbiome in MC, similar to IBD. However, larger-scale studies are needed to confirm this finding [21].

Genetic Predisposition

In a large genetic study and meta-analysis, ancestral HLA haplotype 8.1 was identified as the major genetic risk factor for CC, and an HLA-DRB1∗04:01 susceptibility allele was identified as being protective. Multiple common susceptibility loci were significantly associated with CC risk, suggesting its polygenic nature [20]. Other studies that have investigated HLA associations have found conflicting results. One study reported an HLA pattern similar to that seen in celiac disease, while another found no HLA association. Abnormal HLA expression on colonocytes also has been described. However, given the conflicting results of these various studies, it is difficult to draw conclusions about the role of HLA haplotypes in MC. Familial cases of MC have been reported, but the infrequency of these observations suggests that genetic predisposition is not a major factor in disease [9].

Infections

Several lines of evidence suggest the possibility of an infectious cause for MC, with bacterial translocation in the gastrointestinal tract being theorized to be a mechanism. Bacterial antigens or toxins are suspected to increase inflam-

matory mediators in the colonic mucosa, leading to increased mucosal permeability, increased cytokines, degradation of the collagen matrix, and dysregulation of intestinal subepithelial myofibroblasts [18].

Also, many patients with MC have acute inflammation on biopsy and/or an acute onset of symptoms similar to gastroenteritis, and patients have been reported to respond to antibiotic therapy. Furthermore, MC has many features in common with "Brainerd diarrhea," a chronic diarrhea thought to be infectious, which is characterized by mucosal lymphocytosis on colonic biopsies [9]. However, no causative organism has yet been identified for MC.

Medication Side Effect

An association between MC and the use of NSAIDs has been reported in some studies but not in others and some patients with MC improve with discontinuation of NSAIDs. Several other drugs also have been implicated as possible causes of MC, including proton pump inhibitors, histamine-2 receptor blockers, selective serotonin reuptake inhibitors, beta-blockers, carbamazepine, and others [18]. One study assessed the strength of evidence that individual medications or classes of medications cause MC and concluded that several drugs had strong evidence. However, there are very few cases of positive drug rechallenge, and the number of cases for any specific drug is small, such that a chance association cannot be excluded. Furthermore, some of the drugs thought to cause MC may simply worsen diarrhea, bringing subclinical cases to diagnosis, but do not actually cause the colitis. Regardless, if a potential case of drug-induced MC is identified, discontinuation of the offending medication may lead to symptom resolution [9].

Malabsorption of Biliary Acids

There is conflicting evidence on the role of biliary acids on the pathogenesis of MC. Colonic infusion of biliary acids in animal models may predispose to colitis, and patients with ileal resection causing malabsorption of biliary acids may have diarrhea. An association between atrophy of ileal villi and MC has also been described. However, small studies conducted with bile acid breath tests have shown little or no evidence of malabsorption of biliary acids in patients with MC. Therefore, the validity of this etiology is still uncertain [9, 22].

Abnormal Collagen Metabolism

Collagen typing studies have identified multiple potential abnormalities in patients with CC. Some studies suggest that the abnormal collagen layer is part of a reparative process in response to chronic inflammation, whereas others suggest a primary abnormality of collagen synthesis. Pericryptal fibroblasts regulate the production and deposition of basement membrane collagen. In CC, they appear to be activated leading to excessive collagen production. However, another study found no evidence for increased collagen synthesis as measured by messenger RNA levels and others have not found elevated levels of fibroblast growth factor.

Transforming growth factor β (TGF-β) may play a role in collagen deposition. This growth factor mediates collagen accumulation and, in one study, patients with CC had increased expression of TGF-β mRNA. Vascular endothelial growth factor (VEGF), another important mediator of fibrosis, appears to be upregulated in patients with CC. Furthermore, treatment with Budesonide reduces VEGF levels, at least in the lamina propria.

It has also been theorized that abnormal collagen deposition may be a secondary process in response to ischemia or another insult. However, this would not account for the inflammatory infiltrate that is seen. Also, the severity of diarrhea is more strongly associated with the degree of inflammation and not with the thickness of the collagen band [9, 22].

Laboratory Findings

Routine laboratory work in patients with MC is typically normal. Some patients with MC have increased erythrocyte sedimentation rate (ESR), low albumin, or positive antinuclear antibodies (ANA) or other markers of autoimmunity, although these markers are neither sensitive nor specific for MC [9]. Small studies have demonstrated that fecal calprotectin was slightly, albeit significantly, higher in those with MC compared to patients without organic causes of diarrhea such as IBS. However, the predictive value was low due to a large overlap of patients with active and quiescent disease as well as normal controls. Fecal calprotectin is not currently recommended for excluding or in monitoring MC [23].

Endoscopic and Histological Findings

In MC, the colonic mucosa generally appears endoscopically normal, although occasionally mild findings such as edema or erythema may be seen. Gross ulcerations suggest an alternate diagnosis, although these can be seen in patients with MC who are taking nonsteroidal anti-inflammatory drugs (NSAIDs).

The classic histologic finding in LC is intraepithelial lymphocytosis (IEL), defined as greater than 20 CD3+ lymphocytes per 100 epithelial cells. The IEL density is usually more prominent in the surface than the crypt epithelium. In addition, biopsies show a mixed infiltrate of acute and

chronic inflammatory cells in the lamina propria (Fig. 31.1). CC has similar inflammatory findings on colonic biopsies, although the IEL infiltrate tends to be less prominent. Therefore, the main distinguishing feature of collagenous colitis is a subepithelial collagen layer thicker than 10 μm, compared with a normal band of approximately 5 μm or less (Fig. 31.2). In addition, biopsies often show surface epithelium damage including detachment of the epithelium in some cases. Biopsies can contain neutrophils, with active cryptitis being reported in a third of patients, although acute inflammation should not dominate the inflammatory infiltrate [9]. Although the histological features of the two subtypes may coexist simultaneously, most pathologists consider the presence of a thickened collagen band to be the major diagnostic determinant and, whenever present, indicate a diagnosis of CC [7]. Morphological abnormalities in MC can be diffuse throughout the colon or can be restricted to one area [4]. There are reports of patients transitioning from one type of MC to the other over time or even having evidence for both types on biopsies from a single colonoscopy. This, in addition to the similar response to treatments, raises the question of whether lymphocytic and collagenous colitis are two separate entities or part of a single disorder. The current approach to these diagnoses is to consider them variants of the same condition [9].

At this time, there is no indication for histological monitoring of disease, as histological assessment of remission and relapse is not standardized and correlation between clinical disease activity and histology is weak. In a study of 283 patients, histological features persisted in postdiagnostic biopsies for up to 1 year in 77% with CC and 64% with LC [23].

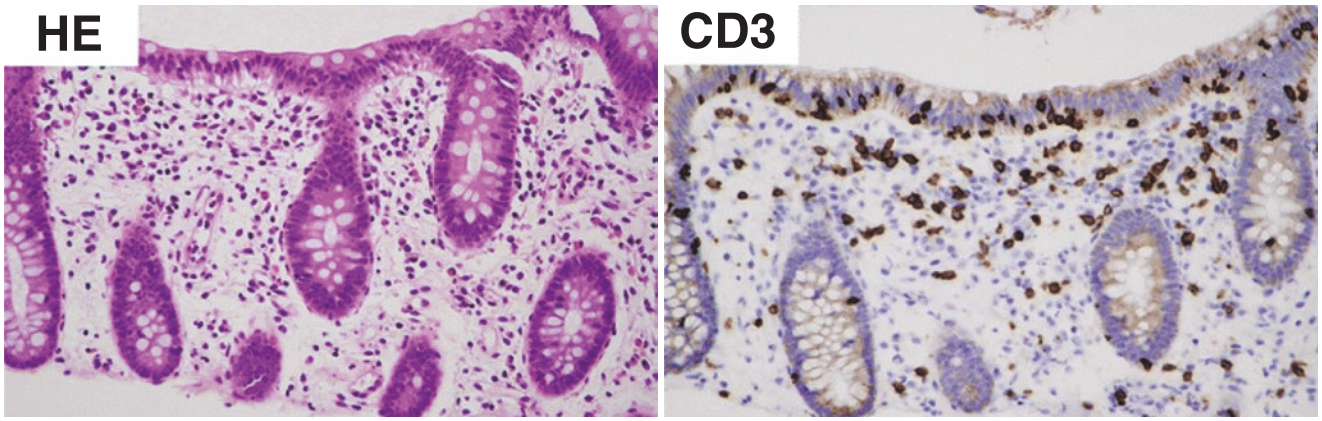

Fig. 31.1 Increase of intraepithelial lymphocytes in lymphocytic colitis. H&E staining (*upper panel*) and CD3 immunostaining (*lower panel*) of the colonic tissue obtained from a lymphocytic colitis patient are shown. Note that immunostaining of CD3 clearly demonstrates the increase of CD3-positive cells in the surface epithelial layer. (Reprinted with permission from Okamoto et al. [48])

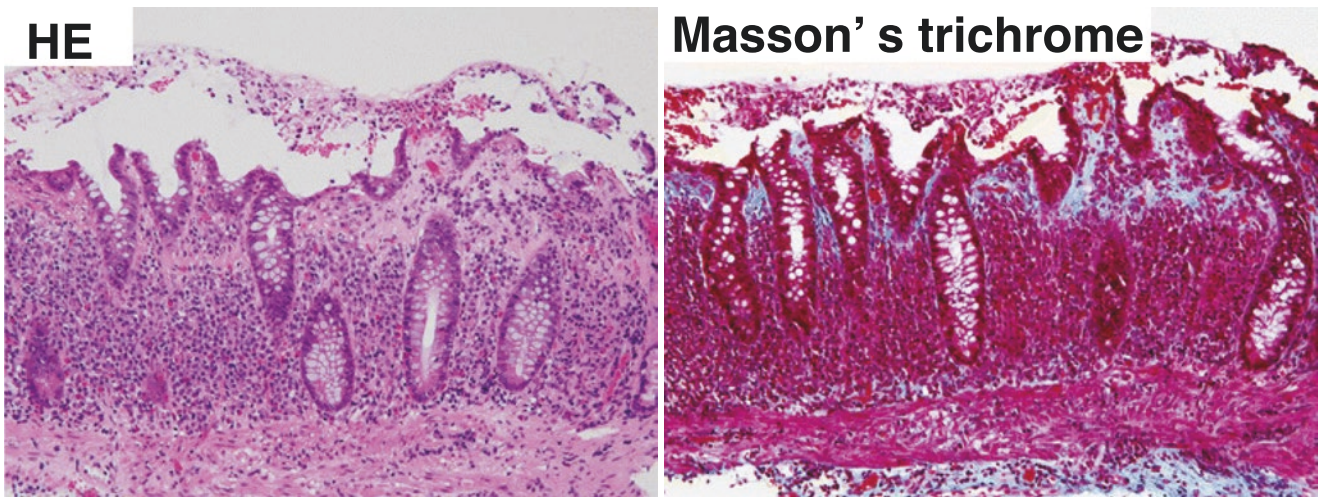

Fig. 31.2 Subepithelial collagen band in collagenous colitis. H&E staining (*upper panel*) and Masson's trichrome staining (*lower panel*) of the colonic tissue obtained from a collagenous colitis patient are shown. Note that thickening of the collagenous layer is clearly observed at the subepithelial area. (Reprinted with permission from Okamoto et al. [48])

Treatment

Unlike other inflammatory colitides, there is no evidence that the persistence of histological inflammation signifies long-term unfavorable outcomes such as colorectal cancer or the need for surgery. The goal of medical therapy is to relieve symptoms and improve quality of life while minimizing drug-related adverse effects [3].

The first step in managing patients with MC is to search for exacerbating factors, including a careful dietary history searching for foods that might contribute to diarrhea, such as dairy in a patient with lactose intolerance or excessive consumption of artificial sweeteners that can lead to diarrhea. It is also important to review the patient's medication list, including over-the-counter products and health food supplements, to search for drugs or other substances that might cause MC or exacerbate diarrhea. In some patients, identification and elimination of these factors may lead to improvement or even resolution of the diarrhea.

Nonspecific antidiarrheal medications such as loperamide or diphenoxylate can be effective in patients with MC and are often used empirically in patients with mild diarrhea. Bismuth subsalicylate may additionally be effective at a dose of 3 tablets (262 mg each) 3 times per day [9]. One open-label study of 13 patients with MC showed clinical remission in 11/13 and histological remission in 9/13 patients with bismuth treatment [24].

For patients with diarrhea who do not respond to antidiarrheals or those with severe symptoms, corticosteroids are typically used. Budesonide, a locally active steroid that undergoes extensive first-pass metabolism in the liver with low systemic exposure, is the best-studied treatment for MC, with four randomized, placebo-controlled induction studies in collagenous colitis [25–28] and three in lymphocytic colitis [4, 29, 30]. In all of these studies, budesonide was superior to placebo for inducing response, with response rates typically in the 80% to 90% range. Budesonide has fewer side effects than prednisone, and unless cost is a significant concern, it is commonly used when corticosteroid therapy is necessary. The efficacy of budesonide is due in part to its potent anti-inflammatory effect in the terminal ileum and proximal colon, [4] with its anti-inflammatory properties also extending to the left colon. Budesonide also improves bile acid malabsorption by upregulating bile acid transporter gene expression in the small intestine [31]. Despite the demonstrated efficacy of budesonide for induction of remission, relapse is common (~70%) when it is discontinued [9].

The American Gastroenterological Association and the European Microscopic Colitis Group both recommend budesonide 9 mg/day for 6–8 weeks as first-line therapy for active MC. In patients who experience clinical relapse after discontinuation of budesonide, low-dose maintenance therapy is recommended, starting at no more than 6 mg/day. Once remission is re-established, the dose is gradually reduced to 3 mg/day, and then to 3 mg every other day. After 6 to 12 months of therapy, another attempt is usually made to discontinue budesonide. If relapse occurs again, budesonide is restarted at the lowest effective dose [4, 9]. Recommendations for long-term therapy are based on studies of budesonide in CC, because no long-term randomized trials of budesonide have been performed in LC [4]. Given the limited systemic availability of budesonide, adverse effects are minimal but may include headaches, nausea, and dizziness. Prolonged steroid use may additionally cause osteoporosis; however, there is little scientific data on this being an issue in patients who are on the medication chronically [32].

Treatment with 5-aminosalicylates such as mesalamine is often considered as a second-line treatment for MC [3]. However, several large uncontrolled studies have reported that only a minority of patients respond to aminosalicylates, and previous studies have shown that Mesalamine 3 g/day administered for 8 weeks was not better than placebo in patients with CC [28] or LC [4].

For patients with steroid-resistant MC, treatment options include bile acid–binding agents or an immunomodulator. Immunomodulators such as azathioprine, 6-mercaptopurine, or methotrexate can be helpful in steroid-dependent or steroid-refractory patients [33–37]. In one single-center retrospective study of patients with severe treatment-resistant MC, azathioprine, and 6-mercaptopurine had a steroid-sparing effect and maintained improvement or remission of diarrhea over a median follow-up of 26 months, with a response rate of 89% [34]. Cholestyramine can be effective, although many patients do not tolerate it because of its texture. Bile-acid binders in tablet form, such as colesevalam or colestipol, might be better tolerated [9]. There have been a few reports of efficacy with the use of antitumor necrosis factor (TNF) therapies such as adalimumab and infliximab in patients with severe steroid-refractory MC [38–40]. Several case series have additionally highlighted the efficacy of Vedolizumab in the treatment of steroid-refractory MC [41–44].

Surgical Treatment Options and Prognosis

Patients rarely require surgery for medically refractory MC. Currently available operations include ileostomy creation with or without a proctocolectomy and ileal pouch anal anastomosis (IPAA), as diversion of the fecal stream normally results in resolution of symptoms [45]. The reported natural history of MC varies considerably. The rate of symptomatic remission ranges from 59% to 93% in patients with LC and 2% to 92% in those with CC. One study reported

spontaneous remission in 15% of patients with CC and treatment-induced remission in another 48% of patients. Only 22% of patients required prolonged therapy. In contrast, clinical trials have reported that only 12% to 40% of patients respond to placebo after 6 to 8 weeks, and an open-label study of steroid therapy reported that 90% of patients required maintenance therapy [46]. In addition, most patients have periods of clinical remission with relapses before lasting clinical remission is achieved [47].

Vasculitides Including IgA Vasculitis (Henoch–Schönlein Purpura)

32

Karunesh Kumar, Jutta Köglmeier, and Keith J. Lindley

Introduction

The vasculitides are a group of inflammatory disorders of the walls of blood vessels (usually the arteries). They are relatively rare in childhood with the exception of Henoch–Schönlein purpura (HSP) and Kawasaki disease (KD). Vasculitis might be primary or secondary to a number of causes including infections, drugs, hypersensitivity reactions, and connective-tissue disorders. The consequences of arterial inflammation include tissue ischemia and necrosis, giving rise to many of the gastrointestinal (GI) manifestations of vascular inflammation such as pain and bleeding.

Vasculitis is usually classified based on the size of blood vessel(s) involved in the inflammatory process (Table 32.1 and Fig. 32.1). Not all of these are seen in the pediatric age group. The vasculitides associated with GI manifestations in childhood are listed in Table 32.2. These manifestations include abdominal pain (potentially due to bowel ischemia or bowel wall thickening and subacute obstruction), GI blood loss (due to GI ulceration, which can be aphthoid, undermined, or fissure like), diarrhea which is often bloody (due to nonspecific inflammation of the ileum or colon), and an acute abdomen as a consequence of a perforation [1]. Vasculitis subtypes have tendency to involve specific areas of the gastrointestinal tract: Kawasaki Disease (KD) along with Granulomatosis with polyangiitis (GPA) and Eosinophilic granulomatosis with polyangiitis (EGPA) commonly involve the esophagus and oral mucosae; SLE-associated vasculitis, polyarteritis nodosa (PAN), IgA vasculitis (IgAV), EGPA, and GPA may be implicated in

Table 32.1 Classification of the vasculitides

Large-vessel vasculitis (LVV)
Takayasu's arteritis
Giant cell arteritis (GCA)
Medium-vessel vasculitis (MVV)
Polyarteritis nodosa (PAN)
Kawasaki disease (KD)
Small-vessel vasculitis (SVV)
(i) Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV)
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss)
Granulomatosis with polyangiitis (Wegener's granulomatosis)
Microscopic polyangiitis
(ii) immune-complex SVV
IgA vasculitis (Henloch–Schönlein; IgAV)
Cryoglobulinemic vasculitis
Hypocomplementemic urticarial vasculitis
Antiglomerular basement membrane disease
Variable-vessel vasculitis (VVV)
Behcet's disease
Cogan's syndrome
Single-organ vasculitis (SOV)
Vasculitis associated with systemic disease
Lupus

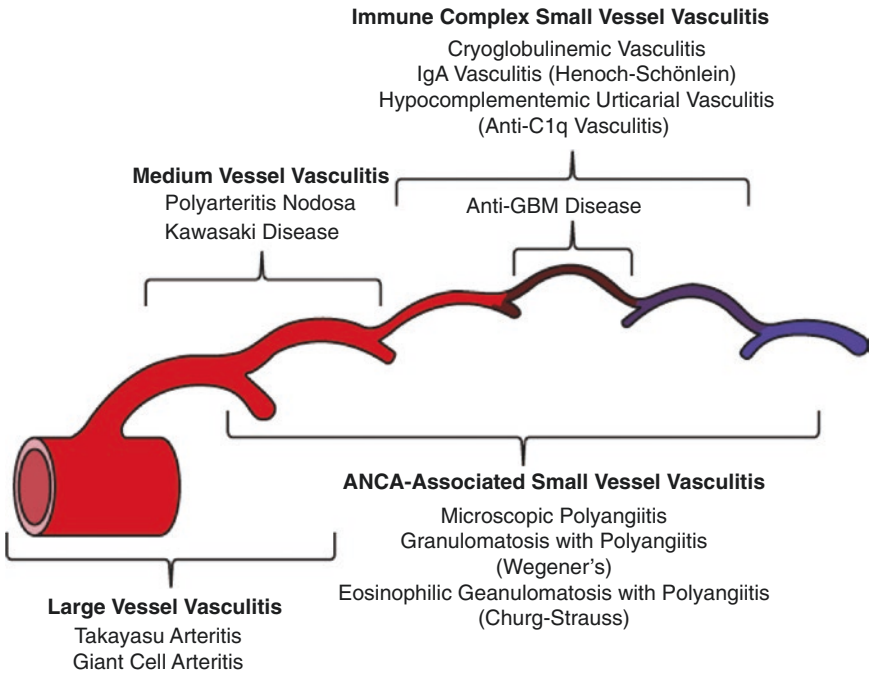

Fig. 32.1 Distribution of vessel involvement by large-vessel vasculitis, medium-vessel vasculitis, and small-vessel vasculitis. Note that there is substantial overlap with respect to arterial involvement, and an important concept is that all three major categories of vasculitis can affect any size artery. Large-vessel vasculitis affects large arteries more often than other vasculitides. Medium-vessel vasculitis predominantly affects medium arteries. Small-vessel vasculitis predominantly affects small vessels, but medium arteries and veins may be affected, although immune-complex small-vessel vasculitis rarely affects arteries. The diagram depicts (from *left* to *right*) aorta, large artery, medium artery, small artery/arteriole, capillary, venule, and vein. Anti-GBM—antiglomerular basement membrane; ANCA—antineutrophil cytoplasmic antibody. *ANCA* Antineutrophil cytoplasmic antibody. Table 32.2 Vasculitides associated with gastrointestinal manifestations in childhood

Henoch-Schönlein purpura
Kawasaki disease
Polyarteritis nodosa (PAN)
ANCA-associated vasculitis (AAV)
Behcet's disease
Systemic disease (lupus and rheumatoid)

stomach vasculitis; PAN, Anti-neutrophil cytoplasmic antibody–associated vasculitis (AAV), IgA vasculitis (IgAV), SLE-associated vasculitis, Takayasu's arteritis (TA), and Giant cell arteritis (GCA) have all been associated with intestinal and mesenteric ischemia [2].

IgA Vasculitis (Henoch–Schönlein Purpura)

IgA vasculitis (IgAV), formerly known as HSP, is an immune-complex, nonthrombocytopenic, small-vessel vasculitis, which typically presents acutely [3]. It is the most common vasculitis seen in childhood with an estimated annual incidence of 3–27/100,000 children in the UK [4]. The disease is characterized by a leukocytoclastic vasculitis with deposition of immunoglobulin A1 (IgA1) immune complexes in vascular tissue, principally capillaries and postcapillary venules. The disease is predominantly seen in children aged 3–10 years with the peak incidence aged 4–6 years. The clinical phenotype seems to change with age as older children have more joint symptoms (as in adult-onset IgAV) and younger children more abdominal symptoms. IgAV is more frequent in the autumn/winter months and will commonly follow an infection [5]. Proposed infective triggers include group A beta-hemolytic streptococcus, Parvovirus B19, *Staphylococcus aureus*, and Coxsackie virus to name a few. It has been suggested that the pathogenesis involves the recognition of galactose-deficient IgA1 by antiglycan antibodies and the deposition of these immune complexes in small vessels.

A recent large series suggests that 100% of patients have skin involvement with 60–70% having "palpable purpura" of the lower limbs and buttocks, 66% have arthritis, which is usually symmetrical affecting the knees, ankles, and feet, and 54% have GI involvement usually with lower GI bleeding or abdominal pain but also intussusception, ileal perforation, and pancreatitis [6]. Renal manifestations are seen in 30% and include nephritic or nephrotic syndromes, which can lead to chronic renal failure in a minority of cases. Rash in IgAV is

characteristic: it starts as macules, then these develop into petechiae, raised purpura, or larger ecchymoses in a symmetrical, gravity-dependent manner or on pressure points. The rash may last for up to a week and recur for few months.

Diagnostic criteria include the presence of purpura or petechiae with lower-limb predominance with one of the following: diffuse abdominal pain, acute arthritis or arthralgia, hematuria or proteinuria and any biopsy showing predominant IgA deposition [7].

Described GI complications of HSP include intussusception, bowel ischemia and infarction, intestinal perforation, late stricturing, acute appendicitis, GI hemorrhage (occult and massive), pancreatitis, and gallbladder hydrops. One large series of patients reported abdominal pain in 58% of children and positive stool occult blood (SOB) in 18% [8]. Frank lower-GI bleeding was present in 3%. Plain abdominal radiology frequently showed dilated thickened bowel loops when the SOB was strongly positive, which was also visualized on ultrasound examination. Intussusception, perhaps the most serious GI complication of HSP, was rare (0.5%), although in other series a prevalence of up to 5% is described. The presence of thickened bowel wall on ultrasound might act as a prognostic marker for duration of hospitalization for HSP [9]. Endoscopic findings vary and can include the presence of circumscribed vascular lesions (rather similar to the palpable purpura seen on the skin) and segmental ischemic change (Fig. 32.2) [10].

Recently, it has been proposed that fecal calprotectin might be an early predictor of abdominal type of IgAV as well as a marker of disease severity [11].

It is usual for children to make a complete recovery from HSP with only supportive treatment with the exception of HSP-associated nephritis, which is the cause of end-stage renal failure in up to 2% of children. Recurrence occurs in around 25% of patients, and they may be more common in older children. Most gastrointestinal manifestations are self-limited, but severe abdominal pain, GI hemorrhage, and/or intussusception will require intervention. Corticosteroids as first line have been used: usually oral at 1–2 mg/kg/day for 2 weeks, and then weaned or pulsed IV methylprednisolone 10–30 mg/kg with a maximum of 1 g/day for three consecutive days may be considered [12]. The use of steroids does not seem to protect against the development of nephritis.

Kawasaki Disease

KD is the second commonest childhood vasculitis, which affects about 8/100,000 children younger than 5 years of age annually in the UK with twice as many cases occurring in the United States (25/100,000) and approximately 20 times the incidence in Japan (265/100,000). In common with IgAV, KD is more prevalent in the winter months [13]. The disease affects predominantly medium- and small-sized arteries and is normally self-limiting. However, coronary artery aneurysms are present in 25% of untreated patients and can lead to myocardial infarction or late coronary artery stenosis. In addition to involvement of the coronary arteries, systemic arterial injury can occur.

Fig. 32.2 Cutaneous purpura and small bowel hyperemia with ulceration in a young adult with HSP. (Reprinted from Hsu et al. [10], with permission from Elsevier)

The seasonality and clustering of KD support an infectious trigger, although to date no single organism has been identified. The much higher prevalence of disease in Japanese and Korean children supports the notion that genetic predisposition is also an important factor and genome-wide association studies have identified a number of genes associated with disease susceptibility and disease phenotype [13].

Diagnosis of classic KD is clinical, comprising the presence of unremitting fever for 5 days or more plus 4/5 or more of the following features: conjunctivitis; lymphadenopathy; polymorphous rash; changes in lips, tongue or oral mucosa, and involvement of extremities including periungual desquamation (see Table 32.3). A careful history may reveal that ≥1 principal clinical features were present during the illness but resolved by the time of presentation. Patients lacking full clinical features of classic KD may be labeled *incomplete or atypical KD* and if coronary artery abnormalities are detected, the diagnosis of KD is considered confirmed in most cases [13].

Apart from disease defining coronary artery involvement, KD is characterized by inflammation in medium-sized arteries in other organs leading to varied systemic manifestations including hepatitis, pneumonitis, aseptic meningitis, myocarditis, pericarditis, pyuria, pancreatitis, and lymphadenopathy [13].Uncommon features of the disease include gallbladder hydrops, GI ischemia, mononeuritis, nephritis, seizures, and ataxia.

Overall, abdominal symptoms, particularly diarrhea, which can be bloody or nonbloody, are a frequent early feature of KD. Abdominal pain is less frequent [14]. Vasculitic appendicitis, hemorrhagic duodenitis, paralytic ileus, and pseudo-obstruction are also described [15, 16]. Bowel wall edema may be evident as segmental thickening of the bowel wall as may gallbladder hydrops [17].

Inflammatory markers (erythrocyte sedimentation rate, ESR, and C-reactive protein, CRP) are inevitably elevated as is the peripheral blood white blood cell count. Thrombocytosis, which can be very marked, usually occurs in the second week of the disease.

Table 32.3 Diagnostic criteria for Kawasaki disease

Criterion	Description
Fever	Duration of 5 days or more plus 4/5 of the following
1. Conjunctivitis	Bilateral nonpurulent with limbic sparing
2. Lymphadenopathy	Cervical, often >1.5 cm
3. Rash	Polymorphous with no vesicles or crusts
4. Changes in lips/mucus membranes	Red cracked lips, "strawberry" tongue, erythema of oropharynx
5. Changes in extremities	Initially: Erythema and edema of palms and soles
	Later: Periungual desquamation

Early treatment of KD with aspirin and intravenous immunoglobulin (IVIG) reduces the occurrence of coronary artery aneurysms. A single infusion of 2 g/kg IVIG (within 10 days) and an anti-inflammatory dose of aspirin (30–50 mg/kg/day in Europe/Japan and 80–100 mg/kg/day in the United States) will reduce the likelihood of developing coronary artery aneurysms in the majority of patients, although approximately 20% of children are IVIG resistant. The dose of aspirin should be reduced to an antiplatelet dose during the thrombocytosis phase of the illness. Patients who continue to have fevers and an ongoing systemic inflammatory response 48 h post IVIG are likely to be IVIG nonresponders and can be treated with intravenous methyl prednisolone for 5 days followed by 2 weeks of oral prednisolone or perhaps anti-tumor necrosis factor (TNF) antibodies [13].

Systemic Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a necrotizing arteritis of medium and/or small arteries, which has been subclassified into systemic PAN and cutaneous polyarteritis. While systemic PAN is generally severe and cutaneous polyarteritis relatively benign, the cutaneous form can go on to develop features of multiorgan involvement. The presenting features of PAN can be very nonspecific and are known to affect a number of systems notably the skin, musculoskeletal system, kidneys, and GI tract. A recent pediatric series documents the most common presenting features of PAN as fever (87%), myalgia (83%), arthralgia/arthritis (75%), weight loss of >5% of body weight (64%), fatigue (62%), livedo reticularis (49%), and abdominal pain (41%). In this series, 59% had GI symptoms comprising abdominal pain (49%), blood in the stools (10%), and bowel ischemia/perforation (8%) [18]. The diagnosis may be delayed as the symptoms are so nonspecific. GI bleeding can be massive, especially when it arises from a Dieulafoy lesion, a submucosal vascular abnormality with a prominent tortuous artery with/without aneurysm formation [19, 20]. Ulcers, which are circumscribed and well demarcated, may also be evident (Fig. 32.3a, b). Following remission induction in PAN, the onset of GI symptoms is a major clinical predictor of clinical relapse. Other symptoms seen in PAN less frequently include cardiac, respiratory, and neurological manifestations.

GI symptoms are generally attributable to ischemia, which can lead to infarction, perforation, or stricture [21] [22]. The systemic vasculitides can also be associated with an ischemic colitis or a nonspecific colitis that can mimic inflammatory bowel disease [23].

The diagnosis of PAN is usually made through a combination of clinical, histopathological, and arteriographic features and relies on one mandatory criterion plus one of five secondary criteria. Mandatory criteria comprise fibrinoid

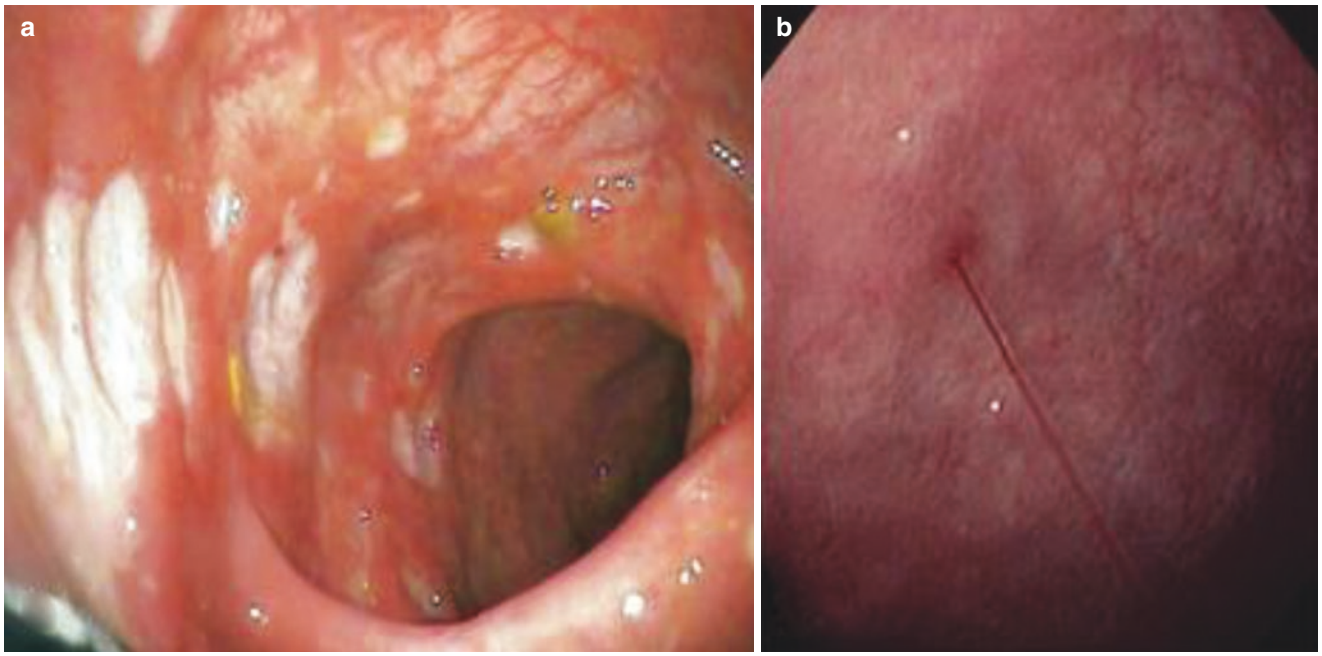

Fig. 32.3 (**a**) Punched-out ulcers with well-demarcated edges in the colon in PAN. Ulcers are typically shallow and irregular often with surrounding erythema. (Reprinted from Vavricka SR et al. Clin Gastroenterol Hepatol 2007; 5(11): A22, with permission from Elsevier). (**b**) Bleeding Dieulafoy lesion in the stomach in a case of PAN. (Reprinted from Maeda et al. [20], with permission from Elsevier)

necrosis of the walls of medium-sized arteries from an affected organ together with an inflammatory response in the adjacent vessel wall, which is characteristic of PAN or angiographic abnormalities (aneurysm, stenosis/segmental narrowing, or occlusion/pruning) of medium or small arteries. Secondary criteria include (i) characteristic skin involvement, (ii) myalgia or muscle tenderness, (iii) hypertension, (iv) peripheral neuropathy/mononeuritis, and (v) renal involvement. Renal, hepatic, and mesenteric arteriography is commonly used as a diagnostic tool in children which overall has a sensitivity of 94% for diagnosing PAN (Fig. 32.4). The microaneurysms that are the hallmark lesions of PAN can be frequently detected in hepatic, splenic, and mesenteric arteries as well as the renal arteries.

There are many differential diagnoses of PAN in children; it is particularly important to exclude monogenic vasculitides such as deficiency of adenosine deaminase type 2 and other autoinflammatory syndromes [24]. ANCA is typically negative in PAN.

A detailed discussion of treatment is beyond the scope of this chapter. Historically, this has involved remission induction with pulsed intravenous methyl prednisolone often with cyclophosphamide and antiplatelet agents followed by maintenance therapy with low-dose steroids and a steroid-sparing agent (usually azathioprine). Biologics may be considered in patients who fail to respond to standard therapy or where concern exists regarding cumulative cyclophosphamide dose; either TNF-alpha or IL-6 blockade or B cell-depleting agents may be considered [24].

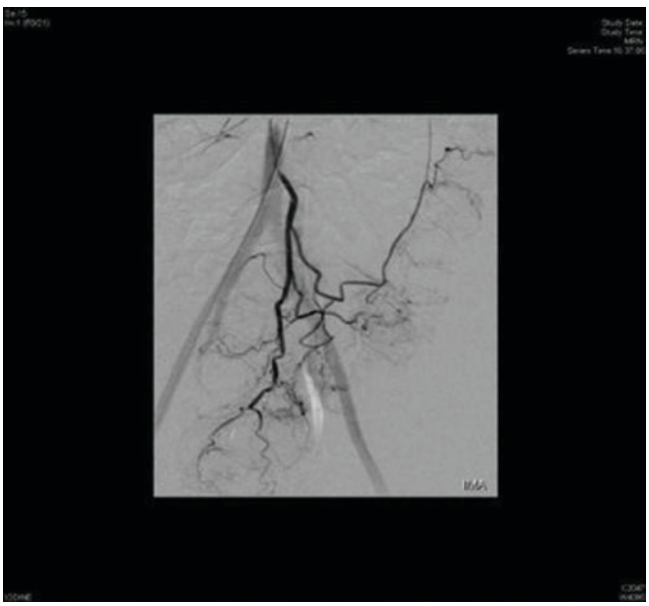

Fig. 32.4 Inferior mesenteric artery angiogram showing vessel caliber changes and aneurysms characteristic of polyarteritis nodosa

Behçet Disease

Behçet disease (BD) is rare in childhood (2/100,000 in Europe). Behçet described a triad of aphthous stomatitis, genital ulceration, and uveitis. It is a variable-vessel vasculitis, which can affect veins and arteries of any size. Three of six items are required to classify a patient as having pediatric

BD: recurrent oral aphthosis (three attacks/year), genital ulceration or aphthosis, skin involvement (necrotic folliculitis, acneiform lesions, erythema nodosum), ocular involvement (anterior uveitis, posterior uveitis, retinal vasculitis), neurological signs (with the exception of isolated headaches), vascular signs (venous thrombosis, arterial thrombosis, arterial aneurysm) [25].

BD is extremely heterogeneous, affecting multiple organ systems with distinct geographical variations in symptoms. For example, GI manifestations are more prevalent in the Far East, while vascular manifestations are seen in the eastern Mediterranean. GI symptoms may be seen in up to 40%, and they are usually isolated abdominal pain or discomfort. Rare features are digestive aphthae, bleeding, and perforation [25]. Vascular manifestations include venous thromboembolism, arterial stenosis, aneurysms, and occlusions. Neuro-Behçets can present with headache, papilledema, central venous sinus thrombosis, and/or brain parenchymal disease causing seizures and focal neurological abnormalities [26].

ANCA-Associated Vasculitis (AAVs)

ANCA-associated vasculitides (AAVs) are multisystemic diseases and include granulomatosis with polyangiitis (GPA, earlier Wegener's granulomatosis), eosinophilic granulomatosis with polyangiitis (EGPA, earlier Churg-Strauss syndrome), and microscopic polyangitiis (MPA). Histopathologically, AAV is characterized by necrotizing changes (granulomatous lesions in GPA and eosinophil-rich granulomatous inflammation in EGPA) in small blood vessels (i.e., capillaries, venules, and arterioles), with few or no immune deposits, and associated with the presence of circulating ANCA autoantibodies that are usually directed against myeloperoxidase (MPO) or proteinase 3 (PR3) [27]. Tissue biopsies are crucial for diagnosis though may not be always necessary. Renal biopsy in case of renal involvement remains the gold standard for diagnosis. Treatment remains based on adult approach comprising remission-induction and remission-maintenance phases. Combination of glucocorticoids and either cyclophosphamide (CYC) or rituximab (RTX) is recommended in induction. Maintenance is recommended with Azathioprine (AZA) or MTX in combination with glucocorticoid. Leflunomide (LEF) or MMF may also be considered as an alternative agent.

Granulomatosis with Polyangiitis (GPA)—Formerly Wegener's Granulomatosis

GPA is one of the antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides (AAV) and is a necrotizing granulomatous vasculitis of small blood vessels [27–29]. The main features of the disease are due to a widespread small-vessel vasculitis with clinical manifestations of a necrotizing glomerulonephritis and respiratory tract granulomata dominating the clinical picture. GI involvement has been described in 6–36% of pediatric patients and may present with abdominal pain; mucosal ulceration of the esophagus, small or large bowel; GI perforation and rarely colitis and catastrophic GI hemorrhage or infarction of the gall bladder, intestine and colon. cANCA positivity is seen in up to 70% of these children.

Eosinophilic Granulomatosis with Polyangiitis (EGPA)

This is another of the AAV, which is extremely rare. ANCA (usually pANCA) is positive in about 30% of cases. Histopathological features are those of a small-vessel (arteries and veins) granulomatous vasculitis with an eosinophil-rich inflammatory infiltrate. In addition, there is an eosinophil-rich granulomatous infiltrate of the respiratory tract and usually a history of asthma, allergic rhinitis, and peripheral blood eosinophilia.

GI-tract involvement is seen in 40–60% of patients causing symptoms of pain (ischemic), ulceration, perforation, and bleeding [27–29]. Independently of vascular involvement, eosinophil-rich inflammation of the GI mucosa can result in symptoms such as diarrhea and perhaps pain. Forty percent of children have gastroenterological symptoms at presentation [30]. The pediatric disease is usually steroid responsive but subject to relapse.

Microscopic Polyangiitis (MPA)

Microscopic polyangiitis is a necrotizing vasculitis of small vessels in which up to 65% of patients are perinuclear ANCA (pANCA) positive. It is uncommon in childhood [31]. The classical presentation is with rapidly progressive glomerulonephritis and alveolar hemorrhage [32]. In common with the other AAV, pain is a dominant GI symptom, although GI blood loss, cholecystitis, ischemic colitis, and bowel perforation are described. GI manifestations can be seen in 11–58% of pediatric patients [27–29].

Single-Organ Vasculitis (SOV)

Systemic vasculitis occurs when vascular inflammation involves multiple territories or organs. In single-organ vasculitis (SOV), the inflammation is restricted to a single organ or part of that organ. By definition, there has to be a

lack of spread outside the single organ for at least 6 months. SOV is known to affect the GI tract and may affect small-, medium-, or large-sized arteries. The condition is not well described in children and is more commonly part of PAN (e.g., appendiceal vasculitis). Patients with gastrointestinal SOV may present with an acute abdomen, and diagnosis may be made based on histological findings after the surgery.

Takayasu Arteritis (TA)

Takayasu arteritis (TA) is a vasculitis predominantly affecting large vessels (mainly the aorta and its main branches). It is most commonly seen in Asia and rarely encountered in the pediatric age group. Diagnosis is based on angiographic abnormalities showing aneurysm/dilatation (mandatory criterion) plus one of the five following criteria: pulse deficit or claudication, four limbs BP discrepancy, bruits, hypertension, and acute phase reactant [7]. Girls are more often affected than boys. Patients frequently complain about headache, abdominal pain, limb claudication, myalgia, arthralgia, and fever. Weight loss is said to occur in about 10% of affected individuals. GI manifestations are rare and occur mainly as ischemic changes due to large involvement in small or large intestine, spleen, or, more rarely, liver. Cases of TA coexisting with IBD have been reported in adult series.

Systemic Lupus Erythematosus–Associated Vasculitis

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease. The presence of anti–double-stranded DNA (anti-dsDNA) antibodies in the blood is a highly specific test for SLE being present in 70–80% with titers of antibody tending to mirror disease activity. Other pathogenic autoantibodies in SLE include antibodies to nucleosomes, Ro (a ribonucleoprotein component), La (an RNA-binding protein), C1q (complement), phospholipids, and the *N*-methyl-D-aspartic acid (NMDA) receptor. Many of these antigens are expressed on the cell surface during the process of apoptosis, and it has been hypothesized that abnormalities of the apoptotic pathway, which are ubiquitous in SLE, are important in the genesis of pathological autoantibodies [33].

Systemic lupus can affect the GI tract causing chronic, nonspecific mucosal inflammation, mucosal ulceration, or vasculitis resulting in mesenteric/GI ischemia (Fig. 32.5a, b). The three possible manifestations of lupus enteritis include lupus mesenteric vasculitis, intestinal pseudo-obstruction, and/or protein losing enteropathy [34]. Gastrointestinal manifestations directly attributable to SLE affect one-fourth of adult patients and vasculitis (usually cutaneous) can be seen in similar number of patients. Commonly, GI symptoms may be because of infection or drug side effects. GIS manifestations has been observed in up to 27.5% children in some series.

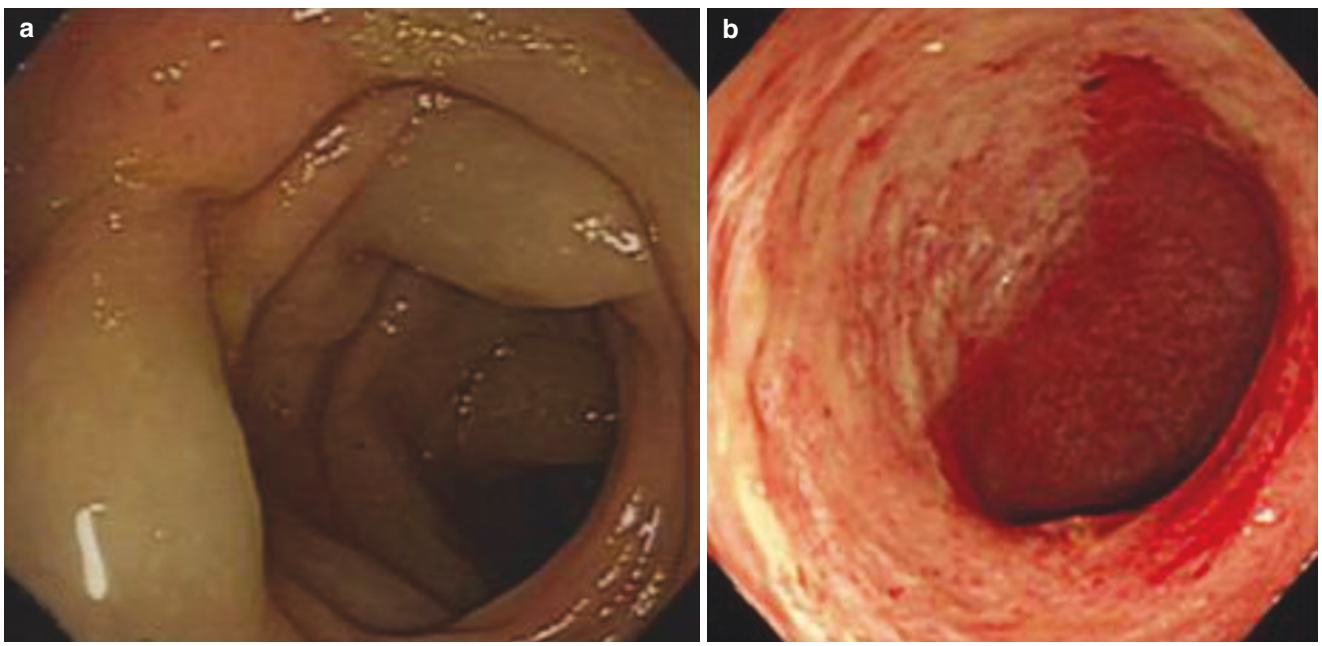

Fig. 32.5 (**a**) Mucosal edema in association with nonspecific inflammation in SLE. (**b**) Colonic mucosal ulceration in SLE. (Reprinted from Lee CK et al. Gastrointest Endosc 2010;72(3): 618–9, with permission from Elsevier)

Abdominal pain is present in 8–40% of published series of individuals with SLE; in children, it is most commonly (32%) due to lupus-associated mesenteric vasculitis [35]. Other causes of pain include pancreatitis (10%), appendicitis (7.5%), and cholecystitis (6%). Patients with vasculitis usually have high SLA disease activity scores (SLEDAI) but do not commonly have substantially elevated inflammatory markers.

The clinical presentation of lupus-associated mesenteric vasculitis commonly mirrors an acute surgical abdomen. It is suggested that individuals with SLE, high SLEDAI, and an "acute abdomen" undergo imaging to look for evidence of vascular compromise before any surgical intervention (Fig. 32.6).

Juvenile Dermatomyositis (JDM)

In juvenile dermatomyositis (JDM), vasculitis affects striated muscle, the skin, subcutaneous tissues, and the GI tract. Children develop weakness of the muscles of the neck, shoulders, and hips, leading to difficulties with swallowing, getting up from sitting, or climbing stairs. Gastrointestinal involvement occurs in 22% to 37% of JDM patients. GI manifestations include dysmotility (dysphagia), vasculitis with associated malabsorption, and other more severe features of GI vasculopathy. Vasculopathy may present with abdominal pain, rectal bleeding, intestinal ischemia, pneumatosis, or life-threatening perforation [36]. GI bleeding and perforation can be catastrophic and are a major cause of death [37].

Fig. 32.6 CT scan of patient with PIMS-TS demonstrating mural thickening of the right colon and ascites

Rheumatoid-Associated Vasculitis

Rheumatoid arthritis (RA) is another systemic inflammatory disorder with articular and extra-articular manifestations. Rheumatoid vasculitis (RV) is a systemic necrotizing vasculitis affecting small- and medium-sized arteries, which is clinically extremely heterogenous and can affect skin, nerves, and abdominal viscera. RV is usually seen in long-standing disease and when there are other extra-articular manifestations, and these patients are always rheumatoid factor positive. It is usual to find raised inflammatory markers (ESR and CRP), polyclonal hypergammaglobulinemia, and often hypocomplementemia. GI involvement is rare in children, but, in common with other vasculitides, can result in ischemia, perforation, and hemorrhage [38].

Pediatric Inflammatory Multisystem Syndrome: Temporally Associated with SARS-CoV 2 (PIMS-TS)

In the spring of 2020, the first wave of the COVID 19 pandemic, caused by the SARS-CoV 2 coronavirus, caused over a million deaths worldwide within 9 months. Children, in general, are not severely affected by SARS-CoV 2 infection but rarely children go on to develop a multisystem inflammatory response developing a syndrome, which shares features with Kawasaki disease and toxic shock syndrome. While not usually the presenting complaint abdominal symptoms / signs are prevalent within this group of children and can be a source of diagnostic confusion.

The RCPCH (UK) has adopted the following definition in its guidance for health professionals [39]:

1. A child presenting with persistent fever, inflammation (neutrophilia, elevated CRP and lymphopenia), and evidence of single or multiorgan dysfunction (shock, cardiac, respiratory, renal, gastrointestinal, or neurological disorder) with additional features (Table 32.4). This may include children fulfilling full or partial criteria for Kawasaki disease.
2. Exclusion of any other microbial cause, including bacterial sepsis, staphylococcal or streptococcal shock syndromes, infections associated with myocarditis such as enterovirus.
3. SARS-CoV-2 PCR testing may be positive or negative.

Table 32.4 Clinical and laboratory features of PIMS-TS

Clinical:
All:
Persistent fever >38.5 °C
Most:
Oxygen requirement
Hypotension
Some:
Abdominal pain
Confusion
Conjunctivitis
Cough
Diarrhea
Headache
Lymphadenopathy
Mucous membrane changes
Neck swelling
Rash
Respiratory symptoms
Sore throat
Swollen hands and feet
Syncope
Vomiting
Laboratory findings:
All:
Abnormal fibrinogen
Absence of potential causative organisms (other than SARS-CoV-2)
High CRP
High D-dimers
High ferritin
Hypoalbuminemia
Lymphopenia
Neutrophilia in most (normal in some)
Some:
Acute kidney injury
Anemia
Coagulopathy
High IL-10
High IL-6
Proteinuria
Raised CK
Raised LDH
Raised triglycerides
Raised troponin
Thrombocytopenia
Transaminitis
Imaging:
Echo and ECG—Myocarditis, valvulitis, pericardial effusion, coronary artery dilatation
Abdominal US—Colitis, ileitis, lymphadenopathy, ascites, hepatosplenomegaly

Adapted from RCPCH Guidance (Ref. [39])

Other definitions have been adopted in other countries / continents although all are broadly similar. For example, the Centers for Disease Control and Prevention (CDC) in the United States has termed the condition as multisystem inflammatory syndrome in children (MIS-C) [40]. The reader is referred elsewhere for further information regarding this rapidly evolving field [41].

Notably KD and PIMS-TS have quite a different epidemiology. For example, KD is seen most commonly in children aged <5 years, whereas PIMS-TS is seen predominantly in older children and adolescents. PIMS-TS is seen most frequently in children with a Black African heritage, whereas KD is most common in Asians.

Common clinical features include fever, gastrointestinal symptoms, rash (variable distribution including limbs, face, generalized), and less commonly conjunctivitis [42]. A high proportion present in shock requiring early transfer to an intensive care setting.

Among the first case series to be reported in the UK is a cohort of 15 patients presenting to a tertiary Hospital Cardiology service [43]. The patients were predominantly male and non-Caucasian with a median age of 8.8 years. Many had either a history of positive SARS-Cov 2 PCR or positive combined IgG, IgA, IgM serology. All had pyrexia for a median of 5 days at presentation and 87% had gastrointestinal symptoms. Another series of 35 children [44] found 87% to have gastrointestinal symptoms including abdominal pain, vomiting, and diarrhea. In this series, approximately 50% had abnormal abdominal ultrasonography with findings including RIF inflammatory changes, mesenteric lymphadenopathy, and bowel wall thickening of the ileum and / or right colon. A further series of children with prominent gastrointestinal symptoms had similar findings on imaging [45]. It is the author's experience that with treatment of the PIMS-TS/MIS-C, these bowel/intra-abdominal findings resolve completely without the need for invasive investigation.

Investigation of Children with Suspected GI Vasculitic Disorders

The diagnosis of vasculitis can be challenging because of the heterogeneity of possible presentations and the diagnosis is often delayed. A high index of suspicion is key to early diagnosis and intervention. The three elements of diagnosis include (i) definition of a clinical phenotype compatible with the diagnosis, (ii) specific serology or radiology, and (iii) histological confirmation if appropriate.

A basic diagnostic evaluation might include blood count and film, inflammatory markers (ESR; CRP), liver function, pancreatic enzymes, ANCA and anti-dsDNA antibodies, rheumatoid factor, complement (C3 and C4), anticardiolipin antibodies, and cryoglobulins. In addition, urine microscopy and a chest X-ray should be undertaken. Immunological investigations might include antistreptolysin O antibody titer (ASOT), ANA, ENA antibodies, ANCA, antiphospholipid antibodies, Immunoglobulins IgG/IgA/IgM/IgE, Complement (C3, C4), and rheumatoid factor.

Infective etiologies might be considered and appropriate investigations might include Tuberculosis screen, viral PCR (e.g., CMV, EBV, enterovirus, adenovirus, VZV, HBV, HCV), Serology for HIV, Rickettsiae, Borrelia burgdorferi, Mycoplasma; Viral serology for Hepatitis B & C, Parvovirus B19). If the differential diagnosis includes autoinflammatory syndromes, then investigations, which might include DNA analysis for MEFV (familial Mediterranean fever), TNFRSF1A (TNF alpha receptor associated periodic fever syndrome, TRAPS), and ADA2 (deficiency of ADA2), should be planned in consultation with an expert rheumatologist.

Further investigations will be directed by the clinical phenotype.

Abdominal ultrasound might allude to bowel wall thickening as might abdominal CT/MRI. CT/MRI might also allude to segmental perfusion defects. Magnetic resonance angiography is not as sensitive as digital subtraction angiography (DSA) in PAN (see below).

Selective visceral DSA is diagnostically very sensitive for systemic PAN and might highlight the site of bleeding if present. Characteristic features of PAN include aneurysms of small- and medium-sized arteries (seen in 40%). Other nonaneurysmal features include arterial cut-off, arterial tapering and stenoses, arterial beading, pruning of the renal arterial tree, and perfusion defects. Overall, arteriographic abnormalities are present in 94% of children with PAN affecting the renal, hepatic, and mesenteric vasculature [18]. Assessment of the GI mucosa by esophagogastroduodenoscopy, video capsule endoscopy, and ileocolonoscopy with biopsy might reveal a plethora of pathologies in vasculitic disorders. Nonspecific colitis is common in childhood systemic vasculitis, and a nonspecific enteritis may be present in SLE [23]. Ulceration may be ischemic or inflammatory in origin. Behcet's ulcers tend to be round, few in number (<5), and focally distributed when compared with Crohn's ulcers, which are more commonly irregular in shape [46]. Ulcers in SLE are typically punched-out. In HSP edema, patchy mucosal redness, erosions, and linear ulceration of the duodenum and ileum are described [46, 47] Purpura similar to that seen in the skin might be seen in the GI mucosa [48]. Mucosal biopsies in Churg–Strauss may demonstrate evidence of eosinophilic GI disease/eosinophilic gastroenteritis.

Lymphonodular Hyperplasia

33

Tuomo J. Karttunen and Sami Turunen

Introduction

Lymphonodular hyperplasia (LNH) of the gastrointestinal (GI) tract, also known as lymphoid follicular hyperplasia, is characterized by a significant enlargement and often accompanied increase of the numbers of isolated lymphoid aggregates in one or several segments of the GI tract or by a similar alteration of the lymphoid nodules of the Peyer's patches of the distal part of the small intestine. By current criteria, enlargement should be severe enough to make the aggregates elevated and visible by endoscopic assessment or radiology, usually the diameter exceeding 2 or 3 mm in the colon.

LNH is rare in adults and common in children [1–6]. However, true prevalence of LNH is largely unknown as only symptomatic patients have studied, and diagnostic criteria have been variable. In children, LNH has been reported in the duodenum in 16–19% [7, 8], in the ileum in about 50% [9, 10] and in the colon and rectum in about 30–46% [9, 11–13]. In majority of reported series, LNH was the only finding. Clinically, LNH can be asymptomatic or associated with variable set of symptoms including abdominal pain, diarrhoea, bleeding or even intestinal obstruction [3].

LNH is considered a reactive condition of the mucosa-associated lymphoid tissue, with a potential to regress along with disappearance of the inducing stimulus or with maturation of lymphatic system. Inducing factors include microbiological or nutritional luminal factors, immune deficiencies and diseases affecting mucosal integrity. However, exact pathogenic mechanisms are largely unknown, and in many cases, no specific aetiology can be identified. In children, LNH in the colon has long been considered to be an incidental and physiological finding, with spontaneous resolution along with maturation of the mucosal immune system [1, 2, 14]. However, a proportion of paediatric cases seem to associate with non-immunoglobulin E (IgE) food allergies [3, 5].

Definition

LNH has usually been defined as a condition characterized by visible increase of the numbers or size or both of mucosal lymphoid nodules which elevate above the surrounding mucosa. LNH can be seen in any part of the GI tract. Diagnosis is based on endoscopic or radiological appearance, and the confirmation of diagnosis may need exclusion of other diseases causing mucosal elevations, such as various lymphoid neoplasms and reactive and neoplastic polypoid lesions (Table 33.1). This definition does not apply for lesser grades of lymphoid hyperplasia, where either increase of the numbers of lymphoid follicles or their enlargement is of lesser degree so that mucosal elevations are not formed. However, it is likely that there is continuum between such lesser grades of hyperplasia and the endoscopically visible lymphoid nodular hyperplasia [14] fulfilling the current criteria, pointing to the idea that the current criteria are arbitrary, and they do not have a clear pathophysiological basis.

Endoscopic Assessment and Criteria

LNH can be detected by using barium enema [6], but currently, the diagnosis is usually based on endoscopic visualization of typical whitish or mucosa-coloured elevations (Figs. 33.1, 33.2, and 33.3). Image-enhanced endoscopy systems like narrow band imaging or blue laser imaging [15, 16] increase visibility of lymphoid nodules and may need different thresholds for the diagnosis of LNH. In cases where there

is any uncertainty of the nature of nodules, a complementary histopathological analysis should be used to exclude other disease processes causing endoscopic nodularity or multiple polypoid lesions (Table 33.1). Endoscopic detection of LNH requires active search and is aided by adequate air insufflation during examination as the folds may hide nodularity [5, 11]. LNH can also be detected by capsule endoscopy [17].

Physiologic number and size of isolated lymphoid follicles are variable as they respond dynamically to the signals from diet and luminal flora [18]. In a normal small intestine, the estimated amount is one per 269 villi in the jejunum and one per 28 villi in the ileum [19]. In the proximal colon, the number is 0.02/mm of muscularis mucosae and in the rectosigmoid 0.06/mm [20]. Areal density of lymphoid aggregates in the colorectum was estimated to be 1.1–2.7/cm^2 [21]. Krauss et al. [14] used high-resolution endoscopy objective counting of lymphoid follicles, and they found that in adults, 1–8 lymphoid follicles per endoscopy field of view in the terminal ileum and caecum can be defined as normal. Size of isolated lymphatic follicles has been estimated to be in the range of 0.1–2 mm [19, 20, 22, 23].

Table 33.1 Gastrointestinal diseases to be considered in the endoscopic and histopathological differential diagnosis of LNH

All anatomical areas	
	Giardiasis
	Granulation tissue polyps
	Inflammatory bowel disease
	Lymphangiectasia
	Lymphoma
	Multiple adenomatous or hyperplastic polyps
	Metastatic tumours
	Familial and sporadic gastrointestinal polyposes
	Ganglioneuromatosis
	Neuroendocrine hyperplasia and neoplasia
Stomach	
	Cystic polyps
	Hyperplastic gastritis
Small intestinal mucosa	
	Duodenal Brunner's gland hyperplasia and adenoma
	Duodenal gastric heterotopia
	Groove pancreatitis
Colon and rectal mucosa	
	Solitary rectal ulcer

By definition, diagnosis of LNH needs increase of the size of the lymphoid nodules, but it may be associated with the increase of their numbers. However, there are no consensus criteria for LNH. Considering the size of the nodules, minimum size for a hyperplastic nodule has been suggested to be 2 [11] or 4 mm [24]. The minimum number of nodules has been described as a "cluster", and a cluster has been defined as a group of minimum of 10 nodules [11, 25]. Typically, the size range of polypoid lymphoid nodules is 3–6 mm in diameter.

Terminal ileum contains physiologically elevated lymphoid nodules, that is, Peyer's patches and the diagnosis of LNH is more subjective in this anatomical location. Autopsy studies have indicated that in children the size and number of these patches increases with age [25], and that in adults these are at their highest in the third decade [26]. Kokkonen graded the abundance of ileal lymphoid nodules in four

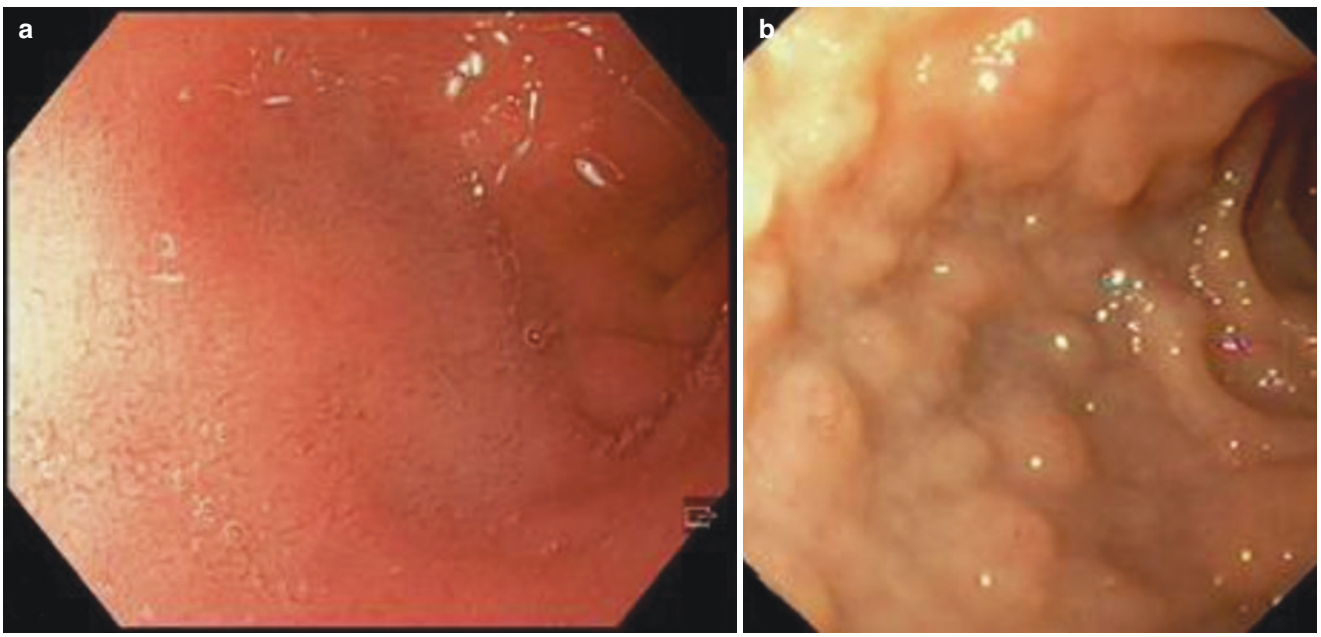

Fig. 33.1 An endoscopic view of the bulb of the duodenum showing normal smooth mucosa (**a**). In lymphonodular hyperplasia, elevations are dispersed along the walls covering the otherwise normal mucosa (**b**)

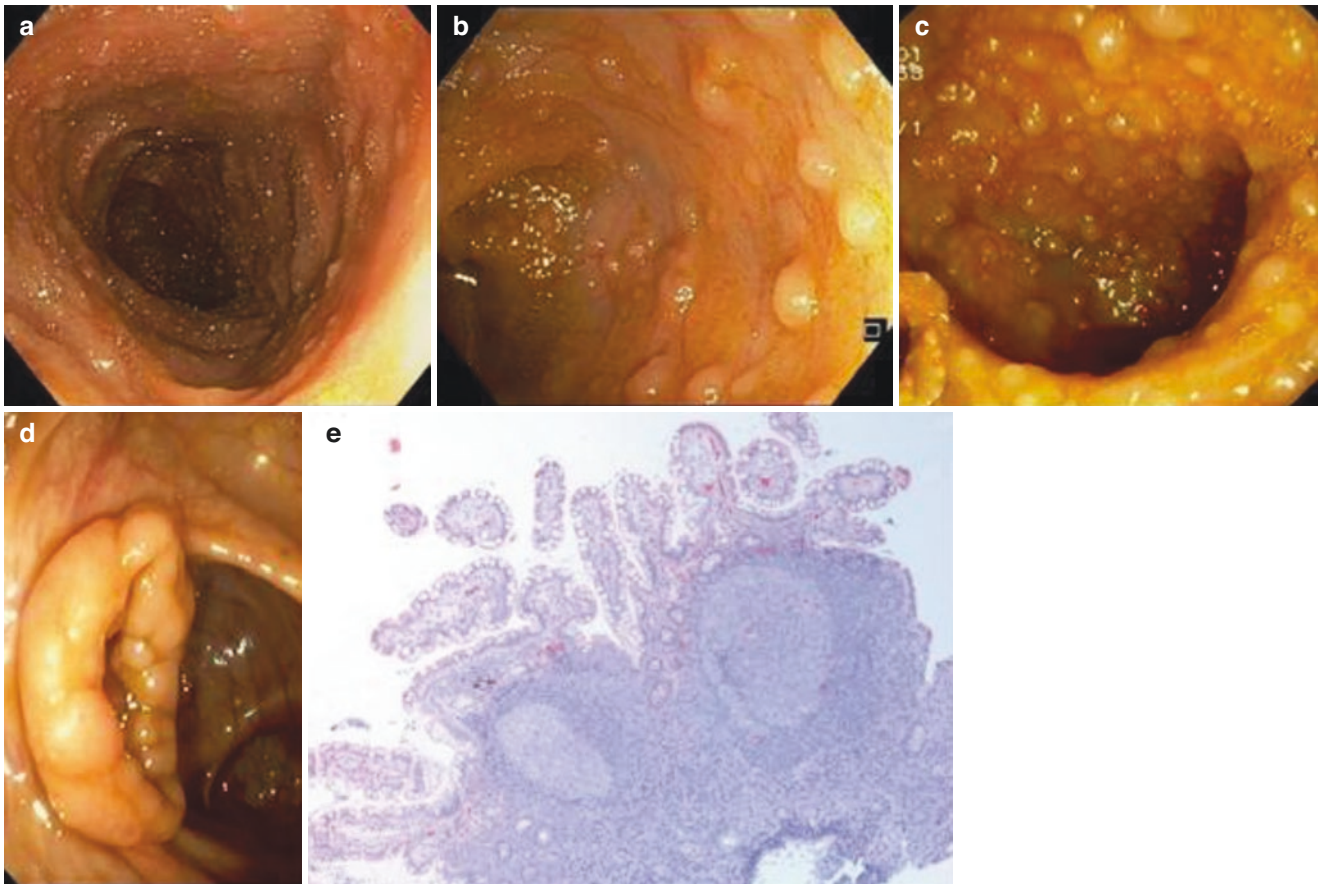

Fig. 33.2 Endoscopic view of the mucosa of a healthy terminal ileum shows usually tiny lymphoid nodules (**a**). In lymphonodular hyperplasia, the nodules are both enlarged and their numbers are increased (**b**) and, in severe cases, may mass on the walls (**c**). In some cases, enlarged lymphoid nodules may extend to the region of ileocaecal valve and be visible even from the caecal side (**d**). The biopsy taken from the terminal ileum with lymphonodular hyperplasia may be filled with lymphoid tissue as large nodules. However, normal long villi can be detected between the nodules (**e**)

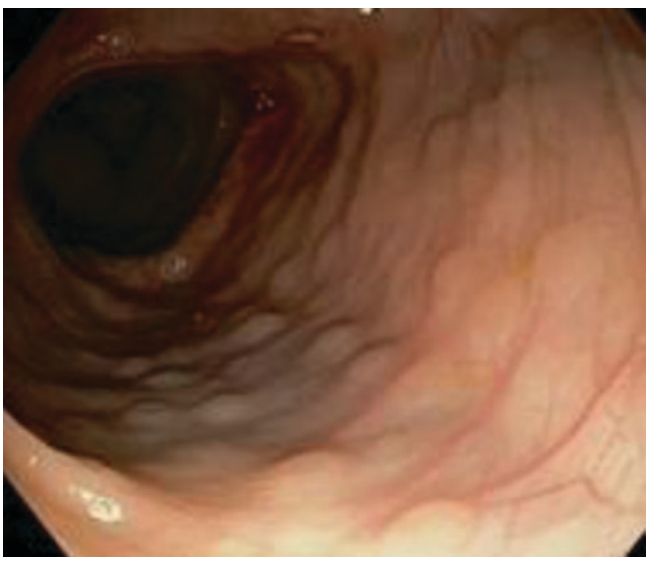

Fig. 33.3 Endoscopic view of colon showing lymphonodular hyperplasia

grades: 0, no lymphoid nodules; 1, mild, lymphoid nodules dispersed on the walls; 2, moderate, lymphoid nodules filling the walls; 3, severe, terminal ileum massed with lymphoid tissue, valve protruding [5] (Fig. 32.2). Counts of lymphoid nodules per visual field of a high-resolution endoscopy in adults in the terminal ileum and caecum indicated that 9–50 lymphoid nodules per field can be defined as lymphoid hyperplasia, and that more than 50 lymphoid nodules per field can be defined as pathological lymphoid aggregates [14].

According to current criteria, increase of the numbers or size of lymphoid nodules less than 2 mm and without endoscopic evidence of nodularity is not diagnostic for LNH. However, as the development of LNH is gradual, even the lesser grades with only numerical increase or increase of the size of nodule without formation of any elevation could have significance. It is obvious that we need more data on the pathophysiology and clinical significance of such lesser grades of lymphoid hyperplasia.

Anatomical Distribution of LNH

LNH may affect any part of the GI tract, and simultaneous manifestation in several parts is not uncommon [5, 9]. Distribution of lesions may provide information of aetiology of LNH (Table 33.2). LNH related with infectious aetiologies tends to be localized. Similarly, LNH related with motility disorders is mostly localized to or close to the affected segment. In contrast, LNH related with immunodeficiency is often diffusely present in the intestinal mucosa. LNH associated with food allergy is often multifocal, but in the duodenum, the bulb is the most commonly affected location [7].

Histological Assessment of LNH

Biopsy specimens from an LNH lesion typically show a single lymphoid follicle or a group of follicles, usually with germinal centres (Fig. 33.2). Such structures are normal components of mucosa, and their occurrence by such is therefore not diagnostic for LNH. Germinal centres are rarely seen in normal lymphoid follicles of healthy gastric [27, 28] or duodenal mucosa. In LNH, a germinal centre is usually present in the follicle and the follicle is enlarged. There is physiological variation in the size of follicles and no criteria regarding a threshold size for histological detection of LNH have been determined. Furthermore, how the tissue sections available represent the largest diameter of the structure makes determination of size difficult. Elevation in comparison with the height of adjacent mucosa is sometimes visible in sections, and suggests LNH. However, such criteria are not so well usable for the second type of the isolated lymphoid follicles of the colon located predominantly in the submucosa [29].

Table 33.2 Aetiology or associated condition of lymphonodular hyperplasia in different parts of the gastrointestinal tract

Part of gastrointestinal tract	Aetiology/associated condition
Stomach	*Helicobacter pylori* infection
Duodenum	Food allergy, non-IgE IBD
	Juvenile idiopathic arthritis
	Immune deficiency (IgA, CVID, APDS, HIV)
	Giardiasis
Ileum	Food allergy, non-IgE Infection (*Salmonella*, *Yersinia*, adenovirus) IBD
Colon	Food allergy, non-IgE
	IBD
	Immunodeficiency (IgA, CVID, APDS, HIV) Irritable bowel syndrome
	Infectious enteritis Hirschsprung's disease Constipation (idiopathic and food allergy associated)
Rectum	IBD
	Chlamydia infection

IgA immunoglobulin A, *CVID* common variable immune deficiency, *IBD* inflammatory bowel disease

In LNH alike reactive germinal centres, tangible body macrophages and a network of dendritic cells are present [30]. Germinal centres are surrounded by a mantle zone containing T and B lymphocytes [29]. Inter-follicular tissue may have some features of the para-cortical zone of lymph nodes, such as high endothelial venules, however, expressing here the mucosal addressin MadCam1 [29, 30].

In the intestine, epithelium overlying lymphoid follicles contains enterocytes and a specialized epithelial cell type M cells [29], showing characteristic microfolds. M cells contain pockets with intra-epithelial lymphocytes. Functionally, M cells act as transporters of luminal antigens to be processed by the cells of lymphatic follicle.

As additional histopathological features in some cases of LNH, observed in children with delayed type of food allergy, the intestinal mucosa may show increase of intra-epithelial lymphocytes including gamma–delta-expressing lymphocytes and cytotoxic lymphocytes [8, 10, 31]. Similarly, the numbers of intra-epithelial eosinophilic leukocytes may be increased in LNH cases associated with food allergy [11]. In cases where LNH associates with specific disease or condition, these may present with characteristic features, such as crypt distortion and diffuse increase of inflammatory cells in IBD-associated cases, and characteristic decrease or absence of plasma cells in common variable immune deficiency [32].

Histopathological differential diagnosis of LNH mainly involves malignant lymphomas of mucosa. They are very rare in children, but the risk is increased in children with immune deficiency or solid-organ transplantation.

Pathophysiology of LNH

GI mucosal lymphatic tissue consists of inductive and effector compartments [33–35]. Luminal antigens are processed, and specific immune responses are generated in the inductive compartment composed of Peyer's patches in the ileum and isolated lymphoid follicles in other parts of the GI tract. Isolated lymphoid follicles are aggregates of T and B lymphocytes and located in either mucosa or submucosa, latter extending to mucosa [19, 29]. The effector compartment is the diffuse mucosal lymphatic infiltrate which is composed of immunoglobulin-producing B cells and effector T cells [29, 33–35].

Luminal commensal and pathogenic flora induces production of IgA response within Peyer's patches and isolated lymphoid follicles [33–35], accompanied with IgM, IgG and IgD responses [35]. At least in mice, such responses involve formation of new lymphoid follicles [18]. Both development and neogenesis are composed of interaction of sub-epithelial stromal cells, epithelial stem cells and lymphoid cells [18, 34, 35]. Germinal centres formed are the places where *IgA* genes of the B lymphocytes mutate and relevant clones are selected. There is evidence that T-independent pathways can give rise to intestinal IgA-secreting plasma cells in isolated lymphatic follicles and diffuse lamina propria, while Peyer's patches can support both T-dependent and T-independent modes of IgA induction [18, 34, 35].

Since the secreted IgA is induced by luminal microbes and other antigens and also participates in the control of the amount of luminal microbial flora, the LNH might be viewed as a sign of IgA dysfunction, where host–microbiome balance is not reached within normal structural limits of lymphoid tissue [18, 19, 35]. Accordingly, also LNH in association with immunodeficiency might be explained as compensatory mechanism to gain the balance. Similarly, increase of the numbers of lymphoid follicles in the colon of patients with infectious colitis [14], or gastric LNH in association with *Helicobacter pylori* infection [7, 27, 28, 36], may represent similar attempt to control the infection by increased production of IgA and suggests that both increase of numbers of lymphoid follicles and their size may be involved. Children with LNH may show more abundant bacterial flora in the ileum than the control children [37], supporting the role of microbial factors in the pathogenesis of LNH. Although not documented, factors modifying access of microbes and other luminal antigens to the mucosa, such as innate immunity responses, mucin and abnormal epithelial permeability [38], might contribute to enhanced humoral immune response involving development of LNH.

Mechanisms linking non-IgE food allergy and LNH [3] are not clear. There is only limited experimental evidence for the role of dietary antigens in mucosal germinal centre response [39]. Association of history of IgE-mediated milk allergy in infancy and increase of anti-allergen IgA levels and LNH [40] supports the idea that LNH, by providing IgA anti-allergen response, might represent an attempt to tolerance [41].

Mechanisms of segmental localization of LNH with some preference to locate close to sphincter-like structures (distal to pylorus; proximal to ileocaecal valve), and association with motoric dysfunction (obstipation and Hirschsprung's disease), are speculative. However, stagnation of intestinal contents related with these anatomical structures or neuromuscular dysfunction might lead the mucosa to be exposed longer to luminal antigens, and thereby increase the local antigen load.

The role of alteration of immune regulatory mechanisms in pathogenesis of LNH is not clear. Bellanti et al. [42] found evidence of deficient T helper cell (Th)1 function in peripheral blood of children with food allergy associated with LNH. In children with delayed type of milk allergy, where majority of patients show LNH, ileal mucosa showed increase of interleukin 6 (IL-6) messenger (mRNA) [43], and duodenal mucosa showed increase of interferon (IFN) gamma mRNA levels [44], increased number of cells expressing IFN gamma [45] and increased IFN gamma, IL-4 and IL-10 secretion [44], possibly indicating imbalance of pro- and anti-inflammatory cytokines.

LNH and Associated Conditions: Food Allergy

Of the conditions associated with LNH (Table 33.2) food allergy is the most frequent. In children, studies performed in four different populations, in Finland [7–9, 46], Italy [11], the USA [42] and Turkey [47], have shown that LNH in duodenal or ileo-colonic mucosa associates with food allergy of the non-IgE type, the most common allergen being milk. Similar association between allergy and ileal and colon LNH has been observed in adults [14, 48]. In contrast, Troncone [49] and Lucarelli [13] found evidence for food allergy in only a minority of symptomatic children with LNH. A review by Mansueto [3] concluded that LNH is present in 49% (range 32–67) of children with food allergy, and conversely, about 66% (range 42–90) of children with LNH have food allergy. In these studies, food allergy was diagnosed based on food challenge-elimination tests, but not all studies were based on state-of-the-art blinded tests [3]. Skin prick tests and serum IgE-based tests were mostly negative. Response time in food challenge test was long – at least several days. These findings indicate that food hypersensitivity associated with LNH is of non-IgE type and characterized by a slow response times of usually several days.

Symptomatic and endoscopical response to elimination diet in delayed type of food allergy associated with LNH has been documented in both adults and children [11, 48]. However, in some studies, the effects of food exclusion did not differ from sell-limiting clinical course with symptomatic treatment [13].

LNH in Other Diseases and Conditions

Chronic mucosal infections (Table 33.2) manifesting in some cases with local LNH include *H. pylori* gastritis [4, 7, 36]. Some enteric bacterial infections may lead to ileal LNH. Giardiasis causes sometimes small intestinal LNH, usually in background of humoral immune deficiency [50].

Chlamydia infection causes some cases of rectal LNH [51]. In general, intestinal bacterial infections increase the number of endoscopically detectable lymphoid follicles [18] and are associated with LNH [16]. LNH may associate with human immunodeficiency virus (HIV) infection [52].

LNH extending through the small intestine associates with genetic immune disorders such as common variable immune deficiency (CVID), where LNH develops in about 20% of cases [53]. Selective IgA deficiency is similarly associated with LNH, nodules containing IgM-expressing cells instead of IgA expression [50]. LNH is one intestinal manifestations of activated PI3Kδ Syndrome (APDS), a newly described form of primary immunodeficiency [54]. In PTEN hamartoma tumour syndrome, where PTEN mutations lead to autoimmune diseases, about 43% of patients have LNH in the intestine [55]. Ileo-colonic LNH associates with familial Mediterranean fever [47].

LNH has been reported in juvenile idiopathic arthritis and connective tissue diseases in the duodenum, ileum and colon [56].

LNH has rarely been described in inflammatory bowel disease, including both ulcerative colitis and Crohn's disease [5, 9, 11]. However, no association with mutations of nucleotide-binding oligomerization domain-containing protein 2/caspase recruitment domain-containing protein 15 gene (NOD2/CARD15) has been detected in LNH [57]. Lymphoid hyperplasia has been found in Hirschsprung's disease in the aganglionic segment [58].

In adults, colonic LNH has been reported in about 31% of patients with irritable colon syndrome [16].

A rare form of segmental lymphoid hyperplasia is located in the distal rectum of adults and children and has been referred to a rectal tonsil [59]. Clinically, rectal tonsil is often associated with rectal bleeding and abdominal pain, but pathophysiology is unknown. However, similar constellation may be caused by a local chlamydia infection [51].

Lymphoid follicular proctitis is a rather poorly defined condition, where rectal mucosal nodularity is related with formation of lymphoid follicles and inter-follicular chronic inflammation. Symptoms are composed of mucoid stools and haematochezia, and occasional response to sulfasalazine treatment suggests that some cases represent a variant of inflammatory bowel disease (IBD) [60].

There are reports suggesting ileal or ileo-colonic LNH to be a common abnormality in children with autistic spectrum disorders, but these findings are highly controversial [3].

Symptoms of LNH

Symptoms in children with LNH are listed in Table 33.3. It is not clear what symptoms can be attributed specifically to LNH as there is no consistent pattern, and some patients have no symptoms. It is obvious that conditions underlying or associating with LNH, such as immune deficiency, constipation or IBD, contribute to symptoms. In cases with LNH as a sole finding, LNH could just be a marker of mucosal immunological activation and not mechanistically contributing to symptoms. In this context, it is of interest that symptoms associated with LNH overlap with those in irritable bowel syndrome, and these conditions share occurrence of signs of overall mucosal immune activation, such as increased intraepithelial lymphocytes in both [7, 61].

Table 33.3 Clinical symptoms commonly reported in paediatric patients examined with gastroduodenoscopy and/or colonoscopy and having nodular lymphoid hyperplasia as an endoscopic finding [2, 3, 5, 11, 42, 46]

Recurrent abdominal pain
Blood in stools
Diarrhoea
Constipation
Anaemia
Nausea/vomiting
Growth retardation or weight loss

Some symptoms may be more specifically caused by LNH. Severe LNH in the terminal ileum can lead to invagination (intussusception). Common association of bloody stools and LNH [11, 12, 48] can be mechanistically explained by sensitivity for mechanical damage associated with any elevated mucosal lesion. Kaplan et al. [12] found that LNH in the colon was commonly associated with friability and ulceration. Observations in Crohn's disease have suggested that M cells overlying the lymphoid follicles form the most vulnerable population of surface epithelium [62], but whether M cells in LNH with other conditions are specifically vulnerable is not known.

Treatment and Prognosis

LNH is the manifestation of underlying immune response and not a specific disease. The initiating factors should be searched for (Table 33.2), and treatment targeting on the aetiology should be considered. In children with irritable colon-like symptoms and idiopathic LNH as a sole finding, budesonide has been used, but no formal trials are available [5].

No systematic and long-term follow-up studies of the development of LNH with or without treatment are available. Partial regression of LNH has been detected in some follow-up endoscopy studies within a year in cases associated with food allergy and treated with elimination diet [11]. In other studies [5], treatment with elimination diet did not induce any change in the LNH grade, although the number of intraepithelial lymphocytes diminished towards normal levels. Lucarelli et al. [13] reported that majority of symptomatic children with ileo-colonic LNH, most without food allergy,

improved clinically in 2–12 months with symptomatic treatment.

There is only scanty information of long-term prognosis of LNH. Risk of intestinal lymphoma is increased in LNH in association with immunodeficiency. In adults, risk is more significant, and some cases even without immunodeficiency have been reported [4]. Colon et al. [2] did not detect any long-term consequences in their unselected cases with LNH. Incidence rates of LNH in adults seem to be much less than children [4], and the overall prevalence of LNH seems to decrease with age, supporting the idea that major proportion of childhood cases not associated with immune deficiency are resolved before adulthood.

Acute Pancreatitis

34

Jonathan Wong, Praveen S. Goday, and Steven L. Werlin

Anatomy and Physiology

The pancreas is a large, J-shaped, flattened gland located in the upper left abdomen that secretes digestive enzymes into the duodenum and produces several important hormones as part of the endocrine system. In adults, it is about 15–20 cm long, lies inferior to the stomach, and is surrounded by the small intestine, spleen, gallbladder, and liver [1, 2]. The pancreas is composed of four sections: head, neck, body, and tail. The uncinate process emerges from the head of the pancreas and lies deep to the superior mesenteric artery and vein, which run behind the neck of the pancreas [3].

The pancreas is both an exocrine and endocrine gland. The exocrine pancreas is made up of acinar and ductal cells that produce and transport digestive enzymes, such as amylase, lipase, and trypsin through a system of small ducts that lead to the pancreatic duct, which runs the length of the pancreas and then combines with the common bile duct carrying bile from the gallbladder proximal to the ampulla of Vater (Fig. 34.1a) [1]. Pancreatic enzymes and bile are then secreted into the small intestine and aid in the digestion of carbohydrates, fats, and proteins. The endocrine cells of the pancreas, located in the islets of Langerhans, produce two main hormones, insulin and glucagon, which together control glucose metabolism. The endocrine cells also produce other hormones including somatostatin and pancreatic polypeptide [4–6].

Pathophysiology

Pathological trypsinogen activation has long been considered the hallmark of AP. Following an initial insult, such as ductal disruption or obstruction, cathepsin B activates trypsinogen to trypsin within the acinar cell. Trypsin then activates other pancreatic proenzymes, leading to autodigestion, further enzyme activation, and release of active proteases. Lysosomal hydrolases colocalize with pancreatic proenzymes within the acinar cell. Pancreastasis (similar in concept to cholestasis) with continued synthesis of enzymes occurs. Lecithin is activated by phospholipase A2 into the toxic lysolecithin. Prophospholipase is unstable and can be activated by minute quantities of trypsin [7, 8]. This leads to cell death and AP. After the insult, cytokines and other proinflammatory mediators are released. Most animal models support this mechanism.

The healthy pancreas is protected from autodigestion by pancreatic proteases that are synthesized as inactive proenzymes; which are then segregated into secretory zymogen granules at pH 6.2, by low calcium concentration, which minimizes trypsin activity. Protease inhibitors are present both in the cytoplasm and zymogen granules [5–8]. Enzymes are secreted directly into the ducts, lessening exposure of the cytoplasmic contents.

In animal models, intracellular activation of trypsinogen to trypsin plays a role only in early acinar injury. For example, in a knockout mouse model of pancreatitis in mice lacking the trypsinogen 7 gene, pancreatitis still develops even though they are unable to activate trypsinogen [8, 9]. In this model, NFkB is activated early in the course and appears to be the primary driver of the proinflammatory response. Recent studies have shown perturbation of mitochondrial permeability and function early in the evolution of experimental pancreatitis [10]. In this model, alcohol causes a collapse of the electrical gradient across the mitochondrial permeability transition pore, leading to depletion of ATP and acinar cell necrosis.

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,

(**b**) Ultrasound of the same patient showing a hypoechoic and edematous pancreas (arrow). (**c**) Late acute pancreatitis in the same patient CT scan demonstrates necrotic nonenhancing distal pancreas (**A**). The pancreatic head is relatively normal (**B**). There is a large amount of peripancreatic fluid (**C**). (Courtesy of Dr. David Gregg)

These observations may be related to abnormal cell signaling as a result of pathological elevation of Ca^{2+} in acinar cells. Abnormal sustained release of Ca^{2+} (as can be seen in excessive levels of cholecystokinin, alcohol, or bile acids) can cause mitochondrial permeability transition pores to open, resulting in loss of membrane potential and subsequent impaired production of ATP. Pathologically elevated Ca^{2+} concentrations have also been implicated in premature trypsinogen activation, impaired autophagy, and activation of the NFkB pathway [11].

Time-course analysis has shown that a burst of electron transfer reactions is associated with the disease-initiation [12]. For example, in the experimental model of mild AP produced by excessive stimulation with caerulein, a CCK analog, the spark from reactive oxygen species can be seen by chemiluminescence within 5 minutes. Simultaneously, there is a huge increase in stress-activated protein kinase. Within 10 minutes, there is an increase in amylase in the venous outflow of the pancreas. Similarly, in endoscopic retrograde cholangiopancreatography (ERCP)-induced acute pancreatitis, analysis of peripheral blood by electron spin resonance spectroscopy identified the burst of reactive oxygen species by the end of the clinical procedure, followed by steep increases in serum levels of amylase, lipase, and trypsinogen.

Histopathologically, interstitial edema appears early. Later, as the episode of pancreatitis progresses, localized and confluent necrosis, blood vessel disruption leading to hemorrhage, and an inflammatory response in the peritoneum can develop. In mild pancreatitis, there is interstitial edema and an inflammatory infiltrate is found. There is no organ dysfunction. In severe pancreatitis, the inflammation is extensive and parenchymal necrosis is present. Multiorgan failure accompanies the inflammation. Following an episode of AP, all histological abnormalities resolve. The factors that determine the severity of an episode of AP are unknown; furthermore, scoring systems utilized in adult patients (Ranson, Glasgow) are not applicable in children [13].

Epidemiology

In adults, AP is one of the most common diseases of the gastrointestinal tract and remains a serious disease. In the United States, AP is the most common gastroenterology discharge diagnosis accounting for more than 553,000 hospital discharges, 881,000 ambulatory visits, and 3413 deaths a year [14, 15]. A recent systematic review demonstrated a global pooled incidence of AP of 34 cases per 100,000 general population per year, with equal incidence in men and women [16].

In pediatrics, it is estimated that approximately 10 new cases per 100,000 children occur annually. In adults, AP is ranked 15th among causes of death from gastrointestinal and liver diseases in adults [17]. In the last 20 years, studies have shown an increase in the annual incidence of AP [18]. The case fatality rate for AP has decreased over time, while the overall population mortality rate has remained unchanged. In adults, mortality from AP is approximately 3% for interstitial pancreatitis and 15% for necrotizing pancreatitis [14]. A recent study of over 2000 pediatric cases of AP treated in an ICU setting found mortality of primary and secondary pancreatitis to be 0.3% and 6.8%, respectively. These data suggest that AP in otherwise well children is unlikely to be fatal but that when AP develops in the setting of other acute or chronic illnesses, outcome may be dictated by that primary illness [19].

Etiology

In adults, 85% of episodes of AP are due to alcohol and cholelithiasis. In contrast, in children, the most common etiologies of AP are: blunt abdominal injuries, biliary stones or microlithiasis (sludging), drug toxicity, and multisystem diseases such as the hemolytic uremic syndrome and inflammatory bowel disease [13, 20, 21]. Other cases follow solid organ and stem cell transplantation or are due to infections, anatomic anomalies, metabolic disorders, and mutations in susceptibility genes. Only 10–20% of cases are now considered idiopathic.

Trauma typically due to bicycle handlebar injuries, automobile accidents, and sports injuries is the cause of about 10–40% of episodes of AP [13, 20, 21] (Table 34.1). Other traumas include ERCP, nonaccidental injury, surgical injury, and total body casting. Because the pancreas is retroperitoneal and lies across the spine, ductal rupture is not uncommon. Diagnosis may be delayed. Most patients with abdominal trauma who are seen in the emergency room get a CT scan; injuries may now be detected earlier than before. Following trauma, unsuspected ductal damage can lead to strictures, pseudocyst formation, and chronic obstruction.

Tumor

Biliary pancreatitis Biliary obstruction due to lithiasis, sludge, anatomic abnormalities, or ERCP is the etiology in 5–20% of pancreatitis in children (Table 34.2). Anatomic causes of biliary obstruction such as pancreaticobiliary maljunction (PBM) and pancreas divisum are increasing recognized [22–24]. PBM and congenital dilatation of the biliary tract are more common in Japanese patients than in western patients. Controversy persists over whether pancreas divisum alone is a cause of AP. Recent studies have not supported either a clear association or a definitive line of treatment for pancreatic disease in the setting of pancreas divisum [23, 24]. Risk factors for biliary pancreatitis in children include obesity and Hispanic ethnicity [25].

Drugs and toxins Drugs and toxins account for 10–20% of children with AP (Table 34.3). In children, valproic acid, L-asparaginase, 6-mercaptopurine, and azathioprine are the most common causes of drug-induced pancreatitis [26]. Azathioprine has on occasion been successfully reintroduced in patients with presumed thiopurine-induced pancreatitis [27].

Infectious Agents Since many patients with idiopathic pancreatitis have a viral-like prodrome, it is difficult to determine the true incidence of infection-associated AP (Table 34.4) [13, 20, 21]. Case series have found that 2–10% of children with AP have a viral cause. This may be an under-

estimate, because many patients with idiopathic pancreatitis may well have had undiagnosed infections. A wide variety of infections have been associated with AP particularly hepatitis A, mumps, and EBV.

Genetics Mutations in an increasing number of genes have been shown to cause pancreatitis, the most common being mutations in the PRSS1, CFTR, and SPINK1 genes. Genetic causes have been reported in 1–14% of cases [28, 29] (Table 34.5). The incidence may well be higher, since it is uncommon to check for genetic etiologies during the first episode of pancreatitis. PRSS1 is the gene that causes *hereditary pancreatitis*. Atypical cystic fibrosis in patients with at least one mild mutation and pancreatic sufficiency are at risk for pancreatitis. At the time of a first episode of AP, patients with mutations in these genes will have courses indistinguishable from patients with pancreatitis from other causes. Unless there is a family history of pancreatitis or cystic fibrosis or there are signs of chronicity on imaging studies, genetic testing is not indicated following a single episode of AP.

series. These cases typically have a course similar to that of pancreatitis from other causes. Autoimmune pancreatitis is rare in children; a 2017 study reviewing case reports over the preceding two decades along with data from two recently established databases (INSPPIRE, CUSL) yielded only 48 cases [30].

Idiopathic In published series, no etiology was found in 12–38% of children with AP [13, 20, 21]. As new etiologies have been found and as workup has become more extensive, newer series have lower rates of idiopathic AP.

Diagnosis

Criteria for the diagnosis of pancreatitis are defined as 2 of 3 of the following: abdominal pain, serum amylase, and/or lipase activity at least 3 times greater than the upper limit of normal and imaging findings characteristic of, or compatible with, AP [13].

Serum lipase is the test of choice for AP, as it is more specific than amylase for acute inflammatory pancreatic disease and should be determined when pancreatitis is suspected. Serum lipase remains elevated longer than amylase after disease presentation. The serum lipase rises by 4–8 hours, peaks at 24–48 hours, and remains elevated 8–14 days, longer than serum amylase. Serum lipase may also be elevated in nonpancreatic diseases (Table 34.7). Diabetic patients appear to have a higher median lipase compared with nondiabetic patients, so an upper limit of normal greater than 3–5 times may be needed in diabetic patients [31]. The clinical condition of the patient must be considered when evaluating amylase and lipase elevations.

In AP, serum amylase usually rises within a few hours after the onset of symptoms and returns to normal within 3–5 days. Serum amylase may remain normal in up to 20% of patients, especially in alcohol-induced AP and hypertriglyceridemia [32]. A variety of conditions may also cause hyperamylasemia without pancreatitis, such as macroamylasemia (Table 34.7).

Providers interpreting amylase and lipase levels in a chronological context should note that as the kidneys excrete these enzymes, nonpancreatic-based elevations may be seen in patients with renal injury or disease [13].

Other laboratory abnormalities that may be present in AP include hemoconcentration, manifested by high hemoglobin and BUN, coagulopathy, leukocytosis, hyperglycemia, glucosuria, and hypocalcemia. Elevated γ-glutamyl transpeptidase and hyperbilirubinemia suggest the diagnosis of cholelithiasis or choledocholithiasis [13, 14].

X-rays of the chest and abdomen may demonstrate nonspecific findings such as atelectasis, basilar infiltrates, elevation of the hemidiaphragm, left- (rarely right-) sided pleural effusions, pericardial effusion, and pulmonary edema. Abdominal x-rays might demonstrate a sentinel loop of intestine, dilation of the transverse colon (cutoff sign), ileus, pancreatic calcification (if recurrent), blurring of the left psoas margin, a pseudocyst, ascites, and peripancreatic extraluminal gas bubbles [14, 33].

Table 34.7 Nonpancreatitis causes of elevated serum pancreatic enzymes

Serum lipase	Serum amylase
Acute cholecystitis	Acidosis
Bowel obstruction	Alcoholism
Celiac disease	Appendicitis
Diabetic ketoacidosis	Bowel obstruction/infarction
Drugs	Celiac disease
Duodenal ulceration	Cerebral trauma
Human Immunodeficiency Virus	Cholecystitis
Idiopathic	Cystic fibrosis
Macrolipasemia	Drugs
Pancreatic calculus	Human Immunodeficiency Virus
Pancreatic tumors	Idiopathic
Renal failure	Liver disease
Trauma (including post-ERCP)	Lymphoma
	Macroamylasemia
	Myocardial infarction
	Pancreatic tumors
	Pelvic inflammatory disease
	Peptic ulcers
	Pregnancy
	Renal failure
	Rheumatoid arthritis
	Trauma
	Ulcerative colitis

Transabdominal ultrasound should be performed on all patients with AP, when gallstones are suspected. Abdominal imaging is useful to confirm the diagnosis of AP, but the routine use of computed tomography (CT) is not recommended during the first 3 days, because it has low yield and rarely alters clinical management [14, 13, 33]. Abnormal imaging findings (such as signs of necrosis) may not develop until 72 hours after symptom onset. Given this, obtaining a CT scan within 72 hours of symptom onset is discouraged by present guidelines [11]. However, if a patient is not improving after 1 week, CT or magnetic resonance imaging (MRI) of the pancreas is recommended to assess for local complications (Fig. 34.1b). CT and/or MRI of the pancreas are also recommended in patients in whom the diagnosis is unclear. CT has over 90% sensitivity and specificity for the diagnosis of AP. Ultrasonography is more sensitive than CT scanning for the diagnosis of biliary stones but can be limited in evaluation of the pancreas itself due to interfering structures [13, 14].

Magnetic resonance cholangiopancreatography (MRCP) and ERCP are essential in the investigation of known or

suspected pancreatic duct disruption, recurrent and nonresolving pancreatitis, and disease associated with gallbladder pathology but have a lesser role in AP [13, 34]. Although there are limited pediatric data, endoscopic ultrasonography has increasingly been shown to be helpful in the drainage of fluid collections in children [35].

Clinical Presentation

Although there have been a number of attempts to develop a scoring system, there is no validated scoring system for children with AP [36, 37]. A retrospective report of 211 patients suggested that a serum lipase >7 times the upper limit of normal within 24 hours of admission predicted a severe course [38]. This however was not been confirmed [13]. Thus, reliable prediction of the course of an episode of AP is currently not possible. Several new classification systems have been proposed for use in adults. None have been tested in children.

Most episodes of AP in children are mild and self-limiting, defined by the absence of organ failure and/or pancreatic necrosis (local complications) [39]. These patients resolve their symptoms rapidly, are usually discharged within 1 week, and mortality is rare [13, 14].

Pediatric AP is classified as mild, moderate, and severe.

Mild Acute Pancreatitis

Cases of mild AP typically resolve within 1 week without local or systemic involvement [40]. The patient with AP has abdominal pain, which may be severe. Some patients have persistent vomiting, and possibly fever. The pain is epigastric or in either upper quadrant. The child often lies with hips and knees flexed lying on the side. The abdomen may be distended and tender, and a mass may be palpable. The patient usually appears extremely uncomfortable, irritable, and may look ill or toxic. The pain can increase in intensity for 24–48 hours, during which time vomiting may increase and the patient might require hospitalization for dehydration and may need fluid and electrolyte therapy. Pain described as dull, colicky, or located in the lower abdomen is not consistent with AP and suggests other etiologies. The prognosis for complete recovery in the acute uncomplicated case is excellent [13, 14, 39].

Moderate Acute Pancreatitis

Patients with moderately severe AP may have transient organ failure that resolves in less than 48 hours, local complications, exacerbation of comorbid disease, and/or systemic complications. The morbidity and mortality are higher compared to that of mild AP. However, the mortality is considerably less than that of severe AP [14, 19, 41]. Depending on the complications, patients may require prolonged hospitalization because of local or systemic complications.

Severe Acute Pancreatitis

Severe AP is defined as AP complicated by persistent organ failure that persists beyond 48 hours and/or death and occurs in 15–20% of patients [14, 19, 41]. Patients with severe AP usually have one or more local and/or systemic complications.

Severe AP is less common in children than in adults [37]. In this life-threatening condition, the patient is acutely ill with severe nausea, vomiting, and abdominal pain [14, 33, 41]. A bluish discoloration may be seen around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign) [42, 43]. Pancreatic necrosis may develop between the second and fifth weeks of illness. Infected necrosis may develop during the second week and a pancreatic abscess as late as the fifth week of illness. Infection is suspected when there is persistent pain and fever.

Mortality is related to the systemic inflammatory response syndrome (SIRS) with multiple organ dysfunction, shock, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, massive gastrointestinal bleeding, and systemic or intra-abdominal infection [44]. In adults, the percentage of necrosis seen on CT scan and failure of pancreatic tissue to enhance on CT scan (suggesting necrosis) predicts severity of the disease [14, 41].

There are now two defined, distinct phases of severe AP, which overlap: the early phase, which usually lasts only 1 week or so, and the late phase, which can persist for weeks to months. The early phase is characterized by the SIRS and/or the compensatory anti-inflammatory syndrome (CARS), which can predispose to infection. Adult patients with severe AP that develops within the early phase (first week) have 36–50% mortality [14]. Development of infected necrosis later in the course of the disease in patients with severe AP also has an extremely high mortality [45, 46]. The late phase is characterized by the persistence of systemic signs of ongoing inflammation, the presence of local and systemic complications, and/or transient or persistent organ failure. Local complications include peripancreatic fluid collections, pancreatic and peripancreatic necrosis, pseudocysts, and walled-off necrosis. By definition, the late phase occurs only in patients with moderately severe or severe AP [41, 47].

Treatment

While the mainstay of treatment for AP is mainly supportive, efforts have been made in recent years to provide more specific recommendations about fluid provision, monitoring, pain management, and nutrition.

Intravenous fluid therapy remains a mainstay in the treatment of AP. In severe pancreatitis, fluid resuscitation in the first 24 hours is critical [48]. Progression to severe AP is thought to be secondary to alteration in the microcirculation of the pancreas by events including hypovolemia, increased capillary permeability, and formation of microthrombi. While consensus on type of fluid remains controversial, crystalloids are preferred over colloids for initial resuscitation. The most recent pediatric consensus statement notes theoretical and potential clinical advantages favor lactated Ringer's solution over normal saline based on adult data, but pediatric data are still lacking [13]. The rate of fluid administration continues to be controversial. Given the goal of improved pancreatic microcirculation, rates of 1.5 to 2 times maintenance over the first 24–48 hours have been recommended. Intravascular fluid losses due to third spacing and losses through an NG tube can rapidly lead to dehydration and cardiovascular instability. So not only is volume expansion important but maintenance of intravascular volume is critical. Vital signs and markers such as BUN, creatinine, and urine output should be closely monitored in the acute period to evaluate for volume overload and acute kidney injury.

The aims of medical management are to relieve pain and restore metabolic homeostasis. Analgesia should be given in adequate doses. A 2013 Cochrane review stated that opioids may be an appropriate choice for pain in AP in adults and may decrease the need for supplementary analgesia [49]. They found that opioids did not increase the risk of pancreatitis complications or significant adverse events. Current consensus guidelines recommend intravenous opioids be used for pain not responding to either acetaminophen or NSAIDs.

In *mild acute pancreatitis,* nasogastric suction is needed infrequently but is useful in patients who have significant vomiting. While vomiting, the patient should be maintained with nothing by mouth. Refeeding can commence when vomiting has resolved. Early refeeding decreases the complication rate and length of stay [13, 40]. While traditional, there are no data to support the use of a low-fat diet. It is not necessary to follow laboratory tests such as serum lipase daily. Recovery is usually complete within 4–7 days.

Analgesia is given as needed. Antibiotics are used to treat infected necrosis, but prophylactic antibiotics are not recommended. Infected necrosis does not occur until the second week of pancreatitis [46].

Endoscopic therapy can be of benefit when pancreatitis is caused by anatomic abnormalities, such as strictures or stones [50]. The endoscopist can dilate the sphincter of Oddi and extract impacted biliary tract stones. This is especially important when the patient has developed cholangitis.

Historically, patients diagnosed with AP were designated as NPO and placed on parenteral nutrition. A recent pediatric guideline recommends enteral nutrition initiation as early as possible [13]. Prompt initiation of EN is thought to prevent bacterial translocation, decrease cytokine response, as well as decrease incidence of gastroparesis and intestinal ileus.

Early EN is begun, whether by mouth, nasogastric tube, or nasojejunal tube, in patients intolerant to oral or nasogastric feedings. When initiated within 2–3 days of onset of pancreatitis, enteral feeding reduces the length of hospitalization, complication rate, and increases survival in adult patients with severe AP [13]. Supplemental parenteral nutrition may be needed in some patients.

Measurement of gastric residuals and abdominal circumference are of limited value and should be discouraged. Residual volume relates to infusion rate. High residuals are common early in enteral nutrition. Gastric distension may be from gas-filled loops of bowel. A rise in serum amylase and lipase is typically associated with enteral feeding. These rises do not imply worsening of the pancreatitis and are not reasons to stop enteral nutrition.

When a patient has persistent fever into the second week of illness or develops fever later, a CT scan is required [14]. When necrotic tissue is seen, fine needle aspiration and culture is indicated [14]. The use of antibiotics in sterile necrosis is not recommended. Antibiotics of choice for infected pancreatic necrosis and abscess are those that are known to penetrate the pancreas including carbapenem, quinolones, and metronidazole [14].

In *traumatic pancreatitis*, surgery is frequently required. In children, surgical therapy of nontraumatic AP may include drainage and resection of necrotic material or abscesses. In stable patients, surgery is deferred at least 2–4 weeks to allow differentiation between necrotic and viable tissues [14]. In gallstone pancreatitis, it is recommended that cholecystectomy be performed before hospital discharge to prevent recurrent episodes [14].

Complications

Most children with acute uncomplicated pancreatitis will do well and recover within 4–7 days. However, about 20% of children with AP will develop a complication, which may prolong the hospital stay or require intervention [13]. Complications are divided into local and systemic. Local complications include acute peripancreatic fluid collections, pancreatic pseudocysts, acute necrotic collections, walled-

off necrosis, splenic/portal vein thrombosis, colonic necrosis, retroperitoneal hemorrhage, and gastric outlet dysfunction. Local complications should be suspected when there is persistent abdominal pain, fever/chills, or organ failure and should prompt cross-sectional imaging to search for these complications [14, 34, 41]. Acute peripancreatic fluid collections are not associated with necrotizing pancreatitis, remain sterile, and usually resolve without intervention. A fluid collection persisting more than 4 weeks is likely developing into a pancreatic pseudocyst. A pancreatic pseudocyst is a peripancreatic or intrapancreatic fluid collection or collections containing no solid material surrounded by a well-defined wall. Acute peripancreatic fluid collections and acute necrotic collections occur within the first 4 weeks of AP, while pancreatic pseudocysts and walled-off necrosis usually arise more than 4 weeks after the onset of AP [13, 39].

Systemic complications occur from the systemic inflammatory response to AP and may be further exacerbated by the need for fluid resuscitation. Systemic complications include de novo occurrence of renal, circulatory, or respiratory organ failure or exacerbation of serious preexisting comorbidities [39, 51].

It should be noted that 15–20% of patients will go on to develop acute recurrent pancreatitis [52].

Future

Over the past 20 years, as the incidence of AP has risen, the percentage of children with idiopathic AP has decreased, with the recognition of more genetic causes, the wide availability of ERCP, and with the advent of new technologies such as MRCP and endoscopic ultrasound. Greater understanding of the pathophysiology of pancreatitis has led to improvement in therapy such as early introduction of enteral feeding and rapid fluid resuscitation in severe pancreatitis.

Since there are limited controlled studies on any of the various aspects of the treatment of AP in children, nearly all the current recommendations are based on publications describing adults. Particular areas that are in need of investigation include a validated scoring system to predict severity of AP in children, fluid resuscitation, use of antibiotics, antioxidants, probiotics, timing of nutrition therapy, and the risks and benefits of advanced modalities such as ERCP and endoscopic ultrasound.

Chronic and Hereditary Pancreatitis

35

Elissa M. Downs and Sarah Jane Schwarzenberg

Introduction

Chronic pancreatitis is the continuation of progressive inflammatory damage to the pancreas that has resulted in irreversible acinar and ductal change, which can eventually cause corresponding loss of endocrine or exocrine function. Children with acute pancreatitis may progress from their initial attack to chronic pancreatitis in a median timeframe of 3.79 years [1] or as little as median 0.7 years [2]. Certain genetic risk factors, such as PRSS1 and SPINK1, may be more likely to present with findings of chronic pancreatitis [3] and children with PRSS1 mutations may progress to chronic pancreatitis more rapidly than those without [1].

Progressive irreversible pancreatic damage leads to intractable pain [4] and significantly impaired quality of life [2, 5]. The burden of disease is high across all age groups, with no significant differences in emergency department evaluations, hospital stays, or missed days of school/work [4] between children and adults. Children with chronic pancreatitis report frequent opioid usage, with high health care utilization, and impaired quality of life [6].

While over time the incidence of both acute and chronic pediatric pancreatitis appears to be rising [7, 8], this is likely due to greater awareness of the burden of pancreatic disease in children. Most recently, cohort studies in the United States have demonstrated a plateau to a decrease in incidence of chronic pancreatitis [9] in pediatrics to 1.9 per 100,000 persons per year and in adults to 24.7 per 100,000 persons per year. Global incidence is less well-documented overall [10], and this is especially true for pediatric chronic pancreatitis.

In pediatrics, our understanding of acute recurrent and chronic pancreatitis has been advanced by several country-wide and global consortia that have combined to produce large enough cohorts to achieve high-quality data collection. Examples include INSPPIRE (*IN*ternational *S*tudy group of *P*ediatric *P*ancreatitis: *I*n search for a cu*RE*), an international multicenter study of acute recurrent and chronic pancreatitis in children [11], and the APPLE study of the Hungarian Pancreatic Study Group, a multicenter study of the course of pediatric pancreatitis with emphasis on the genetic risk factors [12].

Pathophysiology

Models of pancreatic injury suggest a sentinel acute pancreatitis event (SAPE) that, in some children, initiates a pathway toward chronic inflammation. With this event, pancreatic stellate cells can then drive fibrosis from recurrent acinar cell injury [13]. This model has allowed identification of different events or risk factors that lead progression from acute, to acute recurrent, to chronic pancreatitis.

Risk Factors

The most commonly used classification system for risk factors for chronic pancreatitis is the TIGAR-O risk factor classification system [14], which includes *T*oxic/metabolic, *I*diopathic, *G*enetic, *A*utoimmune, *R*ecurrent/severe acute pancreatitis, and *O*bstructive etiologic risk factors (see Table 35.1). Over 20% of children with chronic pancreatitis have more than one risk factor for its development [15]. Depending on the extent of testing done, the exact etiology may, in many cases, only be partially known [14].

As children progress through the stages of acute, to acute recurrent, and then to chronic pancreatitis, proportionality of underlying risk factors shifts toward genetic disease: 73% of children with chronic pancreatitis in recent INSPPIRE cohort assessments were identified as having at least one gene mutation compared to 48% of those with acute recurrent

pancreatitis [3]. In all likelihood, this proportion is falsely low as not all children had a full complement of testing performed [3] and our understanding of pathogenic genetic variants continues to expand over time.

Obstructive risk factors share similar frequency between acute recurrent and chronic pancreatitis and can be found in up to 33% of children [3, 4]. These risk factors may include pancreas divisum, gallstones, biliary cysts, or an anomalous pancreaticobiliary junction among others. The percentage of those with pancreas divisum increases in chronic pancreatitis as compared to acute recurrent pancreatitis, but was not statistically significant in one cohort [3]. The presence of pancreas divisum should not preclude evaluation for other risk factors [16].

Toxic and metabolic risk factors may include exposure to medications such as L-asparaginase [17], or hypertriglyceridemia [18, 19]. While exposure to second-hand smoke may occur in up to 10% of those with chronic pancreatitis [3], different pediatric cohorts demonstrate active smoking is much less common (2–7%) as is active alcohol intake (1–4%) [3, 4] especially when compared to the adult chronic pancreatitis population.

Diagnosis

Establishing the Diagnosis of Chronic Pancreatitis

Standards for the clinical diagnosis of acute, acute recurrent, or chronic pancreatitis were suggested by the INSPPIRE study group in an effort to standardize definitions to guide further research and recommendations into disease management [20]. For a diagnosis of chronic pancreatitis to be established, one of the three conditions must exist: (1) abdominal pain consistent with pancreatic origin and imaging findings suggestive of chronic pancreatic damage; (2) evidence of exocrine insufficiency and suggestive imaging findings; or (3) evidence of endocrine insufficiency and suggestive imaging findings.

Imaging findings may include changes of the duct (irregularity, intraductal filling defects or calculi, stricture, dilatation) or the gland itself (enlargement, atrophy, irregular contour, calcifications) [20, 21] (see Figs. 35.1 and 35.2).

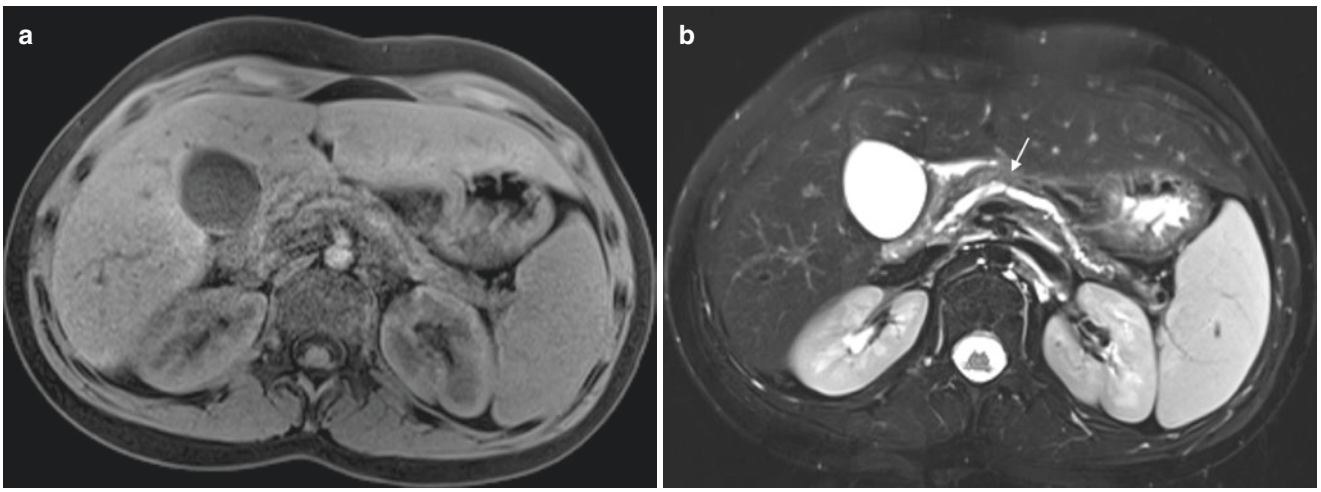

Fig. 35.1 Imaging changes in chronic pancreatitis: Axial (**a**) T1- and (**b**) T2-weighted images with fat saturation. The gland is overall atrophic with isointense to mildly hypointense T1 signal relative to the liver. Notice the abnormally distended pancreatic duct with focal stricture (arrow)

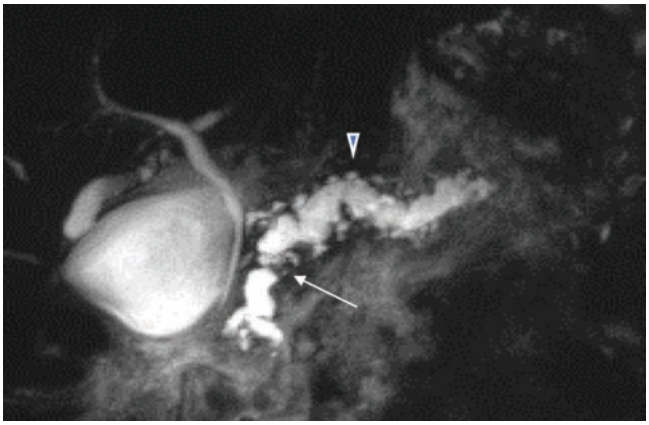

Fig. 35.2 Imaging changes in chronic pancreatitis: On this MIP (maximum intensity projection) image of the pancreatic duct, notice the diffuse ductal enlargement, side branch distention (arrowhead), and focal stricture at the head-proximal body junction (arrow)

Exocrine insufficiency, as diagnosed by fecal elastase-1 <100ug/g stool or a coefficient of fat absorption <90% on 72 hour fecal fat collection [20], will be further discussed below. The diagnosis of endocrine insufficiency follows 2006 World Health Organization criteria, with fasting glucose ≥126 mg/dL (7 mmol/L) or ≥200 mg/dL (11.1 mmol/L) after glucose load [20, 22].

The evaluation of a child for chronic pancreatitis may be difficult. Little evidence guides this process, although expert opinion is available [16]. Choice of imaging depends on many factors, including the quality of the imaging technique, the degree of ionizing radiation, and the possible need for sedation or intubation.

Abdominal ultrasonography (US) is the imaging modality of choice as it is noninvasive, readily available, does not require sedation, and lacks ionizing radiation. US may be more suitable for children given less abdominal fat versus adults as well as better acoustic windowing from the left hepatic lobe [23]. US findings in chronic pancreatitis may include dilated pancreatic duct, calcifications, pseudocysts, and gland atrophy.

Advanced cross-sectional imaging should be considered to better delineate changes seen with chronic pancreatitis, such as dilation and strictures of the pancreatic duct, side branching, and calcific change.

Magnetic resonance cholangiopancreatography (MRCP) is preferred over computed tomography (CT) scanning and its ionizing radiation exposure. However, MRCP may have limitations including inability to visualize small caliber ducts in young children, and sedation might be required to minimize respiratory artifact given longer duration of scanning time [24]. In a large study of pediatric patients with chronic pancreatitis, the sensitivity and specificity of MRCP was 77.1% and 50%, respectively, with diagnostic accuracy of 73% [25], which improved with older teens and more severe disease.

Use of secretin stimulation may improve the detection of more subtle changes of early chronic pancreatitis and improves the sensitivity of MRCP [26]. In a study of children with idiopathic chronic pancreatitis, secretin administration increased the ability to detect dilated side branches, and an irregular or narrow duct as well as pancreas divisum [21]. While changes after secretin stimulation may be statistically significant, it remains a quantitatively small change, so the overall usefulness may be limited [27].

Cross-sectional imaging may also correlate with histopathology. In a study of adults with noncalcific chronic pancreatitis, the number of features on secretin-stimulated imaging significantly correlated with more severe fibrotic histopathology [28].

Endoscopic retrograde cholangiopancreatography (ERCP) for diagnosis of chronic pancreatitis has decreased over time given its invasive nature, need for anesthesia, exposure to radiation, complications (including post-ERCP pancreatitis) [26, 29], and potential limited availability in pediatrics [25]. However, it may better identify, and allow intervention for, pancreas divisum [30].

Endoscopic ultrasound (EUS) performed by appropriately trained endoscopists can be safely and effectively performed in children over 15 kg using standard adult equipment, but still requires general anesthesia [31]. EUS can demonstrate even subtle ductal and parenchymal changes of early chronic pancreatitis [32] and also allows fine-needle aspiration or biopsy if needed. While the Rosemont criteria of EUS changes can be used to diagnose chronic pancreatitis in adults, no such criteria exist in children [31].

Establishing Risk Factors for Chronic Pancreatitis

Once a diagnosis of chronic pancreatitis is made, further testing is necessary to establish the risk factors for the chronic pancreatitis in the child. This may both guide therapy and allow appropriate counseling for the child and other family members.

Following the TIGAR-O system, studies to examine risk factors may include the following:

1. Careful history to uncover possible medications [33, 34] or metabolic disease [33, 35] associated with chronic pancreatitis.
2. Genetic studies to evaluate risk factors for chronic pancreatitis. Note that careful consent for such studies, an explanation of any results, will require a genetic counselor familiar with genetic associations with chronic pancreatitis.

Genetic testing should be performed for all children with otherwise idiopathic pancreatitis and no known risk factors after their second episode of pancreatitis. With a known family history of pancreatitis, genetic testing should be performed after an initial episode.

While target testing can be performed for a known gene, it is possible to have more than one genetic risk factor; in two separate INSPPIRE cohort studies, 9 of 51 children (17.6%) with hereditary pancreatitis had multiple genetic mutations identified [2] in one study and 17 of 112 children (15%) in another [3].

Our knowledge of the pathophysiology of the currently identified genetic mutations comes from their roles in the regulation of trypsin in the pancreas [36].

PRSS1 Mutations in the cationic trypsinogen gene PRSS1, inherited in an autosomal-dominant manner, lead to gain-of-function mutations and overactivation or under/inactivation of trypsin. Early-onset pancreatitis (<6 years old) is associated with PRSS1 [37]. Those with PRSS1 hereditary pancreatitis may be more likely to present with chronic pancreatitis versus acute recurrent pancreatitis [3]

SPINK1 Mutations in the serine protease inhibitor, Kazal type 1 gene SPINK1, may lead to unchecked intrapancreatic trypsin activity and are likely to be clinically important when another process is causing premature activation of trypsin and inflammation [38, 39].

CFTR Mutations in the cystic fibrosis transmembrane receptor gene CFTR may alter bicarbonate secretion [40, 41] and cause duct obstruction due to thickened secretions [42]. Pancreatitis can be an initial presenting sign of cystic fibrosis as these patients may be more likely to have a milder cystic fibrosis phenotype with less severe CFTR dysfunction and may not be identified by newborn screening [43].

Others Additional genetic mutations in trypsinogen regulation have been identified, including chymotrypsin C (CTRC), and the calcium-sensing receptor (CASR). Early-onset pancreatitis has also been associated with CTRC gene mutations [37]. The carboxyl ester lipase (CEL) enzyme expressed in pancreatic acinar cells may lead to protein misfolding that causes a syndrome of endocrine and exocrine dysfunction [44].

3. The diagnosis of autoimmune pancreatitis is challenging in children, as the clinical presentation can be different in children versus adults, and they rarely are positive for IgG4. Diagnosis may be established with combination of clinical symptoms (including acute abdominal pain, obstructive jaundice, and weight loss) and abnormal cross-sectional imaging (such as focal gland enlargement, main pancreatic duct irregularity, distal bile duct stricture) [45].
4. Obstructive risk factors are generally evaluated by MRCP. These risk factors may include pancreas divisum, gallstones, biliary cysts, or an anomalous pancreaticobiliary junction among others as previously discussed

Evaluating the Severity of Chronic Pancreatitis

Complications of chronic pancreatitis include pain and exocrine and endocrine insufficiency. Pain, as a subjective sensation, is difficult to measure. In general, evaluation includes some measure of function (school attendance, participation in sports, and social activities). Pain should be assessed at each clinic visit.

Testing for exocrine and endocrine function should be done yearly [16].

Exocrine Pancreatic Function Assessment

Chronic pancreatitis is the most common cause of exocrine pancreatic insufficiency (EPI) in adults, while cystic fibrosis is the most common cause in children. EPI causes fat malabsorption leading to steatorrhea, weight loss, and nutritional deficiencies. Increased fecal fat may only manifest when the functional reserve of the pancreas falls below 10% [46].

EPI can be measured by several methods. Direct measurement has long been considered the "gold standard" due to high levels of sensitivity and specificity, but is expensive, time consuming, and may only be performed at specialized centers [47].

Direct exocrine pancreatic function testing Older direct methods of pancreatic function testing use an enteric tube to collect pancreatic secretions stimulated from administration of cholecystokinin (provokes enzyme secretion), secretin (provokes bicarbonate production), or both [48].

Variations in these stimulation tests over time have resulted in procedures that are more feasible and better tolerated by patients. These include endoscopic and radiologic studies.

Endoscopic pancreatic function testing (ePFT) has comparable performance to the previous secretin-stimulated Dreiling test. The endoscopic test has greater overall availability, less associated cost, decreased procedure time, and decreased radiation exposure [49]; however, standard protocols and references have not been developed and it does require general anesthesia [50].

Radiologic advancements include a secretin-enhanced MRI that may even allow mild EPI to be detected [51, 52], but would require sedation in younger patients.

Indirect exocrine pancreatic function testing While multiple older methods of indirect pancreatic function testing exist, current commonly used methods to detect EPI include the coefficient of fat absorption (CFA), immunoreactive trypsinogen (IRT), and fecal elastase-1 (FE-1).

Fecal fat measurement entails a 72-hour stool collection while consuming a fixed fat diet [53]. The CFA can be calculated by comparing exact intake versus excretion. Normal CFA values differ by age, with >85% for infants <6 months, and >93% for older infants, children, and adults [54]. If patients are on supplemental pancreatic enzymes, these need to be discontinued prior to the study. Increased fecal fat excretion can be seen in other conditions such as Celiac disease / villous atrophy [53], Crohn disease, or small intestinal bacterial overgrowth [47].

Serum levels of IRT decline as direct function testing demonstrates a parallel decline in bicarbonate output [55]. However, lower levels can also be seen in patients with chronic pancreatitis with normal exocrine function, making this test less reliable. In studies of IRT on patients with cystic fibrosis and EPI, lower IRT levels were associated with steatorrhea [56] and could be used for monitoring for the development of EPI in those over 7 years old [57, 58].

The level of elastase in the stool (FE-1) is the predominantly used test, even though it has limitations. Testing is via a monoclonal antibody ELISA assay, with normal value defined as >200 micrograms of elastase per gram of stool (ug/g) [59]. The assay is specific to the human enzyme and exogenous pancreatic enzyme supplementation will not interfere [60]. The sensitivity of the test is approximately 100% in severe EPI (FE-1 <100 ug/g stool), 77–100% in moderate EPI, and 0–63% in mild EPI (FE-1 <200 ug/g stool) [61, 62]. FE-1 also does not distinguish between primary and secondary causes of EPI and is unreliable on loose stool [63]. For most purposes, the convenience of FE-1 will outweigh its limitations.

Endocrine Pancreatic Function Assessment

Endocrine insufficiency in chronic pancreatitis can happen independently of exocrine insufficiency. This type of diabetes due to islet cell damage and loss, called pancreatogenic or type 3c diabetes mellitus, may reach higher cumulative levels in those with hereditary pancreatitis versus other forms of chronic pancreatitis [64]. In children with acute recurrent or chronic pancreatitis, pancreatic atrophy, hypertriglyceridemia, or coexisting autoimmune disease were more commonly seen in those with already established diabetes [65], and the rate of diabetes in this cohort was 6%. Adult cohort studies have demonstrated that beta-cell function may exhibit more rapid decline in those that were smokers, had undergone previous surgical drainage, or had calcific pancreatitis [66]. Some of these factors are relevant to the pediatric population, highlighting the need for close monitoring.

Indirect endocrine testing Initial testing of endocrine function can be assessed with fasting blood glucose values [67], although there can be variations in fasting values from day to day. By American Diabetes Association [68] and World Health Organization [22] criteria, a fasting blood glucose in the 100–125 mg/dL range indicates impaired glycemia or prediabetes, and a fasting blood ≥126 mg/dL indicates diabetes.

Glycated hemoglobin, or hemoglobin A1c (HbA1c), gives a measure of average blood glucose over the last 2–3 months. By ADA criteria [68], HbA1c of 5.7–6.4% indicates impaired glycemia or prediabetes, and a value ≥6.5% indicates diabetes.

Direct endocrine testing If impairment in fasting blood glucose or A1c is observed, direct challenge is performed with an oral glucose load of 75 grams. At 2 hours post ingestion, blood glucose values ≥200 mg/dL establish a diagnosis of diabetes [22, 68]. Mixed nutrient ingestion (mixed meal tolerance test, MMTT) can distinguish between type 2 and type 3c diabetes mellitus, with limited pancreatic polypeptide (or c-peptide) elevation from baseline in type 3c or pancreatogenic diabetes [67].

Evaluation of Exacerbations

Once the diagnosis of chronic pancreatitis is established, families must be made aware of the need for evaluation during exacerbations. Some testing may be needed when a child with known chronic pancreatitis comes to clinical attention because of abdominal pain, vomiting, and other signs of an acute exacerbation of pancreatitis. These tests differentiate a flare of pancreatitis from other causes of abdominal pain that may present in similar fashion, such as urolithiasis or urinary tract infection, hepatobiliary disease, constipation, bowel obstruction, celiac disease, peptic ulcer disease, or gastritis/gastroenteritis.

Exacerbation Workup

While the pancreatic enzymes, amylase and lipase, can be assessed during a suspected pancreatitis episode, these levels may be only minimally abnormal or may not be elevated at all in a flare of chronic pancreatitis because of pancreatic atrophy and fibrosis [69].

Additional testing may include a hepatic panel (liver enzymes, bilirubin, alkaline phosphatase, gamma-glutamyl

transferase) to assess for hepatobiliary disease, urinalysis with possible culture to identify kidney stones or a urinary tract infection, and screening for Celiac disease if suspected. Imaging may include a complete abdominal ultrasound to identify hepatobiliary, renal, or genitourinary disease or an abdominal x-ray for stool burden or an obstructive bowel gas pattern.

Additional blood work should be pursued to determine potential etiologic risk factors (such as liver enzyme testing, triglycerides, calcium) or for predictors of severity (such as albumin, white blood cell count, blood glucose, lactate dehydrogenase, hematocrit, blood urea nitrogen). Many predictive models of severity have been trialed in both adults and children, but none have enough positive predictive power to use as a single-step criterion of risk for severe pancreatitis and are suboptimal in pediatrics [70].

Treatment

Medical

Pain Management

The chronic abdominal pain that develops in the setting of chronic pancreatitis is multifactorial and requires management from both a pharmacologic and nonpharmacologic standpoint. An inclusive regimen should address components of nociceptive pain, neuropathic pain, and central sensitization of pain [71], but should also include an interdisciplinary approach with psychologists/psychiatrists, integrative medicine providers, and physical/occupational therapists [72] (see Table 35.2).

Current pharmacologic interventions include nonopioid analgesics and opioids to address nociceptive pain. First-line therapy should include nonsteroidal anti-inflammatory agents and acetaminophen/paracetamol. For severe or refractory pain, step-up therapy with opioids can be employed.

Frequent opioid use may be more likely in those children that were older at age of initial pancreatitis diagnosis, were more likely to have the PRSS1 gene mutation, had exocrine pancreatic insufficiency, had constant or severe pain, and had pain that impacted all functional domains [6].

For opioid-sparing effects, the regimen should include neuropathic pain–modifying agents such as antidepressants, and gabapentinoids. Adults with chronic pancreatitis treated with pregabalin had significant pain relief and reduced need for opioid medication [73], although not extensively studied in pediatrics.

Other pain management modalities have been employed to address visceral pain, such as celiac nerve blocks. These can be performed via CT or EUS; injection agents can include alcohol or steroid. However, studies in adults are mixed over a limited follow-up timeframe [74], and only case reports exist in pediatric chronic pancreatitis; they are generally not recommended for children [75].

Table 35.2 Multidisciplinary chronic pancreatitis team

Provider[a]	Role
Gastroenterologists	Pancreatitis and complication management, exocrine insufficiency treatment
Endocrinologist/diabetes educators	Diagnosis and management of endocrine dysfunction
Pain and palliative care providers	Complex pain management
Psychologists/psychiatrists	Adjustment to chronic disease or comorbid mood disorders
Physical therapists	Therapy for physical deconditioning related to chronic disease
Integrative medicine specialist	Nonpharmacologic pain management
Social Work	Connection to resources for patient and family
Child/family life specialist	Assist with procedural-related anxiety
Dietitian	Monitor growth, provide nutrition counseling
Nurse coordinator	Help families to navigate complex care
Surgeon	Surgical management of chronic pancreatitis

[a]Roles are overlapping and a coordinated team approach to management is ideal

Pancreatic Enzyme Replacement Therapy

Supplemental pancreatic enzymes are critical in patients with chronic pancreatitis that has progressed to exocrine insufficiency as a way to optimize fat and vitamin absorption and decrease pain related to malabsorption. A recent meta-analysis of randomized clinical trials limited to those with EPI found that supplemental enzymes decreased fecal fat excretion and improved abdominal pain and thus were clearly indicated [76]. A previous meta-analysis found equivocal results for supplemental enzymes on pain, quality of life, and fecal fat excretion but included those with and without evidence of EPI [77]. It does not appear to be beneficial to provide supplemental enzymes for chronic pancreatitis pain relief in those without EPI [78].

Others

Antioxidant therapy has been hypothesized as a way to control oxidative stress to the pancreas and minimize injury from free radicals; however, an older meta-analysis failed to show benefit [78]. More recent placebo-controlled clinical trials have had mixed results. In a cohort of older adults with chronic pancreatitis (largely alcoholic in origin, with high percentage of smokers), antioxidant therapy did not demonstrate significant improvement in pain scores, quality of life, decreased opiate use, or hospital visits [79]. While in a cohort of younger adults, painful days and analgesic use was

decreased [80], leading the authors to conclude there was benefit.

Psychology

Pediatric psychologists trained in cognitive behavioral therapy (CBT) can teach coping skills, address concomitant mood disorders, and improve overall functioning [72]. An ongoing clinical trial of an internet-based CBT approach will determine the efficacy of this approach on pain management and quality of life specific to children with acute recurrent or chronic pancreatitis [81], especially given access issues to trained health psychologists [72].

Endoscopic

As discussed above, ERCP has largely switched from a diagnostic to a therapeutic modality for obstructive pancreaticobiliary disease and chronic pancreatitis [82]. ERCP with sphincterotomy, ductal dilatation, stenting, and/or stone removal in accomplished hands can lead to improvement in pancreatic drainage and pain as well as decreased episodes of acute pancreatitis [83, 84]. It is a common therapeutic intervention in children with chronic pancreatitis, with 65.8% in the INSPPIRE cohort undergoing at least one ERCP [85]. ERCP appears to offer the most benefit to those children with pancreas divisum or obstructive stones [30].

Notable complications include post-ERCP pancreatitis [26, 29], bleeding, perforation, and infection. A limited trial of endoscopic intervention can be offered in appropriate patients, but step-up surgical therapy should be pursued if patients are not responding [86].

Surgical

Surgical decision-making and technique should be tailored to the patient's disease presentation: pancreatic anatomy, duct size/dilation, or genetic and other risk factors [86].

Cholecystectomy

Given the rise of obesity in the pediatric population and associated biliary disease, adolescents with gallstone pancreatitis should undergo cholecystectomy to reduce the recurrence risk and progression to chronic pancreatitis [87]. When cholecystectomy is delayed, ongoing abdominal pain and further episodes of pancreatitis have been observed [87, 88]. In adults with otherwise idiopathic etiology of acute pancreatitis, cholecystectomy for possible microlithiasis led to a statistically significant decrease in pancreatitis recurrence [89]; however, it is unclear if this strategy would provide benefit in those with already established chronic pancreatitis.

Drainage and Partial Resection Procedures

Procedures such as a lateral pancreaticojejunostomy (Puestow) are indicated for large duct disease for decompressive drainage, but children may be more likely to present with small duct or diffuse disease [90]. In a single center case series of children with chronic pancreatitis undergoing lateral pancreaticojejunostomy, 58.3% of patients reported improvement in abdominal pain over median follow-up of almost 3 years [91], leaving a large percentage still with no improvement in, or recurrence of, abdominal pain.

A pancreaticoduodenectomy (Whipple) resection is indicated for a predominant pancreatic head mass, which is less commonly seen in children but may be performed for associated obstructive jaundice [92] or pancreatic malignancies [93]. Procedures that combine drainage and resection (such as Beger or Frey) may offer more durable results [94, 95], but this has not been seen in all pediatric case series [86].

These procedures should be avoided in children with hereditary pancreatitis [90] given more diffuse pancreatic involvement. In addition, because any surgical resection of the pancreas will lead to lower islet cell yield and increased risk of insulin dependence in the future [96, 97], these procedures should be avoided in those felt to be a candidate for total pancreatectomy islet-auto transplant surgery (TPIAT) [86].

Total Pancreatectomy, Islet Autotransplantation

When patients have failed to respond to maximal medical, endoscopic procedures, or other surgical procedures, total pancreatic (TP) resection can be considered to remove the nociceptive source of chronic unrelenting pain and improve quality of life. This will lead to brittle diabetes if completed alone; thus, it is coupled with islet autotransplantation (IAT) to minimize development of pancreatogenic diabetes. Details of the surgical technique are described in depth in the first large series of TPIAT in children [96], but usually includes total pancreatectomy, partial duodenectomy, Roux-en-Y duodenojejunostomy, cholecystectomy, choledochojejunostomy, splenectomy, the islet infusion, and temporary gastrojejunostomy tube placement. Refinements to the surgical process have occurred over time [98], especially in regards to islet isolation [99].

This is a complex process involving a multidisciplinary team to ensure that patients are appropriate candidates for surgery and that care is optimized prior to surgery. At the University of Minnesota, TPIAT candidates must meet the following criteria: irreversible cause of acute recurrent or chronic pancreatitis leading to chronic pain of greater than 6 months duration, failure of maximal therapies, significantly

impaired quality of life and/or opioid dependence, and adequate islet cell function [96, 97].

Pain relief Pain relief post-TPIAT is accomplished in a high percentage of individuals. In a cohort of those with hereditary pancreatitis, 90% were pain-free post-TPIAT, and improvement in pain was sustained through 10 years of follow-up [100].

Persistent abdominal pain after surgery may be due to gastrointestinal dysmotility and/or central sensitization of pain [101]. Persistent opioid use post-TPIAT has been associated with a prior Whipple or pancreas divisum, greater than 3 previous stents placed during ERCP, and more than 5 years on opioids prior to surgery [98].

Insulin independence Insulin independence has been achieved post-TPIAT. Factors associated with increased insulin independence include female gender [102], lower body weight [102], and, most importantly, more islet equivalents transfused per kilogram of body weight [98, 102, 103]. Prior surgical drainage or partial resection diminished islet yield and was associated with a lower likelihood of insulin independence [96, 97]. Other factors associated with lower islet yield include years with pancreatitis, the surgical era of TPIAT, and, most importantly, pancreatic fibrosis [100].

In the largest series of long-term outcomes in both children and adults after TPIAT, insulin independence (full graft function) or minimal insulin use (partial graft function) was documented at 77% at 1 year, 60% at 5 years, and 47% at 10 years post-TPIAT, which includes 20% that were fully insulin independent at 10 years post-TPIAT [104]. From this study, children (<18 years old) had statistically significant greater likelihood of achieving insulin independence, with odds ratio >9. In a study of TPIAT in children, 82% of young children (under 8 years old) were insulin independent compared to 41% in those over 8 years old [105].

Quality of life Quality of life impairments are seen in both mental and physical domains in children with chronic pancreatitis, far below the normal population [97], and were associated with higher levels of fatigue [5]. After TPIAT, health-related quality of life significantly improved in dimensions of physical and social functioning as well as bodily pain. Physical and emotional summary component scores completely normalized after TPIAT; this improvement was consistently observed through 2 years follow-up post-TPIAT. Functional improvements are noted in better school attendance and decreased activity limitations [96]. In the largest series of long-term outcomes after TPIAT, health-related quality of life continued to improve even at 10 years out from surgery [104].

Younger children (under 8 years old) with lower amounts of pancreatic fibrosis may be good candidates for TPIAT. They have excellent outcomes with high rates of pain relief (100% off opioids at latest study follow-up) and insulin independence (82% vs. 41% in those over 8 years old) [105]. Thus, it is important to consider referral for TPIAT early in young patients with established genetic/hereditary pancreatitis with refractory pain [100, 105].

Congenital Disorders of Intestinal Electrolyte Transport

36

Lavinia Di Meglio and Roberto Berni Canani

Introduction

Congenital diarrheal disorders (CDDs, [OMIM] 251,850) are a group of rare chronic enteropathies characterized by a heterogeneous etiology with a typical onset early in life. In the first few weeks of life, patients affected by CDD usually present with severe diarrhea that within a few hours leads to a life-threatening condition secondary to massive dehydration and metabolic acidosis (or alkalosis in the case of congenital chloride diarrhea, CLD) [1]. The number of conditions included within the CDD group has gradually increased, and many new genes have been identified as functionally related to CDD, opening new diagnostic and therapeutic perspectives [1].

We have proposed a CDDs classification in four groups concerning the main defect:

(i) Defects of digestion and absorption of nutrients and electrolytes
(ii) Defects of enterocyte structure
(iii) Defects of enteroendocrine cells differentiation
(iv) Defects of intestinal immune-related homeostasis

In the context of the first group, the congenital disorders of intestinal electrolytes transport are a subset of diseases characterized by early clinical presentation due to autosomal-recessive defect. These are challenging clinical conditions for pediatric gastroenterologists because of the severity of the clinical picture and the broad range of conditions in the differential diagnosis. Frequently, abnormal fluid absorption begins in utero, manifesting itself as maternal polyhydramnios and/or bowel dilatation. Then soon after birth, patients usually present with severe diarrhea that within few hours leads to a life-threatening condition secondary to massive dehydration and metabolic acidosis/alkalosis [1]. Consequently, these patients require prompt diagnosis and assistance. Milder forms with subtle clinical signs may remain undiagnosed until adulthood when patients developed irreversible complications. In particular, patients with cystic fibrosis (CF) may have a subtle clinical presentation, with prevalent nonintestinal symptoms.

Different mechanisms are responsible for transepithelial ion transport at the intestinal level (Fig. 36.1). In the jejunum, $NaHCO_3^-$ is absorbed via Na^+/H^+ exchange (the secreted H^+ neutralizes an equivalent amount of luminal $NaHCO_3^-$); Cl^- is absorbed passively down this concentration gradient [2]. In the ileum (and, as shown later, also in the proximal colon), NaCl is absorbed via equal rates of Na^+/H^+ and $Cl^-/NaHCO_3^-$ exchanges [2]. At least three Na^+/H^+ exchangers (NHE) have been localized to intestinal brush border membranes and cloned (NHE2, NHE3, and NHE8); NHE2 and NHE3 are found in both small intestine and colon. NHE3 appears to be quantitatively more involved in congenital diarrheal disorders (CDD). NHE2 knockout mouse suffers gastric dysfunction but no intestinal disability has been apprised, whereas the NHE3 knockout mouse suffers from chronic diarrhea. In addition, NHE3 gene mutation results in congenital sodium diarrhea (CSD). A third, Cl^- -dependent NHE is found in crypt cells of the rat distal colon. The NHE first identified in the intestine, NHE1, is present only in the basolateral membrane of enterocytes and is involved in HCO_3^- secretion [3].

Two anion exchangers have also been localized to small-intestinal and colonic brush border membranes and cloned: downregulated in adenoma (DRA) and putative anion transporter 1 (PAT1) [1]. DRA was first cloned from colonic

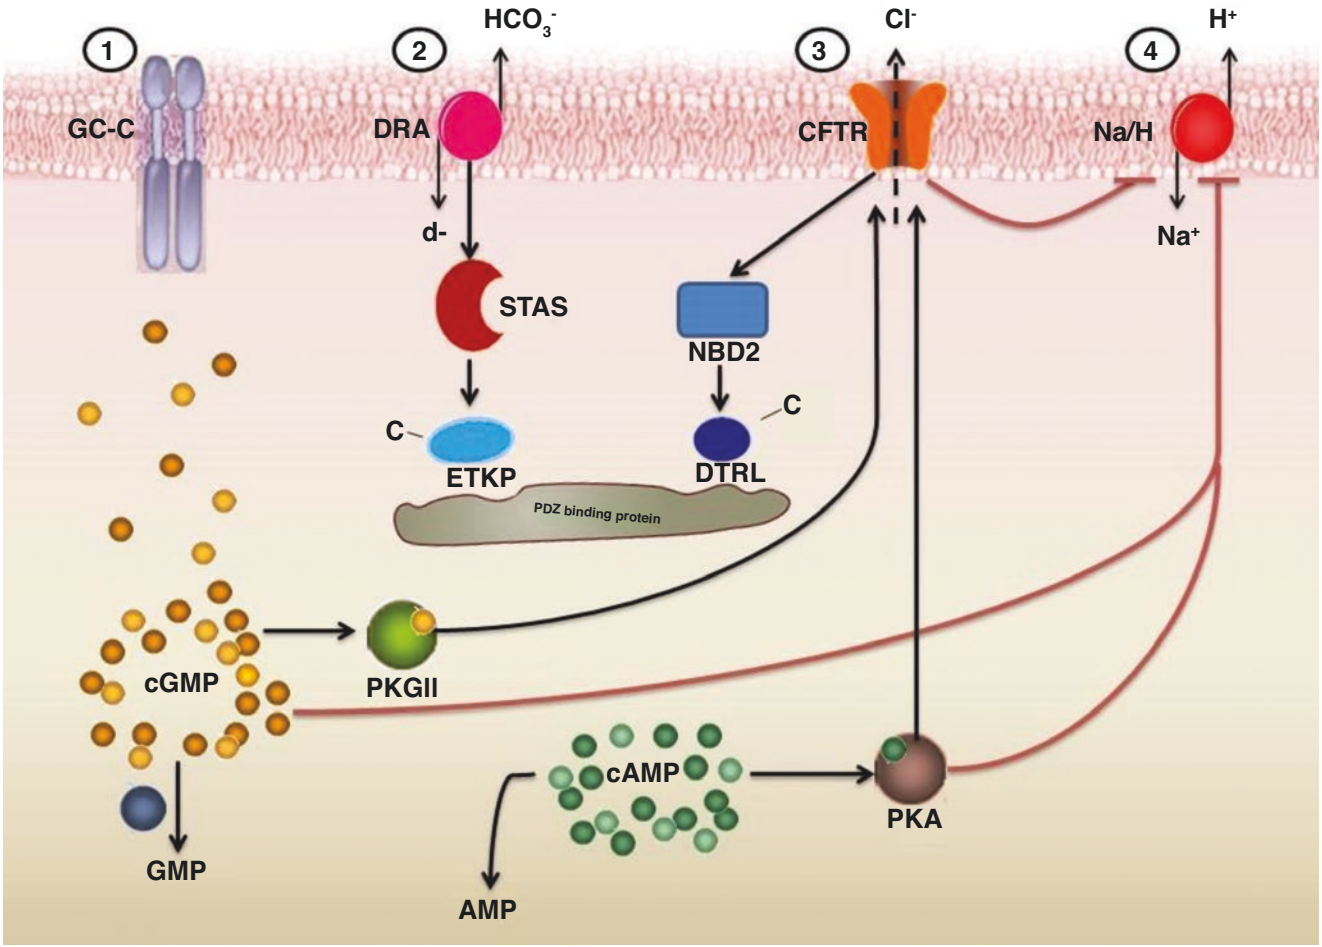

Fig. 36.1 Main pathophysiological mechanisms of congenital disorders of intestinal electrolyte transport
1. Pathophysiological mechanisms of congenital disorders of intestinal electrolytes transport. Familial diarrhea syndrome is due to a mutation in intestinal guanylate cyclase receptor (GC-C) for the endogenous ligands uroguanylin/guanylin. Ligand binding to GC-C increases intracellular levels of cyclic guanosine monophosphate (cGMP). The cGMP activates cGMP-dependent protein kinase II (PKGII). PKGII phosphorylates the cystic fibrosis transmembrane conductance regulator (CFTR), increasing its Cl–-secreting activity and inhibiting electroneutral NaCl absorption. A missense mutation leads to a gain of function, increasing ligand-mediated activation of GC-C and intracellular cGMP levels resulting in chronic secretive diarrhea. 2. Congenital chloride diarrhea is caused by a defect in DRA exchanger, leading to severe watery diarrhea due to Cl – malabsorption. The protein has a C-terminal domain, sulfate transporter, and anti-sigma factor antagonist (STAS) that ensures the correct location of the protein on the apical membrane of enterocytes. The STAS domain also interacts with the R-domain of the CFTR, and it is required for CFTR activation. 3. In cystic fibrosis, there is an alternated activity of CFTR. This membrane protein consists of two membrane-spanning domains, two nucleotide-binding domains (NBDs), and a regulatory domain, which controls channel activity and it functions as a cAMP-dependent chloride channel. 4. Congenital sodium diarrhea probably derives from a defect in apical membrane Na+/H+ exchangers, leading to severe watery diarrhea due to Na + malabsorption
DRA downregulated in adenoma, DTRL Defense Terrain Research Laboratory, cAMP cyclic adenosine monophosphate, AMP adenosine monophosphate, GMP guanosine monophosphate

mucosa; it was found to be downregulated in villous adenomas and carcinomas and, subsequently, was found to incur mutations in the rare "congenital chloride diarrhea." Both DRA and PAT1 are abundant in the duodenum and are present at higher density there than NHE2 and NHE3, suggesting a role in duodenal alkalinization. In the colon, DRA appears to predominate over PAT1. In the descending colon, mineralocorticoid-regulated apical epithelial sodium channels (ENaC) is implied Na^+ absorption [4].

More than two brush border ion exchangers are required, of course, for the enterocyte to engage in transcellular salt absorption. Increased turnover of the Na^+/K^+ pump and the opening of Cl^- and K^+ channels are also necessary, the latter to counteract associated cell swelling, to permit serosal exit of Cl^- taken up from the lumen, and to dissipate the added uptake of K^+ through the pump.

Glucose and Galactose are mainly absorbed by an SGLT1 expressed apically in the brush border of the upper third

small intestinal villi and diffuse out of the cell through the basolateral GLUT2.

SGLT1 uses a Na^+ electrochemical gradient generated by the basolateral Na^+/K^+ ATPase pump: two Na + accompany each glucose molecules [4]. Mutation of SGLT1 is responsible for glucose–galactose malabsorption diarrhea [5]. Fructose is reabsorbed independently by facilitated diffusion process through GLUT5 [4].

The diagnostic approach to CDDs is a multistep process that includes the careful evaluation of the anamnesis and clinical data, results of common laboratory and instrumental procedures, and molecular analysis (Fig. 36.2). The positive familiar history of early-onset chronic diarrhea, polyhydramnios, and/or dilated bowel loops at ultrasound examination during pregnancy are highly suggestive of CDDs. Recently fetal MRI and amniotic electrolytes have shown a potential diagnostic role for congenital sodium (CSD) or chloride losing diarrhea (CLD) [6, 7].

The main symptom is chronic diarrhea (during longlasting than 30 days). In the diagnostic approach, it is important to take into account that infections and food allergy are the most common causes of diarrhea also at this particular

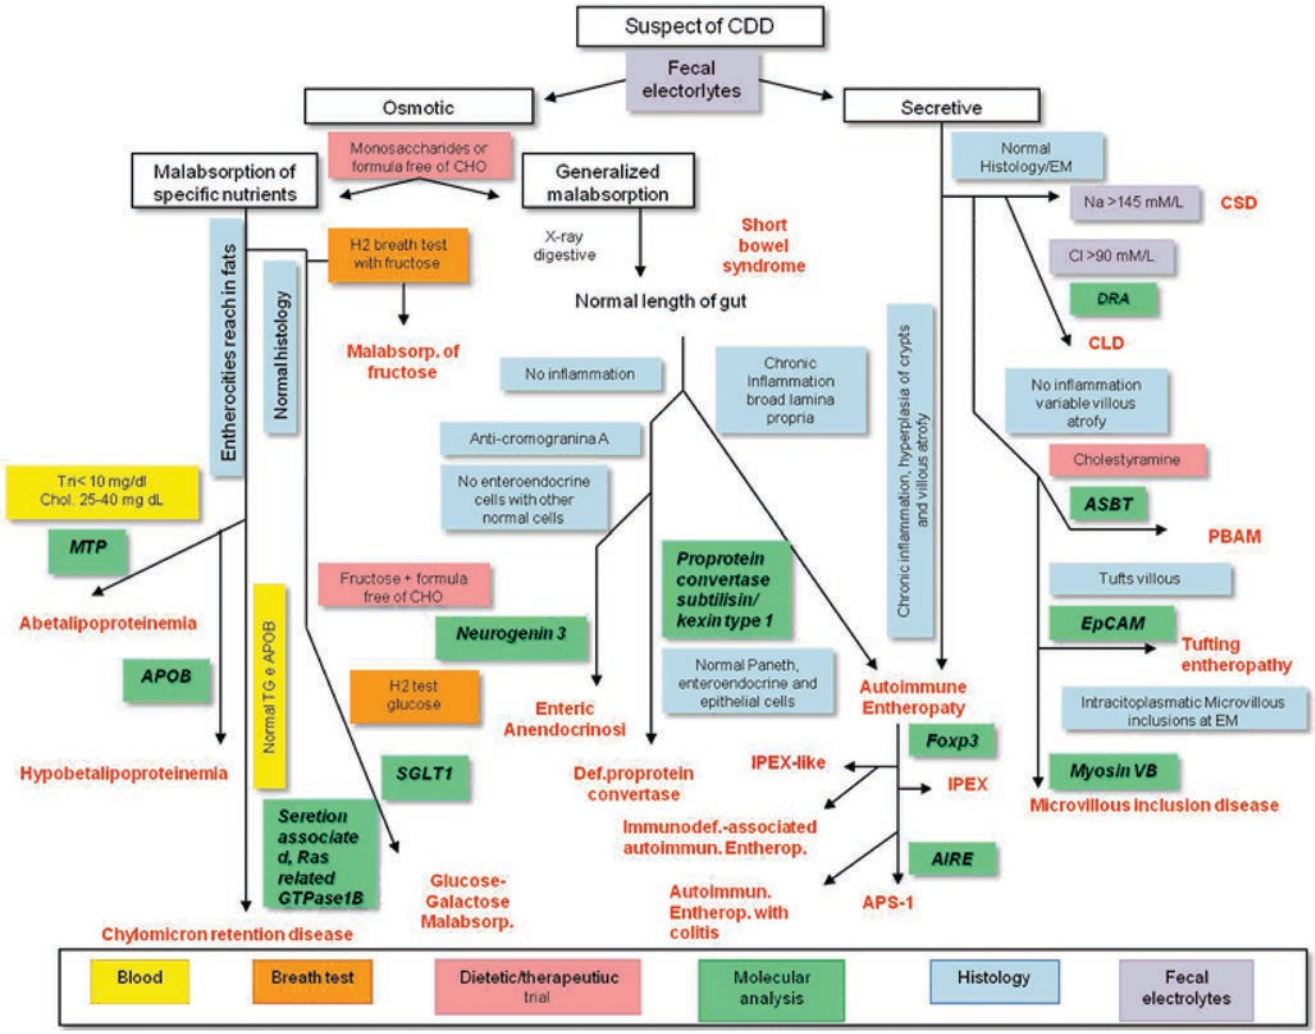

Fig. 36.2 Indications for a modern diagnostic approach to the main forms of CDDs

Indications for an integrated diagnostic approach to the main forms of CDDs. The diagnostic approach is a multistep process that includes the evaluation of anamnesis and clinical data, results of common laboratory and instrumental procedures and molecular analysis. The fundamental step in the diagnostic process of CDDs is the identification of an osmotic or secretory mechanism, leading to diarrhea. Moreover, the determination of stool electrolyte concentration and fecal ion gap is important to discriminate the two mechanisms responsible for CDDs. The next step is laboratory investigation that includes blood gas, blood glucose, ammonium, albumin, triglycerides, and cholesterol, aminoaciduria and the search of reducing substances in the stools, steatocrit, and sweat test. Finally, intestinal biopsy with histologic examination is crucial for the diagnosis of most CDDs. Molecular analysis, when available, is important and could limit invasive procedures

age [8], and that these conditions, together with malformations of the gastrointestinal (GI) tract, should be considered as a primary diagnostic hypothesis in an infant with chronic diarrhea [9]. However, in all cases of chronic diarrhea starting in the first few weeks of life, the presence of a congenital disorder of intestinal electrolyte transport should be excluded. A fundamental step in the diagnostic process is the identification of an osmotic or secretory mechanism leading to diarrhea. In osmotic diarrhea, unabsorbed luminal substances are responsible for the accumulation of fluids in the intestinal lumen and diarrhea significantly improves during fasting; whereas, in secretory diarrhea, fluids are actively secreted in the intestinal lumen and diarrhea continues during fasting [9]. Furthermore, the determination of stool electrolyte concentration and fecal ion gap is important to discriminate the two mechanisms responsible for CDDs (Fig. 36.1). If the ion gap is >50 fecal, the diarrhea is an osmotic diarrhea, in contrast, a low osmotic gap (<50) is typically observed in secretory diarrhea. Direct measurement of Na^+ and Cl^- concentration in the stool may suggest a diagnosis of congenital sodium (CSD) or chloride losing diarrhea (CLD), respectively [9]. When an osmotic mechanism is suspected, the next step of laboratory investigation includes blood gas, blood glucose, ammonium, albumin, triglycerides and cholesterol, aminoaciduria, and the search for reducing substances in the stools, steatocrit, and sweat test (Fig. 36.2). Cystic fibrosis (CF) is suggested by the presence of steatorrhea and confirmed by a positive sweat test. On the other hand, signs of inflammation in children with secretory diarrhea and familiar history of chronic diarrhea justified the suspect of a familiar diarrhea syndrome (FDS). The recent availability of molecular analysis for many of these conditions, such as Next-Generation Sequencing diarrhea-related genes panel, has progressively limited the need for invasive procedures (Fig. 36.2).

Congenital Chloride Diarrhea

Congenital chloride diarrhea (CLD; OMIM 214700) is caused by mutations in the solute carrier family 26 member 3 (SLC26A3) gene, and it is responsible for a life-long secretory diarrhea with high fecal Cl- concentration [10]. The gene, located on chromosome 7.q31, encodes for a transmembrane protein that takes part in the Cl^-/ $NaHCO_3^-$ exchange (Fig. 36.2) [11]. The SLC26A3 is located close to the gene encoding for the cystic fibrosis transmembrane conductance regulator (CFTR), raising a possibility of CFTR modulation in the pathogenesis of CLD [12]. The protein is composed of 764 amino acids that fold to create a transmembrane glycoprotein with hydrophobic segments that cross the membrane 14 times [13]. The C-terminal domain, STAS (sulfate transporter and anti-sigma factor antagonist), ensures the correct location of the protein on the apical membrane of enterocytes, interacts with the R-domain of the CFTR, and it is required for CFTR activation. Studies have shown that deglycosylation of HA-SLC26A3 may contribute to the pathogenesis of diarrhea associated with CDG (congenital disorder of glycosylation), because oligosaccharides protect HA-SLC26A3 from proteolytic digestion enzymes in the intestine [14]. The gene SLC26A3 has also extraintestinal expression: it is expressed in sweat glands, the male reproductive tract, and the kidney, while it is downregulated in human colon adenomas and adenocarcinomas [15–17].

The majority of the SLC26A3 mutations are single-nucleotide substitutions (nonsense, frameshift and missense), while additional mutations as deletions/insertions are minor. These mutations can interfere with the normal life of the protein in many ways: the protein may not leave the *Endoplasmic reticulum* (ER) or the traffic of the protein to the cell surface may be interrupted, as well as the activity of the protein may be reduced, absent, or alternated [13, 18]. There are no shreds of evidence of a correspondence between genotype and phenotype. It has been demonstrated that an identical genetic background of CLD may show different clinical courses [19] or different responses to therapy [20, 21].

Countries with the highest incidence are Finland (1:35,000), Poland (1:200,000), Kuwait (1 in 3200 births), and in Saudi Arabia (1 in 5500) [22–24]. In Arabian countries, the high incidence is due to consanguineous marriages [24]. There is a single mutation in the above-mentioned ethnic groups: in Finns, the p.V317del mutation affects up to 90% of CLD alleles; in Saudi Arabians and Kuwaitis, pG187X is present in more than 90% of altered chromosomes; in Poles, 50% of CLD alleles carry the p.1675dup [10].

The main clinical symptom is life-long watery urine like diarrhea with high Cl- content and low pH [1]. If not treated, diarrhea leads to dehydration, metabolic alkalosis, hyponatremia, hypokalemia, hypochloremia, and failure to thrive.

Usually, diarrhea causes metabolic acidosis; in CLD, a large volume of sodium-rich and bicarbonate low fluid is lost from the body, causing contraction alkalosis [25].

Because of the intrauterine onset of diarrhea, CLD pregnancies are characterized by bowel dilatation, polyhydramnios with normal peristalsis, and the newborn could be mild premature [24, 26]. High levels of amniotic Cl- have been described.

These features are sensible but not specific to CLD. Fetal MRI has been used to differentiate CLD/CSD from intestinal obstruction [7]. Postnatally, CLD patients present prominent abdominal distention due to dilated loops of ileum and colon filled with air and fluid: the loss of a big amount of fluid from the GI tract can lead to severe dehydration; ascites is often present. Hyperbilirubinemia is common and is

caused in part by the dehydration. It is worth remembering that excessive volume and salt depletion reduces the amount of diarrhea and may result in a low fecal Cl^- of even 40 mmol/L such as a stool dilution by urine [24, 27]. After the correction of electrolyte homeostasis by salt substitution, the first thing to do is the measurement of Cl- on a stool sample, eventually obtained with a soft catheter to avoid contamination with urine. A fecal Cl^- >90 mmol/L confirms the diagnosis in most of the cases and leads to molecular analysis of SLC26A3. Untreated patients show retarded growth and development, with mental and psychomotor retardation; a promptly start of therapy is associated with a better growth [19].

The main therapeutic approach is based on substitutive therapy with NaCl/KCl (see Table 36.1) [28]. The short-chain fatty acid, butyrate, is also beneficial in patients affected by CLD [21, 29]. Butyrate could reduce mistrafficking or misfolding of DRA and may enhance gene expression through the activation of a region crucial for high-level transcription. Butyrate is also able to modulate transepithelial ion transport through the stimulation of Na^+/H^+ exchangers 2 (NHE2) and 3 (NHE3) activity and inhibition of Cl- secretion by limiting the action of the cotransporter Na-K-2Cl (encoded by NKCC1) on enterocyte basolateral membrane. Treatment with oral butyrate (100 mg/kg/day) allows a progressive reduction to normal in the number of bowel movements and stool volume, an improvement in stool consistency, and a reduction of fecal incontinence episodes [20]. The starting dose is 50 mg/kg/die and a step-up approach is suggested to reach the 100/mg/kg/day. The effect of butyrate on the stool pattern is evident within the first 48 hours and remained stable during the following days of treatment. The response to butyrate may vary, and this explains the different benefits based on ethnicity [20]. A genotype-depending response was observed by some authors: patients with deletion and missense mutation showed a full response, while a partial response was observed in patients with nonsense or splicing mutations [20]. Other authors showed a different response in children with the same deletion mutation, suggesting that a more complex mechanism is responsible for the response [21].

The long-term prognosis of CLD patients is generally favorable. All of the patients treated adequately reach adult life, because oral salt substitution with NaCl and KCl allows normal growth and development, and the stool pattern tends to improve in the adult age [26, 28]. The most common complications are failure to thrive and psychomotor delay. Chronic kidney disease is described in up to 20% of CLD patients, and in some cases, dialysis or transplantation may be necessary [16]. In males, an important complication is subinfertility, caused by alteration of number, function, and morphology of sperms. In females, cases of pregnant women

Table 36.1 Therapeutic approach to a child with congenital chloride diarrhea

Treatment of acute dehydration			
1. Initial treatment of fluid depletion (over 6–8 h) IV infusion of 0.9% NaCl solution, NO fluids containing bicarbonate 120–500 mL/day for children under 7 years 500–1000 mL/day for children over 7 years			
2. Maintenance therapy (over 24 h) Intravenous 5% glucose 100 mL pro kg (children weight 10 kg) + 50 mL pro kg for each additional kg (children weight between 11 and 20 kg) + 20 mL pro kg for each additional kg (children weight 20 kg) For adult patients: 2000–2500 mL/day NaCl 20 mmol/L added KCl maintenance need + calculated K^+ depletion added (50 mmol/L) If severe hypokalemia, higher KCl doses of even 70 (−100) mmol/L			
3. Replacement of ongoing losses for diarrhea (0.9% NaCl and, if necessary, KCl)			
Salt substitutive therapy in stable clinical condition			
	Small children (0–3 years)	*Older children*	*Adolescents and adults*
NaCl	0.7% (7 g/L; 120 mmol/L)[a]	1.8% (18 g/L; 308 mmol/L)	Equal molar ratios of NaCl and KCl
KCl	0.3% (3 g/L; 40 mmol/L)[a]	1.9% (19 g/L; 255 mmol/L)	Equal molar ratios of NaCl and KCl
Concentration of Cl−	160 mmol/L	563 mmol/L	--
Need for Cl−	6–8 mmol/kg/day	3–4 mmol/kg/day	3–4 mmol/kg/day
Administration	Intravenous[b]/Oral	Oral	Oral
Doses per day	3–4	2–3	2–3
Pharmacological treatment			
Oral sodium butyrate, 100 mg/kg/day[c], divided in two doses			

[a]Intravenous therapy is used for infants until the shift to peroral fluid is possible. During intravenous therapy, the need for additional fluid is 100–120 mL/day (stool volume), which can be taken orally

[b]A "step-up" approach is recommended, starting from a dosage of 50 mg/Kg/day for 7 days, 75 mg/Kg/day for the next 7 days, reaching the final dosage of 100/mg/Kg after 14 days

[c]If a tendency to hyperkalemia: 0.9% NaCl (9 g/L; 154 mmol/L) and 0.2% KCl (2 g/L; 27 mmol/L)

with CCD have been described and ended up uneventfully. Additional complications include intestinal inflammation, hyperuricemia, inguinal hernias, and spermatoceles [26].

Congenital Sodium Diarrhea

Congenital sodium diarrhea (CSD; OMIM 270420) is a rare inherited disorder, characterized by severe diarrhea since birth, with metabolic acidosis, dehydration, and hyponatremia due to enormous fecal losses of Na^+. Fetal polyhydramnios, distended loops, and failure to pass meconium are common features of CSD [30]. Two variants have been described: syndromic CSD and classic CSD and three genes have been identified as relevant: SPINT2 for syndromic CSD, SLC9A3 and GUCY2C for classic CSD [31]. In 40% of classic type, no SLC9A3 or GUCY2C mutations have been found, suggesting that other genes may be implied [31] (Fig. 36.3). The syndromic form of CSD is an autosomal-recessive disease caused by loss-of-function mutations in SPINT2 and is characterized by choanal and/or anal atresia, hypertelorism, corneal erosions, double kidney, cleft palate, and digital anomalies [32]. Mucosal anomalies have been described, resulting in villous atrophy and characteristic tufts of extruding epithelium [31]. Mainly nonsense and splice-site mutation of SPINT 2 have been identified. SPINT2, also known as placental bikunin or hepatocyte growth factor activator inhibitor type 2 (HAI-2), is a potent inhibitor of several serine proteases, with particular attention to matripase and prostasin. These two serine proteases form a reciprocal zymogen activation complex that results in their autoactivation. In the distal colon, activated matriptase-prostasin complex is essential for proteolytic activation of ENaC, a channel is implied in Na + reabsorption. The absence of SPINT2

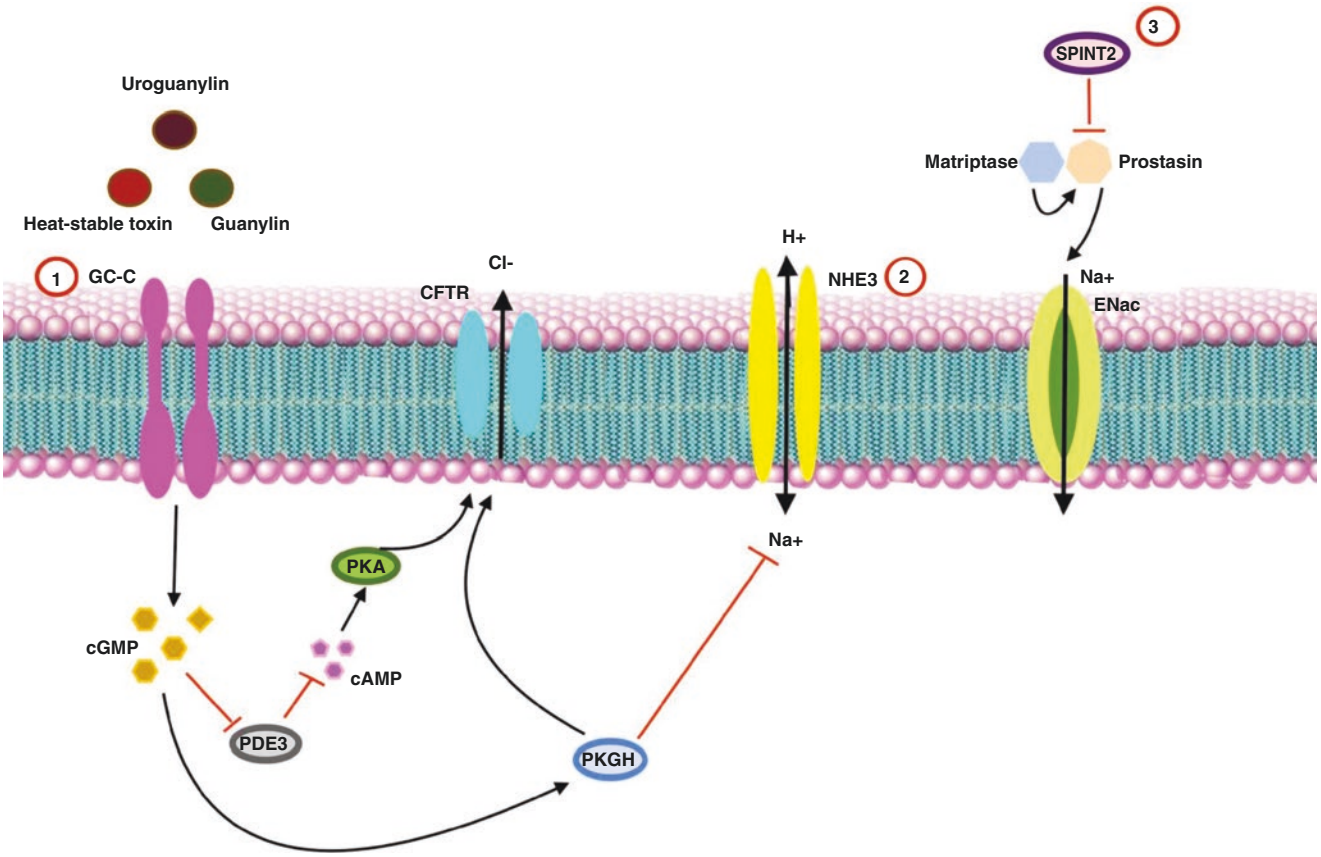

Fig. 36.3 Main pathophysiological mechanisms of congenital sodium diarrhea

1. Classic variant: The autosomal-dominant mutation of GUCY2C results in an alteration of the transmembrane guanylate cyclase GC-C; intracellular levels of cGMP rises without ligand binding. High levels of cGMP inhibit NHE3 via its phosphorylation by cGMP kinase II, causing a "secondary NH3 deficiency" and increase in Cl- secretion by CFTR via PKA

2. Classic variant: autosomal-recessive disease characterized by mutations in SLC9A3 gene that encodes for the NHE3, leading to a less absorption of Na + in the gut

3. Syndromic variant: autosomal-recessive disease caused by loss-of-function mutations in SPINT2, a potent inhibitor of matripase and prostasin. Activated matriptase-prostasin complex is essential for the proteolytic activation of ENaC, a channel that is implied in Na + reabsorption. The absence of SPINT2 results in a 'consumptive depletion" of matriptase, a secondary less activation of prostasin, and less proteolytic activation of ENaC with a decreased sodium absorption

results in a "consumptive depletion" of matriptase, a secondary less activation of prostasin, and less proteolytic activation of ENaC with a decreased sodium absorption [31].

Two forms of the classic variant have been reported. The first one is an autosomal-recessive disease characterized by mutations in SLC9A3 gene that encodes for the NHE3 channel. NHE3 is responsible for the major absorption of Na + in the gut and concurs in the acid-base homeostasis. Truncating and missense mutations were identified, resulting in a reduced function or expression of the transport [31]. The second variant is an autosomal-dominant mutation involving the GUCY2C gene that encodes for the transmembrane guanylate cyclase GC-C receptor for heat-stable enterotoxins that plays an important role in the pathogenesis of acute secretory diarrhea.

Uroguanylin, guanylin, and enterotoxigenic *Escherichia coli* activate this cyclase. The mutation of this gene results in its activation; high level of cGMP inhibits NHE3 via its phosphorylation by cGMP kinase II, causing a "secondary NH3 deficiency," and increases Cl- secretion by CFTR via PKA [31].

This gene is implicated also in familial diarrhea syndrome (FDS); however, the enhanced activity of GC-C in CSD is higher compared to FDS.

No mucosal anomalies have been described in classic type. Classic variant has been associated with a higher risk of inflammatory bowel diseases (IBD) [31, 33].

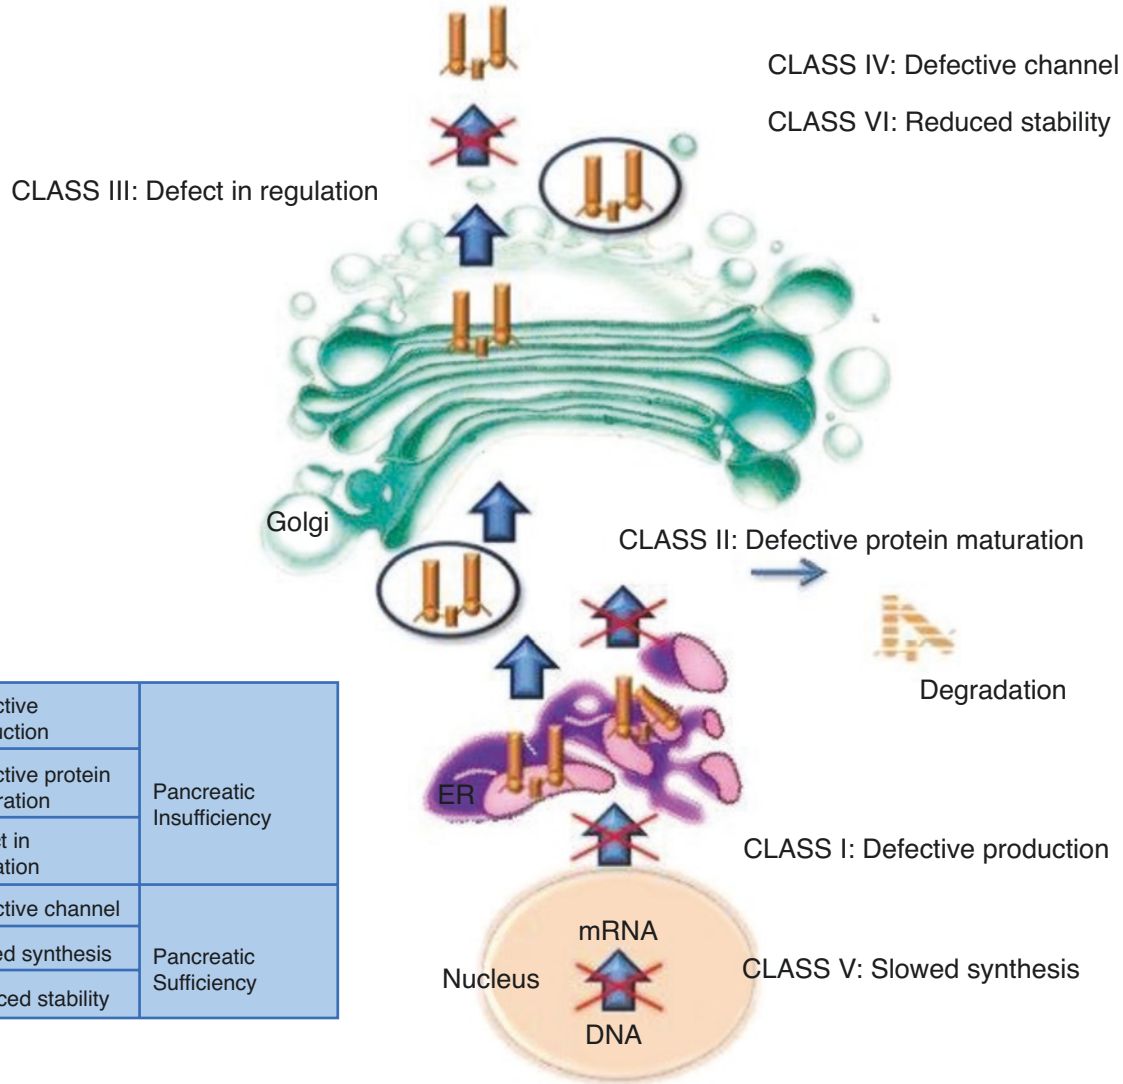
A diagnosis of CDS is made on the findings of life-threatening secretory diarrhea, with voluminous alkaline stools (pH >7.5), containing a high concentration of Na^+ (> 70 mmol/l) associated with hyponatremia (Na^+ <130 mmol/l) and metabolic acidosis. Fecal Na^+ could be normal after an excessive volume and salt depletion. CSD treatment consists of the replacement of losses ions and parenteral nutrition to acquire adequate caloric and fluid intake.

Familial Diarrhea Syndrome

This disease was described for the first time in 32 members of a Norwegian family [34]. Familial diarrhea syndrome (FDS) is characterized by early-onset chronic diarrhea, associated with meteorism, abdominal pain, dysmotility, and inflammatory bowel disease [34]. All affected members show a heterozygous missense mutation in *the GUCY2C* gene, c.2519G > T [p.Ser840Ile]. This gene is implied also in classic CSD [31]. It was been demonstrated that the basal GC-C enzyme activity, cellular cGMP levels, and affinities for ligands are similar in cells expressing either the wild receptor or the mutant one. In contrast, in CSD, basal GC-C enzyme activity is higher compared with wild type [33]. The mutant receptor in FDS is activated by heat-stable enterotoxin, uroguanylin, and guanylin to a greater extent than the wild receptor but not as high as the mutant receptor described in CSD [33]. A missense mutation leads to a gain of function, increasing ligand-mediated activation of GC-C and intracellular cGMP levels. GMP activates protein kinase GII, leading to phosphorylation of the CFTR channel [35]. This activation leads to an efflux of Cl^- (or HCO_3^- in the duodenum) and water into the intestinal lumen, with a reduced Na + absorption due to inhibition of the Na+/H+ exchanger 3 (NHE3) [36]. Another difference from CSD is the absence of prenatal anomalies: no polyhydramnios or bowel dilatation has been reported.

Cystic Fibrosis

Cystic fibrosis (CF; OMIM 219700) (CF) is an autosomal-recessive disorder due to a dysfunction of Cl- channel (CFTR) in the apical surface of epithelial cells. Because of the different locations of CFTR in the human body, CF is characterized by several and various symptoms and it is the main cause of exocrine pancreatic insufficiency in childhood. The prevalence of CF is 1/3500 and occurs with greater frequency in populations of North America, Northern Europe, Australia, and New Zealand [37]. The pathophysiologic basis of CF is characterized by a mutation of CFTR gene, located on chromosome 7, that determines the loss of function of CFTR (Fig. 36.4). CFTR is a member of the ATP-binding cassette (ABC) transporter superfamily. This membrane protein consists of two membrane-spanning domains, two nucleotide-binding domains (NBDs), and a regulatory domain, which controls channel activity, and it functions as a cAMP-dependent chloride channel. CFTR is largely expressed in epithelial cells of the airways, in the GI tract, including the pancreas and the biliary system. More than 2000 different mutations in the *CFTR* gene were identified; however, only 200 mutations cause the disease; the most frequent mutation, present in almost 70%, is the deletion of a single phenylalanine residue at amino acid 508 (ΔF508) [38, 39]. CFTR mutations have been divided into six classes based on how they interfere with the normal life of the protein; however, many mutations can be assigned in more than one class. Class I: No functional protein produced; Class II: Absent or diminished protein processing; Class III: Defective gating; Class IV: Decreasing conductance; Class V: Abnormal splicing; Class VI: Decreased surface stability [40]. Recently, Class VII has been introduced; it represents a variant of Class I. Class VII is also called "unrescuable mutation": no target therapy can be used and it is caused by mutations that result in absence of CFTR mRNA [41]. The loss of function of CFTR determines the inability to secrete NaCl in the respiratory tract. The small amount of water present on the surface of the mucous membrane is insufficient to hydrate secretions that become more viscous and elastic, resulting in



CLASS I	Defective production	Pancreatic Insufficiency
CLASS II	Defective protein maturation	
CLASS III	Defect in regulation	
CLASS IV	Defective channel	Pancreatic Sufficiency
CLASS V	Slowed synthesis	
CLASS VI	Reduced stability	

Fig. 36.4 Synthesis of CFTR and classes of mutation in cystic fibrosis
Synthesis of CFTR and classes of mutation in cystic fibrosis. CFTR gene encodes for a protein that regulates Cl – transport. CFTR is located at membrane level of secretive cells in lungs, gastrointestinal tract, liver, pancreas, and reproductive system. Mutation of Class I is related to the production of the protein: Generally, the protein is not produced at all or in very small quantities. Class II mutations prevent the maturation of protein. In Class III and IV mutations, protein is produced, but works incorrectly. Class V mutations allow a slow production of a small quantities of a working protein. Currently, the effects on clinical outcomes are not clear for all mutations, but a correlation between class mutation and pancreatic involvement is known: Class I, II, and III mutations are generally associated with pancreatic insufficiency, and Class IV and V mutations are associated with pancreatic sufficiency

a slowing of mucociliary clearance and airway obstruction. CFTR dysfunction can also make PH more acid in the respiratory tract. In the normal pancreas, the duct cells secrete Cl- via CFTR. Cl lumen level is important, because this ion will be exchanged with the intracellular HCO_3^-. The absence or dysfunction of CFTR results in a more viscous pancreatic secretion. On the contrary, since the function of sweat glands ductal cells is to absorb chloride, rather than secrete it, in CF, the concentration of chloride and salts in the sweat is very high. Primarily on this principle is based the most important CF diagnostic test. CF has a wide heterogeneity of clinical manifestations related to the high number of mutations and environmental factors. Pulmonary and GI symptoms are the most common. Chronic infections characterized the expression of CF in the airways and are determined by the inability to quickly eliminate microorganisms inhaled, resulting in colonization and inflammatory response in the airway walls. This phenomenon is also determined by the reduction of the secretions antimicrobial activity, resulting in excessive acidity of the fluid surface. Cough is the most common symptom

Table 36.2 Main clinical features of cystic fibrosis

Chronic respiratory disease
Persistent colonization/infection by typical pathogens *(Staphylococcus aureus, non-typeable Haemophilus influenzae, Pseudomonas aeruginosa, Burkholderia cepacia*
Chronic cough and sputum production
Persistent abnormalities on chest radiographs (bronchiectasis, atelectasis, infiltrates, hyperexpansion)
Airways obstruction characterized by bronchospasm and air trapping
Nasal polyps and sinus abnormalities evaluable at radiographs or CT
Digital clubbing
Gastrointestinal and nutritional involvement
Intestine: meconium ileus, distal intestinal obstruction syndrome (DIOS), rectal prolapse
Pancreas: pancreatic insufficiency, recurrent pancreatitis
Liver: chronic liver disease characterized by clinical or histological evidence of focal biliary cirrhosis or multilobular cirrhosis
Nutrition: protein–calorie malnutrition, hypoproteinemia, and edema, complications secondary to a deficiency of fat-soluble vitamins
Salt-wasting syndrome:
Acute salt depletion, chronic metabolic alkalosis
Urogenital abnormalities in male determining obstructive azoospermia

of pulmonary involvement, dry and hacking at first, then loose and productive, usually with purulent expectorated mucus [42]. GI involvement consists of two different clinical entities: meconium ileus and distal intestinal obstruction syndrome (DIOS), both due to an impaired electrolyte and fluid secretion that cause an inspissation of intestinal content and consequent intestinal obstruction, in combination with the known impaired intestinal motility. Classically, patients present fat maldigestion and malabsorption that can be directly attributable to the reduced secretion of lipase/colipase from the exocrine pancreas. Liver disease secondary to cholestasis is present in 30% of patients, and it is responsible for a variety of biliary tract and hepatic complications. Clinical manifestations of liver involvement are characterized by jaundice, ascites, hematemesis from esophageal varices, and signs of hypersplenism, hepatomegaly with steatosis [43]. Male sterility is a constant feature (Table 36.2). A correlation between mutation class and phenotype has been descried. Class I, II, III, VII mutations are associated with a severe phenotype, while Class IV and V results in a mild phenotype with pancreatic sufficiency. However, frequently, the mutations present on both alleles belong to different classes, and the clinical manifestations are the results of both. In addition, "CFTR-related disorders" have been described. In these cases, mutations on CFTR result in atypical disease, and manifestations are limited to few organs. These entities include episodes of recurrent pancreatitis or isolated bilateral bronchiectasis, bilateral agenesis of the vas deferens (CBAVD) with no digestive or respiratory involvement. The variability of clinical expression suggests that phenotype is not just the results of CFTR mutation but is also influenced by non-CFTR factors [44].

The diagnosis of CF is both clinical and genetic. A combination of a positive newborn screening, sweat test >60 and the identification of 2 CF-causing mutations (defined by CFTR2) with symptoms of CF, or positive family history is consistent with a diagnosis of CF. A monosymptomatic clinical entity (CBAVD/pancreatitis/bronchiectasis) associated with CFTR dysfunction that does not fulfill the diagnostic criteria for CF is defined as CFTR-related disorder.

Individuals who had a positive newborn screening but do not fulfill the diagnostic criteria of CF are defined: CFTR-related metabolic syndrome (CRMS) or CF screen positive, inconclusive diagnosis (CFSPID). They should receive a clinical evaluation by CF specialist in order to identify any possible clinical symptoms [45].

With newborn screening, diagnosis is often made before obvious clinical manifestations such as failure to thrive and chronic cough show up. Screening consists of a combination of immunoreactive trypsinogen results and limited DNA testing on blood spots, which are then coupled with confirmatory sweat analysis, and it is ≈95% sensitive [50].

Sweat test, which is considered the gold standard in the diagnosis of CF, is based on the determination of Na + and Cl- concentration in sweat collected after local stimulation with pilocarpine. Levels <35 mmol/L are considered normal; levels >60 mmol/L are considered pathological. Between 35 mmol/L and 60 mmol/L, results are considered borderline; in this scenario, sweat test must be repeated with an extensive CFTR gene mutation analysis, and this patient should receive a clinical evaluation by CF specialist. A positive sweat test alone does not allow to make a diagnosis and, on the other hand, it does not allow to exclude CF if negative: some mutations are associated with a negative sweat test [43, 46, 47]. Generally, sweat tests are not performed in subjects younger than 2 weeks of age and that weigh less than 3 kg. The test is contraindicated in babies younger than 48 hours of age, because high concentrations of sweat electrolytes can be found on the first day of life. If the patient is acutely unwell, dehydrated, edematous, or receiving corticosteroids, the test should be delayed [36]. Another important diagnostic test is the search for genetic mutations of the CFTR gene. Several commercial laboratories test for 30–96 of the most common CFTR mutations. These tests identify ≥90% of individuals who carry 2 CF mutations. These tests are used to confirm but not to exclude the dubious diagnosis, because a lot of mutations have not yet been identified. The genetic study can identify four different mutations categories: CF-causing mutation, mutation of varying clinical consequence, uncharacterized mutation, non-CF-causing mutation. In individuals with a positive newborn screen but with unchar-

acterized or mutation of varying clinical consequence CFTR mutations (<2 CF-causing mutations), the diagnosis of CF can be made by demonstrating CFTR dysfunction by a positive sweat test or nasal potential difference (NPD) or intestinal current measurement [45]. Among other possible diagnostic tests, the evaluation of potential differences across the nasal epithelium is often used. It consists of the demonstration of alterations in chloride secretion of epithelial cells, after stimulation with amiloride, through the measurement of nasal potentials. The assessment of pancreatic function is another test used in CF. This assessment is usually made through the evaluation of steatorrhea, fecal chymotrypsin, fecal elastase, and the duodenal assay after secretin or pancreozymin stimulation [48]. Also intestinal current measurements (ICMs) on rectal suction biopsies have been used to evaluate CFTR dysfunction [49]. The treatment of CF is extremely complex and articulate.

Respiratory system Therapy of bronchial obstruction is based on physiotherapy, which maintains adequate bronchial toilet and on aerosol therapy that has the purpose of liquifying secretions.

Anti-inflammatory therapy has given numerous benefits, despite the contraindications [51]. During exacerbations, an increase of physiotherapy in combination with antibiotic therapy is indicated. Antibiotic therapy should be guided by the results of sputum culture, preferably using intravenous drugs at high doses [52, 53]. In the most severe case, lung transplant is curative.

Gastrointestinal tract Pancreatic insufficiency is generally treated with substitution therapy by administration of pancreatic extracts formulated into microspheres gastroresistant. Therapy of meconium ileus and distal intestinal obstruction syndrome should be as conservative as possible, with the use of high volume water enemas and subsequently enema with gastrografin, in association with the rehydration therapy. Surgical therapy is reserved for cases of drug therapy failure. In addition, a hypercaloric diet is recommended.

Advanced in therapy New therapies have been approved and more are still in the experimental phase: correction of gene mutation, correction of the altered protein, and activation of the alternative channels to CFTR. Ivacaftor and Lumacaftor are the two mutation-specific drugs approved for clinical use. Ivacaftor is a potentiator and has been approved for Gly551Asp and eight other Class III mutations and for Class IV Arg117His mutation. Lumacaftor plus Ivacaftor is approved for the treatment of homozygous Phe508del [41].

Congenital Disorders of Lipid Transport

37

Allie E. Steinberger, Emile Levy, and Nicholas O. Davidson

Introduction

Congenital disorders of intestinal lipid absorption include a clinically heterogeneous group of conditions whose molecular genetic basis has been assigned to key intracellular proteins that function in the delivery and transport phases of the lipid absorption pathway. These key intracellular proteins are encoded by gatekeeper genes that coordinate distinct components of a stepwise process involving uptake, compartmentalization, and complex intracellular lipid assembly, and their subsequent packaging into multicomponent vesicular structures called chylomicrons (CMs). The pivotal steps in CM assembly involve mobilization of membrane-associated complexes into vesicular transport vehicles within the lumen of the endoplasmic reticulum and Golgi, and ultimately vectorial delivery to the basolateral membrane of the enterocyte for extrusion and transport into mesenteric collecting lymphatics. The critical role of gatekeeper genes, particularly MTTP, APOB, and SAR1B, has been replicated and refined in both preclinical and cell-based models, and we now know more about the function and importance of their cognate proteins. Mutations, duplications, or deletions in these genes may give rise to steatorrhea with consequent fat malabsorption, failure to thrive, hypocholesterolemia, and hypotriglyceridemia in early childhood. In addition, unrecognized failure to thrive and lipid malabsorption syndromes may lead to progressive ataxic neuropathy and retinal degeneration because of the attendant malabsorption of fat-soluble vitamins, particularly vitamins A and E. With early diagnosis and appropriate nutritional supplementation, these particular complications can be avoided and general life expectancy should be unaltered.

We will review the major genetic syndromes associated with congenital lipid malabsorptions, the molecular genetic and pathophysiologic basis underlying defective lipid absorption, and describe the clinical manifestations and management of these patients.

Intestinal Lipid Absorption Overview

The reader is referred to recent comprehensive reviews of intestinal lipid absorption [1–4], but the essential features will be summarized below (Fig. 37.1). Complex lipids [principally long-chain TG, but also cholesterol ester (CE) and glycerophospholipids (GP)] are enzymatically lipolyzed to yield fatty acids (FA), cholesterol, and monoglycerides (MG), which are then transported through micelle-dependent uptake across the brush border membrane of villi, with distinctive membrane carriers responsible for FA and cholesterol uptake [3]. Once in the enterocyte, the lipolytic products (FA and MG) are bound to FA-binding proteins (FABP) and transported to the endoplasmic reticulum (ER) for synthesis of new TG, CE, and MG. The re-esterification of TG occurs mainly through the actions of diacylglycerol acyltransferase 1 (DGAT1), which likely functions in close proximity to the ER (Fig. 37.1). These TG droplets exist in both cytosolic (principally apical) compartments as well as within the ER membrane. Mobilization of TG droplets from within membranous domains requires the integrated actions of two gatekeeper genes for chylomicron (CM) formation: namely, microsomal triglyceride transfer protein (MTTP) and apolipoprotein B (APOB) with its intestine-specific isoform, APOB48. In this scenario, the resident endoluminal ER

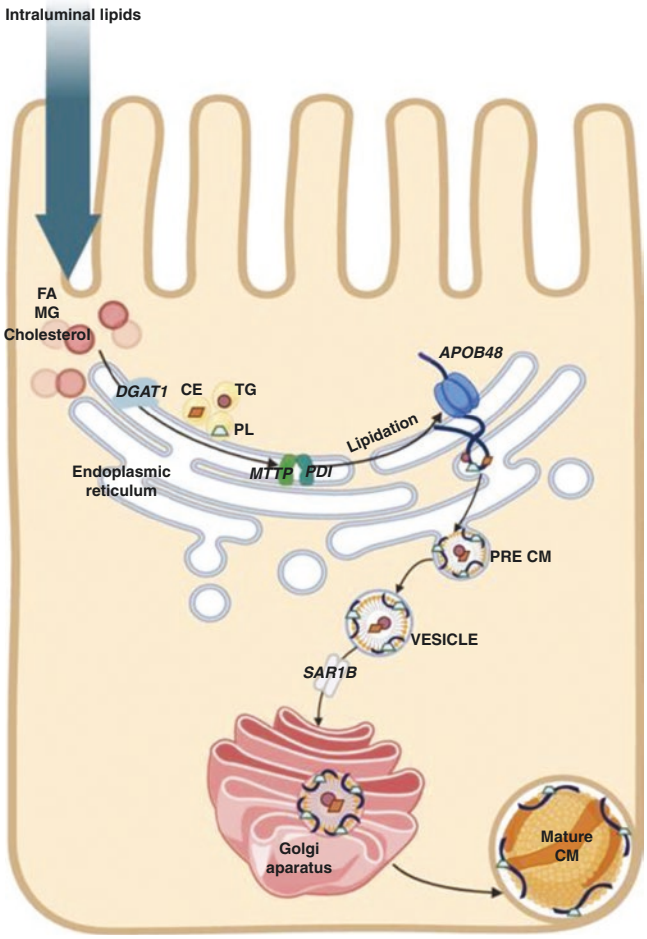

Fig. 37.1 Overview of intestinal lipid absorption: Key genetic regulators. Following digestion of dietary and biliary lipid, the component lipid species, including long-chain fatty acid, (FA) monoglycerides (MG), and free cholesterol (FC), are transported across the brush border membrane into the apical compartment of villus enterocytes. FA, MG, and FC undergo re-esterification into triglyceride (TG), cholesterol ester (CE), and phospholipid (PL), which is mediated in a series of enzymatic steps including diacylglycerol acyltransferase 1 (DGAT1). The newly synthesized TG exists in both cytosolic and intramembranous forms within the endoplasmic reticulum (ER) membrane, where DGAT1 also resides. The heterodimeric ER protein microsomal triglyceride transfer protein (MTTP) exists in a complex with the chaperone protein, protein disulfide isomerase (PDI), to physically translocate neutral lipid droplets from the ER bilayer membrane to an acceptor protein, APOB. Mammalian enterocytes synthesize a truncated APOB protein referred to as APOB48. The fusion of APOB and TG droplets, mediated by MTTP, is the critical and rate-limiting step in prechylomicron assembly. Following processing in the ER, the prechylomicron undergoes vesicular transport to the Golgi, mediated by fusion with COP proteins and SAR1B. Following further maturation in the Golgi, the chylomicron particle (CM), containing APOB48 and a cargo of TG, CE, and PL, is transported into the lymphatic compartment and delivered into the peripheral circulation

protein MTTP physically transfers the lipid droplet from the bilayer by mediating a physical interaction with the nascent amphipathic APOB protein, which acts as a structural acceptor during translation and extrusion into the ER lumen [5]. Luminal fusion of TG droplets with APOB48 generates a pre-CM particle, which then undergoes progressive modification and vesicular transport to the Golgi apparatus. This process is mediated by the Sar1-ADP Ribosylation factor, type B (SAR1B), which initiates vesicle formation for coat protein complex II (COPII)-dependent transport to the Golgi. The pre-CM particle then undergoes terminal modifications within the Golgi such as coat removal and acquisition of neutral lipids, and is ultimately secreted across the basolateral membrane as a mature CM (Fig. 37.1).

Molecular Genetic Basis for Congenital Defects in Lipid Absorption: Overview

Several rare genetic disorders of lipid absorption have been identified and their molecular basis characterized [5–9]. These include abetalipoproteinemia (ABL), which is an autosomal-recessive disorder caused by mutations or deletions in the *MTTP* gene [5]; familial hypobetalipoproteinemia (FHBL), an autosomal-codominant disorder, which is typically caused by mutations in the *APOB* gene [6]; chylomicron retention disease (CRD, also known as Anderson's disease), which is an autosomal-recessive disorder caused by mutations in *SAR1B* [7]; and congenital diarrhea, which is linked to defects in *DGAT1* [10, 11]. While the cardinal feature of lipid mucosal infiltration is common to all the disorders, the site of lipid droplet accumulation within the enterocyte shows subtle distinctions based on the molecular defects. Flaws associated with ABL and FHBL result in lipid droplet accumulation throughout the cytoplasm, both free and membrane-bound, but typically do not generate lipid particles within the ER lumen (Fig. 37.2a). Both ABL and FHBL interrupt intestinal lipid absorption at the initiation stage of pre-CM formation and thus completely attenuate CM assembly, which results in the generation of large intracellular cytosolic lipid droplets. As a result of the block in lipoprotein assembly and secretion (affecting both intestinal and hepatic lipoprotein secretion), the plasma in ABL and FHBL subjects contains very low levels of APOB containing lipoproteins (APOB48, APOB100) and virtually undetectable levels of very-low- and low-density lipoproteins (VLDL, LDL). Those subjects also manifest increased intestinal neutral lipid droplets containing TG and CE in the apical cytoplasm. These conditions will be discussed in more detail below. The defect in CRD, by contrast, is focused at a later stage in CM formation and blocks the maturation and exit of CM and pre-CM particles from the ER [12, 13]. The accumulation of lipid droplets and pre-CM particles within membranous domains is schematically illustrated in Fig. 37.2a. CRD will be discussed in a later section.

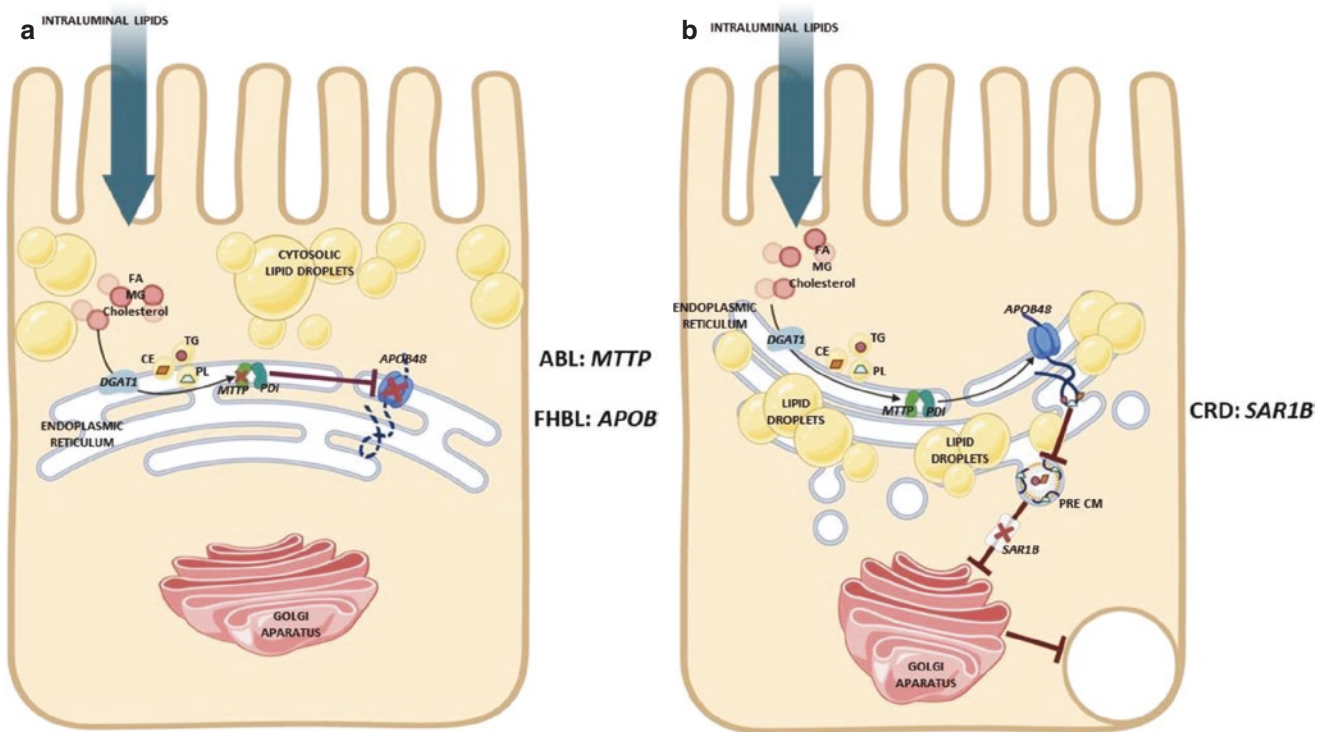

Fig. 37.2 (**a**, **b**) Lipid droplet accumulation in genetic disorders of intestinal lipid absorption. (**a**) Based upon the pathways outlined above, defects or mutations in *APOB* (responsible for familial hypobetalipoproteinemia, FHBL) or in *MTTP* (responsible for abetalipoproteinemia, ABL) eliminate the earliest steps in CM assembly and thus lead to lipid droplet accumulation, apical more than basolateral, with no lipid particles visible within ER profiles. (**b**) The phenotypes resulting from mutations or deletions in *SAR1B* (responsible for chylomicron retention disease, CRD) contrast with those for ABL and FHBL and result in interruption of the later stages of CM maturation and processing, leading to pre-CM accumulation (brown) within the ER lumen

Congenital Disorders of Chylomicron Assembly: Genetics and Clinical Features of Abetalipoproteinemia (ABL) and Familial Hypobetalipoproteinemia (FHBL)

Defects in either of the gatekeeper genes that promote CM assembly (i.e., *MTTP* and *APOB*) produce congenital intestinal lipid malabsorption. Both of these disorders generally present in infancy as failure to thrive, with (severe diarrhea), characteristically low serum lipid levels, and other complications (including ataxia and retinitis pigmentosa) along with the coincident malabsorption of fat-soluble vitamins [13]. However, the clinical phenotypes in both ABL and homozygous FHBL may be quite variable as discussed below.

Abetalipoproteinemia (ABL, OMIM #200100): Molecular Genetics and Prevalence

ABL is a rare, autosomal-recessive disorder with an estimated prevalence of <1 per 100,000 [14] and an estimated incidence of <1 per 1,000,000 [15]. To date, <30 MTTP mutations have been identified in more than 50 ABL patients (21.3% missense, 7% nonsense, 12% small insertion/deletion, 3% gross insertion/deletion, and 27.7% splicing variants) [15–22]. There is strong evidence for a founder effect in Ashkenazi Jewish patients, where a conserved haplotype with a common truncating mutation (p.G865X) was discovered in Israel with a carrier frequency of 1:131 and an estimated ABL incidence of 1:69,000 [23]. Some but not all of the reported ABL probands are the offspring of consanguineous marriage, an observation replicated across different national registries [18, 23]. A range of mutations and deletions has been described in the *MTTP* gene in association with ABL, and affected subjects may be either homozygous for a single mutation or compound heterozygous for different mutations. While there was initially thought to be no relationship between genetic heterogeneity and clinical phenotype, there is now some evidence to suggest differential severity based on the functional characterization of the individual mutations [24, 25]. Milder phenotypes have been associated with S5901 missense mutations [26]. In another report, two genetically distinct cases of ABL within the same family yielded starkly different phenotypes. The proband with concurrent MTTP mutations at p.R540C and c.1867 + 1G > A demonstrated only serum lipid derangements, while a cousin with a homozygous splicing mutation

at c.1867 + 1G > A had severe clinical manifestations that were refractory to high-dose vitamin supplementation [25]. Though other epigenetic and environmental factors could be playing a role, it appears that homozygosity results in a more severe phenotype than compound heterozygosity of the same mutation [25]. Certainly, more data is needed to better characterize the genotype–phenotype correlation in ABL.

Abetalipoproteinemia (ABL, OMIM #200100): Clinical Features and Management

Although ABL typically manifests in infancy as failure to thrive, there is a wide range of presentations in the first two decades of life, suggesting that there are either environmental or other genetic modifiers that influence some of the clinical features. Infants classically present with diarrhea, severe fat malabsorption, and failure to thrive. The hallmarks of ABL include extremely low plasma cholesterol and TG levels, very low or undetectable levels of APOB, low to absent levels of fat-soluble vitamins, essential fatty acid (EFA) deficiency, and red blood cell acanthacytosis [14, 17, 26].

The clinical phenotypes of low or absent levels of lipids and APOB in the serum result from the virtually complete block in lipoprotein secretion from both enterocytes and hepatocytes. This phenotype reflects the inability of both enterocytes and hepatocytes to lipidate the nascent APOB protein as it traverses the ER membrane (Fig. 37.2a).

The clinical features of ABL are multisystemic, including hematologic (acanthocytosis, anemia, hemolysis, coagulopathy), gastrointestinal (fat malabsorption, failure to thrive, hepatic steatosis, fibrosis, cirrhosis), neurodegenerative, musculoskeletal (myositis, muscle weakness, osteopenia), and cardiovascular (cardiomegaly, cardiomyopathy) [4]. Consequent to the fat malabsorption and defective CM production, patients have very low levels of fat-soluble vitamins, particularly vitamins A and E. Among the neurological sequelae of these vitamin deficiencies in ABL is pigmentary retinal degeneration. This condition can result in progressive vision impairment, starting with subtle losses of night and color vision in early stages and leading to complete vision loss if left untreated [4, 14]. Spinocerebellar ataxia is another devastating neurologic manifestation likely reflecting malabsorption of liposoluble vitamins [9]. The observation that ABL subjects, diagnosed and treated early with long-term high-dose supplementation of vitamins A (100–400 IU/kg/day) and E (100–300 IU/kg day) [27], maintain retinal and neurological function provides indirect but strong evidence that deficiency of these vitamins is responsible for the phenotypic outcomes [28, 29]. However, the exact mechanisms linking ABL to neurologic deficits are yet to be fully elucidated [29, 30].

ABL subjects require lifelong maintenance on a low-fat diet (<30% of total calories, 5–20 g/day) with reduced long-chain FAs to minimize steatorrhea [4, 28]. To avoid EFA deficiency, adequate intake of oils rich in polyunsaturated fats (i.e., olive, corn, safflower, soy bean; 5 g/day) should also be provided [4]. Early supplementation with oral fat-soluble vitamins is key. The current recommendations include vitamin A and E (as above), vitamin D (800–1200 IU/day), and vitamin K (5–35 mg/week) [4, 28]. For clinical monitoring purposes, it is worth noting that there is no discernible dose-to-tissue concentration relationship and that even with high-dose vitamin E supplementation, plasma levels rarely return to the normal range [31]. This is because of the dual defect that exists in vitamin E metabolism in ABL, reflecting both the block in intestinal absorption and also the inability of the alpha tocopherol transfer protein to repackage vitamin E into nascent VLDL in the liver [32]. Because circulating plasma lipid levels are so low in ABL subjects, plasma levels of alpha and gamma tocopherol may not reflect tissue (particularly adipose) concentrations, but nevertheless may be a useful surrogate to monitor long-term compliance [14]. Lastly, while there is conflicting data as to whether long-term vitamin A and E supplementation causes increased oxidative stress in the plasma of ABL patients, platelet antiaggregatory properties were never lost [29, 30, 33]. As such, the benefits greatly outweigh the risks.

ABL subjects warrant routine clinical monitoring to mitigate the severe complications associated with the disease process. Growth parameters are important markers of good nutritional status and should be closely followed. Although full growth potential might not be reached, with early intervention, ABL subjects can attain a normal growth velocity [28]. Additional long-term surveillance should include neurological and ophthalmological evaluations, bone mineral density scans, coagulation studies, and liver function tests and liver magnetic resonance spectroscopy to monitor for the development of steatohepatitis, which has been associated with progressive liver disease requiring liver transplantation [34, 35].

Familial Hypobetalipoproteinemia (FHBL, OMIM #107730): Molecular Genetics and Prevalence

FHBL is an autosomal-codominant disorder whose molecular basis most commonly resides in mutations in the *APOB* gene on chromosome locus 2p23-24 [36]. Unlike ABL, heterozygous FHBL subjects are typically asymptomatic with low circulating levels of total cholesterol, LDL cholesterol, and APOB generally discovered on routine lipid panels. Heterozygous FHBL, recognized through population-based plasma lipid screening for subjects at or below the 5th percen-

tile, is present in ~1:500–1:1,000 [36, 37]. The estimated birth prevalence of carrying a truncated APOB gene is 1:3,000 [38]. Homozygous FHBL (Ho-FHBL) by contrast is extremely rare with an incidence of <1:1,000,000 and perhaps 20 index cases whose molecular genetic basis is known [28, 39, 40]. The known mutations are linked to structural defects in the APOB gene, which interfere with the translation of the full-length protein APOB100 [4]. The truncated forms, ranging from APOB2 to ABOB89, are unable to undergo adequate lipidation despite normal levels of MTTP and thus prevent exportation of TGs via CMs from the enterocyte (Fig. 37.2a) and via VLDL from the liver [41]. The APOB fragments resulting from truncating mutations may be detected using denaturing gel electrophoresis and are present at very low circulating levels in plasma (undetectable if <27.6). Notably even heterozygous subjects exhibit lower abundance of the mutant (not exceeding 30%) compared to the wild-type (APOB100) allele [4]. This observation suggests the plasma lipid profile of the proband's parents may be an important diagnostic adjunct for delineating these conditions and further indicates that transcription or translation of the mutant allele in FHBL is also defective [42]. Serum lipid and APOB profiling can help delineate between Ho-FHBL and ABL in cases of diagnostic uncertainty. Namely, obligate heterozygote parents of Ho-FHBL will have markedly lowered total cholesterol, LDL, and APOB, whereas heterozygous ABL parents will be within normal range due to the recessive nature of the disease [28, 43].

In addition, FHBL is genetically heterogeneous with several kindreds described in whom the trait is inherited in an autosomal-dominant manner without mutations in the *APOB* gene but rather with linkage to a locus on chromosome 3p21, between D3S2407 and D3S1767 [42]. This low cholesterol syndrome linking to chromosome 3 has emerged as a unique entity, Familial Combined Hypolipidemia (FHBL2, OMIM #605019), caused by mutations in Angiopoietin-like protein-3 (ANGPTL3). ANGPTL3 is a hepatic-derived protein that inhibits lipoprotein lipase (LPL), the primary mechanism by which TG-rich lipoproteins are cleared, and endothelial lipase (EL) [41, 44]. Homozygous or compound heterozygous loss-of-function (LOF) mutations in ANGPTL3 are associated with increased lipolysis and clearance of lipoproteins with a subsequent decrease in circulating lipid levels [45]. FHBL2 is characterized by low plasma TC, TG, HDL, LDL, APOB, APOA1, and FFA without other clinical manifestations of FHBL (see below) [46]. Importantly, there appears to be no difference in the prevalence or severity of hepatic steatosis between FHBL2 subjects and noncarrier controls [41], and there is no intestinal lipid malabsorption phenotype. Data does suggest, however, that ANGPTL3 mutations confer a reduced risk of cardiovascular disease [44, 47]. The estimated prevalence of heterozygous carriers of LOF mutations in ANGPTL3 ranges from 1:309 to 1:237 [44, 48].

Mutations in proprotein convertase subtilisin/kexin type (PCSK9) are another well-described cause of FHBL. PCSK9 is a serine protease that augments degradation of hepatic LDL receptors to increase plasma LDL cholesterol levels. Loss-of-function (LOF) mutations cause dramatic increases in LDL uptake in the liver with consequent reduction in plasma LDL and APOB levels. Unlike APOB truncations, FHBL due to PSCK9 mutations is not associated with any clinical symptoms of fatty liver disease or intestinal lipid malabsorption. Conversely, PCSK9 LOF mutations also confer lower lifetime risk of cardiovascular disease in a gene dose–dependent manner [8, 41, 49].

Familial Hypobetalipoproteinemia (FHBL, OMIM #107730): Clinical Features and Management

The clinical manifestations of FHBL are heterogeneous. While heterozygous FHBL subjects are largely asymptomatic with mild fatty liver disease (3–5-fold greater than healthy controls), the phenotypic range for Ho-FHBL subjects is broad [40]. Severely affected individuals typically present in infancy or early childhood with failure to thrive, steatorrhea, and fat malabsorption, as in ABL. Yet others present in adulthood with incidentally discovered hepatic steatosis, very low levels (<5th percentile) of plasma lipids, and undetectable circulating APOB100 [4, 39]. This clinical variability has been linked to the degree of *APOB* truncation, with shorter isoforms (<34%) exhibiting an earlier-onset and more aggressive phenotype [35].

In general, the clinical course and management of severe Ho-FHBL subjects follows the same principles as described above for ABL. Homozygous cases demonstrate similar sequelae of intestinal fat malabsorption, including malnutrition, hypocholesterolemia, hepatic steatosis, acanthocytosis, and deficiencies in critical fat-soluble vitamins and essential FAs. If left untreated, these defects can result in progressive ocular, neuromuscular, hematological, and endocrine deficits with retinal degeneration, spinocerebellar ataxia, anemia, and insulin resistance, respectively [4, 28, 35, 50]. A more sinister concern longer term for FHBL subjects is the development of cirrhosis [51, 52] and hepatocellular carcinoma [9, 35, 39, 43]. The observations in relation to hepatic lipid accumulation in subjects with FHBL due to APOB truncations were not replicated in homozygous FHBL2 subjects linked to chromosome 3p21, reinforcing the concept that the clinical phenotypes among FHBL subjects are very variable [53, 54]. Homozygous FHBL subjects should therefore undergo regular evaluation of fat-soluble vitamin sufficiency with necessary supplementation and periodic monitoring of the myriad complications, as referenced above for ABL subjects. In this group, special attention should be given to the

potential for progressive hepatic steatosis and steatohepatitis (transaminases, liver magnetic resonance spectroscopy) and monitoring for progressive complications including fibrosis and hepatocellular cancer.

Chylomicron Retention Disease/Anderson's Disease (CRD, OMIM #246700): Molecular Genetics and Prevalence

Chylomicron retention disease/Anderson's disease was identified by Roy and colleagues in 1987 [55]. Although this disorder appears to be the same as that described by Anderson in 1961 [56], the term "CRD" is preferred nowadays, as it is more indicative of the pathology. CRD is a very rare, autosomal-recessive disorder with fewer than 50 cases described worldwide [12], and whose molecular genetic defect resides in the SAR1-ADP Ribosylation factor, type B (SAR1B), which belongs to the Ras superfamily of GTPases. SAR1B mutations induce an accumulation of pre-CM transport vesicles [12], as seen on intestinal biopsies and illustrated schematically in Fig. 37.2b.

SAR1B is a single polypeptide of 198 amino acids and functions as molecular switch controlled by the exchange of GDP and GTP. SAR1 is cytosolic in its GDP form and is recruited to the ER by the exchange of GDP for GTP to initiate COPII-coated vesicle formation. SAR1-GTP forms a coating protein complex (COPII) with two heterodimers SEC23/24 and SEC13/31. COPII initiates budding and captures cargo to eject vesicles from the ER to the Golgi apparatus [57]. The SAR1B GTPase cycle then allows cytosolic COPII proteins to exchange on and off the membrane at specific sites on the ER to regulate cargo exit. As a result, genetic defects in SAR1B affect the transport of pre-CM cargo from the ER to the Golgi apparatus where they usually undergo additional glycosylation before being released from the enterocyte. CMs are transported from the ER to Golgi, probably inside the pre-CM transport vesicle or PCTV [58]. PCTV shares several proteins including COPII (SEC13-31, SEC24, and SAR1) [59]. Siddiqi et al. [60] earlier showed that PCTV formation can occur in the absence of SAR1, and later showed that PCTV fusion with Golgi requires the presence of SAR1 [61].

The first investigation of genetic defects in eight families disclosed three frameshift (75-76 delTG, 555-558 dupTTAC, 349-1 G > C) and five missense mutations (109 G > A, 409 G > A, 537 T > A, 536 G > T, 542 T > C) [7]. The second exploration of the genetic abnormalities from eight families identified three new molecular aberrations: a stop codon mutation (364 G > T), a 5946 bp deletion (total exon 2), and a missense mutation (554 G > T) [62]. Thereafter, a new mutation G19T (changing a glutamic acid to a STOP codon) was found in the seventh exon [63], while two additional mutations were detected in exon 2 (G11D) and exon 4 (D75G) [64]. Recently, a novel homozygous deletion at position 142 (c.142delG) led to the replacement of the aspartic acid at position 48 by a threonine and gives rise to a frameshift-derived premature stop codon 17 amino acids further on (p.Asp48ThrfsX17), thereby resulting in a truncated protein (only 32% of the length of the normal protein and 24% of the normal sequence) [12]. Finally, the analysis of *SAR1B* gene mutations in Tunisian children revealed a proband homozygous for a novel nucleotide transition in exon 4 (c.184G > A), resulting in a nonconservative amino acid substitution (p.Glu62Lys) [65]. In order to provide a unifying explanation for the functional impairment of SAR1B mutated proteins, investigators have turned to information gleaned from the SAR1B crystal structure, computational analysis, and sequence alignment [66]. For example, the nonsense mutations and whole deletion of exon 2 in SAR1B yield truncated proteins that are predicted to modify the affinity of SAR1B for GDP and GTP, thereby affecting its interaction with the endoplasmic ER and other components of COPII machinery. In addition, the missense mutations in SAR1B likely yield nonfunctional proteins that alter the conformational and/or structural properties of SAR1B. Because SAR1B expression is detected in multiple different tissues, there are frequent clinical manifestations of CRD in organs beyond the gastrointestinal tract. As an example, cardiac abnormalities, myolysis, increased CK levels, and cardiac abnormalities were associated with the G19T mutation [63].

Genotype–Phenotype Associations in CRD

Recent studies compared the patients of two cohorts of CRD patients from France and Canada in order to compare the severity and long-term evolution as a function of the SAR1B gene mutations [67]. In both series, most of the CRD patients were symptomatic at diagnosis (before age of 1) and the disease was definitely more severe in infants. This is consistent with the observation that the CRD had profound impact on weight *Z* scores in Canadian children (1.5 ± 1 years) who were significantly younger at diagnosis than the French subjects (6.4 ± 1.3 years). The catch-up growth and bone mineral density improvement in the French cohort were not as encouraging in the French cohort compared to the Canadian patients, possibly because of the delayed initiation of a low-fat diet with a high polyunsaturated/saturated fatty acid ratio and of supplements of fat-soluble vitamins A, D, and E. In general, the neuro-ophthalmic manifestations detected at the time of diagnosis proved largely reversible with treatment. Although the effect of missense mutations on the protein was considered less deleterious than those mutations that introduce stop codons or that specified deletions, the clinical phenotype (i.e., growth, neurological impairment, hepatic

steatosis, lipid disturbances) was not significantly different in CRD patients based on the underlying genetic mutation [67]. According to the findings of this largest group of CRD patients so far reported, genotype–phenotype correlations are not obvious, suggesting that CRD might represent a more complex trait rather than a simple autosomal-recessive disorder [67]. Additional work is required to determine whether modifier genes are involved in the ER-to-Golgi transport.

Chylomicron Retention Disease/Anderson's Disease (CRD, OMIM #246700): Clinical Features and Management

CRD presents with failure to thrive probably resulting from fat malabsorption and constant, nonspecific diarrhea that begins shortly after birth. Other digestive symptoms include vomiting or abdominal swelling. Light microscopic examination generally reveals few morphological irregularities in the small intestine of CRD patients [12]. Following an oral fat bolus test meal and ultrastructural examination, numerous CM-size lipid droplets are evident within the cytoplasm of enterocytes. Many of these CM-size lipid droplets are bound by membranes of the smooth ER and clustered mostly in the supranuclear region, whereas only few of them were visualized within vesicular structures, likely part of the Golgi complex. The larger lipid vacuoles are not membrane-bound [13]. Importantly, the intercellular spaces were completely juxtaposed and no CMs were evident in the interstitium between adjacent enterocytes and in the area around the basement membrane. Hepatomegaly and a moderate degree of macrovesicular steatosis have been detected in a few cases [55, 68]. Nonspecific moderate hepatic cytolysis is very frequent but correlates only poorly with steatosis and/or hepatomegaly. Areflexia (combined with proprioceptive abnormalities) and electromyographic abnormalities (reduction in sensory nerve conduction velocity and decreased sensory nerve action potential amplitudes) were among the neurological abnormalities described in CRD children [55, 69, 70], but more severe neurological degeneration, such as ataxia, myopathy, and sensory neuropathy, has also been reported in CRD adults [71]. Sometimes, muscular pain and cramps are present in CRD children, while cardiomyopathy with a decrease in ejection fraction to 40% (normal >60%) has been described in adults [63]. Only minimal ophthalmic complications characterize CRD patients and include micronystagmus, mild deficit in the perception of the blue-yellow axis, and delayed dark adaptation [55], while abnormal visual evoked potentials have been evidenced by functional testing [72]. Poor mineralization and delayed bone maturation have also been observed in CRD [69].

Fat malabsorption in CRD impairs the absorption of fat-soluble vitamins, with vitamin E being the most affected, as observed in ABL subjects [73]. Vitamin A levels in plasma are frequently decreased, but generally correctable following oral supplementation. Finally, vitamin D or K insufficiency can be detected in up to half of CRD patients, and can also be corrected with oral vitamin supplementation. In CRD, acanthocytosis is rare, sometimes transient. Acanthocytosis when it occurs reflects low plasma vitamin E levels, which is a key to red cell membrane integrity. In association with muscular abnormalities, creatine kinase levels were elevated at diagnosis and have been associated with neurological impairment [72]. As previously noted, hepatic abnormalities may be present.

In contrast to ABL and FHBL, fasting triacylglycerol concentrations are usually normal, but severe hypocholesterolemia is prominent with levels of low-density lipoprotein-cholesterol and APOB100 at the lower limits of normal. Similarly, CRD patients display limited capacity to produce high-density lipoproteins. Importantly, CMs failed to appear in the circulation after a fat meal test explaining the deficiency of fat-soluble vitamins and essential fatty acids. However, patients with CRD express the apolipoprotein species essential for CM synthesis, including APO-AI, APO-AIV, and, importantly, APOB48 [12, 74].

Although CRD resembles ABL and FHBL symptomatically with respect to dietary fat malabsorption and its consequences, examination of plasma reveals a key distinction. Plasma from CRD patients contains APOB100 at normal levels but no APOB48 especially after a fat meal. As detailed above, plasma from ABL and FHBL subjects contains virtually no detectable APOB100, because the defect impairs secretion of lipoproteins from both the liver and small intestine [14]. Intestinal transcription of APOB100 mRNA and its posttranscriptional editing to APOB48 mRNA was normal in CRD subjects [75]. Both APOB and MTTP along with CM-size lipid droplets were detected in enterocytes from CRD subjects, suggesting that enterocytes can synthesize prechylomicron particles, but fail to process these intravesicular particles into mature chylomicron particles that can be secreted into the lymphatic circulation. Other attempts to identify the underlying mechanisms in CRD confirmed that the primary defect is not in the de novo synthesis of APOB48 protein, although reduced glycosylation of APOB was revealed in intestinal biopsies taken from CRD patients [74].

As with ABL and homozygous FHBL, CRD needs to be recognized early because of its adverse effects on growth and potential for neurological, ocular, hepatic, and other extraintestinal complications. Accurate diagnosis can be readily established using ultrastructural identification of CM-size lipid droplets clustered in the enterocytes, with the absence of fat outside the cells. However, sequencing of the short SARA2 gene provides a quick, safe, nonexpensive, and noninvasive diagnostic tool. Consumption of medium-chain triglycerides can aid in more rapidly correcting malnutrition in

infants, but total fat intake and particularly long-chain fatty acid consumption should be limited. The patients must be advised to take adequate intake of essential fatty acids and fat-soluble vitamins. In addition, vitamin E supplementation is critical for the prevention of the progression of neurological findings, while vitamin A should be administered at high doses to prevent ophthalmologic complications. Early vitamin D supplementation is also recommended in all patients to avoid bone growth and development abnormalities, and vitamin K should be given in cases of coagulopathies and abnormal clotting parameters.

Immunodeficiency Disorders Resulting in Malabsorption

38

Lavinia Di Meglio, Laura Carucci, and Roberto Berni Canani

Introduction

Primary immunodeficiencies are a group of at least 200 disorders, often inherited, that are caused by intrinsic defects of the immune system. The defects can affect humoral (B cell) immunity, cellular (T cell) immunity, both T and B cell immunity, and innate immunity. The adaptive and innate immune cells are generated and produced in the primary lymphoid organs (bone marrow and thymus), while the coordination of adaptive immune response takes place in the peripheral secondary lymphoid organs (spleen, lymph nodes system, and epithelial- and mucosa-associated lymphoid tissues such as Peyer patches in the small intestine) [1].

Gut is considered the largest lymphoid organ in the body, containing the majority of lymphocytes and producing large amounts of immunoglobulins (Ig). Gastrointestinal (GI) disorders affect about 5–50% of patients with primary immunodeficiencies, and severe malnutrition could be present in 50–60% of cases. The mucosal immune system, together with gut microbiome, plays a pivotal role in host defense against infections and in maintaining immune tolerance through direct and indirect mechanisms. In particular, gut microbiome could influence host immune system by the production of immunoregulatory metabolites such as short-chain fatty acids (SCFAs). Dysfunction of the regulatory mechanisms maintaining this complex and dynamic balance in the gut may lead to damage and mucosal inflammation and development of GI diseases [1–3].

It is not surprising that GI disorders, besides being very common are often the initial presenting manifestations in patients with primary immunodeficiencies (Table 38.1) [3].

In pediatric patients, GI manifestations of primary immunodeficiencies are mainly induced by infection, inflammation, or autoimmunity. In adult patients, malignancy could be a frequent additional condition. These manifestations, showing the same clinical features, could mimic the classic forms of diseases (in the absence of immunodeficiency) such as celiac disease, food allergy, or inflammatory bowel disease, but they are often unresponsive to conventional therapies.

Evaluating a Child with Suspected Primary Immunodeficiency

GI disease may be the first presentation of an underlying immunodeficiency; for this reason, it is crucial to consider immunodeficiency in any child with recurrent or chronic severe diarrhea, malabsorption, and failure to thrive that is resistant to conventional treatments. In the diagnostic investigation of chronic diarrhea, primary immune deficits (PIDs) should be included. The European Society of Immunodeficiencies (ESID) has suggested 10 warning signs for suspicion of PID (Table 38.2) [2].

Primary immune deficits are relatively common (1:500) but likely underdiagnosed [1].

The type of immunodeficiency provides susceptibility to different infectious agents: prevalence of bacterial infections could indicate B cell deficiencies mostly if they occur after 6 months of life, since maternal Igs protect the newborns

Table 38.1 Main primary immunodeficiencies and associated gastrointestinal features

Immunodeficiency	Main gastrointestinal manifestations
Selective IgA deficiency	Chronic diarrhea Celiac disease Nodular lymphoid hyperplasia
Agammaglobulinemia, X-linked or AR	Chronic diarrhea Malabsorption IBD-like disease
Hyper-IgM syndrome	Chronic diarrhea Progressive liver disease Sclerosing cholangitis Liver cancer
Common variable immunodeficiency	Chronic diarrhea Nodular lymphoid hyperplasia Flat villous lesions IBD-like disease Atrophic gastritis
Severe combined immunodeficiency	Chronic diarrhea Oral candidiasis IBD-like disease
Chronic granulomatous disease	Granulomatous colitis Perianal fistulae Hepatic abscess Gastric outlet obstruction Small bowel obstruction Granulomatous stomatitis Oral ulcers Esophageal dysmotility IBD-like disease
Wiskott-Aldrich syndrome	Colitis Malabsorption IBD-like disease
IPEX and IPEX-related disorders	Severe enteropathy with watery often bloody diarrhea associated with eosinophilic inflammation
Interleukin-10 and interleukin-10-receptor defects	IBD-like disease with early-onset enterocolitis, perianal disease (multiple abscesses and enterocutaneous fistula)
Hermansky–Pudlak syndrome type 1	Granulomatous colitis

IBD inflammatory bowel disease, *IPEX* immune dysregulation, polyendocrinopathy, enteropathy, X linked [3]

Table 38.2 Warning signs for suspicion of PID

≥4 new ear infections within 1 year
≥2 serious sinus infections within 1 year
≥2 pneumonia infections within 1 year
Failure of an infant to grow normally or gain weight
Recurrent abscesses of deep skin or organs
Persistent oral or skin thrush
Requirement for intravenous antibiotics to resolve infections
≥2 deep-seated infections
A family history of PID

PID primary immune deficits [2]

during this period (Fig. 38.1). Fungal or viral infections, mostly if they occur at birth or within 6 months of life, could indicate T cell deficiencies, while severe mixed (bacterial, viral, and/or fungal) infections, particularly early in life, suggest combined (T and B) immunodeficiencies.

Careful clinical evaluation is crucial for recognition of patients with PID. A full physical clinical exam is mandatory: facial anomalies, absence of lymph nodes, and atypical heart murmur suggest DiGeorge syndrome; absence of lymph nodes with physiological heart sounds are classic features of severe combined immunodeficiency (SCID). Also skin manifestations (such as eczematous dermatitis, chronic mucocutaneous candidiasis, and cutaneous viral infections such as disseminated molluscum contagiosum) may be a clinical presentation of PID [4].

Due to the high incidence of GI disease in these patients, early evaluation of the GI tract is useful for children with certain or suspect immunodeficiency, to prevent potentially irreversible tissue damage [3].

Diagnostic algorithm in child with recurrent GI symptoms needs for a stage approach, in order to rule out differential diagnosis, to perform screening immunological tests, and to refer an immunologist when an immunodeficiency is suspected (Table 38.3) [3, 5, 6].

An accurate microbiological analysis of stool samples is mandatory to rule out the presence of common or unusual pathogens (e.g., *Giardia lamblia*).

Immunological screening tests include complete blood count, evaluation of quantitative levels of immunoglobulins (IgG, IgA, IgM, and IgE), and antibody titers. Hypogammaglobulinemia can result from impaired production and/or protein loss; the latter is excluded by measuring serum albumin and urinary protein levels; enteral loss of protein can be excluded by measurement of stool alpha-1-antitrypsin level (normal values <0.9 mg/g stool) [1, 7].

Based on medical history, clinical manifestations, and pattern of infection, if humoral defect is suspected, quantification of IgG subclasses may be helpful in the assessment of an immunodeficiency, especially in IgA deficiency. Ig serum levels increase during the life course, so comparison with age-matched controls is necessary for correct interpretation. Further evaluation of a humoral defect includes the qualitative aspect of the antibody response, such as IgG titer to measles, tetanus, *Haemophilus influenzae* type b, pneumococcus, and varicella. If antibody titers are absent or low, vaccinations may be administered, followed by evaluation of postvaccination titers 4–6 weeks later. It is important to underline that children receiving chronic treatment with steroids may have reduced serum Ig levels; however, the antibody response would be preserved in this case [1, 7].

When mixed and/or T cell deficiency are suspected, especially in the presence of blood cells count abnormalities, it is important to ask for a lymphocyte panel to assess the number of lymphocytes and subpopulations (T cells, B cells, CD4+ T cells, and CD8+ T cells), because lymphopenia may occur secondary to excessive loss of the cells into the lumen or through the trapping of cells in the inflamed bowel wall. Severe lymphopenia in an infant (<2000/mm^3) is a critical finding that, if associated with history of recurrent and severe

m month, *y* year
For the first 6 months of life, maternal IgG, that passively crosses the placenta during gestation, is mainly responsible for the immune protection of the newborn. In the newborn, Igs start to be produced around 6 months of life and they gradually increase during the life. The period between 3 and 12 months could be characterized by transient low IgG levels due to maternal IgG reduction and gradually infants IgG production [1, 2]

infections, should lead to an immediate immune evaluation for severe combined immunodeficiency (SCID). Thrombocytopenia and small platelet size, mostly if eczema and recurrent bacterial infections occur, suggest a diagnosis of Wiskott–Aldrich syndrome (WAS). In all cases, exclusion of secondary causes of immunodeficiencies should be performed, mostly if there is clinical suspicion based on history or results of the lymphocyte panel (Table 38.4) [8, 9].

Depending on the clinical picture and on the results of these initial tests, the further step is the study of cellular immune function. The study of lymphocyte proliferation in response to mitogens and antigens provides more definitive data on T cell function. Failure of lymphocytes to respond to mitogens usually indicates severe impairment of T cell function, as in the case of SCID. These tests may not be possible in patients with significant T cell lymphopenia. Advanced testing can be performed to investigate specific disorders. For example, when chronic granulomatous disease (CGD) is suspected, investigation of neutrophil function is mandatory; this is accomplished with a dihydrorhodamine assay to determine a reduction or absence of phagocytic respiratory burst. Flow cytometric analysis of expression of cell surface and intracellular proteins can help in immune deficiency differential diagnosis: X-linked hyper-IgM (through the examination of CD40 ligand), WAS (through the examination of WAS protein, WASp), and immune dysfunction, polyendocrinopathy, enteropathy, and X-linked syndrome (IPEX; through the examination of FOXP3). Quantitative, real-

time polymerase chain reaction for T cell receptor excision circles is used in the neonatal screening assay for SCID. Genetic testing to identify carrier states or specific mutations can be performed for X-linked agammaglobulinemia (XLA), SCID, and DiGeorge syndrome (Table 38.5). In many cases, the evaluation of GI tract, in addition to laboratory tests, can be done via radiographic imaging and intestinal biopsy specimens. It is often helpful to ask the pathologist to review slides when a question of immunodeficiency exists, given some of the unique pathologic findings or lack thereof (e.g., plasma cells) [3].

Table 38.5 Primary immunodeficiencies: main laboratory findings and molecular defects

Immunodeficiency	Laboratory findings	Molecular defect
Selective IgA deficiency	Serum IgA absent or near absent, usually <10 mg/dL Normal IgG and IgM levels although IgG2 subclass deficiency may be present Impaired specific antibody response in some patients	Gene defect unknown Defective maturation of B cells into IgA-secreting plasma cells
Agammaglobulinemia, X-linked or AR	Absent IgM, IgG, and IgA B cells <1% of lymphocytes Absent specific antibody response	X-linked (BTK) Autosomal-recessive (μ heavy chain, λ5, Igα, Igβ, BLNK, PIK3R1, LRRC8, and TCF3)
Hyper-IgM syndrome	Low IgG and IgA Normal or increased IgM Normal or increased B-cell numbers Impaired specific antibody response Decreased T-cell responses in CD40L/CD40 deficiency	Mutations in CD40L, CD40, AICDA, UNG, NEMO, IKBA, IκBα, PI3K
Common variable immunodeficiency	Low IgG and IgA and/or IgM Absent specific antibody response Normal or decreased B-cell numbers Variably decreased T-cell responses	Mutations in ICOS, CD19, mutations in ICOS, CD19, CD20, CD81, TNFRSF13B, TNFRSF13C; mostly unknown
Severe combined immunodeficiency	Low TRECs Decreased serum immunoglobulins Marked diminished/absent T-cell, B-cell, and NK cell numbers depending on functional deficiency Diminished response to mitogens PHA, ConA, PWM	Multiple defects: RAG1/2, JAK3, CD45, CD3 chain, ZAP70, Artemis, ligase 4, Cernunnos, IL-2RG, IL-7Rα, ADA; defects in T and B cells
Chronic granulomatous disease	Defective oxidative burst in neutrophils by DHR or NBT equivalent	Multiple defects: X linked owing to defects in CYBB encoding the gp91 phox component of NADPH oxidase autosomal recessive owing to defects NCF1, NCF2, or CYBA defects in components of NADPH oxidase
Interleukin-10 and interleukin-10-receptor defects	Pathological response to functional tests using STAT3 and/or TNF-α assays	Mutations in IL-10, IL-10 receptor
Wiskott-Aldrich syndrome (WAS)	Immunoglobulins variable in concentration secondary to accelerated synthesis and catabolism (decreased IgM; normal or slightly low IgG; often increased IgA and IgE) Antibody response to polysaccharides decreased. Normal B-cell numbers. Progressive decrease in T-cell numbers with abnormal lymphocyte responses to anti-CD3. Platelet numbers are reduced and small in size.	Mutations in WAS; cytoskeletal defect affecting hematopoietic stem cell derivatives
Hermansky–Pudlak syndrome, type 1	Normal platelet count Prolonged bleeding time with abnormal platelet function assays Absence of δ granules on freshly isolated plasma with electron microscopy	Mutation in the HPS1 gene on chromosome 10q23 that forms part of BLOC-3, HPS2, HPS3, HPS4, HPS5, HPS6, HPS7, HPS8, HPS9, HPS10

ADA adenosine deaminase, *AICDA* activation-induced cytidine deaminase, *AR* autosomal recessive, *BLNK* B cell linker protein, *BLOC-3* biogenesis of lysosome-related organelles complex-3, *BTK* Bruton tyrosine kinase, *CYBA* cytochrome b α subunit, *CYBB* cytochrome b β subunit, *DHR* dihydrorhodamine, *ICOS* inducible costimulator, *JAK3* Janus activating kinase 3, *NADPH* nicotinamide adenine dinucleotide phosphate, *NCF* neutrophil cytosolic factor, *NF-κB* nuclear factor-kB, *PHA* phytohemagglutinin, *PWM* pokeweed mitogen, *RAG* recombinase activating gene, *TBX1* T-box 1, *TNFRSF* TNF-receptor superfamily, *UNG* uracil DNA glycosylase, *STAT3* signal transducer and activator of transcription-3, *TNF-α* tumor necrosis factor-α, *NBT* nitroblue tetrazolium, *NEMO* nuclear factor-kappa B essential modulator, *PIK3R1* phosphoinositide-3-kinase regulatory subunit 1, *LRRC8A* leucine-rich repeat-containing protein 8A, *TCF3* transcription factor 3 [7, 11, 17–19, 25, 26, 30, 31, 36, 38, 41, 45–49, 52, 59, 61].

Predominant B-Cell (Antibody) Deficiency

Selective IgA Deficiency

Selective IgA deficiency is the most common primary immunodeficiency; it is defined as a decreased serum level of IgA (IgA <7 mg/dL) in the presence of other normal Ig isotypes, T-cell immunity, and natural killer activity. The worldwide incidence of IgA deficiency differs by ethnic background; the prevalence varies among ethnicities from 1:100 to 1:1000, in Caucasians being much higher than that in Asians, with a prevalence of around 1:3000 in the USA [10].

IgA is the key Ig in the respiratory and GI tracts, which provide the most intimate interface between the environment and self [11]. The reduced, and not absent, counts of IgA-bearing B cells in the peripheral circulation and the absence of serum IgA suggest that this disease is the result of a defect in IgA-bearing B lymphocyte to turn into IgA-secreting plasma cells [12].

The manifestations are variable in IgA deficiency; patients can be asymptomatic (in up to 90% of subjects) or can incur in recurrent infections of the respiratory (particularly *H. influenzae* and *Streptococcus pneumoniae*) and GI tracts, autoimmune diseases, allergies, and malignancies.

Autoimmune diseases are a frequent finding in IgA deficiency, mainly autoimmune cytopenias, juvenile rheumatoid arthritis, thyroiditis, systemic lupus erythematosus, and celiac disease.

IgA deficiency sometimes progresses to common variable immunodeficiency (CVID); in fact, these diseases often share a common genetic and familial predisposition (IGAD1) [10].

Other related conditions include anaphylactic transfusion reactions; if replacement therapy is required, the patients should be screened for anti-IgA antibodies and treated with low or absent IgA blood products if the need for transfusion arises.

GI manifestations are frequent in symptomatic patients with selective IgA deficiency. *Giardia lamblia* infections can occur in these patients, causing bloating, cramping, excessive flatus, and watery diarrhea. The infection can be chronic, despite treatment with metronidazole, resulting in malabsorption with steatorrhea and villus flattening [13]. The degree of mucosal damage is related to the duration of the infection. Diagnosis is made by examining the stool for cysts or trophozoites of *G. lamblia*, or by examination of duodenal aspirates, which can yield more determinate results. The incidence of selective IgA deficiency in celiac disease has been demonstrated to be ten-fold higher than in the general population, given shared human leukocyte antigen (HLA) haplotypes [14]. Secretory IgA can bind to wheat gluten and gliadin, and the absence of IgA may lead to abnormal processing of these antigens [13]. The symptoms of celiac disease are similar in patients with or without IgA deficiency, the only differentiating feature is that immunohistochemical staining of small-intestinal biopsies reveals an absence of IgA-secreting plasma cells in IgA-deficient patients. Antigliadin IgA, antitissue transglutaminase IgA, and anti-endomysial IgA antibodies cannot be used as screening tests for this population; tissue transglutaminase IgG may be a better screening test [13]. Celiac disease associated with IgA deficiency is usually responsive to gluten withdrawal, failure response to a gluten-free diet should lead one to consider CVID [3, 13–15]. The histologically GI mucosa appearance is typically normal; however, especially in the duodenum, it can show nodular lymphoid hyperplasia (NLH) [13–15].

Multiple nodules are found in the lamina propria, superficial submucosa of the small intestine, or both, and occasionally can occur in the stomach, large intestine, or rectum. The lesions can be associated with mucosal flattening, causing malabsorption and even obstruction when large. In children, NLH tends to regresses spontaneously and is associated with mild symptoms; on the other hand, in adults, the prognosis is uncertain. Diagnosis is made by small-bowel endoscopy sometimes with the help of contrast barium or MRI studies [13–15]. Large amounts of IgM-bearing cells can be found in the immunohistochemical staining, possibly as compensation for the absent IgA. These patients may benefit from oral steroid therapy or, if *G. lamblia* or *H. pylori* infections occur, the eradication of that concomitant infections has been associated with a regression of NLH [13–15].

Persistent NLH has been associated with lymphomas, usually B-cell tumors and gastric carcinomas; so, in case of refractory NLH, a biopsy should be performed during endoscopy to rule out these diseases [15].

The diagnosis is based on at least one of the following:

- Increased susceptibility to infection
- Autoimmune manifestations
- Affected family member

AND diagnosis after fourth year of life

AND undetectable serum IgA (when measured with nephelometry less than 0.07 g/L) but normal serum IgG and IgM (measured at least twice)

AND secondary causes of hypogammaglobulinemia have been excluded

AND normal IgG antibody response to all vaccinations

AND exclusion of T-cell defect [7]

The threshold of 4 years of age is used to avoid premature diagnosis of IgA deficiency, which may be transient in younger children due to delayed ontogeny of IgA system after birth [11].

In IgA deficiency, the mainstay of the therapeutic approach is the treatment of associated diseases. If the patient experiences recurrent infections, daily prophylactic antibiotics on a continuous or seasonal intermittent basis may be beneficial [11]. IL-21 or the combination of CD40 L/anti-CD40, IL-4, and IL-10 is potential target for new therapeutic modalities [10, 16].

X-Linked Agammaglobulinemia

XLA is a primary immunodeficiency that results from a maturation arrest of pre-B cells with subsequent B cell generation failure, absence of plasma cell in lymphoid tissues, the virtual absence of all classes of Ig, small tonsils, and lymph nodes. The incidence is approximately 1 in 100,000 live births. The gene involved in XLA encodes for Bruton tyrosine kinase (BTK), and it is located on X-chromosome (Xq21.3-Xq22). It is an X recessive disease, so classically, it presents in male individuals, female carriers can be detected, and prenatal diagnosis of affected or unaffected male fetuses can be accomplished. There are about 554 different mutations of BKT gene. Similar phenotypes can result also from other mutations: autosomal-recessive agammaglobulinemia has been associated with mutations in genes that encode for μ heavy chain, λ5, Igα, Igβ, BLNK, PIK3R1, LRRC8, and TCF3. Autosomal-dominant mutations have been reported too [17, 18].

BTK is an intracellular tyrosine kinase protein expressed in most of hematopoietic cells: high levels are registered in all B-cell lines, no expression is reported in T cell precursors and natural killer (NK) cells. The abnormal BTK induces a maturational arrest of B lymphocytes at the pre-B cell stage, resulting in a normal number of pre-B cells in the bone marrow, but no mature B cells in the periphery. Peripheral $CD19^+$, $CD20^+$, and $CD23^+$ B cells are usually less than 0.1%.

IgG, IgA, and IgM levels are low or absent. There is no production of isohemagglutinins or antibody after vaccinations. The majority of males with XLA are asymptomatic during the first 4–6 months of life thanks to mother's transmitted antibodies; then, they present severe and repeated infections caused, mainly, by extracellular pyogenic and encapsulated organisms, often Gram positive (such as *S. pneumoniae, S. aureus, Neisseria, Haemophilus*, or *Mycoplasma*) [19].

The infections may interest respiratory, GI, and genitourinary tracts. Systemic infections (septicemia or meningitis) are less common but frequent, as well as osteomyelitis, septic arthritis, cellulitis, or skin abscesses. In such cases, we can observe chronic fungal infection or *Pneumocystis jirovecii* pneumonia. Viral infections are, usually, self-limiting except for hepatitis or enteroviruses despite a good T-cell response. GI manifestations are reported in 35% of individuals and can be so severe that parenteral nutrition and immunomodulatory therapy may be required [19].

The most common GI manifestations are intermittent diarrhea (38%), chronic diarrhea (26%), abdominal pain, gastroesophageal, reflux disease, and gastroenteritis [20]. Chronic diarrhea is often accompanied by secondary malabsorptive syndrome associated with a protein-losing enteropathy [21]. The main pathogens involved in these infectious diarrheas are *G. lamblia, Salmonella* spp., *Campylobacter jejuni,* and *Cryptosporidium parvum*; enteroviral infections (such as *Coxsackievirus* and *Echovirus*) are also common and can lead to severe neurologic defects. Sometimes chronic diarrhea is related to small bowel bacterial overgrowth. GI infection treatments must be based on adapted culture methods and adequate prolonged therapy. Cases of malabsorption and bacteremia due to infection of *Helicobacter pylori* and *Campylobacter jejuni* resistant to many antibiotics have been described [22].

It is important to highlight that the most common cause of death is chronic enteroviral infection [23, 24]. Inflammatory bowel diseases (IBDs) are common findings in XLA patients: the prevalence is 8 times higher compared to general population [20]. Some patients with XLA present small-bowel strictures and transmural intestinal fissures similar to Crohn's disease, without granulomas or plasma cells. XLA patients generally do not develop NLH. XLA occasionally manifests with different clinical spectrums such as autoimmune diseases or cancer (gastric adenocarcinoma and colorectal cancer). In particular, chronic atrophic gastritis with pernicious anemia is also a common finding that predisposes to gastric adenocarcinoma [23].

Diagnosis is based on clinical features and typical laboratory results: fewer than 2% circulating B cells (CD19 and CD20), preferably in two separate determinations and a normal number of T cells (CD3, CD4 and CD8).

AND serum IgG levels below:

−200 mg/dl in infants aged <12 months
−500 mg/dl in children aged >12 months

OR normal IgG levels with IgA and IgM below 2SD
AND onset of recurrent infections before 5 years of age [7].
It could be confirmed by molecular analysis [19].

Early diagnosis of XLA with immediate initiation of therapy is crucial for ensuring good outcomes for the affected patients. A delayed diagnosis could lead to long-lasting sequelae such as bronchiectasis, hearing loss, or liver cirrhosis due to chronic hepatitis. XLA treatment consists of replacement IgG therapy, either intravenous (intravenous gammaglobulin [IVGG]) or subcutaneous. Early IVGG replacement therapy decreases the rates of admission and morbidity for chronic complications, such as bronchiectasis

and chronic lung disease, and prevents fatal complications like meningoencephalitis. In addition, IVGG may represent also a potentially beneficial treatment for Crohn's disease in these individuals [19]. Appropriate IVGG should be started at 6–8 weeks of age, because around 25% of the XLA patients show clinical symptoms before 4 months of age. Antibiotics treatment for documented or suspected infections is necessary, because commercial preparations of IgG could not have adequate titers against uncommon organisms.

Hyper-IgM Syndrome

Hyper-IgM syndromes are a group of rare inherited immunodeficiencies characterized by impairment in B cell class switch recombination (CSR) and somatic hypermutation (SHM) resulting from defects in the CD40 ligand/CD40 signaling pathway. They are characterized by high levels of IgM associated with low or absent levels of IgG, IgA, and IgE [25, 26]. Several variants of hyper-IgM syndrome have been described and result in different phenotypes:

1. *X-linked hyper-IgM syndrome*

It is the most common form accounting for almost 65–70% of all cases. This condition could derive from two different gene mutations.

The first gene encodes for the CD40 ligand (CD40L) expressed on T-cells, and it is defined as hyper-IgM syndrome type 1(HIGM1). CD40L is a member of tumor necrosis factor (TNF), and mutations are typically reported on the extracellular domain that interacts with CD40. CD40 is expressed on APCs (B cells, monocytes, macrophages, and dendritic cells), and mutations of CD40 are associated with autosomal-recessive hyper-IgM syndrome type 3 (HIGM3). Because of the lack of this ligand on T cells, there is no interaction with CD40 on B cells and impossibility to go through CSR or SHM. B cells cultured can produce not only IgM, but also IgG, IgA, and IgE: this confirms that the defect interests T cells. Mitogen proliferation may be normal, but NK cell and T cell cytotoxicities are frequently impaired. Antigen-specific responses may be decreased or absent. Males with this syndrome present small tonsils, absence of palpable lymph nodes. Neutropenia, thrombocytopenia, and anemia are common [25]. The second gene, located on X-chromosome, is NEMO; it encodes for a nuclear factor-kappa B (NF-kB) nuclear factor [25].

This factor acts with IKBA/IκBα, they are involved in the pathway activated by CD40L-CD40; autosomal mutations of IKBA/IκBα lead to a similar phenotype. Mutations of NEMO are described mainly in the C-terminal domain. In males, this form is clinically associated with anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID); in females, it causes incontinentia pigmenti [25].

2. *Autosomal recessive hyper-IgM syndrome*

This is less common compared to X-linked type. The most common forms are caused by defects in the CD40-activated RNA-editing enzymes AID and UNG, which are required for CSR and SHM. AICDA encodes for AID and it is located on chromosome 12, mutations of this protein lead to HIGM2; UNG gene is located on chromosome 12, and mutation of it causes HIGM5 [26]. During CSR and SHM, AID generates deoxyuracils in the switch regions of Ig heavy chain, then UNG removes deoxyuracils generating double-strand breaks.

In this case, B cells cultured are not able to produce all classes of Ig; this confirms that there is a real defect in the B cell; however, no alteration in the numbers of CD19+ B cells, CD27+ memory B cells, and T-cell immunity is found [25, 26].

3. *Autosomal dominant hyper-IgM syndrome*

Other genes can cause similar phenotype: heterozygous gain-of-function mutations in PI3K, a kinase activated by CD40-CD40L, belong to this group [25].

Distinctive clinical features for these patients allow presumptive recognition of mutation, this is important to choose the best therapy.

The range of clinical findings varies, even within the same family.

Over 50% of males with HIGM1 develop symptoms by the age of 1 year due to the presence of maternal antibodies, and more than 90% are symptomatic by the age of 4 years. The clinical presentation of the hyper-IgM syndrome is similar to XLA, with recurrent pyogenic infections such as otitis, sinusitis, pneumonia, or tonsillitis that start in the first 2 years of life in patients regardless of the type of mutation [25, 26].

In addition, patients that presented mutations on CD40-CD40L genes are also susceptible to a variety of opportunistic and intracellular pathogens such as mycobacterial species, fungi, and viruses; in about 40% of cases, these individuals present pneumonia by *Pneumocystis jirovecii*. Significant neurologic complications are seen in 10–15% of males with HIGM1. In at least 50%, a specific infectious agent cannot be isolated [25, 26].

In patients with mutations that do not involve CD40-CD40L genes, the risk of opportunistic infection is lower because of unaffected T-cell immunity.

GI symptoms are the second most common symptoms and include mostly chronic diarrhea and liver involvement, and it occurs in almost one-third of HIGM1 patients [27].

The main pathogens that cause diarrhea are *Cryptosporidium parvum* (the most common), *G. lamblia, Salmonella*, or *Entamoeba histolytica.*

GI complications can cause failure to thrive and weight loss.

Neutropenia often causes oral or rectal ulcers and gingivitis or mucosal abscess, and it is common in patients with mutations involving CD40 complex.

Liver disease, a serious complication of HIGM1, historically, was observed in more than 80% of affected males by age 20 years. Cholangiopathy with *Cryptosporidium* in the biliary tree, B and C hepatitis, and cytomegalovirus (CMV) infections with a possible evolution in cirrhosis or hepatocellular carcinoma are common findings [25]. Hepatic involvement is associated with high gamma-glutamyltransferase levels; this alteration can predict a possible development of sclerosing cholangitis with a risk of cholangiocarcinoma. Liver tumors account for approximately 25% of mortality in X-HIGM.

Screening for patients with sclerosing cholangitis by magnetic resonance cholangiopancreatography (MRCP) and serum cancer antigen 19–9 levels every 6 months have been suggested [27].

Gastrointestinal diseases are also presented less severely in AID-/UNG -deficient patients when compared to X-HIGM.

Tumors of the GI tract (carcinoid of the pancreas, glucagonoma) are common life-threatening complications in adolescents and young adults with HIGM1 [26–29]. Affected males also have an increased risk for lymphoma, particularly Hodgkin's disease associated with Epstein–Barr virus infection. In individuals with AID or UNG mutations, enlarged lymph nodes and hepatosplenomegaly, especially during early childhood, can be apprised; they result probably from overactivated germinal centers, and these conditions have been associated with a higher risk of lymphoma [27].

In addition, spontaneous rib fractures are frequent among HIGM1 patients, probably due to a T-cell dysfunction osteopenia.

Autosomal-recessive forms have usually a later onset and are often associated with a higher rate of autoimmune disorders (such as diabetes mellitus, autoimmune hepatitis, autoimmune thrombocytopenia, and Crohn's disease). Neutropenia is less common [27, 28].

The reported median survival of males with HIGM1 who did not undergo a successful allogeneic hemopoietic stem cell transplantation (HSCT) is less than 25 years, and liver disease is the main predictor of overall outcome and mortality [28].

P. jirovecii pneumonia in infancy, liver disease, and carcinomas of the liver and GI tract in adolescence or young adulthood are the major causes of death [29].

Laboratory evaluation is fundamental: these patients have low or absent levels of IgG, IgE, and IgA associated with normal or high levels of IgM (very high levels of IgM are typical of the autosomal-recessive form) and IgD. B and T lymphocyte levels are usually normal. The diagnosis of HIGM1 is based on a combination of clinical findings, family history, absent or decreased expression of the CD40 ligand (CD40L) protein on flow cytometry following in vitro stimulation of white cells, and molecular genetic testing of CD40LG (previously known as TNFSF5 or CD154).

The only curative treatment currently available is allogeneic hematopoietic cell transplantation, ideally performed before the onset of life-threatening complications and organ damage. No difference in survival rate between patients that received transplant and patients that were treated with IVGG has been apprised in patients with X-linked mutation [26]. Gene-editing may be a future approach [29].

Other effective therapies are the monthly replacement of Ig and antibiotics for specific infectious complications. To reduce the risk of *Cryptosporidium* infection, it is recommended that patients boil or filter water. In patients with neutropenia, it is possible to use granulocyte colony–stimulating factor (G-CSF) [26–29].

Common Variable Immunodeficiency

Common Variable Immunodeficiency (CVID) with an estimated prevalence of 1/100,000 to 1/50,000 is the most common symptomatic primary antibody-deficient syndrome.

The diagnosis is based on at least one of the following:

- Increased susceptibility to infection
- Autoimmune manifestations
- Granulomatous disease
- Unexplained polyclonal lymphoproliferation
- Affected family member with antibody deficiency

AND marked decrease of IgG and marked decrease of IgA with or without low IgM levels (measured at least twice; <2SD of the normal levels for their age).

AND at least one of the following:

- Poor antibody response to vaccines (and/or absent isohemagglutinins); i.e., absence of protective levels despite vaccination where defined
- Low switched memory B cells (<70% of age-related normal value)

AND secondary causes of hypogammaglobulinemia have been excluded [7].

The genetic study is not mandatory but should be encouraged [30].

Most patients are diagnosed with CVID between the ages of 20 and 40 years; however, the diagnosis commonly is delayed by 6–8 years, even after the onset of characteristic symptoms [30].

The genetic basis of CVID is unknown in most cases (85%) and the impairment of B cells can occur at five different stages: B-cells production; early peripheral B-cells maturation or survival; B-cells activation and proliferation; germinal center; postgerminal center.

The defect can be either of B cell either of other cells committed in B-Cell activation. Not only B cells and plasma cells are typically low, also CD4, NK, and other cells levels can be reduced.

In only 5–15% autosomal-dominant/autosomal-recessive inheritance has been described, and the genes implied are inducible T cell costimulator (ICOS), tumor necrosis factor receptor superfamily member 13B (TNFRSF13B, also known as TACI), tumor necrosis factor receptor superfamily member 13C (TNFRSF13C, also known as BAFFR), CD19, CD20, CD21, CLTA4 [31].

GI symptoms are the second most common symptoms after sinus-pulmonary infections in CVID patients, as up to 50% of patients have chronic diarrhea with malabsorption; malabsorption is one of the main responsible reasons for nonmalignant mortality [31]. GI problems can be either infective or inflammatory.

Recurrent intestinal infections are mainly caused by *G. lamblia, C. jejuni,* or *Salmonella*, pathogens frequently associated with profound B cell immunodeficiencies [32].

Noninfective diarrhea and malabsorption have also been ascribed to the onset of IBD or intestinal villous atrophy mimicking celiac disease, a condition observed in 31% of CVID patients with GI symptoms or anemia [15]. Sometimes celiac disease is present too and the differential diagnosis is difficult; antibodies (antitissue transglutaminase, antigliadin, and anti endomysial) are not useful; on the other hand, the genetic study of HLA and the absence of plasma cells in the mucosa can be helpful to differentiate villous atrophy and celiac disease; the response to gluten-free diets is not always satisfactory [15].

CVID mucosa alterations are characterized by the lack of eosinophils, diffuse superficial lesion with apoptotic bodies, and high levels of lymphocytes in crypts. These features are histologically indistinguishable from acute graft-versus-host disease (GVHD) [32].

Liver involvement has been described in 10% of CVID patients; autoimmune reaction, infection, and malignancy are the most common conditions. A biopsy may be necessary to diagnose liver autoimmune disease, since often, the autoantibodies are low [33].

Atypical sarcoid-like lesions are described in 8–22% of patients with CVID; they typically can be appraised in lungs, lymph nodes even in the spleen, and in the GI tract [31].

Atrophic gastritis, which resembles autoimmune gastritis developing into pernicious anemia, may occur in the absence of demonstrable antiparietal cell antibodies in CVID patients.

Treatment of pernicious anemia in CVID consists of monthly replacement of vitamin B12 and careful monitoring of the gastric mucosa for changes associated with malignancy. Gastric adenocarcinoma, in the setting of atrophic gastritis or *H. pylori* infection or de novo, has an increased frequency in CVID patients [31, 32].

Several studies have been done to evaluate a possible correlation between alteration of microbiota and phenotype severity among CVID; a positive association between severe phenotype and higher microbiota dysbiosis has been apprised [34].

Patients are treated with monthly infusions of IgG; this treatment alone may not be effective in treating other manifestations of this disorder. Although the inflammatory process responds to steroid therapy, prolonged therapy with steroids is not advisable for CVID patients. Other immune modulators such as 6-mercaptopurine (6-MP) or azathioprine (AZA) can be used in addition to Ig replacement therapy. Careful use of budesonide may be required if unresponsive to 6-MP or AZA until the symptoms are controlled (e.g., reversal of weight loss and dehydration). In severe cases of malabsorption, when a significant loss of essential nutrients (e.g., calcium, zinc, and vitamins A, E, and D) leads to bone loss and neurologic deficits, limited use of total parenteral nutrition may be required [31, 32].

Combined T and B Cell Immunodeficiency

Severe Combined Immunodeficiency

Severe Combined Immunodeficiency (SCID) includes a group of disorders characterized by impaired development of the cellular and humoral immune functions. The overall incidence of all types of SCID is approximately 1 in 58,000 births [35]. This condition is uniformly fatal in the first 2 years of life unless immune reconstitution can be accomplished. The common characteristic of all types of SCID is a severe impairment of T cell development, with a virtual lack of circulating autologous T lymphocytes and the absence of functional T-cell responses. SCID can be divided into two main classes: with (B + SCID) and without (B − SCID) B lymphocytes and a further subdivision based on the presence of NK in NK+/NK−. However, a new classification is needed based on the novel discoveries: SCID with a normal number of T cells (T+) but a deficit in the T-cell intracellular signaling, resulting in a functional impairment, has been described [36, 37].

SCID results from mutations in known genes that encode components of the immune system crucial for lymphoid cell development (Table 38.5).

The phenotype can vary from severe combined immunodeficiencies (SCID) to some mild form defined as combined immunodeficiencies (CIDs).

Moreover, when the mutated gene is implied in the V(D)J recombination, these mutations result in radio-sensibility (RS) and are defined as RS-SCID [36].

Affected individuals appear to be normal infants at birth but begin to suffer from excessive infections and failure to thrive coincident with the waning of transplacentally acquired maternal IgG between 2 and 4 months of age and, without any treatment, death occurs typically by the first 2 years of life [37].

Most males with typical X-SCID come to medical attention between ages 3 and 6 months.

During the first year of life, nearly all untreated males with X-SCID present failure to thrive, oral/diaper candidiasis, absent tonsils, and lymph nodes, recurrent and persistent infections, despite conventional treatments, especially from opportunistic organisms such as *P. jirovecii*. Additional features include immune dysregulation and autoimmunity-associated with rashes, GI malabsorption, and short stature: 10–15% of patients have a "delayed" clinical onset by age 6–24 months and a smaller percentage of patients have "later"'onset, diagnosed from ages 4 years to adulthood, showing less severe infections, and gradual immunologic deterioration [36].

All patients with SCID have very small thymuses. The spleen appears depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped. GI disorders often occur in SCID patients. Oral, esophageal, and perianal candidiasis is common and can affect oral intake [3, 13, 15].

Intractable diarrhea may begin slowly and progress to massive, watery, bloody, and mucopurulent. The stool should be sent to a laboratory to check for viral and opportunistic infections, especially rotavirus. Chronic infection with rotavirus has been reported in patients who have received the live vaccination. CMV and adenovirus infections also have been identified in GI biopsy specimens. GI biopsy specimens show hypocellular lamina propria, without plasma cells or lymphocytes. Villous atrophy may occur in some infants probably secondary to the damage of the intestine after viral or bacterial infections [13, 15]. A hereditary multiple intestinal atresia is described as an unusual and rare form of recurrent intestinal atresia, which can be associated with SCID [34, 35]. Graft versus host disease (GVHD) and a GVHD-like process affecting colon and small intestine can occur in patients with SCID who received blood transfusions or allogeneic bone marrow transplantation. Early recognition and diagnosis are crucial for these patients. The diagnosis is based on at least one of the following:

- Invasive bacterial, viral, or fungal/opportunistic infection
- Persistent diarrhea and failure to thrive
- Affected family member

AND manifestation in the first year of life
AND HIV excluded
AND 2 of 4 T cell criteria fulfilled:

- Low or absent CD3 or CD4 or CD8 T cells
- Reduced naive CD4 and/or CD8 T cells
- Elevated g/d T cells
- Reduced or absent proliferation to mitogen or TCR stimulation [7]

The number of B and NK cells varies according to the underlying genetic defect. In rare cases, maternal engraftment of T cells may cause near-normal T cell counts. Serum levels of Ig are usually very low, and specific antibody responses are impaired.

Diagnosis of infants is often delayed by several months as a result of the protection of maternal antibodies; however, after the introduction of the screening, an advanced diagnosis has been done. Since 2018, in all states of USA, quantitative polymerase chain reaction (PCR) measurement of T-cell receptor excision circles (TRECs) has been introduced. TRECs are indicators of T-naive and are not produced by T mature cell; a control (b-actin) is measured to differentiate samples with true TREC levels from samples with poor quantity [35].

If the screening indicates a possible SCID, the next exam is flow cytometry that confirms the diagnosis. When there is a prior SCID-affected child with a known specific molecular defect, prenatal diagnosis can be made through genetic testing. After diagnosis, treatment relies on the prevention of principal complications until allogeneic HSCT, which is the definitive treatment [38, 39]. Replacement Ig therapy is given, as well as prophylaxis for *P. jirovecii* pneumonia. Live vaccinations should not be given to the patient or the patient's caregivers, because they can cause life-threatening infections. Blood products are irradiated before administration to prevent GVHD [36].

The genetic diagnosis is not mandatory before proceeding with HSC; however, for some specific mutations (SCID-X1 and adenosine deaminase (ADA-SCID)), gene therapy and enzyme replacement therapy (ADA-SCID) are possible options, so genetic diagnosis should be promoted in case of the suspect of these mutations [35]. Without treatment, death usually occurs in the first 2 years; with HCT cell transplantation, the 2-year survival rate was approximately 95% in

infants without previous infections, 81% in those with previous infections.

A better outcome is associated with an early HSC; in patients receiving HSC under 3.5 months of age and prior to infection, the 5-year survival was 80–95% [39, 40].

Disorder of Phagocytes Function

Chronic Granulomatous Disease (CGD)

CGD is an uncommon primary immunodeficiency (affecting 1 in 250,000 live births) caused by an inability of the phagocytes to produce adequate reactive oxygen metabolites to kill ingested microorganisms and leads to recurrent or persistent intracellular bacterial and fungal infections and to granuloma formation. This impairment in killing is caused by any of the several defects that may occur in one of the five genes that encode for the five subunits of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex also defined as NOX2, which generates the microbicidal respiratory burst [41].

The most common form is X-linked, involving the gp91phox subunit, that, with the autosomal-recessive form, involving the NCF1 subunit, accounts for 90% of CGD. Autosomal-recessive mutations of the other three genes encoding for p22phox, p67phox, and p40phox are responsible for the 10% of CGD [41].

Patients with CGD are susceptible to severe and recurrent infections from catalase-positive organisms (e.g., *Staphylococcus aureus, Burkholderia cepacia, Serratia marcescens, Aspergillus species, Chromobacterium violaceum,* and *Nocardia* species) at epithelial surfaces (e.g., skin, gut, lungs) as well as in organs with a large number of phagocytes such as the liver.

The disease becomes apparent during the first 2 years of life in most patients. Besides infections, these individuals suffer from inflammatory manifestations that are twice more common in X-linked GCS [41].

The classic inflammatory finding is the granuloma; granulomas are noncaseating, matched with fibrotic tissue; they typically affect hollow viscera, are not related to infection, and tend to respond to steroid therapy [41].

GI clinical manifestations are reported in almost 50% of patients with CGD and can sometimes be the first symptom. Up to one-third reports diffuse or lower abdominal pain; the main manifestations reported are chronic diarrhea, malabsorption with steatorrhea and vitamin B12 malabsorption, perianal abscesses, fistulae, GI tract infections, liver abscesses, hepatosplenomegaly, oral ulceration, noninfective esophageal ulcers, esophageal dysmotility, and characteristic obstructive lesions associated with granulomatous infiltration [42].

CGD subjects with inflammatory bowel disease (IBD) often present with signs and symptoms similar to those seen in Crohn's disease (CD) and ulcerative colitis (UC). However, in contrast to CD and UC, CGD-IBD may have distinctive histopathologic findings: in acute and chronic colitis, the main findings are crypt abscess and lymphoplasmacytic with more eosinophils, fewer neutrophils, and numerous lipid-laden macrophages located in the lower third of the mucosa near crypt bases. Macroscopically, in CGD-IBD, the inflammation involves the rectum, is transmural, and is not associated with dysplasia. CD-associated antimicrobial antibodies can be indiscriminately high in patients with CGD with or without GI problems and are useless to differentiate CD from CGD-IBD. It is critically important for the clinician to consider the possibility of CGD in patients with a "Crohn-like" disease in whom a history of recurrent infections and abscesses is noted [42].

Diagnosis of CGD is made by demonstrating a lack of oxidative burst by the nitroblue–tetrazolium test or a flow cytometric test using dihydrorhodamine (DHR) dye and confirmed by Western blot and molecular analysis. Individuals with <10% DHR oxidase activity have a high risk of infection and need therapy. In addition, some authors suggest promoting the same management in individuals with 10–20% DHR activity due to a still high risk of infection [43].

The diagnosis of CGD needs also at least one of the following features:

- Deep-seated infection due to bacteria and/or fungi (abscesses, osteomyelitis, lymphadenitis)
- Recurrent pneumonia
- Lymphadenopathy and/or hepatomegaly and/or splenomegaly
- Obstructing/diffuse granulomata (gastrointestinal or urogenital tract)
- Chronic inflammatory manifestations (colitis, liver abscess, and fistula formation) [7]

Management of CGD includes antibiotic prophylaxis with trimethoprim-sulfamethoxazole and itraconazole to reduce the incidence of bacterial and fungal infections, although breakthrough infections do occur. Prophylactic administration of subcutaneous interferon-γ also has been used [44].

CGD-IBD typically responds rapidly to treatment with steroids followed by the addition of a salicylic acid derivative and/or a purine antimetabolite. Additional therapy used form CGD-IBD are hydroxychloroquine, anakirna, and TNFα inhibitors; TNFα inhibitors can lead to severe life-threatening infections, so they must be used with caution. In some severe form, bowel surgery may be needed [42, 43].

Hematopoietic stem cell transplantation from an HLA-identical donor can be curative for CGD and gene therapy may be an option in the future [44]. More than 50% remains alive ≥25 years after diagnosis [41].

Immune Dysregulation Diseases

IPEX and IPEX-Like Disorders

IPEX and IPEX-like disorders are a group of disorders characterized by immune dysregulation and autoimmunity that result from defects in T regulatory cells, development, and function. The main disease of this group is "immune dysregulation, polyendocrinophaty, enteropathy, X-linked (IPEX)," resulting from mutations affecting FOXP3.

The diagnosis of IPEX is based on at least one of the following:

- Severe and protracted enteropathy with villous atrophy in a male infant
- Severe, often multiple endocrinopathies

AND exclusion of hypogammaglobulinemia
AND at least one of the following:

- Low or absent Foxp3 expression by CD4 + CD25+ on flow analysis
- No overt T cell defect (proliferations are normal)
- Elevated IgA and IgE levels
- Normal CD25 expression [7]

Several other gene defects that affect T-regulatory cell function also give rise to an IPEX-like phenotype. Some are autosomal recessive and involve the following genes: LRBA, CD25, ITCH, CTLA4, IL2RA, STAT5B, DOCK8, MALT-1; autosomal-dominant mutations involve STAT1 gene and STAT3 gene; these last two are the most common and account for almost 38%. Table 38.6) [45–49].

In addition, two other genes have been associated with IPEX-like syndrome (TTC37, TTC7A); homozygous mutation of TTC37 results in trichohepatoenteric syndrome characterized by growth restriction, diarrhea, trichorrhexis nodosa-like hair morphology, hepatopathy, facial dysmorphism, and immunodeficiency. TTC7A homozygous mutation results in IPEX-like disorder and multiple intestinal atresia [47].

The diagnosis of IPEX-like is based on at least one of the following:

- Severe and protracted enteropathy with villous atrophy in a male infant
- Severe, often multiple endocrinopathies

Table 38.6 Clinical and laboratory features of IPEX and IPEX-like disorders

	IPEX	CD25	STAT5b	STAT-1	ITCH	DOCK8	MALT-1
Associated features	None	None	Growth failure	Vascular anomalies	Dysmorphic growth failure	Growth failure	Growth failure, facial dysmorphy
Autoimmunity							
Eczema	+++	+++	++	++	++	+++	+

CMV cytomegalovirus, *EBV* Epstein-Barr virus, *VZV* varicella zoster virus, *IGF* insulin-like growth factor–binding protein, *IGFBP* insulin-like growth factor–binding protein [45–49]

AND exclusion of hypogammaglobulinemia
AND at least one of the following:

- Normal Foxp3 expression by CD4 + CD25+ on flow analysis
- No overt T cell defect (proliferations are normal)
- Elevated IgA and IgE levels [7]

IPEX typically presents during the first 2–3 months of life, IPEX-like disorders around 17 months of life; in some cases, the symptoms can start at birth or even in delayed childhood or adolescence. A correlation between genotype and phenotype has not been established; however, IPEX nonsense and frameshift mutations have been associated with a more severe phenotype [50].

The initial triad of symptoms is classically characterized by secretory diarrhea (at times mucoid or bloody) unresponsive to fasting, eczema, and diabetes mellitus. Clinical presentation can be similar to severe food allergy, although these patients are generally unresponsive to the elemental formula. Three distinct histological patterns have been described: they are not mutually exclusive: graft-vs-host disease-like pattern, celiac disease-like pattern, and enteropathy with intestinal goblet cell autoantibodies pattern [50]. The main histologic features include total or partial villous atrophy, lymphocytic, eosinophil, plasma cell infiltration in the lamina propria, and destruction of mucosal, submucosal, and muscular layer sparing.

Antienterocyte antibodies are usually present; however, they are considered accessory findings rather than pathogenetic factors. The GI problems lead to severe alterations of the nutritional status and glucose metabolism. Skin involvement can range from mild to severe manifestations, it usually does not respond to treatment and there is a high risk of bacterial superinfection. Other autoimmune manifestations, including hyperthyroidism, hypothyroidism, autoimmune hemolytic anemia, thrombocytopenia, and neutropenia, have been reported [51].

B-cell subsets and CD3+ T cells, including CD4+ and CD8+ subsets, are present in normal numbers and proliferate to mitogens and antigens, although affected patients typically have decreased number of regulatory T-cells and are unable to suppress T-cells proliferation.

Serum IgG, IgA, and IgM levels are usually normal but can be slightly reduced from enteric protein loss. IgE levels usually are increased, and eosinophilia is frequently present. The diagnosis is made by showing decreased FOXP3 protein expression and a reduction in the number of regulatory T cells. The diagnosis also can be confirmed by mutation testing of the FOXP3 gene [47]. A mutation on FOXP3 is appraised in 50% of cases; in the other 50%, the mutation involves one of the causative IPEX-like disorder genes [47].

Autoantibodies to harmonin and villin are considered specific diagnostic markers of IPEX and could be of help to differentiate IPEX, including atypical cases, from other early disorders associated with severe enteropathy. In addition, they become low in patients well controlled either with immunosuppression (IS) or HSCT [51].

Patients are often severely ill by the time a diagnosis of IPEX is made. In the absence of aggressive therapy, children usually die before 2–3 years of age as a result of malnutrition, electrolyte imbalance, or infection [51]. No differences between IPEX and IPEX-like in long-term survival have been reported [51].

Symptomatic treatment includes bowel rest with total parental nutrition and, if necessary, insulin injections and red blood cell and platelet transfusions. The only curative treatment available is HSCT with 15 years survival rates of 73.2%. Immunosuppression (IS) has been used as an alternative to HSCT; the most effective immunosuppressant is rapamycin followed by cyclosporine, tacrolimus, sirolimus, and steroids. IS therapy is associated with a higher 15 years survival rate (86.6%); however, IS is not curative and chronic therapy may be toxic and may facilitate opportunistic infections [50, 51]. Gene therapy may be an option in the future.

Interleukin-10 and Interleukin-10-Receptor Defects

IL-10 pathway plays a critical role in the control of inflammation by limiting the secretion of pro-inflammatory cytokines, including TNF-α, IL-1, IL-6, and IL-12. Homozygous loss-of-function mutations of the genes that encode for either IL-10 or IL-10 receptor (IL-10R) have been associated with very early-onset IBD (VEO-IBD). IL-10R is a tetrameric receptor composed of two alpha-unit (IL-10R1) encoded by IL-10RA and two beta-unit (IL-10R2) encoded by IL-10RB; IL10RA is specific for IL-10, ILRB can bind also IL-22, IL-26, IL-28, and IL-29 [52].

Mutations in these genes have been apprised in 4–25% of VEOIBD; a Korean study reports a mutation in ILRA in 50% of IBD diagnosed within the first year of age [53, 54].

These patients present within the first year of life with enterocolitis and perianal disease, as well as the formation of multiple abscesses and entero-cutaneous fistula, requiring several surgical interventions.

The microscopic appearance of the mucosa is characterized by the presence of ulcer lesions with eosinophils, inflammatory infiltrates in the epithelium, cryptic abscesses extending to the muscularis mucosa, and drop-out necrosis [54].

Patients also suffer from chronic folliculitis and recurrent respiratory infections.

Skin and respiratory infections are more common among IL-10RB mutation, since it binds IL-22 that is involved in skin and lung epithelial immunity.

Hearing loss has been reported too and might be caused by the multiple high respiratory tract infection. In addition, EBV-associated lymphomas have been described among individuals with IL10RB mutation probably because IL10RB is implied in the γ-interferon pathway [53–55].

Although rare, pediatric patients with IBD and perianal disease should be screened for IL-10 and IL-10R deficiency. Defects in the IL-10R may be evaluated by functional assays.

Peripheral blood mononuclear cells from healthy individuals show strong phosphorylation of the signal transducer and activator of transcription-3 (STAT3) upon stimulation with IL-10, whereas peripheral blood mononuclear cells from IL-10R deficient patients do not. Functional abnormalities can be confirmed by sequencing IL-10RA and IL-10RB [56].

In addition, decreased CD41/CD81 T-cell ratio; high, low, or normal NK; B; T cell; increased or decreased serum immunoglobulin levels that may require immunoglobulin substitution have been reported. No genotype–phenotype correlation has been described.

The management of these patients includes various anti-inflammatory drugs, such as steroids, methotrexate, thalidomide, anti-TNFα monoclonal antibodies, and even fecal microbiota transplantation. However, in many cases, no remission or long-term improvement is achieved.

Surgery may be needed in case of high inflammation.

Both IL-10 and IL-10 receptor deficiency can be successfully treated by HSCT [57].

Immunodeficiency-Associated with Other Defects

Wiskott Aldrich Syndrome (WAS)

WAS is a rare X-linked primary immunodeficiency characterized by microthrombocytopenia, eczema, recurrent infections, and an increased incidence of autoimmunity and malignancies. In the USA, the incidence has been estimated at 1:250,000 male births.

The disease is caused by mutations in the WASp gene, which is involved in actin polymerization cytoskeletal remodeling during the hematopoietic cell differentiation and development [58]. A 5-point severity score has been introduced to differentiate patients with milder presentation (score <2) from those with a severe or well-defined classic type (>3–5) [58, 59].

The most severe form of WAS is associated with mutations that lead to absent or truncated protein, and individuals with this class of mutations develop the classic WAS.

Mutations that lead to full-length, but reduced quantity of WASp present thrombocytopenia with minimal, if any, immunodeficiency.

Missense mutations that do not affect WASp expression and lead only to intermittent thrombocytopenia.

The fourth class of mutations is caused by a missense mutation in the WASp Cdc42-binding site.

Of note, platelets have reduced size in the first three classes of mutations described as the pathognomonic sign of the diseases and no tendency toward neutropenia. Individuals with the fourth class of mutations demonstrate no thrombocytopenia and normal-sized platelets, but they typically develop neutropenia (and often a complete loss of this cell line) with infections [59].

Thrombocytopenia results form more than one pathogenic pathway: accelerate peripheral destruction, antiplatelets antibodies, and impaired functionality. Interestingly, megakaryocytes are normal or increased in numbers in the bone marrow and normal platelet production is apprised in vitro.

WAS can also be associated with other immune defects, including abnormalities of humoral and cell-mediated immunity. Patients with WAS usually are male infants presenting in the first few months of life with the above clinical picture accompanied by bleeding and bloody diarrhea. Although GI complications are not prominent, malabsorption and nonspecific colitis may be encountered, and higher rates compared to the general population of IBD and IBD-like disease have been reported [3, 13, 15]. Serious infections also occur. Encapsulated organisms are frequent pathogens that may cause life-threatening complications, including pneumonia, meningitis, and sepsis. Severe presentations of viral infections from VZV, HSV, EBV, CMV, and HPV have been reported [58, 59].

Opportunistic infections can also present under the form of *Pneumocystis jirovecii*.

Atopic symptoms are frequently present, and eczema develops in more than 2/3 of these patients.

Eczema may improve as the patient gets older, although serious complications such as secondary infection (e.g., cellulitis, abscess) or erythroderma can occur. Autoimmune manifestations are really common (70%): cytopenias, arthritis, vasculitis, IgA nephropathy, and Henoch-Schönlein purpura have been reported [59].

A higher incidence of malignancy has been described, predominantly non-Hodgkin type and often EBV-induced [59].

Laboratory evaluation reveals normal or slightly low IgG levels, high IgA and IgE levels, and low levels of IgM that are secondary to accelerated synthesis and catabolism.

Antibody responses to polysaccharide antigens are decreased. Platelet numbers are reduced and small in size. Patients have low B cell levels during infancy that normalize in adulthood, while their T cells show a progressive decrease

in number and function. Diminished lymphocyte proliferation in response to mitogens occurs in approximately 50% of patients. The number and phagocytic activity of neutrophils are normal, although chemotactic responses are defective.

The diagnosis is based on at least one of the following:

- Eczema
- Recurrent bacterial or viral infections
- Autoimmune diseases (incl. vasculitis)
- Malignancy
- Reduced WASP expression in a fresh blood sample
- Abnormal antibody response to polysaccharide antigens and/or low isohemagglutinins
- Positive maternal family history of XLT/WAS AND male patient with thrombocytopenia (less than 100,000 platelets/mm^3) (measured at least twice)

AND small platelets (platelet volume <7.5 fl) [7]

Screening for WASp mutations is performed by flow cytometry; however, this does not identify carriers of, or those patients with, X-linked thrombocytopenia. Sequence analysis of the WAS gene is essential to confirm the diagnosis [59]. Curative therapy for WAS is hematopoietic cell transplantation and lentiviral vector–mediated HSPC gene therapy [59, 60]. Conventional management includes antibiotic prophylaxis as well as platelet transfusions in severe situation; prophylactic transfusions to maintain normal platelet counts are discouraged, since it can result in the development of anti-HLA antibodies and should be used only in a life-threatening situation [59, 60].

Hermansky–Pudlak Syndrome (HPS)

HPS is a rare autosomal-recessive disease that displays genetic heterogeneity; there are ten known subtypes (HPS1-10) [61]. All subtypes are characterized by tyrosinase-positive oculo-cutaneous albinism and bleeding diathesis that results from a platelet storage pool deficiency.

HPS1-2-4 may present also with pulmonary fibrosis and HPS1-4-6 with granulomatous colitis. HPS gene is ubiquitously expressed and encodes for a molecule that is critical in trafficking to lysosome-like organelles like melanosomes and platelet dense granules [61].

Systemic complications are associated with the accumulation of ceroid lipofuscin.

The bleeding diathesis can result in easy bruising, frequent epistaxis, gingival bleeding, postpartum hemorrhage, colonic bleeding, and prolonged bleeding with menses or after tooth extraction, circumcision, and other surgical procedures. Pulmonary fibrosis, a restrictive lung disease, typically causes symptoms in the early 30's and can progress to death within a decade; it is probably caused by macrophages that constitutively produce inflammation mediators [61]. Granulomatous colitis, which occurs in 20–30% of patients with HPS1-4-6, has clinical features suggestive of UC and pathological features similar to that of CD including non-necrotizing granulomas, fissuring, and transmural inflammation. The colitis usually manifests in the first or second decades of life; it can be severe and not always responds to therapy; occasionally, colectomy may be required [61]. Although the colon is primarily involved in HPS, any part of the GI tract, including the gingiva, can be affected. GI complications are responsible for 9% of deaths [3, 13, 16, 61].

In the case of pulmonary fibrosis, death occurs during the 4th–fifth decades.

The diagnosis is based on the presence of oculo-cutaneous albinism and bleeding diathesis despite a normal number of platelets.

For HPS2, the diagnosis is based on oculo-cutaneous albinism

AND chronic neutropenia

AND at least one of the following:

- Bleeding diathesis
- Recurrent infections
- Hemophagocytic lymphohistiocytosis (HLH)

AND defective cytotoxicity caused by impaired degranulation [7]

The next step is to evaluate the absence of δ granules on freshly isolated plasma with electron microscopy. The bleeding time test is unreliable. Molecular analysis is recommended. In case of HPS type 1-2-4, high-resolution computed tomography of the chest (HRCT) is used to diagnose pulmonary fibrosis; the biopsy is not suggested due to the high risk of bleeding. Pirfenidone and lung transplantation are used against pulmonary fibrosis. Infliximab and steroids are used against GI manifestations [61, 62].

Protection from the sun is mandatory due to an increased risk of melanoma and basal-cell cancer.

Warfarin, ibuprofen, and aspirin should be avoided; single donor platelets transfusion may be used in the setting of trauma and desmopressin can be administered to prevent bleeding complications [61, 62].

Exocrine Pancreatic Insufficiency

39

Amornluck Krasaelap, Steven L. Werlin, and Praveen S. Goday

Introduction

Exocrine pancreatic insufficiency (EPI) refers to insufficient secretion of pancreatic enzymes (acinar function) and/or sodium bicarbonate (ductal function), resulting in maldigestion and malabsorption of nutrients [1]. The symptoms and manifestations of EPI are largely due to an inability to digest fat. Symptoms are typically nonspecific but must be suspected in every child with steatorrhea (excess fat in the stool), failure to thrive of unexplained reasons, fat-soluble vitamin deficiency, as well as in children with recurrent pancreatitis [2] (see Chap. 34). References 3–29 constitute a comprehensive review of all known forms of EPI [3–29]. Table 39.1 lists both relatively common as well as rarer genetic causes of this condition.

EPI can also develop from nonpancreatic disorders [30]. In celiac disease, inflammatory bowel disease, or other conditions with proximal small-bowel mucosal inflammation, EPI can be caused by impaired release of secretin and cholecystokinin (CCK), which are potent stimulators of pancreatic secretion. Gastrointestinal surgery such as pancreatectomy, gastrectomy, small-bowel resections, or even esophagectomy may also result in EPI due to altered pancreatic enzymes and gastrointestinal hormone levels.

Exocrine Pancreatic Insufficiency in Cystic Fibrosis

Cystic fibrosis (CF) is the most common etiology of EPI in children. CF is an autosomal-recessive condition caused by defects in the cystic fibrosis transmembrane regulator (CFTR) gene. Although the severity of EPI is highly dependent on the specific genotypic mutation, about 85% of patients with CF develop EPI by 1 year of age [31].

Pathophysiology of Exocrine Pancreatic Insufficiency in Cystic Fibrosis

Mutations of the CFTR gene cause impaired chloride transport at the apical surface of epithelial cells [32] and disturb chloride-coupled bicarbonate transport [33] and sodium channel activity [34]. Pancreatic secretion of chloride, bicarbonate, sodium, and potassium in response to combined CCK and secretin stimulation is impaired in all patients with CF, regardless of pancreatic function status [35]. Bicarbonate secretion is most impaired, and defective electrolyte secretion leads to reduced fluid secretion [36]. Defective bicarbonate secretion results in impairment in the luminal flow of pancreatic enzymes and proenzymes and impairment in the trafficking of zymogen granules, leading to a severe block in acinar cell secretion followed by loss of cellular function, cell death, fibrosis, and eventual pancreatic insufficiency that leads to a decline in all the enzymes secreted by the pancreas [32, 36].

In healthy people, only 5–10% of the normal postmeal pancreatic enzyme output is adequate for normal digestion, indicating the large reserve capacity of the pancreas [32]. This reserve capacity means that clinically significant malabsorption is not evident until at least 90% of the exocrine cells of the pancreas are destroyed [37]. In normal individuals, the presence of free fatty acids in the proximal small bowel causes release of CCK, which in turn stimulates pancreatic secretion [38]. When pancreatic insufficiency begins to develop, this feedback loop is impaired and the site of maximal digestion shifts to the more distal bowel [32]. This results in larger amounts of nutrients being delivered to the distal bowel with changes in motor and secretory function of the more proximal bowel [39, 40]. These changes, in turn, lead to quicker intestinal transit and malabsorption [40].

Whether a patient is pancreas sufficient (PS) or EPI has clinical and prognostic significance in CF. PS does not mean normal pancreatic function but that enough pancreatic function is present to avoid the need for pancreatic enzyme replacement therapy (PERT). Patients who are PS are more susceptible to pancreatitis [41], while EPI patients have more severe lung disease, malnutrition, and liver disease [42].

Shwachman–Diamond Syndrome

Shwachman–Diamond syndrome (SDS) is the second most common cause of EPI in children. SDS is an autosomal-recessive disorder characterized by congenital anomalies, pancreatic insufficiency, bone marrow failure, and predisposition to myelodysplasia and acute myeloid leukemia (AML) [43]. Mutations in the Shwachman–Bodian–Diamond syndrome (*SBDS*) gene on chromosome 7q11 can be found in approximately 90% of classically presenting patients with SDS [44]. The SBDS gene is involved in ribosomal function [45], and ribosomal subunit assembly is impaired in patients with SDS [46]. These mutations usually result in reduced, but not absent, protein expression. In mice, targeted deletion of the gene results in embryonic death, suggesting that some expression of this gene is necessary for survival [47]. The exact mechanism by which this leads to pancreatic insufficiency is unknown. One study found that patients negative for mutations in the SBDS gene may have more severe hematological manifestations while having milder pancreatic disease [48].

The incidence of SDS is 1:76,000 individuals with a male: female ratio of 1.7:1 [49, 50].

The classic presentation of SDS is in infancy with failure to thrive, diarrhea, and neutropenia. SDS infants have an

average birth weight at the 25th percentile [50]. Growth failure with malnutrition is common in the first year of life, and height velocity falls such that height remains below the third percentile in 38–56% of patients [51, 52]. After diagnosis, and with appropriate therapy, most children regain normal growth velocity, though height and weight remain below the third percentile [53]. Steatorrhea is caused by decreased secretion of pancreatic enzymes, while ductular fluid and electrolyte secretion of the pancreas remain normal [54, 55]. EPI tends to be diagnosed within the first 6 months of life with 90% of patients being diagnosed in the first year [54]. Spontaneous improvement in pancreatic function can occur in later childhood with 50% of patients by age 4 years having normal fat absorption and no longer requiring pancreatic enzyme supplementation [54]. The pancreas in SDS exhibits a characteristic fatty replacement, which can be visualized on ultrasound, CT, and, perhaps, best by MRI [56].

Hepatomegaly and raised serum liver enzymes are common in children with SDS [57]. These resolve by the age of 5 years, and no long-term consequences have been observed [57].

Neutropenia is the most common cytopenia and can be persistent, intermittent, or cyclic and may vary from mild to severe [50]. Anemia with low reticulocyte counts [50] and elevations in fetal hemoglobin are each seen in 80% of patients [58]. Thrombocytopenia can also be seen. Bone marrow biopsy is usually hypoplastic with increased deposition of fat [58, 59]. Patients with SDS have a propensity to developing infections due to the neutropenia and the occasional functional neutrophil deficits that are seen in SDS [60]. Patients with SDS develop clonal changes in the bone marrow, which may or may not be associated with an increased risk of myelodysplasia or acute myeloid leukemia (AML) [61]. Due to the predisposition to myelodysplasia and AML, all patients with SDS should be referred to a pediatric hematologist. Based on data from several registries, the frequency of both myelodysplasia and AML increases with increasing age [48, 62, 63]. Hematopoietic stem cell transplantation should be considered for treatment of severe pancytopenia, myelodysplasia, or AML [64].

The bony dysplasia of SDS manifests as short stature and delayed appearance but subsequent normal development of secondary ossification centers [50]. There is variable metaphyseal widening and irregularity that is most often seen in the ribs in early childhood and in femurs later in childhood and adolescence [65]. Rarely, skeletal involvement may be extremely severe and generalized [50]. Usually, these metaphyseal changes are clinically insignificant, but rarely, they may lead to limb deformities and fractures [65].

A characteristic pattern of neurocognitive and behavioral difficulties has been described in SDS [66].

A high degree of suspicion may be needed to diagnose milder cases of SDS. A study of 37 children with SDS found that neutropenia (81%), diarrhea (58%), failure to thrive (73%), lipomatous infiltration of the pancreas (~90%), low fecal elastase (82%), and skeletal (38%), congenital, and endocrine malformations (65%) were all inconsistently present [67].

Serum immunoreactive trypsinogen (IRT) and pancreatic isoamylase concentrations can be useful markers of the pancreatic phenotype in SDS [68]. In healthy children, serum IRT concentrations are at adult levels at birth, while pancreatic isoamylase concentrations are low at birth and reach adult levels by 3 years of age [68]. In contrast, in SDS, young children have low serum IRT concentrations, which then rise with age, while serum pancreatic isoamylase activities are low at all ages. Serum IRT is generally low in EPI patients with SDS, while a normal value does not rule out EPI. Serum isoamylase concentrations are not useful in determining PS or EPI. Hence, when SDS is suspected, a serum IRT should be obtained in children <3 years of age, while serum pancreatic isoamylase should be obtained in children ≥3 years of age [50].

The diagnosis of SDS is made using the criteria shown in Table 39.2. The combination of exocrine pancreatic dysfunction and hematological abnormalities when other known causes of exocrine pancreatic dysfunction and bone marrow failure are excluded gives rise to a clinical diagnosis of SDS [50]. CF should be ruled out with a sweat test, while Pearson syndrome can be differentiated by a bone marrow examination and imaging of the pancreas. Cartilage hair hypoplasia, which presents with diarrhea (but not with EPI), cytopenia, and metaphyseal chondrodysplasia, is more common in certain populations such as the Amish.

Exocrine Pancreatic Insufficiency in Chronic Pancreatitis

All children with chronic pancreatitis should be assessed for EPI at least annually and more often if symptoms develop in the interim. Children should be assessed for EPI using a stool elastase and should be considered EPI if the stool elastase <200 ug/g. EPI in children with chronic pancreatitis is managed in the same manner as EPI from any other cause.

Pearson Syndrome

Pearson syndrome (formerly Pearson Marrow-Pancreas syndrome) is a rare genetic condition with unknown prevalence. Pearson described a syndrome of refractory, transfusion-dependent sideroblastic anemia with vacuolization of the bone marrow and EPI [9]. Other variable features may include hepatic failure, proximal renal tubulopathy, watery diarrhea, patchy erythematous skin lesions, neutropenia, and thrombo-

Table 39.2 Diagnostic criteria for Shwachman–Diamond syndrome [50]

Clinical and molecular diagnostic criteria
Clinical diagnosis Fulfill the combined presence of hematological cytopenia of any given lineage (most often neutropenia) and exocrine pancreas dysfunction
Hematologic abnormalities may include the following: (a) Neutropenia <1.5 × 10^9/L on at least 2 occasions over at least 3 months (b) Hypoproductive cytopenia detected on 2 occasions over at least 3 months
Tests that support the diagnosis but require corroboration: (a) Persistent elevation of hemoglobin F (on at least 2 occasions over at least 3 months apart) (b) Persistent red blood cell macrocytosis (on at least 2 occasions over at least 3 months apart), not caused by other etiologies such as hemolysis or a nutritional deficiency
Pancreatic dysfunction may be diagnosed by the following: (a) Reduced levels of pancreatic enzymes adjusted to age [fecal elastase, serum trypsinogen, serum (iso)amylase, serum lipase]
Tests that support the diagnosis but require corroboration: (a) Abnormal 72-hr fecal fat analysis (b) Reduced levels of at least 2 fat-soluble vitamins (A, D, E, K) (c) Evidence of pancreatic lipomatosis (e.g., ultrasound, CT, MRI, or pathological examination of the pancreas by autopsy)
Additional supportive evidence of SDS may arise from the following: (a) Bone abnormalities (b) Behavioral problems (c) Presence of a first degree-family member diagnosed before with SDS
Other causes of pancreatic insufficiency should be excluded, in particular when the SBDS gene mutation analysis is negative
Molecular diagnosis: biallelic SBDS gene mutation Positive genetic testing for SBDS mutations known or predicted to be deleterious, e.g., from protein modeling or expression systems for mutant SBDS
Caveats: Many situations arise when molecular diagnosis is NOT confirmatory in the presence of clinical symptoms: No identified mutations (about 10% of cases) Mutation on one allele only Gene sequence variations that have unknown or NO phenotypic consequence A novel mutation, such as a predicted missense alteration, for which it is not yet possible to predict whether it is disease causing SBDS polymorphisms on one or both alleles. Large population studies may be needed to exclude a sequence polymorphism as a bona fide irrelevant variant

cytopenia, and high serum lactate/pyruvate ratios [69]. This condition should be considered in the differential diagnosis of SDS. In this syndrome, vacuolization of the marrow is seen, while in SDS, the bone marrow is dysplastic; the pancreas is fibrotic in Pearson syndrome, while it is fatty in SDS [70]. Pearson syndrome is caused by large deletions or rearrangements in mitochondrial DNA, which are more abundant in the blood than in other tissues [69]. Diagnosis is suspected based on clinical findings and can be confirmed by Southern blot analysis, which detects rearrangements of mitochondrial DNA [71]. This syndrome is usually fatal in infancy, but some children who survive past infancy develop severe neurological symptoms such as proximal myopathy, seizures, ataxia, or abnormal movements, suggestive of another mitochondrial DNA disorder, Kearns-Sayre syndrome [72]. In children without multisystem involvement, bone marrow transplantation or unrelated cord blood cell transplantation has been suggested as a mechanism to manage the severe hematological manifestations of this syndrome [71].

Johanson–Blizzard Syndrome

Johanson–Blizzard syndrome (JBS) is a rare autosomal-recessive disorder caused by mutations in the *UBR1* gene on chromosome 15q15.2 [73, 74]. UBR1 encodes an E3 ubiquitin ligase that is involved in proteolysis [74]. However, the exact causative mechanism of EPI in JBS is unknown, but likely due to a near-total absence of pancreatic acini and replacement by fat. A small beak-like nose (due to aplasia or hypoplasia of the alae nasi) and EPI in early infancy are most consistently present, while other features in decreasing order of occurrence include dental anomalies, congenital scalp defects, sensorineural hearing loss, growth and psychomotor retardation, hypothyroidism, imperforate anus, and genitourinary anomalies [75].

Clinical Symptoms of Exocrine Pancreatic Insufficiency

The symptoms of fat malabsorption, which have been best described in CF, are abdominal pain, constipation, flatulence, and diarrhea [32]. Diarrheal symptoms are not different between PS and EPI patients in CF [32]. Hence, these symptoms are not good markers of EPI and definitely not measures of adequacy of PERT.

EPI can result in significant malnutrition and nutritional deficiencies, particularly of fat-soluble vitamins A, D, E, and K [76]. Zinc, iron, calcium, folic acid, magnesium, and selenium deficiencies have been described in CF [76, 77]. In CF, the presence of liver disease and enteropathic changes may create further nutritional issues.

Diagnosis of Exocrine Pancreatic Insufficiency

The ideal test of pancreatic function should be specific, non-invasive, able to quantitate pancreatic function, able to indicate the need and the appropriate dosage of substitutive enzymes even during therapy, cost-effective, and broadly available [78]. No such test is presently available [78]. Tests

Table 39.3 Exocrine pancreatic function tests

Direct tests	Indirect tests
Nonstimulatory test Fecal elastase-1 Fecal chymotrypsin Immunoreactive trypsinogen (IRT), lipase, and isoamylase levels	Spot fecal fat[a] Steatocrit[a] 72-hour fecal fat excretion test ^{13}C-labeled mixed-triglyceride breath test
Stimulatory test Secretin stimulation test Cholecystokinin stimulation test Secretin-cholecystokinin stimulation test	

[a]Not recommended

for EPI can be performed by measuring pancreatic secretion (direct tests) or by estimating the consequences of malabsorption (indirect tests) [1]. Common tests for EPI are summarized in Table 39.3.

Indirect Pancreatic Function Tests

The standard indirect pancreatic function test measurement of fat absorption is the 72-hour fecal fat excretion test. The coefficient of fat absorption (CFA) is calculated as follows:

((Fat ingestion – Fat excretion) / Fat ingestion) × 100(%). Normal CFA values are >85% in infants <6 months of age, and >95% in older children. During this time, stool is collected while consuming a standardized high-fat diet or more typically ingestion is recorded in a detailed food diary [79]. Microscopic examination of a spot stool sample using Sudan stain to detect fat droplets or the acid steatocrit is not recommended due to their lack of sensitivity and specificity.

The ^{13}C-labeled mixed-triglyceride breath test (^{13}C -MTG) is a noninvasive method of assessing lipase activity [80, 81]. Orally administered ^{13}C-labeled fatty substrates are digested by the pancreatic lipase; the released free fatty acids or monoglycerides are absorbed in the gut and oxidized in the liver to $^{13}CO_2$, which is rapidly exhaled in breath and can be measured. Several studies have shown a good correlation of ^{13}C -MTG and fecal fat quantification, with high sensitivity and specificity for the diagnosis of EPI [82, 83]. ^{13}C -MTG can also be used to assess the efficacy of PERT.

The disadvantages are the unavailability of the test in the United States, variability of test protocol, and the age limit as younger patients may not be able to follow the testing instructions. The test results can be influenced by other conditions such as liver disease, gastrointestinal dysmotility, and lung disease.

Direct Pancreatic Function Tests

Fecal elastase-1 is the most commonly used test to diagnose EPI. The test, although called fecal elastase-1, does not actually measure elastase-1 as this is transcriptionally silenced in humans. The test actually measures chymotrypsin-like elastases (CELA) 3A and 3B [77]. These enzymes are secreted by the pancreas and do not undergo degradation in the gut. The monoclonal fecal elastase-1 test only identifies the human form of the enzymes; hence, the test can be done even when the patient is receiving porcine-derived PERT [84]. It is inexpensive with good sensitivity and specificity for detection of EPI. The sample needs a very small amount of stool (≥1 gram) and is stable for weeks at room temperature [85]. Falsely low values may be obtained when the stool is dilute as in any diarrheal illness or in the presence of enteropathies.

After 2 weeks of age, PS patients can be differentiated from EPI patients using a cut-off of 200 μg/gram [86], whereas others have suggested that 180 μg/gram is a more accurate cut point in patients with CF [87]. Fecal elastase-1 can also be used in the annual monitoring of CF patients with PS to identify the onset of EPI.

In patients with CF, the presence of a low fecal elastase-1 is usually considered diagnostic of EPI despite the fact that fecal elastase-1 correlates poorly with fecal fat excretion [88]. In other conditions, especially in children who present with poor growth or malabsorption, the next steps after obtaining a fecal elastase-1 level are less clear. Also, preliminary reports suggest that drugs regulating CFTR (e.g., ivacaftor) may increase fecal elastase-1 and potentially convert children with EPI to PS; however, more data are needed to confirm these findings [89–92].

The CF Foundation recommends an evaluation of pancreatic functional status by fecal elastase or coefficient of fat absorption for all children with CF under 2 years of age [93]. Fecal elastase should be repeated at age 1 year in children diagnosed with EPI in infancy, especially in those with an initial fecal elastase value of >50 μg/gram to ensure that those with a falsely low fecal elastase value do not receive PERT unnecessarily [85].

Fecal chymotrypsin is a less sensitive and specific marker of pancreatic function than fecal elastase-1. However, this test, which does identify porcine enzymes, can be used to monitor compliance to PERT in patients who are known to be EPI [94].

Serum IRT of less than 20 ng/mL is specific for EPI [95]. Serum IRT levels, as a part of newborn screen, are at adult levels at birth in healthy newborns, but markedly elevated in newborns with CF regardless of whether their mutation is pancreatic sufficient or insufficient [96, 97]. Serum IRT levels are generally reduced later in life in patients with EPI, but a normal value does not rule out EPI.

Stimulatory tests or direct pancreatic function tests using secretagogues such as CCK and/or secretin are currently considered the gold standard to evaluate EPI. Unlike indirect pancreatic function tests, this assay can evaluate contents of pancreatic fluids and differentiate EPI from specific pancreatic enzyme deficiencies.

The original test performed by using Dreiling tubes was time-consuming and poorly tolerated by patients, so it has been replaced by an endoscopic method [98, 99]. Either secretin or CCK is administered intravenously prior to endoscopic intubation. Within 10 minutes, pancreatic fluid is collected from the duodenum (close to the ampulla of Vater). The pancreatic fluid can be evaluated for pH, protein content, amylase, lipase, trypsin, chymotrypsin, elastase, and electrolytes including bicarbonate [100].

The pancreatic stimulation test appears to be one of the most sensitive tests for the diagnosis of severe chronic pancreatitis and EPI, but it is less sensitive in less advanced disease. False abnormal results may be reported in patients with diabetes, celiac sprue, advanced liver disease, or those with a recent episode of acute pancreatitis [101].

Pancreatic stimulation testing may be performed with the use of a magnetic resonance cholangiopancreatography (MR PFT) to help assess pancreatic anatomy and quantify exocrine pancreatic function. Adult data support the use of MR PFT as a noninvasive and radiation-free method. However, a standardized protocol with an exact interpretation of findings needs to be developed for use in children [102, 103].

Management

Much of the data on management of pancreatic insufficiency in children is extrapolated from CF. In general, the symptoms of pancreatic insufficiency can be more easily controlled in conditions other than CF than in CF. PERT remains the mainstay of treatment for patients with clinical symptoms of pancreatic insufficiency or laboratory signs of malabsorption in CF and non-CF EPI [104]. In CF, PERT is indicated in all infants with two CFTR mutations associated with EPI [93]. FDA-approved PERT are summarized in Table 39.4. All PERT products are of porcine origin and con-

Table 39.4 FDA-approved pancreatic enzyme products

	Dosages available (lipase/protease/amylase units)	Bead/ microsphere diameter (mm)	Notes
Creon ®	3000/9500/15,000 6000/19,000/30,000 12,000/38,000/60,000 24,000/76,000/120,000 36,000/114,000/180,000	0.7–1.6	Oral, delayed release capsules

tain a mixture of the digestive enzymes, lipase, protease, and amylase in varying proportions. However, because lipase plays the main role in therapy, PERT dosage is based on the content of lipase units [104].

Enzyme dosing can be based on body weight (units of lipase/kg per meal) or the amount of fat present in the food (units of lipase/grams of fat eaten), but dosing based on body weight is more practical. In infants with CF, PERT doses are generally 2000–4000 lipase units per 120 mL of formula or per breast-feeding. In all other patients with EPI, the dose is gradually adjusted based on weight gain and absorption to a maximum of 2500 lipase units per kilogram per meal (not to exceed 10,000 lipase units/kilogram per day or 4000 units lipase/ gram dietary fat per day) [105]. Higher doses have been associated with fibrosing colonopathy and are not recommended [106]. Other side effects of PERT include soreness in the mouth and perianal irritation [107]. Allergies may occur due to the porcine origin of the enzyme preparations [107]. Hyperuricemia which was seen with older preparations is rarely seen now [108]. A sudden introduction of PERT to patients with uncontrolled fat malabsorption may lead to severe constipation with accompanying abdominal pain [107].

Enteric-coated microspheres or mini-microspheres of <2 mm in size are the preparations of choice for PERT. The efficacy data of micro- or minitablets of 2.2–2.5 mm in size is limited. In infants, the enzyme microspheres are mixed with a small amount of breast milk or infant formula or soft, acidic food with a pH of less than 4.5 such as applesauce and given via spoon immediately before the feed. In older children, the enzyme should be distributed to a full dose with main meals, and half that dose with snacks. Enzymes should either be given at the beginning of the meal or given half at the beginning and half midway through the meal, particularly if the feeding time is longer than half an hour. The capsules should be swallowed whole without crushing or chewing at as early an age as possible. In a tube-fed patient, PERT in a cartridge form can be connected directly to the enteral feeding pump.

Dietary fat restriction and very high-fiber diets should be avoided in children in EPI (CF and non-CF). Small, frequent, high-energy meals are recommended. However, some children with poor growth, particularly with CF, may not respond to high-calorie foods and oral high-calorie beverages. These children may be candidates for supplemental nocturnal gastrostomy tube feeding. In these patients, pancreatic enzymes should be given before and after the tube feeding or a digestive-enzyme cartridge that can be connected to the enteral feeding system can be used and has been shown to be effective in children with CF. While a polymeric formula is typically used, some children may require a protein hydrolysate formula due to uncontrolled malabsorption or poor growth despite adequate caloric intake. In children receiving the maximum dose of PERT, additional benefit may be obtained by the addition of zinc supplementation (1 mg elemental zinc/kg per day) [93] or acid-blockade medications (proton pump inhibitor) to prevent deactivation of enzymes by reducing luminal acidity. Other causes of malabsorption should be considered if no improvement is observed with all these strategies.

The efficacy of PERT can be observed by the improvement of malabsorptive symptoms such as steatorrhea, bloating, or poor weight gain and the nutritional status of the patients. However, there is no correlation between PERT dose and symptoms [32]. If no improvement is observed, a repeat quantitative fecal fat estimation with PERT or fecal chymotrypsin might be helpful.

In children with CF, CF-specific vitamin preparations are recommended. These vitamin preparations as well as the regular assessments of vitamin status should be considered in all children with pancreatic insufficiency. All patients with EPI should have measurement of fat-soluble vitamins (A, D, E, and K) at diagnosis and then every 6–12 months or every 3 months after a change in vitamin therapy [109]. It is recommended that these vitamins be taken with a fat-containing meal along with PERT. Monitoring of other vitamins, minerals, or trace elements is not routinely recommended unless deficiencies are clinically suspected.

Celiac Disease

40

Stefano Guandalini and Valentina Discepolo

Introduction

Celiac disease (CD) is a complex autoimmune disorder elicited by the ingestion of gluten (the main storage protein in wheat, barley, and rye) in genetically predisposed individuals expressing specific human leukocyte antigen (HLA)-class II haplotypes (called DQ2 and DQ8) and causing an inflammatory disorder of the small intestine. CD is characterized by a variable combination of elevated titers of celiac-specific autoantibodies, an inflammatory enteropathy with variable degrees of severity, and a gastrointestinal (GI) as well as a wide range of extra intestinal complaints [1] whose severity varies from asymptomatic to life-threatening. CD is well known to be often associated with other autoimmune conditions such as type 1 diabetes and autoimmune thyroiditis [2], as well as with some congenital disorders such as Down [3, 4] Turner [5], and most recently also Williams-Beuren syndrome [6].

Epidemiology

Currently, it is estimated that CD has a global prevalence around 1% of the general population [7], although there are important variations between different geographical areas [8–10], even within a single country [11]. Furthermore, CD is more prevalent in females than males [7]. However, since studies of prevalence based on screening do not show such clear-cut difference, it is currently thought that the female predominance could also in part be attributed to the fact that men appear to underutilize health-care services [12, 13]. Over the past several years, it has also become clear that CD prevalence has been progressively increasing [9, 14–18]. While the availability of reliable serological tests to screen for CD as well as an increased awareness, especially in North America, can be considered responsible for increased diagnostic rates, reliable epidemiological data convincingly show worldwide a true increase in prevalence, of the order of doubling rates every 20 years or so. In Northern Sweden, an epidemiological investigation employing a combined serological/endoscopic approach in an unselected population of 1000 adults found a prevalence of almost 2% [19]. Since obviously genetic changes cannot be blamed for this rapid change, a variety of environmental factors have been called as potentially responsible for such increase, but their respective role is still unclear [20]. In fact, for some suspected factors the evidence is at best equivocal or contradictory, among them newer varieties of wheat obtained by breeding techniques [21–23], seasonality and modalities of delivery [24–28], and exposure to antibiotics [29–33]. On the other hand, infections in early life [34, 35] and especially respiratory infections [36] including influenza [37] and infections by *Enterovirus* [38] appear likely to increase the risk of CD development. In this respect, the finding of the role of reovirus in inducing inflammatory response to dietary antigens and favoring CD development [39] appears a key finding. Interestingly, vaccinations do not represent a risk factor [40].

Infant feeding practices have also been deeply scrutinized in a number of observational and interventional studies, and their results can currently be summarized as follows [41, 42]:

- Breast feeding, long thought to have a protective effect on the development of CD, appears not to be beneficial in this regard [43–46].
- Avoidance of cow's milk in early life (suggested to reduce the risk of CD later in life in children at genetic risk) has no protective effect [47].

- Early (before the end of the third month) introduction of gluten is not recommended as it is considered a risk factor [48]. In contrast to this, however, a recent prospective study in the UK [49] showed a different scenario, suggesting on the contrary that – similar to some food allergies – early introduction of gluten could be associated with a *reduced* rate of subsequent CD. As it can be seen therefore, the field is still a rapidly evolving one.
- Introducing gluten in small amounts [44] or after the first year of life [43] does not offer protection, as the strongest factors favoring the onset of CD appear to be gender and HLA status.
- Intake of large amounts of gluten during the first 2 years of age increases the risk of CD in genetically susceptible children [45].
- The possible role of maternal diet during pregnancy and on diet of the child after weaning in influencing the onset of CD has also been investigated. A recent study on more than 80,000 participants [50] showed that higher maternal fiber intake (median 29.5 g/day) was associated with a lower risk of CD in the offspring, and that gluten intake during pregnancy (median 13.0 g/d) was associated with a higher risk of childhood CD, suggesting that maternal diet during pregnancy could impact later CD autoimmunity [50].
- In a large prospective study of dietary patterns of young children, Barroso et al. [51] found that high consumption of vegetables and grains and low consumption of refined cereals and sweet beverages are associated with lower odds of developing CD autoimmunity, the first step in the development of the disease. Thus, an eating pattern that can be reasonably liked to a Mediterranean diet, as opposed to the "Western" diet that appears to be linked with various chronic inflammatory disorders, may have a protective effect.

A plausible mediator of many of the environmental factors mentioned is therefore the microbiome, whose composition and modifications have been shown to play a critical role in the onset (or prevention) of allergic and inflammatory disorders. In recent years there has been therefore an increasing focus on the role of microbiota in the development of CD [52] (see below).

Etiopathogenesis

Like most multifactorial disorders, CD is the result of a complex interaction between genes and immune status of the host and environmental triggers.

Genetic Factors

The weight of genetic predisposing factors in CD pathogenesis is relevant, as initially suggested by the observation of a strong familiar aggregation [53], with a prevalence of CD among first-degree relatives of around 10%. The most important and best-characterized susceptibility gene is the HLA class II; in particular, the HLA-DQ2 and HLA-DQ8 alleles are required for CD development. The concordance rate is about 30% among HLA-identical siblings, 80% in monozygotic twins, and 10% in dizygotic twins [54]. The HLA-DQ2 molecules are expressed on the surface of antigen-presenting cells and contain positively charged pockets that preferentially bind negatively charged epitopes, such as deamidated gliadin peptides (DGP), and present them to cluster of differentiation (CD)-4$^+$ T cells, thereby activating them [55, 56].

The Central Role of HLA-DQ Haplotype

HLA genes are located on chromosome 6 and are divided into three classes (I–III). HLA-DQ (6p21.3) belongs to class II and is composed of a heterodimer located on antigen-presenting cells and encoded by HLA-DQA1 and HLA-DQB1. Each of the copies of the HLA-DQ gene encodes for a heterodimer, resulting in four proteins (one couple per chromosome). HLA-DQ2 homozygote (DQB1*02 on both chromosomes) subjects have the highest risk to develop CD, fivefold higher than heterozygotes [57, 58]. Even if rarer in the general population, DQ2 homozygosis is characteristic of 25% of all CD patients and often relates to a more severe clinical outcome, as suggested by its association with earlier disease onset [59, 60] and its higher prevalence in patients with refractory CD [61], a rare but severe complication of CD. As a matter of fact, the immune response arising in homozygous individuals is stronger than the response in heterozygous individuals [53, 62]. The most common configuration (more than 50% of CD patients) is represented by DQ2.5 (DQB1*02/DQA1*05) heterozygotes [58]. HLA-DQ8 is found in 5–10% of CD patients [58, 63], with HLA-DQ8 homozygosis conferring increased risk compared to HLA-DQ8 heterozygosis [64]. It must be noted that about 5% of CD patients carry only one of the HLA-DQ2 heterodimer alleles (HLA-DQA1*05 or HLA-DQB1*02), therefore encoding for the so-called half heterodimer. These patients constitute the overwhelming majority of CD subjects not carrying the full HLA-DQ2 and/or -DQ8 alleles [65]. The highest risk group includes individuals who inherit both DQ8 and DQ2. Only less than 1% of patients who fulfill clinical criteria for CD do not carry the DQ2 (including half heterodimer) nor the DQ8 alleles [65]. Thus, in the clinical practice, CD can be virtually excluded in individuals lacking

HLA-DQ2 or HLA-DQ8. Interestingly, 30% of European descent individuals carry HLA-DQ2 susceptibility allele; however, only about 4% of these individuals will develop CD [57]. This suggests that even though those molecules are necessary, they are not sufficient to induce the disease, implying that other genetic and environmental factors must contribute to it.

Non-HLA Genetic Susceptibility Factors

HLA alleles explain 35% of the disease genetic susceptibility, while the remaining is due to numerous non-HLA genes that singularly contribute to a much lower extent to CD heritability. Genome-wide association studies (GWAS) performed over the years identified 40 CD-associated susceptibility loci (including the HLA locus) [66]. More recently a meta-analysis identified 2 additional non-HLA CD risk loci reaching genome-wide significance, bringing the number up to 41 [67]. Notably, 64% of the non-HLA loci were shared with at least another autoimmune disease (e.g., type 1 diabetes), reinforcing the idea that autoimmune disorders may share common pathogenic pathways [68]. In those regions, more than 115 non-HLA genes have been associated to CD, individually contributing only modestly to the overall disease risk. Twenty-eight of them encode for molecules involved in the immune response, reinforcing the central role of immune dysregulation in CD pathogenesis. Post-GWAS will need to focus on elucidating the functional basis of these genetic variants and in particular the role of regulatory variation. Furthermore, considering multiple gene variants may help refine risk prediction models and identify high-risk individuals that could benefit from preventive strategies.

Environmental Factors

The high impact of genetic predisposing factors in CD does not exclude a key role of the environment in triggering disease development. In fact, as mentioned above, the increased incidence of CD in the past decades cannot be explained by genetic drift and most likely results from faster changes in the environment. In an elegant review, Abadie et al. [69] showed that CD prevalence does not perfectly correlate, as it would be predicted, with the levels of wheat consumption and frequencies of HLA-DQ predisposing alleles, thus emphasizing the role of environmental factors in CD onset.

The role of infant feeding practices on CD development has been discussed above. Below, we will discuss the role of viral infections and intestinal microbiota.

Viral Infections

Infective agents have been investigated as environmental factors that contribute to trigger CD, as suggested by both epidemiological and genetic studies. GWAS identified polymorphisms in genes involved in the response to viral infections to be associated with CD. Higher rates of summer births were described in children with CD, suggesting that exposure of 4–6-month-old infants to winter-linked viral infections such as rotavirus may play a role. The first correlation between viruses and CD dates back to the 1980s when a homology between alpha gliadin and a protein of the human adenovirus [70] had been described and related to increased frequency of adenovirus infection in CD patients [71] compared to controls. Increased anti-rotavirus antibody titers have also been associated with a moderate, but significantly increased risk of CD in HLA-susceptible children [72]; subsequently [73] anti-rotavirus antibodies have been found related with CD but not with type 1 diabetes mellitus (T1DM) onset, despite the common genetic background and similar pathogenic mechanisms. Over the past decade, several publications have explored the association between viral infections and CD development. Overall, they reported that a high number of infections in the first months of life are associated with an increased risk of later CD development [74]. Of note, the risk increased synergistically if, in addition to infectious episodes, dietary gluten was first introduced in large amounts after breastfeeding was discontinued [35]. Respiratory infections in particular [37, 75] appear to be the ones most commonly associated with CD. Importantly, the risk variance explained by respiratory infections was higher than that explained by sex or HLA [36]. And recently, a clear role for *Enterovirus* infections in early life has also been reported [38]. Altogether these observations provide a strong support for the role of viral infections in CD development. Nevertheless, despite viral infections being very common and HLA-DQ2/8 being present in about 40% of the general population, only 1% develops CD, raising questions about the pathogenic mechanisms behind this association. The first work showing evidence for a mechanism behind the association of viral infections and CD was published in 2017 and showed that a specific strain of reovirus (T1L), despite being cleared by the host, could disrupt immune homeostasis at intestinal sites of oral tolerance by suppressing peripheral regulatory T cell conversion and promoting a proinflammatory T helper cell response to orally ingested gluten [39]. Importantly, the two responses depended on distinct but interplaying pathways. Lastly this study showed increased anti-reovirus antibodies in CD patients, suggesting that the risk of later disease development is independent from the severity or virulence of the infection; in fact reovirus causes asymptomatic infections in humans. Whether there is an early time window during which infections are more likely to promote CD, remains to be determined, as well as the interplay with other factors such as timing and amount of first dietary gluten introduction, breastfeeding, and declining of maternal antibody titers.

Finally, the role of viral infections beyond promoting loss of tolerance to gluten, such as their ability to enhance the progression of the disease to tissue damage, is unexplored.

Intestinal Microbiota

The composition of intestinal microbiota as well as bacterial metabolic products can affect intestinal epithelium function and mucosal immune homeostasis. Both quantitative and qualitative differences in the composition of the intestinal microbiome have been observed in patients with autoimmune disorders [76, 77], as well as CD, as recently reviewed [52] when compared to healthy individuals. In addition, disease activity and response to the diet may also play a role [78].

The variability between fecal and duodenal microbial niches, the different methodologies used across studies, and the heterogeneity of CD patients make the identification of a CD-specific microbiota a hard task. Nevertheless, most evidences point to an expansion of Proteobacteria and opportunistic pathogens such as *Neisseria* [79] or *Escherichia coli*, as well as higher bacterial virulent genes, supporting the idea of a shift toward a proinflammatory microbial community [78].

Even when looking at children at higher genetic risk to develop CD, an increase in pathogenic bacteria has been observed [80]. In fact, the HLA genotype seems to influence the early intestinal microbial composition [81]. Moreover, non-HLA genes associated with protection to infections or bacterial recognition have been related to CD, suggesting that a genetically determined pattern of microbial colonization might influence the immune maturation process and thus promote later CD onset [82].

Currently, it is still unclear whether the observed changes in the microbial composition are the cause or the result of the intestinal inflammatory process. Indeed, epithelial alterations, such as those described in CD, could create a specific environment favoring the selective colonization of some microbial species, thus contributing to the creation of the microenvironmental milieu that favors the disease development. This is clearly a rapidly evolving field, likely to bring important new acquisitions in the near future.

Pathogenesis

CD is a chronic inflammatory disorder with autoimmune features, characterized by a gluten-specific T cell-mediated immune response arising in the small intestinal mucosa upon gluten ingestion. In genetically susceptible individuals, gliadin peptides activate stress pathways and provide ligands for innate immune receptors, leading to the release of proinflammatory mediators that then sustain the T cell response both in the lamina propria and in the epithelium (Fig. 40.1). This inflammatory reaction typically involves both the innate and the adaptive arms of the immune response [83]. In this model, two hits are required, each one being necessary but not sufficient for the development of CD: one is the activation of stress markers in intestinal epithelial cells and the second is the rise of a gluten-specific proinflammatory $CD4^+$ T cell response in the lamina propria. These two events lead to the full activation of lymphocytes in the intestinal epithelium (intraepithelial lymphocytes (IELs)), final responsible of tissue destruction [84, 85].The major players of the pathogenic events leading to full-blown CD are illustrated in the following sections.

Gluten

The immunological reaction occurring in CD patients follows the ingestion of gluten-containing cereals: wheat, rye, and barley. Glutenins and gliadins, typical gluten components, are responsible for the viscosity and elasticity of the wheat dough [86]. Their high concentration of glutamine and proline residues (35% and 15% of the total amino acid content) renders them highly resistant to gastrointestinal enzymes. Indeed, the lack of prolyl-endopeptidase activity in any of the human digestive enzymes prevents enzymatic attack of proline-rich domains in gluten proteins. Thus, at the end of a normal, full digestive process of gluten, many gliadin peptides remain undigested in the intestinal lumen. The mechanism through which such peptides reach the intestinal lamina propria is not entirely clear. Gliadin is able to enhance gut paracellular permeability via zonulin-mediated pathway, a molecule involved in tight junction disassembly, as suggested also by genetic studies associating tight junction genes with CD [87]. Moreover, there is evidence that gluten can cross the intestinal epithelium through the transcellular pathway once tolerance to gluten has been broken.

Even though an increase in intestinal permeability has been shown in CD, a retro-transcytosis pathway has been described for secretory antibodies, potentially having a role also for gliadin transport. In fact, the transferrin receptor CD71, normally expressed on the basolateral side of enterocytes, is overexpressed on the luminal side of the intestinal epithelium in active CD patients, leading to an apical-to-basal retro-transcytosis of gliadin peptides complexed with secretory IgA [88]. This process protects gliadin fragments from degradation and facilitates their access to the intestinal lamina propria, thereby perpetuating the inflammatory process.

Tissue Transglutaminase 2 and Autoantibodies

In the lamina propria, tissue transglutaminase 2 (tTG), a calcium-dependent transamidating enzyme, mediates the conversion of glutamine residues into glutamic acid, introducing negatively charged residues into gliadin peptides that act as immunogenic epitopes binding to HLA-DQ molecules with relatively higher affinity, thus representing a pre-

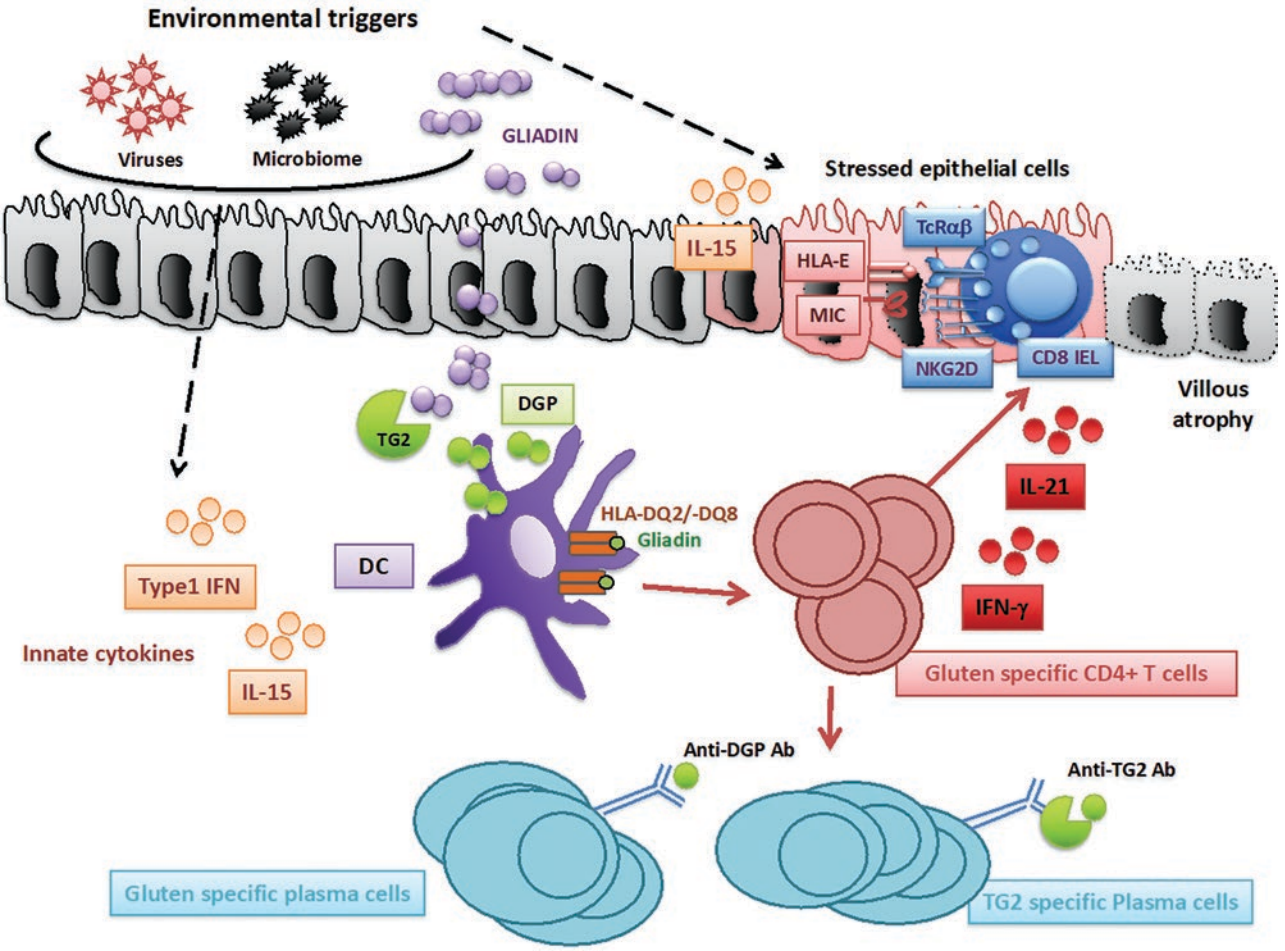

Fig. 40.1 CD pathogenesis. Celiac disease (*CD*) is a multifactorial disorder induced by gluten in genetically susceptible subjects. Several environmental factors (i.e., viral infections, alterations in microbiome composition, etc.) can contribute to trigger the disease by inducing epithelial stress in the intestinal mucosa, and the production of innate immune cytokines, such as interleukin (*IL*)-*15* and type-1 interferon (*IFN*). Those cytokines contribute to create a proinflammatory environment that enhances dendritic cell (DC) activation. Undigested gliadin peptides (*purple circles*) reach the intestinal lamina propria where they are deamidated by tissue transglutaminase 2 (*TG2*). Deamidated gliadin peptides (DGP) are more suitable to be presented by HLA-DQ molecules. Only DCs expressing the CD-associated HLA-DQ2 and/or HLA-DQ8 molecules (*orange*) can present deamidated gliadin peptides (*green circles*) to naïve CD4⁺ T cells (*red cells*). Inflammatory DCs (*purple*) enhance the rise of a gluten-specific CD4⁺ T cell response, characterized by the production of high levels of proinflammatory cytokines such as *IFN-γ* and *IL-21*. Furthermore, gluten-reactive CD4⁺ T cells provide the required help to TG2-specific B cells, presenting TG2-gliadin complexes, in a hapten carrier-like manner, and drive TG2-specific antibody production by plasma cells (*light blue cells*). IL-15 and IL-21 contribute to the full activation of cytotoxic CD8⁺ intraepithelial lymphocytes (*IEL*). An increased epithelial expression of stress markers (i.e., MIC, HLA-E, and IL-15) is also required to enable activated CD8⁺ IEL to target the intestinal epithelial cells and determine villous atrophy in CD patients. NKG2D natural killer group 2, member D, MIC macrophage inhibitory cytokine

requisite for a gluten-specific T cell response [89]. In addition to its crucial role in inducing post-translational modification of gluten peptides, tTG is also the main autoantigen for CD. In fact, increased serum levels of anti-tTG IgA (or IgG, in case of IgA deficiency) autoantibodies is a key diagnostic feature of CD. Their production seems to occur at the level of the small intestine. The most accepted hypothesis for their formation is that the enzyme tTG cross-links itself to gluten during the substrate-enzyme interaction [90]. Once internalized, those complexes are processed and gluten epitopes bind HLA-DQ molecules of the B cell that may allow gluten-reactive CD4⁺ T cells provide the required help to tTG-specific B cells in a hapten carrier-like manner and drive tTG-specific antibody production. In fact, a very high proportion of the gut plasma cells, which expand massively in the lamina propria during active CD, were shown to produce IgA specific for gluten or TG2 or both.

The Intersection of Adaptive and Innate Immune Responses in CD

Gluten contains a large number of peptides capable of stimulating T cells [91]. Dendritic cells present negatively charged glia-

din peptides through HLA-DQ2 or HLA-DQ8 molecules to naïve CD4+ T cells, thus enhancing a gluten-specific T helper 1 (Th1) inflammatory response, characterized by the production of high levels of interferon gamma (IFN-γ) and interleukin (IL)-21 in the small intestinal lamina propria (Fig. 40.1). The gluten-specific CD4+ T cell response, which contributes also to the autoantibody's generation, is sustained by several cytokines, including IL-15 and IL-21, that synergistically promote gluten-mediated increase of IFN-γ production. The expression of IL-21, enhanced by gluten, is very high in active CD patients, while it is downregulated in potential CD [92], suggesting that this cytokine plays a key role in the development of tissue damage. The rise of a gluten-specific CD4+ T cell response could be triggered by specific viral infections, as shown for reovirus T1L strain that can induce loss of tolerance to oral antigens via an IRF-1-mediated pathway [39], but also possibly by bacterial antigens. Once activated, the gluten-specific T cell response contributes to amplify the inflammatory response; nevertheless, as evident in potential CD patients, the gluten-specific T cell adaptive immune response alone can occur even in the absence of villous atrophy, suggesting that other signals are required to induce tissue damage.

In addition to the immunodominant epitopes, which, as discussed, are presented to CD4 naïve T cells, gliadin also contains fragments which are able to enhance epithelial stress and induce innate immune effects [93]. The most studied fragment is the peptide 31–43 (P31–43) of α-gliadin, which is able to upregulate major histocompatibility complex (MHC) class I-related molecules (MICs) [94], to activate the mitogen-activated protein (MAP) kinase pathway and induce apoptosis in intestinal epithelial cells. P31–43 induces cell proliferation and actin cytoskeleton rearrangements in *in vitro* and *ex vivo* models [95, 96]. The proliferative response elicited by P31–43 in CD mucosa involves epidermal growth factor (EGF)/IL-15 cooperation. In addition, P31–43 enhances the expression of IL-15 in the small intestinal epithelium. IL-15 contributes to enhance the expression of activating natural killer receptors (NKRs) on IELs and impair the function of regulatory T cells in CD patients [97]. Activating NKRs are required for the acquisition of cytolytic property by IELs. In addition to IL-15, type-1 IFNs, innate cytokines promoted upon viral infections, are responsible for inhibiting the regulatory T cell response that counterbalance the proinflammatory T cells [39]. The interplay between the adaptive gluten-specific T cell response and the innate immune pathways is key to determine the full activation of IELs that finally leads to villous atrophy.

IELs Activation and the Induction of Tissue Damage

The profound remodeling of the small intestinal architecture typical of CD is characterized by intraepithelial lymphocytosis, villous atrophy, and crypt hyperplasia. IELs represent a heterogeneous population including TcRα/β CD8 cells, NK-like cells, and TcRγ/δ cells. An increase in both TcRα/β and TcRγ/δ populations has been described in CD patients; however, the role of the former has been investigated more extensively than the latter in the context of CD pathogenesis. A permanent reshaping of the TcRγ/δ IELs compartment has been recently described in CD as characterized by an expansion of gluten-sensitive and IFN-γ-producing Vδ1+ IELs that the exclusion of dietary gluten was insufficient to revert [98].

TcRα/β IELs are the final responsible for tissue destruction. A fully active phenotype characterized by an upregulation of activating NKRs, downregulation of inhibitory NKRs, and expression of granzyme B and perforin is typically found in active CD patients [84]. The activation of their cytotoxic properties requires also stimuli from the epithelial compartment. An increased expression of stress molecules, such as nonclassical MHC class I molecules (i.e., MIC and HLA-E), has been found in intestinal epithelial cells of active CD patients, as part of the innate stress response induced by gluten or by other environmental triggers. Notably, MIC and HLA-E are ligands for NKG2D and CD94, respectively, activating NKRs that are upregulated on IELs in active CD patients and whose expression is enhanced by IL-15 [83–85].

Increased levels of both IL-15 and IL-21 in the duodenal mucosa of untreated CD patients cooperatively promote the activation of TcRα/β IELs by increasing their transcriptional, proliferative, and cytolytic activities [99]. The evidence that low levels of both cytokines are found in potential CD patients supports their key role in tissue damage. The activation of IELs, with increased Fas ligand expression, results in epithelial cell apoptosis and villous atrophy via interactions with Fas on intestinal epithelial cells.

The end result of the above-described immune events is the typical CD lesion characterized by intraepithelial lymphocytosis, crypt hyperplasia, and villous atrophy. These changes occur in a continuum: from a normal mucosa to a complete flattening of the villi in a slow progression. Marsh described in detail such progression [100] and his scoring system is utilized by pathologists to classify CD duodenal damage as follows:

Type 0 or pre-infiltrative stage (normal)
Type 1 or infiltrative stage (increased IELs)
Type 2 or hyperplastic stage (type 1 + hyperplastic crypts)
Type 3 or destructive stage (type 2 + villous atrophy of progressively more severe degrees, denominated 3a-partial atrophy, 3b-subtotal atrophy, and 3c-total atrophy)

A Mouse Model of CD

To shed light on the reciprocal contribution of the innate and adaptive immune responses in the context of CD pathogen-

esis, a triple transgenic mouse model has been recently developed [101]. It does not only express the human HLA-DQ8 (I), one of the alleles that predisposes to CD development, but reproduces also the overexpression of IL-15 in both the small intestinal epithelium (II) and the lamina propria (II), similarly to what is observed in active CD patients. This animal model spontaneously develops villous atrophy after protracted gluten ingestion, which is restored upon gluten withdrawal. Notably, when lacking one of the three above-mentioned trans-genes, the intestinal damage was prevented, thus showing that overexpression of IL-15 in both mucosal compartments (epithelium and lamina propria) is required for the development of villous atrophy upon gluten exposure in a genetically predisposed host. Importantly, this model allowed to demonstrate that the gluten-specific $CD4^+$ T cells, the HLA-DQ8 expression, the cytokine IFN-γ, and the enzyme tTG have a crucial role in tissue destruction, suggesting new avenues for potential therapeutic strategies. Lastly, the availability of an animal model in which the tissue damage develops and reverts in response to gluten provides a key tool for testing newly developed drugs.

Clinical Presentations

Atrophy of the villi of various degrees (from partial to total) with crypt hyperplasia results from the inflammatory changes described in the previous section and is correlated with the extent of the specific autoantibodies (see below under "Diagnosing Celiac Disease"). It should be noted however that the severity of the villous atrophy does not predict the long-term outcome of CD [102]. Malabsorption of nutrients thus ensues and with this, understandably, a number of gastrointestinal symptoms. But the clinical manifestations of celiac disease go well beyond the intestine, so that basically all systems and organs can be involved, leading to a variety of extra-intestinal manifestations. In fact, CD presentation has substantially changed over time [103–106], both in children and in adults, moving from a malabsorptive disorder causing blatant GI symptoms and malnutrition (with failure to thrive being a common occurrence), to a more subtle condition causing a variety of extra-intestinal manifestations that can occur either with or without a concomitant GI involvement. Moreover, it is also well known that CD may be entirely asymptomatic, as we have come to know from screening unselected populations or first-degree relatives of known patients. It is no surprise therefore that the diagnostic rate around the globe is quite dismal, as both the general public and the health-care providers may miss the oligo- or a-symptomatic individuals as well as those whose symptoms do not include obvious GI involvement [107].

Table 40.1 lists the main presentations of CD. As it can be seen, the clinical manifestations can be protean, thus making the diagnosis not obvious in most cases. When CD has its onset in infancy and very early childhood, the GI manifestations typically prevail and can be quite aggressive, resulting in a clinical picture of malnutrition and failure to thrive, often associated with a protein-losing enteropathy. Subsequently, however, the onset may be more subtle, and extra-intestinal manifestations become more common.

GI Manifestations

Among the most frequent GI manifestations of CD are abdominal pain and bloating [108]. Chronic or intermitted diarrhea, characterized by bulky, foul-smelling, greasy stool, is also a very common symptom in children with CD. Its occurrence, however, is progressively becoming less frequent than in the past [105]. Counterintuitively, long-standing and occasionally severe constipation can be the presenting manifestation in a significant portion of both

Table 40.1 Main presenting signs, symptoms, and laboratory changes in celiac children

GI manifestations	Extra-GI manifestations	Laboratory findings
Abdominal pain, bloating	Weight loss/failure to thrive	Elevated CD-specific antibodies Hepertransaminasemia
Diarrhea	Delayed puberty	Anemia (especially iron-deficient)
Vomiting	Short stature	Vitamin D deficiency
Constipation	Dermatitis herpetiformis	Osteopenia
Anorexia	Aphthous ulcers/geographical tongue	
Intussusception	Dental enamel defects	
Celiac crisis	Osteopenia, osteoporosis	
	Arthritis, arthralgia	
	Alopecia areata	
	Headaches, migraine	
	Peripheral neuropathy	
	Idiopathic seizures	
	Sad mood/depression	
	Psychiatric disorders	
	Fatigue	

pediatric and adult patients [108–110]. Constipation appears to be related to a well-documented delay in oro-cecal transit time [111] possibly caused in part by disturbed upper GI motor function [112]. Other presenting symptoms related to the GI tract are vomiting (especially in infants and toddlers), weight loss, or failure to thrive. Poor appetite, occasionally severe like a true anorexia [113], can be an accompanying symptom, leading – particularly in cases of delayed diagnosis – to severe malnutrition and cachexia (Fig. 40.2). However, it should be noted that children with CD can also be overweight or obese, as well documented in the literature [114–116], so that the absence of malnutrition should by no means rule out the possibility of CD.

Recurrent intussusception, an uncommon but important GI sign, was first described in 1997 [117] and is now a well-described occurrence in CD children, known to be more frequent in undiagnosed CD children than in control populations [118].

More rarely CD can have its onset with a dramatic, acute presentation, referred to as "celiac crisis." This term describes a sudden onset episode of explosive diarrhea associated with protein-losing enteropathy, hypoalbuminemia, and profound electrolyte abnormalities with metabolic acidosis leading to dehydration and lethargy, occurring most commonly before the diagnosis of CD and in young children, although documented in adults too [119].

Fig. 40.2 Typical GI presentation in young children. Left panel: a 19-month-old girl at the time of diagnosis. Right panel: the same patient 6 weeks later

Extra-Intestinal Manifestations and Laboratory Changes

Extra-intestinal symptoms (Table 40.1) occur at similar rates in children and in adults [120]. In children, short stature, fatigue, and headache appear to be the most common. Failure of proper height gain can be an isolated initial presentation of CD [120, 121] and can be found in up to 10% of children being investigated for short stature. If diagnosed with enough time before the onset of puberty, it typically responds well to the GFD [120]. While some of the extra-intestinal manifestations such as weight loss, fatigue, short stature, and delayed puberty can be attributed to nutritional deficiencies and their metabolic consequences, others follow different and often poorly understood pathways.

Dermatitis herpetiformis (*DH*) (Fig. 40.3) is considered the skin manifestations typical of celiac disease [122]: autoantibodies against epidermal transglutaminase (TG3), the supposed autoantigen of DH, are at play in this condition also characterized – but by no means constantly – by villous atrophy. Rare in children, DH affects mostly teenagers and adults who present symmetrical, pruritic blisters followed by erosions, excoriations, and hyperpigmentation. The most involved sites are mainly the extensor surfaces of elbows and knees, followed by shoulders, buttocks, sacral region, and face. Itching of variable intensity, scratching, and burning sensation immediately preceding the development of lesions are common. The diagnosis of DH is made by a direct immunofluorescence biopsy of unaffected skin in close proximity to an active lesion [123]. Pathognomonic granular IgA deposits at the dermo-epidermal junction are seen (2 D). Its treatment is based on a strict GFD that is typically extremely effective. Dapsone and/or other drugs can be used during the early phase of treatment, until the GFD becomes effective [124].

Oral manifestations are well described too, among them, dental enamel hypoplasia, geographical tongue, and aphthous ulcers. Dental enamel hypoplasia has been reported with a prevalence ranging from 10% to 97% [125–129],

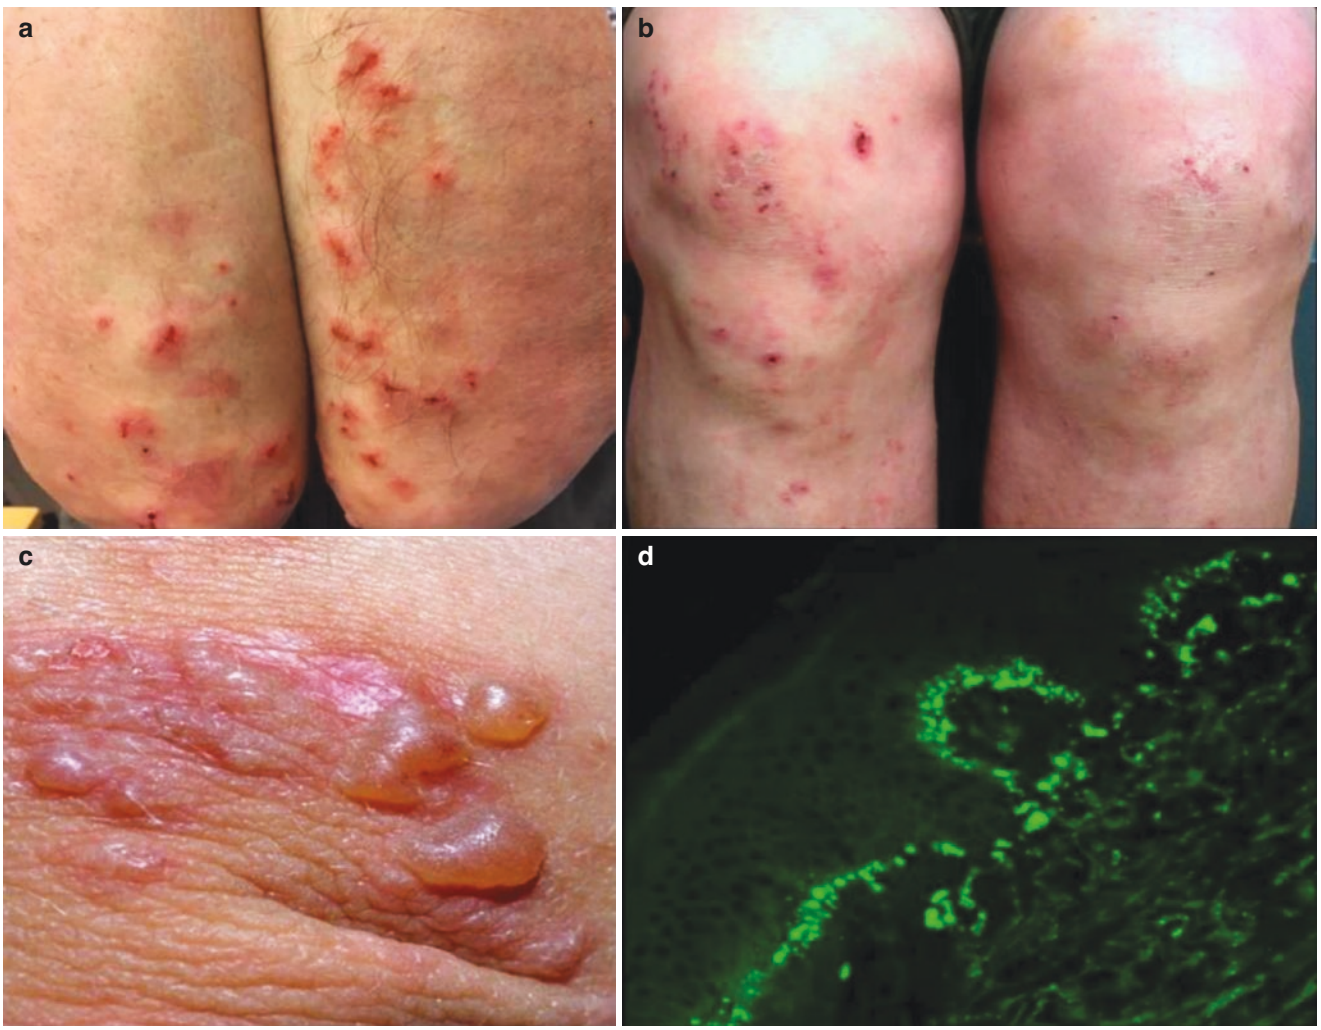

Fig. 40.3 Dermatitis herpetiformis [from Ref. [122], reprinted with permission]. Typical scratched papules and macules on the elbows (**a**) and on the knees (**b**). Fresh small blisters on the elbow (**c**). Direct immunofluorescence showing granular IgA deposits in the basal membrane zone between the epidermis and dermis (**d**)

more commonly in children. This defect is thought to be secondary to nutritional deficiencies and immune disturbances during the period of enamel formation, mostly the first 7 years of life [130]. Other enamel defects that can be associated to CD are enamel pitting, grooving, and partial or complete loss of the enamel. Of note, dental enamel defects can be found in children in the absence of any other symptoms, as documented in a large epidemiological study in Italian children [131], and are therefore a useful screening tool. Aphthous ulcers can be present in children with CD [132], although they are neither characteristic nor specific to CD since they can also be associated with other medical conditions such as inflammatory bowel disease and Behcet's disease. CD has been reported as more prevalent in children with geographic tongue, a benign inflammatory condition of unknown etiology usually involving the dorsal surface and lateral borders of the tongue, than in the general population [133]. As in many of the extra-intestinal manifestations, geographic tongue too can occur in the absence of GI involvement.

Low bone mineral density is found in many newly diagnosed patients [134] and, in some cases, especially in adults, is advanced to osteoporosis and can be associated with fractures [135]. The etiology of such bone alterations in CD is multifactorial, thought to be mostly secondary to the combination of intestinal malabsorption and chronic inflammation. Recently, higher serum OPG, telopeptide, and lower serum pro-peptide have been found in adult CD patients with low bone mineral density, suggesting an increased bone turnover [136]. Low bone mineral density apparently responds well to the GFD in CD children, and recent data suggest that adult patients too can improve their bone mineral density after some years on GFD [137].

Joint involvement, though not too common, has been described in children and adults with CD [138], and it is suggested that patients presenting with unexplained articular manifestations be tested for CD [139, 140].

Alopecia areata is a common form of hair loss in childhood, affecting about 1–2% of the population and characterized by a sudden onset of patchy hair loss on the scalp. It is considered an autoimmune condition, and it has been shown to be more common in children with CD [141], once again even in the complete absence of GI manifestations. Good response to the GFD has been observed [120].

Children with CD have an increased frequency of *neurological symptoms* compared to controls [142]. The most common is definitely headache [143–145] that appears in 18% of children [145] and in most cases responds well to the GFD [120]; but also peripheral neuropathy [142] and seizures [146] are well described; ataxia on the other hand is described almost exclusively in adult cases [147]. The prevalence of epilepsy in CD children also appears to be higher than expected, as reported in a recent large epidemiologic study [148]. Seizures are often generalized tonic-clonic, but partial and occasionally absence seizures are also reported. In some patients with CD and epilepsy refractory to antiepileptic drugs, seizures have been controlled with a GFD [149, 150]. Hence, it is recommended that patients with epilepsy without a clear etiology should be screened for CD, as an early diagnosis and treatment might be beneficial. Relatively common in children and especially in adolescents are also psychiatric issues [151] including anxiety, often with recurrent panic attacks, hallucinations, and depression that appear to persist into adult life [151]. A moderately increased risk of suicide in CD patients has also been reported [152]. Interestingly, there is some evidence that the GFD may help in alleviating depression in celiac adolescents [153].

Elevation of *liver* transaminases is well described in pediatric CD, either idiopathic or associated to autoimmune hepatitis, and is thought to be present in about one-third of all children with CD [154], while CD is found in 12% of children with mild unexplained hypertransaminasemia. Of note, GFD normalizes transaminase levels in most patients with CD within a few months.

Anemia in CD children can be the end result of several different, and sometimes combined, causes [155]; however, the single most common type of anemia is due to iron deficiency (IDA). IDA may be the only clinical abnormality identified in many patients and can be the presenting feature of CD, especially in older children and adults [156]. Anemia at CD diagnosis is associated with more severe histological and serological presentation in children [156, 157]. However, even when asymptomatic, CD can lead to IDA; in a large series of patients with asymptomatic CD, IDA was indeed found in almost half of the patients, with adults having a higher incidence than children: 46% versus 35% [158].

The most common *vitamin deficiency* found in children with CD at diagnosis is vitamin D [159, 160], a factor likely to contribute to the low bone mineral density [161]. Testing for its level is therefore recommended [162] at diagnosis, when instruction on age-appropriate intake of calcium and vitamin D, in order to provide adequate replenishments, should be provided during nutritional counseling along with the need for exercise to promote bone health.

Disease Associations

Autoimmune and some chromosomal disorders have been known for a long time to be associated with CD. In addition, several large-scale epidemiological investigations have revealed a growing number of additional associated conditions, although in most cases the reasons for such associations and their clinical relevance remain unclear (Table 40.2). Among the conditions with increased prevalence in CD, mostly occurring however in adults, are asthma [163],

Table 40.2 Main conditions associated with celiac disease

Diseases	Autoimmune conditions	Genetic/ chromosomal disorders
Juvenile idiopathic arthritis	Type 1 diabetes mellitus	Selective IgA deficiency
Asthma	Thyroid disease: Hashimoto thyroiditis Graves-Basedow disease	Down syndrome
Eosinophilic esophagitis	Addison disease	Turner syndrome
Gastroesophageal reflux	Psoriasis	Williams-Beuren syndrome
Pancreatitis	Systemic lupus	
Adrenal insufficiency		
Idiopathic dilated cardiomyopathy		
Atrial fibrillation		
Cataracts		
Uveitis		
Renal disease		
Stroke		
Chronic obstructive pulmonary disease		

chronic obstructive pulmonary disease [164], cardiac disorders and strokes [165–167], gastroesophageal reflux disease [168], pancreatitis [169], ocular complications [170, 171], idiopathic dilated cardiomyopathy [165], renal disease [172], adrenal insufficiency [173], and systemic lupus [174].

Of note, in children, the association with eosinophilic esophagitis has been described [169] and the effect of GFD in both conditions has been assessed [175].

Autoimmune Conditions

CD shows a strong association with autoimmune disorders, thought to be mostly due to a shared genetic component in the HLA region [2]. The best described association is with T1DM, a condition sharing common pathogenetic mechanisms with CD [176]. Indeed, CD has a prevalence of approximately 10% among T1DM patients [177–179]. About two-thirds of children diagnosed with CD after T1DM onset have elevated levels of celiac antibodies at the time of T1DM diagnosis or within the first 24 months; however, an additional 40% of patients develop CD a few years after T1DM onset [180], and even adults with a long history of T1DM show a progressively higher prevalence of CD [181]. Thus, it is recommended that T1DM children be repeatedly tested for CD. Of note, it has been shown that the presence or absence of GI symptoms in children with T1DM has no predictable value for biopsy-confirmed CD or not [182]. In fact, many diabetic children who come to be diagnosed with CD have minimal or no symptoms. Testing children with T1DM for CD is recommended by the American Diabetes Association; the International Society for Pediatric and Adolescent Diabetes; the British Society of Paediatric Gastroenterology, Hepatology and Nutrition; the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) in their 2012 as well as 2020 guidelines; and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition [1, 183–187]. As patients with T1DM can however have mildly elevated titters of TTG-IgA independently of CD, it is recommended to proceed with the confirmatory biopsy only when their titer is >3 times the upper limit of normal (ULN). Clearly, once diagnosed with CD, children with T1DM need to follow a strict GFD; however, its effects on diabetic control are unclear. In fact, glycemic control, both in children with or without malabsorption, has been found either improved or unaffected [181].

Autoimmune thyroid diseases (both Hashimoto's thyroiditis and Graves-Basedow disease) are more frequent in CD children than in controls [188]. In these patients, GFD does not appear to prevent the progression of the autoimmune process [189].

Addison disease, mostly in adults, has an increased prevalence in CD patients as well [190]. Psoriasis appears to be more prevalent in CD patients, too [191].

The issue of whether the onset of autoimmune disorders in CD patients is favored by the ingestion of gluten (either before or after diagnosis) remains controversial. An increased prevalence of autoimmune disorders was found in parallel with the increasing age at diagnosis of CD [192], suggesting that prolonged exposure to gluten may indeed favor the onset of autoimmune conditions. However, as further studies on this issue have revealed conflicting results, the issue is still unclear [193].

Genetic/Chromosomal Disorders

Selective IgA deficiency has also been associated with CD. In fact, about 14% of IgA-deficient children are celiac [194] and about 2% of CD children are IgA-deficient [195]. While clinically not relevant, this association bears important implications in the strategy for diagnosing CD (see below). CD prevalence has been found to be between five- and tenfold higher in children with Down syndrome [3, 4], Turner syndrome [5], and Williams-Beuren syndrome [6] than in the general population; hence, they need to be screened for CD. Finally, given the high prevalence among first-degree relatives of CD patients [196], they must be screened too for CD even if asymptomatic.

Diagnosing CD

Given the various clinical manifestations of CD, which can also be asymptomatic, as well as the association with other conditions, clearly the first requisite for diagnosis is a high degree of suspicion. Table 40.3 lists the circumstances that demand testing for CD regardless of the presence or absence of symptoms. The availability of very sensitive and specific IgA autoantibodies, generated in the small intestinal mucosa and detectable in the serum, such as the tTG-IgA or anti-endomysium IgA (EMA-IgA) [197], has given the physician a powerful screening tool. In addition, another class of antibodies has also been found valuable in screening and in following up CD patients: the anti-deamidated gliadin peptide (DGP) antibodies (both IgA and IgG), produced against the gliadin peptides after they have been modified by the tTG [198].

The first step in screening for CD in subjects of any age who are on a gluten-containing diet is the serum level of tTG-IgA [1, 185, 186, 199], considered to possess the highest degree of sensitivity, thus basically avoiding missing any case of CD. Total serum IgA levels however need to be added in order to ascertain that the individual can produce tTG-IgA and identify IgA-deficient subjects. In those cases, both tTG-IgG and DGP-IgG [200, 201] can be usefully checked as markers of CD.

In 2012, an ad hoc task force of ESPGHAN published revised criteria [1] and produced an evidence-based algorithm that allowed the physician to skip the duodenal biopsy under certain circumstances, namely, in patients showing a genetic asset and a history compatible with CD and very elevated titers (more than ten times the ULN) of tTG-IgA, along with a positive EMA titer. In the years that followed, many observations were carried out in various parts of the world, including in North America [202], basically validating this suggested approach. Then in 2020, after gathering multicenter experience, ESPGHAN went further eliminating the need to document a consistent genetic asset as well as the presence of CD-compatible symptoms, stating "If TGA-IgA is ≥10 times the ULN and the family agrees, the no-biopsy diagnosis may be applied, provided EMA-IgA will test positive in a second blood sample. *HLA-DQ2/-DQ8 determination and symptoms are not obligatory criteria*. CD diagnosis can be accurately established with or without duodenal biopsies if given recommendations are followed" [186]. It is estimated that by applying this approach, about 50% of children presenting with a suspected CD can be diagnosed without a biopsy. In addition, a recent study in the USA [203] estimated that using this algorithm could avoid "between 4891 and 7738 pediatric endoscopies per year in the United States," thus resulting in a considerable cost saving. The algorithm presented in Fig. 40.4 (from Ref. [186] summarizes accordingly the diagnostic steps for a child/teenager suspected of CD).

Table 40.3 Subjects to be screened for CD

All those presenting the conditions listed in Tables 40.1 and 40.2
First-degree relatives of celiac patients
Autoimmune conditions
Type 1 diabetes
Autoimmune thyroiditis
Autoimmune hepatitis
Addison's disease
Hashimoto Thyroiditis
Graves-Basedow disease
Genetic/chromosomal disorders
Selective IgA deficiency
Down syndrome
Turner syndrome
Williams-Beuren syndrome

Subjects with normal serum IgA and normal tTG-IgA CD can be excluded, given the high sensitivity of the test; however, the rare seronegative CD patient has been described [204], more commonly among adults [205]. Thus, in the presence of a strong clinical suspicion, it would be appropriate to still proceed with the diagnostic biopsy even with normal CD-specific antibodies. A recent consensus statement [206] recommends that – after having ruled out alternative causes for villous atrophy – patients with suspected CD who are seronegative but have villous atrophy and are HLA-DQ2 or DQ8-positive should be put on a GFD and then re-assessed endoscopically after 1–3 years on a GFD, to evaluate resolution of the villous atrophy that would confirm the diagnosis. On another hand, if the subject has positive tTG-IgA, but at titers lower than 10 times normal and/or with a negative EMA, then the EGD would be necessary.

During the upper endoscopy it is important to obtain at least four biopsies from the distal duodenum, and one or two from the bulb; otherwise the diagnostic yield may be jeopardized by the occasional patchy duodenal lesions. In interpreting the pathology of the duodenal biopsies, caution must be exerted for findings of Marsh type 1, especially when not supported by positive serology. In fact, such increase in IELs ("lymphocytic duodenosis") has been found to be due to CD in no more than 16–39% of cases [207, 208]. Thus, additional conditions (Table 40.4) must be carefully ruled out before concluding for CD. As for those with a Marsh type 0, the call is even more delicate. In fact, patients could be defined as "potential CD" if tTG-IgA and EMA titers are positive; while in case of low titers of tTG-IgA and a negative EMA, the possibility of a false-positive tTG-IgA must be considered. This occurrence is especially common, for unclear reasons, in children with T1DM, where tTG-IgA has also been found to spontaneously normalize [209–211]. Asymptomatic patients with mild elevation of tTG-IgA but a normal biopsy should therefore remain on a gluten-containing diet and be carefully monitored.

Potential Celiac Disease

More complex is the decision about the need for a GFD for true "potential" CD children and adolescents. A large prospective study conducted in Italy [212] with up to 12 years of follow-up of 280 of these children investigated the possible risk factors associated with the development of villous atrophy. The children underwent serologic tests twice a year and a small bowel biopsy every 2 years. During the follow-up period, 42 (15%) of 280 children developed villous atrophy, whereas 89 (32%) children no longer tested positive for tTG-IgA or EMA. The cumulative incidence of progression to villous atrophy was 43% at 12 years. Of interest, the factors most strongly associated with development of villous atrophy were numbers of γδ IELs followed by age (younger children having less chances of developing full-blown CD) and HLA-DQ2 homozygosity.

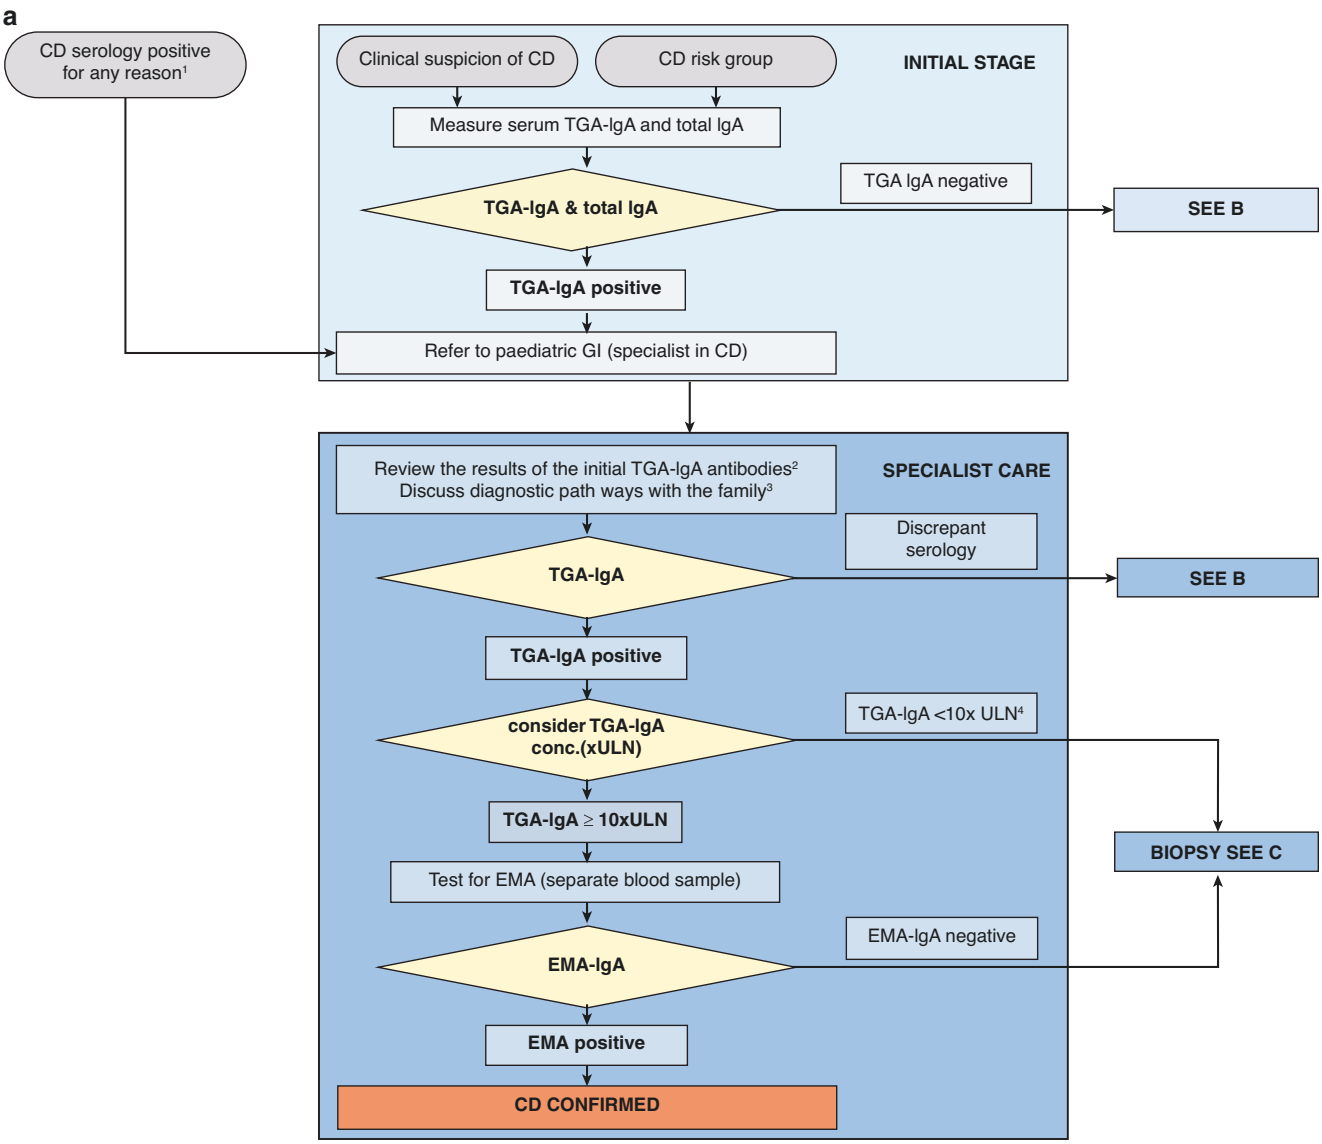

Fig. 40.4 Algorithm for diagnosis of celiac disease [from [186], reprinted with permission]. (**a**) in IgA-competent subjects, (**b**) in IgA-deficient subjects, and (**c**) for biopsy

[1] Other than TGA-IgA, including point-of-care tests and DGP

[2] Check the value also in relation to the cutoff and repeat the test if questionable or borderline. No need to retest if done with validated assay with calibration curve. Test with conventional TGA-IgA test if positive POCT and TGA has not been measured quantitatively

[3] Convey the message that the diagnosis of celiac disease with or without biopsy confirms the need for a lifelong gluten-free diet and that re-evaluation after introduction of the diet would need prolonged re-exposure to gluten with a series of further investigations

[4] If TGA-IgA is only borderline positive, confirm sufficient gluten intake and consider re-testing of TGA-IgA and EMA

[5] Low for age or <0.2 g/L above the age of 3 years

[6] For example, dermatitis herpetiformis, in which serology is frequently negative

[7] The cutoff for normal numbers of IEL is >25 cells/100 enterocytes. The action done at the initial stage in primary care (light blue) is separated from specialist care (dark blue)

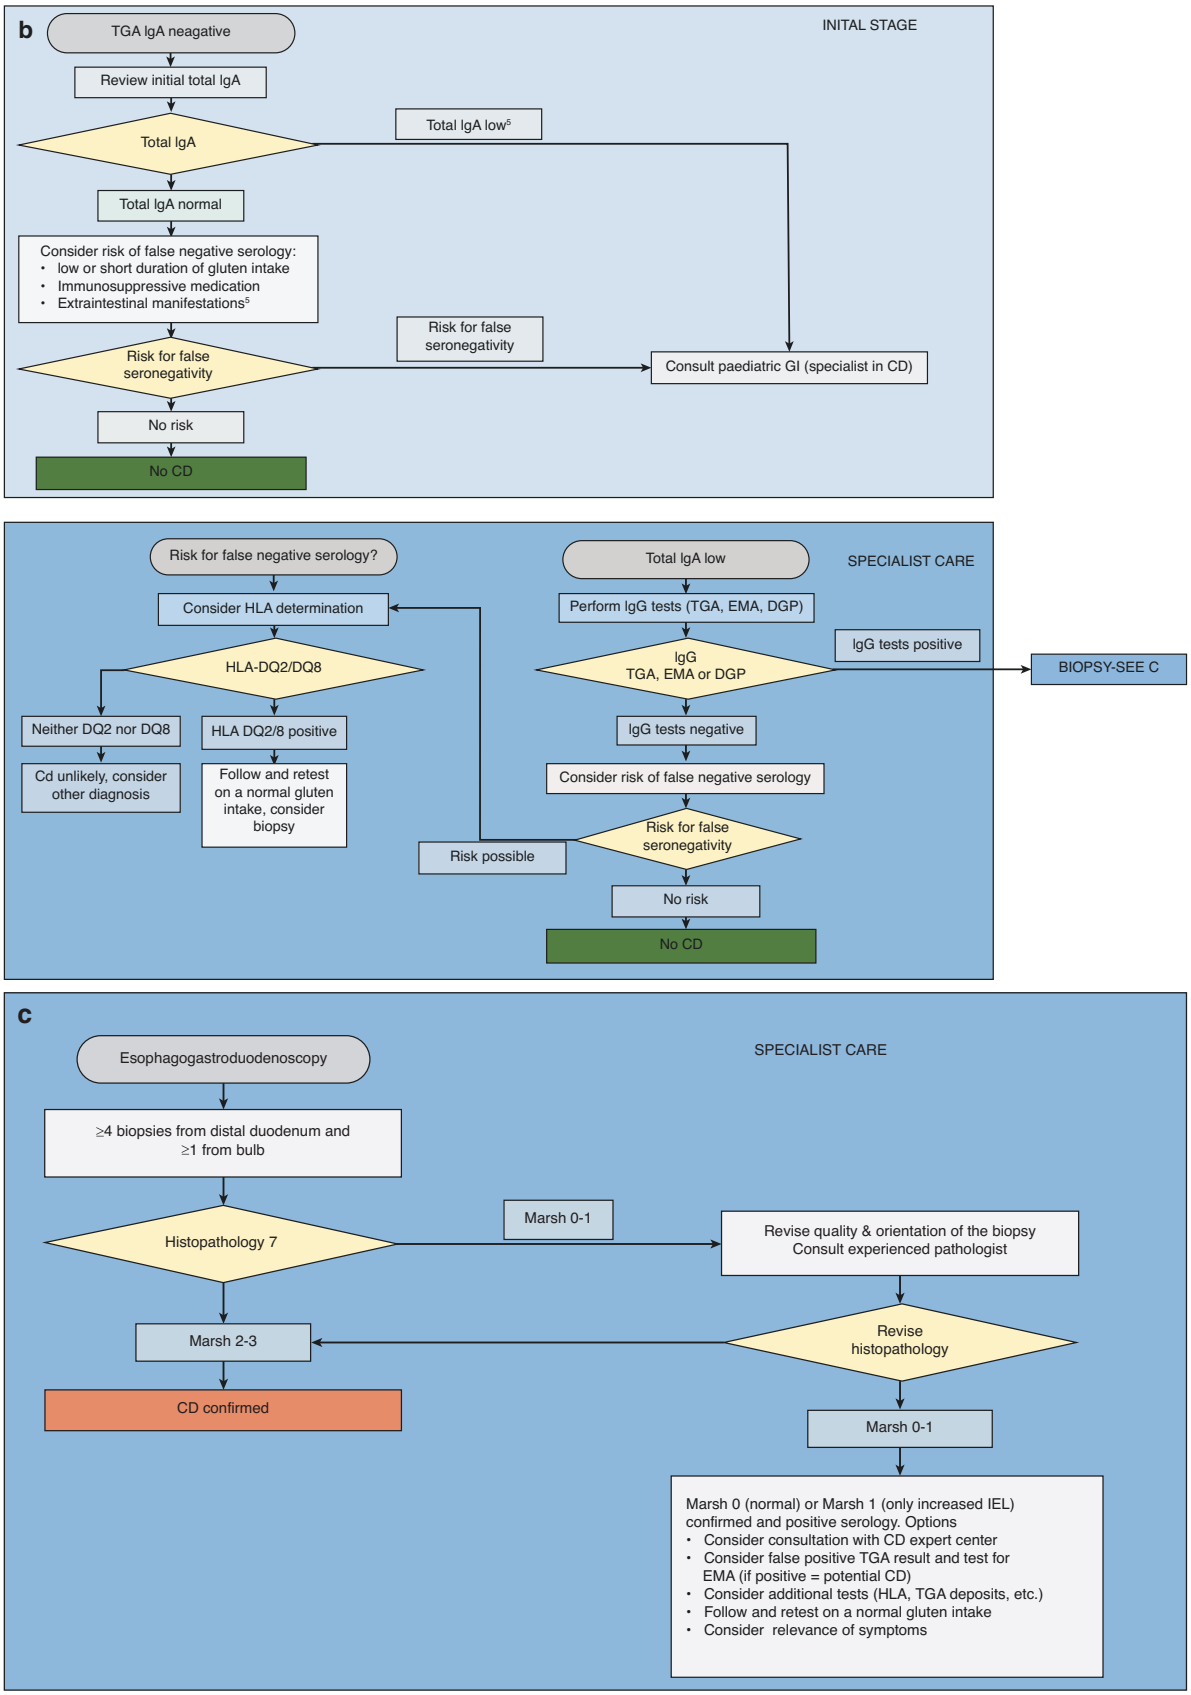

Fig. 40.4 (continued)

Table 40.4 Conditions causing lymphocytic duodenosis (Marsh type 1 changes)

Celiac disease
H. pylori gastritis
Small-bowel bacterial overgrowth
NSAID and other drugs
Immune dysregulation
Crohn's disease
Food protein-induced enteropathy
Infections
NSAID (nonsteroidal anti-inflammatory drugs)

Thus, in practical terms the decision on whether to put a potential CD patient on a GFD must be taken with great care, on an individual basis, after having properly informed the parents and obtained their full agreement. It goes without saying that if a potential celiac is left on gluten, he/she must be periodically followed.

Nonresponsive Celiac Disease

While the GFD appears to be very effective in children, a minute portion of patients would have persistent elevated serology and/or symptoms, configuring a condition of "nonresponsive CD." In these circumstances, a careful analysis of all potential causes is needed, keeping in mind that by far the commonest is ongoing ingestion of gluten that can be detected and resolved by the use of a rigorously supervised and strict GFD [213]. Among the less frequent causes of nonresponsive CD, recently a superimposed cow's milk protein allergic enteropathy has also been described [214]. The term "refractory CD" (RCD) instead refers to the persistence of intestinal villous atrophy (with or without persistent positive serology) for more than 1–2 years despite a strict GFD in patients with CD. This condition occurs rarely and its diagnosis remains difficult. RCD has been subdivided into two subgroups according to the normal (RCDI) or abnormal (RCDII) IELs phenotype, the latter considered as a low-grade intraepithelial lymphoma with a poor prognosis [215]. Despite some debate, there is scarce evidence for the existence of this condition in children. Hence, before concluding that a child presents true RCD, it is strongly recommended investigating properly other causes. As mentioned, in addition to ongoing inadvertent ingestion of gluten, they would include conditions such as Crohn's disease, autoimmune enteropathy, small bowel bacterial overgrowth, cow's milk protein allergy, and pancreatic insufficiency.

Treatment

CD is a lifelong condition and a strict GFD is currently the only available effective treatment. The dietary restriction must include wheat, rye, barley, and their derivatives such as triticale, spelt, and kamut. Other cereals such as rice, corn, and buckwheat are perfectly safe for CD patients and can be used as wheat substitutes.

How strict should the diet be? While the exact amount of gluten that can be tolerated daily by CD patients is unknown and is likely to be subject to a wide interindividual variability, there is evidence that a daily intake of less than 10 mg is safe for all patients, while the majority of them would react at levels equal or higher than 100 mg per day [216, 217]. This very strict diet proves to be very hard to follow, and in fact there are numerous reports in the literature showing that many celiac patients, especially in the adult population, experience an involuntary intake of gluten exceeding the safe amounts [218, 219]. A source of concern for risk of contamination with gluten in children is their school activities. A recent test on surfaces that could be contaminated with gluten revealed that there is indeed a potential for gluten exposure at school that varied among different materials (higher for paper mache and baking products) [220]. Inadequate adherence to the GFD has been recently assessed in a systematic review gathering almost 8000 children [221] that showed rates of adherence ranging from 23% to 98%. As expected, adolescents were more at risk of nonadherence, while children whose parents had good knowledge about CD adhered more strictly. Nonadherence is associated with patient growth, symptoms, and quality of life. To explain at least in part such lack of adherence, one must note that children (especially older ones and teenagers) may not present any symptom after inadvertent gluten ingestion or sporadic intentional consumption of gluten-containing products. On the other end of the spectrum, there is some evidence that using "hypervigilance" in adhering to the diet may be detrimental, especially in teenagers, on quality of life [222]. Additionally, the GFD often results in choice of manufactured GF products that are higher in sugar and fats and lacking in fiber and micronutrients, so that children on GFD experience unbalanced nutrition, from excessive caloric intake [223] to micronutrient deficiency [223–225]. Furthermore, in a study on a large number of adults, it was found that those following a GFD had significantly higher urine levels of total arsenic and blood levels of mercury, lead, and cadmium, possibly as a result of larger intake of fish and rice [226]. Recently, assessing the dietary preferences of a cohort of children with CD, we find that processed food

items have become a staple of the GFD, and in many cases, these products were consumed to the exclusion of healthy alternatives [227]. Variable effects on body mass index (BMI) have been observed after beginning the GFD, likely the result of different approaches to feeding habits in various sociocultural environments [228–230].

Safety of consuming oats (a non-gluten-containing cereal) had been a matter of debate for a very long time, with reiterated proofs – summarized in a recent meta-analysis [231] that non-contaminated oats are indeed perfectly safe; in addition, a good source of fiber and nutrients, including oats, adds variety and palatability to the diet.

The GFD, particularly in pediatric age, has a strong record of efficacy in resolving the presenting symptoms of CD [232]: while GI symptoms appear to be better responding than extra-intestinal ones to GFD, constipation appears to have the worst rate of improvement for both children and adults at only 74% and 58%, respectively [233]. Among extra-intestinal manifestations short stature and psychiatric disorders showed the worst rates of improvement in children [233]. GFD resulted in greater rates of improvements for GI than for extra-GI manifestations, both children and adults [120, 234]. Furthermore, in general, improvement in children was more rapid than in adults. Even more important, healing of the damaged duodenal mucosa has been documented in the vast majority of children after 1–2 years on GFD [235, 236]. Thus, even if up to 20% of the patients *re-biopsied in large part due to persistent symptoms* (hence, a small minority of the total) may have persistent mucosal damage [237], systemic re-biopsying in CD children on GFD is not recommended [238].

Assessing dietary compliance is not always an easy task, since serology often fails to reveal slight transgressions. Therefore, a periodical follow-up is needed, and the importance of a lifelong diet should be constantly reinforced, especially to asymptomatic patients. Recently, a test has been developed [239] and later marketed that allows the detection in samples of stools (more sensitive) and urine (less sensitive) of even minimal amounts of gluten that had been ingested in the previous 48 h. By using this method, studies in adults found that gluten ingestion occurs frequently despite efforts to follow a strict GFD [240, 241]. While this is a useful tool in verifying if recently developed symptoms can be attributed to a suspected, inadvertent ingestion of gluten, it must be kept in mind that it cannot be relied upon to verify prior, long-standing compliance.

In summary, following a strict GFD is not easy, may expose to nutritional deficiencies/excesses and risks, and carries an impact on quality of life, especially in adults. In addition, there is a subgroup of CD patients (i.e., RCD) who fail to respond even to a strict GFD, thus reinforcing the concept that GFD could not be considered a cure for all CD patients. As a result, in the last decade research has focused on numerous alternative forms of treatment.

Each one of these recently reviewed [242] alternatives is aimed at attacking a specific point in the pathogenesis of CD (Fig. 40.5): from genetically modifying the gliadin-containing grains in order to eliminate the toxic peptides, to enzymatically degrading the ingested gluten (endopeptidases) in the stomach before they reach the small intestine (latiglutenase [243] and AN-PEP [244]); from utilizing probiotics to affect the microbiota in symptomatic patients on GFD [245] to polymers that would sequester gliadin peptides (BL-7010) preventing them from crossing the intestinal barrier [246]; from agents like larazotide able to modulate the tight junctions in order to block the entry of such peptides [247] to inhibiting the deamidation of gliadin peptides by the TG2 (ZED 1227); and from blocking these peptides from adhering to the HLA-DQ2/HLA-DQ8 receptors [248] to interfering at various levels with the subsequent steps of immune activation by CD4 T-cells and their cytokines. Among the latter, recently the development of a promising therapeutic vaccine (Nexvax2) has been halted as it "did not provide statistically meaningful protection from gluten exposure for celiac disease patients when compared with placebo" [249]. All of the other approaches listed above are in various phases of active development [242], from preclinical to phase II clinical trials, but at this time none has been FDA-approved.

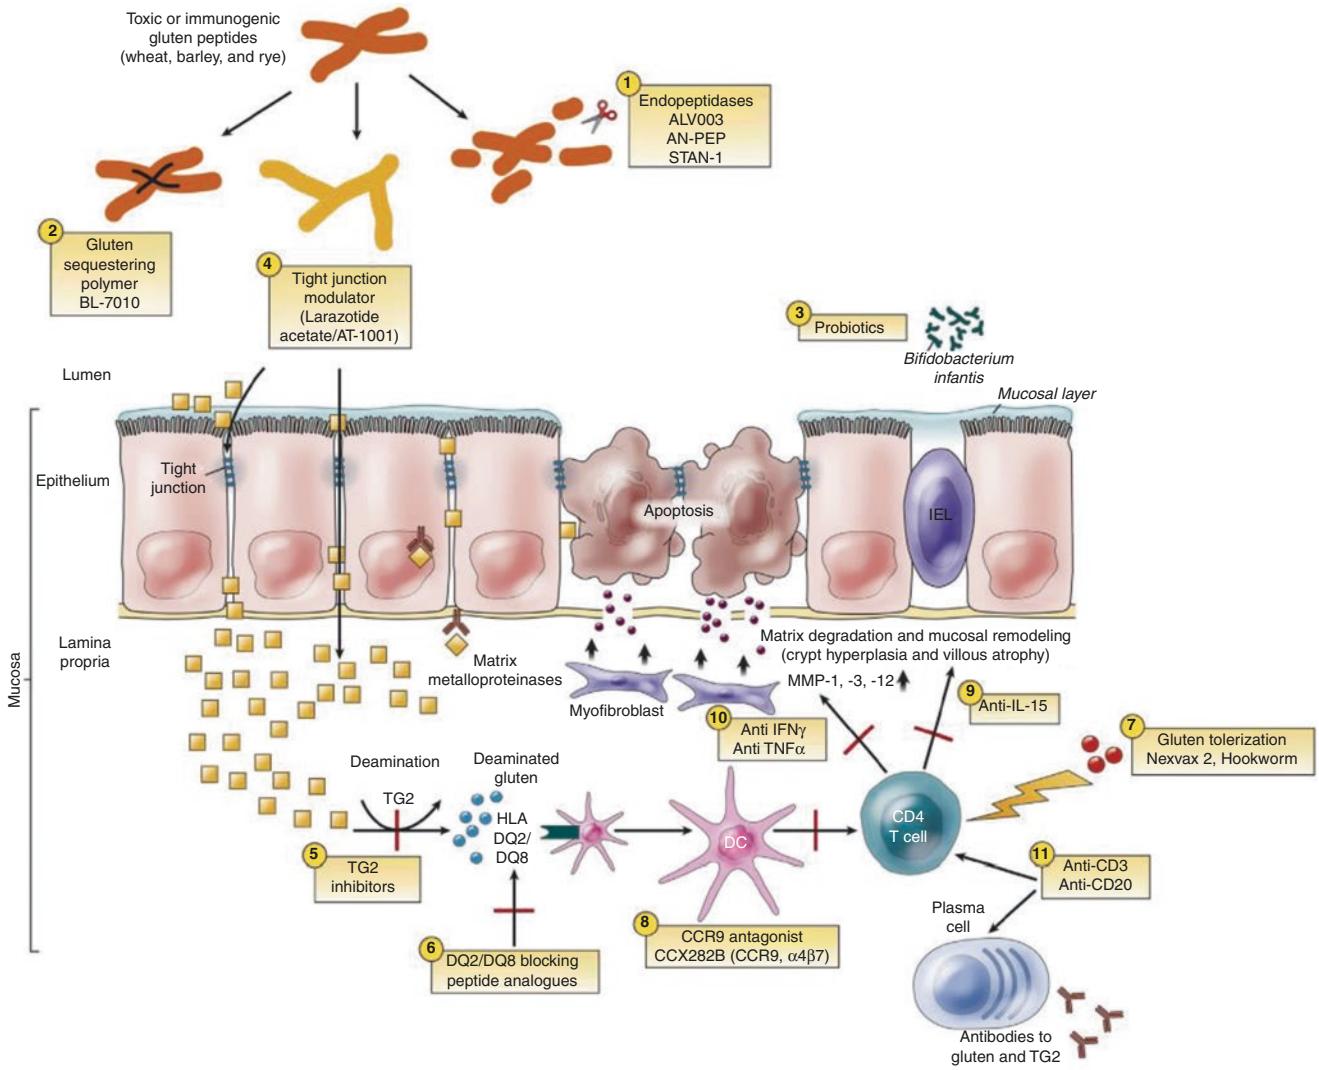

Fig. 40.5 New nondietary therapies for celiac disease (from Ref. [242] with permission). (1) Endopeptidases: Latiglutenase (formerly ALV003), AN-PEP, and STAN-1 degrade gluten into nonimmunogenic particles, thereby alleviating mucosal injury. (2) Gluten-sequestering polymer: BL-7010 binds to intraluminal gliadin and prevents its release and breakdown into immunogenic peptides. (3) Probiotics: Bifidobacterium infantis protects epithelial cells from damage caused by gliadin by downregulating the proinflammatory immune response. (4) Tight junction modulator: Larazotide acetate/AT-1001 works as a tight junction modulator to prevent gliadin-induced epithelial permeability. (5) TG2 inhibitor: Blocks the transformation of native gliadin peptides to the far more antigenically potent deamidated gliadin peptides. (6) DQ2/DQ8 blocking peptide analogues prevent presentation of gliadin from activating T cells. (7) Gluten tolerization: Nexvax2 and hookworm (*Necator americanus*) inoculation aim to downregulate the immune response to gluten. (8) CCR9 antagonist: CCX282B blocks this chemokine receptor to block lymphocyte homing. (9) Anti-IL-15 is a monoclonal antibody that may prevent immune-mediated tissue destruction. (10) Anti IFN-γ may prevent inflammation. (11) Anti-CD3 antibodies suppress gluten-activated T cells; anti-CD20 antibodies suppress B cells

Cystic Fibrosis

41

Zev Davidovics and Michael Wilschanski

Introduction

This chapter focuses on disease pathobiology of the gastrointestinal, nutritional, and hepatic manifestations of cystic fibrosis (CF).

CF is an autosomal recessive multisystem disease, the highest incidence being in individuals of North European descent. Intense follow-up and treatment have improved the median survival to nearly 50 years, and in many countries, over 50% of individuals are older than 18 years of age. Even though the main cause of death is chronic lung disease, gastroenterological symptoms feature prominently as 85% of patients have exocrine pancreatic insufficiency (PI), and around 10% suffer from significant liver disease.

Cloned in 1989, the CF transmembrane conductance regulator gene is situated on chromosome 7. The CFTR protein has two nucleotide-binding domains, two membrane-spanning domains, and a unique regulatory domain. This protein acts as a cyclic adenosine monophosphate (cAMP)-dependent chloride channel and localizes to the apical membrane of secretory and absorptive epithelial cells within the intestine, liver, sweat gland, pancreas, airway, and the vas deferens [1].

An inability of duct lumens to hydrate macromolecules is responsible for a number of CF manifestations. A body of pathologic evidence indicates that organ damage can be traced to ductal or glandular plugging by macromolecules that have precipitated in concentrated secretions. For instance, mucus secretions in the bronchi and the intestine are viscid and inspissated, and the crypts are distended as though obstructed. A deficit of ductular fluid flow and altered biochemical and physiologic properties of secretions underlie this situation.

The CFTR Gene

There are over 2000 mutations in the CFTR gene, and they have been divided into six classes [2]. This classification system provides the opportunity to evaluate the effects of genotype on phenotype by considering the effects of CFTR mutations on CFTR protein function. Nevertheless, it should be emphasized that this classification system is limited by the fact that the functional consequences of many rare mutations (particularly missense mutations) are unknown and cannot be predicted.

Class I mutations include mostly nonsense, frameshift, or missense mutations that result in defective protein biosynthesis (truncation, deletion, etc.). The nonfunctional products are efficiently degraded within the cell. Class II mutations, such as F508del, produce a misfolded functional CFTR protein, which is degraded intracellularly preventing trafficking to the apical surface of the cell. Class III mutations affect channel activation by preventing binding and hydrolysis of ATP at one of the two nucleotide-binding domains (NBD1, NBD2). Class IV mutations produce a protein with impaired function due to abnormal anion conduction. Due to a variety of mechanisms including abnormal splicing, promoter mutations, or inefficient trafficking, class V mutations result in a reduced number of normally functioning CFTR molecules on the apical surface. Class VI mutations result from truncation of the C-terminus of CFTR and produce a functional protein which is unstable at the apical membrane surface. Mutations belonging to classes I–III and VI confer little or no functional CFTR at the apical membrane. As a consequence, inheritance of homozygous or compound heterozygous mutations belonging to these classes is predicted to have severe consequences. Mutations belonging to classes IV and V on the other hand which confer (or are presumed to confer) some residual CFTR-mediated channel function would be expected to have milder consequences. In fact, it is patients with at least one mutation

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_41

belonging to classes IV or V who generally present with symptoms in late childhood or adulthood.

Diagnosis of CF

The diagnosis is clear if the patient has a sweat chloride concentration >60 mmol/L with at least one recognized phenotypic characteristic which includes chronic sinopulmonary disease, salt loss syndromes, and, in males, obstructive azoospermia [3, 4]. The majority of CF patients will have one established CF causing mutation on each CFTR allele. The diagnosis of CF should not be automatically considered if the sweat chloride concentration is >60 mmol/L. There is a list of disorders with high sweat tests which is expanding (Table 41.1).

At the other end of the spectrum, problems arise when there is a CF phenotype in one or more organ systems, and the sweat chloride level is borderline (30–60 mmol/L).

Electrophysiological testing using nasal potential difference (NPD) measurements may aid in the diagnosis of CF patients with normal or borderline sweat tests and negative or uninformative genetic test results [5, 6]. This test measures transepithelial sodium and chloride transport in the nasal epithelium. The function of CFTR in chloride secretion is intimately related to the inwardly directed sodium transport via the epithelial sodium channel (ENaC). The activity of these two channels is the basis for NPD. A catheter is placed under the inferior turbinate and is connected via a series of electrodes to a voltmeter and recorder. The nasal epithelium is perfused with solutions which inhibit sodium transport and activate chloride transport. In CF patients, the readings are markedly dissimilar from controls. Another electrophysiological tool is the intestinal current measurement (ICM) which measures CFTR function ex vivo in rectal biopsy using a modified Ussing chamber [7]. Testing should only be carried out by an experienced individual in a specialist research center where objective reference values have been established.

Hypothyroidism

CFTR Dysfunction: Gastrointestinal Consequences

Exocrine Pancreatic Abnormalities

Exocrine Pancreatic Function

In pancreatic ductal epithelia, the CFTR protein is highly expressed, allowing fluids and anion to enter the ductal lumen. Thereby, luminal chloride is exchanged for bicarbonate, giving evidence that CFTR is permeable to bicarbonate [8]. According to Quinton's hypothesis, the defect in bicarbonate transport is indeed the primary defect in CF [9]. This results in an increased volume of alkaline fluid, allowing the acinar cells to remain in a soluble state, due to the highly concentrated proteins secreted. Absent or reduced CFTR channel function impairs chloride and bicarbonate to enter the ducts which results in reduced volume of a more acidic fluid [10]. The acidic milieu within the acinar lumen also leads to impaired reuptake of GP2, the zymogen-granule-associated protein [11]. The consequences of mutations in the CFTR gene have been demonstrated by pancreatic function studies showing that CF patients have low flow secretions with a high protein concentration, presumably which will precipitate in the duct lumina causing obstruction, damage, and atrophy (Fig. 41.1).

These changes begin in utero, and after birth, the process continues with the small duct obstruction leading to a larger duct obstruction. For several months afterward, there is a release of proteins, originating in the pancreas, into the bloodstream. This pathological process forms the basis for the immunoreactive trypsinogen (IRT), the neonatal screening test for CF. The reason has yet to be determined, but, interestingly enough, the infant is asymptomatic while this wholesale destruction of the exocrine pancreas is occurring. Eventually, this process results in severe inflammatory changes, obstruction of ducts by mucus and calcium-containing debris, the destruction of acini, and generalized fibrosis. The high IRT does show that some exocrine pancreatic tissue is still present and may have a bearing on possible small molecule therapy targeted at the remainder of the pancreas which may rescue enough tissue to cause viability of the remaining pancreas. This of course contradicts the popular belief that the pancreas is entirely nonfunctioning at birth (see below CFTR correctors and potentiators).

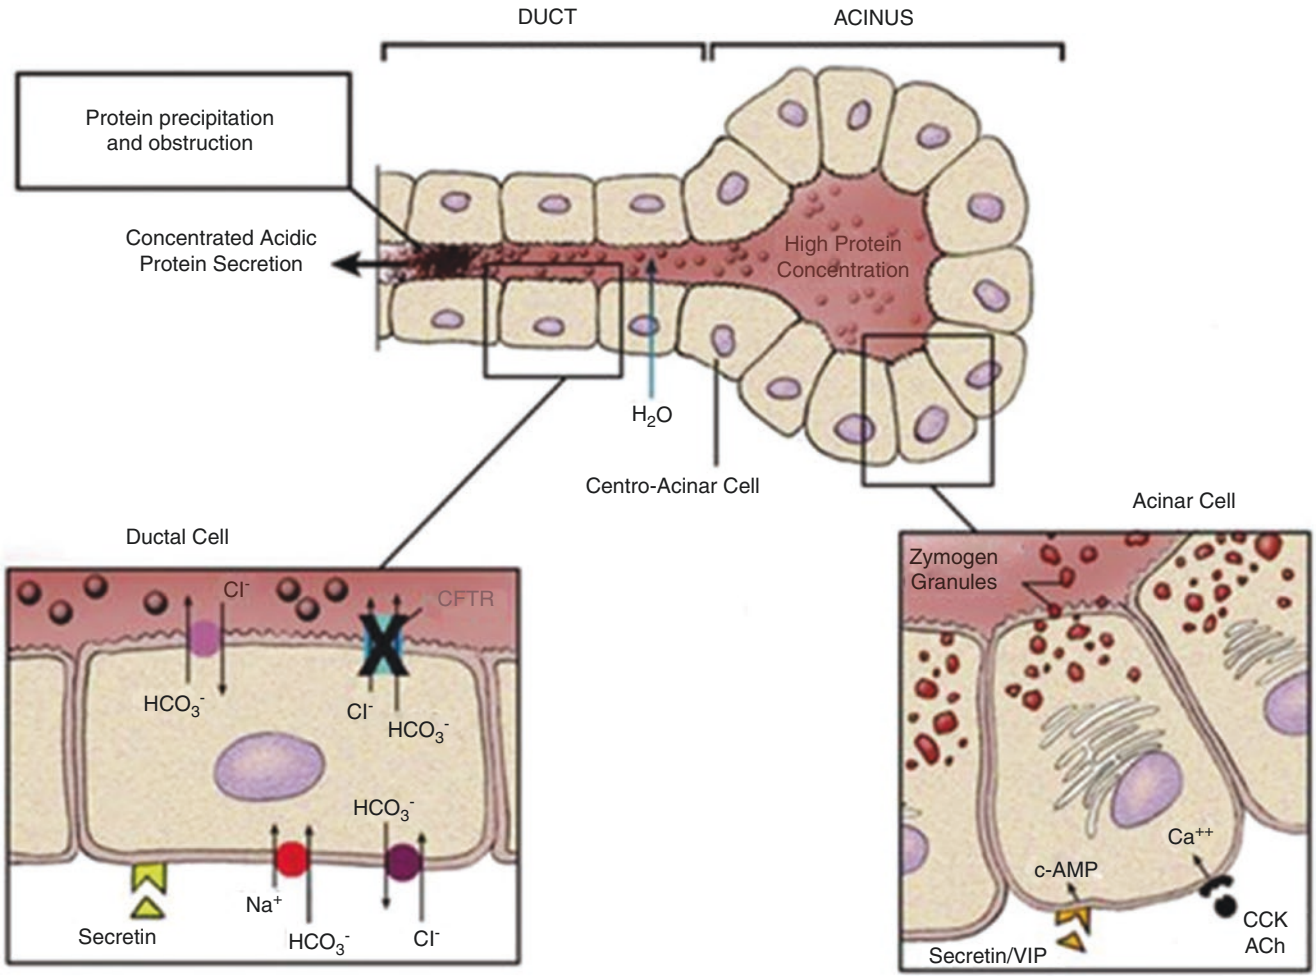

Fig. 41.1 Pathogenesis of pancreatic disease in cystic fibrosis (CF) [12]. Acinar cells secrete large quantities of protein, primarily in the form of digestive enzymes, into the acinar lumen. Under normal circumstances, anions (chloride and bicarbonate) are secreted into the ductal lumen via the cystic fibrosis transmembrane regulator (*CFTR*) and bicarbonate exchangers. This provides a driving force for the movement of fluid into the lumen of the duct and maintains the solubility of secreted proteins in a dilute, alkaline solution. In CF, impaired anion transport into the proximal ducts results in decreased secretion of more acidic fluid, which leads to precipitation of secreted proteins. Intraluminal obstruction of the ducts then causes progressive pancreatic damage and atrophy (Reproduced from Ref. [12], Copyright 2007, with permission from BMJ Publishing Group Ltd). *cAMP* cyclic adenosine monophosphate, *ACh* acetylcholine, *CCK* cholecystokinin, *VIP* vasoactive intestinal peptide

One of the most remarkable observations is that genetic factors exquisitely influence the degree of pancreatic disease and its rate of progression. CF patients are classified as pancreatic insufficient (PI) or pancreatic sufficient (PS). PI patients comprise approximately 85% of all CF patients. PI patients present with maldigestion, as evidenced by steatorrhea (fecal fat greater than 7% of fat intake in infants over 6 months of age and over 15% under 6 months of age), requiring these patients to have pancreatic enzyme replacement therapy (PERT) with meals. PS patients, however, have evidence of pancreatic damage, but retain sufficient endogenous exocrine pancreatic function to sustain normal digestion [13] due to the fact that ductal CFTR in PS patients is partially functional, thereby allowing anions and fluid to enter the ductal lumen. This provides further evidence that mutant CFTR may be acting on other apical anion exchangers rather than on chloride ion conduction itself [14].

The exocrine pancreatic status is directly linked to genotype [15]. Analysis of particular CFTR mutations in patients with pancreatic phenotypes (PI vs. PS) revealed two categories of alleles: "severe" and "mild." Patients homozygous or compound heterozygous for severe alleles belonging to classes I, II, III, or VI confer PI as opposed to patients with a mild class IV or V allele even when the second mutation is severe. These patients are termed "PS." Plausible explanation of this observation finds all known mild alleles belong to class IV or class V, all of which are (or predicted to be) associated with some residual chloride channel activity at the epithelial apical membranes. Although these mutations confer sufficient CFTR function to prevent the pancreas to be

completely destroyed, many PS patients have reduced exocrine pancreatic capacity and are associated with an increased risk of pancreatitis, as discussed below. A very small number (2–3%) of patients carrying severe mutations on both alleles are PS at diagnosis; however, most patients will experience a gradual transition from PS to PI. A few missense mutations (e.g., G85E) confer a variable pancreatic phenotype.

Recurrent Pancreatitis

Many PS patients have reduced exocrine pancreatic capacity and are associated with an increased risk of pancreatitis, even though mild mutations confer sufficient CFTR function to prevent the pancreas to be completely destroyed. As first reported by Shwachman in 1975, recurrent acute and chronic pancreatitis are relatively infrequent complications of CF. In this retrospective study, only 0.5% of CF patients had pancreatitis. Durno et al. reported more recently an incidence of 1.7% in a cohort of over 1000 patients followed over a period of 30 years [16]. All of the pancreatitis patients were classified as PS, but this subgroup of PS patients, in fact, appeared to be highly susceptible to pancreatitis, since almost one in five was affected by this complication. In a seminal paper of the largest study to date of CF PS patients, Ooi et al. determined the association between severity of CFTR genotype and the risk of pancreatitis [17]. They examined a large cohort of 277 PS patients from 2 CF centers, of which 62 had well-documented pancreatitis. The mutations were divided into three main groups: severe, moderate–severe, and mild in using a novel pancreatic insufficiency prevalence (PIP) score. It was found that the proportion of patients who developed pancreatitis was significantly greater for genotypes in the mild group than the moderate–severe group. Thus, the more mild mutations were associated with increased risk of pancreatitis. CFTR mutations may contribute to the development of pancreatitis along with other genetic and environmental factors [18].

Diagnosis of Pancreatic Phenotype

With the increasing worldwide use of neonatal screening programs, patients may present with symptoms of CF or be entirely asymptomatic. Making a determination in all patients, whether the patient is PI or PS is essential to enable a rational use of oral PERT [19]. When patients have steatorrhea (oil droplets on stool microscopy), hypoalbuminemia, and low fat-soluble vitamin levels, the diagnosis of PI is straightforward. However, the lack of these findings does not exclude PI; therefore, more formal testing is required. In the past, direct exocrine pancreatic stimulation testing was administered. Unfortunately, this was an invasive, time-consuming procedure and not widely used in most centers. Indirect pancreatic testing with 72-h fecal fat measurements should be encouraged and be used as follow-up for pancreatic exocrine status and response to therapy. Due to the technical difficulties surrounding the performance of this test, most laboratories are utilizing the fecal elastase-1 test instead, with its main advantage being that it does not need prolonged stool collection. Pancreatic elastase is secreted into the duodenum and is found at relatively high concentrations in stool (>500 μg/gm stool).

The use of fecal pancreatic elastase-1 has now become a common diagnostic test for assessing exocrine pancreatic status. The advantages and limitations of fecal elastase-1 in CF have been discussed by Kalnins et al. in a review article [20]. The cutoff levels of fecal elastase for PI range between 100 and 200 μg/g stool; a majority of centers use the upper level of 200 μg/g stool. With the use of 200 μg/g stool weight, some patients may be falsely identified as PI. The Toronto group compared stool elastase values to the 72-h fecal fat in both known PI and sufficient patients and found that an elastase value of 100 μg/g stool had a 99% predictive value in ruling out PI based on an abnormal fecal fat. Cade et al. showed that patients with pancreatic sufficiency on the basis of a normal fecal fat balance study were found to have fecal elastase values in the range of 100–200 μg/g stool; elastase levels were compared with the fecal fat test coefficient of fat absorption (CFA) [21]. Whether defining PI as <93% or 90% CFA, cutoff levels of fecal elastase of < 100 μg or <200 μg/g stool for either monoclonal or polyclonal methods were positive predictors of insufficient pancreatic function. However, patients with pancreatic sufficiency were not included in this study population. Moreover, these observations question the validity of defining the cutoff for PI as a fecal elastase value below 200 μg/g stool. In a different study of 21 known PS patients, a poor correlation was found between fecal fat excretion and elastase-1 [22]. The fecal elastase result will define clearly whether a patient is PI or sufficient, in a majority of cases, provided the test is done accurately. In situations such as in acute diarrhea, short gut, or stool from an ileostomy, where stool is more watery, fecal elastase levels may be lower than expected; therefore, it would be advisable to wait until the diarrhea resolves, or until a sample that is more formed is available. A definitive answer on pancreatic status may not be provided in those patients with less common genetic variations, where there are no supportive clinical features of PI, and fecal elastase values are often borderline. In such cases, elastase can be used to monitor pancreatic status, in conjunction with ongoing evaluation of clinical and nutritional status [23].

Oral Pancreatic Enzyme Replacement Therapy

Prior to 2010, pancreatic enzyme products were exempt from the Federal Food, Drug, and Cosmetic Act of 1938 and did not require approval of the Food and Drug Administration (FDA). Since then, a plethora of products became available to the public without the need for strict preclinical and clinical studies. The FDA has since mandated that all manufacturers of pancreatic enzyme products in the USA must seek approval.

Currently, there are various preparations approved and available for use [24–30]. During one study on Creon, a fixed dose of 72,000 lipase units with meals and 36,000 with snacks was evaluated. The study was a double-blind, randomized, placebo-controlled trial of 54 adult patients with chronic pancreatitis or post-pancreatic surgery. The treatment arm showed a difference in CFA of 19.3% over placebo (85.6 vs. 66.3).

Most commonly available PERT products showed a similar nutrient absorption rate between 83% and 87% fat absorption. The dosages of these products are based on the lipase units contained in the product. It is now common for patients to change from one product to another using a 1:1 lipase ratio and then titrating for maximum efficacy. The North American CF Foundation has published guidelines according to the age of the patient and according to the grams of fat ingested per day [31].

The importance of the correct enzyme ingestion in infants and children is a major concern. There is often difficulty in feeding infants capsules or microspheres however small they may be. The continued use of the unprotected powder enzymes for infants until 1 year of age is common in some centers. In infants, these enzymes may have some advantage over the enteric-coated versions in certain situations. The efficacy of unprotected powder enzymes (in tablet or powder form) has not been directly compared to the enteric-coated version in infants, but infants treated with this approach do achieve growth and weight gain, proving their efficacy [32]. In addition to their use for infants, unprotected powder enzymes are often used to help digest enteral tube feedings where oral administration of enzymes is not possible, or when jejunostomy feeds are required.

Breastfeeding mothers should be instructed on proper infant mouth care after enzyme delivery when the unprotected powder enzymes are provided to these infants. It is recommended that soft cotton swabs or a washcloth dipped in sterile water be used to wipe the inside of the infant's mouth and inside the gums. This will prove to be sufficient to prevent gum erosion to the infant and nipple irritation to the mother.

For infants with meconium ileus requiring surgery or those with an ileostomy, the powder enzymes may provide the advantage of immediate release in the duodenum. Theoretically, this will improve nutrient digestion compared to the pH-sensitive, delayed release enteric-coated microsphere enzyme products. Tablets without a protective coating can be crushed if the powder version in capsules or in bottles is not readily available.

The production of specially designed enzymes for the small child has been a recent advancement. A multicenter cross-over study in CF infants who were randomized to receive CfC (Creon for children) or regular enzyme for 2-week periods was performed; it compared a spoon administration containing 5000 lipase units with the standard Creon 10,000 capsule [33]. The parental preference was the primary end point; over 75% of the parents preferred CfC over the standard preparation.

Theoretically, the addition of bicarbonate to enteric-coated enzyme preparations might raise the proximal intestinal pH and thereby optimize dissolution of the enteric coating and improve enzyme activity. There were conflicting studies on efficacy when compared to standard, pH-sensitive microsphere enzymes. One study demonstrated that there was no improvement when compared to a standard enzyme preparation [34]; another study showed improvement in fat absorption with the bicarbonate-containing enzyme [35]. However, in both studies, approximately 80% fat absorption was achieved using the bicarbonate-containing enzyme, and Kalnins et al. [34] found the same degree of fat absorption with the conventional enteric-coated enzyme product.

Oral PERT is not formulated for use with continuous enteral tube feedings especially overnight. Parents often add standard formulation enzymes several times a night and this causes hardship. A new therapy that advances EN tube feeding is a single-use digestive enzyme cartridge connected in line with the EN feeding set. Lipase is bound to a beaded polymer retained in the cartridge. The efficacy of this device has been confirmed in two studies with improvement in gastrointestinal symptoms and laboratory improvement of omega-3 fatty acid levels in erythrocytes [36, 37].

An important factor for clinicians and families of a CF patient or those with CF to understand and appreciate is that although enzyme therapy for those with PI allows for normal growth and weight gain in most individuals with CF, unfortunately, it does not completely correct nutrient malabsorption. There are several reasons for incomplete nutrient digestion with the currently available enzyme products. A proportion of the unprotected powder enzymes or tablets may become inactivated by prolonged exposure to gastric acid. This results in decreased duodenal active enzyme recovery. Enteric-coated microspheres, which dissolve at a pH of >5.5, may only be released in the ileum if duodenal

milieu does not reach this pH as occurs in CF. From prior intubation studies, evidence is confirmed that release of enzymes from enteric-coated microspheres is delayed in CF, and thus, they are delivered beyond the duodenum, even as far distal as the ileum. This results in a nutrient digestion occurring in the more distal small intestine, but not in the duodenum and proximal jejunum as in health. Not only maldigestion but also malabsorption contributes to the insufficient assimilation of nutrients. Fatty acid absorption as well as the digestion of triglycerides is impaired in subjects with CF [38]. Other contributing factors to nutrient malabsorption include incomplete lipid solubilization caused by a depleted bile salt pool and thick intestinal mucus. This may affect the unstirred water layer, reducing absorption of fatty acids into the small intestine epithelium. Therefore, a degree of malabsorption is to be expected for reasons mentioned. Consequently, achieving >90% nutrient digestion as evaluated by 72-h fecal fat studies is not likely to occur in a majority of patients with CF.

Patients should not be automatically encouraged to increase their PERT intake if they experience gastrointestinal symptoms such as abdominal pain, bloating, or loose stools, as there are many other etiologies for these symptoms including compliance. For persistent symptoms, a fat balance study should be performed to titrate dose and proton pump inhibitor (PPI) should be considered. After which, if the patient does not experience any improvement, investigations for non-pancreatic disease should be explored. Awareness of these factors by both clinicians and patients will help to guide a rational approach to enzyme therapy in CF; an individualized approach to treatment is recommended.

Hepatobiliary Disease

There are a wide variety of hepatobiliary disorders associated with CF (Table 41.2); almost all patients with CF have evidence of hepatobiliary disease. There are no clinical consequences for the vast majority of patients.

Table 41.2 Hepatobiliary complications of CF

Hepatic	Approximate frequency (%)
Neonatal cholestasis	5
Steatosis	20–60
Focal biliary cirrhosis	11–70
Multilobular cirrhosis	5–7
Liver failure	Rare
Biliary	
Microgallbladder	5–20
Distended gallbladder	3–20
Cholelithiasis and sludge	10–25
Intrahepatic sludge/stones	Unknown
Extrinsic compression of common bile duct	Unknown
Cholangiocarcinoma	Unknown

The pathognomonic hepatic feature of CF is focal biliary cirrhosis. Intrahepatic biliary ductal secretion is dependent on CFTR-mediated chloride transport for adequate hydration of the lumen (Fig. 41.2). Loss of CFTR function causes the biliary ductules to become obstructed with thick periodic-acid–Schiff positive material leading to acute and chronic periductal inflammation, bile duct proliferation, and increased fibrosis in scattered portal tracts. Remarkably, adjoining portal tracts are frequently normal. Over 40 years ago, postmortem studies showed evidence of mild focal disease in 11% of infants, 27% of those dying at 1 year, and in more than 70% of adults. Clinically, significant portal hypertension resulting from severe multilobular cirrhosis develops in only 5–7% of patients. This is termed "CF-associated liver disease" (CFLD). CFLD is the single most important non-pulmonary cause of death, responsible for 2.5% of overall mortality in CF. The average age of diagnosis of CFLD is 10–11 years of age, and 90% are diagnosed before the age of 20 [39]. Following routine examination or by laboratory evidence of hypersplenism, most patients are asymptomatic and are often identified by the evidence of hepatosplenomegaly. Hepatocellular function remains well preserved for many years, even decades. Splenomegaly is a consistent finding, and the liver edge is often nodular and hard.

About 40–50% of CF patients exhibit intermittent elevations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), or gamma glutamyltransferase (GGT), which are generally 1–2.5 times above the upper reference limits. Biochemical markers of liver disease do not reliably identify patients with multilobular cirrhosis nor do they predict the development of end-stage liver disease. Furthermore, patients with advanced multilobular cirrhosis may have normal liver biochemistry test results. As hyperbilirubinemia is rare, elevated serum gamma globulin level is more likely to be associated with chronic pulmonary inflammation. CFLD occurs predominantly in PI patients. Thus, severe class I, II, or III mutations on both alleles appear to be a risk factor [40]. A male preponderance of severe CFLD has been shown in most studies.

Why a minority of patients with the same severe CFTR mutations progress to CFLD is unclear. However, it has been hypothesized that non-CF modifier genes, such as polymorphisms in genes that upregulate inflammation, fibrosis, or oxidative stress, confer an increased susceptibility. In a multinational gene modifier study of the different candidate genes, the SERPINA 1 Z allele of alpha-1 antitrypsin deficiency was found to be strongly associated with CFLD. This result is intriguing as the CF patient requires a double hit to develop CFLD. Hitherto undefined environmental factors are also likely to be involved.

Gallstones develop in 1–10% of patients with CF. There is also an increased incidence of a variety of intrahepatic and extrahepatic abnormalities of the biliary tree. Nonfunctioning microgallbladders are common, although it

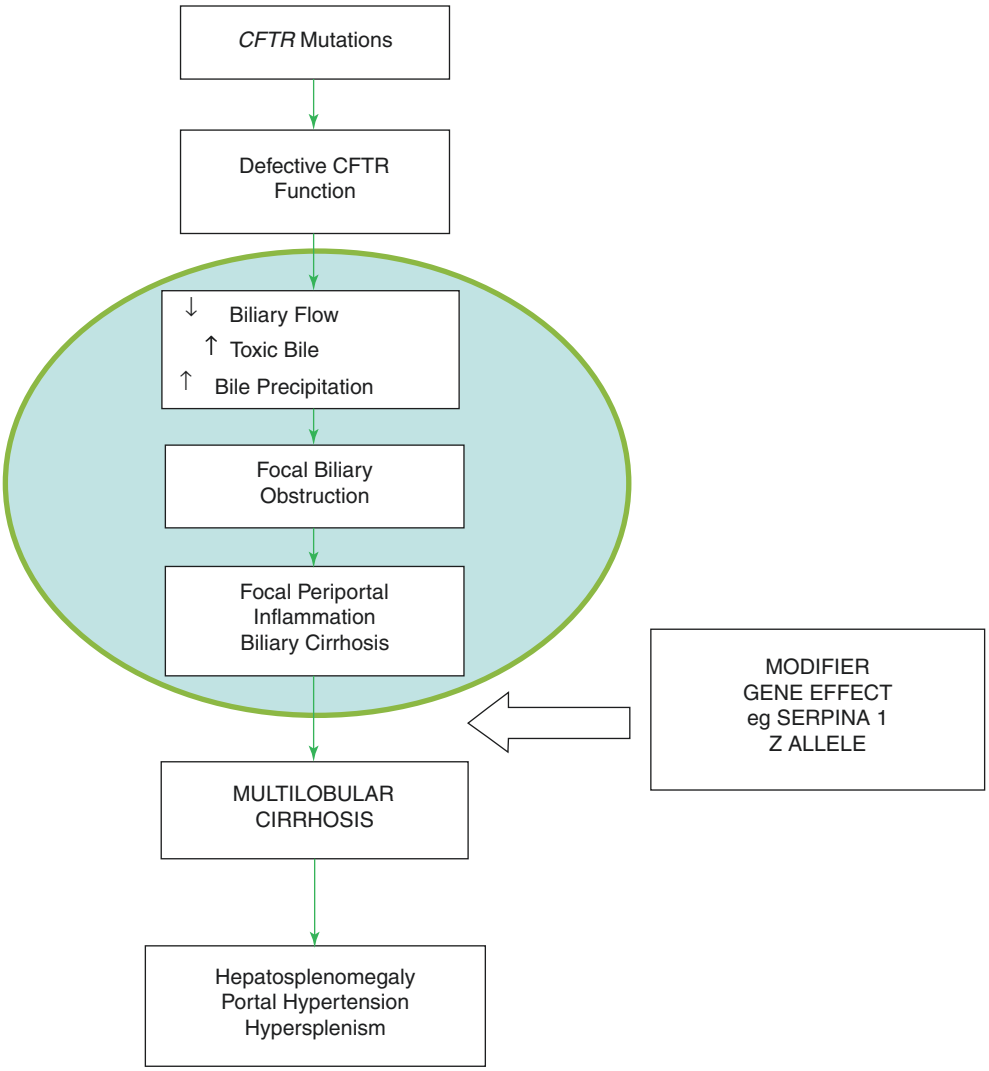

Fig. 41.2 Pathogenesis of cystic fibrosis-related liver disease [12]. Lack of functional CFTR in the biliary ductules causes dehydration, increased concentration, and lack of alkalinization of the duct contents. This causes precipitation of biliary secretions and ductular obstruction. In the majority of patients, the pathologic changes are focal and appear to be clinically inconsequential (*circled area*). However, approximately 5–10% of CF patients proceed to develop clinically significant liver disease with evidence of multilobular cirrhosis and portal hypertension. Susceptibility to more severe liver disease may be modulated by other genetic and/or environmental factors (Reproduced from Ref. [12], Copyright 2007, with permission from BMJ Publishing Group Ltd)

is seen less frequently that patients with CF have distended gallbladders appearing obstructed. Stones may also be commonly visualized within the larger intrahepatic and extrahepatic biliary tree. Debray et al. have proposed using the knockout mouse model that the gallbladder itself, rather than the bile duct epithelia, may be the major site for a bile acid shunt, the cholecystohepatic shunt, from the gallbladder back to the liver [41].

The principal cause of CF-associated liver disease remains controversial; it has been postulated that common duct obstruction results from extrinsic compression by fibrosis within the head of the pancreas. Following ERCP or transhepatic cholangiographic imaging, changes resembling primary sclerosing cholangitis (i.e., beading and stricturing of the intrahepatic and extrahepatic ducts) are quite commonly observed [42]. These changes are likely due to accumulation of protein, mucus, or sludge within the biliary lumina.

An alternative hypothesis of the etiology of CFLD, derived from the histopathological study of liver biopsies, suggests vascular changes, namely, obliteration of portal vein branches with fibrosis leading to portal hypertension [43].

A combined European and North American initiative (ESPGHAN and North American Society for Pediatric Gastroenterology, Hepatology and Nutrition) has convened to reach a uniform definition and classification of CFLD,

which will likely shape diagnostic criteria. In current clinical practice, the diagnosis of CFLD frequently is based on the Debray et al. [44] criteria. A drawback of using these criteria is that varying phenotypical types of liver involvement are included, and it is not always clear whether these are clinically relevant or play a role in development of cirrhosis or portal hypertension. Advances in understanding CFLD pathophysiology will likely guide the discovery of more phenotype specific markers and treatments. It seems reasonable to assume that longitudinal rather than single measurements may become important for the diagnosis and follow-up of CFLD, as well as combinations of diagnostic tests rather than an isolated test or modality.

Diagnosis and Management

Studies are being performed to evaluate early liver disease in CF. Clinical examination is necessary to look for signs of chronic liver disease and organomegaly; routine biochemistry is generally not helpful. The evidence of liver disease is often subclinical until CFLD develops as previously stated. As raised serum liver enzymes in a CF patient may be due to the waxing and waning of liver tests in CF. Persistent increases in liver tests may be due to other diseases entirely; it is imperative to consider hepatitis (infectious or autoimmune), Wilson disease, and other causes of steatosis (malnutrition, diabetes mellitus) as possible causes when reviewing these patients. A small number of infants may present with neonatal cholestasis, in particular those with MI, usually resolving with no long-term effect [45].

In most centers, ultrasonography of the hepatobiliary system is available, and it includes Doppler measurements of flow in the portal vein; however, the positive predictive value of a normal scan and sensitivity is low [46]. Elastography (Fibroscan R), a new test of liver stiffness (which may be a marker of fibrosis), is used in other chronic liver diseases such as hepatitis C. Early diagnosis of CFLD cannot presently be made on the basis of ultrasound alone [47].

Guidelines by Debray et al. [44] recommend that in order to delay progression of CFLD, ursodeoxycholic acid treatment should be initiated. In a Swedish study, there was evidence that biochemistry is improved as is liver histology [48]; however, this treatment and in particular the recommended dose have been challenged after a trial of high-dose ursodeoxycholic acid in another cholestatic liver disease, primary sclerosing cholangitis, was terminated due to severe side effects [49]; further studies are obviously needed.

A number of investigational avenues targeting different aspects of liver disease are being explored. Bile acid analogues: NorUDCA (a side chain-shortened homologue of UDCA with one less methylene group) undergoes cholehepatic shunting leading to a bicarbonate-rich hyperchloresis. This drug has direct anti-inflammatory, anti-fibrotic, and anti-proliferative properties and stimulates alternative bile acid detoxification and elimination routes. It has shown encouraging effects in the clinic improving serum liver tests in primary sclerosing cholangitis, an immune-mediated liver disease with biliary morphological similarities to CFLD, although antibiotics, but not norUDCA, reduced biliary injury in a CF mouse model [50, 51].

Follow-up and management of CFLD are the same as for other chronic liver diseases except for the use of beta-blockade prophylaxis for variceal bleeding. This needs to be thoroughly examined in CF patients in consultation with the pulmonologists. Selection criteria for liver transplantation have not been established. Apart from the routine indications, there appears to be evidence that earlier liver transplantation, before the development of significant and irreversible nutritional and pulmonary deterioration, may be helpful. However, large, long-term studies have been difficult to perform [52].

Intestinal Complications

Meconium Ileus (MI)

Most patients born with MI present within 24–48 h with evidence of intestinal obstruction with abdominal distension, bilious vomiting, and failure to pass meconium. MI occurs in 15–20% of CF patients [53].

Diagnostic aids include a family history of CF and a plain radiograph which may show large distended loops of small bowel and a ground-glass appearance in the right lower quadrant due to inspissated meconium in the ileocecal area.

A diagnostic procedure which may be therapeutic is the performance of a contrast enema. The hypertonic enema may lavage the plug of meconium, and, provided the infant is stable, this procedure may be repeated several times in order to avoid surgery. Surgery is, of course, necessary for complicated MI.

A small proportion presents with perforation in utero with meconium peritonitis and subsequent intra-abdominal calcification which may only be diagnosed incidentally during third trimester ultrasound examinations. Postnatally, up to 50% of MI patients may have additional problems including malrotation with volvulus or intestinal atresia, termed “complicated MI.”

In a consortium which examined over 3700 cases of MI, several apical transporter genes were found to modify meconium ileus [54], thus appearing that modifier gene(s) together with two severe CFTR alleles confers an increased likelihood of MI. It remains possible that modifier genes with or without environmental factors may explain the variability and severity of other intestinal complications such as distal

intestinal obstruction syndrome (DIOS). In a subsequent study, linkage analysis identified a modifier locus for MI on human chromosome 12p13.3 [55].

Distal Intestinal Obstruction Syndrome

Frequently in older children and adults with CF, DIOS, a chronic, recurrent form of partial intestinal obstruction, occurs. DIOS is frequently confused with other common causes of abdominal pain in patients with CF and almost exclusively in those with PI. Unique to CF, DIOS results from a buildup of adherent, thick intestinal contents in the terminal ileum and proximal colon. The reported frequency is variable, consequently, but a recent study shows a prevalence of 18% in adults [56]. DIOS may be related to the specific inflammatory status of the intestine in CF. Intestinal inflammation has been shown in the mouse model [57], and in a study using capsule endoscopy in CF subjects, macroscopic small bowel inflammatory signs were observed and we coined the term "CF enteropathy" [58]. This finding has since been confirmed by other groups [59]. Patients with DIOS usually complain of intermittent episodes of pain, which may or may not be localized to the right lower quadrant. Non-tender, or mildly tender, palpable mass can be felt in the right lower quadrant (although it may not always be localized there). Some patients suffer from intractable chronic pain that is difficult to treat, and on rare occasions, there is complete bowel obstruction.

The European Society for Pediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) Cystic Fibrosis and Pancreatic Disease Working Group defines complete DIOS as the combination of (1) complete intestinal obstruction, as evidenced by bilious vomiting and fluid levels on abdominal radiography with (2) a fecal mass in the ileocecum and (3) abdominal pain and or distension. Incomplete or impending DIOS is defined as (1) a short history of abdominal pain and/or distension and (2) a fecal mass in ileocecum but without signs of complete obstruction [60].

While the exact cause of DIOS is unknown, various precipitating factors have been proposed including abnormal properties of intestinal mucus, dehydration of intraluminal contents, slow intestinal transit, poor compliance with pancreatic enzyme therapy, and a prior history of MI and possibly inflammatory changes in the intestine. DIOS should not be confused with simple constipation which is common in CF patients with PI. Although unlike DIOS a right lower quadrant mass is usually not palpable, the rectum will characteristically be full of stool on physical examination, and stooling patterns and consistency are abnormal. Patients undergoing major surgery, such as lung or liver transplant, carry an increased risk of DIOS during the immediate postoperative period.

With other CF-associated or non-CF gastrointestinal disease including appendiceal disease, intussusception, Crohn's disease, fibrosing colonopathy or malignancy, and nonspecific symptoms and signs may occur; therefore, abdominal ultrasound and CT scans may be necessary.

In complete DIOS, the patient usually requires hospitalization and IV rehydration. Patients with incomplete DIOS respond to oral rehydration combined with mineral oil or polyethylene glycol preparations. Enemas of sodium meglumine diatrizoate (Gastrografin or Telebrix) may be performed by experienced radiologists, but the enema must enter the ileocecal valve to get above the obstruction. Treatment of DIOS is still largely empirical due to few randomized controlled trials. Local instillation of diatrizoate in the cecum via colonoscopy has been described [61]. Surgery is seldom required if early aggressive medical management is performed. Laparoscopy and washout are recommended for consideration before resection. A single episode of DIOS is a risk factor for recurrence; maintenance therapy should be considered along with regular follow-up by the gastroenterological service [62].

In a prospective study performed in 10 countries, 112 episodes were prospectively studied. Delayed arrival at hospital and prior weight loss had a significant impact on the time needed for DIOS resolution [63].

Appendiceal Disease

The incidence of acute appendicitis in CF is reported to be lower than in the general population. Nevertheless, patients who develop this complication carry a greater risk of a delayed diagnosis and an increased incidence of complications such as appendiceal abscess. The possible factors include luminal obstruction of the appendix with thick mucus, delayed intervention due to mistaken diagnosis of DIOS, or masking of acute symptoms by chronic antibiotic use.

Intussusception

In 1–2% of adult CF patients, intussusception occurs, approximately 10–20 times higher than in the general population. Most cases are ileo-colic, and 25% are associated with small bowel obstruction [64]. Sticky, muco-feculent material which adheres to the intestinal epithelium may act as the lead point in intussusception. Plain abdominal X-rays are often nonspecific, showing fecal loading, or less often a small bowel obstruction. Presentation is usually with intermittent abdominal pain. Classical appearances of intussusception may be seen on barium studies and include a lobulated soft tissue mass and a "coiled spring" usually situ-

ated in the right iliac fossa. The "doughnut sign" on transverse scan and "pseudo-kidney" on longitudinal scan are some of the ultrasound examination findings. Intussusception is often intermittent and resolves spontaneously, and it may also be observed in asymptomatic patients as an incidental finding during abdominal imaging [65].

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a multifactorial problem with contributions from both the severity and treatment of lung disease, physiotherapy, transient inappropriate lower esophageal sphincter relaxation, and delayed gastric emptying. GERD is common in CF patients, and there is some evidence that GERD may contribute to the progression of respiratory disease either by pulmonary aspiration of refluxed gastric contents or by neurally mediated reflex bronchoconstriction secondary to irritation of the esophageal mucosa [66]. This is debatable as the GERD may be secondary to the lung disease. Other complications include malnutrition due to increased losses through emesis or reduced energy intake from dysphagia and esophageal strictures. Since silent GERD is common in CF patients, a lack of reported symptoms does not exclude this diagnosis. Bile acids are found in the sputum of children with CF suggesting bile reflux [67]. While esophageal pH or impedance monitoring is helpful, upper endoscopy and biopsy are recommended especially when drug trials have failed in order to define the extent of disease and to rule out other esophageal pathology such as eosinophilic esophagitis.

Fibrosing Colonopathy

A complication of CF involving mainly the colon was reported in young patients with CF in 1994 [68]. The term "fibrosing colonopathy" was used to describe what became recognized as an iatrogenic complication, resulting in considerable morbidity and some mortality. Many patients were initially diagnosed as having inflammatory bowel disease as their symptoms include worsening abdominal pain, intermittent bowel obstruction, and passage of blood and mucus. The proximal colon developed a concentric ring of fibrosis below the submucosa, but in some patients, the concentric fibrosis extended to the entire colon, producing the shrunken "pipe stem" effect. There is considerable hypertrophy of the muscularis mucosa, and the submucosa shows variable degrees of inflammation with eosinophils and mixed inflammatory cells. In the UK and the USA, case-control studies showed a strong statistical association between this complication and dose of pancreatic enzymes (often in excess of 50,000 U lipase/kg body weight) [69]. This led to a reevaluation of the safety of pancreatic enzymes [31]. Notwithstanding, there was no evidence that the excessive doses of enzymes that were used by many clinicians actually improved efficacy or improved abdominal symptoms attributable to maldigestion. Several countries have implemented strict dosing guidelines for PERT. However, a few additional cases of fibrosing colonopathy have been reported in the USA and the UK giving further evidence that "enzyme overdosing" still occurs and also emphasizes the need for close monitoring of enzyme doses in all patients with CF.

Intestinal Infections

The vast majority of patients are asymptomatic, but patients with CF generally demonstrate significantly higher rates of *Clostridium difficile* (32–50%) than the general population (2%), as is the case with healthy neonates. However, on rare occasions severe, potentially fatal cases of pseudomembranous colitis have been reported [70]. Presenting with acute toxic megacolon without diarrhea, the clinical manifestations may be atypical, and absence of diarrhea could be due to the lack of intestinal CFTR function. An immunological protection from diarrhea may be due to chronic antibiotic therapy allowing chronic colonization with this pathogen. Alternatively, the unique intestinal environment in CF patients may provide a favorable milieu for this organism. Another hypothesis is due to an abnormality in receptor binding of the toxin, and there is a reduced risk of clinical complications in CF.

Up to 25% of patients in the general population will have recurrence of their *Clostridium difficile* infection following completion of a treatment course [71]. For recurrent or treatment refractory cases of *Clostridium difficile* infection in the general population, fecal microbiota transplantation (FMT) has proven to be >90% effective in treating the infectious diarrhea [72]. Asymptomatic carriage rates for *Clostridium difficile* are higher for patients with CF than the general population [73], with some studies showing up to 50% of CF patients receiving antibiotics to have *Clostridium difficile*-positive stool [74]. The increased carriage rate along with a decreased infectious rate makes the diagnosis, treatment, and follow-up of infectious *Clostridium difficile* much more difficult in this population. While no studies have specifically looked at the efficacy of FMT for recurrent *Clostridium difficile* infection in patients with CF, one case report by Dunwoody et al. showed that prophylactic FMT in a CF patient with recurrent *Clostridium difficile*-positive diarrhea following antibiotic treatments helped prevent future episodes of diarrhea [75].

CF patients have been reported also to have an increased colonization rate of other bacterial species. This could include *Lactobacillus* spp., *Pseudomonas* spp., *Staphylococcus*, and *Enterococcus*. It has been suggested that CFTR itself acts as a receptor for certain organisms, thereby creating a loss of CFTR affording a form of protection from the consequences of infection. The clinical significance of this is unclear.

In patients with increased diarrhea, abdominal distension, and anorexia, *Giardia lamblia* should be considered as it is a common intestinal parasite and may be more common in patients with PI from any cause including CF [76].

Small-Intestinal Bacterial Overgrowth

CF patients often complain of abdominal pain, bloating, and changes in bowel habit and these common symptoms may be related to the changed microbiota. Indirect evidence points to an estimated prevalence of around 50% of CF patients presenting with small-intestinal bacterial overgrowth (SIBO) [77, 78]. Risk factors include abnormal accumulation of surface mucus (which may allow proliferation and adhesion of bacteria), the reduced alkaline flushing of the upper intestine, and the altered intestinal mucins (which may have limited protective functions). Intestinal dysbiosis is well-documented in cystic fibrosis [79]. Additionally, there is an increased risk of SIBO following intestinal resection due to MI. SIBO may contribute to malabsorption in some patients with CF, although data are limited. The prominent histological feature of the CF mouse's small intestine is mucus accumulation, which occludes the crypts and coats the villus surfaces. The mucus obstruction of the crypts is believed to interfere with innate defense mechanisms of the Paneth cells residing at the base of the crypts, secreting a variety of antibacterial products. One may speculate that SIBO of the CF mouse small intestine is similar to that reported in humans, as there is evidence of intestinal inflammation characterized by increased mucosal infiltration of mast cells and neutrophils and a 40-fold increase in luminal bacteria, and treatment of the bacterial overgrowth reduces mucus accumulation [80].

Emerging evidence suggests that changes in microbiota occur within the first year of life and are associated with early growth failure in the infant with CF [81] and poor clinical outcomes [82]. As stated earlier, intestinal inflammatory changes have been identified macroscopically in people with CF, and this may be due to the altered composition of the gut bacterial ecosystem [58, 59]. Intestinal inflammation as measured by fecal calprotectin is inversely correlated with growth in children with CF [83]. Using a germ-free CF mouse model, Meeker et al. have shown that mutated CFTR alone alters the microbiome [84].

Rectal Prolapse

A feature of CF is rectal prolapse, mainly occurring only in PI patients; however, there have been PS patients observed with prolapsed rectums. Children presenting with recurrent rectal prolapse should be referred for a sweat chloride test to exclude CF.

Celiac Disease and Crohn's Disease in CF

CF was first described as a distinct clinical entity from celiac disease approximately 70 years ago. Reports since then suggest that the prevalence of celiac disease in patients with CF is higher than in the general population [85, 86].

The prevalence rate of Crohn's disease in CF patients is seven times higher than in those reported controls by Lloyd Still et al. [87]. Although there have been many cases reported prior to the description of fibrosing colonopathy, some of them may have been due to the complications of high-dose enzyme therapy and should be considered in CF patients presenting with suspicious symptoms and signs.

Gastrointestinal Malignancy

Early detection of CF especially neonatal screening, improvements in nutrition, bronchial clearance, antibiotics, and organ transplantation have led to a tremendous increase in life expectancy. Currently the median life expectancy in North America for a CF patient born in 2015 is 45 years, and CF now has a majority of patients who are adults. Gastroenterologists are increasingly involved in the care of the multiple complications in CF patients [12]. One of the corollaries of CF becoming an adult disease is that patients suffer from adult problems including in particular gastrointestinal malignancies especially colon cancer [88].

The effect of nonfunctioning CFTR protein on the intestine is being recognized. The impaired electrolyte transport leads to mucosal barrier dysfunction leading to bacterial colonization, and mucosal inflammation. This has been well documented in cftr-knockout mice, and in humans we coined the term CF enteropathy after studying the intestinal mucosa with video capsule endoscopy which has been repeated by other researchers [58, 59]. On the molecular level, absence of cftr causes upregulation of oncogenic genes [89]. The inflammatory state in the gastrointestinal tract in CF patients promotes oncogenesis.

Epidemiological studies have suggested that CF is associated with an increased risk of gastrointestinal tract cancers. Colon cancer is the most common and represents the most significant risk. The risk was higher in male patients, those with PI and a history of DIOS [90]. Early detection of

colorectal cancer and removal of adenomatous polyps result in significant reduction in mortality. There is consensus endorsing population-wide screening for colon cancer beginning at 50 years of age. An excellent single-center study from Minnesota showed that in CF adults there is a fivefold increase in colonic neoplasms from the age of 40 [91]. The risk of CRC in patients with CF increases markedly after organ transplantation with the risk being over 25 times the age-adjusted baseline [92].

Yamada et al. have performed the first meta-analysis of the risk of gastrointestinal cancers in patients with CF compared to the general population [93]. The overall risk of gastrointestinal cancer was significantly elevated (SIR (standardized incidence ratio) 9.37) with significant increase in transplanted patients as well. The SIR of site-specific cancers of small bowel, colon, biliary tract, and pancreas was elevated.

The marked increase in the incidence of CRC prompted the North American CF Foundation to set up a Task Force whose findings have been published [94]. Colonoscopic screening for CRC should begin at 40 years of age with rescreening every 5 years. In patients who have had adenomas detected, this is increased to every 3 years. In transplanted patients, screening should begin at 30 years of age within 2 years of transplantation.

The emergence of gastrointestinal cancer as a potentially significant clinical problem in adult CF patients is a direct consequence of the greatly improved life expectancy. There is a possibility that chemopreventive drugs and the new CFTR modulator drugs (see below) which increase the expression of CFTR protein at the apical surface may also decrease the incidence of gastrointestinal cancers.

However, the meta-analysis has shown that CF should be added to the list of gastrointestinal cancer syndromes deserving special considerations for screening and surveillance [95].

Nutritional Complications

Malnutrition and lung disease are interrelated [96]. Care for CF involves attention to nutritional status to promote the most favorable outcomes. An experienced dietitian in the field of CF would play an essential role in the care of CF patients and should be an integral part of the CF team.

Nutritional Intake

A good nutritional diet regime is associated with improved lung function parameters, thus offering parents and patients with CF more motivation to adhere to prescribed therapies such as enzymes, vitamins, and a balanced, high-energy dietary intake. Studies from the 1980s changed the face of nutritional management of CF and proved that high-fat and high-energy diets were far superior to the old low-fat diet routines [97]. A diet that is composed of 35–40% of calories from fat is recommended in order to meet the energy demands of those with CF.

This diet regime given to infants from a neonatal screening program has demonstrated that normal growth can be achieved into adolescence. Farrell et al. found that the anthropometric indices of nutrition were significantly better in screened subjects compared with non-screened CF subjects up to the age of 16 years [98]. Recommendations by the North American Cystic Fibrosis Foundation Consensus Committee on Nutrition and European Cystic Fibrosis Society include appropriate evaluation of nutritional status at all ages and a diet that is age appropriate, with sufficient energy to meet needs for normal growth and weight gain [99, 100].

Feeding guidelines for infants with CF recommend breast milk as the primary source of nutrition for the first year of life [101]. Breastfeeding has been shown to be protective for the infant with CF. Breast-fed CF infants compared to formula had improved lung function with a reduced occurrence of infections during their first 3 years. Breast milk can provide the complete nutritional support for infants with CF during for the first 4–6 months. It is proven to be more efficient if supplemental energy is added to fortify a portion of the breast milk feeds with formula or by fortifying formulas to a more concentrated energy level for those infants on a combination of breast milk and formula or on formula alone. If breastfeeding is not an option or if supplementation is required, regular cow's milk-based infant formulas can be used [32]. In most cases, there is no need for a predigested formula. In warmer climates, sodium supplementation may often be recommended if reported to have a higher degree of loss in sweat. A total of 2–4 mmol/kg supplementation of milk or solids with table salt to provide per day is recommended; however, due to potential for errors in the accuracy of the measurement of the salt, liquid mineral mix solutions prepared by hospital pharmacies are often advised. Breast milk or formula intake should be supplemented with complementary solids after the first 4–6 months for increased energy. For the exclusively breast-fed infant, meat may be recommended as the first food due to its increased energy content and more importantly for its iron and zinc content. At 1 year of age, whole milk is recommended unless breast milk is continued.

Toddlers and Children

As the dietary intake and degree of physical activity vary with preschool-age toddlers and children, the addition of calorie-rich food is considered important. Self-feeding skills,

habits, and food preferences are established at this stage. Mealtimes should be a positive experience. School activities may conflict limiting snacks and adherence to enzymes; it is recommended that the health-care providers inform parents of appropriate strategies to support compliance with enzyme therapy.

Older children require higher nutrient intake due to acceleration of their growth; unfortunately, the progression of lung disease may compromise the nutritional status, as it increases the energy demands, interfering with appetite and resulting in decreased energy intake. If oral intake is not enough to support expected growth or nutritional status, a more aggressive nutritional intake via enteral tube feeding may be required and is best presented as a positive approach to help improve quality of life and health. However, a thorough evaluation of the nutritional failure must be completed before this type of support is implemented. The following should be considered and addressed as part of the evaluation: Behavioral and emotional issues, compliance, medical complications including GERD, cystic fibrosis-related diabetes (CFRD), or distal intestinal obstruction syndrome (DIOS) should be considered. Enteral tube feeding may provide approximately 30–50% of estimated daily energy requirements with appropriate enzyme therapy, generally delivered as overnight feed. The decision varies from individual patients as to when supplemental enteral nutrition is to be commenced. Some centers use intravenous lipids as an adjunct to enteral nutrition particularly in patients with low serum fatty acid concentration [102]. If total parenteral nutrition is used in non-post-surgical situations, weight gain is usually not sustainable once this support ceases.

The importance of the clinical staff being made aware of the overall nutritional status of their patient population allows for more focus on nutritional support. The sharing of these results with patients and families provides for teamwork and collaboration opportunities.

Fat-Soluble Vitamins

The neonatal diagnosis via screening programs is well documented. In non-screened populations, overt deficiencies are well described including benign intracranial hypertension [103], night blindness [104], rickets [105], hemolytic anemia [106], and coagulopathy due to vitamin A, D, E, and K deficiencies, respectively. Due to ongoing mild to moderate fat malabsorption, fat-soluble vitamin supplements are required for CF PI patients [107]. The European Guidelines are similar to those of North America, with the exception of a higher recommended vitamin A dose (4000–10,000 IU) and a higher starting dose of vitamin E and vitamin K (100 IU and 1 mg). This discrepancy is due to the lack of controlled studies that aid in defining lower limits of intake that support normal serum levels. For example, those patients who are PS, who do not require pancreatic enzyme supplementation for normal growth, have normal serum vitamin blood levels, and they do not require vitamin supplementation. There is some evidence that supplementation of fat-soluble vitamins in PS patients may be associated with decreased incidence of pulmonary exacerbations possibly due to the antioxidant effect of these compounds [108]. The North American CF Foundation Committee on vitamin D guidelines [109] advises higher supplemental amounts of vitamin D than in the CF vitamin supplements currently available for individuals with suboptimal serum 25-hydroxyvitmain D levels. Therefore, additional vitamin D supplements are recommended with the annual monitoring of serum vitamin levels for vitamins A, E, and D. Vitamin K may be difficult to monitor as the test used to assess serum levels, PIVKA (protein induced in vitamin K absence), is not routinely available. However, obtaining serum PIVKA or at least prothrombin levels are advised for those patients with hemoptysis or hematemesis and in patients with liver disease. More studies are needed in order to establish the minimum requirement of vitamin K [110]. The amount of vitamin K in vitamin supplements marketed to CF patients is unlikely to be sufficient. Toxicity of fat-soluble vitamins is very rare in CF; the one exception is post-lung transplantation (see below).

Bone Health

In CF patients, a decrease in bone mineral density (BMD) may begin in early childhood [111]. The nutritional status, serum calcium, vitamin D and K levels, pulmonary infection, exercise program, glucocorticoid medication, and class of CFTR mutation are all influencing factors of bone health. Poor BMD is a reflection of bone health [112]. Therefore, monitoring of BMD is recommended during routine visits.

Lung Transplantation

Patients with CF may present with added nutritional challenges pre- and post-lung transplant. Pretransplant, energy intake is often affected and most likely to be suboptimal, therefore requiring increased nutritional support via enteral tube-feeding support [113]. During pre- and post-lung transplantation, reduced BMD is a concern [114]. Post-transplant, patient's appetite usually improves, and oral intake is sufficient, with less and eventually no dependence on enteral tube-feeding support. Post-transplant, it is recommended to leave the enteral tube in place for a period of about 6 months to avoid insufficient oral intake to meet the energy needs and routinely blood monitor the fat-soluble vitamin levels. After transplantation, hypervitaminosis A has been reported,

although the etiology of this novel finding is unclear [115]. It may impact drug interactions, altered absorption, increased hepatic synthesis of retinol binding protein, or impaired retinol metabolism. The prescribed amount of vitamin supplements may need to be altered, as vitamin A levels may be elevated. Counseling patients that respond well post-transplant regarding lower energy food options is recommended as patients may experience an increased appetite due to the effects of corticosteroids and decreased rate of growth in children. These patients will benefit from an exercise and rehabilitation plan for lung performance and nutritional status [116].

Novel Therapies

Probiotics

There is increasing evidence that the CF gastrointestinal microbiome is altered, and that this dysbiosis contributes to disease manifestations in the GI tract [80]. One of the therapeutic strategies is to replace the "missing" elements of the microbiome. Probiotics, when administered in adequate amounts, may confer a health benefit on the host. Potential mechanisms of action include changes in respiratory and stool microbiome, thereby affecting respiratory and GI symptoms and systemic inflammation. A systematic review examined the effect of probiotics on respiratory, GI, and nutritional status in CF patients and showed a reduction in pulmonary exacerbations with an improvement in subjective GI symptoms [117]. Two studies measured the effect of probiotics on fecal microbiota composition and showed a significant increase in the proportion of Bacteroidetes and Firmicutes [118] and a significant increase in Bacteroides [119]. In a pilot study from the ESPGHAN Working Group, probiotic supplementation did not influence fecal calprotectin, pulmonary function, pulmonary exacerbations, and microbiome. However, 13% of patients normalized their gut permeability which requires further study [120].

Coffey et al. have performed a Cochrane study on probiotics in CF and concluded that there is some evidence that probiotics improve laboratory markers of intestinal inflammation but have not been proven to affect respiratory function [121].

Characterization of the microbiome in CF will enable personalized medicine. Strategies of restoration of a beneficial microbial structure or function could potentially offer novel treatment options.

CFTR Correctors and Potentiators

The emergence of novel targeted agents, which directly correct CFTR, has created new treatment opportunities for patients with cystic fibrosis. There are two main types of new treatment modulators and potentiators which are in clinical use for class II and III mutations.

The first drug is Ivacaftor, a CFTR potentiating drug which was successful in treating class III mutations. Remarkably, this drug improved respiratory function and decreased sweat chloride concentration to near-normal levels and caused a substantial weight gain [122].

The second drug was a combination of Ivacaftor and Lumacaftor for the more common class II mutations [123], and recently a triple combination of Ivacaftor, Lumacaftor, and Tezacaftor has shown impressive improvement in the most common class II mutation F50 del homozygote and heterozygote patients [124, 125].

The increase in weight cannot be explained by the improvement in respiratory function alone leading to speculation that these drugs also improve the function of the gastrointestinal tract. There is increasing evidence that there are direct effects of the modulator drugs on the gastrointestinal tract [126]. There is increasing evidence that exocrine pancreatic function improves in patients with class III mutations taking Ivacaftor with the intriguing notion that if treatment is started early enough, exocrine pancreatic function may be preserved [127, 128]. Many patients carrying class III mutations suffer from recurrent pancreatitis and this is markedly reduced on Ivacaftor therapy [129].

Ooi et al. have shown that treatment with Ivacaftor reduced stool calprotectin significantly and changes in the microbiome (increased presence of Akkermansia spp. and decreased Enterobacteriaceae spp.), suggesting an improvement in intestinal inflammation [130].

The availability of these novel drugs will enable research into specific disease processes affecting the liver, intestine, and exocrine pancreas in CF.

In conclusion, children and adults with CF have a wide range of gastroenterological manifestations. Gastroenterologists must be involved to improve the quality of life and outcomes of these patients.

Small Intestinal Bacterial Overgrowth

42

David Avelar Rodriguez, Paul MacDaragh Ryan, and Eamonn Martin Mary Quigley

Introduction

Small intestinal bacterial overgrowth (SIBO) is a heterogenous disorder characterised by an excessive growth of select microorganisms within the small intestine. This excessive bacterial biomass, in turn, disrupts host physiology in a myriad of ways, leading to gastrointestinal and non-gastrointestinal symptoms and complications [1]. SIBO is a common cause of nonspecific gastrointestinal symptoms in children, such as chronic abdominal pain, abdominal distension, diarrhoea, and flatulence, amongst others [2–5]. In addition, it has recently been implicated in the pathophysiology of stunting [6], a disease that affects millions of children worldwide. Certain risk factors, such as acid-suppressive therapies [7–10], alterations in gastrointestinal motility and anatomy [11–20], and impoverished conditions [21–26], have been shown to predispose children to SIBO. Despite the relatively high prevalence of SIBO in children, it remains a poorly understood disorder. In fact, only a small number of studies have been published in the last two decades. Due to the relative scarcity of available literature and the recent emergence of novel, informative data regarding the underpinnings of the disease, an update for practicing paediatricians is now warranted. This chapter aims to comprehensively outline the most current information on SIBO in children, with particular emphasis on recent progress in our understanding of gut microbiota.

The Gastrointestinal Tract and Gut Microbiota

Within the lumen of the gastrointestinal tract reside gut microbiota, who represent a complex and susceptible microbial consortium composed of enteric-adapted bacteria, acquired in the very early stages of life and developing in concert with the host [27, 28]. This mutualistic homeostasis is achieved through a range of mechanisms which maintain a life-long symbiotic microbe-host relationship, providing a plethora of important functions: from vitamin and short-chain fatty acid (SCFA) production to immunoregulation and neuropeptide secretion (for review see Ref. [29]).

The composition and functionality of gut microbiota are shaped and influenced by a multitude of intrinsic and extrinsic factors, such as genetics, mode of delivery, gestational age, feeding type and diet, pharmaceuticals, and even exercise [29]. The composition of gut microbiota exhibits variations related to the anatomical location in the gastrointestinal tract, which is, in turn, influenced primarily by factors such as luminal oxygen concentration and pH as well as the presence of bile and digestive enzymes. Indeed, bacterial numbers increase from about 10^3 to 10^4/mL in the stomach to approximately 10^{11}/mL in the colon [30–32]. Colonic microbiota represent the largest prokaryotic community in the human body, representing nearly 0.3% of the overall host body weight [33]. Although composed largely of four bacterial phyla – Actinobacteria, Firmicutes, Bacteroidetes, and Proteobacteria – the infantile gut microbiome is dominated by Actinobacteria, with Firmicutes emerging to dominate after infancy [34]. In general, bacteria from the Actinobacteria (e.g. *Bifidobacterium*), Firmicutes (e.g. *Faecalibacterium*, *Clostridium*, *Ruminococcus*, *Lactobacillus*), and Bacteroidetes (e.g. *Bacteroides*, *Prevotella*) phyla are largely regarded as commensal microorganisms, while a significant portion of gastrointestinal pathogens belong to the Proteobacteria phylum (e.g. *Escherichia*, *Shigella*, *Salmonella*, *Klebsiella*, and *Helicobacter*) [35, 36]. In

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_42

addition to this diverse community of bacteria, the human gastrointestinal tract is also home to an extensive array of viruses [37], fungi [38], and archaea [39]. While it remains unclear at present as to whether the former two kingdoms play a significant role in SIBO pathogenesis, methanogenic archaea, such as *Methanobrevibacter* spp., have been directly implicated in a methane-specific form of the disorder [40].

It is important to note, however, that despite the substantial advances made in the study of gut microbiota, small bowel microbiota remain poorly understood [41, 42]. Whereas colonic microbiota are more easily accessible and can be sampled via colonoscopy or faecal samples [43], sampling of small bowel microbiota poses a major challenge due to the invasiveness of the procedures (upper endoscopy) involved and the technical difficulties associated with these (such as avoiding contamination by oral microbiota). However, it appears that gut microbiota from stool samples and that from small bowel (sampled directly from small intestinal stomas) correlate well according to a small study of children with short bowel syndrome, particularly in relation to bacterial distribution, if not bacterial load [44]. The REIMAGINE (Revealing the Entire Intestinal Microbiota and its Associations with the Genetic, Immunologic, and Neuroendocrine Ecosystem) study [45] is an ongoing initiative that sets out to investigate the small bowel gut microbiome in health and disease.

Epidemiology in Children

The prevalence of SIBO in children has been explored in a wide spectrum of clinical contexts, including children living in impoverished conditions, individuals with chronic abdominal pain (CAP), as well as those who suffer from irritable bowel syndrome (IBS), stunting, and obesity, amongst other diseases. SIBO prevalence ranges from about 9% in children taking proton pump inhibitors (PPIs) [7] to approximately 90% in those with stunted growth [6] and chronic abdominal pain (CAP) [2]. However, it should be noted that data on the epidemiology of SIBO in children is limited by the small number of studies available, the lack of appropriate controls in some studies, and the varying test methodology employed and diagnostic cut-offs applied.

Pathogenesis

SIBO can negatively impact the host in a range of ways [1, 30, 46–54]. These include bacterial carbohydrate fermentation leading to excess gas production and fluid secretion [1]; bacterial deconjugation of bile acids resulting in poorly absorbed liposoluble vitamins as well as stimulation of colonic secretion and motility [18]; consumption of macronutrients and micronutrients by bacteria (bacterial-host nutrient competition), leaving the host with less available nutrients for absorption [51]; villous blunting leading to carbohydrate malabsorption [13, 55–57]; decreased short-chain fatty acid production [6, 58]; intestinal and systemic inflammation [16, 25, 59]; and increased gut permeability (Fig. 42.1). It should be noted that a recent systematic review [46] and clinical study [25] found conflicting and contradictory evidence with regard to effects on gut permeability.

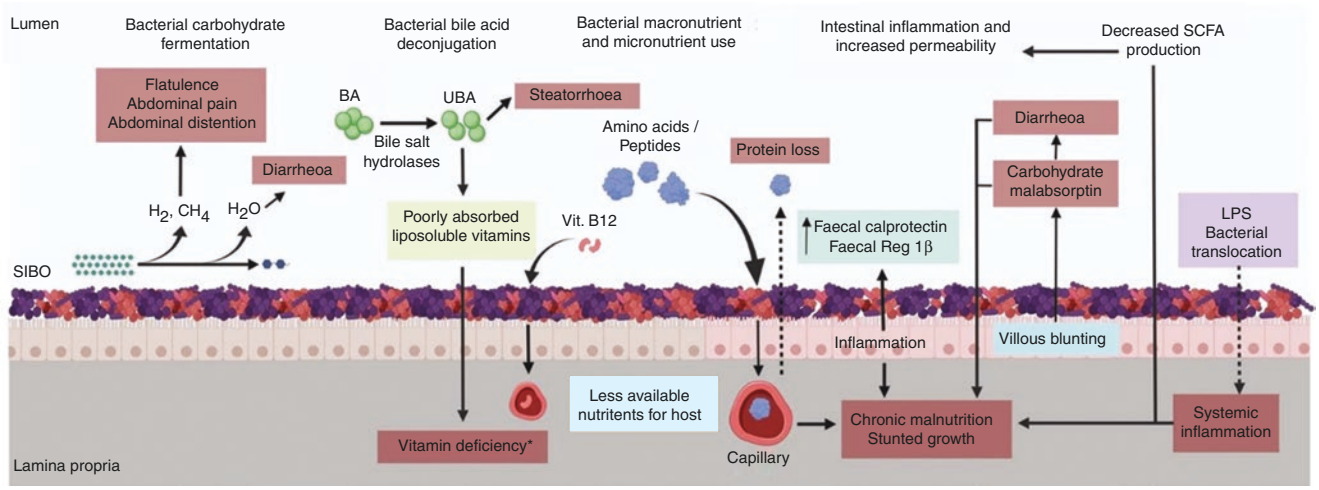

Fig. 42.1 Mechanisms through which SIBO affects the host. *The dotted arrows indicate increased intestinal permeability. * Includes vitamins A, D, E, and B_{12}. Vitamin K is synthesised by the gut microbiota, and thus its deficiency in this context is very unlikely. BA, bile acids; UBA, unconjugated bile acids; LPS, lipopolysaccharides*. Risk Factors

Acid-Suppressive Therapies

Gastric acid plays a crucial role in preventing pathogens from colonising the human alimentary tract, particularly the proximal portions [60]. Several extrinsic and intrinsic factors are known to alter this natural barrier [61], with one of them being proton pump inhibitor (PPI)-induced hypochlorhydria. PPIs are commonly prescribed for the treatment of gastroesophageal reflux disease (GERD) and, sometimes, for gastroesophageal reflux (GER) in children [62]. These drugs decrease gastric acid secretion by blocking the enzyme H^+/K^+-adenosine triphosphatase located in the apical membrane of parietal cells [63]. It has been estimated that approximately 34% [62] of paediatric patients treated with PPIs develop adverse effects, including infectious diarrhoea, *Clostridium difficile* infection, respiratory infections, and SIBO [64–70]. In addition, PPIs have also been shown to alter faecal gut microbiota of children and adults [71, 72]. In theory, the resultant acid suppression creates a more favourable environment for bacteria to overgrow, particularly Gram-positive, aerobic bacteria [30], leading to SIBO. However, a recent observational study [6] found contradictory evidence: despite the high prevalence of SIBO seen in the patient cohort (i.e. 96%), gastric pH was found to be in the acidic range (i.e. pH 2.7). It is important to note that pH measurements were only obtained from the study group and lacked normal reference values for comparison.

To date, four studies have assessed SIBO risk in children on acid-suppressive therapies [73]. In a study of children taking PPIs [7], of whom 77% took PPIs for over 12 months, SIBO was detected in 8.9% of children taking a PPI and in 3.7% of controls. In another study [10], the glucose hydrogen breath test (GHBT) was performed before and after a 3-month trial of omeprazole treatment in children with histologically proven peptic esophagitis, with 22.5% of children developing SIBO. Moreover, Rosen et al. [8] cultured the gastric fluid of children taking PPIs for at least 4 weeks and whose last dose was taken within 24 hours of sampling. Compared with the control group, the PPI group was found to have a significantly higher prevalence of gastric overgrowth (46% vs 18%), which was mainly caused by potential pathogens such as *Staphylococcus* and *Streptococcus*. In a double-blind, placebo-controlled randomised clinical trial [9], children were randomly assigned to one of two 4-week treatment groups: omeprazole/placebo group or omeprazole/probiotic. SIBO was excluded at baseline in all. Following the 4-week intervention, a second GHBT indicated that SIBO was present in 33% and 26% of omeprazole/probiotic group and omeprazole/placebo group, respectively.

Two meta-analyses [74, 75] of adult patients evaluated the association between PPI treatment and SIBO risk. In the most recent meta-analysis [74], 19 observational studies involving a total of 7055 adult subjects were included. Even though a high degree of heterogeneity was identified, the authors concluded that PPI therapy was associated with a modest risk for SIBO (odds ratio 1.71, 95% CI 1.20–2.43) after adjusting for study quality. The second meta-analysis [76] included 11 studies with a total of 3134 adult subjects. Likewise, the authors found a statistically significant association (OR, 2.282, 95% CI 1.238–4.205) between PPI therapy and SIBO, but only when the diagnosis was made with a "highly accurate testing modality" such as duodenal/jejunal aspirate and culture. It is important to note, however, that all the studies included in both meta-analyses were observational in nature and different diagnostic approaches (culture or breath tests) were used for SIBO diagnosis.

In conclusion, it appears that PPIs are a (perhaps weak) risk factor for SIBO, but only when this is assessed by culture-dependent approaches. The clinical implications are unclear given the overall low odds ratios (~2) and the lack of controls. Thus, until better data are available, it may be prudent to be judicious in prescribing long-term PPIs for children with GERD, and perhaps more importantly, that their use is avoided in children with GER [65, 67].

Intestinal Motility Disturbances

In addition to the acidic environment created by gastric acid, gut motility is critical to preventing SIBO. The migrating motor complex (MMC), a cyclic motor pattern that occurs during the interdigestive state, plays an important role in preventing the development of bacterial overgrowth within the small intestine [77]. In fact, the MMC is commonly referred to as the "intestinal housekeeper" given its role in this aspect of gastrointestinal health [78]. Under physiological conditions, the MMC sustains the aboral progression of luminal content in the small intestine between meals, thereby preventing stasis and SIBO. On this basis, an absent or disrupted MMC may lead to bacterial overgrowth [78].

The typical example of a disorder of gut dysmotility leading to SIBO is systemic sclerosis, with approximately 40% of adult patients being affected [47]. Despite the relatively high prevalence of gastrointestinal symptoms in children with juvenile systemic sclerosis (jSS) [79], to our knowledge, no studies have investigated the association of SIBO with jSS.

A somewhat more common example of gut dysmotility associated with increased risk of SIBO is cystic fibrosis (CF) [80]. Prevalence of SIBO in children with CF ranges from 30% [11, 81] to 56% [12] in different study cohorts. A study

[13] that used the HBT to evaluate orocecal transit time and SIBO in children with CF found that CF children had a significantly higher SIBO prevalence and the orocecal transit time was significantly longer than in healthy individuals. Data from animal studies showed that CF mice had a higher prevalence of SIBO than wild-type mice [82], which is thought to be due to slowed intestinal transit – possibly due to unabsorbed lipids leading to a triggering of the "ileal brake" – and/or smooth muscle dysfunction [80, 83], as well as mucus accumulation which acts as an anchor for bacteria, thereby facilitating overgrowth [76, 82]. Pancreatic insufficiency, a known risk factor for SIBO, might also play a role. Thus, the multifactorial nature of CF, including gut dysmotility, impaired mucus clearance, and a deficiency of pancreatic enzymes, seems to put children at a higher risk of developing SIBO.

Constipation has been shown to be associated with SIBO. However, the causative or consequential nature of this interaction is unclear. In theory, slower orocecal transit seen in constipation may fail to clear the luminal content, thereby increasing the risk of SIBO. On the other hand, methane, a biologically active gas produced instead of hydrogen by some individuals from bacterial fermentation of carbohydrates, can delay intestinal transit, which in turn may lead to constipation. In a study of children with myelomeningocele [14], SIBO was diagnosed in 39% (7/18), and, interestingly, all methane producers had a delayed orocecal transit time. Moreover, another study found a 42% (21/50) prevalence of SIBO amongst children with retentive faecal incontinence, of whom 8 had methanogenic SIBO, 11 had hydrogen-type SIBO, and 2 had mixed (methane and hydrogen)-type SIBO. In addition, 48% of patients with faecal incontinence were found to have high basal methane concentrations (>10 ppm) as compared with 10% of control subjects [15]. Furthermore, in a study of children with constipation [20], methane production was found in 73.5% (25/34) of children with constipation and soiling as compared with 1% of children with constipation alone.

The notion that a slowed intestinal transit may predispose to SIBO is supported by two recent studies in adults [84, 85]. In the most recent study [84], two patient groups (PPI group and PPI/prokinetic group) underwent GHBT and lactulose hydrogen breath test (LHBT) and evaluation of orocecal transit time. Interestingly, SIBO was more common in the PPI alone group than in the PPI + prokinetic group, and SIBO-positive patients had slower orocecal transit times than SIBO-negative patients. However, it is important to note that the overall SIBO prevalence was only 8.8% (13 subjects), and even though the authors measured both hydrogen and methane, it was not specified whether the three patients with methane-positive SIBO had normal or delayed orocecal transit times. Furthermore, in the second study [85], 29 female patients with functional constipation were prospectively enrolled in a 2-week trial of lubiprostone. Gastrointestinal transit and SIBO were evaluated by the wireless motility capsule (WMC) and lactulose hydrogen/methane breath tests, respectively. At baseline, 68% of patients had increased levels of both hydrogen and methane, suggesting SIBO. After treatment completion, 41% of patients became SIBO-negative, which was paralleled by a 30% increase in small bowel transit time. However, it is important to mention that the authors considered methane positivity as an increase of ≥3 ppm, which differs from the current guidelines in which methane positivity is defined as an increase of ≥10 ppm [86]. It is challenging to interpret these results for two reasons: (1) all patients had constipation and were methane producers at baseline (i.e. methane production of ≥3 ppm); thus, this suggests constipation may have been caused by intestinal methane production rather than constipation leading to SIBO; or simply, the methane values present in these patients could be physiological; and (2) the fact that lubiprostone "cured" 41% of patients suggests that by increasing intestinal transit (and thus intraluminal clearance), faecal stasis decreases, which might secondarily prevent the development of SIBO.

Anatomical Alterations

Anatomical boundaries, and particularly the ileocecal valve, are considered crucial for maintaining a harmonised microbial community within the human alimentary tract, Absence or dysfunction of the ileocecal valve has been shown to predispose patients to SIBO, as colonic bacteria are thought to be "backwashed" into the small intestine, thereby leading to coliform-type SIBO development [30].

Paediatric intestinal failure is a chronic disease variably characterised by altered intestinal motility and anatomy, absence of the ileocecal valve, and prolonged use of antacids and antibiotics, which increases the risk of SIBO [87, 88]. Over the past few years, a plethora of research has been conducted on SIBO in children with intestinal failure. Children with intestinal failure have high rates of SIBO, ranging from 40% [16, 18] to 78% [17, 19] in different study cohorts. Absence or dysfunction of the ileocecal valve [16, 18, 19], a shorter small bowel remnant [89], as well as use of parenteral nutrition (PN) [17, 90] are factors independently associated with an increased risk of SIBO in these children. Furthermore, children with intestinal failure and clinical SIBO appear to be more likely to develop ambulatory central line-associated bloodstream infection, possibly due to increased intestinal permeability and bacterial translocation [91]. An interesting study [92] that evaluated the faecal gut microbiota of children with short bowel syndrome found that those on PN had decreased diversity and increased numbers of Proteobacteria as compared with those who were weaned

from PN. None of the PN patients had an ileocecal valve, and, of these, four out five patients evaluated for SIBO were on with antibiotics, which may explain the observed microbiota perturbations.

Taken together, these findings demonstrate that paediatric intestinal failure is a multifactorial process with an increased risk of SIBO. Resection of the ileocecal valve, in particular, appears to be a common finding in children with intestinal failure and SIBO, strongly suggesting the role of this structure in SIBO prevention. In line with this, a study of adult patients [93] investigated the ileocecal junction pressure using the wireless motility capsule and the presence of SIBO by the LHBT and small bowel aspirate and culture. Interestingly, the authors found a combination of SIBO-predisposing factors in their patient cohort: (1) the small bowel transit time in SIBO patients was significantly slower than those without SIBO, (2) the gastric pH was significantly higher in SIBO patients than those without SIBO, and (3) the mean ileocecal junctional pressure was significantly lower amongst SIBO patients than those without SIBO. Thus, these findings reinforce the fact that an "incompetent" ileocecal valve predisposes to SIBO and emphasise the multifactorial nature of the disease.

Impoverished Conditions and Poor Socioeconomic Status

Impoverished conditions, which are commonly associated with a lack of basic sanitation services such as clean water, appropriate sewage, and collection of household garbage, may be a risk factor for SIBO. Six studies (one from Myanmar [21], three from Brazil [22–24], and two from Bangladesh [25, 26]) have investigated this association in children.

A study from Myanmar (in a Burmese village) [21] investigated the prevalence of SIBO in children using the LHBT. Around 85% of the village's population obtained drinking water from surface wells and ponds, and approximately 10% used rainwater for the same purpose [94]. SIBO was diagnosed in 27% of children (53/195), with males being more commonly affected than females. In another study [22], SIBO prevalence was significantly higher in children living in a slum compared with controls living in households with appropriate sanitation services (37.5% vs 2.1%, respectively). Another study from Brazil [23] documented significantly higher prevalence of SIBO in slum-dwelling children in comparison to their socioeconomically advantaged counterparts (30.9% vs 2.4%, respectively). Interestingly, the authors did not find statistically significant differences in the environmental variables (i.e. water contamination with coliforms, access to public water network, access to public sewage, and public collection of household garbage) between the SIBO-positive and SIBO-negative slum dwellers. In another study by the same group [24], 60% of children were found to have SIBO, and their faecal gut microbiota analyses showed a significantly higher number of *Salmonella* spp. and lower numbers of Firmicutes. Moreover, in a study of 90 Bangladeshi children belonging to the lowest socioeconomic strata [25], 16.7% had a positive GHBT; furthermore, the odds of developing SIBO were increased by the presence of an open drain/sewer outside the home (OR, 4.78; 95% CI, 1.06–21.62). In the same cohort of children [95], and using 16 S V4 rDNA to analyse faecal gut microbiota, a *Lactobacillus* bloom was noted in children with a positive GHBT. A recent study on the faecal gut microbiota of children living in urban slums in Mumbai, India, found a dominance of Proteobacteria [96]. Although the authors did not perform breath tests to diagnose SIBO, it is known that bacteria belonging to the Proteobacteria phylum are the most common causative agents of SIBO.

Taken together, these findings demonstrate that children living in poor sanitation conditions, particularly those involving exposure to contaminated water, may have a higher risk of developing SIBO and a disturbed gut microbiome. However, it is important to mention that none of these studies provided a clear pathophysiological mechanism through which such unsanitary conditions predispose children to the disease. It has been hypothesised that repeated exposure to abnormal levels of lipopolysaccharides found in soil and drinking water may disrupt the MMC, causing intestinal stasis (as seen in patients with gut dysmotility), thereby leading to SIBO [48]. However, while this hypothesis appears to be biologically plausible, to date, no studies have evaluated it.

Other Risk Factors for SIBO

Immunodeficiency and celiac disease (CD) have also been regarded as potential risk factors for SIBO. As for immunodeficiency disorders, a small-scale study [97] on children with immunodeficiency syndromes (i.e. IgA deficiency, hypogammaglobulinaemia, and T cell defects) found SIBO in 41% of patients via jejunal aspirate and culture, and the most common clinical manifestation was chronic diarrhoea. Moreover, a recent small study of adult patients with common variable immunodeficiency [98] found SIBO in 40% of the cohort, with co-occurrence of abdominal pain and anaemia being significantly more common in SIBO-positive than SIBO-negative individuals. In another study [99], 4% ($n = 12/296$) of young adults with chronic diarrhoea and malabsorption syndrome were found to have hypogammaglobulinaemia. Of these, 25% ($n = 3/12$) were diagnosed with SIBO. Although these findings show a relatively high prevalence of SIBO in children and adults with immunodeficiency syndromes, large-scale studies are needed in order to further support this association.

As for CD, a recent systematic review [100] of studies in adults with CD documented a 20% pooled mean prevalence of SIBO. The authors concluded that SIBO may be common in patients with CD who do not improve following institution of a gluten-free diet. Two studies characterised microbiota composition and diversity amongst children with CD [101, 102] and found that those with active CD had a higher abundance of members of the phylum Proteobacteria [101] and lower ecological indices of genus *Lactobacillus* [102] as compared to healthy individuals and CD patients in remission. Although these studies did not set out to evaluate SIBO per se and as such did not report CFU/g, the higher abundance of Proteobacteria and lower ecological indices of genus *Lactobacillus* seen in children with CD may indicate a disturbed microbial ecosystem. Certainly, a study that evaluates the presence of SIBO in children with CD, either by the H_2/CH_4 breath test or small intestinal aspirate and culture, would be of great interest.

Although less studied, SIBO has also been noted to be more prevalent in nutritionally deficient disease states including intestinal failure requiring parental nutrition [90] and cystic fibrosis [81]. It is important to note, however, that SIBO can develop even in the absence of any of the aforementioned risk factors. In line with the findings by Boissieu et al. [3] and our own experience, many children who test positive for SIBO are "healthy" and have no evident risk factors. There are clearly many questions to be addressed by future studies regarding the risk factors for SIBO in children.

Aetiology of Paediatric SIBO

SIBO can be caused by archaea or bacteria, by one or more microorganisms, by Gram-positive or Gram-negative bacteria, and by anaerobic or aerobic microorganisms [30]. In a cross-sectional study in which patients underwent duodenal aspirate and culture for the diagnosis of SIBO (diagnostic threshold of $>10^3$ CFU/mL) [103], SIBO was diagnosed in 20% of cases, being caused by one microorganism in 54.7% of cases and by two microorganisms in the remainder. In addition, the vast majority of bacterial isolates belonged to the phyla Proteobacteria and Firmicutes, with the most common being *Escherichia coli*, *Enterobacter* spp., *Klebsiella* spp., *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Acinetobacter baumannii*, *Stenotrophomonas maltophilia*, *Citrobacter freundii*, *Serratia marcescens*, and *Enterococcus faecium* (in descending order of frequency). In another study that used the same diagnostic threshold [104], SIBO was diagnosed in 19.4% of adult subjects, and, again, most bacterial isolates were members of the phyla Proteobacteria and Firmicutes (*Escherichia coli*, *Enterococcus* spp., *Klebsiella pneumoniae*, *Proteus mirabilis*, *Acinetobacter baumannii*, *Citrobacter freundii*, and *Serratia marcescens*), and in 75% of cases the overgrowth was due to one microorganism. In the remainder, SIBO was caused by two microorganisms, with the most common being *E. coli/K. pneumoniae* and *E. coli/Enterococcus* spp. Furthermore, Gutierrez et al. [17] conducted a retrospective study on children with intestinal failure who underwent duodenal aspirate and culture. SIBO was diagnosed in 70% according to the more stringent diagnostic threshold of $>10^5$ CFU/mL. Again, the most common causative microorganisms were members of the phyla Proteobacteria and Firmicutes, with the most common being *E. coli*, *Streptococcus viridans*, *K pneumoniae*, *Enterococcus* spp., and *Pseudomonas aeruginosa*. The overgrowth was due to more than one bacterium in a minority of patients. Moreover, Galloway [18] diagnosed SIBO in 43% of children with intestinal failure, of whom five out of six patients had overgrowth due to two different microorganisms and only one had overgrowth caused by one microorganism, with *Enterococcus* and *Klebsiella* being the most frequently isolated bacteria.

In a more recent cross-sectional study of adult subjects with non-alcoholic steatohepatitis (NASH), and employing the diagnostic threshold for SIBO of $\geq 10^5$ CFU/mL and defining low-grade bacterial overgrowth as $\geq 10^3$ CFU/mL [105], 20% and 60% of cases are diagnosed with SIBO and low-grade bacterial overgrowth, respectively. Amongst the SIBO cases, Proteobacteria (*Pseudomonas aeruginosa*, *Klebsiella pneumonia*, and *Acinetobacter* spp.) were the most commonly isolated microorganisms, followed by members of the Firmicutes phylum (*Streptococcus* spp. and *Enterococcus faecalis*); 20% of cases were due to overgrowth of more than one microorganism.

Taken together, these findings demonstrate that in most cases, SIBO is caused by a single microorganism belonging to the phylum Proteobacteria [36], particularly coliform bacteria such as *E. coli* and *Klebsiella* spp. However, it is important to consider three aspects: (1) culture-dependent approaches were used in these studies, which means that there was a risk of missing bacteria that remain difficult to culture under clinical laboratory conditions; (2) only two studies were conducted on children [17]; and (3) SIBO was studied in a wide spectrum of clinical contexts, including IBS, intestinal failure, and non-alcoholic steatohepatitis. Thus, the specificity of such microbiota alterations for SIBO must be interpreted in the context of these potentially important confounders.

Next-generation sequencing (NGS) methods such as 16S ribosomal RNA (rRNA) sequencing provide a reasonably high-resolution and relatively cost-effective way to study the human gut microbiome [106–108]. Only one study in children [6] has used NGS to evaluate gut microbiota in the context of SIBO. Vonaesch et al. [6] conducted a novel, cross-sectional study on stunted and healthy children from

Madagascar and the Central African Republic, in which 16S rRNA amplicon sequencing was used to analyse the faecal gut microbiota composition of both groups and to confirm the presence of bacteria identified by gastric and duodenal fluid aspirate cultures. Despite the use of a higher diagnostic threshold for SIBO (i.e. $>10^5$ CFU/mL), SIBO was diagnosed in 96% of stunted children (Madagascar, 100%, and Central African Republic, 88%) and, interestingly, the most common causative microorganisms were oropharyngeal colonisers such as *Streptococcus* spp., *Staphylococcus* spp., *Haemophilus* spp., *Moraxella* spp., and *Neisseria* spp. In addition, microbiota sequencing revealed overrepresentation of oropharyngeal species (e.g. *Streptococcus* spp., *Haemophilus* spp., *Neisseria* spp., *Rothia* spp., *Actinomyces* spp., and *Gemella* spp.) and enteropathogens (e.g. *Escherichia coli*, *Shigella*, and *Campylobacter*), as well as underrepresentation of butyrate producers (e.g. *Clostridia* spp.) in stunted children compared with controls.

More recently, as part of the REIMAGINE initiative [45], a study was conducted on adult subjects who underwent upper endoscopy and whose duodenal aspirates were cultured and analysed by 16S rRNA sequencing [109]. The authors used a lower threshold of $>10^3$ CFU/mL for SIBO diagnosis. Compared with non-SIBO subjects, the α-diversity of the duodenal microbiome of SIBO subjects was decreased, and their predominant phylum was Proteobacteria (particularly Gammaproteobacteria), which was three-fold more abundant than in non-SIBO subjects, whose predominant phylum was Firmicutes. Again, these findings support the role of Proteobacteria as an important causative agent of SIBO.

Clinical Features and Complications

Paediatric SIBO is a heterogenous disorder that manifests itself through nonspecific symptomatology, including gastrointestinal and non-gastrointestinal symptoms [30, 110]. The most common signs and symptoms reported in the literature are chronic abdominal pain, abdominal distension, diarrhoea, flatulence, belching, steatorrhoea, fetid stools, mucus in stools, fatigue, nausea, and stunted growth [2–6].

SIBO and Functional Gastrointestinal Disorders

A small number of observational studies have evaluated the association between FGIDs and SIBO in the paediatric population.

In a study of children with abdominal pain-related functional gastrointestinal disorders (irritable bowel syndrome [IBS], functional abdominal pain [FAP], functional dyspepsia [FD], and FAP syndrome) [4], amongst the 14.3% SIBO-positive subjects (positive GHBT), the most common symptoms were fatigue (75%), altered defecation pattern (71%), nausea (68%), and bloating (66%). However, only altered defecation pattern, loss of appetite, and belching were significantly more common in SIBO-positive than SIBO-negative subjects; diarrhoea and flatulence did not reach statistical significance. In another study of children with chronic abdominal pain (FD, IBS, and FAP) and controls [111], 91% of cases and 35% of healthy controls had a positive breath test, respectively. Surprisingly, there were no differences in the presence of gastrointestinal symptoms, such as bloating, gas, incomplete evacuation, constipation, diarrhoea, mucus in stool, or straining, between SIBO-positive and SIBO-negative subjects; however, it is important to mention that only seven control subjects were included, in comparison to a very disproportional number of abdominal pain sufferers. Moreover, in a study that evaluated the prevalence of SIBO in children with IBS [112], SIBO prevalence was higher amongst those with IBS compared to their healthy counterparts (65% vs 7%, respectively). In a small retrospective study [113], children with chronic abdominal pain and atopy were more likely to have SIBO than non-atopic children and especially those with allergic rhinitis, asthma, and cow's milk protein allergy. Taken together, these findings suggest that SIBO is a frequent underlying diagnosis in children with functional abdominal pain disorders (i.e. IBS and FD), thus suggesting a role in their pathogenesis.

The IBS-SIBO interaction in adults has attracted a tremendous amount of research and controversy in the last decade. A systematic review and meta-analysis [114] of observational studies in adults estimated the prevalence and determined predictors of SIBO in IBS. The authors found an overall pooled SIBO prevalence of 38% (95% CI 32–44) as well as a 4.7 (95% CI 3.1–7.2) pooled OR for SIBO in IBS subjects as compared with healthy controls, and surprisingly, PPI use was not associated with SIBO. It should be noted that there was significant clinical and test modality heterogeneity between these various studies [115]. Even though a growing body of literature suggests an association between the two disorders, it is unclear whether SIBO precedes IBS or vice versa [116, 117]. Thus, until better data are available, children presenting with IBS-like symptomatology may merit evaluation for SIBO, such as by a H_2/CH_4 breath test. The role of SIBO role in IBS is comprehensively reviewed elsewhere [54, 118].

Constipation, another FGID, has been associated with intestinal methane production in adults and children (methanogenic SIBO) [119]. A 2011 meta-analysis [120] of nine studies (1277 subjects) found a significant association between methane production on a breath test and constipation (OR 3.51, CI 2.00–6.16). In a study of animal and human

models [121], intraluminal infusion of methane reduced small bowel transit by 59% in canine models as compared with controls, and methane was also found to increase intestinal contractile activity in guinea pigs and in patients with IBS. In contrast, in a study of children living in a slum [23], the authors did not find an association between methane and constipation in the patient cohort; in fact, none of these children had constipation despite a 30% prevalence of methanogenic SIBO. In another study [122], the effect of rifaximin on breath methane and colonic transit in adult patients with constipation was investigated. The authors found that a larger percentage of patients with chronic constipation were methane producers (>10 ppm) and had slower colonic transit times as compared with controls. Methane producers ($n = 13$) were randomly assigned into two groups: rifaximin group (14-day trial) and placebo group. After treatment, the rifaximin group had a significantly lower area under the curve for methane production and colonic transit time normalised in 66% of cases as compared with the placebo group, in whom colonic transit time did not normalise. Thus, these findings support the association between methanogenic SIBO and constipation. The most important question to be answered is whether it would be cost-effective to perform methane breath tests on all children with "functional" constipation, considering the relatively high prevalence of the disorder. What we know from small-scale studies is that children with constipation and retentive faecal incontinence are more likely to be methane producers than children with constipation alone [15, 20]. These children may benefit from antibiotic therapy. However, large-scale, prospective studies are warranted in order to (1) clarify the relationship between methanogenic SIBO and constipation and (2) determine whether children with methanogenic SIBO and constipation benefit from antibiotic treatment.

In a recent retrospective study in a cohort of children with various gastrointestinal manifestations and feeding difficulties [123], 26% of children were diagnosed with SIBO by duodenal aspirate culture (>10^5 CFU/mL), and interestingly, 50% of these were also found to have lactase deficiency on analysis of enzyme activity, possibly due to villous blunting.

SIBO and Systemic Disorders

Increasing evidence suggests that SIBO may be implicated in the pathogenesis of stunted growth [6, 25] and environmental enteric dysfunction (EED; formerly known as environmental enteropathy and, in the past, as tropical sprue) [24, 48, 49, 53]. Approximately 20% of children under five suffer from poor linear growth (also known as stunting) worldwide [124]. Intraluminal competition for micro- and macronutrients between the excessive bacterial biomass and the host [125], as well as other SIBO-induced factors such as diarrhoea, carbohydrate malabsorption, protein loss, increased intestinal permeability, and intestinal and systemic inflammation, may lead to a negative caloric balance in the host, thereby resulting in stunted growth and malnutrition. Such factors, too, characterise EED; thus, it appears that SIBO may play an important role in both EED and stunted growth [6, 126]. In a study conducted in Madagascar and the Central African Republic [6], nearly all of the cohort of stunted children was diagnosed with SIBO (i.e. 96%), and another study from Bangladesh [25] also found an increased prevalence of SIBO at 16.7% in stunted children. However, research from an impoverished community in Zambia, Africa [127], failed to demonstrate an increased prevalence of SIBO in malnourished children, with only four children (8%) having a positive breath test. A retrospective study that included data from 162 children found that children with a positive HBT had significantly lower heights and weights than those with a negative HBT [128]. In a different study [96], the faecal gut microbiome of a cohort of undernourished children from Mumbai, India, was characterised by a Proteobacteria dominance, despite the fact that most children were breastfed. Taken together, these findings suggest a possible role for SIBO in the pathogenesis of stunting. Thus, it may be reasonable to perform a hydrogen/methane breath test as part of the clinical approach to children with poor linear growth.

Although SIBO has been widely described amongst undernourished children, emerging evidence suggests that, at the opposite end of the nutritional spectrum, children with excessive adipose tissue also seem to have high rates of SIBO. In a recent prospective study of overweight and obese children, almost 2/3 of the cohort had a positive LHBT, but all children exhibited increased inflammatory markers, including non-SIBO children, suggesting that SIBO may be an incidental rather than a causative factor in overweight and obese children [129]. Despite this, a clear association appears to be emerging between SIBO and non-alcoholic fatty liver disease (NAFLD). A recent meta-analysis found that NAFLD patients had an overall 2.8 relative risk of SIBO compared to healthy control cohorts [130]. In a cohort of 89 overweight and obese children, significantly higher rates of liver steatosis were uncovered in those with SIBO (70.9%) compared to those without (41.4%) [131]. In addition, the children affected by SIBO had higher average glucose levels and homeostatic model assessment (HOMA) indices, reflecting poorer glycaemic control and insulin intolerance. Similarly, in a case-control study of 30 overweight/obese children with SIBO and 28 overweight/obese children without SIBO, it was found that liver steatosis was more than twice as prevalent in the former population (70% vs 32%, respectively) [132].

Moreover, although deficiencies of liposoluble vitamins (A, D, and E) and vitamin B_{12} have been documented in adults [133, 134], no studies have explored this in children with SIBO. However, in a recent, small study of children with short bowel syndrome [135], those who were being treated for SIBO with metronidazole (5/13) had persistently

elevated levels of methylmalonic acid, suggesting lower levels of vitamin B_{12}. Menaquinone (vitamin K2) is produced by gut microbiota [136], and thus, from a physiological standpoint, it would seem counterintuitive to suggest that vitamin K deficiency would arise in a bacterial-abundant environment. Nonetheless, a recent case report described a 17-year-old female with vitamin K deficiency possibly caused by SIBO. The authors speculated that the vitamin K deficiency seen in this patient may have been the result of reduced menaquinone-producing bacteria, expansion of vitamin K-consuming bacteria, or severe malabsorption [137]. Further gut metabolome studies [138] are needed to elucidate SIBO's role in vitamin deficiencies.

Currently, there are no guidelines on the diagnosis or treatment of SIBO in children. Given the heterogenous and nonspecific nature of the disease, it is challenging to decide in whom to initiate an evaluation for SIBO.

Diagnosis

SIBO can be diagnosed by invasive and non-invasive methods. The non-invasive methods include breath tests, while invasive methods comprise culture-dependent and culture-independent approaches.

Hydrogen and Methane Breath Testing

Although subject to debate and controversy [139–141], H_2 and CH_4 breath tests are increasingly being used due to their availability in healthcare facilities; because they are inexpensive, easy to use, and non-invasive (which is extremely important in paediatrics); and because the results can be interpreted on the same day of the test (the H_2/CH_4 breath test procedure is thoroughly reviewed elsewhere [86, 142, 143]). According to the 2017 North American Consensus [86], the diagnosis of SIBO is *suggested* when there is an increase in H_2 of ≥20 ppm over baseline within the first 90 minutes of the test with either lactulose or glucose, or when there is an increase in CH_4 of ≥10 ppm at any time point during the test (Fig. 42.2). On the other hand, the older Rome Consensus [143] recommended the use of glucose as substrate due to its greater accuracy and defined SIBO as an increase in H_2 of ≥12 above baseline by using the GHBT.

In order to understand the mechanisms behind H_2 and CH_4 breath testing, one must be aware of two concepts: orocecal transit time and intraluminal gas production. The human body has no means of producing H_2 and CH_4 other than through intraluminal microbial fermentation and methanogenesis, respectively [86, 143–145]. As previously mentioned, colonic microbiota are predominated by fibre-fermenting anaerobes, mainly those belonging to the phyla Actinobacteria and Firmicutes [146]. Undigestible carbohydrates reaching the colon are readily fermented by hydrogenogens (H_2-producing bacteria) [147], and hence a physiological increase in H_2 is expected in the colon. Intraluminal H_2, in turn, is absorbed into the systemic circulation and is transported to the lungs where it can then be released through exhaled breath [142]. Moreover, the orocecal transit time – the elapsed time between ingestion of a substance until it reaches the cecum – has been shown to be around 90 minutes in both adults and children, as assessed by the LHBT [148]. Thus, in the presence of SIBO, substrate administration will result in a small bowel H_2 peak, occurring before the orocecal transit time has completed (i.e. 90 minutes).

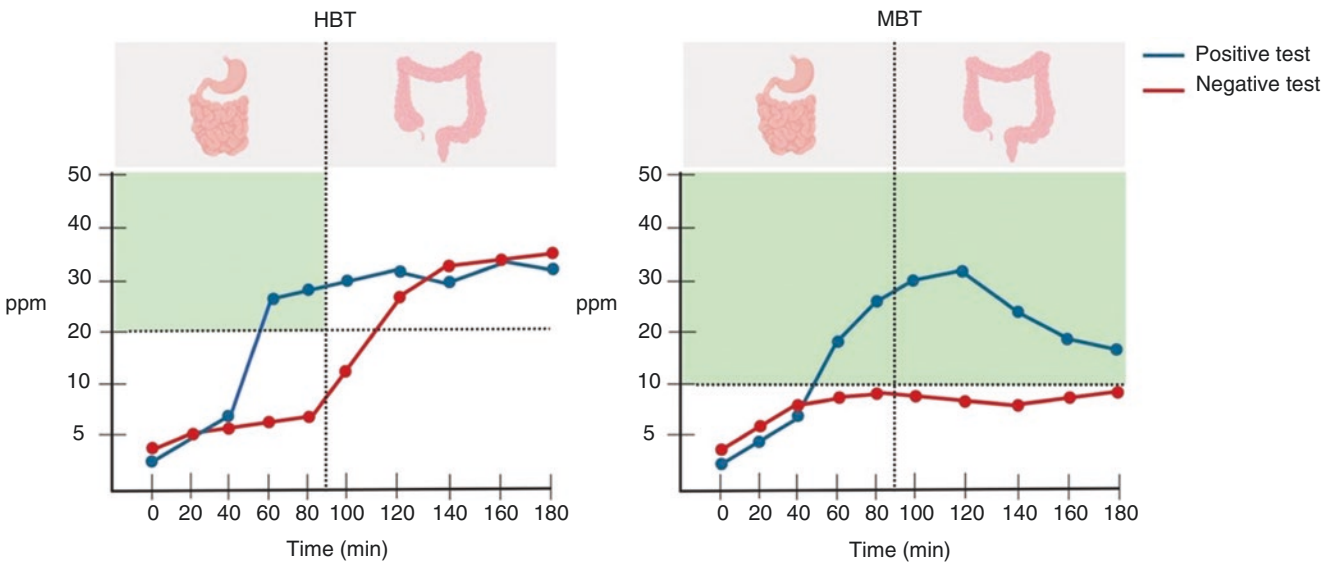

Fig. 42.2 Graphical representation of the hydrogen and methane breath tests. *The vertical dotted line indicates the completion of the orocecal transit time, and the horizontal dotted line indicates the current diagnostic thresholds for SIBO. The green shaded areas indicate where the test is considered positive*. (Created with BioRender.com. Developed under a CC BY 4.0 license and previously published in Front Pediatr. 2019 Sept 4;7:363)

Glucose and lactulose are the substrates usually used in breath tests to diagnose SIBO. The former is a monosaccharide which is readily absorbed in the proximal small intestine, and the latter is a synthetic, undigestible disaccharide that reaches the cecum intact. In the presence of SIBO, glucose administration will result in a H_2 peak which is produced in the small intestine (i.e. <90 minutes); in addition to this peak, lactulose administration can give rise to a second – colonic – H_2 peak: the early peak produced by bacterial overgrowth in the small intestine and the second one caused by colonic fermentation [86, 142]. However, both substrates have their own advantages and limitations. By using glucose, false-negative results can arise in the presence of bacterial overgrowth in the distal small bowel (i.e. ileum), as glucose is readily absorbed proximally. In addition, accelerated orocecal transit can give rise to false-positive results as the substrate reaches the colon rapidly, thereby undergoing premature fermentation by colon bacteria – this can occur with both glucose and lactulose [139]. False-negative results can also arise in the absence of H_2-producing bacteria or in the presence of CH_4-producing microorganisms (discussed below) [143]. Based on a 2008 systematic review [149], the sensitivity and specificity of the GHBT ranged from 20% to 93% and 30% to 86%, respectively, and the sensitivity and specificity of the LHBT from 31% to 68% and 44% to 100%, respectively. The most recent systematic review and meta-analysis [150] found a pooled sensitivity and specificity for the GHBT of 54.5% and 83.2%, respectively (positive likelihood ratio 2.45 (95% CI, 1.51–3.97), and negative likelihood ratio 0.60 (95% CI, 0.45–0.80)). As for the LHBT, the pooled sensitivity and specificity were 42% and 70.6%, respectively (positive likelihood ratio 1.30 (95% CI, 0.77–2.22) and negative likelihood ratio 0.79 (95% CI, 0.57–1.08)). It is important to mention that study heterogeneity was identified in almost all of the variables included. The authors concluded that the GHBT is the preferred method given its higher diagnostic yield. Moreover, in a study by the REIMAGINE group [45], the sensitivity and specificity of the LHBT were 57.14% and 84.61%, respectively, in subjects diagnosed with SIBO based on the $>10^3$ CFU/mL threshold. However, this study was limited by the small number of patients who underwent breath tests.

Methanobrevibacter smithii, a member of the domain Archaea and the most abundant methanogen in the human alimentary tract, produces CH_4 as an end product of hydrogen metabolism (hydrogenotrophic methanogenesis), by using one molecule of carbon dioxide and four molecules of H_2. The archaeon is extremely oxygen sensitive and relies completely on hydrogenogens for CH_4 production, due to its inability to metabolise monosaccharides. For this reason, *Methanobrevibacter smithii* is considered an "obligate cross-feeder" [144]. Furthermore, since the archaeon utilises H_2 to produce CH4, it can lead to a falsely negative HBT. Thus, it is recommended that both H_2 and CH4 are measured in order to avoid this [86].

In conclusion, despite the limitations of the H_2/CH_4 test [141], it remains a useful tool in the diagnosis of SIBO in children due to its practical and non-invasive nature. Importantly, there are no reported significant side effects for the hydrogen/methane breath test other than transient abdominal pain and/or vomiting during the test.

Culture-Dependent Approaches

Culture-dependent approaches are considered the current gold standard for definitive SIBO diagnosis. A small intestinal (i.e. duodenum or jejunum) aspirate is obtained at upper gastrointestinal endoscopy through a sterile catheter, or alternatively via capsule or antegrade double-balloon endoscopy [151], and stored anaerobically prior to culture for both aerobic and anaerobic bacteria on media such as MacConkey's or blood agar [109]. When based on the culture of a proximal jejunal aspirate, a bacterial concentration of $>10^3$ CFU/mL is regarded as indicative of SIBO [86, 110], although there is some heterogeneity in the literature in this regard and some experts recommend a threshold of $>10^5$ CFU/mL as more specific [152].

Despite being regarded as the gold standard, there are several notable limitations to this approach. Firstly, endoscopy-guided aspiration is invasive, is expensive, and requires specialist input, limiting its availability and application in certain settings. Secondly, we know from microbiome research that standard clinical laboratory culture-based approaches have the potential to detect only a minority of the extant bacterial consortium. In addition, care must also be taken not to contaminate samples or sampling apparatus with oropharyngeal microbes, thereby contributing to false positives. Likewise, the significant heterogeneity in aspirate sampling protocols impacts substantially on test outcome and accuracy. For example, one study previously used air, rather than nitrogen or carbon dioxide, during endoscopy to recover aspirate samples in suspected SIBO and, not surprisingly, then went on to culture anaerobic bacteria from just 1 of 50 samples [153]. Other variables include the specific site of sampling and volume of aspirate. The lack of standardised protocol and diagnostic consensus for what has been long regarded as the gold standard undoubtedly contributes to the massive variation in SIBO prevalence and incidence rates reported in the literature. This, in turn, limits comparability between studies and ultimately hinders research progress in the field. There is an urgent need for standardisation and validation of protocols and diagnostic criteria. Ethical constraints on the performance of endoscopy on healthy control children continue to present an obstacle to the vali-

dation of normal values for aspirates; therefore, the development of accurate less invasive diagnostic approaches assumes considerable urgency.

SIBO in the Era of Next-Generation Sequencing

As alluded to previously, culture-independent approaches based on molecular technologies have become the most widely applied modalities for studying both the composition and metabolic activity of gut microbiota. There are several considerations to be addressed when selecting a methodology, including sample type, DNA extraction method, sequencing modality and platform, as well as bioinformatic pipeline (reviewed comprehensively in Ref. [43]).

In general, the composition of gut microbiota is currently most cost effectively studied through 16S rRNA sequencing. The 16S region is a highly conserved region of rRNA within all taxa of bacteria, which displays sufficient variation and divergence in sequence to allow differentiation at the genus level. Although it has been central to progress in the field of microbiome research, 16S rRNA sequencing is crucially limited by the fact that it does not generate absolute data on quantities of bacteria, but rather provides investigators with a relative abundance of taxa within a sample. The second modality which is indeed worthy of consideration is metagenomic shotgun sequencing. While 16S rRNA sequencing provides an overview of microbiota composition, metagenomic shotgun sequencing goes a step further by informing us of both who is there and of what are they metabolically capable of.

Although such sequencing capabilities are now commonplace in microbiological and medical research laboratories, uptake and application to SIBO research have been comparatively slow, and, as a result, there is a dearth of relevant clinical data available. Despite this, several clinical studies which targeted alternate, but related, gastrointestinal disorders have provided some intriguing data on the disorder. In line with this, some small studies have reported on the gut microbiome of IBS cohorts, many of which were confirmed to suffer from concomitant SIBO. One such study investigated faecal microbiota of a cohort of 30 Chinese patients with diarrhoea-predominant IBS, 14 of whom were also confirmed to have SIBO by LHBT [154]. At baseline, this cohort displayed reduced microbiota diversity, increased relative abundances of *Bacteroidetes*, and decreased relative abundances of *Firmicutes* when compared to healthy controls. In addition, the IBS cohort was shown to have reduced relative abundances of the genus *Lactobacillus*, as well as several genera associated with butyrate production. Following a 2-week course of rifaximin clinical symptoms improved and repeat LHBT demonstrated remission of SIBO in 65% of SIBO-positive subjects. However, faecal microbiota displayed only minor alterations in taxa post-treatment, a result which has been mirrored in similarly designed trials of rifaximin in IBS [155, 156]. Indeed, it must be reiterated that less than half of the IBS cohort studied in this trial were confirmed to have concomitant SIBO and the samples investigated (i.e. faeces) may bear little resemblance to the site most relevant to the disease; therefore, no definitive conclusions on SIBO pathogenesis should be drawn from this data.

With regard to SIBO in children, one study outlined above aimed to investigate microbiota in sub-Saharan children with stunted growth [6]. In addition to faecal microbiota analysis, it was deemed pertinent to retrieve and analyse microbiota of small intestinal aspirates, due to its role in nutrient absorption and malnutrition. The authors described a form of microbial "decompartmentalisation", in which oropharyngeal-associated microbes were found to be over-represented in the small intestine of these children, 91% of whom tested positive for SIBO. Although this was deduced primarily from culture-based methods, it is consistent with preliminary reports suggesting that SIBO is not caused by migratory colonic microbes [157]. In turn, 16S rRNA sequencing of duodenal microbiota in these subjects revealed a community containing near-equal parts *Proteobacteria* (32.4%), *Bacteroidetes* (29.6%), and *Firmicutes* (25.6%), with lower numbers of *Fusobacteria* (9.2%) and *Actinobacteria* (1.7%). Critically, however, this study was severely limited by the fact that there were no appropriate controls. Therefore, we are left, once again, with a degree of speculation on the potential role and composition of the small intestinal microbiota in SIBO.

These studies demonstrate that SIBO has been regarded largely as a sign or sequela of a gastrointestinal disorder, rather than a discrete disorder in itself. This perspective has meant that the pathogenesis of SIBO has been rarely addressed directly, but rather has been of peripheral interest in studies where there has been an overlapping interest. Having said this, perhaps the most informative effort to characterise SIBO to date has come from a recent investigation of 126 adults displaying gastrointestinal symptoms (66 SIBO positive and 60 SIBO negative) [158]. The authors found that, although duodenal aspirate culture results did not correlate with symptoms, the aspirate microbiome was significantly altered in symptomatic participants. This altered microbiome was characterised primarily by decreased levels of the genus *Prevotella* and enhanced microbial metabolism of ascorbic acid. In addition, it was identified that age, recent antibiotic exposure, PPI use, and diet were the major contributors to the disruption of the microbiome and onset of symptoms. In line with this, the investigators demonstrated that the restriction of dietary fibre in healthy previously high-fibre consuming individuals had significant effects on the microbiome and triggered gastrointestinal symptoms regarded as common in SIBO. This study identified several potentially targetable components of SIBO pathogenesis and

represents an excellent blueprint for the future study of the disorder.

Treatment

The first goal in the management of SIBO should be to identify and address, where possible, any underlying causes, be they anatomical (such as stenoses or fistulae), pathological (e.g. celiac or inflammatory bowel disease), or physiological (e.g. suppressed acid secretion or impaired motility). In many cases, unfortunately, either the underlying cause cannot be corrected (e.g. short bowel) or none is apparent and management rests on the suppression or elimination of bacterial overgrowth. Nutritional deficiencies related to SIBO must also be addressed.

Antibiotics continue to represent the mainstay of SIBO management. Due to the relative inaccessibility of duodenal samples for culture and difficulty in differentiating the culpable microorganism in a diverse ecosystem such as the small intestine, antibiotic therapy is generally initiated on an empiric basis. A previous meta-analysis of antibiotic use in the context of SIBO found that the non-systemic antibiotic, rifaximin, was by far the most commonly used [159]. While the meta-analysis ruled in favour of antibiotic use over placebo (effectiveness ratio 2.55, CI 1.29–5.04), rifaximin failed to reach a significant degree of superiority (effectiveness ratio 1.97, CI 0.93–4.17). However, just three studies were deemed appropriate for this analysis and their heterogeneity limited the applicability of this result. In line with this, the systematic review went on to reveal that monotherapy with 1200 mg/day rifaximin was efficacious, with an overall 60.8% remission rate. Moreover, the efficacy of this antibiotic was increased to 85% when combined with partially hydrolysed guar gum, albeit in a single trial. Two studies included in the systematic review investigated the use of metronidazole, demonstrating a normalisation of breath tests in 51% of SIBO patients, while a single small study reported remission in all 14 patients recruited and treated with ciprofloxacin.

A more recent systematic review and meta-analysis of rifaximin therapy in SIBO included data from over 1300 patients [160]. A dose-dependent response was demonstrated for eradication rates, and, in line with the previous systematic review, the most commonly used dose was 1200 mg/day, with one study reporting 600 mg/day and another 1600 mg/day. The investigators found an overall eradication rate of 70%, with adverse events reported in less than 5%. In addition, in a subset of studies which assessed symptom severity and resolution, a meta-analysis revealed symptom remission in 68% of patients who were found to have been successfully eradicated.

While the studies included in the above meta-analysis were all conducted on adult cohorts, one study previously investigated the use of rifaximin in children [161]. Applying a regimen of 600 mg/day for 1 week, the investigators reported a breath test normalisation rate of 64% (n = 21/33). In light of the limited available data, a dose response study of rifaximin in a paediatric population would indeed be of interest. Finally, one study investigated the efficacy of a combination regimen of trimethoprim-sulfamethoxazole (TMP-SMT; 30 mg kg^{1} d^{1}) and metronidazole (MTZ; 20 mg kg^{1} d^{1}) twice daily for 2 weeks in slum-dwelling children suffering from SIBO [162]. When retested for SIBO by breath test 1 month after commencement of this therapy, the authors noted 95% (n = 19/20) resolution of the disorder. However, the lack of a placebo or non-intervention control group limits assessment of temporal effects on SIBO status. Taken together, these results indicate that antibiotics are an effective means of treating SIBO in children; the paucity of studies overall and of comparative studies, in particular, limits our ability to make definitive recommendations.

While antibiotics remain the first line and gold-standard approach to SIBO management, there are additional or alternative approaches that may have applications in the future, but the efficacy of which remains uncertain at present. For instance, there is biologic plausibility to the hypothesis that there may be a role for a low-FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diet in decreasing fermentable substrates in the context of SIBO. Low-FODMAP diets aim to greatly deplete or entirely eliminate the highly fermentable simple carbohydrates which are commonly found in certain dairy products, fruits, vegetables, nuts, and legumes, with the ultimate aim of graded reintroduction of specific FODMAPs to elucidate the most culpable source [163].

Interestingly, probiotics have also previously been considered as potential agents in the management of SIBO [164]. In line with this, a more recent meta-analysis revealed that probiotic interventions resulted in reduced H_2 levels and increased rates of decontamination when compared to placebo. More intriguing, however, is that probiotics also demonstrated more favourable results when compared directly to metronidazole treatment. Despite this, the best results overall were obtained when probiotics were combined with rifaximin or minocycline. Indeed, a recent open-labelled clinical trial performed in a cohort of patient with concomitant SIBO and systemic sclerosis found that *Saccharomyces boulardii* in combination with metronidazole was considerably more efficacious in resolving the condition than either therapy in isolation after 2 months of treatment [165].

Finally, there is some evidence to suggest that certain statins may have a role in depleting *Methanobrevibacter*

spp., thereby offering a novel therapy for methane-specific SIBO [166, 167]. In line with this, a modified-release formulation of lovastatin, termed SYN-010, has been created to deliver the drug in a biphasic manner during transit, thereby avoiding considerable degradation and absorption in the upper gastrointestinal tract [168]. A dose of 42 mg/day of SYN-010 for as few as 7 days was demonstrated to significantly reduce methane production when compared to placebo in a multi-centre double-blind randomised controlled trial [169]. The efficacy and safety trial of this intervention is currently being investigated in IBS (ClinicalTrials.gov ID: NCT03763175). The effect of this drug appears to be primarily due to the inhibition of HMG-CoA reductase, thereby preventing the formation of mevalonate, a primary precursor of key membrane lipids specific to archaea. This mechanism, along with several others, has been previously reviewed extensively elsewhere [40] and so will not be discussed further herein.

Prognosis

At present, it is unclear whether the changes in gut microbiota that characterise paediatric SIBO have long-term detrimental effects; large-scale, longitudinal prospective studies are warranted.

Conclusion

Paediatric SIBO is a heterogenous and poorly understood entity, whose prevalence and incidence are difficult to determine due to lack of uniformity and consensus of its diagnostic criteria. However, based upon the available literature, it appears that SIBO is a common underlying diagnosis in children who present clinically with certain functional disorders and stunted growth, as well as in children with a history of acid-suppressive therapies, intestinal motility disturbances, anatomical alterations, or impoverished conditions. Further research with integration of culture-dependent and culture-independent approaches is needed in order to (1) understand the pathogenesis of paediatric SIBO, its clinical presentation and prognosis, and (2) establish global consensus on diagnostic criteria for SIBO.

Short Bowel Syndrome

43

Cecile Lambe and Olivier Goulet

Introduction

Short bowel syndrome is the leading cause of intestinal failure in adults and in children. By definition, SBS is due to intestinal malabsorption following the resection of a significant portion of the small intestine. Intestinal failure (IF) can be defined as a critical reduction of the gut mass or its function below the minimum needed to absorb nutrients and fluids required for adequate growth in children [1].

IF due to SBS may be reversible or irreversible, depending on a number of factors such as the underlying cause of SBS, the length of the remaining intestine, the preservation of the colon, the ileocecal valve, and the treatment used to develop or restore intestinal capacity.

Definition and Etiology

SBS may be secondary to prenatal diseases causing abnormal development of the GI tract (intestinal atresia, gastroschisis, extensive aganglionosis, etc.) or post-natal ischemia-related events such as midgut volvulus, necrotizing enterocolitis (NEC), trauma, and tumor. SBS remains a rare disease but its prevalence increases due to better management and overall survival. However, the true incidence of SBS is not precisely known since its early management involves both pediatric surgeons and neonatologists. The anatomy of the residual intestine is essential to predict gut adaptation and to guide management. The degree of malabsorption is proportional to the length of jejunum resected and will be compensated to some extent by the ileum and/or by the process of adaptation in response to the loss of intestinal surface. The colon is also an important player in reducing diarrhea and malabsorption.

SBS usually follows extensive surgical resection leaving the SB length below a critical value for adequate nutritional supply. A severely reduced mucosal surface results in malabsorption with subsequent diarrhea, water-electrolyte imbalance, and malnutrition [1, 2]. Exact measurement of the remnant intestine remains difficult even with the help of radiographic assessment [3]. At birth, term neonates have a SB length of approximately 250 cm and their intestines lengthen during the first year of life [4]. Preterm infants have a greater potential for bowel growth since their intestines lengthen substantially during the last trimester of gestation [5]. "Short" bowel is difficult to define clearly in children since the length of the small bowel changes so much according to the term of birth: a measure from the ligament of Treitz at first surgery, a measure compared to the birth term, a percentage of resection, etc. Befza et al. [6] have suggested using the percentage of expected small bowel/large bowel length for age based on established norms. It is an interesting approach but unfortunately it is difficult to apply in clinical settings. Our advice would be to quote the measure of the remaining small bowel length from the ligament of Treitz or from the pylorus and to note at what age the measure was performed, usually at first surgery. The cutoff length for SBS is related to a number of factors. In general, SBS occurs after a massive resection leaving less than 40 cm of viable small bowel. A residual bowel length of only 15–40 cm has been associated with bowel adaptation, intestinal autonomy, and PN weaning, but, most of the time there is scant information regarding long-term growth [6–14]. In adults the cutoff length is 150 cm. In children, patients should be considered with SBS if the remaining short bowel length is inferior to 80 cm but this cutoff can vary according to the age of the child (the older the child, the higher the cutoff length). Numerous factors determine SBS prognosis: the underlying diagnosis, the type of segments preserved, the presence of the ileocecal valve (ICV) and the colon, a long-term stoma

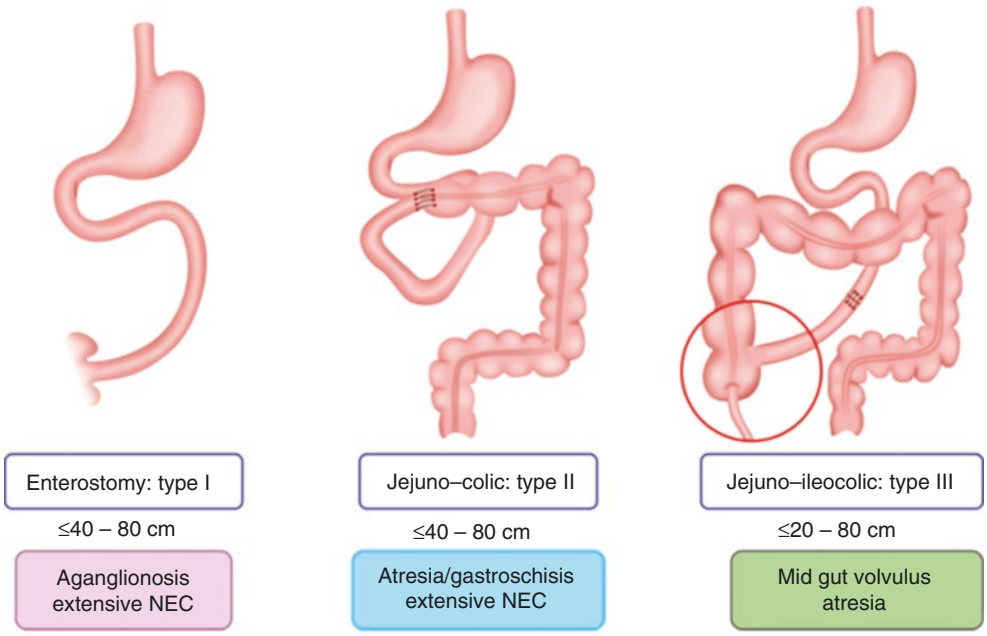

Fig. 43.1 Anatomy of short bowel according to the type of the remnant bowel. The most frequent cause of resection is mentioned for each type

versus a primary anastomosis, the number of surgical procedures, as well as the age of the patient at the time of surgery [6–14]. Classification of SBS in three types is helpful for the understanding of different outcomes (Fig. 43.1). Other factors are relevant to the development of SBS such as the functionality of the residual bowel, especially the motility disorders [15].

Intestinal Atresia

Intestinal atresia is the most frequent congenital abnormality causing SBS. The classification of jejunoileal atresia delineates four different types from a mucosal defect with an intact mesentery to multiple atresia with V-shaped mesenteric defects. Type IIIb, also called "apple peel syndrome," is the most common with a proximal jejunal atresia with a distal bowel that develops around a single retrograde blood vessel. Multiple intestinal atresia has been associated with severe combined immune deficiency [16–18] (Fig. 43.2).

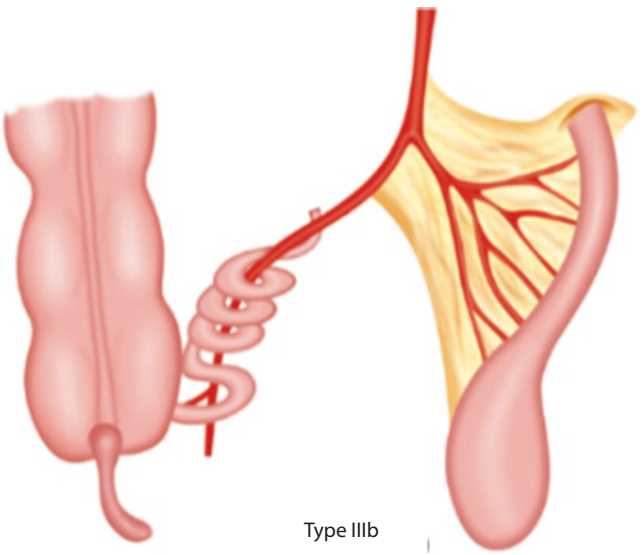

Fig. 43.2 Intestinal atresia: apple peel syndrome

At birth there are signs of bowel obstruction. Surgery procedure with end-to-end anastomosis or jejunostomy, with or without tapering, should be performed early and is highly dependent on the extent of the atresia, the importance of the distension of the proximal small bowel, and the experience of the surgeon. Motility disorders are common on both segments but can recover with time and appropriate care [15].

Gastroschisis

Gastroschisis is an abdominal wall defect characterized by an intact umbilical cord with evisceration of bowel generally to the right of the cord and without a covering membrane. Incidence in Europe is about 3 per 100.000 births [19, 20] and is due to unknown factors although maternal age, drugs during pregnancy, and genetic factors have been identified to play a role [21]. Around 40% of babies with gastroschisis are born to a mother under the age of 20 compared with only 9% of overall births. Prenatal diagnosis is routinely performed allowing choice of the place, the timing, and the mode of delivery. Most clinicians agree on the need for a C-section when the liver is outside the abdomen; in other cases the mode of delivery and the place of the procedure (on the ward or in the operating room) do not seem to influence the prognosis [22, 23]. Early surgical management aims to reduce meticulously the herniated viscera into the abdomen while avoiding high intra-abdominal pressure. When immediate

reduction is not possible, the surgeon uses a prosthetic silo created from silastic or Teflon for protecting the bowel until it slowly reintegrates into the abdomen. Long-term survival of neonates with gastroschisis is over 95% [24]. However, associated factors such as intestinal atresia, perforation, ischemia, and dysmotility caused by amniotic fluid peritonitis lead to short bowel syndrome and long-term PN is necessary in 10–20% of cases.

Long-Segment Hirschsprung's Disease – Intestinal Aganglionosis

Hirschsprung's disease (HD) derives from a congenital malformation of the enteric nervous system (ENS) [25, 26]. It displays an incidence of 1 in 5000 live births with a 4:1 male-to-female sex ratio. This severe congenital condition is caused by the absence of colonic neural ganglia and thus lack of intrinsic innervation of the colon due in turn to improper colonization of the developing intestines by ENS progenitor cells. The disease has been linked to mutations in genes that encode the crucial signals for the development of the enteric nervous system, including the RET and EDNRB signaling pathways [27]. The genetics of HD is complex and can involve mutations in multiple genes. In 80% of infants, the aganglionosis is confined to the rectum and sigmoid, but it may extend to encompass the entire colon (total colonic aganglionosis) or very rarely (less than 1% of HD) affect the entire intestine subtotal or total intestinal aganglionosis (TIA).

The TIA or sub-TIA is revealed early after birth with abdominal distention and bilious vomiting most of the time after delayed meconium passing. During surgery the extent of the aganglionic segment of the small intestine and the appropriate placing of a stoma should be guided by perioperative histopathological examinations of biopsies. Because of the absence of functional colon (SBS type 1, Fig. 43.1), infants with <80 cm of ganglionic small intestine are likely to have permanent IF requiring very long-term PN [28]. An early referral to an expert intestinal failure unit should be made for the child with TIA to optimize the fluid-electrolyte and nutritional management [29].

Malrotation and Midgut Volvulus

Midgut volvulus (MGV) can happen at any time in life. Any physician should know how to recognize the symptoms in a child with the sudden occurrence of acute abdominal pain, intermittent green bile stained vomiting, abdominal distension, and in some cases blood in the stool suggesting intestinal obstruction from the volvulus. Whether hemodynamic disorders are present or not, MGV is a surgical emergency to avoid massive small bowel infarction, and no investigations such as mesenteric vessel Doppler or contrast serie should delay the surgery. MGV in the newborn may develop as a result of malrotation but may also occur without, more often in premature infants with lax tissue. MGV may occur later in life as a result of malrotation or as a complication of previous surgery. The incidence of malrotation in children 1–18 years of age is 5.3 per million population [30]. Malrotation is caused by an abnormal process occurring during the fifth gestational week when the fetal small intestine forms a loop which extrudes into the umbilical cord. The fetal gut subsequently undergoes enlargement, elongation, and return to the abdominal cavity with rotation and fixation [31]. The fixation of the intestine may be abnormal, with fibrous bands (Ladd's bands) forming between the duodenum and the right colon with a short mesentery allowing the bowel to twist causing bowel obstruction and loss of blood supply. Intrauterine MGV is thought to be the cause of intestinal atresia type IIIb described above. Surgical management of MGV is an emergency involving detorsion of the volvulus, restoration of circulation, separation of adhesions between bowel loops, and an attempt to preserve bowel length. A conservative resection of only clearly necrotic tissue is recommended, while bowels with questionable viability should be left in situ and re-evaluated 24–36 hours later during a "second look laparotomy."

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) remains the leading cause of SBS in premature infants. The incidence of NEC is inversely correlated with gestational age and birth weight. Incidence of NEC varies in areas around the world [32, 33]. NEC presents usually with variable symptoms: feed intolerance, gastric aspirates, abdominal distension, bilious vomiting, and blood in the stool. Local tenderness or an abdominal mass may be apparent on clinical examination and progression to pneumoperitoneum and sepsis with respiratory failure and shock. Emergency treatment of NEC includes stopping feeds supported by TPN, nasogastric decompression, fluid and electrolyte resuscitation, broad-spectrum antibiotics, and, in selected cases, respiratory support. Severity, whether mild or critical, determines the duration of medical therapy. Surgery for NEC should be limited as it may lead to bowel resection. However, surgery is indicated by (i) the presence of pneumoperitoneum, indicating perforation of the intestine, (ii) a clinical deterioration despite maximal medical treatment, (iii) abdominal mass with persistent intestinal obstruction or sepsis, and (iv) development of intestinal stricture. Acute surgical management of NEC involves competing priorities of controlling sepsis and preserving bowel length. Bowel-preserving strategies for NEC, designed to limit SBS, are based on peritoneal drainage, venting ostomy, limited resection, or a combination of them. Drainage-based strategies are generally preferred in smaller neonates, while laparotomy-based strategies are favored in larger patients, especially those with a more limited extent of intestinal injury. Comparisons of drainage-based and resection-based

approaches are limited by confounding variables, and neither approach is clearly superior with regard to subsequent SBS [34, 35]. Prevention of NEC is debatable, especially regarding the date and type of feeding [36]. Finally, the incidence of NEC has not changed significantly despite the dramatic advances in perinatal care. Given the role of inflammatory mediators in its pathogenesis, newer immune modulators are being studied as potential agents for prevention/treatment of NEC [37]. Recent data suggest that probiotics administration might be helpful in decreasing incidence of NEC in preterm infants [38].

Consequences of Gut Resection

Intestinal Resection

The more extensive the resection of the small intestine, the greater the loss of absorptive surface area for transport of nutrients, water, and electrolytes. The remaining bowel is characterized by a compromised absorptive capacity due to the severely reduced mucosal surface resulting in diarrhea, fluid and electrolyte imbalance, and failure to thrive [39]. The consequences of the resection depend not only on the length, the surface area, and the site of the resected intestine but also on the functional capacity of the remaining intestine and its ability for adaptation [6, 11, 40–43]. The first phase following small bowel resection is associated with massive losses of water and electrolyte. Severe diarrhea due to fluid and electrolyte malabsorption is increased by gastric hypersecretion, bile salts, the loss of the ileocecal valve, and undigested nutrients causing osmotic diarrhea. During this period, total PN is required in association with small amounts of substrates provided by the enteral route, orally, or by continuous gastric infusion as soon as intestinal transit has recovered.

Resection of the Jejunum

The resulting malabsorption concerns all nutrients as well as minerals, electrolytes, trace elements, and most vitamins. Severe diarrhea following extensive jejunal resection is associated with steatorrhea and creatorrhea. Moreover, the resection of the jejunum reduces the secretion of cholecystokinin and secretin leading to a decrease in biliary and exocrine pancreatic secretions which may lead, in turn, to a reduction in nutrient absorptive capacity. The reduced production of cholecystokinin, vasoactive intestinal peptide (VIP), gastric inhibitory peptide, and serotonin may cause gastric hypersecretion seen more frequently after jejunal resection. The degree of malabsorption is proportional to the length of jejunum resected and will be compensated, to some extent, by the ileum and/or by the process of adaptation in response to loss of intestinal surface. In general, resections of the proximal intestine are more manageable than distal resections because the extent of structural and functional adaption exhibited by the ileum is greater than that of the duodenum or jejunum.

Resection of the Ileum

Despite the fact that, normally, most nutrients are absorbed in the proximal jejunum, the residual ileum is able to adapt and to assume the role of macronutrient absorption. However, the specialized cells of the terminal ileum, where vitamin B12 /intrinsic factor receptors are located and where bile salts are reabsorbed, cannot be replaced by jejunal hypertrophy. Thus, the ileum has specific functions which the jejunum cannot substitute. In addition resection of the distal ileum usually includes the ileocecal valve (ICV). Ileal resection impairs vitamin B12 absorption which can cause macrocytic anemia and neuropathy. Finally, extensive loss of the ileum reduces transit time by suppressing the so-called ileal brake. It has been shown that the ileum has a greater potential for adaptation than the jejunum. In addition, ileum is the site of enteric hormone release, such as enteroglucagon, which are essential in the process of adaptation after extensive resection (see below).

Ileocecal Valve Resection

The resection of the ileocecal valve (ICV) decreases transit time (ileal brake) and allows colonic bacteria to enter and populate the small intestine increasing the likelihood of the development of a severe form of SBS [44–46]. Bacterial overgrowth may negatively impact on digestion and nutrient absorption, as bacteria compete for nutrients with enterocytes. Thus, ICV resection represents an additional major cause of malabsorption of nutrients, water and electrolytes, dehydroxylation of bile salts, mucosal injury, and motility disorders. The lack of ICV appears to greatly influence the period required to achieve intestinal autonomy following efficient small bowel adaptation [11, 40–43]. In addition, ICV resection increases the risk of sepsis of intestinal origin that occurs more frequently in infants without the ICV than in those with an intact cecum [47].

Resection of the Colon

The colon is a crucial partner for small intestinal adaptation and function in SBS patients by involving fluid and electrolyte absorption, absorption of medium-chain triglycerides, and production of short-chain fatty acids for malabsorbed energy salvage [44–46]. The removal of both ileum and colon obviously drastically increases fluid loss, dehydration, and volume depletion and causes hypocalcemia and hypomagnesemia. Preservation of the colon in cases of major small intestinal resection appears to lessen the severity of SBS.

Besides the anatomical impairment and its consequences, small bowel resection may be aggravated by several associ-

ated disorders: gastric acid hypersecretion occurs in 50% of pediatric patients with SBS, while hypergastrinemia is inconstant [48–50]. Acid hypersecretion occurs early after resection and depends on the extent of the resection. Hypersecretion is transitory but it increases with enteral feeding leading to a larger amount of intestinal fluid loss. Gastric acid hypersecretion, by reducing duodenal pH, decreases the activity of pancreatic enzymes, such as amylase and lipase, which in turn increases fat malabsorption. Gastric emptying of liquids is more rapid following jejunal resection although intestinal transit may still remain normal because of the braking effect of the ileum [50]. The loss of inhibition on gastric emptying and intestinal transit in children without a colon is related to a significant decrease in peptide YY (PYY), glucagon-like peptide I (GLP-I), and neurotensin [51]. Rapid gastric emptying may contribute to fluid losses in children with SBS.

Intestinal Adaptation After Extensive Resection

Adaptation of the remaining intestine is an extraordinary physiological process that begins soon after the resection. It is a slow process that gradually increases the bowel absorption capacity of nutrients, electrolytes, fluid, and trace elements. This adaptation process relies on the hyperplasia of the intestinal mucosa (Fig. 43.3) and the hypertrophy of the bowel in length and in width: increased diameter and wall thickness [52]. Mucosal hyperplasia is characterized by an increased number of enterocytes per unit of SB length, an increased rate of enterocyte proliferation, and an increased villous height and crypt depth. In animals, it was shown that epithelial hyperplasia following gut resection resulted in increased mucosal mass, including higher mucosal wet weight, higher protein content, as well as higher DNA and RNA content per unit of bowel length. The complex regulation of gut mucosal growth involves a multitude of factors, including hormonal mediators, such as glucagon-like peptides, neurotensin, peptide YY, growth hormone, and insulin-like growth factor [52]. Additionally, oral or enteral feeding stimulates the release of enterotrophic hormones which may further improve the process of gut adaptation [53–56]. Besides nutrients, other factors seem to play an important role in the mucosal adaptation process: epidermal growth factor (EGF) present in human milk and produced in the salivary glands and duodenal cells is a trophic substance for the gastrointestinal tract [57, 58]. Polyamines (spermine, spermidine), whose synthesis is dependent on ornithine decarboxylase activity, greatly enhance intestinal cell turnover and protein synthesis [59]. Exogenous prostaglandin has been shown to stimulate mucosal hyperplasia in the gastric antrum and in the jejunum [60].

Role of the Colon in the Adaptation Process

When preserved, the colon, by hosting the largest part of intestinal microbiota, plays a predominant role in the physiological adaptation of the intestine after intestinal resection. The colon is capable of reducing loss of energy and producing trophic factors [45]. In animal models, supplementation of an elemental diet with pectin, which is fermented to short-chain fatty acids (SCFAs) in the colon, improved adaptation of the small intestine and colon in SBS [61]. The supplementation of parenteral nutrition with SCFAs or their intra-cecal infusion reduced mucosal atrophy and intestinal immune dysfunction following massive small bowel resection [62].

In addition to their local effects, systemic SCFAs, in animal studies, can affect the motility of both the stomach and the ileum through neuroendocrine mechanisms, probably through the expression of enteroglucagon family peptides

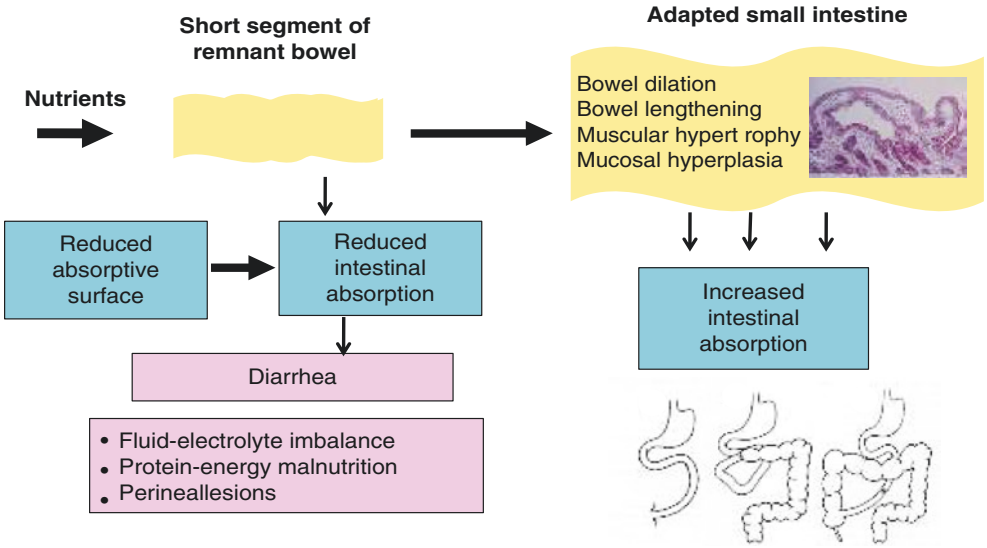

Fig. 43.3 Consequences of small intestinal resection and mechanisms of bowel adaptation

and peptide YY [63]. Furthermore, both systemic and enteral SCFAs exert a trophic effect on the jejunum by increasing mucosal mass, DNA, and villus height [64]. Since SCFAs are the preferred energy source for colonocytes, in patients with SBS the colon becomes an important organ for calorie salvage. Unabsorbed carbohydrates are metabolized by the intestinal microbiota to SCFAs [45]. In turn, SCFAs may be considered as systemic nutrients and as trophic factors directly by developing colon mucosa trophicity [65] or indirectly by promoting the release of GLP-2 [63].

Restoration of intestinal continuity, such as anastomosis of the small intestine with the colon, should be done whenever possible. With improved colonic water and electrolyte absorption, PN can then be discontinued or at least decreased. In addition, anastomosis enables colonic fermentation of unabsorbed carbohydrates from the small intestine to occur, being an important source of energy assimilation. In spite of small intestine malabsorption in patients with SBS, both hyperphagia and adaptation of the remaining colon improve patient outcomes. A study evaluated morphology, proliferation status, and transporters' expression level in the epithelium of the remaining colon of SBS adult patients compared to controls [66]. It seems that in hyperphagic SBS patients with severe malabsorption, adaptive colonic changes include an increased absorptive surface with an unchanged proliferative/apoptotic ratio and well-preserved absorption NHE2, NHE3, and PepT1 transporter mRNA levels [66]. As mentioned before, the preservation of the colon and its associated microbiota is essential for energy salvage, in reducing the need for PN and in improving the outcome of SBS patients. Bacteriological analysis based on culture-dependent methods has found that the microbiota of SBS patients are mainly composed of lactobacilli, but neither qualitative nor quantitative information is available regarding the other main bacterial groups [67]. Few data have been reported in pediatric SBS but have mostly shown low intestinal dysbiosis and reduced microbiota diversity [68, 69]. In the adaptation process, the colon becomes almost as important as the remaining small bowel [70].

Thus, the adaptation of the remaining small bowel is dependent on exogenous and endogenous factors, emphasizing the usefulness of optimal nutritional status to produce these factors using PN and the necessity of early enteral feeding after resection especially with oral feeding and human milk.

Management

Early Management

Mothers of infants with a prenatal diagnosis of one of the conditions causing SBS should be transferred before delivery to a highly trained specialized center. After birth, early management should be conducted by a multidisciplinary team including pediatric surgeons, neonatologists, and pediatric gastroenterologists trained in clinical nutrition. Ideally, a management strategy should be established by the team with the aim of performing conservative surgery and preventing complications. Procedures should be adapted to the etiology of SBS, the medical setting, and the experience of the surgeon as seen above.

The neonatal medical team needs to be highly trained in the management of long-term parenteral nutrition, fluid and electrolyte management of the ostomy output, prevention of feeding disorders, prevention of intestinal failure-related complications, and the management of central lines. ESPGHAN guidelines [71] are helpful for the management of PN but do not take into account many specificities of neonatal SBS. The end of the first phase of management is considered to be accomplished when the patient has recovered from the surgical procedure and is stable on PN with controlled intestinal losses and motility.

Long-Term Management of SBS: PN, Oral Eating, and Prevention of Complications

Once the acute phase is over, the management relies on three main areas:

- Provision of parenteral nutrition to ensure normal fluid-electrolytes status and growth.
- Promotion of bowel adaptation with oral feeding.
- Prevention of complications.

Growth with Parenteral Nutrition

Growth is essential and cannot be jeopardized. Parenteral nutrition should provide all the adequate nutritional supply to the child allowing optimal growth. Such nutritional support should follow the latest ESPGHAN recommendations [71] which include the use of 1.5–2.5 g/kg/day amino acids through a pediatric solution, a caloric intake consisting of 70–80% of nonprotein energy substrates, and 20–30% energy provided by a 20% intravenous fat emulsion.

Maintenance amounts of vitamins and trace elements are added to the PN solution by using commercially available preparations. Calcium, phosphate, and magnesium are also added to the solution according to the patient needs and the stability of the solution. Composite lipid emulsions containing fish oil have been shown to be beneficial to prevent cholestatic liver disease.

During the early phases of therapy, serum electrolytes, glucose, urea, and calcium should be measured daily. When the patient's condition and the intestinal losses become stable, blood monitoring can be less frequent. Excess fluid and electrolyte losses may complicate the management of SBS

patients, particularly in patients with high-output jejunostomies. Fluids with a sodium concentration of 130 mEq/L are used to replace jejunostomy. Replacement fluids intravenously may be adjusted based on electrolyte concentration of the lost fluids. Monitoring urine sodium concentration for excessive retention (<10 mEq/L) may indicate the need to provide more sodium, even if serum values are near normal. Excessive magnesium losses can occur with large ostomy volumes, and appropriate magnesium replacement may also improve calcium utilization. Zinc and selenium losses increase with watery diarrhea and high ostomy output. Zinc deficiency can lead to a decreased activity of zinc-dependent intestinal metalloenzymes, such as alkaline phosphatase, leucine aminopeptidase, and other intestinal disaccharidases, and delay intestinal adaptation. Zinc supplements are often used empirically, given that serum values do not reliably reflect body stores.

During the first few months after resection, H_2-receptor blocking agents (ranitidine/famotidine) should be given intravenously to inhibit gastric hypersecretion [48, 72] added to the PN solution, the drug being delivered as a continuous infusion. H_2-blockers, by increasing duodenal pH, also improve the digestion and absorption of nutrients.

Parenteral nutrition should not be stopped until normal growth can be achieved with oral and/or enteral feeding alone. Once the patient is stable, discharge on home parenteral nutrition (HPN) should be considered and organized, home parenteral nutrition being the only viable option for long-term parenteral nutrition. A common mistake is to stop PN when it is considered that the child tolerates enough enteral caloric intake according to RDA, under-estimating the residual intestinal malabsorption. The goal of intestinal adaptation is to develop the ability to withdraw artificial nutrition, thanks to a compensatory increase in the mucosal surface area and absorption capacity. The two indicators which have historically been used to predict weaning from PN in children, residual bowel length measured at final surgery and serum citrulline, though helpful, have not proven to be highly reliable prognostic factors in SBS patients [73–76]. In clinical practice, the degree of intestinal insufficiency may be measured by the percentage of PN required for normal body weight gain and growth. PN requirements remain, therefore, the best measure of the degree of intestinal sufficiency in this setting [2].

Indeed, progress in intestinal adaptation should be assessed using the *decrease of PN intake* instead of the *increase of enteral intake* which is widely used in publications. We do point out this change of paradigm to take into account the malabsorption syndrome inherent to SBS. Expressing PN dependency in nonprotein calories divided by REE (calculated using Schofield equation) allows us to have an indirect marker of intestinal adaptation according to the age, the gender, the weight, and the height of the child [77]: if the ratio decreases, the PN dependency diminishes reflecting the increase of intestinal absorption capacity, independently of enteral intake. The gold standard for measuring intestinal absorption is a stool balance analysis consisting of the collection and the measurement of all food intake and all fecal output by bomb calorimetry over a period of 3 days, but cannot be conducted in clinical settings especially in small children [76, 78].

Promotion of Bowel Adaptation

The management of SBS patients aims at promoting the physiological process of bowel adaptation by using as much as possible the GI tract especially by oral feeding (OF) which is more physiological than enteral tube feeding (ETF) [79]. PN itself aims in promoting normal somatic growth during the time bridge for achieving full intestinal autonomy. PN should not be stopped until adequate growth can be achieved with only OF and/or ETF.

The optimal strategy for enteral feeding, OF versus ETF and bolus versus continuous, remains debatable [79]. As seen above, the secretion of factors contributing to intestinal adaptation is related to the arrival of undigested nutrients in the intestine. Moreover, OF promotes the release of epidermal growth factor (EGF) from salivary glands and increases GI secretion of trophic factors [80]. Sialoadenectomy in animals significantly attenuates villous height, total protein, and DNA content after small bowel resection that is reversed by the administration of both systemic and oral EGF [81]. The advantages of oral feeding, when feasible, include the maintenance of sucking and swallowing functions, the learning of hunger-satiety mechanisms, nutritional self-regulation, the interest and enjoyment associated with eating, as well as the stimulation of growth factors and hormones released by the GI tract promoting adaptation. Alternating fasting and feeding periods along with cyclical PN avoids permanent secretion of insulin and excessive fat synthesis and deposition (steatosis, fat body mass).

Feeding must be started as soon as possible after surgery. In an infant, breastfeeding should be encouraged, or when it is not possible, an extensively hydrolyzed formula with a high proportion of medium-chain triglycerides can be used [79–82]. Breast milk contains IgA, growth factors, nucleotides, long-chain fatty acids, glutamine, and other amino acids that promote intestinal adaptation [83–87]. In addition, breastfeeding has been associated with improved immune function, as well as the genesis of a fecal microbiota rich in lactobacilli and bifidobacteria, all of which may improve SBS prognosis. On the other hand, breast milk contains lactose, which is sometimes not well tolerated in patients with reduced intestinal surface area. Human milk also contains glutamine and growth factors, such as epidermal growth factor, which possibly promote bowel adaptation. Extensively hydrolyzed formulas are mostly used when whole protein feeds are not tolerated, while amino acid-based formulas (AABF) have been used as a last resort. The AABF are generally used in the treatment of food allergies or in case of

milk protein hydrolysate intolerance [88, 89]. True food allergies have been rarely documented in children with SBS. Two retrospective studies report that the use of an AABF was associated with earlier weaning from PN and also a reduced rate of allergies [90, 91]. However, the very small sample sizes and the lack of a control group in these studies limit the applicability of these findings and do not support the recommendation of using AABF to all children with SBS and IF. Moreover, commercially available AABF contain lower levels of MCT than EHF. Finally, if the child has very short bowel with food aversion, a more palatable formula such as a classic polymeric formula with lactose can be used to stimulate oral feeding.

When oral feeding is not possible, ETF may be administered either continuously or in frequent small boluses, initially aiming at supplying a minimal enteral feeding (20–25 Kcal/kg/ day) and then increased gradually as tolerated with larger boluses during the day and continuous feeding overnight. In addition, aggressive ETF may also result in an overloaded gut syndrome with abdominal discomfort, intestinal distension, and loss of self-regulation of intake leading to eating disorders.

Feeds should be increased gradually as tolerated. Too much may be deleterious. Tolerance is key and should be evaluated by measuring stool number and volume and by the observation of vomiting, irritability, and intestinal distension. Many factors can affect stool volume in SBS, including the length of the residual intestinal segment and the type of segment (the more proximal the resection, the larger the fluid and sodium losses), and the mucosal and endoluminal variables (residual enzymatic activity and absorptive capacity, bacterial overgrowth). On one hand, *continuous* feeding appears to improve growth and adaptation through the optimization of absorption by challenging the enteral capacity [82, 92], but on the other hand forced continuous ETF may result in bowel dilation [93].

Thus, the mode of feeding still remains debatable among the different centers. In summary, feeding a child with SBS should always take into account the physiology, the psychological behavior of the infant (mother-child feeding relationships, acquisition of oral skills, abdominal and digestive comfort of the child), and finally the nutritional efficiency. Oral feeding should always be promoted even in small quantities. Continuous tube feeding should be avoided: despite the slight increase in absorption, the changes in motility patterns it induces (Figs. 43.4 and 43.5) lead to abdominal dilation and eventually deleterious SIBO. As seen above, enteral feeding is the most important

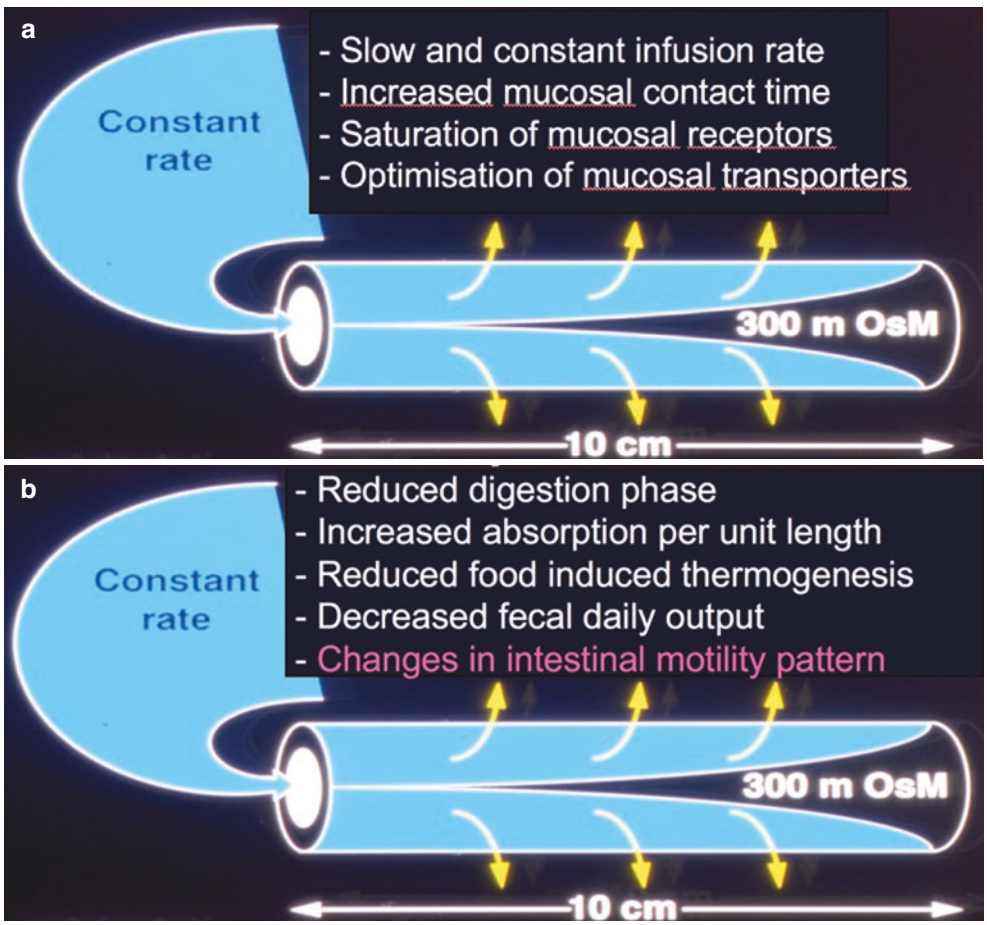

Fig. 43.4 Continuous feeding increases absorption but induces change in motility pattern

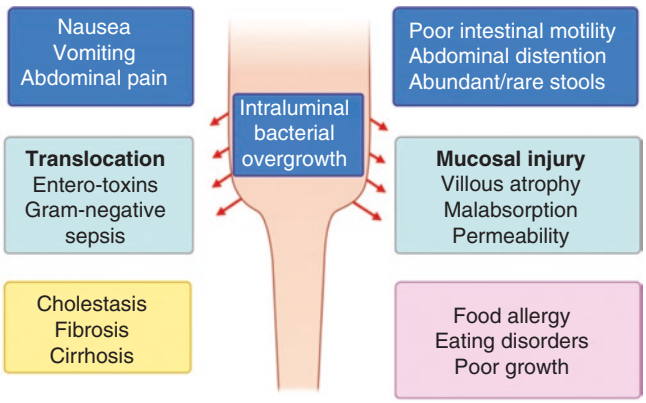

Fig. 43.5 Consequences of overfeeding a dilated intestine with subsequent intestinal stasis and small intestinal bacterial overgrowth (SIBO)

factor to promote adaptation; nevertheless, it is important to avoid overfeeding.

Prevention of Complications

Small Intestinal Bacterial Overgrowth (SIBO)

SIBO is a specific complication of SBS in patients with IF. Small intestinal bacterial overgrowth (SIBO), characterized by the presence of excessive bacteria in the small intestine, is typically described as a malabsorptive syndrome occurring in the context of gut stasis syndrome. It is generally accepted that CTF offers the advantages of optimal digestion and absorption rate [82, 92]. However, continuous infusion changes the intestinal motility pattern in the absence of a fasting period [93]. Significant dysmotility – impairing intestinal bacterial clearance – leads to small intestinal bacterial overgrowth (SIBO) with subsequent translocation and Gram-negative sepsis. SIBO and cholestasis are common especially in patients without ICV and those having abnormal motility (e.g., intestinal atresia, gastroschisis, NEC). Aggressive continuous ETF is often attempted for mimicking "hyperphagia" and enhancing absorption with the aim of weaning the child off PN, which is thought to be the cause of liver injury. These patients present with dilated loops of bowel containing residual non-absorbed nutrients. This strategy results in increasing SIBO that causes mucosal inflammation and increased permeability leading to sensitization and allergy as well as bacterial translocation, sepsis, cholestasis, and irreversible liver disease [2, 93, 94] (Fig. 43.5).

Diagnosis of SIBO remains challenging. Classic clinical signs include feeding intolerance, vomiting, nausea, liquid stools – although the colon is in continuity – higher malabsorption, higher dependence to PN than expected, and liver disease. There is no easy biological tool for the diagnosis. There is hope in the application of modern molecular techniques to the study of the small intestinal microbiome, together with some innovative sampling techniques, such as real-time intestinal gas sampling, which may soon allow the clinician to truly define the spectrum of SIBO [95].

Treatment of SIBO is controversial – ranging from large spectrum antibiotics in the short or the long term, to prebiotics or probiotics [96–99]. Repeated administration of large spectrum antibiotics may improve SIBO temporarily but lead to the risk of selection of highly resistant bacteria without treating the underlying cause of SIBO. Stopping aggressive ETF and performing nontransplant surgery to reduce the small intestine diameter may restore intestinal motility and decrease SIBO (see below). Indeed, surgical procedures such as longitudinal intestinal lengthening and tailoring (LILT) or serial transverse enteroplasty (STEP) aim not only to enhance the bowel length but also to reduce the diameter of dilated intestinal loops, thus, improving its motility and reducing SIBO [100–102].

In conclusion we consider that the best treatment for SIBO is surgery, which is far more efficient and less deleterious than antibiotics. Often the same causes repeat the same effects. It should always be questioned why SIBO developed in the first place – the main factor being a dilated loop – either caused by force feeding (usually continuous tube feeding) or anastomosis stricture or dysmotility due to the cause of SBS or a combination of all three. To avoid the recurrence of dilation and SIBO, it is critical to understand the underlying mechanism and to stop force feeding.

IFALD

IFALD is due to a combination of factors, but with the recent improvements in parenteral nutrition and lipid emulsion, these days it is mainly due to SIBO in SBS-IF patients. Many academics continue to talk about *PN*-related liver disease, suggesting that PN is the cause of liver disease. Cholestatic liver disease (CLD) has been shown to be more frequent in SBS patients than in any other IF conditions [103]. Out of 175 neonates with abdominal pathology requiring surgery, the patients with SBS (n = 40) suffered significantly more morbidity than the group without SBS in all categories of investigation (surgical complications, septic events, CRS, PN weaning delay, liver disease, and duration of hospitalization). The case fatality rate was 37.5% in patients with SBS versus 13.3% in patients without SBS (P = 0.001). Most deaths were caused by liver failure or sepsis and occurred within 1 year from the date of surgery. Nowadays, the most appropriate wording should be *intestinal failure*-associated (or related) liver disease (IFALD) [2, 104, 105]. It is probably the most important and the most life-threatening complication affecting children with SBS-IF on long-term PN. The prevalence of the disorder is unknown since there is no established definition of liver disease in this setting, and it is unclear as to whether IFALD should be diagnosed on the basis of clinical, biological, or histological criteria. However,

persistent elevation of serum conjugated bilirubin level is considered the most relevant biochemical marker of progressive IFALD. The main factors contributing to liver injury in these patients are recurrent catheter-related sepsis, prematurity and low birth weight, lack of enteral feeding, disruption of entero-hepatic biliary acid cycle (proximal stoma, ileal resection), intestinal stasis, and SIBO (obstruction, dysmotility, lack of ileocecal valve, aggressive tube feeding, etc.). It should be stressed that the most important factors leading to IFALD are those related to individual patient characteristics and, importantly, the episodes of catheter-related bloodstream infections or SIBO [106–108]. Interestingly, Finnish pediatric surgeons reported an association between bowel dilation, bowel-derived sepsis, and cholestatic liver disease [94], confirming the hypothesis of a link between bowel dilation, SIBO, and IFALD in SBS patients [2]. Factors that link infection to cholestasis are either cytokines or microbial TLR2 or TLR4 agonists [109]. Liver targets primarily include hepatocytes, but also extend to Kupffer cells, cholangiocytes, endothelial cells, and stellate cells. There are no direct studies of bile flow in humans given endotoxin, but there is sufficient indirect evidence to link endotoxin and endotoxin-induced cytokines to cholestasis. During severe sepsis, including septic shock, hyperbilirubinemia is usually a central clinical finding, often out of proportion to typically mild elevations in serum transaminase. Interestingly, TNF alpha administered in humans has shown significant hyperbilirubinemia, further supporting a link between cytokines and cholestasis [110]. An important role in this process is played by liver inflammation caused by extra-hepatic infections in which microbial products brought to the liver through the bloodstream, either directly or through production of cytokines, lead to alterations of the bile flow. The inflammation associated with these changes may cause rapid fibrosis and eventually biliary cirrhosis with end-stage liver disease [106, 111–114].

IFALD develops frequently at a very early age, especially in premature infants in whom liver immaturity, frequent sepsis, and necrotizing enterocolitis (NEC) facilitate liver inflammation and severe damages. At this young age PN is most often administered continuously over 24 hours and CRS is common. The combination of these factors makes the onset of cholestatic liver disease likely. The treatment relies on preventative strategies and acting on reducing the risk factors. Ursodeoxycholic acid (UDCA) can be implemented if tolerated. Preventative strategies should focus on oral feeding to increase bile flow and intestinal bacterial clearance, the avoidance of continuous tube feeding, the prevention and surgical treatment of SIBO, the restoration of intestinal continuity, the improvement of catheter care to reduce infections, cyclic PN to reduce continuous hyperinsulinemia, and the reduction of inflammation by using fish oil-based lipid emulsion.

IFALD and Intravenous Lipid Emulsions

While the pathogenesis of IFALD is multifactorial, studies have identified a possible link between intravenous lipid emulsions (ILE) containing high dose of soybean oil and liver disease [115, 116]. Three characteristics of ILE are involved as etiologic factors in the process of liver disease: high phytosterol content [117, 118], low anti-oxidant (low amount of alpha-tocopherol) of traditional emulsion containing pure soybean oil [119, 120], and the pro-inflammatory nature of omega-6 fatty acids. Fish oil-containing lipid emulsions offer several potential advantages including decreased omega-6 and increased omega-3 PUFA concentrations, high amounts of alpha-tocopherol, and reduced phytosterol content. Studies in PN-dependent children at risk for developing IFALD have shown that fish oil-based ILE reduced the risk of cholestasis and improved biochemical measures of hepatobiliary function compared with soybean-based ILE. The infusion of pure fish oil ILE (exclusively ω-3 FAs) allowed the reduction of intake of pro-inflammatory ω-6 and phytosterols while increasing the amounts of alpha-tocopherol, a powerful antioxidant agent [105, 119, 120]. The evidence gathered on the beneficial effects of fish oil-based ILE in these patients has led to its use in clinical practice. However, different approaches have been developed in North America as compared to Europe. In North America, following the study by Gura et al. [121] and Cowles et al. [122], a pure fish oil-based ILE (Omegaven®) has been promoted as the unique ILE to be available on the US market. In Europe, as in many other countries, it has become possible to use a composite ILE containing a mixture of soybean oil (30%), coconut oil (30%), olive oil (25%), and fish oil (15%) (SMOF-lipid®). Both ILEs contain 200 mg/L of alpha-tocopherol. Some concerns have been raised on providing fish oil ILE as the sole source of lipids over a long period of time. Omegaven® provides less essential ω-6 fatty acids than what is currently recommended in infants and young children [123]. Randomized, double-blind, controlled trials in preterm babies stratified by body weight have analyzed a set of parameters (clinical data, laboratory data, fatty acids in plasma and red blood cells, plasma levels of alpha-tocopherol and alpha-phospholipids) after infusion of PN with SMOF-lipid® or soybean oil-based ILE [124–126]. The SMOF-lipid® emulsion increased the content of eicosapentaenoic EPA and docosahexaenoic (DHA) acids and reduced the ω-6/ω-3 ratio, improving also liver function tests. In a study evaluating the long-term effects of SMOF-lipid® versus a soybean oil-based ILE in pediatric patients on home PN, no differences between biochemical and nutritional outcomes were recorded, but there was a clear association between the use of SMOF-lipid® and a significant decrease of bilirubin levels that conversely increased in the soybean oil-based group [127]. Muhammed et al. examined the effect of the switch from a soybean oil-based lipid emulsion to

SMOF-lipid® in 17 children with cholestasis [128]. Over a period of 6 months, the use of SMOF-lipid® was associated with a marked statistically significant reduction in the levels of bilirubin when compared with the soybean oil-based lipid group. In a recent clinical trial, Diamanti et al. [129] showed that compared to Intralipid® (pure soybean oil-based ILE), SMOF-lipid® reduced the risk of progressive IFALD in children with intestinal failure.

Infants and children with SBS are at high risk of developing IFALD. Therefore, composite lipid emulsion containing fish oil should be preferred in these patients from the very early phase of management as a preventative measure. In the absence of available composite lipid emulsion, fish oil (Omegaven®) should be used in combination with soybean and coconut oil with added alpha-tocopherol.

Catheter-Related Issues

Infections

Central catheter-related bloodstream infections can be life-threatening, and the recurrence of sepsis is associated with cholestasis and progressive liver disease, especially in young infants [106]. Tunneled catheters should be used to prevent the migration of skin commensal flora to the bloodstream. Central catheters should always be handled with sterile technique by experienced staff, the lines should be changed every 24 hours, and the insertion site should be regularly monitored with antiseptic dressing every 72 hours.

In the case of home PN, parents and/or caregivers should be trained by specialized teams in the sterile technique of catheter handling (connection and disconnection of the PN infusion), in the insertion site dressing, and in more basic care such as giving a bath and going swimming, which, if done inappropriately, can lead to catheter infections. In case of recurrent infections or loss of vascular access, antiseptic locks (such as ethanol or taurolidine) should be implemented and allow to decrease the rate of catheter infection below 1/1000 catheter-days. Bacterial translocation from SIBO is directly linked to intestinal dilation [94] and contributes to recurrent sepsis and subsequent liver damage.

Catheter salvage strategy should always be preferred – except in case of *Staphylococcus aureus* infections – since multiple catheter insertions might repeatedly damage vein walls and promote thrombosis [130].

Exit-site infections can usually be treated using twice-daily antiseptic dressing changes and local antibiotics, but sometimes extend toward tunnelitis requiring an emergency catheter removal.

Thrombosis

Thrombosis of central venous access should be avoided at all cost since it compromises the possibility of further parenteral nutrition and may be an indication for early intestinal transplant. Thrombosis is a rare event in children but the central catheter is a major risk factor: 85% of thrombosis in children occurs in children with a central catheter. Thrombosis is caused by several factors: stasis, vascular trauma, and hypercoagulability. The catheter itself is a thrombotic surface and causes blood flow reduction due to its size in small infant veins. The parenteral nutrition solution is hyperosmotic. Premature infants have an immature coagulation system. Infections especially with *Staphylococcus aureus* increase the risk of thrombosis. Preventative measures such as inserting the thinnest catheter adapted to the size of the child, prevention and early treatment of catheter infections, and catheter salvage strategy are essential. Anti-coagulant therapy can be discussed in case of extensive thrombosis but has not demonstrated its efficacy in the prevention of catheter-related thrombosis.

Occlusion of the catheter is prevented by pulse-flushing. In case of occlusion, thrombolytic agents can be used punctually.

D Lactic Acidosis

Clinical manifestations such as abdominal distension, bloating, and nausea – due to colonic microbiological hypermetabolism – may impair daily life and should be monitored. They are the consequences of the intestinal malabsorption leading to the arrival of a huge load of undigested CHO in the colon. This condition may be worsened by hyperphagia or aggressive tube feeding. One rare complication of colonic hypermetabolism, which is clearly different from small intestinal bacterial overgrowth (SIBO), is D-lactic acidosis.

D-Lactic acidosis (D-LA), also referred to as D-lactate encephalopathy, is a rare neurologic syndrome that occurs in individuals with SBS or following jejunoileal bypass surgery [131, 132]. Fortunately, this complication is very rare. Symptoms typically present after the ingestion of high-carbohydrate feedings. Neurologic symptoms include altered mental status, slurred speech, and ataxia, with patients often appearing drunk. Onset of neurologic symptoms is accompanied by metabolic acidosis and elevation of D-lactate plasma concentration. L-Lactate concentration, which is reflected by serum lactate concentration, is normal. Thiamine deficiency should be excluded [133]. D-Lactate fecal concentration may be assessed routinely [65].

Lactobacilli and other bacteria, including *Clostridium perfringens* and *Streptococcus bovis*, ferment unabsorbed carbohydrate to D-lactic acid, which cannot be metabolized by D-lactate dehydrogenase. These organisms may proliferate in an acidic environment that may be promoted by the metabolism of unabsorbed carbohydrates to SCFAs. The mechanism for the neurological symptoms is unknown. They have been attributed to the D-lactic acid, but it is unclear if this is the cause or whether other factors are responsible [65]. Treatments described in case reports have included observation with spontaneous resolution, oral metronidazole, neomycin, van-

comycin (for 10–14 days), and avoidance of "refined" carbohydrates [134]. Probiotics, prebiotics, and synbiotics have been used but without clear efficacy [135, 136]. Prevention of D-lactic acidosis relies on avoiding high load of carbohydrates. In some patients, it might need increasing or resuming PN when symptoms are too frequent.

Perianastomotic Ulceration

Perianastomotic ulceration is a rare but severe complication after intestinal resection and anastomosis. It is described mostly in children [137, 138]. The main symptom is subclinical intestinal bleeding leading to severe iron deficiency anemia. A survey reported patients with anastomotic ulcerations after intestinal resection in infancy focusing on predictive factors, medical and surgical treatment options, and long-term outcomes [137]. Eleven patients were reported. The diagnosis was often delayed for several years. No predictive factor (including the primary disease, the length of the remnant bowel, and the loss of the ileocecal valve) could be identified. Numerous treatment options were tried, including antibiotics, probiotics, and anti-inflammatory drugs, but none proved to be effective to induce prolonged remission. Even after surgical resection, relapse was observed in 5/7 children. The mechanism leading to anastomotic ulcerations remains unknown but it is likely that intestinal microbiota dysbiosis plays an important role. Another recent study reported 14 cases revealed by severe anemia, diarrhea, abdominal pain, and growth failure in average 11.5 years after surgery [138]. Ulcerations were multiple in most cases ($n = 11$), located on the upper part of the ileocolonic anastomosis ($n = 12$), and were difficult to treat. No granulomas were seen but lymphoid follicles were frequent. In addition, either anti-saccharomyces cerevisiae antibodies (ASCA) or anti-neutrophil cytoplasmic antibodies (ANCA) were positive in 4/9 tested patients and 8/11 genotyped patients exhibited a NOD2 mutation ($P < 0.0002$ when compared to healthy controls). Contrary to previous reports with limited follow-up, no medical or surgical treatment could prevent recurrences. Because relapse may occur several years after discontinuation of PN, long-term follow-up is needed. Frequent relapses causing chronic iron deficiency anemia might benefit in the future from fecal transplantation.

Eating Disorders

Children with SBS-IF often develop oral aversions and eating disorders. It was pointed by Moreno Villares et al. that tube feeds delivered by either gastrostomy or a nasogastric tube, often used in infants to provide adequate caloric and nutrient intake, may induce eating disorders [139], along with surgery, fasting, and pain in the first weeks of life. It is important to introduce oral feeding early to avoid the development of poor feeding skills who receive artificial nutrition. Children in transition for tube to oral feeding may display oral-motor, sensory, and developmental feeding problems. There is limited research and information on which to base interventions that will preserve and develop oral motor and feeding skills. Interdisciplinary teams are needed to effectively address these complex oral feeding problems [140]. Accurate identification of the underlying issues will allow healthcare providers to develop interventions to improve feeding outcomes for children with SBS and to avoid the use of tube feeding. In clinical practice, the role of nurses for supporting the development and the psycho-motor coordination in neonates should be emphasized in order to prevent eating disorders. Later in life, it is very challenging to develop healthy eating behavior in children with long-lasting eating disorders who remain dependent on tube feeding [141].

Growth Failure

Growth failure in children with SBS is usually a direct consequence of inappropriate management and forced PN weaning. The slow transition from PN to full oral feeding requires time during which nutritional status has to be maintained at an optimal level. Trying to wean off PN too rapidly in an infant with neonatal SBS leads to the risk of failure to thrive and metabolic complications. PN intake should be increased for achieving optimal growth and nutrition. A common mistake consists in adding PN and EN calories. The sum of PN and EN even if fitting the RDA may not be sufficient for growth because of intestinal malabsorption. However, some other factors might contribute to growth difficulties in children with SBS (Table 43.1).

Other Complications

Biliary Lithiasis

Patients with SBS are at high risk of developing gallstones. The lack of stimulation of gallbladder emptying (absence of proper meals) and the disruption of the bile entero-hepatic cycle along with the use of certain antibiotics contribute to the accumulation of sludge in the gallbladder predisposing to the formation of gallstones. Premature infants are especially exposed to cholelithiasis because of their low production of conjugated bile acids.

Systematic cholecystectomy is not recommended as it can lead to surgical complications such as post-ischemic stricture of the common bile duct. Medical treatment with urso-

Table 43.1 The main causes of failure to thrive in SBS patients

Insufficient and/or unadapted parenteral nutrition intake
Trace elements deficiencies (especially zinc)
Sodium depletion from high ostomy output
Inefficient enteral tube feeding (malabsorption, SIBO)
Gut mucosal inflammation from bacterial overgrowth
Chronic metabolic acidosis (D-lactic acidosis)
Repeated sepsis (catheter related, translocation, etc.)
Intestinal failure-associated liver disease (IFALD)

deoxycholic acid is indicated in oligosymptomatic and asymptomatic lithiasis with transparent, soft, cholesterol-rich stones. Cholecystectomy is indicated in case of recurring episodes of cholecystitis or gallstone migration.

Oxalate Renal Lithiasis

In SBS patients with colon in continuity, bile salt deficiency prevents full solubilization and absorption of fatty acids, which then bind preferentially to intraluminal calcium. Under normal conditions, calcium binds to oxalate in the distal intestine, forming a precipitate that is expelled in the stool. But when calcium instead binds to fatty acids, excess free oxalate is absorbed by the colonic mucosa and excreted by the kidney, leading to hyperoxaluria and an increased risk for renal calcium oxalate stones and deposits. This complication is rare in young children but might occur in teenagers with persistent fat malabsorption and hyperphagia. To offset the risk of nephrolithiasis, patients should limit their intake of dietary oxalate and increase calcium consumption to limit residual free oxalate in the colon [142] (Fig. 43.6).

Alternative Treatments

Nontransplant Surgery

Autologous Bowel Reconstruction

Surgical approaches aiming at maximizing gastrointestinal digestive and absorptive function are crucial to the management of SBS. These include stoma closure and restoration of bowel continuity together with resection of strictures and closure of fistula. Some surgical procedures have aimed at slowing intestinal transit in the hope that it would improve absorption, such as construction of intestinal valves, reversed intestinal segments, and colon interposition: clinical benefits remain poorly defined in pediatrics. Conversely, surgical interventions aiming at increasing the length of the bowel by reducing the diameter of the dilated loop result in reducing the stasis in the dilated bowel (and decreasing SIBO in the process) and, by increasing the length of the bowel, increase the contact time between luminal nutrients and mucosa (without stasis) which might improve the overall absorption. Indeed, these procedures aim not only to increase the intestinal length but also to reduce the diameter of the dilated intestinal loop with subsequent reduction of SIBO. The most common procedures are longitudinal intestinal lengthening and tapering (LILT) developed by Bianchi in Manchester, UK [143], and serial transverse enteroplasty (STEP) developed by Kim et al. in North America [144] (Fig. 43.7a, b). The precise indications and the potential benefits of these procedures remain a matter of debate [145, 146]. Classical conditions and indications for bowel-lengthening surgery include the presence of a large intestinal diameter (>3–4 cm) for at least 20 cm of small bowel and a minimum total bowel length of 40 cm.

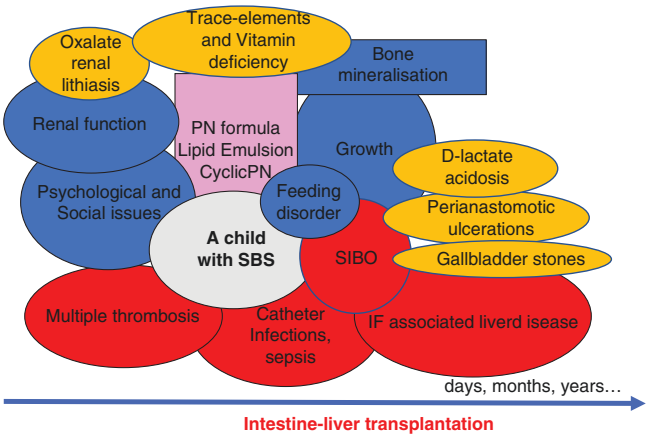

Fig. 43.6 Complications associated with SBS-IF

LILT involves longitudinal splitting of the remnant small bowel along its mesenteric and anti-mesenteric border, ending up with two tubes of bowel of identical length each with their own blood supply which are then joined together [143]. The advantages of the LILT procedure (Fig. 43.7a) include the conservation of the normal orientation of the muscular fibers allowing more physiological peristaltic contraction, and the possibility to further perform a STEP procedure on the operated segments. The disadvantages are the risk of vascular complications during surgery making LILT more technically demanding as compared to the STEP procedure [143–146]. The STEP procedure involves the use of a surgical stapler applied sequentially from alternating and opposite directions to the dilated loop, in a transverse, partially overlapping fashion creating a zigzag-like channel of approximately 2 to 2.5 cm in diameter (Fig. 43.7b). This operation has the great advantage of being simple and reproducible; unlike LILT, no anastomosis is needed, and the mesenteric blood supply is not put at risk. If the bowel re-dilates, a further STEP procedure can be undertaken. However, results after STEP and re-STEP procedure are not as performant as expected [101, 102, 147–149].

Theoretically, these two surgical techniques do not increase the small bowel surface area although they increase the bowel length. However, by reducing bowel dilation, intestinal stasis, and SIBO, they restore intestinal mucosal integrity. Indeed, a 5-year follow-up cohort study after STEP confirmed the efficiency of this procedure to increase intestinal absorption. Interestingly, both D-xylose – a marker of carbohydrate absorption and mucosal integrity – and plasma citrulline, a marker of small bowel enterocyte mass, increased significantly postoperatively [150]. This suggests that STEP procedure by reducing SIBO restores small intestinal mucosa integrity and improves villous size within the first weeks following the procedure.

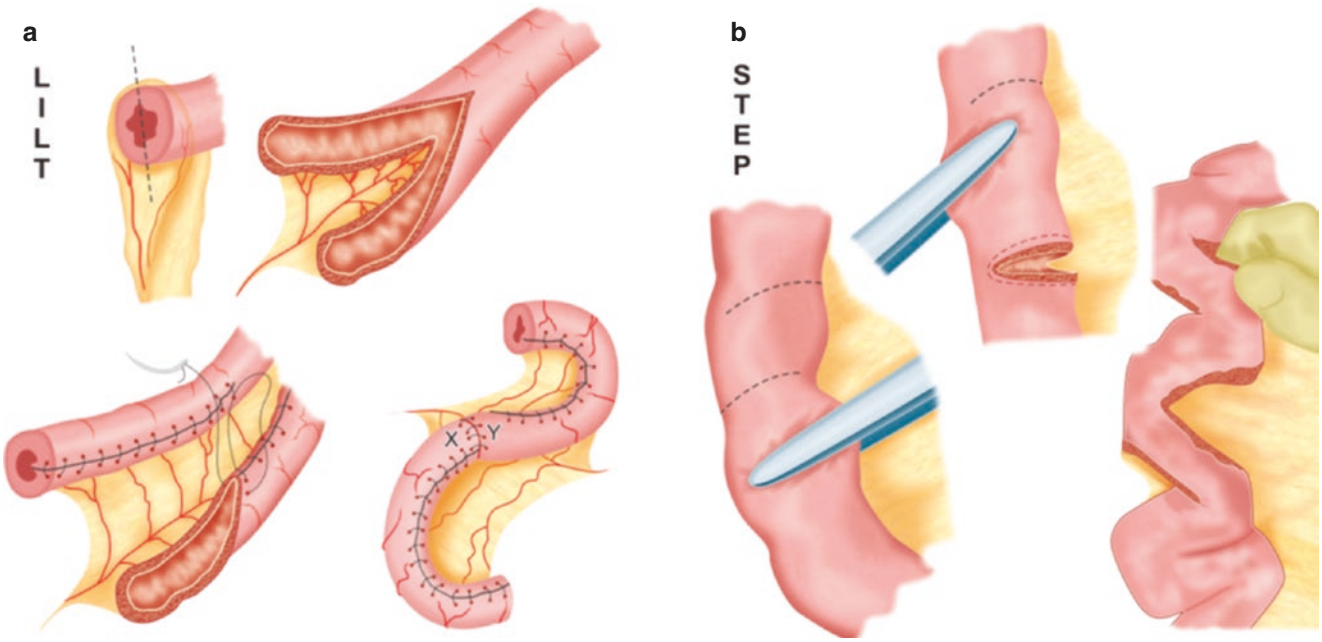

Fig. 43.7 Nontransplant surgery in the short bowel syndrome: LILT, longitudinal intestinal lengthening and tailoring; STEP, serial transverse enteroplasty

Surgical Management of TIA

The surgical management of TIA/NTIA is challenging and the role of autologous intestinal reconstructive surgery (AIRS) is controversial [150, 151]. A recent cross-sectional study concludes that AIRS may be performed in carefully selected patients [151]. It may be an effective way to enhance residual bowel absorptive function and to reduce PN requirements.

Usually, surgery is performed as a simple jejunostomy just above the aganglionic intestine at diagnosis. The subtotal enterectomy is delayed to either pull-through procedure or intestinal transplantation. In patients with TIA/NTIA, we would advise subtotal enterectomy of the aganglionic segment at an early age, to avoid chronic sepsis in the excluded bowel and its deleterious consequences on the liver. If the stoma is normally ganglionic with normal motility of the stomach, duodenum, and initial jejunum, we would consider to lengthen the small bowel by sero-myotomy (about 40 cm) and perform a new stoma in the same operation [150–152]. This procedure aims at lengthening the small bowel for about 40 cm for slowing the transit and increasing the absorption surface. A longer segment may cause obstruction since sero-myomectomy removes achalasia but does not restore motility. Our experience with this procedure is positive without obstructive symptoms. It is now clear that the aganglionic bowel left in the abdomen may cause a severe condition related to diversion colitis. The question of the loss of the abdominal domain in the view of future Tx should be balanced with the high risk of causing sepsis and liver disease in the short term. Any bacteria-related inflammation of the excluded bowel (diversion colitis), by injuring the mucosa, increases permeability, enterotoxin release, and bacterial translocation and in turn causes portal inflammation and subsequent cholestasis/fibrosis/cirrhosis. Even if these children have to undergo liver and intestinal transplantation, staged closure of the abdominal wall would be possible even with the lack of room in the abdomen. We think this does no longer justify maintaining the aganglionic bowel inside just "to keep room." Nontransplant surgery and intestinal transplantation (ITx) are complementary surgical tools in the complex management of TIA/NTIA.

New Treatments (GLP-2 Analogs, Insulin, EGF)

Hormonal Therapy and Other Adaptive Treatments

Hormonal therapy is promising in the management of infants with SBS. The role of recombinant human growth hormone (rhGH) alone or in combination with glutamine has been investigated. Inconsistent results have been reported in adults receiving rhGH, with reported side effects [153]. A few studies of rhGH alone or in combination with glutamine have been carried out in PN-dependent children with SBS [154–156]. Despite some decrease in PN requirements during treatment, these trials showed little benefit on body composition and mucosal absorption in the long term.

Epidermal growth factor (EGF) has been shown to have a role both in maintaining epithelial tissues and in controlling intestinal adaptation. In clinical setting, five SBS pediatric

patients (<25% bowel length predicted for age) received 100 mg/kg per day given mixed with enteral feeds for 6 weeks [57]. All patients showed a significant improvement in carbohydrate absorption and improved tolerance of enteral feeds (enteral energy as percent of total energy, 25% ± 28% pretreatment vs. 36% ±24% post-treatment; mean ± SD ($P < 0.05$)). EGF treatment was not associated with significant changes in intestinal permeability, the rate of weight gain, or liver function tests. However, this study involving only five patients assessed with discussable parameters did not allow to draw any conclusion whether EGF treatment was efficient and EGF treatment has not been developed any further.

Oral insulin has been shown to influence intestinal structure and absorptive function. The effects of parenteral and oral insulin on structural intestinal adaptation, cell proliferation, and apoptosis were shown in rats [157]. This favorable effect of insulin is relevant and is now considered in SBS patients [158], but is still at the stage of clinical research.

Other relevant treatments associated with a trophic effect on the bowel mucosa such as short-chain fatty acids may be beneficial in children with SBS [159].

Glucagon-like peptide 2 (GLP-2) is produced by the L-cells of the terminal ileum in response to luminal nutrients and has a trophic effect on the intestine, promoting absorption and adaptation. GLP-2 has been shown to increase the surface area of the gut mucosa, upregulate nutrient absorption, improve gut-barrier function, increase intestinal blood flow, and decrease bone resorption. The effect of GLP-2 analogs on the gastrointestinal function was assessed in patients without a terminal ileum and colon who have functional short bowel syndrome with severe malabsorption and no postprandial secretion of GLP-2 [160]. Balance studies were performed before and after treatment with teduglutide. Treatment with teduglutide (0.05 mg/kg/day) improved the intestinal absorption of fluid and energy and increased body weight. It is now demonstrated with several double-blind placebo control studies that teduglutide improves intestinal absorption and nutritional status in SBS adult patients [160, 161]. Factors associated with teduglutide response were baseline parenteral support volume, bowel anatomy, and SBS features [162]. A study was performed in young infants correlating postprandial GLP-2 levels with intestinal length, nutrient absorption, and patient outcome [163]. These results suggest that in infants with intestinal dysfunction, GLP-2 levels are correlated with residual small bowel length and nutrient absorption and may be predictive of outcome. GLP-2 might be the most logical medical approach for early management of SBS patients especially those with ileal resection. A 12-week, open-label study enrolled SBS PN-dependent patients aged 1–17 years [164]. It was concluded that teduglutide (GLP-2 analog) was well tolerated at 0.025 or 0.05 mg/kg/d and was associated with trends toward reductions in PN requirements and advancements in enteral feeding. However, study limitations included its short-term, open-label design, small sample size, and heterogeneity of both patients and management because of the multicenter study. The effects of the treatment rapidly faded at the stop of treatment to come back to pretreatment PN requirements. The study was extended to 24 weeks [165] and enrolled 59 children: 24 received 0.025 mg/kg of teduglutide, 26 received 0.05 mg/kg/day, and 9 received standard of care (SOC). The 24-week study confirmed the results observed in the 12-week study [164] with a similar safety profile and a reduction of caloric PN support of 43% in the treated groups ($p < 0.05$). Most of the reduction was observed in the first 12 weeks of treatment, and only 5 children could be totally weaned off PN: 2 of these children had a remaining small bowel length of 120 cm which hardly qualifies them as "short" bowel syndrome children and the 3 others had over 40 cm of remaining small bowel with more than 70% of remaining colon – which should have been sufficient to wean off PN without the use of teduglutide. These results question the selection of patients and raise the question of which patients should benefit from this costly treatment with a lack of hindsight for a treatment for life starting in childhood. An open-labeled monocenter pediatric study is underway using teduglutide at the dose of 0.05 mg/kg/d which included children with severe SBS-IF who had reached a plateau in adaptation aiming at evaluating the reduction of PN intake and the increase in intestinal absorption using balance studies [166]. This trial might give us more answers on which patient should benefit the treatment. Other analogs of GLP-2 (apraglutide, glepaglutide) are under trial in adult patients in order to either increase the effect on the intestine or increase the half-life of the treatment.

Inhibitors of Dipeptidyl Peptidase-4

Dipeptidyl peptidase-4 (DPP4) inhibitors are used in routine for the treatment of type 2 diabetes mellitus. Interestingly, GLP-2 analogs have been developed so they could resist longer to the action of the DPP4.

Sueyoshi et al. have experimented the use of orally active DPP4 inhibitor to determine the efficacy of this approach to promote adaptation after resection in a mouse model of SBS. Treatment led to differential effects over time with greater absorptive function at early time points and enhanced proliferation at later time points. The action seemed to peak by 30 days regarding intestinal epithelial cell proliferation and GLP-2 plasma levels [167–169]. This approach has not yet been developed for human use.

Tissue Engineering

In order to develop novel approaches to the treatment of short bowel syndrome, some research teams have focused on the development of an artificial intestine by placing intestinal

stem cells on a bioscaffold that has an absorptive surface resembling native intestine and taking advantage of neovascularization to develop a blood supply. Although there are recent advances in biomaterials, vascularization, and intestinal organoids and progress toward development of a functional epithelium and mesenchymal niche, lots of challenges still remain in the field and human application is still in the far future [170–173].

Long-Term Prognosis (PN and Weaned Patients, Growth, Adult Height)

SBS mortality decreased during the last decade following the implementation of "intestinal rehabilitation centers" [174]. Multidisciplinary management, improved prevention of SIBO and sepsis by performing autologous bowel reconstruction [143–149], prevention of catheter-related bloodstream infections with taurolidine or ethanol lock procedures [175, 176], and use of last generation of lipid emulsions [13] allowed to prevent the development of irreversible IFALD and evolution toward nutritional failure. As a matter of fact, the rate of intestinal transplantation decreased in the meantime [177].

Children with SBS who survive the first weeks of life and who are not weaned off PN in the first months of life should benefit from home parenteral nutrition with a multidisciplinary follow-up involving pediatric gastroenterologists, surgeons, anesthesiologists, dieticians, specialized nurses, psychologists, and occupational therapists. The PN formula should be tailor-made and regularly adjusted to the child's needs. About 60% of children with SBS who are discharged on home parenteral nutrition can be weaned after 2 to 4 years [76, 178]. The other patients will remain on PN, usually with one or several nights a week of PN, unless GLP-2 analog treatment allows weaning or intestinal transplantation is considered.

In patients with TIA/NTIA, appropriate management strategies are not well established. Nutritional management includes cyclic PN (home PN) associated with oral feeding for reducing the risk of liver disease and promoting oral skills. Continuous attention is needed in the daily long-term management of these unstable infants and children with a permanent risk of dehydration and subsequent complications such as hypercalcemia and renal failure. Normal growth is achieved if PN is adapted especially according to the high water-electrolyte losses.

Special consideration should be given to the link between the hospital and the home care teams. Fostering coordination of surgical, medical, and nutritional management is vital to provide high-quality, integrated care of patients with IF, thus markedly improving the survival of these patients [178]. The three most important issues in the management of children with SBS-IF include (i) a good and early link between primary caregivers and IF programs, (ii) the presence in the program of both intestinal rehabilitation and intestinal transplantation expertise, and (iii) the participation in the network of the organizations providing home PN solutions. The expertise required to prescribe PN both at home and in the hospital usually comes from a dedicated hospital-based nutritional team with a thorough knowledge of energy expenditure, nutrient and trace element requirements by age, appropriate central catheter handling, and awareness of the risk and complications of long-term PN. Home PN must be tailored to the single patient and his or her family, always maintaining the goal of counteracting the deleterious effects of intestinal failure. Official guidelines and position statements on central catheter handling and PN prescription have been published [71].

Collaborative strategies must be developed in order to reduce mortality and morbidity in patients with SBS-IF, especially for those who are referred for permanent IF or intestinal transplantation.

Some studies have reported the long-term growth and nutrition status of children with neonatal SBS after weaning off PN [22, 179–181]. Improved care of patients with SBS significantly achieved more optimal weight gain for age compared with the decade 1980 [179]. However, the final genetic target size is not always achieved, while some deficiencies may be evidenced [180, 181]. Indeed, children with SBS are still at risk for different nutrient malabsorption even after weaning off PN for a long time. They may develop such an "overloaded gut syndrome" with failure to thrive requiring, for some, PN to be restarted. Therefore, they need very long-term follow-up, regular monitoring, and intensive nutritional care to prevent various nutrient deficiencies. On the other hand, long-term follow-up is mandatory, not only for growth monitoring but for assessment of micro-nutrient deficiency (e.g.. zinc status in the case of high stool output, liposoluble vitamins, and vitamin B12 in the case of ileal resection) and search for biliary lithiasis if the gallbladder was not removed.

Nutritional Failure and Intestinal Transplantation for SBS-IF

Although a large percentage of children with SBS-IF can survive with long-term PN, a proportion of patients eventually develop life-threatening complications such as severe septic episodes, fluid and electrolyte imbalance, loss of venous access for PN, and end-stage liver disease [2, 182]. In these patients, nutrition has failed both in the enteral and the parenteral routes. These patients are considered to have "nutritional failure" and should be referred for intestinal transplantation (ITx) as early as possible [2, 182].

Unfortunately, relatively few advances have been achieved in the field of ITx and multivisceral transplantation in the last 10 years with no significant improvement in the long-term patient and graft survival [183]. According to the intestinal transplant registry, approximately 2080 ITx have been carried out in 2010 children since 1985. Overall, 1-year and 5-year patient and graft survival were 72.7%/66.1% and 57.2%/48.8%, respectively. Rejection remains the largest contributor to long-term graft loss, while sepsis is the main cause for patient death [183] and quality of life may improve [184]. These sobering figures mandate the adoption of all relevant strategies to avoid ITx until new protocols are available to achieve a better outcome.

There is probably a different threshold for ITx on both sides of the Atlantic Ocean. The European approach is more inclined to support long-term home PN, which is cost-effective and provides a better quality of life, rather than to refer a child for ITx. Support for this view comes from Pironi et al. who have performed a 3-year prospective study including both adults and children on long-term PN for IF [185]. They compared "non-candidates" for ITx (no indications nor contraindications) with "candidates" who had an indication according to the USA Medicare and Medicaid Services definitions, and a high risk of death or morbidity according to the American Society of Transplantation position paper [186, 187]. The results showed that only patients with nutritional failure due to IFALD or major catheter complications had an increased risk of death on home PN, thus supporting its use as the primary treatment for IF [187]. Therefore, it was suggested that ITx should be used only as a life-saving procedure [2, 188]. Although experienced transplantation centers have suggested that the role of ITx should be expanded to a pre-emptive/rehabilitative procedure applicable to all patients with irreversible IF, the recent findings have shown that home PN is the treatment of choice for IF in adults as well as in children. An early referral is essential to prevent or optimize the long-term management of IFALD. Central venous-catheter-related major complications might be indications for a pre-emptive intestinal transplantation in selected patients. As a matter of fact, "nutritional failure" should be regarded mostly or even only as a clear indication to ITx [2].

Isolated liver Tx has been performed for IFALD in SBS-IF patients. Taha et al. reported a group of children with SBS and IFALD who have the potential for adaptation in the residual bowel underwent isolated LTx [189]. The prognosis remains poor after this procedure – 8 survivors out of 14 [189]. This procedure should be avoided by preventing IFALD. If performed, it should be exercised with extreme caution. These children need careful assessment before isolated LTx and close follow-up with an experienced multidisciplinary team to monitor nutritional outcomes and may need consideration for transplant or nontransplant surgery in the long term [190].

In patients with TIA, ITx is undertaken according to the occurrence of complications (fluid-electrolyte disorders, sepsis, IFALD) and/or the wish of parents for another quality of life. In 12 patients with TIA, an outcome rate of 62.5% in the LITx group and 75% in the ITx group, both with half colon grafting, was reported [191]. All the surviving patients were weaned off PN, after a median of 57 days. Pull-through of the colon allograft was carried out in all patients. Fecal continence is normal in all but one of the surviving children. When long-term graft tolerance is achieved, growth is normal and quality of life improved [190, 192].

Conclusion

Pediatric short bowel syndrome requires specialized and individualized strategy from the diagnosis to the discharge home and further. Intestinal rehabilitation programs provide this complex care with the goal of achieving enteral autonomy and oral feeding without intestinal transplantation. The establishment of multidisciplinary intestinal rehabilitation programs at leading centers has improved the survival of children with SBS-IF, while the morbidity associated with both IF and PN has significantly decreased.

Recent advances in the knowledge of factors related to PN and IF complications and improvements in the medical and surgical management of SBS result in better outcomes for these patients. It is interesting to note that the most recent International Intestinal Transplantation Registry reports evidence of a worldwide trend of reduction in the number of pediatric ITx. This might be explained by at least several factors:

- Provision of guidelines and training.
- Development of intestinal rehabilitation centers with increasing IF expertise.
- Enlarged use of nontransplant surgery.
- Better prevention of IFALD, with fish oil-based lipid emulsions and SIBO treatment.
- Improved prevention of catheter-related sepsis by using taurolidine or ethanol locks.
- Promotion of oral or bolus feeds.
- Onset of hormonal treatment in SBS-IF by using GLP-2 analogs.

Major efforts are still needed to improve the outcome of ITx that will likely remain part of the armamentarium required to prolong the survival of children with life-threatening complications of SBS. Nevertheless, the European experience has led to support of a more conservative approach more inclined to home PN, limiting referrals for ITx only to children with nutritional failure.

Malnutrition

44

Susan C. Campisi, Amira Khan, Clare Zasowski, and Zulfiqar A. Bhutta

Introduction

In 2018, close to 5.3 million children under 5 years of age died globally, with nearly 45% of these deaths attributable to undernutrition [1]. Undernutrition including stunting, wasting, and micronutrient deficiencies is a pervasive issue in the global under-five population, with an estimated 144 million children stunted and 47 million wasted (see Fig. 44.1). Around 14.3 million children fall into the severely wasted category. Conversely, the prevalence of childhood overweight and obesity is increasing worldwide (see Fig. 44.2), and a staggering 38.3 million children less than 5 years of age are overweight or obese [2]. Asia and Africa bear the biggest burden of all forms of under-five malnutrition with nearly 50% of all stunted children and the same proportion of all overweight children living in Asia. Lower-middle-income countries are struggling with this debilitating double burden of malnutrition in young children, adolescents, and adults. An estimated 64% of all stunted, 75% of wasted, and 37% of overweight children live in lower-middle-income countries [2]. If trends are not reversed, increasing rates of childhood underweight and overweight will have vast implications, not only for future health and healthcare expenditures but also for the overall development of nations.

The hidden burden of micronutrient deficiencies in young children heightens the risk of stunting, suboptimal cognitive development, reduced immunity, and frequent disease. Undernutrition, overweight, and micronutrient deficiency are now collectively termed as the triple burden of malnutrition. As per estimates, nearly 42% of all under-five children are anemic, with anemia often being used as a proxy for estimating iron deficiency [3]. Importantly, iodine insufficiency is the single biggest cause of brain damage and impaired cognitive development in children. Iodine deficiency in the pregnant mother can manifest as congenital hypothyroidism or cretinism in infants, which can affect 5–15% of the population in regions where iodine deficiency is endemic. Globally, deficiency of vitamin A affects nearly one-third of all children aged 6–59 months and is the leading cause of preventable childhood blindness. The highest rates of vitamin A deficiency in children are seen in sub-Saharan Africa and South Asia where nearly 48% and 44% of children 6–59 months, respectively, are affected [4]. Other notable micronutrient deficiencies are zinc and vitamin D. Zinc is critical for optimal growth and immunity. Given their higher nutrient requirements, children under 5 years of age are more likely to have a zinc deficiency. Regions identified as those

with inadequate zinc intake are also often those with higher stunting prevalence.

Though considerable progress has been made in the last few decades, the world is still not on track to meet the 2025 global nutrition targets related to maternal, infant, and young child nutrition. The global exclusive breastfeeding rate of infants under 6 months stands at 42.2%, and substantial efforts will be needed to meet the target of a rate of 50% within the next 5 years. For under-five stunting, the global annual rate of reduction will need to be accelerated from the current 2.2% to at least 4.0% to achieve the 2025 target [5]. Alarmingly, many countries in Africa and Western Asia are

dealing with the double burden of malnutrition, with childhood stunting and overweight coexisting at the individual level, highlighting the importance of understanding and addressing the determinants of poor nutritional outcomes [5].

The impact of the COVID-19 pandemic will further impede and, even, reverse progress in many regions. With disrupted health systems, inconsistent access to food, and reduced coverage of interventions, childhood wasting is expected to increase during COVID and may account for 18–23% of additional under-five deaths [6].

School-Age and Adolescence

School-age (5–10 years old) is a phase of continued physical growth and rapid development. Nutritional deprivation and disease are common in this group and can manifest as wasting, underweight, stunting, and micronutrient deficiencies. Overweight and obesity are also a rising issue among this group. Adolescence (10–19 years) is a period of increased nutrient and energy needs for critical biological and psychosocial changes taking place. Importantly in this age group, adolescent girls, especially in low-resource settings, are at higher risk of undernutrition and iron deficiency anemia owing to menstrual losses, poor diets, and early pregnancies. Every year 12 million women aged 15–19 years give birth and nearly 800,000 more give birth before they are even 15 years old [7]. These young girls are at even greater risk of nutritional deficiencies, morbidity, and mortality.

Unfortunately, there are gaps in the nutritional data of these two groups, especially school-age children. Recognizing this evident gap, researchers are increasingly prioritizing the 5–19-year group. Though school-age children are at less risk of morbidity and mortality as compared to the first 5 years of life, poverty, increased nutritional needs, limited access to nutritious food, and frequent worm infestation lead to many nutritional issues such as stunting, iron deficiency anemia, and iodine deficiency in 5–10-year-olds. Iron deficiency is the primary cause of DALYs in school-age children and nearly 25% of all school-age children are anemic [8]. Further, evidence indicates that nearly 37% of all school-age children do not consume sufficient iodine which leads to impaired cognitive development.

Evidence indicates that in many countries nearly half of all adolescents are stunted, reflecting chronic undernutrition and growth retardation over the years. Data on the prevalence of underweight in adolescent females (13–17 years) shows it to be less than 5% in most countries with some exceptions such as Maldives, Vietnam, Sudan, and Cambodia where nearly 18%, 16%, 14%, and 13% of young girls (13–15 years) are underweight, respectively. Importantly, overweight and obesity are rising in this group with nearly 28% of adolescent females in the Eastern Mediterranean region being overweight, followed by Western Pacific (25%) and the Americas (25%) [9].

Iron deficiency remains the most common micronutrient deficiency in adolescents. Females, predictably, bear the greater burden of iron insufficiency and the consequent anemia, with South Asia and sub-Saharan Africa having the highest rates of iron deficiency in adolescents. Insufficiency of iodine is also a critical cause of DALYs lost in adolescent females and males especially in South Asia, sub-Saharan Africa, the Middle East, and North Africa. Other important micronutrient deficiencies in this age group include vitamin A, zinc, calcium, and vitamin D. There is growing evidence of vitamin D insufficiency in adolescents especially females, in many regions of the world including Europe, North America, and the Middle East. However, accurate data on the prevalence of micronutrient deficiencies in adolescents is limited.

Risk Factors

Risk factors for undernutrition and overweight range from broad national-scale determinants to individual specific and factors that affect various ages and periods of life. While there are factors distinct to specific age groups, many risk factors overlap.

Undernutrition is more than just a consequence of not eating enough food or illness. Numerous basic and underlying causes contribute to the development of undernutrition in under-five and school-age children and adolescents. National socioeconomic and political determinants have an impact and include political stability, economics, food security, poverty, and literacy among others. Natural disasters including famine, floods, and other emergencies have detrimental effects. Several social factors such as poor socioeconomic conditions, unstable contexts, limited access to care, poor living conditions, and household food insecurity exacerbate the issue of undernutrition. At a more intermediate level, suboptimal feeding practices including delayed initiation of breastfeeding, lack of exclusive breastfeeding, formula feed, delayed and inadequate complementary feeding, as well as poor WASH practices can all contribute to the poor nutritional status of under-five children.

Maternal factors such as maternal stunting, undernutrition, lack of education, poor nutrition during pregnancy, and consequent intrauterine growth restriction are associated with increased odds of stunting in the children [10]. Important to note is that lack of maternal education is associated with both increased childhood undernutrition and overweight, illustrating the significance of maternal education and awareness for optimal child nutrition.

Worrisome food insecurity is critical, but a factor that is potentially even more important in children is the inability to

absorb what they do take in because of repeated or persistent intestinal infections. Severe infectious diseases in early childhood, such as measles, diarrhea, pneumonia, meningitis, and malaria, can cause acute wasting and have long-term effects on linear growth. The most important of these infections is diarrhea, hence the need for understanding the impact and mechanisms of malnutrition and diarrhea, which form a vicious cycle of enteric infection worsening and being worsened by malnutrition. Several recognized processes by which enteric infections cause malnutrition range from well-recognized anorexia and increased catabolic or caloric demands to direct protein and nutrient loss or impaired absorptive function [11].

In older children, the same social factors also influence diets and nutrition status. Additionally, inadequate intake, nutrient-poor diets, unhealthy food choices, and repeated infections can lead to undernutrition and micronutrient deficiencies. Parasitic infections, most common in school-age children, also increase the risk of micronutrient deficiencies, particularly iron deficiency. Importantly, there are many common personal, lifestyle, environmental, and macrolevel factors and determinants that can lead to contrasting suboptimal nutritional outcomes, whether undernutrition or overweight and obesity, as illustrated in the causal factor framework (Fig. 44.3).

Adolescence is a period of rapid growth when maximum height and bone length is achieved. During the growth spurt, nutrient requirements may be double what they are during the rest of the adolescent period. These increased requirements put this group at a higher risk of undernutrition. Inadequate nutrition can affect physical growth and reproductive maturation. Nutrient-poor diets, such as junk food popular in this age group, and a lack of dietary diversity can lead to micronutrient deficiencies. Importantly, ongoing blood loss during menstruation puts adolescent girls at a higher risk of iron deficiency. Early marriages and pregnancies put them at even greater risk of undernutrition and micronutrient deficiencies.

The risk factors for being overweight and obese in childhood and adolescence are multifactorial. With suboptimal infant and young child feeding and increased consumption of processed and energy-dense food, the risk of overweight and obesity even in children under 5 years of age is increasing. Mixed feeding, use of formula milk, inclusion of processed foods in complementary diet, and a rising trend of giving sugar-laden drinks and snacks have increased the risk of obesity in infants and toddlers. Less physical activity and increased screen time escalate the probability of young children being overweight. Maternal obesity and gestational diabetes are also recognized as risk factors for infant obesity.

School-age and adolescent periods are formative years of life and habits formed during this time have lifelong implications. Children start becoming independent with many lifestyle influences outside the home environment, such as school, friends, and social media. Globally, in urban and rural communities, diets increasingly comprise high-fat, high-sugar, and high-sodium foods including fast food, ready-to-eat snacks, and soft drinks. Such foods are often

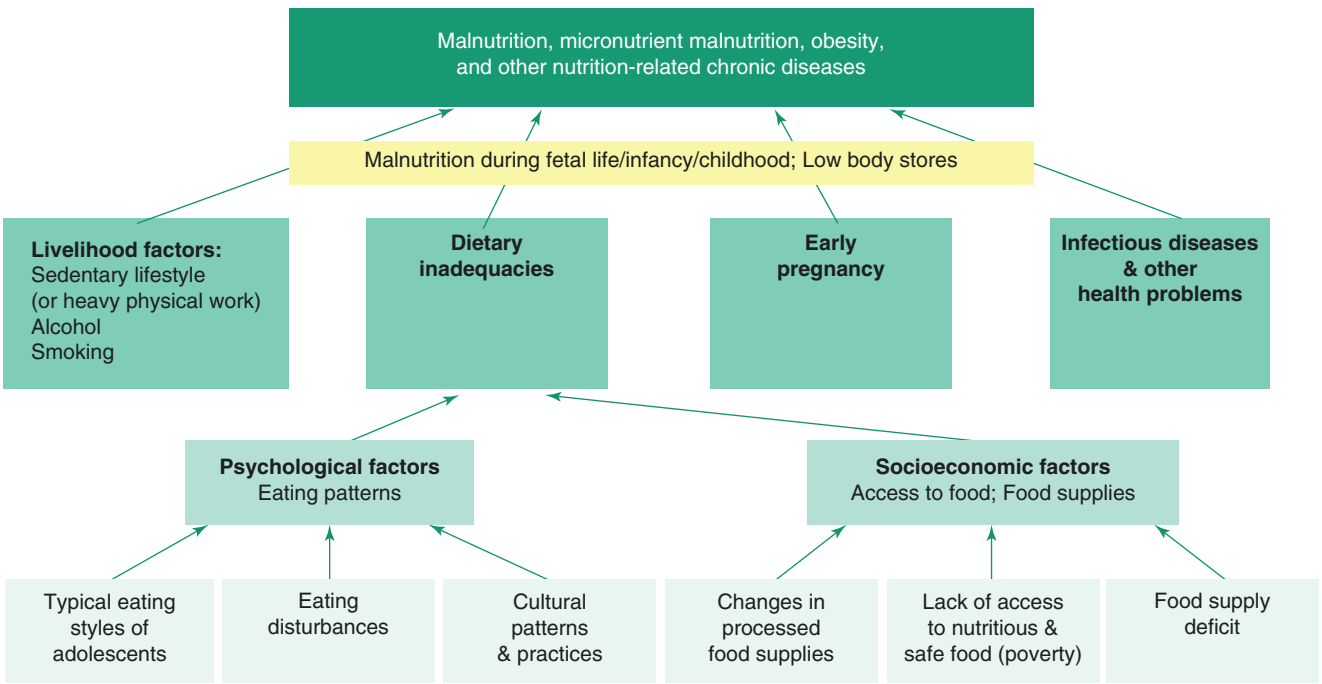

Fig. 44.3 Conceptual framework of nutritional problems and causal factors in adolescence. (Adapted from: WHO [12])

readily available and relatively cheap, making them tempting options, particularly for low-income families. Unhealthy diets, physical inactivity, and poor sleeping habits put older children at greater risk of overweight and obesity. A family history of overweight further increases the risk. The adolescent period is critical in terms of psychosocial development, and many adolescents face stress and depression which can lead to disordered eating such as binge eating, fad diets, skipping meals, and not eating at home – all behaviors that increase the risk of being overweight and unhealthy.

COVID-19 and Malnutrition: The impact of the COVID pandemic and the consequent response will undoubtedly affect the nutritional status of women and children in the long term. Modeling exercises estimate that with disrupted coverage of maternal and child health interventions and reduced food access wasting could increase by 10–50% leading to additional under-five deaths and maternal mortality. Additionally, experts predict a rise in micronutrient deficiencies, maternal undernutrition, and intrauterine growth retardation that would ultimately impact growth and increase childhood stunting [13].

Figure 44.4 summarizes the impact of COVID-19 on various drivers of maternal and child nutrition. Multiple factors, from basic drivers including diverted policies and redirected resources to poverty, limited food access, altered care-seeking behaviors, and unhealthy household environments, will most likely lead to poor nutritional intake and increased disease in populations.

As studies have shown, the effect of COVID-19 on household food security is not only an issue for low-income settings, with high-income settings also reporting nearly a 30% increase in household food insecurity, especially in vulnerable communities [14, 15]. Unemployment and suspension of school meal programs have led to an increased demand for food banks and food distribution programs.

Short- and Long-Term Consequences of Malnutrition on Growth and Development

Serious consequences of malnutrition can cause immediate disability but also long-term consequences that may manifest at later life stages. Additionally, cognitive, developmental, social, mental health, and economic consequences threaten the future economic productivity of these individuals impacted by malnutrition. As we have seen, the global burden of malnutrition is serious, with its impact potentially persisting throughout the life course for individuals, communities, and countries [16, 17]. In this section, the consequences are discussed for being underweight, overweight/obese, and having nutrient deficiencies.

Underweight

Being underweight is associated with impaired linear growth, impaired cognitive and motor function, weakened immunity, mortality, and various morbidities, sarcopenia, cardiac and renal dysfunction, and immunological defects. Childhood undernutrition may cause as many as 3.1 million deaths annually [18]. Adolescent undernutrition is also harmful to the health and wellbeing of individuals and societies and is also the beginning of one's reproductive life [19]. Being

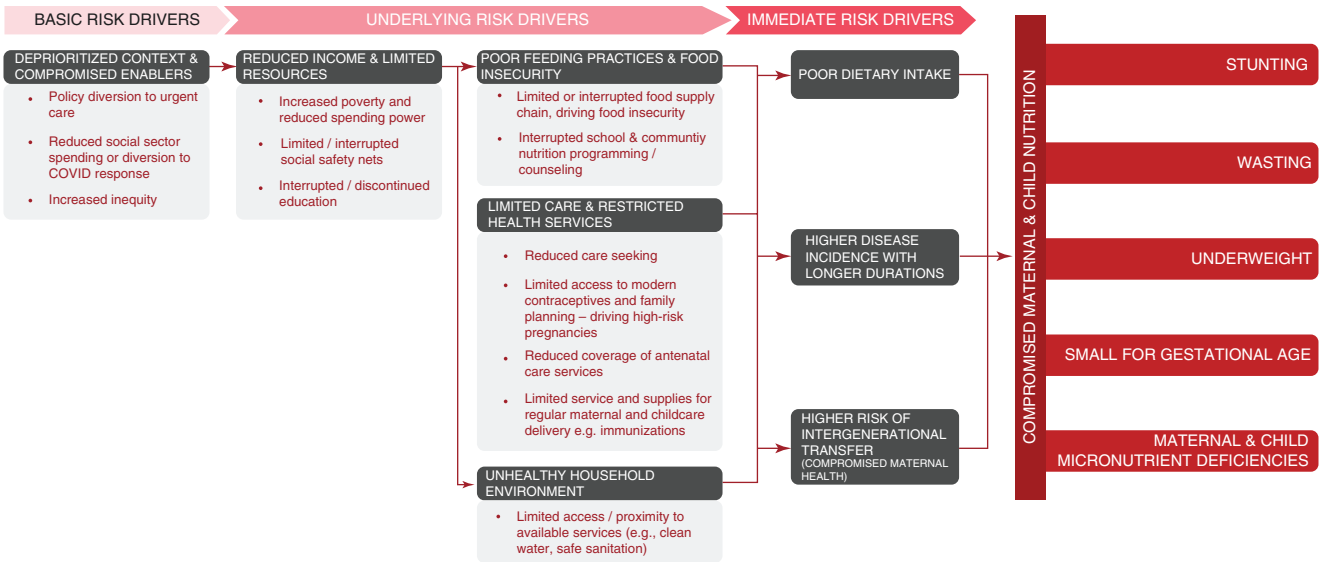

Fig. 44.4 Direct effects of COVID-19 on basic, underlying, and immediate drivers of acute and chronic malnutrition. (Source: Akseer et al. [13] (*Used with permission*))

underweight during adolescence may progress the burden of undernutrition into further generations [19].

Children Under 5 Years of Age

Underweight has negative effects on an individual possibly starting from before birth and lasting throughout the whole life course [20]. Birth weight is an important indicator for child health, and about 80% of newborns who die every year are low birth weight (LBW). This is because they were either born preterm, small for gestational age, or both [21]. LBW newborns who survive have a greater risk of both short- and long-term adverse health consequences than their normal-weight counterparts [21]. LBW has been associated with neonatal death, lower academic performance, long-term neurologic disability, impaired language development, reduced cognitive abilities, and increased risk of disease including cardiovascular disease (CVD) and diabetes [22]. Fetal conditions may also affect development and result in children being born SGA. Improper nourishment from the placenta during fetal development may result in intrauterine growth restriction (IUGR). IUGR places stress on the developing fetus and may result in metabolic syndrome later in life; however, not all SGA infants experienced IUGR. SGA infants, in general, may have more abdominal fat later in life and are at an increased risk of metabolic syndrome later in life, possibly due to catch-up growth and rapid refeeding in early life [23]. It has been suggested that early catch-up growth is needed for preterm infants to allow for proper neurodevelopmental outcomes, but this rapid weight gain is likely to affect the long-term health of LWB (and normal weight) infants [24].

Low birth weight, childhood stunting, and wasting all deplete components of metabolic capacity [25]. After birth, infant and child mortality is the most serious consequence of undernutrition. According to the WHO, 45% of all child deaths are linked to malnutrition [26]. A major driving force of infant mortality is the decreased immune function in underweight infants and children [27]. This immune dysfunction may result in illness from communicable diseases such as diarrhea and pneumonia and increase the risk of mortality [27]. Undernourished children may also have impaired liver, kidney, and thyroid function [28]. Furthermore, gastrointestinal changes in undernourished children include a stunted microbiome which may cause gut dysbiosis and increase the risk of intestinal infection [29]. Major cognitive, motor, and behavioral consequences are also important as brain development in early childhood may also be affected by protein-energy malnutrition. This includes a smaller brain size in malnourished children. The developmental abnormalities are likely to affect the infant socially, personally, and economically beyond infancy. In the long term, underweight children are also at risk of metabolic syndrome, central fat distribution, and obesity. This outcome is thought to be a major driver of the double burden of malnutrition. Although they are the most serious forms of undernutrition, even mild forms of undernutrition can have developmental effects as well as increase the risk of metabolic syndrome later in life [30].

School-Age Children (6–9 Years)

Undernutrition in school-age children also has serious long- and short-term consequences. Stunting is a marker of multiple pathologies associated with increased morbidity and mortality, loss of physical growth potential, reduced neurodevelopmental and cognitive function, and an elevated risk of chronic disease in adulthood [31]. The growth failure as well as being underweight may contribute to an increased lifetime risk of osteoporosis. As in infancy and early childhood, undernutrition puts an excess metabolic strain on the body which may increase the risk of metabolic syndrome and CVD later in life. The catch-up growth and rapid refeeding early in life may contribute to metabolic syndrome later in life [32, 33]. The immune system is also weakened with undernutrition, and these children may be more susceptible to communicable diseases and have more difficulties in recovering. Cognitive, motor, and behavioral delays persist into school-age if proper nutrition is not obtained. This undoubtedly has negative implications for school, learning, and academic achievement. This, in turn, has long-term economic consequences. Impaired intellectual development may be ameliorated when the malnutrition is resolved.

Adolescents (10–19 Years)

Significant gaps exist in the literature regarding adolescent malnutrition. Puberty which occurs during early adolescence increases nutritional requirements due to the period of rapid growth known as the pubertal growth spurt [34]. Adolescents may not reach their linear growth potential as this required increased nutrition to fuel a growth spurt [19]. Being underweight may also delay puberty [35]. The consequences for adolescent girls may persist into future generations as undernutrition and stunted growth may increase the risk for low birth weight in offspring [36]. Underweight adolescents also have an increased risk of osteoporosis [37]. Reduced cognitive capabilities and reduced work outputs may lower the academic achievement and work output of these adolescents as well. Collectively, these consequences may seriously reduce the economic productivity of individuals entering the workforce [38].

Overweight/Obesity

Excess body fat and overweight or obesity are important risk factors for many adult diseases. Being overweight in infancy, childhood, and adolescence is likely to persist for whole life [39]. Not only does this pose a significant risk to health, but

it also contributes to social, behavioral, and mental health problems. Collectively, these consequences contribute to a large economic burden in HIC and LMIC [40]. Obesity during childhood increases the risk for abnormalities in cardiovascular function, glucose homeostasis, pulmonary function, and cognition during childhood, as well as risk for obesity (and therefore mortality) in adulthood [18].

Children Under 5 Years of Age

The most important risk factors for being overweight or obese in children under 5 years of age are those that occur early in life. High birth weight has been associated with an increased metabolic load which may increase the risk of metabolic syndrome later in life [41] and a higher risk of hypoglycemia after birth and birth defects [42]. High birth weight has also been suggested as a risk factor for developing leukemia, obesity in childhood and adulthood, and later CVD [43]. Although high birth weight may have negative consequences, low birth weight remains a more important risk factor for many morbidities and all-cause mortality [43].

School-Age Children (6–9 Years)

Arguably, the most important consequence of childhood obesity is the increased disease risk in adulthood. Overweight children often remain overweight adults [44]. Aside from long-term, chronic disease risk, there are also immediate consequences in childhood. These include early type 2 diabetes or prediabetes, fatty liver disease, sleep apnea, type 2 diabetes, asthma, hepatic steatosis (fatty liver disease), CVD, high cholesterol, cholelithiasis (gallstones), glucose intolerance and insulin resistance, skin conditions, menstrual abnormalities, gastrointestinal reflux, impaired balance, and orthopedic problems [45]. The social and psychological health effects add to the burden as obese children are at risk of depression, anxiety, bullying, and low self-esteem [46]. Because low birth weight and catch-up growth may contribute to childhood overweight, the double burden of malnutrition is rapidly increasing across the globe.

Adolescents (10–19 Years)

Adolescent obesity, as with childhood obesity, leads to an increased risk of morbidity and mortality due to cancer, CVD, and metabolic diseases in adulthood. In this period that encompasses puberty, overweight can influence the progression of pubertal milestones [35]. Multiple studies have shown that the secular trend of puberty timing in girls is related to the increasing trend of childhood obesity [47, 48]. This may be related to catch-up growth in infancy and childhood [49]. Obesity in peripubertal girls may also be associated with hyperandrogenemia and a high risk of adolescent polycystic ovary syndrome, which is the leading cause of infertility in women, and also increases the risk of metabolic syndrome, diabetes mellitus type 2, CVD, and endometrial cancer. In boys, obesity may delay puberty but there is less evidence than in girls [50]. There are also important mental health and behavioral consequences in this period of change including anxiety, depression, lack of self-esteem, lower quality of life, as well as social problems that include bullying and a lower lifetime earning potential [19].

Nutrient Deficiencies

Micronutrient deficiencies are a major problem across the globe and can pose a threat to the long-term health of infants, children, and adolescents. Micronutrient deficiencies may be associated with stunted growth, cognitive delays, weakened immunity, and other morbidities [51]. For pregnant women, the lack of essential vitamins and minerals can increase the risk of low birth weight, birth defects, stillbirth, and even death. Clinical manifestation of micronutrient deficiencies can be devastating.

Children Under 5 Years of Age

Micronutrient deficiencies can start in fetal life if the mother is malnourished. Zinc, iron, and iodine deficiencies are very prevalent in pregnant women [52]. These deficiencies can result in abnormal fetal development [52, 53] and increase the infant's risk of chronic disease due to altered organ development, size, and function. Vitamin A deficiency in pregnancy may cause preterm birth which is a risk for child mortality. Iron, iodine, and vitamin A deficiencies in infancy and childhood have serious and lifelong consequences and remain common in many LMICs. In early development, vitamin A and iodine are crucial for brain development. Iodine deficiency remains the most important cause of avoidable brain damage [54]. Iodine deficiency can cause abnormal myelination of neurons, hearing impairment, and hypothyroidism. This deficiency is of crucial importance as there are long-term economic impacts when a child fails to meet intellectual capacity. Iron deficiency causes impaired reactivity and coordination in infants: psychomotor and mental development [55] may persist with iron therapy which is why preventing deficiency is needed. A lack of sufficient iron intake may significantly delay the development of the central nervous system as a result of alterations in morphology, neurochemistry, and bioenergetics [56]. Vitamin A deficiency increases the risk of respiratory and diarrheal infections, growth failure, night blindness, and permanent blindness. Vitamin A deficiency can contribute to stunting and infant mortality [57, 58]. Additionally, retinoic acid is critical for brain development, and a deficiency is associated with learning and memory problems and decreased plasticity of the hippocampus. Zinc deficiency impairs immune, nervous, and endocrine functions, increases the susceptibility to infection, and restricts physical growth [59]. Vitamin D deficiency pre-

vents bone mineralization and causes rickets which may cause permanent changes to bone structure. In this period of rapid growth, adequate vitamin D is needed. Vitamin D is also needed for optimal nerve, muscle, and immune function [60]. Micronutrient deficiencies threaten health in the long and short term and hurt the economy of countries with widespread micronutrient deficiency [61].

School-Age Children (6–9 Years)

Children in this age group share the consequences for micronutrient deficiencies observed in early childhood. Iron is important for cognitive development. It is also needed for proper musculoskeletal growth. The most common cause of anemia is iron deficiency, and anemia can decrease school performance, productivity in adult life, quality of life, and the general income of affected individuals [62]. Vitamin A is still needed in school-age children for immune function and preventing night blindness [63]. Furthermore, iodine deficiency may affect cognition by disturbing normal brain development, and it may affect cognition by altering brain function possibly due to altered thyroid function [64]. The maturation of brain regions responsible for higher cognitive function continues to mature in childhood and adolescence.

Adolescents (10–19 Years)

Delayed growth, goiter, increased risk of infection, blindness, anemia, and inadequate bone mineralization, along with other psychological, social, and economic consequences, remain a concern in adolescents with micronutrient deficiency. Iron deficiency, especially common in adolescent girls, has adverse effects on productivity and cognition in the general population and is the leading cause of anemia during pregnancy, contributing to 20% of all maternal and perinatal mortality and low birth weight [65]. Zinc deficiency in adolescence may alter sex hormone metabolism and impair growth and immunity [38]. Vitamin D is needed in this period of growth for bone growth, strength, and development. Vitamin D deficiency may reduce bone density and increase the lifetime risk of osteoporosis, fractures, and decreased quality of life during later life stages [66]. Iodine and vitamin A continue to be needed for brain development, immunity, growth, and eye health [67].

Interventions

The causes of malnutrition are complex and multifaceted; therefore, improving childhood malnutrition requires double-duty actions to address the double burden of malnutrition which occurs when undernutrition coexists with overweight, obesity, and diet-related non-communicable diseases [68]. Such interventions have also been categorized as nutrition-sensitive or nutrition-specific interventions [69]. Some examples of nutrition-specific interventions for malnutrition include food fortification and supplementation, while nutrition-sensitive interventions include education, clean water, sanitation, agriculture programs, regulatory interventions, and deworming [70]. Generally, interventions appear most successful where there is a strong political commitment along with collaboration between government, nongovernment, national, and international organizations [71].

Age Group 0–5 Years

Neonatal Interventions

Widespread interventions to reduce the risk of LBW, SGA, and preterm birth involve improving women's preconception/conception nutritional status. Anti-malarial drugs and maternal nutrition education have also been shown to benefit neonatal outcomes [72, 73]. The benefits of preconception/conception supplementation are nuanced, but a few systematic reviews have demonstrated that oral supplementation with vitamin A, low-dose calcium, zinc, or MMN (multiple micronutrients) can have a considerable effect in decreasing LBW, SGA, and preterm birth (PTB) [73–75]. Vitamin A with other micronutrients (iron plus folate) reduced LBW by 33% versus micronutrient supplements without vitamin A [74]. However, vitamin A alone did not reduce LBW compared with placebo or no treatment. Oral low-dose calcium supplementation (less than 1 g/day) significantly reduced LBW by 80% but did not affect the risk of SGA [76]. Oral zinc supplementation in adolescent pregnancy reduced the likelihood of LBW by 61% as evidenced by a systematic review of five RCTs [77]. A significant reduction of LBW in the range of 11–14% and a significant reduction of SGA in the range of 10–17% were observed following multiple micronutrient (MMN) supplementation [75]. However, when comparing MMN containing iron and folic acid versus placebo, the effect was not statistically significant. In the aforementioned trials, the effect on PTB was unaffected or not statistically significant. A systematic review by Muanda et al. (2015) suggests that women receiving anti-malarial drugs have also been shown to have a reduced risk of LBW 27% compared with women not receiving these drugs during pregnancy [78]. The intervention did not affect the risk of PTB and other outcomes were not reported. Finally, nutrition education LBW was reduced by 96% and PTB by 54% for women receiving nutritional education to increase energy and protein intake compared with no nutritional education in pregnancy as evidenced by a systematic review [72]. No effect on SGA was seen for this intervention. Other interventions did not have a meaningful effect on these neonatal outcomes.

Breastfeeding Interventions

In children 0–5 years of age, breastfeeding and effective complementary feeding are of paramount importance to ensure optimal nutrition and thus proper growth and development. All-cause mortality, as well as infection-related mortality, was lower in exclusively breastfed infants (0–5 months of age) as opposed to predominantly, partially, and non-breastfed infants [79]. Additionally, children 6–11 and 12–23 months of age who were not breastfed had 1.8- and 2.0-fold higher risk of mortality, respectively, when compared to those who were breastfed. The risk of infection-related mortality was double in non-breastfed children when compared to breastfed children aged 6–23 months. Fortified breast milk interventions improved short-term growth in weight, length, and head circumference in preterm infants compared to unfortified or micronutrient fortified breast milk, while not increasing the risk of necrotizing enterocolitis or feed intolerance [80]. In preterm and LBW children unable to obtain breast milk from their mother, a systematic review by Quigley and colleagues demonstrated that feeding with formula compared with donor breast milk resulted in higher rates of weight gain, linear growth, and head growth but had no effect on all-cause mortality or on long-term growth or neurodevelopment [81].

Breastfeeding rates are far from optimal despite its clear benefits [82–85]. Breastfeeding interventions can be effective and have higher improvements in breastfeeding rates when delivered in a combination of settings [85]. Greatest improvements in early initiation of breastfeeding were achieved when counseling or education was provided in home and community, exclusive breastfeeding in health systems and community, and continued breastfeeding rates in health systems and home settings with the most effective interventions being support at the health system such as level baby-friendly hospital environments [85]. Interestingly, a 2015 systematic review and meta-analysis found no significant effect of breastfeeding promotion interventions on child growth on length or height z-scores [86].

Complementary Feeding Interventions

The WHO complementary feeding guidelines recommend that infants at about 6 months should be introduced to nutritional foods in addition to breastfeeding [87]. Improving complementary diets of children aged 6–23 months is a recommended approach for reducing stunting in children under 5 years old, but the potential of these interventions to prevent wasting is inconclusive [88]. Complementary foods containing iron (naturally or fortified) help prevent iron deficiency and maintain iron status in the first year among infants at risk of insufficient iron stores (but not infants with already low iron stores) [89]. A recent Cochrane review [90] was unable to confirm any benefit of a meat-based intervention compared to a dairy-based intervention or fortified cereals on linear growth and weight gain.

Stunting, Wasting, and Underweight Interventions

Interventions most commonly implemented for childhood stunting, wasting, and underweight include supplementation, nutrition education and counseling, growth monitoring and promotion, immunization, water, sanitation and hygiene, and social safety nets [71]. As evidenced by a systematic review of children 6–24 months of age in LMICs [91], iron plus folic acid supplementation and multiple micronutrients improve height-for-age z-score (HAZ) but only MMN reduces the risk of stunting. This review also found that flour in the caloric range of 270–340 kcal and fortified lipid-based nutrient supplements containing 220–285 kcal decreased the risk of stunting compared to standard of care, but these interventions and other food supplements did not show improvements for HAZ [91].

Water, Sanitation, and Hygiene (WASH) Interventions

Hygienic conditions prevent diarrhea and parasitic infections which could cause reduced absorption and nutrient losses, reduced appetite, and diversion of energy and nutrients from growth to the immune system [92, 93]. Repeated intestinal infection may also cause environmental enteropathy which increases the small intestine's permeability and reduces nutrient absorption [94]. WASH interventions alone improved HAZ when delivered over 18–60 months and for children under 2 years of age as evidenced by a systematic review [95]. This review also showed that interventions combining WASH with nutrition had a strong effect on stunting and underweight (weight for age z-score) and a modest effect on wasting. Thus, a synergistic effect of WASH and nutritional interventions is of interest. Another systematic review [96] also linked WASH interventions to increased mean HAZ. Additionally, a systematic review that studied results in LMICs [97] showed diarrhea risk reductions between 27% and 53% in children 0–5 years old, depending on the WASH intervention type.

Micronutrient Deficiency Interventions

Interventions for stunting, wasting, and underweight overlap with many micronutrient deficiency interventions. Micronutrient supplementation is the most popular intervention for both single micronutrient and multiple micronutrient deficiencies. According to a 2019 review of systematic reviews, the most effective strategies with the clearest evidence for addressing micronutrient deficiencies in children 0–5 include optimal cord clamping, anthelmintic treatment, anti-malarial treatment, and supplementation of single or

multi-micronutrients [98]. Delayed cord clamping is an effective intervention for reducing anemia in early life. In helminth endemic areas, iron status can be improved by anthelmintic treatment, and anti-malarial treatment can improve ferritin. In deficient populations, single iron, vitamin A, and MMN supplementation can improve iron, vitamin A, and multiple micronutrient status, respectively. While the impact of home fortification on multiple micronutrient status remains questionable, commercial iron fortification may improve iron status [98].

Food Fortification Interventions

Food fortification may be one of the most cost-effective and safe strategies to reach populations at large as deemed by the Copenhagen consensus [99]. Home fortification is preferred over commercial fortification from a cost perspective [100]. However, evidence from a review of systematic reviews indicates that multi-micronutrient home and commercial fortification did not significantly increase HB, serum ferritin, zinc, or vitamin A consistently [98]. Another systematic review [101] does not show a clear benefit of point-of-use multiple micronutrient fortification for a child or maternal anemia and hemoglobin.

Iron Supplementation and Fortification Interventions

Iron supplementation and fortification have been widely proven at the systematic review level to improve ferritin and hemoglobin concentration [98]. Delayed cord clamping has been shown to improve the hematological and iron status of both preterm and term infants after the neonatal period, as evidenced by a systematic review [102]. Systematic review evidence shows that malaria treatment increases serum ferritin but does not decrease the risk of anemia after 12 weeks [103]. A systematic review by Neuberger and colleagues (2016) found that iron status was improved the most in malaria-endemic areas when iron supplementation was combined with anti-malarial treatment [104].

Vitamin A Supplementation and Fortification Interventions

Vitamin A supplementation interventions not only reduce the risks associated with vitamin A deficiency but have also been associated with a reduction in the risk of all-cause mortality [105].

Zinc Supplementation and Fortification Interventions

Zinc supplementation and fortification have been shown to increase serum zinc concentration in several reviews [106–108]. Petry and colleagues (2016) found that low-dose daily iron and zinc use during 6–23 months of age has a positive effect on child iron and zinc status [109].

Intervention to Decrease Bodyweight

In children under 5 years of age, feeding is influenced and, in most cases, controlled by parents, school, and other authorities making community and family interventions important for preventing childhood overweight and obesity. Breastfeeding, along with its aforementioned benefits, also may lower rates of obesity later in life. Other chronic diseases that are reduced by breastfeeding include diabetes (both type 1 and type 2), obesity, hypertension, cardiovascular disease, hyperlipidemia, and some types of cancer [110]. There is no conclusive evidence, at a systematic review level, of when the best time to introduce complementary foods to reduce the risk of overweight [111]. A systematic review [112] found home-based interventions with family involvement, preschool/early childhood settings, multicomponent interventions across multiple settings, and healthcare settings as possible options. A 2019 Cochrane review by Bown and colleagues suggests that interventions that include diet combined with physical activity interventions can reduce the risk of obesity in children aged 0–5 years, while physical activity interventions only do not have a significant effect [80]. A community approach to these interventions was shown to be the most useful for the overweight. This review also suggests a promising role for increasing the accessibility of education on diet and physical activity for disadvantaged families to prevent childhood obesity while making the interventions culturally acceptable. Another systematic review [113] found that school-based interventions are effective in reducing excessive weight gain of children. This review found significant results for the effectiveness of single-component intervention (physical activity), but emphasizing the enjoyment of physical activity sessions was critical for the interventions. Preschool interventions should be an avenue of intervention as food choices are shaped at this early age.

School-Age Children (6–10 Years)

Antihelminthic Interventions

Malnutrition research is abundant regarding children under 5 years; however, school-age children are an important group of interest to reduce the burden of malnutrition. An intervention for school-age children is routine treatment with antihelminthic drugs. One systematic review [114] shows evidence of an association between helminth infections and micronutrients (mostly iron and vitamin A) in school-age children. However, evidence from two systematic reviews, one by Taylor-Robinson and colleagues [115] and one by Welch and colleagues [116], does not justify treating all schoolchildren at regular intervals with deworming drugs in areas where helminth infection is common. Although deworming has not demonstrated meaningful improvements in height, hemoglo-

bin, cognition, school performance, or mortality, it has demonstrated modest increases in weight; nevertheless, the WHO recommends widespread deworming [117].

Supplementation Interventions

Iron supplementation safely improves hematologic and non-hematologic outcomes among primary-school-age children in low- or middle-income settings and is well-tolerated [118]. A systematic review of studies among children 0–10 years of age [119] showed that zinc supplementation may modify fat-free mass among children with pre-existing growth failure.

Fortification Interventions

Large-scale food fortification (LSFF) of staple foods to prevent micronutrient deficiencies has been shown to have significant improvements in the micronutrient status of children despite programmatic and implementation limitations [120]. Other hematologic markers also improved following food fortification among children with vitamin A, iron, and MMN, suggesting some conjoint benefits. MMN fortification, when compared to placebo/no intervention, has demonstrated reductions in anemia, iron deficiency anemia, and micronutrient deficiencies (iron, vitamin A, vitamin B2, and vitamin B6), but MMN fortification was not associated with any significant benefits on HAZ, WAZ, and WHZ [121]. The fortification of foods with vitamin D has also been associated with improvements in the vitamin D status of children aged 2–11 years [122]. Additionally, vitamin D food fortification has also been associated with improved blood concentrations, deficiency prevention, and improved IQ levels [123].

Intervention to Decrease Bodyweight

A recent Cochrane review highlighted the importance of this age group for overweight and obesity interventions [124]. This review found that interventions with physical activity alone or in combination with diet can decrease the risk of obesity for this age group (no evidence was found for the effectiveness of diet only). Multicomponent behavior-changing interventions that incorporate diet, physical activity, and behavior change may be beneficial in achieving small, short-term reductions in BMI, BMI z-score, and weight in children aged 6–11 years as evidenced by a systematic review [125]. However, sustained reduction in these parameters is necessary to reduce the burden of overweight in children. Interventions for overweight and obesity in this age group primarily target diet and physical activity and are typically school-based, community-based, or home-based interventions. School-based interventions with combined diet and physical activity components and a home element had the greatest effectiveness in a systematic review of children of preschool and school-age children [17]. Multicomponent lifestyle interventions have been consistently shown to have a beneficial effect on weight loss and obesity prevention. Evidence on the use of multicomponent interventions in the treatment of childhood overweight and obesity was shown in a 2017 systematic review [126].

Adolescence (10–19 Years)

Underweight and Micronutrient Deficiency

Nutrition interventions specifically for adolescents seem to be less important for boys, whereas iron and MMN supplementation may have meaningful benefits for adolescent girls. A systematic review by Salam and colleagues [127] identified the most pertinent interventions for adolescent nutrition. This study primarily found evidence suggesting an overall significant reduction in anemia with iron/iron-folic acid supplementation (primarily in females) alone or in combination with other micronutrient supplementation. Furthermore, nutrition strategies, mainly consisting of calcium and zinc supplementation, among "pregnant adolescents" showed statistically significant improved birth weight, decreased low, and preterm birth. Other interventions that studied the effect of various micronutrient supplementation/fortification on body mass index (BMI) and MMN fortification did not provide certain evidence. Secondarily, iron supplementation irrespective of folic acid may improve hemoglobin concentrations, and calcium/vitamin D supplementation may improve serum vitamin D levels, and body bone mineral density may be marginally improved with calcium-only supplementation and calcium and vitamin D supplementation. These results mirrored a systematic review by Lassi and colleagues [67] that suggested that iron alone, iron plus folic acid, zinc, and MMN supplementation in adolescents can significantly improve serum hemoglobin concentration [67]. It also suggested that zinc supplementation in pregnant adolescents showed improvements in preterm birth and low birth weight. Regarding underweight adolescents, there was limited evidence on food/protein energy supplementation in adolescents. Overall, studies have found limited evidence supporting micronutrient supplementation/fortification among adolescents on health and nutritional status [67, 127].

Intervention to Decrease Bodyweight

Adolescent obesity is multifaceted with a lack of guidelines for proven weight loss success interventions. Multidisciplinary interventions which include family support and guided behavior modification appear to be one type of effective method to combat adolescent overweight and obesity [128]. Additionally, a recent Cochrane review suggested the beneficial impacts from programs that combine the promotion of healthy dietary habits with physical activity on preventing obesity in children and adolescents, especially school-based

programs [124]. The absence of clearly proven strategies to prevent or treat obesity demonstrates the complexity of the etiology of obesity [129].

Conclusions

Commitments made by countries to the Millennium Development Goals (MDGs) have significantly helped decrease maternal and infant mortality and childhood stunting. The Sustainable Development Goals (SDGs) aimed to build on those successes while expanding goals to adolescents who were largely ignored in the MDGs [130].

Supporting adolescent policies in addition to childhood nutrition policies and strategies represent important targets to improve malnutrition among children and adolescents. For almost two decades, reports have highlighted the need for expanded global health programs and policies targeting adolescents [131, 132]. In response to this *call for action*, the SDGs included 90 youth-related indicators [130]. The latest Sustainable Development Report, however, only identifies two SDG goals that are on track to achieve Goal 1 (No Poverty) and Goal 13 (Climate Action) [133]. Adolescent nutrition guidelines in many LMIC are limited in scope as they focus on school feeding, obesity, and supplementation for some micronutrients [134].

Continued gains in decreasing childhood and adolescent malnutrition will be negatively impacted by COVID 19. Concerted efforts will require greater national nutrition programs and enhanced intersectoral approaches among government and nongovernment agencies to overcome these new challenges.

Enteral Nutrition

45

Mora Puertolas and Timothy A. Sentongo

Introduction

Enteral nutrition (EN) or enteral tube feeding (ETF) as currently practiced is a technique for nutritional support which delivers a homogeneous, liquid nutrition admixture into the digestive tract by tube, into the stomach, duodenum, or the proximal jejunum. The inception of enteral feeding dates back to 3500 years ago in ancient Egypt, when practitioners used rectal enemas to administer wine, milk, broth, and other nutrients to the ill [1, 2]. The first documented delivery of EN through a tube inserted into the esophagus was by Capivavacceus of Venice in 1598, who constructed a device from animal bladder. Recognition of the importance of nutrition therapy during injury and recovery from disease rapidly grew in the 1930s and 1940s and led to development of specialized commercial enteral feeding products in the 1950s and modern EN formulas in the 1970s [1, 2]. In 1980, Guaderer and colleagues at Rainbow Babies and Children's Hospital in Cleveland, Ohio, USA, were the first to describe the technique of inserting feeding gastrostomy tubes (GT) without requirement for laparotomy, that is, percutaneous endoscopic gastrostomy (PEG) tube [3]. EN may be administered via oral, nasal, gastrostomy, or jejunal routes (Fig. 45.1).

EN is used to preserve nutritional status, support normal growth, and treat malnutrition when oral feeding is inadequate or not possible. EN is more physiologic, usually safer, easier to administer, and less costly compared to parenteral nutrition (PN). Therefore, EN should be preferred to PN in infants, children, and adolescents with malnutrition and/or nutritional risk, when the intestinal tract is usable to provide sufficient nutrients for achieving optimal growth or catch-up growth [4]. EN may be administered rapidly as a bolus into the stomach, or more slowly over several hours as a continuous infusion into the stomach, duodenum, or jejunum. The underlying disease and patient tolerance are what determines whether to use bolus or continuous feeds. The physiological basis of continuous EN makes it of great interest in pediatric patients with feeding intolerance and other gastrointestinal (GI) disorders [4]. EN may be used as the sole source of nutrition or to just supplement a patient's oral and/or PN intake. Also, depending on the indication, EN may be used daily or just on a periodic basis. While EN is normally initiated in the hospital, continuing it at home has become a common option. Home EN may be used long term or just as a temporary bridge until children achieve oral food intakes that support adequate growth and nutritional status. Even though home EN is an effective method of meeting a child's growth and nutritional requirements, health practitioners should not disregard the mixed acceptance by families and sometimes negative impact on quality of life [5–7].

Physiological Basis of Continuous Enteral Feeding

Gastrointestinal Motility

The rate of gastric emptying, and secretion of pancreatic biliary fluids, is regulated by the infusion rate, calorie density, and osmolality of the enteral feeds [8]. In the case of gastric administration of continuous feeds, a rate of continuous gastric emptying related to the infusion rate can be achieved if the infusion rate, calorie density, and osmolality of the mixture are not excessive. Steady-state gastric emptying of 1 kcal/mL formula can be maintained at infusion rates of ≤3 mL/min. When the infusion rate is excessive and higher than the gastric emptying rate, the risk of vomiting increases. As caloric load and/or osmolality of the formula increases, the gastric emptying rate is reduced to maintain a constant calorie load delivered into the duodenum. Thus, EN

PEG/J: Percutaneous endoscopic gastrostomy jejunal tube

consisting of very calorie-dense formulas should initially be administered very cautiously. The individual nutrient composition of the formula has a lesser effect on gastric emptying function than the caloric density, except for the type of triglyceride: long-chain triglycerides (LCTs) cause greater delays in gastric emptying than medium-chain triglycerides (MCTs).

Gastric emptying is dependent on duodenal function. The effects of continuous enteral nutrition (CEN) on intestinal motility can be analyzed by manometry. Motor migrating complexes are observed in adults during CEN, as during fasting state [9]. In small preterm infants, duodenal motor activity is higher following slower infusion of gastric feeds than with rapid boluses, and this is associated with lower postprandial gastric contents [10]. During administration of jejunal feeds, energy loads at rates within the physiologic range of gastric emptying (≤4 kcal/min) initiate normal-motor small-bowel motor responses; however, increasing the osmolality (>600 mosmol) has a significant inhibitory effect on small-bowel contractile and propagative activity [11] and thus greater likelihood for intolerance. Very few data are available about the changes of colonic motility induced by CEN; however, the continuous gastric infusion of nutritive formula modifies the gastrocolic reflex. Gallbladder motility is maintained during CEN as assessed by increased serum cholecystokinin (CCK) and ultrasonography [11, 12]. Emulsified LCTs delivered to the duodenum have a potent stimulating effect on CCK release and gallbladder contraction [13]. Conversely, whereas dietary MCTs are more efficiently absorbed and rapidly metabolized compared to LCTs [14], they are very weak stimulants for CCK release, gallbladder contractility, and hence luminal postprandial bile acid concentrations. Biliary complications such as sludge or cholelithiasis are rare during long-term CEN.

Digestive Secretion and Hormonal Response

Gastric secretion depends mostly on protein intake and, in the case of elemental diet, on amino-acid composition. Gastric secretory response is reduced by lipids and not influenced by carbohydrates. It has not been demonstrated whether or not the type of diet (i.e., elemental, semi-elemental, or polymeric) modifies gastric acid secretion [15]. Secretion of CCK and pancreatic polypeptide (PP) is maintained during CEN [12]. All forms of oral and enteral feeding

stimulate pancreatic synthesis and secretion of fluids and enzymes through CCK, secretin, and PP. Pancreatic secretions can be reduced by 50% if a low-fat elemental formula is used for duodenal feeding. Stimulation of pancreatic trypsin synthesis or secretion can be inhibited by delivering EN into the mid-distal jejunum [16]. The mechanism involves increased secretion of the "ileal-brake" hormones glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) [17, 18] which inhibit production of pancreatic secretions and motility in the proximal GI tract. Gastrin secretion is also maintained during CEN, but its response to protein load is decreased. Gastric or duodenal CEN stimulates insulin secretion depending on the type of infused nutrients. The glycemic and insulinemic response induced by EN parallels that of oral feeds and is significantly lower than PN [16]; therefore, less risk for steatosis.

Effects of CEN on Mucosal Trophicity

The effects of elemental formulas (totally absorbed in the upper GI tract and providing minimal residue to the distal bowel) on small-bowel mucosal trophism remain controversial. In studies comparing intestinal trophicity and function in animals fed elemental diets versus regular chow, there was similar digestive function but significantly decreased mucosal mass in the distal bowel of animal-fed elemental diets. These changes could be the consequence of the almost complete absorption of nutrients within the proximal part of the small bowel, leading to lack of stimulation of the distal segment [19, 20]. This suggests an ability of EN to achieve bowel rest in the distal part of the bowel, providing efficient treatment for ileocolic inflammatory diseases.

Effects of CEN on Energy Expenditure and Feeding Tolerance

Thermogenic effect of feeding is related to the increase of energy expenditure for synthesis and secretion of digestive enzymes following ingestion of food. The increase in energy expenditure induced by CEN in normal subjects is lower than when the same nutrients are administered by bolus feed [21]. Finally, the slow and continuous administration of nutrients into the GI tract through CEN allows the achievement of optimal utilization despite intestinal illness. In fact, by changing the conditions of flow and of contact between the nutritive formula and the digestive tract, CEN may increase the capacity for intraluminal digestion and intestinal absorption. This feeding technique does not appear to provide benefit in patients without intestinal disease [22, 23]; however, it seems logical and efficient when the absorptive surface is reduced, for example, short bowel syndrome (SBS), villous atrophy, enterocutaneous fistula, or proximal enterostomy. CEN has been associated with better feeding tolerance, nutrient absorption, and growth than boluses or oral feeds in infants and adult patients with intestinal disease [24, 25].

Indications

Indications for EN are different from indications for PN, since the use of EN as nutritional support is based on normal or at least partially preserved gut functions. The decision tree for the route of feeding is determined based on aspiration risk, motility function of the stomach, and anticipated duration of need for EN support. See Fig. 45.2. EN can be used on any patient with normal GI absorptive function but unable to adequately be fed by mouth. The conditions commonly encountered are listed in Table 45.1.

Conditions with Normal Intestinal Absorptive Function

EN is required in cases of inability to eat normally, that is, in those situations that are secondary to structural or functional abnormalities of the upper GI tract or neurological impairment of the processes involved in sucking and/or swallowing (see also Chap. 20). Esophageal diseases including esophageal atresia, fistula, or stenosis, often resulting from sequel of epidermolysis bullosa, are among the conditions that can benefit from EN, usually through gastrostomy or duodenal tubes [26, 27]. The choice of feeding through gastrostomy versus transpyloric tube must be assessed according to the patient age, disease, and condition (Fig. 45.2). Children with chronic diseases inducing immaturity or inability to feed orally, especially with sucking and swallowing troubles as seen in neurologically impaired children, with neuromuscular chronic diseases or cerebral palsy, also require EN, using GTs.

Premature Infants

EN via nasogastric or orogastric tube is routinely used in premature infants younger than 32 weeks' gestation because of uncoordinated suck, swallow, and breathing related to immaturity [28]. Human milk is the preferred feed because of its immunological benefits. Preterm infant formulas come fortified with protein, calcium/phosphorous, and a calorie density of 22–24 kcal/oz. to meet the high nutritional requirements of infants. A Cochrane systematic review of treatment trials did not provide evidence of any beneficial effect from transpyloric feeding over gastric feeding on feeding tolerance, growth, and development in preterm infants [29].

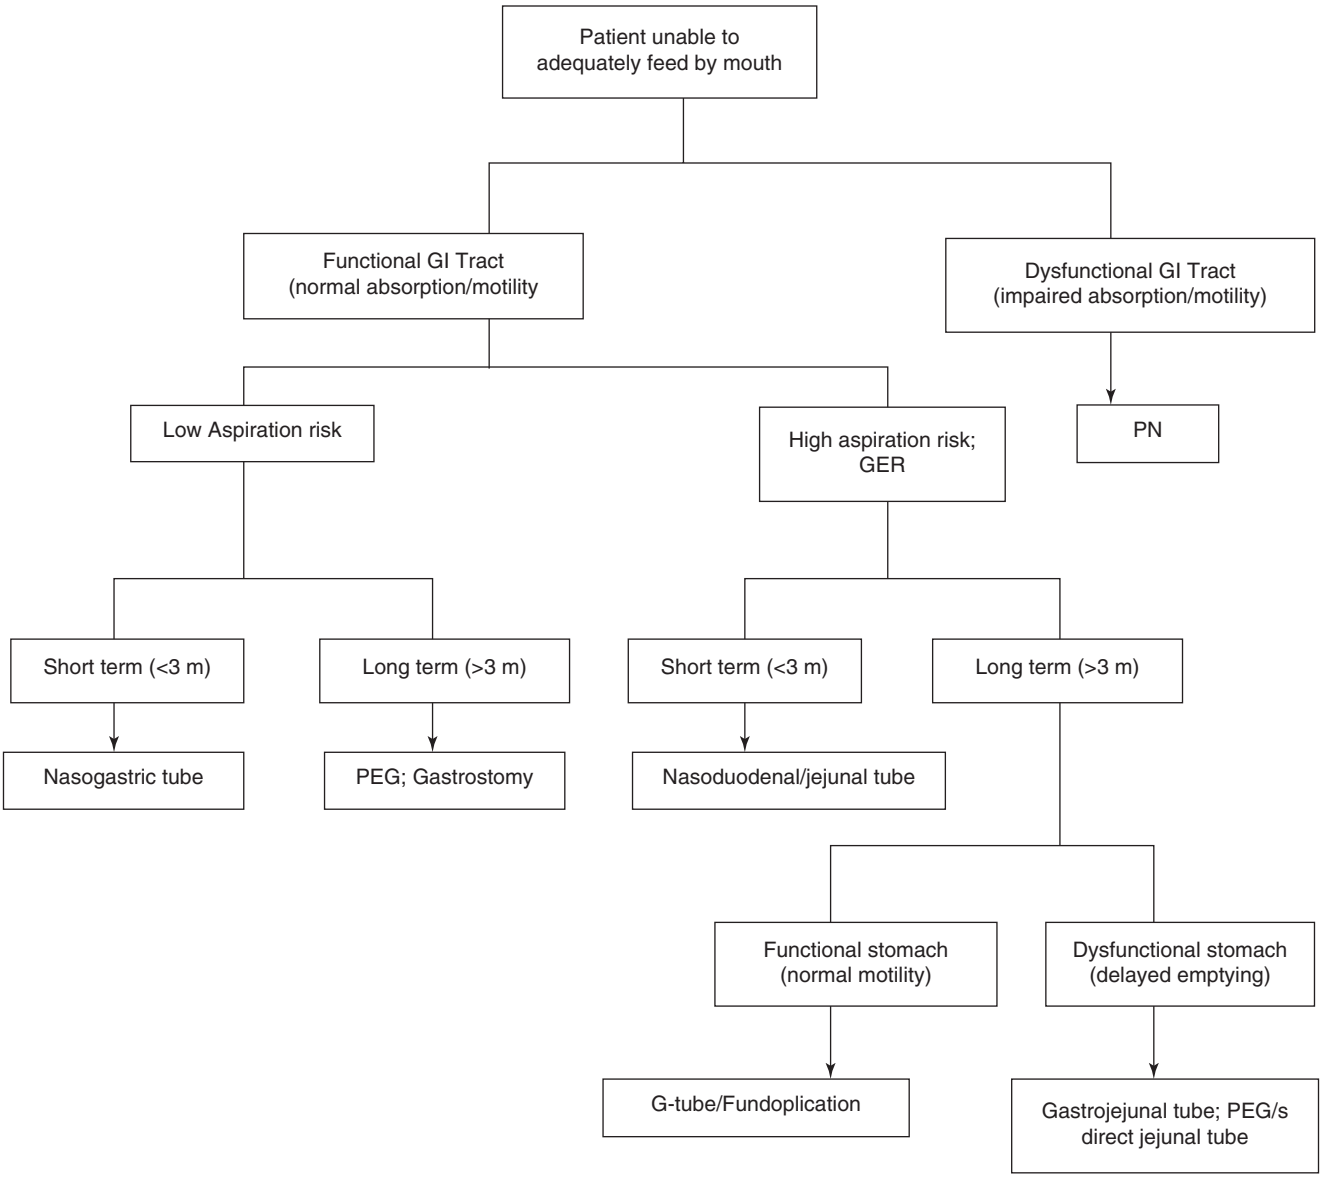

Fig. 45.2 Decision tree for the route of EN. *GER* gastroesophageal reflux, *PN* parenteral nutrition, GI gastrointestinal, PEG percutaneous endoscopic gastrostomy, PEG/J percutaneous endoscopic gastrostomy/jejunostomy, G-tube gastrostomy tube

Therefore, gastric feeding administered by bolus or continuously is the preferred approach for EN in preterm infants, where its use appears to also have a role in preventing necrotizing enterocolitis [30] (see also Chaps. 6 and 7).

Restrictive Eating Disorders: Anorexia Nervosa and Avoidant Restrictive Food Intake Disorder

Anorexia nervosa (AN) is a life-threatening psychiatric condition characterized by disordered eating behaviors, significantly lower than expected body weight, intense fear of becoming overweight, and a distorted body image. It is managed by a multidisciplinary team of health providers including psychiatrists, child and adolescent medicine pediatricians, nutritionists, and social workers. Indications for inpatient therapy include presence of suicidal or aggressive behaviors; severe bradycardia, hypotension, electrolyte imbalance, dehydration, and hypothermia; and medical complications, for example, seizures and pancreatitis [31]. Weight restoration is one of the major predicators for favorable short- and long-term outcomes in patients with AN [32]. Also, restoration of body weight is associated with improvements in malnutrition-induced cognitive impairments, thus facilitating psychological and psychiatric therapy [33].

Nutritional support in AN and avoidant resrictive food intake disorder (ARFID) remains very controversial. The

Intestinal pseudo-obstruction
Crohn's disease
Malabsorption disorders
Cystic fibrosis
Chronic liver disease

FTT failure to thrive

oral feeding route is preferred; however, patients are given the option of voluntary or forced EN if resistant to therapy and/or severe malnutrition, that is, body mass index (BMI) < 13 kg/m^2 or z-score ≤−3 in adolescents [34, 35] and weight-for-height z score <−3 in younger children [36]. Other options like GT and PN are considered in young children or severe and chronic cases [31]. Follow-up of adults treated with EN during adolescence did not show any long-term benefits or adverse outcomes on growth, recovery, or persistence of AN or risk for development of psychiatric comorbidities [37]. The initial range of prescribed energy intake varies from 10–60 kcal/day to 1000 kcal/day and >1900 kcal/day with progressive increase during the course of hospitalization [31, 32]. The main complication of nutritional management is risk for developing re-feeding syndrome: hypophosphatemia, hypokalemia, edema, and increased hepatic transaminases. The risk factors associated with re-feeding syndrome include food intake <50% of estimated energy requirements for >1 month [38], greater severity of malnutrition, abnormal electrolytes prior to re-feeding, use of EN or PN, and weight loss >15% within the preceding 3 months [31, 32]. Patients may be preemptively treated with phosphate and thiamine supplements during the early phases of nutritional management.

Inborn Errors of Metabolism

EN is part of the standard therapy used to prevent biochemical abnormalities, metabolic decompensation, and catabolism in patients with inherited disorders of metabolism, for example, hepatic glycogen storage disease (GSD) and enzyme deficiencies of the urea cycle. Patients with GSD type 1 (glucose-6-phosphatase deficiency) develop hypoglycemia and compensatory biochemical abnormalities of lactic acidosis, hyperuricemia, hyperlipidemia, and platelet dysfunction all stemming from the primary defect of inability to dephosphorylate glucose-6-phposphate to free glucose. Managing GSD type 1 involves overnight continuous high-carbohydrate feedings and frequent daytime feedings supplemented with uncooked cornstarch [39, 40]. EN consisting of a glucose/glucose polymer solution or a sucrose-free, lactose-free/low formula enriched with maltodextrin may be used. EN should be started within 1 h after the last meal. Likewise, an oral or EN should be given within 15 min after discontinuation of the continuous EN because of the risk for hypoglycemia. Gastrostomy is contraindicated in patients with GSD type 1b because of complications in case development of inflammatory bowel disease and local infections [40]. Continuous EN should provide a glucose infusion rate of 7–9 mg/kg/min in children younger than 6 years, 5–6 mg/kg/min in children aged 6–12 years, and 5 mg/kg/min in adolescents [40]. Intermittent feedings of uncooked cornstarch may be used if continuous nighttime EN is not an option. No significant differences in biochemical parameters or growth have been found between patients with GSD type 1 receiving overnight continuous EN compared to scheduled feeds of uncooked cornstarch [41, 42]. The starting dose for uncooked cornstarch is 0.25 g/kg and optimal dose is 1.75–2.5 g/kg of ideal body weight every 6 h [40, 41, 43]. Patients with GSD type 3 (debrancher enzyme deficiency) have impeded glycogenolysis; however, gluconeogenesis is endogenously enhanced to maintain adequate glucose production. Therefore, nutritional management of patients with GSD type 3 involves frequent high-protein feedings during the day and a high-protein snack at night. Patients with GSD IV (brancher enzyme deficiency), GSD VI (phosphorylase deficiency), and GSD IX (phosphorylase kinase deficiency) respond to the high-protein diets similar to what is recommended for patients with GSD type 3 [44].

Inherited defects in urea synthesis are inborn errors of nitrogen detoxification and arginine synthesis due to defects in the urea cycle enzymes, namely, carbamoyl phosphate synthetase 1, ornithine transcarbamylase, argininosuccinate synthetase, argininosuccinate lyase, and arginase [45]. They may present at any age with symptoms ranging from poor feeding to coma shock and death. Other clinical symptoms may include lethargy, vomiting, ataxia, confusion, behavior changes, hypotonia or spasticity, hyperventilation (leading to respiratory alkalosis), and seizures. The main biochemical abnormalities are hyperammonemia and increased plasma concentrations of glutamine [46]. The symptoms of metabolic crisis are usually precipitated by protein intake in excess of what the patient can metabolize,

catabolism of lean body mass resulting from intercurrent infection, trauma, inadequate energy intake, or inadequate intake of protein or essential amino acids. Management of patients with urea cycle defects involves a combination of carefully restricting protein intake and therapy with nitrogen-scavenging drugs, for example, sodium benzoate, sodium phenyl acetate, or sodium phenyl butyrate [45]. The nutritional management includes (1) administration of sufficient energy to support anabolism, (2) restriction of protein intake to that tolerated by the patient without producing excess NH3, (3) provision of essential amino acids in adequate amounts to support growth, (4) supplementation of "conditionally" essential arginine or citrulline in all except arginase deficiency, and (5) provision of all required minerals and vitamins in amounts appropriate for age [47]. During hyperammonemic metabolic crisis, the nutritional management consists of providing high-energy low-protein intakes [48]. Successful long-term management requires a dedicated metabolic dietician and physician to make frequent dietary adjustments while closely monitoring progress. Patients with neurological handicaps or developmental delays, feeding difficulties, poor appetite/refusal of food, compliance problems with the diet, and/or medications will require use of nasogastric or gastrostomy feeding tubes to ensure adequate intake [45, 49]. Patients in metabolic crisis with symptomatic hyperammonemia (>500μM/L) and/or lack of response despite 3–6 hours of appropriate medical treatment should have management escalated to hemodialysis [45].

Hypermetabolic States

Hypermetabolic states include patients with burns, cancer, and head injury. Much of the morbidity and mortality in severely burned patients is connected to the prolonged hypermetabolism and catabolism, impaired wound healing, and sepsis. Whenever GI function permits, EN is superior to PN in patients with burns [50]. EN results in better regulation of the postburn catabolic hormones and inflammatory cytokine responses than PN [50, 51]. Furthermore, early EN support of patients with severe burns helps maintain gut mucosal integrity, which has the beneficial effect on reducing risk for gut-derived endotoxemia and infections [52].

Graft Versus Host Disease

Traditionally, PN is given as the first option for nutrition support in children undergoing chemotherapy and/or bone marrow/stem cell transplant. The reasons cited range from intestinal injury and poor GI tolerance secondary to conditioning and myeloablative therapy, intestinal graft versus host disease (GVHD), oral mucositis, epistaxis, and parental refusal of EN. However, whenever GI function permits, EN is equally as effective as PN, associated with lower risk for infection, and more cost-effective [53–56]. A prospective study comparing EN and PN in children with bone marrow transplants had poor enrolment into the EN group. Initiation of EN prior to transplant was associated with better overall tolerance. The EN group was also less likely to develop cholestasis [55]. A more recent Cochrane database review of nutrition support in patients of all ages with bone marrow or stem cell transplants failed to find evaluable data that properly compared efficacy and superiority of EN versus PN. However, the overall findings suggested that in patients without GI symptoms, intravenous fluids and oral diet should be considered as preference to PN [57].

Renal Failure

Supplemental nutrition should be given to children with renal failure to promote positive nitrogen balance and meet energy needs [4]. Children with chronic renal failure are at risk for malnutrition and growth retardation from persistent anorexia, inadequate protein calorie intake, chronic metabolic acidosis, azotemia, hormonal and metabolic disturbances, and catabolic diseases associated with uremia, for example, infections. Long-term EN is effective in preventing growth retardation in children with chronic renal disease and persistent anorexia, especially if started before the age of 2 years [58, 59], but singly may not lead to catch-up growth [60]. There is a positive correlation between efficacy of dialysis and linear growth of children with chronic renal failure [61]. Therefore, the combination of aggressive nutrition support with whey protein-based formulas in children age <2 years, whole protein enteral formula (1–1.5 kcal/mL) in older children [62], and enhanced dialysis is necessary for inducing growth in children with chronic renal failure [63]. Growth hormone therapy is recommended if there is persistent growth retardation despite adequate nutrition support [62, 64]. Ultimately, catch-up growth in height is mainly seen in children who undergo renal transplant before the age of 6 years [65].

Congenital Heart Disease

Inadequate calorie intake is the predominant cause of growth failure in infants and children with congenital heart disease. Different approaches for nutrition intervention are utilized during the preoperative, postoperative, and post-discharge periods, respectively [66]. Infants with cyanotic congenital heart disease and complex ventricular lesions are particularly susceptible to malnutrition and growth failure [67]. Approximately, 50% of infants with surgically treated univentricular lesions get discharged home on EN via nasogastric or GT [68].The causes of malnutrition include an imbalance between energy intake and expenditure, malabsorption, and/or end organ dysfunction due to impaired cardiac output. Infants with severe congenital heart disease have normal resting energy expenditure [69–71] but may have increased total energy expenditure [72], thus indicating that they expend large amounts of energy above basal requirements, which places them at risk for inadequate calorie intake when feeding at normal rates. Perioperative injury to the recurrent laryngeal nerve may lead to feeding difficulties from swallowing dysfunction and vocal cord paralysis [73]. Other contributing factors include pulmonary hypertension, tachypnea, and fatigue interfering with oral feeding; medications associated with anorexia, for example, diuretics; prescription of fat-restricted diets in patients who develop chylous effusions; and GI nutrient loss in patients who develop post-Fontan protein-losing enteropathy. Post-Fontan protein-losing enteropathy is managed with therapies directed at improving cardiac hemodynamics and controlling inflammation [74].

Digestive Indications

Since EN has a trophic effect on the intestinal mucosa and helps maintain mucosal integrity, it plays an important role in the treatment of many digestive diseases, either replacing or complementing oral feeding. Digestive diseases leading to an anatomical or functional reduction of the absorption capacity of the small bowel represent the first group; they include SBS, protracted diarrhea with villous atrophy, and inflammatory bowel disease.

Severe Protracted Diarrhea of Infancy/ Congenital Diarrheas and Enteropathies

A syndrome of intractable diarrhea of infancy was first described by Avery et al. in 1968. Its definition, presentation, and outcome have considerably changed during the past two decades [75]. This syndrome was defined as persistent diarrhea despite prolonged bowel rest requiring long-term total parenteral nutrition (TPN) in children when no effective treatment is available [76, 77]. Recent advances in understanding pathogenesis and increased availability of genetic testing have led to improved classification and characterization of many previously idiopathic chronic diarrhea illnesses of infancy [78]. Persistent and severe diarrhea presenting in the first weeks of life are now characterized as congenital diarrheas and enteropathies (CODEs). Most are monogenic diarrheal disorders that can be broadly classified into five major categories: (i) epithelial nutrient/electrolyte transport, e.g., congenital chloride diarrhea, congenital sodium diarrhea, glucose–galactose malabsorption, primary bile acid diarrhea, and acrodermatitis enteropathica; (ii) defects in epithelial enzymes and metabolism, e.g., congenital lactase deficiency, sucrase–isomaltase deficiency, trehalase deficiency, enterokinase deficiency, DGAT1 deficiency, PLVAP deficiency, abetalipoproteinemia, hypobetalipoproteinemia, chylomicron retention disease, dyskeratosis congenita, and Kabuki syndrome; (iii) epithelial tracking and polarity disorders, e.g., microvillus inclusion disease, tufting enteropathy, syndromic Na+ diarrhea, trichohepatoenteric syndromes 1 and 2, familial hemophagocytic lymphohistiocytosis 5, and TTC7A deficiency; (iv) enteroendocrine cell dysfunction, e.g., enteric anendocrinosis, x-linked lissencephaly and MR, proprotein convertase 1/3 deficiency, and Mitchell–Riley syndrome; and (v) immune dysregulation-associated enteropathy, e.g., IPEX, ICOS deficiency, ADAM17 deficiency, EGFR deficiency, CD55 deficiency, CTLA4 deficiency, LRBA deficiency, and XIAP. Algorithms are now available that improve evaluation, diagnosis, classification, and management of CODEs [78]. The CODEs resulting from defects in digestion, absorption, and transport of specific nutrients and electrolytes have normal villus and crypt architecture and thus may respond to dietary regulation restriction of the specific nutrients and electrolytes. Those with defects in enterocyte structure, epithelial cell defects, or abnormal villus to crypt ratios and morphology resulting from immune-mediated injury also have very poor tolerance of diet or EN and thus often need lifelong PN or allogenic intestinal transplantation [78]. Severely malnourished infants with some types of particularly severe celiac disease, intolerance to cow milk proteins, and protein hydrolysates or with specific malabsorption syndromes, such as Anderson's, disease may also benefit from CEN [79].

Short Bowel Syndrome

SBS is the leading cause of intestinal failure in newborns as well as infants and young children, and it is most commonly the result of an extensive intestinal resection during the neonatal period. EN is often used in these circumstances,

although several controversies over the ideal nutritional treatment of children with SBS remain [80]. EN is prerequisite for intestinal adaptation. EN exerts its trophic effects through direct contact with enterocytes and stimulation of local hormones. EN may also upregulate the expression of disaccharidases and peptidases in the colon of children with SBS, creating greater absorbtive capacity with less surface area [81]. The mechanism of this intestinal adaptation is believed to be in part due to changes in the microbiome, which are influenced by the presence or absence of an ileocecal valve [81]. PN therapy without any EN is associated with increased risk for intestinal failure-associated liver disease [82] (see also Chap. 43).

Disorders of Motility

In neonatal abdominal surgery for congenital or acquired disease, CEN, usually combined with PN, offers prolonged nutritional support which has transformed the prognosis in many conditions and is particularly important in the following situations: (1) reduction of the absorptive surface with enterocutaneous fistulae or extensive intestinal resection and (2) functional disorders of gut motility, such as malfunctions of duodenojejunal anastomosis, "plastic" peritonitis after repeated interventions, gastroschisis, and omphalocele.

Chronic intestinal pseudo-obstruction syndrome is a disabling disorder of enteral feeding characterized by repetitive episodes or continuous symptoms and signs of bowel obstruction, including radiographic documentation of dilated bowel with air–fluid levels, in the absence of fixed-lumen-occluding conditions [83]. Pseudo-obstruction is classified as "congenital" if newborn infants present with symptoms persisting for the first 2 months of life. "Acquired" pseudo-obstruction applies when previously well patients present with feeding intolerance from pseudo-obstruction symptoms persisting longer than 6 months [83]. Most patients with intestinal pseudo-obstruction require decompression stomas, ileostomies, and colostomies to relieve the recurring obstruction symptoms. Long-term PN is required in a significant proportion of children with pseudo-obstruction [84–86], and even then, administration of at least small volumes of CEN is essential and encouraged for prevention of PN-associated liver disease [87] and maintenance of bowel mucosal integrity [88].

Crohn's Disease

Enteral feeding has been used for many years, particularly in Europe, not only to improve nutritional status and growth but also to influence disease activity in patients with Crohn's disease (CD) [89–97]. The European Society for Parenteral and Enteral Nutrition (ESPEN) published updated guidelines in 2019 outlining a role for EN in inflammatory bowel disease not only in the context of providing nutritional support, especially before and after surgery, but also to induce remission and even as maintenance therapy [98]. It was shown that CEN diet is as effective as high-dose corticosteroids in inducing remission in pediatric patients with CD and has the added benefit of improved growth and development without the steroid side effects [99, 100]. However, serial meta-analysis conducted by Griffiths et al. in 1995, 2001, and 2007 suggested that therapy with EN was inferior to corticosteroids for inducing clinical response in patients with active CD [101–103]. All three analyses largely included adult studies, and several pediatric studies showing striking efficacy were excluded owing to methodological weakness. A more recent meta-analysis that focused on 11 randomized controlled pediatric studies still reported similar efficacy for EN and corticosteroids for inducing remission in CD but also cited limited data [104]. Two recent meta-analyses outlined not only that EN is as effective as corticosteroids in inducing remission but also highlighted mucosal healing as an advantage of EN over corticosteroids [105, 106]. The mucosal healing induced by EN is comparable to other first-line therapies, including infliximab, with the additional finding of fewer adverse effects in patients receiving EN compared to infliximab [107]. The benefits of EN appear to be more favorable in children than adults, including correction of impaired growth. The GROWTH CD Study, one of the largest multi-center prospective studies on this topic to date, further underscored the utility of EN in improving growth arrest, in addition to inducing remission, in pediatric patients with new-onset mild to moderate CD, even after correcting for confounders such as baseline severity and concomitant use of immunomodulators [108]. Thus, EN is an underused therapy with the advantage of preserving growth, while remission is achieved and therefore must be promoted [109]. There is no relevant data showing any significant difference in clinical outcome based on composition of the EN, that is, elemental, protein hydrolysates, or polymeric formula. Indeed, the beneficial effect in achieving remission appears not to be related to the mode of delivery or to the type of diet (no beneficial effect of elemental versus polymeric or semi-elemental) but rather to the reduced antigen load and mostly to changes in the intestinal microbiota [99]. The positive effects of EN also did not appear to differ if EN was administered orally or via CEN [99]. The Crohn's Disease Exclusion Diet (CDED) in combination with EN was shown to be a useful salvage regimen for patients who had poor response to anti-TNF therapy [110]. Removal of antigenic material, alteration in intestinal microflora, changes in gut

hormone levels, and the presence of bioactive transforming growth factor-β (TGFβ-1) in casein-based formulas may all play a role in the clinical success of EN [111, 112]. This change in the microbiota of patients receiving EN is believed to be the mechanism that leads to mucosal healing in these patients [113]. Glutamine-enriched polymeric diet offered no advantage over a standard low-glutamine polymeric diet in the treatment of active CD [114]. EN may be also helpful in correction or maintenance of the nutritional state, especially during a relapse of CD [100]. EN is part of the preparation for surgical procedure and may be useful during recovery, especially after intestinal resections or enterostomies. More on the treatment of Crohn's disease can be found in Chap. 28.

Other Malabsorption Syndromes

Cystic Fibrosis

Malnutrition and impaired growth affect approximately 23% of children with cystic fibrosis (CF) [115], and growth within the normal range of weight-for-length and BMI is associated with better pulmonary function and long-term survival. The CF Foundation recommends that growth assessment using percent ideal body weight (%IBW) be discontinued and instead rely on age-appropriate weight-for-length percentiles in children aged <2 years and BMI percentiles in children aged 2–20 years. The nutritional goals in children with CF are to maintain and support growth at weight-for-length or BMI at or above the 50th percentile [115]. Growth abnormalities in patients with CF have a multifactorial etiology including active CF-pulmonary or sinus disease, inadequate or ineffective pancreatic enzyme therapy, inadequate calorie intake, anorexia, presence of CF-related hepatobiliary disease, CF-related diabetes, infectious enteritis, small-bowel bacterial overgrowth, and other comorbid intestinal conditions including celiac disease and inflammatory bowel disease [116]. Whereas these disorders require specific therapy, nutrition monitoring and intervention in patients with CF should always be implemented regardless of comorbid disease. Improved weight status in patients with CF often requires energy and protein intakes ranging from 110% to 200% of normal needs in healthy people [116, 117]. However, even with an optimal approach to oral feeding, some patients respond poorly to nutritional counseling alone. Therefore, use of EN to supplement dietary intake is recommended to help restore and maintain nutritional status, especially in children aged 13 years and older who present with persistent growth deficits despite nutrition counseling [115]. The utilization of supplemental EN by patients with CF increased from 8.5% in 2001 to 11.1% in 2011 [118], thus indicating greater engagement of nutritional therapy. EN is generally performed during the night over 8–10 h with the initial goal of providing 30–50% of the estimated requirements [116, 119]. Patients with CF are then asked to eat and drink as much as possible during the daytime. Standard formulas containing intact protein, long-chain fat, and calorie densities of 1.5–2.0 kcal/mL are generally well tolerated with appropriate dosing and administration of pancreatic enzymes [116]. Semi-elemental formulas may be tolerated better in patients with excessive anorexia, bloating, or nausea. The data are unclear whether formulas with medium-chain triglycerides are advantageous over regular formula in patients with CF [116, 119].

Nasogastric tube (NGT) feeding is generally used as a first step. The tube is passed every night, 1–2 h after dinner, and removed in the early morning before physical therapy so that patients are not disturbed during the daytime for school attendance. In some children, NGT becomes increasingly uncomfortable because of nausea, vomiting, nasal discomfort as a result of nasal polyposis, or dislodgement during coughing in cases of pulmonary exacerbation. Gastrostomy tube (G-tube) is the preferred modality for administering home nocturnal EN when long-term EN is anticipated. Generally, G-tubes are perceived well by patients with CF who rely on EN therapy for poor weight gain or weight loss. On the contrary, patients and families without G-tubes were found to be apathetic toward their value, citing fear of interference with activities, embarrassment, pain, and discomfort [120]. Therefore, there is need for more accurate information about benefits and lifestyle in patients with G-tubes. Good early childhood nutritional status is associated with better pulmonary function and long-term survival in patients with CF [121]. However, poor growth and advanced lung disease have been associated with poor outcomes regardless of adherence to EN [122]. There is also currently insufficient evidence to determine whether nutritional rehabilitation after onset of malnutrition improves pulmonary function in patients with advanced CF-related lung disease, therefore the importance of a proactive approach of growth monitoring and early nutritional intervention to optimize growth in children and adolescents with CF. It is important to assess for gastroesophageal reflux before starting EN. Patients should also be monitored for glucose intolerance during administration of EN, especially during illness, therapy with steroids, and if not gaining weight. Insulin therapy should be administered as needed in patients with glucose intolerance [116, 119].

Chronic Liver Disease

Mechanisms leading to protein–energy malnutrition and requirement for EN in infants and children with chronic liver disease are multifactorial and dependent on the type of liver injury [123]. Malnutrition in cholestatic liver disorders is from reduced biliary secretion and intraluminal bile concentrations resulting in malabsorption of lipids and fat-soluble vitamins [124]. Protein and energy requirements are increased by different mechanisms including hypermetabolism [125], portosystemic shunting and ascites, futile metabolic pathways [126], and the energy demands from complications such as sepsis or variceal bleeding [127]. Liver disease from inborn errors of metabolism, for example, galactosemia, tyrosinemia, GSD, and Wilson's disease, requires specific dietary restrictions and EN feeding protocols to prevent hypoglycemia and other forms of metabolic decompensation. Patients with fulminant hepatic failure may be well nourished and nutritionally independent at clinical presentation but later require EN because of impaired mental status. Anorexia is common in children with chronic liver disease resulting from organomegaly, abdominal pressure effects of ascites, congested gastric mucosa, reduced motility from portal hypertension, central effects of unidentified toxins, dietary manipulations such as fluid restriction, or use of unpalatable feeds. Several factors contribute to long-chain polyunsaturated fatty acid (PUFA) deficiency including low PUFA intake, malabsorption, and disturbed metabolism of long-chain PUFAs. Finally, the interaction of growth hormone with insulin-like growth factor 1(IGF-1) and its binding proteins constitute an important mechanism linking nutrition and growth.

The most common cause of cirrhosis in children is biliary atresia, and the only definitive therapy is liver transplant [128]. A total of 60–80% of affected children are moderately to severely malnourished prior to transplantation [124], and poor nutritional status prior to transplantation is associated with prolonged hospital stay, increased risk for death, and high cost of medical care [127, 129, 130]. Supplemental EN or PN to improve nutritional status is the one intervention known to improve pre- and post-transplant growth and clinical outcomes in children with end-stage liver disease [131–134].

Anorexia, inadequate calorie intake, and failure to thrive are prevalent in children with chronic liver disease [124]; therefore, EN is recommended to supplement per oral food intake [127]. NGT feeding may be safely used without increased risk for bleeding in patients with portal hypertension varices [135, 136]. G-tubes should be avoided in children with chronic liver disease and portal hypertension because of likely portal-hypertensive gastropathy with increased bleeding risk from gastric varices [127]. MCTs are nutritionally advantageous in patients with cholestasis because bile is not required for digestion and they're rapidly absorbed into the portal circulation. MCTs may be administered separately as supplements; however, the selected EN should not contain more than 80% of fat as MCT because of the risk of inducing essential fatty acid deficiency [137]. Children with weight-for-length or body mass index z scores <−3 fall into the category of severe malnutrition, which is associated with a >9-fold risk for mortality [138], and therefore should be prioritized for nutritional intervention. Patients with chronic cholestatic liver disease have increased metabolism [125], futile metabolic pathways [126], and malabsorption; therefore, the goal for supplemental EN is to enable a daily calorie intake of 140–200% of estimated requirements [124]. Children with chronic cholestatic liver disease should continue receiving fat-soluble vitamins (A, D, E, and K) regardless of the amounts listed in EN [139]. Protein intake of infants and children should not be restricted except in cases of intractable encephalopathy [139], and, even in these cases, protein intake should remain within the adequate intake range of 1–2 g/kg/day [140] and accompanied by sufficient intake of non-protein calories to prevent inappropriate utilization of protein for energy synthesis [141]. Children with cholestatic liver disease have increased requirements for branched-chain amino acids (BCAA) compared to healthy controls [142]. However, nutritional outcome studies using either BCAA-enriched or standard formulas reported growth benefits in all recipients of EN [131, 132]. Furthermore, a Cochrane review did not find BCAA-enriched formula protective against encephalopathy when compared to iso-nitrogenous non-BCAA-enriched formulas [143]. Therefore, there is currently insufficient evidence to recommend the use of BCAA-enriched formulas over standard non-BCAA-enriched formula.

Chylothorax

Nutritional management of chylothorax involves adherence to EN or an oral diet enriched with medium-chain triglycerides, restriction of long-chain triglycerides, and supplementation with essential fatty acids and fat-soluble vitamins [144]. Nutrition support during the preoperative period utilizes EN in infants who are hemodynamically stable and early use of PN if otherwise. The immediate postoperative period is characterized by fluid restrictions and hemodynamic instability and therefore requires active involvement of a dietician and reliance on PN to meet goal calories. Once hemodynamic stability is established, enteral feeding is introduced while following standardized protocols that include screening for swallowing dysfunction and management of GI symptoms, for example, reflux. Nutrition surveillance should be performed continually pre- and post-discharge

to guide further interventions including use of calorie-dense formula and home tube feeds [66].

Techniques of Delivering Enteral Nutrition

The route of EN administration should be individually tailored, depending on the underlying condition (Fig. 45.1). Enteral feeding is preferable to PN, and therefore it should be immediately implemented in children with functional GI but unable to feed per oral. The absolute contraindication to EN includes mechanical obstruction of the GI tract (unless indicated for decompression), active peritonitis, uncorrectable coagulopathy due to increased risk of bleeding, or bowel ischemia [145, 146]. The intragastric route of administration is the most commonly used in children, since it is the more physiologic route which permits the action of salivary and gastric enzymes, the bactericidal action of gastric acid, and the better mixing with biliary and pancreatic secretions. Therefore, the duodenal or jejunal route is used in very few circumstances in children. For intragastric administration EN, NGT, or GT may be used. NGT feeding is the best initial approach to EN, to evaluate the tolerance of EN before placing a permanent GT, and/or when a brief period of EN support is anticipated.

NGT is made of polyvinylchloride (PVC), polyurethane, or silicone. Modern feeding tubes are made of either silicone or polyurethane [147]. Polyurethane tubes come externally and internally impregnated with a water-activated lubricant to ease insertion through the nasopharynx and facilitate removal of introducer wires [148]. They are also more resistant to degradation and deterioration when compared to silicone tubes. Tube size (outer diameter) is described in French gauge (Fr) units. The millimeter conversion can be derived by dividing each Fr by π (3.14). The length of insertion for a nasal- or oral–gastric feeding tube to be in a child is determined by using either the morphological markers of "nose–ear–mid-xiphoid–umbilicus" span or age-specific prediction equations. Length predictions based on just a "nose–ear–xiphoid" span are likely to result in a placement that is too proximal [149]. At the time of NGT placement, aspirating fluid and measuring a pH $\leq$ 5 are the most reliable bedside tests confirming gastric placement in children [150]. However, the usefulness of this test may be limited in patients being treated with gastric acid suppressants. Simple auscultation is not a reliable method for assessing position because injection of air into the tracheobronchial tree or pleural space can produce an indistinguishable sound. Therefore, an abdominal X-ray is the gold standard for establishing location of the NGT tip [150].

Duodenal or jejunal tube placement is more difficult; the patient should be placed in the right lateral position and, if necessary, after an intravenous injection of erythromycin. The position of the distal end of the tube is then checked by abdominal X-ray. Careful nasal fixation of the tube is used to avoid displacement; it is taped to the upper lip, the ipsilateral cheek, and the external ear. In some particular indications for EN, the feeding tube may also be introduced through the mouth, especially in patients with congenital or acquired nasal obstruction and premature infants on respiratory therapy with continuous positive air pressure (CPAP). The placement of NGT made of PVC is easier, but these tubes should be changed more frequently as they become more rigid. Silicone or polyurethane NGT may be used over 3-week periods or more. However, silicone and polyurethane are generally more flexible and easily displaced by vomiting. They are preferentially used for transpyloric and long-term EN. Individualized goals for growth, nutrition, and when to discontinue EN should be established prior to insertion of a feeding tube. Use of EN may only be temporary in acutely ill but previously healthy children, or as a long-term source of supplemental nutrition in children with chronic inadequate per oral food intake, and the sole source of nutrition in children with severe disability in per oral feeding.

When a child's duration on EN is longer than 30 days and feeds well tolerated yet low anticipation for timely acquisition of adequate per oral feeding skills, transition to a feeding gastrostomy should be considered [146, 147]. Percutaneous approach to placement of gastrostomy has revolutionized the placement of enteric feeding tubes in children. The standard approach involves use of a gastroscope for gastric transillumination and stoma site identification. This is followed by percutaneous introduction of a guide wire that gets grasped using the gastroscope and then orally withdrawn. Thereafter, the gastrostomy catheter is attached to the oral end of the guide wire and then pulled in an antegrade manner through the oropharynx, esophagus, and stomach and then across the gastric and abdominal walls [151]. It may be placed using GI endoscopy and surgical laparoscopy or by interventional radiology [147]. Following placement, postoperative care mostly involves pain management, and most providers permit the use of GT within 12–24 h. The initial PEG tube is changed after 2–3 months, by which time a good tract has formed. Button-replacement gastrostomy devices provide patients a cosmetic advantage in the case of long-term EN.

Percutaneous placement of gastrostomy or jejunostomy is contraindicated in patients with previous abdominal surgery, abnormal abdominal anatomy, or severe deformities of the chest and spine which modify the position of the stomach and other intra-abdominal viscera. In such cases, a surgical GT should be placed. The implantation of a jejunal feeding tube, via G-tube (gastrojejunal tube), is a possible method for the treatment of inadequate oral feeding in patients who are affected by gastroesophageal reflux (GER), gastroparesis, and increased risk for aspiration and is thus an alternative to fundoplication and prokinetic medications [151, 152]. However, gastrojejunal feeding tubes are also prone to technical complications requiring replacement because of clog-

ging and recoil of the jejunal catheter back into the stomach [152]. EN may be delivered as boluses or prolonged continuous feeding using a feeding pump, syringe, or controlled delivery by gravity. Pumps recommended for pediatric use have to provide clear flow rate display and alarms. Miniaturized and battery-powered pumps are specially designed for home and ambulatory EN.

Nutrients

Nitrogen

The absorption of amino acids is more rapid and efficient when given in the form of short peptides than free amino acids [153, 154]. Therefore, in order to maximize nitrogen assimilation in patients with marked impairment of gut absorptive capacity, the ideal EN should consist of di- and tripeptides and free amino acids [154]. In addition, the quality, in terms of digestion and intestinal absorption of protein hydrolysates, depends on the type of hydrolysate, for example, lactalbumin is superior to casein [155]. However, in patients with normal GI function, EN with formulas consisting of protein hydrolysates offers no nutritional or absorptive advantage over EN based on formula consisting of free amino acids or intact protein [156]. Thus, the initial formula in patients with normal GI function should be based on intact protein or polypeptides, with a lower osmolality, rather than on a mixture of free amino acids and short polypeptides.

Carbohydrates

Disaccharidase enzymatic activities are depressed in disease involving the small intestine mucosa. Lactase appears to be the most sensitive to injury and the last of the disaccharidases to recover. In addition, certain drugs such as neomycin or colchicine depress the intestinal disaccharidases. Thus, it is important to avoid dietary sources of lactose. Other disaccharides should also be omitted from the solution used for initial feeding as their corresponding brush border enzymatic activities are reduced. The carbohydrate source allowed during the EN in patients with normal GI function can be lactose. However, patients with impaired GI function should be fed an EN containing lacto-free glucose polymer as the carbohydrate source.

Lipids

The main dietary lipids are triglycerides structurally made up of three fatty acids linked to a glycerol molecule. The fatty acids contain between 2 and 24 carbon atoms (C: 2 and C: 24). Classification of the triglycerides is based on length of the fatty acid chain, that is, short-chain triglycerides (SCT) contain fatty acids that range in length from 2 to 4 carbons (C: 2 to C: 4); the MCTs contain fatty acid chains ranging from 6 to 12 carbons (C: 6 to C: 12); and LCTs have >12 carbons. In contrast to the LCTs, dietary MCTs are hydrophilic and do not require bile salts or micelle formation, and their free fatty acids are directly absorbed into the portal system without requirement for re-esterification into chylomicrons [14, 157]. MCTs are hydrolyzed faster than LCTs in the small intestine by pancreatic lipase; they are converted almost exclusively into free fatty acids and glycerol and reach directly the portal circulation and the liver. Nevertheless, in the case of pancreatic insufficiency, MCTs may also be absorbed intact. The excessive use of MCT-containing diet can lead to osmotic diarrhea as a result of their rapid hydrolysis. Dicarboxylic aciduria has been described in infants supplemented with MCT-rich formulas without any proof of deleterious effect [158]. The provision of essential fatty acids (EFA) must be considered since MCTs contain no EFA. Furthermore, MCTs decrease LCT absorption; thus, supplementation with linoleic acid is necessary. However, its addition to a formula based on MCTs may be insufficient to prevent EFA deficiency, thus making it necessary to provide EFA parenterally. Nevertheless, most formulas containing MCTs also include up to 50% of lipid as LCTs. LCTs in excess in the intestinal lumen, especially if they are hydroxylated by bacteria, reverse the rate of water and electrolyte absorption and increase malabsorption. Finally, a lipid intake of 3–4 g/kg/day may be achieved, depending on absorption capacity and digestive tolerance.

Other Components

Recommendations concerning energy, water, and electrolyte supplies in premature and full-term infants are provided in the chapter on PN in the premature infant. In older children, the recommended energy intake is based on recommended daily intake (RDI) values or may be estimated using the World Health Organization (WHO) weight, age, and gender prediction equations or directly measured using an indirect calorimeter [140]. The minimum daily fluid requirements with some exceptions may be estimated using the "Holliday–Segar" calculation, which is an extrapolation based on daily calorie expenditure. For weights ranging from 0 to 10 kg, the estimation is 100 mL/kg/d; from 10 to 20 kg, the estimation is 1000 mL plus 50 mL/kg for each kilogram of body weight more than 10; and over 20 kg, the estimation is 1500 mL plus 20 mL/kg for each kilogram more than 20 [159].

Choice of a Formula

Enteral feeding formulas are divided into several families. The choice of a formula is made according to numerous parameters like protein–calorie needs, digestive function,

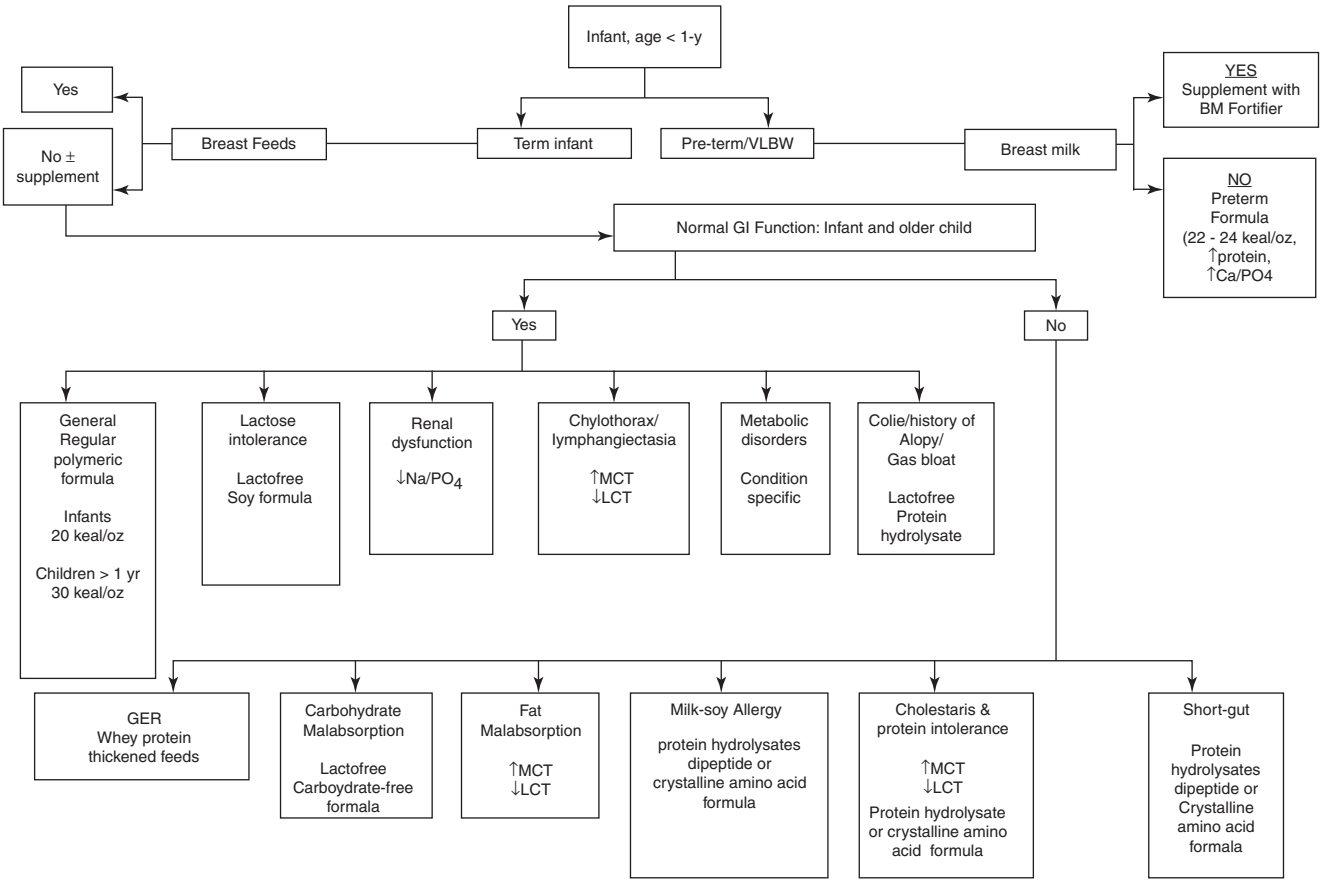

Fig. 45.3 Algorithm for selection of formula. GER gastroesophageal reflux, MCT medium-chain triglycerides, LCT long-chain triglycerides, EN enteral nutrition

protein sensitivity, motility status, and tolerance to fluid intake, all obviously dependent on the age and on the underlying disease (Fig. 45.3). In preterm, newborns, and young infants with normal intestinal function, human milk or standard infants formulas supplemented with long-chain polyunsaturated fatty acids (LCPUFA) may be used. Formulas for preterm infants are unique in being more calorically dense (72–90 kcal/100 mL) with increased protein (1.8–2.3 g/100 mL), calcium (70–108 mg/100 mL), and phosphorus [160]. The preterm formulas are continued after hospital discharge in preterm or small for gestation-age infants when discharge growth parameters are below appropriate post-conception growth, and continued until achievement of catch-up growth [160]. Breast milk and standard infant formulas have a calorie density of 0.67 kcal/mL with lactose as the carbohydrate source and fat source compromised of LCTs and LCPUFA (DHA and EPA). Commercial polymeric formulas are available for older children (age >1 year), and blenderized diets can be prepared using food from the kitchen and may be used in the nonstressed patients with normal gut function. The calorie density of formulas used in older children (age >1 year) ranges from 1 kcal/mL (standard) to 1.5–2.0 kcal/mL (calorically dense).

In the case of GI disease, the choice of the nutritive solution must take into account not only the child's age and nutritional status but also the underlying digestive disease, for example, the presence of anatomical and functional changes in the intestine, whether due to an extensive reduction of the absorptive surface, to enteropathy, or to pancreatic insufficiency. Limiting factors in such cases are impairment of gastric, biliary, and pancreatic secretions, disturbances of the intestinal flora, and malabsorption. Most standard (1 kcal/mL) polymeric formulas have osmolality within the range of 300–360 mosmol/kg. Oligomeric (hydrolysate/semi-elemental) and elemental (crystalline amino acid based) enteral formulas are designed for use in patients with malabsorption such as in short bowel syndrome, CF, cholestasis, food allergy, or intolerances. These diets include dipeptides, tripeptides, and a few free amino acids, combined with LCTs and MCTs, and carbohydrates including glucose polymers and maltodextrins.

The osmolality of a solution is determined by the number of particles within it. Likewise, the osmolality of enteral formulas is directly influenced by the calorie density and whether it is made up of intact protein, peptides, or amino acids. Therefore, free amino-acid-based formulas tend to have a

higher osmolality. Children with severe malabsorption or short bowel syndrome unable to tolerate peptide-based formulas (protein hydrolysates) might benefit from the free amino-acid-based formulas [161, 162]. Nutritional formulas in which each of the constituents is modified independently are mostly used in special conditions, for example, selective malabsorption. In that case, glucose may be given initially as calorie source, the amount being increased progressively and controlled according to the stool volume, pH, and absence of reducing substances in the stools. In the first days of feeding, at least a molar ratio of glucose and sodium is maintained.

Regulation of Intakes and Rhythm of EN Delivery

EN should be progressively introduced depending on the child's nutritional status and the indications for EN. In the case of digestive disease, CEN can be used after a brief or prolonged period of PN. The first step includes the progressive reduction of the parenteral intake and the stepwise increase of EN according to the digestive tolerance.

The rhythm of EN delivery depends on the underlying disease. Intermittent feeding using bolus is more physiological and well tolerated when the digestive function is normal. Continuous cyclic nocturnal EN is better tolerated in some patients who do not tolerate bolus feeding and provides less interference with daytime oral intake. On the other hand, continuous 24/24 h rhythm of delivery is indicated in the case of impaired digestive function. The weaning period varies from few days to several weeks or months. Eating disorders can be avoided by the maintenance of sucking and swallowing functions during the period of CEN. On the other hand, it has been demonstrated that nonnutritive sucking intervention during CEN in preterm infants resulted in faster transition from feeding tube to oral feeds, better bottle feeding performance, enhanced growth and intestinal maturation, and decreased duration of hospital stay compared to preterm infants without the intervention [163, 164]. In older children, weaning from EN may include a period of continuous nighttime feeding supplemented by several meals in the daytime until the latter account for 50% of the total intake. Oral feeding must be carefully increased because of the relatively low intestinal activity due to long-term CEN.

Complications of Enteral Nutrition Therapy

Although complications occur rarely, they can be quite serious. Strict adherence to the procedure is indicated and careful supervision is essential to prevent them. See Table 45.2.

Table 45.2 Complications of enteral feeding tubes and therapy

Nasogastric	PEG/gastrostomy
Complications during tube insertion	
Arrhythmias	Aspiration
Pyriform sinus perforation	Hemorrhage
Esophagus perforation	Peritonitis
Tube in pulmonary tree/pulmonary intubation	Necrotizing fasciitis (rare)
Pneumothorax	Ileus
Empyema	Fistulous tracts
Gastric perforation	Perforation of viscera
Duodenal perforation	–
Complications when in situ	
Otitis media	Peristomal infection
Sinusitis	Stomal leakage
Epistaxis	Buried bumper
Nasal mucosal ulceration	Gastric ulcer
Pulmonary aspiration	Inadvertent removal
Gastroesophageal reflux	–
Tube dislodgement	–
Functional complications	
Diarrhea	
Clogging	
Knotted tubes	
Contaminated feeds: *Cronobacter* spp. (formally *Enterobacter sakazakii*), *E. cloacae*	
Re-feeding syndrome	
Feeding aversions	

Functional Complications of Feeding Tubes

The functional complications of enteral feeding tubes include tendency to clog, which occurs 18–45% of the time [165]. The risk is higher in smaller-diameter tubes, and the cause of occlusion includes interaction of protein-based formulas with an acidic environment and medications, and complete obstruction from knotting of the feeding tube [165–167]. Clogged NGTs should be readily replaced without the need to apply extraneous efforts to unclog. However, a good effort should be made to unclog blocked nasojejunal and gastrojejunal tubes because they are more difficult to insert. Clogging and occlusion can be minimized by frequently flushing the tube before and after administration of feeds. Water is more effective than carbonated beverages for flushing and unclogging occlusions. Sterile water is preferred for flushing because several published cases of infection were traced to tap water [145]. Persistently clogged tubes despite water flushes may respond to installation of one crushed tablet of Viokase (pancreatic enzyme) in 5 mL water and pH raised to 7.9 using NaOH instilled into the tube using a 50 mL syringe under manual pressure for 1 min, then clamping the tube for 5 min [167]. Other options include trial of meat tenderizer or use of mechanical devices such as Fogarty balloon and biopsy brush. Failure to unclog the tube requires replacement of the tube [145].

Gastrointestinal Complications

Risks and complications start with passage of NGTs, which can be hazardous in any patient, especially those with poor or impaired gag reflex, absent cough reflex, or altered consciousness. Furthermore, presence of a cuffed endotracheal tube is not guaranteed protection against pulmonary intubation. Therefore, feeding should not begin until proper placement of the tube is verified [146]. The bedside assessment tools of visually inspecting for color and testing for pH of aspirates may be inaccurate because small bore tubes may collapse resulting in failure to drawback aspirates, and therapy with gastric acid suppressants may affect the measured pH. The auscultation method is also problematic because sounds may be transmitted to the epigastrium regardless of tube placement in the lung, esophagus, or stomach. Some protocols call for the first feed to be water to ensure tolerance [146]. Overall, abdominal X-ray is the gold standard for establishing location of the NGT tip [150].

Aspiration pneumonia is the most threatening complication associated with NGT feeding [146]. Irregular flow rate of infusion, delayed gastric emptying due to the underlying disease or to medications, GER, tube placement or migration into the distal esophagus, behavioral vomiting, and formula intolerance are risk factors for vomiting and aspiration. The general prevalence of feeding-tube-related aspiration pneumonia is unknown; however, the incidence in critically ill patients ranges from 25% to 40% [163] with both oropharyngeal and gastropharyngeal contents implicated. The risk factors in critically ill patients include decreased level of consciousness, vomiting, malpositioned feeding tube, larger-diameter NGT, and bolus feeding. The preventative measures include keeping the patient in a semi-recumbent position, continuous aspiration of subglottic secretions, and change from bolus/intermittent to continuous EN [168, 169]. Tubes placed past the third portion of the duodenum are associated with decreased risk of aspiration [146].

Diarrhea is the most common complication of EN and is reported in up to 68% of patients [146]. Increased stool losses occur when the combined absorptive capacity of the small bowel and the salvaging capacity of the colon are exceeded (see Ref. [170] for a review of the role of the colon in short bowel syndrome) and may result in dehydration and hypoglycemia. The causes include inappropriate composition of the formula for the underlying disease, high formula osmolality and rate of infusion, intraduodenal infusion, hypoalbuminemia, and bacterial contamination of the formula. The volume of endogenous fluid flux into the jejunum is directly proportional to the osmolality and rate of infusion of the EN [171]. Therefore, since higher osmolality (>300 mosmol/kg) feeds will induce greater endogenous fluid flux into the bowel, their rates of infusion should be increased cautiously.

Mechanical, Infectious, and Metabolic Complications

NGT-related mechanical complications include nasal trauma, laryngeal ulceration, or stenosis, and esophageal or gastric perforations. Duodenal perforations have been reported in association with transpyloric feeding tubes in preterm infants, neonates, and critically ill children regardless of whether they are polyvinyl, silicone, or polyurethane feeding tubes [172–174]. In one series of 526 critically ill children receiving transpyloric EN, the prevalence of GI complications was 11.5%. These included abdominal distension and/or excessive gastric residue (6.2%), diarrhea (6.4%), GI bleeding, necrotizing enterocolitis, and duodenal perforation (0.9%). The major factors associated with risk for developing these complications were shock, epinephrine dose >0.3μg/kg/min, and hypophosphatemia [175]. Therefore, frequent re-evaluation and a high index of suspicion are required in this patient population. Complications from PEG placement may occur during the immediate postoperative period and/or delayed for several days. The postoperative complications include aspiration, hemorrhage, peritonitis, necrotizing fasciitis, peristomal infections, prolonged ileus, fistulous tracts, and inadvertent removal. The delayed complications include site infections, persistent peristomal leakage/irritation, buried bumper syndrome, gastric ulcer, fistulous tracts, inadvertent tube removal, and fungal tube infections, especially affecting silicone tubes leading to tube degradation and malfunction [145]. Children without fundoplication may go through a period of worsened reflux symptoms [176–178] that may respond to slower advancement of EN or necessitate a brief period of change to continuous feeding schedule.

Patients with PEGs placed too close to the pylorus, and 24–30% of children with fundoplication, may develop metabolic dumping characterized by postprandial tachycardia, diaphoresis, lethargy, refusal to eat, gas bloat, and water diarrhea in association with bolus feeds [179–181]. Establishing a screening protocol for postprandial hypoglycemia in patients with history of fundoplication is important because approximately 46% of affected children fail to exhibit symptoms [181]. The diagnosis of dumping is confirmed by a glucose tolerance test showing postprandial hypoglycemia preceded by postprandial hyperglycemia. The management options include initial avoidance of boluses, change to continuous feeding schedule, modification of the EN to avoid

lactose, change to a complex carbohydrate source, supplementation of bolus feedings with uncooked cornstarch [182–185], and in refractory cases, therapy with ascorbate (disaccharidase inhibitor) [186].

Infectious Complications

EN has been associated with outbreaks of antimicrobial-resistant organisms. *Cronobacter* sp. (formally *Enterobacter sakazakii*) is a rare but one of the most important worldwide causes of outbreaks of neonatal sepsis and meningitis associated with non-sterile powdered infant formula or human milk fortifier, and has a mortality of 40% [187]. Ninety-nine percent of affected patients were infants aged <2 months. The infection was acquired by infants in hospital or at home, and the predominant risk factor was the use of powdered infant formula or human milk fortifier [187, 188]. Therefore, the US Food and Drug Administration has issued the recommendation that the use of powdered infant formulas and human milk fortifiers should be minimized in hospitalized preterm or immunocompromised neonates [189]. Ready-to-use commercial formulas are sterile and therefore recommended for EN in hospitals.

Other sources of organisms include post-manufacturer microbial contamination exogenously introduced during manipulation of the formula and through retrograde contamination of the feeding tube system by the patient's endogenous flora. The enteral feed administration sets become colonized externally by microbes grown from the enteral tube hub and may serve as a reservoir of organisms that can be cross transmitted [190–192]. Commercial liquid formulas received from the manufacturer are required by regulatory agencies to be shelf-stable and free of enteric pathogens. The more common sources of organisms are usually exogenous the patient acquired through contamination of locally prepared or post-manufacturer manipulation of ready-to-use formula [190]. Microbial contamination of the enteral tube hub may result from retrograde migration of endogenous bacteria along the tubing system [193], following which nosocomial cross-transmission to other patients may occur when care providers handling the enteral tube hub fail to practice strict infection control procedure [194, 195]. Therefore, adherence to standard precautions is critical when handling enteral feeding apparatuses. The bacterial contamination of the nutritive solution with enterotoxin-producing bacteria like coliforms or *E. cloacae* [192], at the time of preparation, storage, or delivery to the patient, has been associated with gastroenteritis and/or septicemia [191, 196]. The relationship between bacterial contamination of enteral formula and diarrhea may be a matter of debate. When EN is delivered into the stomach, there is a protective effect from gastric acid. Therefore, the risk of bowel contamination is theoretically higher when EN is delivered distal to the pylorus. Since necrotizing enterocolitis (NEC) may occur in premature infants and neonates suffering from hypoxia and infections, the abdomen must be checked daily very carefully. Because of the risk of infectious complications and NEC, using gastric route, avoidance of duodenal infusions, and utilization of ready-to-use preterm formulas are recommended in preterm infants.

Re-feeding Syndrome

This is a metabolic syndrome induced by feeding that occurs in previously starved or chronically malnourished patients. The syndrome is characterized by hypophosphatemia, hypokalemia, hypomagnesemia, arrhythmia, edema, congestive heart failure, and increased risk for death. The incidence of re-feeding syndrome in children is not known; however, it is reported in up to 50% of hospitalized adults documented to be malnourished [197]. It results from rapid anabolism induced by increased insulin secretion in response to provision of nutrients. The increased glucose load, with corresponding increase in the release of insulin, leads to cellular uptake of glucose, potassium, magnesium, and phosphate. This rapid shift in electrolytes from the extracellular to intracellular space results in hypokalemia, hypomagnesemia, and hypophosphatemia. Insulin also exerts a natriuretic effect on the kidneys resulting in sodium and fluid retention. The anabolism may unveil or cause other nutrient deficiencies, for example, thiamine deficiency and beriberi, further leading to life-threatening circumstances [198]. The pre-nutrition therapy determinants of risk for developing re-feeding syndrome include patients underfed or not fed for at least 10–14 days (regardless of therapy with crystalloid intravenous fluids), acute weight loss of >10% in the preceding 1–2 months, severe malnutrition as defined by <80% ideal body weight or weight-for-age z-score <−3 [36], decreased pre-albumin [199], anorexia, marasmus, edematous protein–energy malnutrition (kwashiorkor), children of neglect, cerebral palsy, and other conditions causing dysphagia [198]. The risk for developing re-feeding syndrome is higher during the first 5–7 days of implementing nutritional therapy. The metabolic derangements can be avoided by initiating feeds at a calorie intake of 50–75% of the measured or estimated resting energy expenditure with appropriate supplementation of phosphorus. The calorie intake is then increased by 10–20% per day with close monitoring and correction of biochemical parameters until the calorie goal is met [200].

Home Enteral Nutrition (HEN)

Indications

HEN is a logical alternative to long-term hospitalization when a long-term enteral nutritional support is necessary (more than 1 month) in a patient in stable clinical condition. HEN has been proven to be an effective and safe method, compatible with the best possible quality of life [201–203]. Major cost-savings induced by home EN as compared to hospitalization have been demonstrated. The importance of families' teaching and medical follow-up to prevent somatic and psychological complications should not be underestimated [76].

Organization

The quality of home EN programs depends on the organization of multidisciplinary nutrition support teams based on a tight collaboration between the different professionals including physicians, home care nurses, dieticians, pharmacists, and social workers. In some countries, pumps, disposable equipment, and nutrients for HEN are mainly delivered by hospitals, while in others, such as in the USA where they are the most developed, home care companies participate to patients' training and provide a delivery service and a 24 h emergency phone contact. With expansion of the home care industry, it is important to ensure that adequate standards of care are provided. The American Society for Parenteral and Enteral Nutrition and the British Association for Parenteral and Enteral Nutrition have produced such standards [4, 204].

Parents' Teaching

Tolerance and efficacy of EN should first be assessed in the hospital before transitioning to HEN. As for HPN, HEN in children is feasible only when the family is highly motivated and able to deal with technical aspects. Parent's teaching is based on a nutrition multidisciplinary hospital team including physician, nurse, dietician, and pharmacist. Parents are taught not only about technical aspects but also about risks, complications, and their prevention. The hospital team ensures a 24/24 h phone contact and regular follow-up, in tight cooperation with the general practitioner. The help of a community nurse may be required, especially in the case of placement of a nasogastric tube.

Results

Quality of Life

Although HEN, like HPN, is usually considered by children and families as an improvement of their quality of life, psychological consequences of this technique have to be carefully estimated and prevented. The placement of a NGT is distressing to parents and children. A NGT in situ for continuous 24/24 h infusion is a major problem, particularly in oldest children and adolescents, because it induces an unwelcome public interest. These problems are solved by the use of gastrostomy. Children and families may also suffer from the suppression of meals taken together, which are usually considered as an important moment of the family life. Adequate psychological preparation and follow-up improve tolerance of children and parents to HEN [205, 206].

Outcomes

Outcome studies on HEN patients have been fewer than those on patients on HPN. Improvement of the nutritional status and low mortality rate (always related to major underlying diseases) are usually described in children on HEN [207].

Cost and Funding

HEN is far from being as expensive as HPN. The total cost per day of HEN was about $35 in the USA in 1992, when the cost per day of HPN was about $300 [208]. The cost-savings associated with providing HEN estimated by the British Association for Parenteral and Enteral Nutrition in 1994 were about 70% [204]. In most countries, patients on HEN are funded by the National Health Service, although in the USA they are mostly paid for by insurance companies [204, 209].

Acknowledgment The authors wish to express their gratitude to Prof. Olivier Goulet and Virginie Colomb, authors of the first edition of this chapter, upon which they built the previous and current update.

PN	Parenteral nutrition
PNDD	Primary non-digestive disorders
SBS	Short bowel syndrome

Introduction

Parenteral nutrition (PN) can be defined as the infusion of nutrients directly into the bloodstream, by passing the gastrointestinal tract. PN is a lifesaving supportive treatment in intestinal failure (IF) that should be considered one of the major medical advances of the last century. The use of PN has enabled even the sickest child, including the most premature of infants, to survive whilst the underlying disease is diagnosed and treated. With improvement in PN and neonatal intensive care outcome, the number of infants and children surviving with IF has greatly increased over the last 15 years [1].

IF has been defined as the inability to absorb sufficient fluid and nutrients from the intestine to maintain homeostasis and normal growth and development even when the most suitable enteral nutrition (EN) is given via the most appropriate artificial feeding device for the patient [2]. The three major aetiologies of chronic IF are short bowel syndrome (SBS), intestinal motility disorders and small intestinal mucosal disease.

PN treatment is used not only for IF with an underlying primary digestive disorder (PDD) but also for IF secondary to primary non-digestive disorders (PNDD). PNDD diagnoses include other major organ failure, oncology and immunological disorders as well as organ transplants including bone marrow transplant. Please see Table 46.1 for aetiologies of intestinal failure (IF).

PN should be prescribed and administered in an appropriate clinical setting with multidisciplinary team (MDT) support [3]. Despite the success of well-managed PN treatment, if used incorrectly, there is a potential for harmful effects to outweigh the benefit to the child. Complications of PN can be life-threatening. In other words, PN is not just another drug to be prescribed. The support needed includes a comprehensive laboratory service, nutrition pharmacy, dietetics and microbiology support in addition to specialist medical and nursing skills [3].

When administering PN the aim of treatment is to stabilise the child at the same time as investigating, diagnosing and treating the underlying cause of the IF with the aim of regaining enteral autonomy. In some children with severe underlying disease unresponsive to treatment, long-term PN is continued at home. This chapter will also discuss when to consider intestinal transplant and the rare situation in which

Table 46.1 Aetologies of Intestinal failure (IF)

Primary digestive disorder	Primary non-digestive disorder
Post-operative abdominal surgery	Prematurity
Short bowel syndrome (SBS). Aetiologies include: Necrotising enterocolitis (NEC) Gastroschisis Intestinal atresia Congenital short bowel/ antenatal volvulus Total colonic + small intestinal aganglionosis	Major organ failure For example, neurodegenerative disorders
Protracted diarrhoea with faltering growth Aetiologies include: Tufting enteropathy Tricho-hepato-enteric syndrome Microvillous inclusion disease TTC7a deficiency Other genetically inherited diarrhoea Autoimmune enteropathy Unknown aetiology	Chemotherapy Radiotherapy
Motility disorder: Paediatric intestinal pseudo-obstruction (PIPO) Intestinal dysmotility	Severe trauma Extensive burns
	Bone marrow transplant Systemic immunodeficiencies

it might be more appropriate to withhold treatment when a child has such profound ill health beyond the gastrointestinal tract that prolonging life with PN would increase suffering with no chance of recovery.

The chapter will focus on the use of PN in children and infants beyond the neonatal period. (Please see Chap. 53 for the use of PN in neonates and premature infants.)

Definitions of PN and EN

'Total' PN (TPN) is the term used for infusion of all the individual's nutritional requirements into the bloodstream. 'Partial' PN is an incomplete parenteral infusion of the patient's daily nutrient requirements. In most circumstances partial PN is given.

Intestinal failure (IF) has been divided into three groups: type I IF for acute self-limiting condition, type II when the patient is metabolically unstable and remains PN dependent for weeks or months and type III when a stable patient has a chronic underlying disease and requires long-term PN for months or years. Type III IF patients are usually discharged home on PN treatment [4].

The term EN will be used in this chapter to cover any food or artificial commercially available liquid feed that is taken by mouth or given into the intestine.

History and Development of PN

Attempts to feed directly into the bloodstream have been made ever since the circulatory system was first described by William Harvey in 1628. For example, in 1656 Sir Christopher Wren infused ale and opium into dogs using a bladder and sharpened quill. Survival was limited to a few days [5].

In order for PN to be safely used in the clinical setting, appropriate non-toxic protein, carbohydrate and lipid sources were required in a form that was stable in solution and could be infused directly into the bloodstream. In 1937 the first suitable protein source was developed when a casein hydrolysate was successfully infused in adults. In 1940 a crystalline L-amino acid solution was first used clinically in children. These solutions were eventually available for routine use in the 1960s by which time technical difficulties and high commercial costs were overcome.

Carbohydrate energy sources trialled included fructose, sorbitol, ethanol and glucose. Glucose was metabolically the most appropriate energy source but was associated with venous thrombosis. Then in 1968 Dudrick et al. found that by using a large central vein to infuse glucose, thrombophlebitis was avoided [6]. Despite this success it was not possible to provide sufficient calories with carbohydrate and amino acid alone in a small enough fluid volume for a child's needs. If PN were to be viable, a fat source was needed. An artificial 'chylomicron' composed of soybean oil and egg phosphatides was developed by Wretlind and Schuberth in 1963 [7]. As a result, PN was provided on a commercial basis from the late 1960s. The same soybean lipid is still in use today.

Constituents of PN

PN is a complex mixture of sterile nutrients in a suitable form to be safely infused directly into the bloodstream. It consists of carbohydrate lipid and protein with added electrolytes, vitamins and minerals. In 2018 an expert working group produced comprehensive guidelines on the use of PN in children on behalf of the European Society of Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), the European Society for Clinical Nutrition and Metabolism (ESPEN), the European Society for Paediatric Research (ESPR) and the Chinese Society of Parenteral and Enteral Nutrition (CSPEN) [8–15]. The guidelines provide comprehensive guidance on intravenous formulation and safe infusion.

The standard carbohydrate source used in PN is dextrose. The protein is an amino acid formulation based on egg protein and, in the neonate, on breast milk. Lipid is usually supplied as a separate infusion to which the fat-soluble vitamins, vitamins A, D, E and K, can be added. Water-soluble vita-

mins and trace elements are added to the amino acid and carbohydrate-containing bag.

The PN is formulated to provide the carbohydrate, amino acids and lipid according to the child's nutritional needs taking into account age-related requirements and nutritional status. It is formulated within the stability parameters for the constituents [8–15]. Whilst some constituents of the formulation are relatively stable, others can precipitate when exposed to high concentrations of certain nutrients. For example, sodium concentration can be increased without problem, whereas the concentrations of calcium and phosphate have to be carefully titrated [12]. If PN is made up in a two-bag system with separate lipid, calcium and phosphate are stable in a higher concentration than when in an all-in-one bag that includes the lipid.

For many years soybean was the sole lipid source. However, over the last 10–15 years, olive oil, fish oil and coconut oil have been used. (See Table 46.2 for some of the available mixed lipid emulsions.) Mixed lipid emulsions are the recommended treatment for children who need PN for more than a few days [9].

The advantage of soybean lipid is that it contains the essential fatty acids (EFA) alpha-linolenic acid (LNA) and linoleic acid (LA) in adequate concentration. However, it is relatively low in vitamin E and is a source of phytosterols that have been implicated in the aetiology of intestinal failure-associated liver disease (IFALD) [16]. (Please see IFALD below.) Lipid should represent about 30% of non-protein energy, and linoleic acid should be 1–2% of total energy. The maximum lipid utilisation rate is about 3.3–3.6 g/kg/day. In order to prevent EFA deficiency in term infants and in children, a lipid emulsion dosage providing a minimum LA intake of 0.1 g/kg/day can be given, which also provides an adequate intake of linolenic acid with all ILEs currently registered for paediatric use [9] (see Table 46.2).

Trace minerals and vitamins are available in mixed formulations or can be added individually to PN [13]. They are usually incorporated in bespoke PN during the manufacturing process but need to be added to standard bags prior to infusion. Iron is not routinely included in view of the risk of iron-associated liver cirrhosis. However, iron can be added in children on prolonged treatment who are unable to tolerate an enteral iron supplement [13]. Certain additional substances can be directly added to the formulation such as the non-essential amino acid glutamine and certain medication, such as the H-2 receptor antagonist, ranitidine [15].

Table 46.2 Examples of parenteral nutrition lipid solutions[a]

Clinoleic 20% (Baxter): 20% soybean oil, 80% olive oil
Intralipid: 20% (Baxter) pure soybean oil
Lipidem (B. Braun): fish oil, olive oil, soybean oil
Lipofundin (B. Braun): medium-chain (MCT) and long-chain triglycerides (LCT) MCT/LCT®: 20% 1:1 weight, soybean and coconut oil
Omegaven 20% (Fresenius Kabi): pure fish oil[b]
SMOF lipid® 20% (Fresenius Kabi): 30% soybean, 30% MCT, 25% olive, 15% fish oil

[a]These are examples and not a comprehensive list
[b]Omegaven is not licensed for sole lipid use and should be given alongside another lipid infusion other than in exceptional short-term circumstances

PN should be formulated in a licensed compounding unit. The unit should have access to their own stability data based on available guidelines from national and international guidelines [3]. An automated system in a specialised sterile unit is usually used to mix the PN ingredients according to international pharmaceutical standards. The final formulation is supplied in a sealed sterile bag. The nutrients for a 24- or 48-h period are contained within one or two bags. If in two separate bags, one will contain the amino acids, dextrose and electrolytes, either with or without added trace elements and water-soluble vitamins; and the other lipid- and fat-soluble vitamins.

Stability of the PN formulation can be a major problem in children when compared to adults since the child has a relatively high calcium and phosphate requirement: two salts that readily precipitate [12].

Types of PN Formulations and Pharmacy Arrangements

1. A standard age and body weight-appropriate bag. Standard pre-prepared commercially available bags are the treatment of choice for all patients other than those with complex intravenous needs [17]. The lipid emulsion and solution containing amino acids and dextrose are usually in two separately sealed compartments of the same bag. The user can break the seal between the two (so that the bag becomes one) if the patient requires both to be infused or just infuse the amino acid and dextrose and discard the lipid section. If the patient requires extra electrolytes, a certain amount of, for example, sodium can be added to certain bags immediately prior to infusion, preferably in a sterile compounding unit in the hospital pharmacy. Vitamins and trace elements usually need to be added to the bags or given enterally. Most patients even with profound IF can absorb sufficient vitamins and minerals unless totally nil by mouth or high gastric losses. The manufacturers' instructions need to be followed with regard to additions. Standard bags can have a shelf life for several days, weeks or months, and some can be stored at room temperature. There are an increasing variety of standard paediatric bags available.

2. Individually formulated/bespoke PN bags are the most appropriate treatment for unstable hospitalised children with unpredictable variation in daily fluid and electrolyte needs. They are usually prescribed and manufactured on a daily or 48-h basis according to the patient's requirements. The 'shelf life' of these bags is usually approximately 48–96 h. This bespoke PN is normally made up as two separate bags: (1) amino acid and dextrose with electrolytes, trace elements and water-soluble vitamins and (2) lipid with fat-soluble vitamins. The pharmacy manufacturing of PN is usually within the hospital.
3. Certain PN manufacturing pharmacies have sufficient expertise and stability data to provide individually prescribed PN with prolonged stability for up to about 4 weeks. All-in-one bags with the lipid, vitamins and minerals in a single compartment together with the amino acids and dextrose are manufactured to the patient's needs. There will be a gradual breakdown of certain vitamins, for example, photo-degradation of vitamin A during storage. However, with regular (usually 3 monthly) monitoring of blood levels, vitamin levels can be maintained in the normal range. These pharmacies usually supply PN to patients with chronic IF on long-term treatment who are at home [18].

When to Start PN

It is essential that all attempts are made to feed a child enterally unless contraindicated, e.g. intestinal obstruction or ileus post-gastrointestinal surgery, prior to commencing PN. Once the need for PN has been established, it usually needs to be commenced promptly. Nutritional support should be begun within 1–5 days if a child is unable to tolerate EN and is not expected to recover intestinal function within the next few days.

Exceptions to early PN introduction are the acutely unwell child with multi-organ failure and children in intensive care during the first week of admission. A randomised controlled multicentre trial of 1440 children admitted to intensive care recorded a significantly better outcome for children if PN was delayed until the second week [19]. However, the children were given micronutrients, i.e. vitamin, mineral and trace element supplements during the first week.

How to Start PN

When starting PN the child's age, weight and length/height, nutritional state, intestinal losses, other infusions, any enteral feed and fluid tolerance all need to be taken into account. It is usually the best practice to stabilise the patient and start PN during normal working hours (other than in the premature neonate). (See Table 46.3 for the steps that need to be taken when commencing PN.)

Table 46.3 How to start parenteral nutrition (PN)

1. Obtain secure central venous access
2. Assess maintenance fluid and electrolyte requirements from patient's length/height and weight[a] (estimated height/measurement in the last 3 months may be used if the child is critically ill and can't be measured)
3. If uncertain of accurate weight, e.g. fluid overload and not possible to accurately measure the child, check mid-upper arm circumference (MUAC)
4. Check whether there are cardiovascular, respiratory and/or renal abnormalities that might limit fluid tolerance and hence volume of the PN infusion
5. Check blood electrolytes, Ca, PO4, Mg and urine Na, and adjust electrolyte levels in PN accordingly
6. Add extra fluid and electrolyte requirements for excessive intestinal losses, or if the losses are highly variable, give as a separate infusion
7. Subtract volume of other treatments infused, such as Na, fluid and dextrose infused with, e.g. inotropes and antibiotics[b] If the child has residual absorptive capacity and remains on partial EN, the volume and nutrient content should be taken into account as well although only partial absorption is usually assumed
7. Prescribe PN using the fluid volume available adding nutrients according to the pharmaceutical guidelines for concentrations of constituents
8. Day 1: start with 60% requirements, and increase to full PN constituents prescribed over 4–6 days in order to limit risk of refeeding syndrome
9. Obtain appropriate equipment for infusing PN: a giving set to connect the central venous catheter to the bag of PN + an infusion pump
10. Place a filter in the giving set: Lipid emulsions and all-in-one mixes membrane pore size of 1.2–1.5μm Aqueous solutions 0.22μm
11. Monitor weight and blood electrolyte levels on a daily (or twice daily) basis for the first 5–7 days

[a]Parenteral fluid and electrolyte requirements are prescribed using the child's weight. However, the actual weight in a sick child may be overestimated if the child is fluid overloaded or under-estimated if there has been weight loss. By plotting the height/length on the centile chart, the appropriate weight for the child can be estimated, i.e. the same centile for age as the height. The patient's PN can then be prescribed using that weight as the prescribing/working weight. If the weight is very different to the child's current weight, e.g. the severely under-nourished/wasted child, a weight between the actual and expected weight can be used in the first instance and gradually increased towards the expected weight as the child's nutritional state improves

[b]Children in intensive care often have restricted total fluid intake and require other intravenous infusions in addition to PN. It may not be possible to give the required nutrients in the volume available for the PN infusion. Once the child improves clinically, fluid restrictions and infusion volumes are eased and the PN can be increased

Venous Access for PN Infusion

In order to safely administer PN with a sufficiently high concentration of nutrients for a child to thrive, the PN needs to be infused through a central venous catheter (CVC). The tip of the catheter should be sited low in the superior vena cava above the pericardial sac (or above the first lumbar vertebra, i.e. above the renal veins if inserted via a femoral vein) [20]. The appearance on the chest x-ray should be with the tip 1 cm above the carina in the older child and 0.5 cm in smaller children and infants [20]. The catheter is usually placed via the internal jugular, subclavian or femoral vessels or via a peripheral vessel. The femoral veins are less suitable than the superior vessels, since the exit site is in the nappy area and susceptible to faecal contamination (unless the catheter is tunnelled under the skin). In general, the CVC should be tunnelled under the skin to reduce the risk of skin microbiota infecting the bloodstream [20]. Ideally a single-lumen catheter should be used in order to limit the risk of infection. In certain children who depend on multiple intravenous infusions, a double-lumen catheter may be required. Catheters made from silicone or polyurethane should be used in preference to those from other materials since more flexible. A cuffed catheter is preferred to hold the catheter in situ with subcutaneous positioning of the cuff. However, an uncuffed peripherally inserted central catheter (PICC) with the tip centrally placed can also be used, particularly if it is likely to only be needed for several days or a few weeks rather than for several months. The major advantage of an uncuffed catheter is that it can be removed without the need for general anaesthesia. Although the use of a PICC is only recommended for a few weeks, it is possible for a PICC to function successfully for longer, even in children at home on PN.

A subcutaneous PORT is not usually appropriate for PN infusion since access is via a transdermal needle that remains 'in situ' when it is used [20]. If the needle becomes dislodged, the PN may be infused into the tissues with significant tissue damage that can require plastic surgery. The needle should be checked regularly during infusion which is not feasible in a child cared for by parents at home.

It is the best practice to insert the central venous catheter (CVC) under radiological control in order to minimise damage to the blood vessel during insertion. Limiting vascular damage is particularly important if the patient might require long-term PN. Loss of patency of major blood vessels is one of the indications for referral for intestinal transplant.

In some children on long-term home treatment, the CVC can remain 'in situ' for 8–10 years or longer. The CVC may eventually need to be changed routinely when the tip becomes displaced from the superior vena cava due to the child's growth. There is a risk of the CVC becoming embedded in the wall of the blood vessel with the need for removal by a vascular surgeon. In view of this risk, elective CVC change may need to be considered before 10 years in situ. Ideally the CVC should be dedicated to the infusion of PN in order to preserve patency and minimise the risk of CRBSI. In children who have had frequent cannulation of blood vessels and/or excessive anxiety associated with venepuncture, it may be extremely difficult to obtain blood samples from a peripheral vein. The distress and/or time attempting peripheral venous access may outweigh the potential complications of using the CVC for blood sampling and/or other infusions.

PN Infusion and Cycling

1. The PN should be infused via a pump. In hospital static pumps are used, whereas the child at home benefits from a portable pump with a backpack for the PN bag itself [18]. The pump should be positioned within 30 cm of the heart. The infusion should pass through a 1.2-μm filter if a lipid contains infusion and a finer 0.22-μm filter if lipid-free [3]. The infusion is usually over 24 h when PN is commenced.
2. As soon as the child is sufficiently stable, a reduction in infusion hours should be trialled. Infants weighing under about 4.5 kg are unlikely to tolerate even 1 h off PN unless they are absorbing at least 20–30% of nutrients enterally. To start cycling PN, the infusion rate should be 'wound down' during the final hour of infusion in order to limit the risk of hypoglycaemia. The initial wind down would be to reduce the PN rate to 50% for 30 min and then 25% of the original rate for the final 30 min after 22 h of infusion and to have 1 h free from the infusion. The blood sugar level should be checked during the hour off PN. If there is no evidence of hypoglycaemia, the PN can then be reduced by a further hour every few days aiming for 12 h of minimum infusion.

Monitoring on PN Treatment

The key to successful treatment with PN is careful monitoring. Monitoring should include clinical observations, urine and blood biochemistry and haematology and anthropometry. (Please see Table 46.4 for details.) Patients should also have daily medical and dietetic review.

Role of the Nutrition Support Team

It is important to bring all professionals contributing to the management of the PN together to work as the nutrition support team (NST) [3]. The team usually comprises specialist

Table 46.4 Monitoring the hospitalised patient on PN treatment

Clinical observations: Temperature, heart rate, respiratory rate, blood pressure, 6 hourly minimum
Ward urine analysis: Glucose and ketones until stable[a] Re-start checking urine ketones if PN glucose concentration increased
Weight[b] (ideally on the same scales and at the same time of the day): Daily for 5 days (twice daily if excessive fluid losses/difficult fluid balance) Twice weekly once stable and then weekly
Blood sodium, potassium, urea, creatinine, calcium, magnesium phosphate, liver function, full blood count and triglycerides: Minimum daily for 5 days Twice weekly once stable and then weekly
Urine sodium[c]: Twice weekly and then weekly once stable Re-check 24–48 h after increasing sodium in PN if level was previously low
At start of cycling PN: Check blood glucose regularly, e.g. initially at 30 min intervals after stopping the infusion
Long-term in-patient treatment > 27 days repeat 4–6 weekly: Zinc, copper, selenium + CRP Vitamins A and E, clotting studies, vitamin D Ferritin, iron, TIBC Anthropometry: length/height, weight, mid-upper arm circumference Head circumference in children <2 years of age
1. *PN treatment > 3 months consider*: Thyroxine, thyroid-stimulating hormone (TSH) Carnitine Vitamin B 12

[a]The maximum infusion rate of glucose through a central vein should be 1.0–1.5 g/kg/h; if greater than this, glycosuria is highly likely
[b]In certain conditions when fluid balance is altered, weight may not be a useful measure. For example, children in renal failure or with low blood albumin may retain fluid within the body tissues and those with intestinal pseudo-obstruction may 'pool' fluid within dilated intestinal loops
[c]inaccurate if on diuretic treatment

physicians, pharmacists, dietitians and nurses with access to a microbiologist, laboratory support and additional professionals as required. There could be a need for a paediatric surgeon, psychologist, social worker and/or speech therapist.

The overall aim of treatment with PN is to support appropriate weight gain and growth whilst minimising complications (related to underlying disease as well as to PN) and aiming for intestinal autonomy.

Roles of the team include reviewing individual patients on PN treatment, education, setting local guidelines and following international guidelines.

All children receiving PN treatment should be reviewed on a regular basis and at least weekly by the NST [21]. The team may either prescribe or advise the medical team caring for the patient. The NST will participate in ensuring the child gains and maintains a good nutritional state, participate in managing the complications of PN and encourage and support weaning from PN if achievable. They will usually support the patient through four phases of treatment:

1. Stabilise the patient.
2. Aim for appropriate weight gain—usually 'catch up' weight gain required.
3. Maintain weight centile appropriate for patient's length/height.
4. Withdraw/wean PN and give increasing volume of oral food or liquid enteral nutrition.

The most important complications are described below:

Complications of PN

The most frequent complications associated with PN are metabolic, inappropriate weight gain, infectious, catheter-related, liver disease and thromboembolic disorders. Each of these problems will be discussed below.

Metabolic Disorders

Common metabolic problems are refeeding syndrome, electrolyte abnormalities and inappropriate weight gain. Initial PN complications are most commonly related to fluid and electrolyte imbalances [22].

Refeeding syndrome develops when full nutrition is commenced too rapidly after a period of extremely poor nutritional intake. As the body changes from catabolism to anabolism potassium, phosphate and magnesium are taken up into the cells with a rapid reduction in blood levels. If severe, refeeding syndrome can be life-threatening. The maximum possible phosphate will be needed in the PN. An oral or peripheral blood infusion of phosphate and/or potassium may be required alongside the PN if the amount required exceeds the concentration that is stable within the pharmacy guidelines for PN formulation.

Inappropriate Weight Gain

Inadequate weight gain is a frequent problem with PN. Four possible reasons are (1) fluid restriction, (2) infusing a lower volume of PN than that prescribed, (3) under-prescribing and (4) negative sodium balance or low total body sodium.

It may not be possible to infuse sufficient volume of PN to supply adequate calories and protein in the critically ill child with other major organ failure even when the PN formulation is at the maximum concentration when the child is fluid restricted. The child may only tolerate limited fluid volume, and a proportion of the fluid that they can have may be taken up with other infusions such as inotropes and antibiotics. It may be necessary to infuse the medications in the minimum

possible fluid volume and to ensure that whenever possible medications are prepared in 10% dextrose to maximize calorie intake.

Secondly, the volume of PN actually infused is often less than the volume prescribed. For example, the PN infusion may be stopped to infuse other treatments through the same CVC lumen. The length of time taken for those infusions needs to be taken into account when calculating the rate of the PN infusion to ensure the total PN volume required is prescribed in the hours available.

The PN prescription is usually based on body weight. It is important that the prescriber uses the patient's expected weight for length/height rather than the actual weight. If the weight centile is significantly lower or higher than the length/height centile the appropriate weight for height should be estimated, i.e. check the child's height/length centile on the growth chart and use the weight for the equivalent centile to the height/length for calculating PN requirements (see Table 46.4).

Low total body sodium is another frequent longer-term problem, particularly when intestinal stoma sodium losses have not been adequately replaced. Measurement of urine sodium is one of the most helpful investigations in the absence of diuretic treatment or renal failure. Patients with a low urinary sodium level, < 10–20 mmol/l, may have a low total body sodium and are unlikely to gain weight appropriately [23]. Extra sodium may need to be added to the PN infusion. If a patient is weaning from PN, the sodium supplement is best given enterally.

It is also important to be aware of over-feeding. Excess nutrients and in particular carbohydrate and lipid have been associated with liver disease [24] and carbohydrate with increased carbon dioxide production and worsening respiratory function [8].

Infection

Infection associated with PN may be a bloodstream infection related to the catheter, a catheter-related bloodstream infection (CRBSI), infection of the skin and/or sub-cutaneous tissues around the catheter exit site or rarely in the PN formulation itself.

CRBSI is one of the most common potentially life-threatening PN complications. In order to minimise the risk of the child becoming seriously unwell, the condition needs to be recognised as soon as it starts to develop and treatment commenced without delay. Symptoms include a fever of 38 °C or higher or other signs suggestive of septicaemia in that particular child (some children do not have a high temperature even with CRBSI). Blood for culture should be taken via the CVC and if possible peripherally as well. At least two broad-spectrum antibiotics should be commenced to treat potential gram-positive and gram-negative bacterial infection. The antibiotics need to be administered via the CVC. If there is more than one lumen, then treatment should be rotated between the lumens in order to eradicate the infection. Once cultures are available, the antibiotic regime should be tailored according to the bacteria detected. For example, if the organism is only cultured from one lumen, then treatment should only be given via that lumen. In children (other than neonates or those with a significant immunodeficiency), the antibiotics can be stopped if cultures are negative after 48 h. PN should be continued whilst treating the infection unless the child develops severe cardiovascular compromise when the infusion is commenced. A 'Y' connector needs to be attached to the 'giving set'/infusion tubing for antibiotic administration.

In order to limit the risk of CRBSI, the CVC connections and disconnections should be kept to a minimum and only done by trained professionals. The CVC hub should be cleaned with 2% chlorhexidine when connecting and disconnecting the CVC [25]. The skills of professionals who access CVCs should be regularly reviewed and updated as necessary.

There is also the risk of infection of the skin at the catheter insertion site that can track along the subcutaneous portion of the catheter. If insertion site infection fails to respond to antibiotic treatment, the catheter may need to be removed. Rarely the PN formulation itself can be contaminated during the manufacturing process despite all the sterile pharmaceutical precautions taken. Treatment strategy would be the same as for CRBSI. The child is of course also at risk of the usual acute childhood infections.

CVC Occlusion and Venous Thrombosis

Catheter-related complications include catheter blockage, breakage and displacement. Central venous catheter (CVC) occlusion may occur with deposition of lipid and/or calcium and phosphate precipitates within the lumen. Obstruction can also be positional if the tip of the CVC rests against the wall of a blood vessel. Occlusion may be cleared with alteplase, urokinase or alcohol line lock [26]. Limiting lipid infusions to two or three times a week helps prevent CVC occlusion related to fat deposition.

Thrombosis is a rare but potentially serious complication. It may involve the catheter itself or blood vessels. It can present with difficulty when flushing the catheter. A child with superior vena caval obstruction may have facial puffiness. Ultrasonography is used to diagnose smaller vessel thrombosis whilst venography is required for diagnosis of major vessel blockage. If the catheter alone is thrombosed, a streptokinase or urokinase flush may be used. Alteplase and interventional radiological techniques may be required to

unblock major venous thrombosis. If treatment is unsuccessful and there is loss of access to four or more major veins, intestinal transplant assessment is needed [27]. Pulmonary embolus (PE) is a rare complication that should be considered in the child on PN treatment who is acutely unwell with no clear aetiology or classical PE symptoms[28].

Liver Disease

A common and potentially life-threatening complication is IF-associated liver disease (IFALD). Risk factors of IFALD include prematurity, lack of enteral intake, recurrent CRBSI, other infections, length of time on PN treatment, overfeeding, intestinal bacterial overgrowth, certain drug treatment and certain components of PN [29]. Constituents of PN solutions implicated include a high carbohydrate load and the soya component of lipid. Soybean contains phytosterols that have been associated with liver disease by inhibiting bile acid secretion [16]. Management strategies for limiting IFALD are shown in Table 46.5. Reducing the hours of PN infusion and limiting lipid to alternate days appear to improve liver function [26]. The use of newer mixed lipid emulsions (see Table 46.2) including olive oil, MCT and/or fish oil as well as soybean has also been associated with less IFALD [30]. Safety data using mixed lipid types have been published for premature infants and children [31]. When affected patients have changed to pure Ω-3 fish oil-based lipid (Omegaven 10%, Fresenius Kabi) infusions, severe cholestasis has improved or even resolved [32].

Table 46.5 Management to minimize intestinal failure-associated liver disease (IFALD) [9, 24, 29, 30]

1. Introduce enteral feed at the earliest opportunity Enteral feed should be continued for intestinal integrity in addition to the protective effect on the liver even if only small volumes are tolerated
2. Cycle PN at the earliest opportunity (see infusion section above)
3. Administration of a mixed lipid emulsion with a good omega 3/omega 6 ratio including fish oil: If totally dependent on PN, ensure minimum LCT lipid for adequate essential fatty acids If PN needed for >14 days, use a mixed lipid emulsion In cholestasis avoid pure soya lipid even if PN is only needed for a few days Limit the lipid infused or stop completely if patient is tolerating some enteral nutrition or unlikely to need the PN for > a further 14 days Reduce the number of lipid infusions/week to, e.g. alternate days or just 2–3 times/week at the earliest opportunity
4. Treat any underlying infection promptly: Even with appropriate treatment, there may be a temporary increase in liver enzymes with CRBSI or other intercurrent infections
5. Consider ursodeoxycholic acid at 10 mg/kg TDS
6. If there is evidence of intestinal bacterial overgrowth, investigate and treat

Enteral feeding even if less than 10% of the total energy intake is an important factor in preventing/reversing cholestasis [29]. Ursodeoxycholic acid may be beneficial although it is not always well tolerated. Small intestinal stasis can be associated with bacterial overgrowth and if present should be treated [30]. Copper and manganese are usually excreted in the bile and can become hepatotoxic in cholestatic patients. Please see Table 46.5 for management strategies for limiting IFALD.

If IFALD is persistent and worsening, early referral for assessment by an intestinal transplant centre is recommended [2].

Enteral Nutrition and Weaning from PN

Enteral autonomy is usually achieved in four stages:

1. On starting PN aim to stabilise the patient.
2. Aim for appropriate weight gain on PN—usually 'catch up' weight gain required.
3. Maintain weight centile appropriate for patient's length/height.
4. Withdraw/wean PN and give increasing volume of oral food or liquid enteral nutrition.

The aim is to give a mixed diet by mouth with the range of foods and amount eaten tailored to the patient's enteral tolerance with the ultimate aim of weaning off PN and onto diet alone.

Enteral nutrition is given alongside PN in two contexts:

1. Early introduction of oral food or EN as trophic feeds should be given alongside PN treatment if at all possible [3]. The major benefits of minimal/trophic enteral nutrition include:
   - Prevention of intestinal mucosal atrophy
   - Maintenance of the enterohepatic circulation (see Table 46.5)
   - If given by mouth, retention of feeding skills

However enteral nutrition will need to be limited if there are significant adverse consequences such as excessive fluid losses, vomiting or abdominal pain associated with its introduction.

2. Secondly, once a child is tolerating EN well, the possibility of increasing EN and weaning from PN is considered. At this stage the child should be in an improved nutritional state. The aim should be to reduce the PN and give the maximum EN tolerated.

It is important to be purposeful when weaning. There are a variety of weaning strategies that can be used. Please see Table 46.6.

Table 46.6 Strategies for weaning PN [3, 33]

The speed of weaning from PN varies widely: If severe IF, feed volumes may need to be increased slowly, according to the digestive tolerance, e.g. an increase of 1 ml/h every 24 h Some other children can abruptly return to full nutrition over a few days Children with chronic IF on PN at home will often need gradual introduction of enteral nutrients over weeks or even months, e.g. severe SBS
The weaning plan should be made with the MDT
Ensure parents are aware of the risk of continuing PN versus the benefit of weaning Involve the parents/carers in drawing up the weaning strategy
The smaller infant will almost certainly need an artificial feeding device: the volume of feed needed to wean is usually so great that the child will not willingly ingest sufficient orally
Maximise absorptive ability with a liquid enteral feed given continuously via tube feeding with a volumetric infusion pump or 2 hourly boluses in a small infant
Allowing the older infant to breast/bottle-feed and have solid food and the child to eat and drink rather than giving a liquid enteral feed is usually more successful
If oral feeding is contraindicated, a liquid enteral feed should be given
Make one change at a time
In the first instance, avoidance of common dietary antigens can be beneficial, e.g. avoidance of cow's milk, egg, wheat and soya. Slow onset/non-IgE-mediated food allergy is common in infants with an enteropathy and in SBS secondary to NEC or volvulus probably subsequent to ischaemic damage
Prioritise the weaning rather than risking setbacks by introducing a new food that precipitates symptoms that interfere with the weaning process. Once the PN has stopped, the diet can be expanded again
Offer food little and often. A child with ultra-SBS may not tolerate a full meal
It is usually possible to stop a night of PN if clinically stable on about 50% requirements enterally
If the child is lethargic the day after a night without PN, the most common problem is sodium deficiency [33]: 1. Check urine sodium the a.m. after the night off PN 2. Give oral/enteral NaCl (1 mmol/ml) usually starting with 1–2 mmol/kg 3. If larger amounts Na needed 30% NaCl (5 mmol/ml) can be used
If the child has large intestinal fluid losses and poor fluid intake, oral rehydration solution may be more appropriate than a concentrated sodium solution
If high output, proximal stoma/jejunostomy trial double concentration Dioralyte/oral rehydration solution [34]
Never be complacent about the child's safety on PN even if they have not had any significant complications such as CRBSI. There is always a risk whilst the CVC is in place

The child's weight needs to be checked regularly, for example, twice weekly in the hospitalised child and once a month in the child weaning slowly from PN at home. It is important to be aware whether the child can afford to lose weight during the weaning process. Many children on PN are kept on a centile that is above their height/length centile. It is acceptable for their weight to fall to the equivalent centile to their height when weaning. As long as the child was initially in a good nutritional state, it will not harm them to lose weight at the time of weaning.

When weaning the older infant or child, it is usually best to reduce the volume of the PN first, and the child will then hopefully start to eat and drink more (or if on a liquid enteral feed, tolerate an increase in volume). The PN is often best reduced gradually, e.g. by 10% increments initially. Once the child is managing about 50% of requirements enterally, a whole night without PN can be considered in a child who can eat and drink. If the child is dependent on a liquid feed, the reduction might be continued more gradually.

Failure to Wean from PN as Expected

When it is not possible to wean a child from PN who appears clinically ready to do so, the following investigations should be considered:

1. Re-check urine Na since this is a good indicator of total body sodium (unless on diuretic treatment) + urine specific gravity. Check the first sample after disconnecting PN in the morning. If low, start an oral/enteral Na supplement. A child with a low total body sodium is unlikely to thrive [23].
2. Dietary assessment by a dietitian with IF experience.
3. Faecal reducing substances for sugar malabsorption if watery diarrhoea/high stoma losses.
4. Stool elastase for pancreatic malabsorption.
5. Intestinal endoscopy with mucosal biopsies for histological (and in certain cases electron microscopy) examination.
6. Urine organic acids should be checked for bacterial metabolites and blood for D-lactate and consider H2 breath test since intestinal bacterial overgrowth may present with worsening gastrointestinal symptoms and lethargy.
7. Consider a radiological contrast study to exclude strictures and other abnormalities particularly in the child who has had previous intestinal surgery.
8. Consider the possibility of fabricated or induced illness. If suspected, one-to-one 24 h nursing care may be needed as well as limiting the mother's involvement in the child's care.

Preparation for Home PN: Care in Hospital

Whilst most patients wean from PN regaining intestinal function within days or weeks of starting PN treatment, there are a small number who become dependent on PN for longer. These children should be considered for discharge home on treatment with PN if after extensive investigation and treatment by a specialist multidisciplinary paediatric gastroenterology service, it is not possible to significantly improve the

underlying disease, and the IF is expected to persist for at least two further months. Every attempt should have been made to wean the child from PN using the most appropriate type of feed given via the most suitable feeding device. The patient should be assessed by the IF rehabilitation service for home PN if not already under their care.

Many services will discharge an infant home from about 4 months of age at which stage the infant should tolerate several hours off the PN infusion. However, some services discharge even younger infants once they are stable, even when still on continuous PN [35]. The use of portable pumps has improved mobility for children when connected to PN. Most infants are able to tolerate a 10-h period without PN from about 4.5 kg (if weight is in the normal centile range for age), depending on their enteral tolerance and nutritional state.

The aetiology of chronic IF requiring long-term/home PN is most commonly short bowel syndrome (SBS). Infants with ultra-SBS, i.e. with < 10 cm in length of post-duodenal small intestinal remnant after surgical resection will almost certainly require long-term/home PN. Home PN is also needed for children with other PDD and for some PNDD such as life-limiting severe immunodeficiency, chronic graft versus host disease post bone marrow transplant and IF secondary to severe neurological impairment, please see Table 46.1.

Treatment at home with care by parent(s)/carer(s) who have been formally trained to administer PN and instructed what to do if complications arise gives the child the best chance of long-term survival with minimal complications [18]. It has been clear for some years that the advantages of homecare include improved quality of life, reduced incidence of CRBSI [36] and IFALD, improved psychosocial circumstances and reduced cost of treatment [18]. The aim of PN at home should be to incorporate the child's care into the family's lifestyle and not to have a 'hospital at home'. The child can attend school and participate in other childhood activities including swimming. It is also possible to enjoy family holidays again. Most parents will return to their previous employment.

However, the home environment needs to be a safe place for PN administration. Ideally there should be running water easily accessible from the child's bedroom, reliable electricity supply and sufficient space to connect/disconnect PN. At least one parent/caregiver (and if at all possible two) should to be formally trained. In certain circumstances a nurse may visit the home to connect and disconnect PN, twice daily. Appropriate social support should be organised (including financial support in many countries) and arrangements for appropriate home equipment including a portable pump. In many countries a homecare company supplies the PN and related equipment. Ideally PN should be supplied in a single bag that includes the lipid with the vamin-dextrose to simplify care with only one infusion pump needed. Shared care should be set up with the most local hospital to the child's home and the specialist centre (if the specialist centre is not close to the families' home) in order to ensure treatment can be started promptly for emergencies such as suspected CRBSI [18].

The current UK guidelines recommend that a viable home PN service should manage at least 10–20 patients with an MDT [37]. The composition is similar to the hospital MDT described above. Table 46.7 gives details of the steps needed to arrange transition from hospital to homecare. Good communication is essential for successful management of PN at

Table 46.7 Preparation for discharge home [18]

1. The patient's hospital team and the IF rehabilitation team need to meet to ensure treatment is rationalised to the simplest possible management plan
2. The IF rehabilitation doctor and nurse should meet with both parents (unless the father is unknown), even if they live apart It is important to establish the need for both parents to be involved in the child's care It also gives the home PN team the opportunity to explain the child's condition and future care plan and prognosis to both parents It is best to train both parents even if one of them will lead on care The other parent should aim to do at least one connection/disconnection each week to maintain skills
3. If there is only one parent available, a second relative may be prepared to be trained in order to support the single parent. If parents are physically unable to perform the procedure, a community-based nurse may do so
4. Aim to reduce PN infusion time to a minimum of 12–14 h overnight if possible
5. Ensure good venous access with single-lumen tunnelled CVC. A PICC line can be used at home if functioning well. Doble lumen CVC may be used if other intravenous infusions also required.
6. Arrange a home visit to check facilities for managing PN: Running water easily accessible from the child's bedroom Reliable electricity supply Sufficient space to connect/disconnect PN Space for a dedicated fridge to store PN bags (may be outside the house)
7. Arrange funding and source a home PN supplier: Arrangements vary from country to country. Currently, in the UK, there is a national framework for home PN with central government funding In many countries (including the UK), a commercial homecare company manufactures and delivers the PN, and ancillary equipment including the fridge to the patient's home The PN formulation should have a minimum of 7 days of stability and preferably 21–28 days Deliveries limited to twice monthly if sufficient stability available
8. A specialist nurse should undertake the training programme with the parent(s) or carer(s) to cover the process of connecting and disconnecting PN and a plan of what to do when complications arise: The parent/carers need to be available for a 30-h training programme over a 10-day period Training may be completed sooner or in some cases take longer In the unlikely event that a parent fails to train, they may be offered a second training period after discharge home and watching their partner or a nurse connecting/disconnecting for a few weeks A one-person aseptic non-touch technique (ANTT) for connecting and disconnecting the catheter enables just one parent/carer to perform the connections and disconnections in the simplest manner possible
9. Shared care needs to be formally set up with the most local hospital for acute medical emergencies (e.g. suspected CRBSI or CVC displacement): Parents would usually continue to connect and disconnect the PN and connect other infusions/antibiotics to limit risk when in hospital

Table 46.7 (continued)

10. A discharge date should be set and a pre-discharge meeting arranged via video, telephone or face to face with parents present Attendees include the IF rehabilitation team specialist doctor and nurse, a community nurse, a local hospital consultant, parents and other professionals as needed. Please see Table 46.8 for meeting agenda. Minutes should be sent to all participants including parents
11. The child should be discharged home as soon as the parent/carer training has been completed (unless intercurrent medical problems arise) and if feasible after a 48-h period of self-care in hospital

Table 46.8 Points for discussion in the discharge meeting [33]

1. Patient's clinical history
2. Patient's current medical needs
3. Date of local hospital and IF rehabilitation team first out-patient clinics
4. Background information about the home PN service (non-specialist professionals may have never dealt with home PN before)
5. Create an action plan for parents to follow if/when problems arise: Fever or other symptoms suggestive of CRBSI Blocked, broken or displaced CVC
To discuss any psychosocial concerns and plan for support if needed
To ensure the different professionals and the family know how to contact the specialist centre
To arrange a date for a follow-up meeting 3–6 months after discharge should it be needed

home. A pre-discharge planning meeting is instrumental in setting up good homecare. Please see Table 46.8 for the meeting agenda.

Management at Home

Once established on PN at home, the focus is to ensure the child thrives with appropriate weight gain. At the same time, there are two main aims of treatment: firstly, to wean off PN by introducing enteral nutrition (EN) at the earliest opportunity and, secondly, to ensure that the child has the best possible quality of life whilst on PN.

Regular monitoring is essential to ensure treatment is given in the most efficient manner possible, to prevent complications (and if any do occur to detect them at the earliest opportunity) and to document changes in the patient's overall clinical condition [18].

Monitoring needs to include the patient's weight gain and growth, any metabolic abnormalities, infection, and liver and thromboembolic disorders [18]. Routine blood tests can be done as infrequently as once every 3 months in the stable child on PN at home.

Complications of Long-Term/Home PN and Their Management

Children at home are susceptible to the same complications as children on short-term hospital PN but are less likely to have certain metabolic problems and have some additional longer-term issues. The most common longer-term PN complications are CRBSI, displacement, breakage or blockage of the CVC, metabolic bone disease and IFALD [38].

Parents/carers should have the details of the nearest acute paediatric centre to take the child to have a blood sample taken for culture and two broad-spectrum antibiotics commenced if CRBSI is suspected. Treatment should be rationalised once a positive blood culture is available and stopped if the culture is negative after 48 h (see CRBSI above) after discussion with the specialist IF rehabilitation service.

In patients who have > one CRBSI at home, prophylactic anti-bacterial line locks such as taurolidine [39], ethanol or EDTA [40] should be considered.

The local acute paediatric service would usually manage a blocked CVC with an alteplase or urokinase infusion [2]. They should also manage treatment of infection of the CVC insertion site or subcutaneous infection along a tunnelled CVC. The local service would also be expected to stabilise a child with a displaced or fractured CVC prior to transfer to the specialist centre for CVC repair or replacement. Treatment should be discussed with the specialist service.

Other complications of long-term PN treatment are poor bone mineralization [41], abnormal body composition [42], gallstones [43] and rarely thrombotic complications such as pulmonary emboli [28].

Monitoring for potential bone disease includes blood ALP, Ca, P04 levels every 3 months if stable, vitamin D and parathyroid hormone every 6 months and bone age annually. From the age of 5 years (when there is a normal range to compare), bone density can be checked annually [18].

Management of IFALD has already been described under 'optimising PN management in hospital'. Additional investigations at home include an annual ultrasound scan to investigate for gallstones as well as liver parenchymal disease. Early referral to a hepatology transplant service is necessary if liver disease develops.

Specific Features of PN at Home

In the same way as in hospital, the hours that the PN is infused should be limited to the minimum possible, usually 12 h overnight. The child and family can participate in usual daytime activities. It can be difficult for the family to pursue a reasonably normal lifestyle if a child is connected for more than 14–16 h, although portable pumps facilitate improved mobility.

Every effort should be made to supply all PN requirements in a single bag for each infusion night in order to have one giving set and infusion pump. Most children will have two separate formulations to be used on different nights of the week since the lipid-containing infusion is usually limited to two or three nights/week, with the dextrose and amino acid preparation without lipid given on intervening nights.

The PN bag for home use is usually made with extra volume/'overage' in case the child's requirements increase.

In smaller infants, the rate of infusion should be reduced/wound down for the final hour or so (usually 50% of the full hourly rate for 30 min and 25% rate for the final 30 min prior to disconnection) in order to minimise the risk of rebound hypoglycaemia when the infusion is stopped.

When a child on PN at home is clinically stable and has at least some enteral tolerance, an attempt should be made to increase enteral intake and reduce PN. Points to consider when weaning PN at home are [18]:

- In order to improve quality of life, the PN should be reduced to the minimum possible number of nights/week at the earliest opportunity.
- If the child only tolerates a liquid enteral feed via an infusion rather than drinking it and is unlikely to gain enteral autonomy, the hours of infusion should be limited to just one or two per day.
- As soon as an infant can tolerate about 50% of requirements enterally, PN can be reduced to a maximum of five nights and possibly less.
- Rather than going straight to a night off PN, the parents/carers can halve the infusion volume one night a week and check if the child is well the next day. If successful they can stop the PN one night, the following week.
- If a night without PN can be tolerated, reduce the PN infusions to five nights/week with the two nights off spread through the week.
- If excess weight loss ensues when infusions are reduced, first increase the PN on the nights it is given, and review weight gain rather than immediately increasing the number of infusions.
- Enteral sodium supplements are often required the evening before and the morning after a night off PN.
- Growth and development should be monitored and PN adjusted as necessary. Dietetic input is essential to ensure earliest possible introduction of EN. Dietitians will usually contact families between face-to-face consultations when actively weaning.

When discharged, the child should be sufficiently stable to cope with the same PN formulation being given for a week, in order to give the homecare pharmacy a reasonable time to make changes to the formulation. If changes to the PN are required more frequently, the volume should be increased/reduced and supplemented enterally if extra electrolytes required. A portable infusion pump should be supplied to enable the child to be mobile in the evenings after connecting the PN. Many portable pumps have a rucksack to help support mobility when the child is connected to the infusion.

In certain circumstances, for example, when using a commercially available standard bag, the vitamins may be added at home. When patients have residual intestinal function, most vitamins (especially water soluble) can be adequately absorbed from the gastrointestinal tract.

The IF rehabilitation team should regularly audit the homecare service.

The family should have ease of access to contact the specialist centre by electronic messaging and phone calls. Face-to-face review by the specialist MDT intestinal rehabilitation service is usually only necessary on a 3-month basis when the child is stable [18].

Laboratory investigations/monitoring are also only needed 3 monthly when stable.

Appropriate investigations include blood urea, electrolytes, urine sodium, full blood count, vitamin A and E, ferritin, copper, zinc and selenium.

Vitamin D, manganese [13] and thyroid function should be checked annually. Other annual investigations include abdominal ultrasound to review the liver and kidneys and chest x-ray to assess position of the CVC (if in situ >12 months). Children aged over 5 years should have annual measurement of bone age and bone density [18].

The underlying intestinal disease predisposing the child to IF should be reviewed regularly and treatment appropriately adjusted.

Quality of Life in Children on PN at Home

Children who remain on PN into adult life can have a good quality of life [18]. Adolescents can do well at school and progress to higher education [44]. Children who remain on PN into adult life can gain employment [45].

Regaining Enteral Autonomy and Weaning PN Treatment

Weaning a child from PN to oral/enteral nutrition can be one of the most complex aspects of management. Even with extensive investigation and assessment of intestinal function, it is only certain whether a child has adequate intestinal function by reducing the PN and either allowing the child to eat or increasing infused liquid EN accordingly. Please see Table 46.7. Weaning from PN to EN at home usually takes place with:

- Dietetic support from the specialist unit.
- The main aim is to reduce the number of PN infusions/week.
- PN reduction can be done safely at home with support from the multidisciplinary IF rehabilitation team.

Transition to Adult Care

A small proportion of children remain on PN throughout childhood and need to transition from paediatric to adult care

on PN treatment [44]. Transition needs to be arranged on an individual basis since there are a limited number of patients on long-term care and each will have their individual needs. Although issues relating to transition are the same as for other chronic conditions, transfer needs to be performed between specialist IF units with the experience and resources to ensure the child complies with the process.

The two major changes are as follows: (1) the adolescent takes on 'ownership' of the condition, and (2) the parent relinquishes responsibility. The experienced units have the ability to provide a bespoke service for each patient with a professional (usually a specialist nurse) to provide support. The transition process can take 2 years for such complex patients.

Other treatment strategies : when long - term / home *PN* is inappropriate.

Intestinal Transplant

Despite a marked improvement in outcome in specialist IF rehabilitation centres with current PN management, there are still a small number of children who 'fail' PN treatment. Children who cannot continue with long-term PN and are not weaning from PN should be assessed for intestinal transplant. The indications for transplant are loss of vascular access, end-stage liver disease, unstable fluid balance and poor quality of life [27]. The transplant can range from small intestine alone to inclusion of the stomach and/or colon and if required the liver and other abdominal organs, multi-organ transplant. The outcome for long-term PN, despite the risk of potentially life-threatening complications such as CRBSI, can be up to 95% long-term/5-year survival [18, 46]. In contrast the 5-year survival for intestinal transplant according to the 2016 Scientific Registry of Transplant Recipients was 68% with 60% graft survival [47].

Withdrawing PN Treatment

Home PN was originally set up for otherwise healthy children with IF to be discharged home for a good quality of life. However, children with co-existing major organ failure are now referred for PN treatment at home. In some of these children, the burden of care is so great that long-term home treatment might prolong suffering when the child has no hope of eventual recovery and will never be capable of an independent life. In such situations ethical issues need to be addressed. For example, children with severe neurological impairment can develop intestinal dysmotility and hyperaesthesia with increasing age. The PN has often been started for what was thought to be an acute self-limiting illness that has progressed, and it has not been possible to wean the child off treatment. Early assessment by the hospital palliative care team should be arranged.

If it is agreed that a child with a life-limiting condition is started on PN, an 'end of life plan' should be discussed at an early stage. The plan is a guide, and parents can ask for it to be altered in a crisis if they change their minds. In other cases the child's condition may deteriorate when already on PN treatment. An MDT meeting can be held, and if appropriate a plan made for withdrawing PN treatment if it is considered inappropriate (for example appears to be causing rather than relieving suffering if continued). Psychosocial support and review should be made available.

Outcome

Management of PN is now so successful that a child can grow and develop normally on PN treatment throughout childhood and into adult life even when unable to tolerate little/no enteral nutrition.

In children with a primary digestive disorder, life expectancy is good. As long ago as 2012, a European survey reported a 2-year survival rate of 97%, 5-year survival rate of 89% and 10-year rate of 81% [46]. Outcome of different series varies according to the severity and diagnoses of patients discharged home [18].

Children can grow and develop normally on PN. IFALD usually improves in children discharged home. The number of intestinal transplants has been falling since 2008 [47] as IF rehabilitation management has improved.

Summary

A good nutritional state is a prerequisite for normal growth and development in childhood and a sense of well-being. The effects of inadequate nutrition in childhood may have lifelong consequences with stunted growth and intellectual development in addition to worsening any systemic illness. The child who develops IF today can expect to survive into adult life with a good quality of life with the support of PN managed by a multidisciplinary IF rehabilitation team.

Intussusception

47

Rachael Essig, Brian A. Jones, and Mark B. Slidell

Introduction

Intussusception is a common cause of abdominal pain in children under 3 years of age. At the time of John Hunter's description of intussusception in 1793 [1], it was a nearly uniformly fatal diagnosis. In 1836 the very first therapeutic air enema was completed using a bellows followed in 1876 by Hirschsprung's development of a hydrostatic reduction technique [1, 4]. There were some improvements in patient outcomes following the introduction of these mechanical reduction techniques in the late 1800s; however, Frederick Treves still reported a case fatality rate greater than 70% in an operative series from 1885 [2, 3]. The first reports of fluoroscopic guided reduction with enemas were reported in 1927 [5], and the current success rate of radiologic reduction techniques should be greater than 80% to 90% in most centers [6, 7]. With advances in modern medicine, this disease is now consistently diagnosed and treated with minimal morbidity or mortality. In the current day and age, the mortality rate is <1% for both radiologic reduction and surgical intervention [8].

Incidence and Demographics

Intussusception is one of the most common sources of intestinal obstruction in children with an incidence of approximately 0.5 and 2 in 1000 infants and children [9]. The most common age of presentation is 3 months to 2 years with 40% of cases occurring between 3 and 9 months of age and 90% of cases occurring in children under the age of 3 years [10]. Intussusception is nearly twice as common in males as females [4, 9, 11].

Etiology

While overall 90% of all intussusception presentations have idiopathic etiologies, it is thought these are related to hypertrophy of the Peyer's patches in the small intestine from viral illnesses common in the pediatric population [12]. It has been noted 30% of pediatric patients presenting with intussusception had a prior viral illness [9].

The most common lead point for intussusception appears to be lymph node enlargement; however, it is uncommon to identify a pathologic lead point beyond typical lymphadenopathy secondary to inflammation. A pathologic lead point is estimated to occur only about 10% of the time, and this is typically in a child over 5 years old [9]. Extra-luminal processes such as intestinal duplication or Meckel's diverticulum can lead to intussusception as well as intra-luminal processes like polyps, inspissated feces, and parasites (Table 47.1) [9]. Older patients are more likely to have a pathologic lead point with up to 60% of children between the ages of 5 and 14 years old presenting with a lead point due to causes such as a Meckel's diverticulum, intestinal polyp, intestinal duplication, or lymphoma [13, 14].

Other rare causes of intussusception related to intestinal wall pathology include Crohn's disease, celiac disease, and intestinal allergies [9]. Intussusception may also occur in Henoch-Schonlein purpura secondary to submucosal

	Polyps
Other etiologies	Neuronal intestinal dysplasia
	Celiac disease
	Cystic fibrosis
	Bleeding disorders
	Henoch-Schonlein purpura
	Hemophilia
	Leukemia

hemorrhages that focally alter the normal peristalsis of the intestine leading to an aperistaltic lead point [9]. Intestinal pseudo-obstruction is another incompletely understood phenomenon in which a pseudo-obstruction of the small intestine may occur without any defined lesion within the intestine [9]. There are also iatrogenic sources of intussusception with the most common occurring around feeding tubes, such as a jejunostomy tube within the small bowel [4].

Pathophysiology

The pathophysiology of intussusception is that a lead point causes a portion of the intestine, known as the intussusceptum to invaginate and telescope into a distal segment of bowel called the intussuscipiens (see Fig. 47.1) [15].

This leads to an obstruction of the intestinal lumen. Eventually, with time the natural progression of intussusception leads to intestinal necrosis. Necrosis is caused by pressure on the mesentery of the intussusceptum by the intussuscipiens which leads to an obstruction of venous outflow. The ensuing edema in the intussusceptum peaks at the apex [15] of this segment of the bowel. An obstruction of venous outflow impairs arterial inflow leading to ischemia and eventual necrosis and perforation.

The most common type of intussusception in the pediatric age group is ileocolic, which occurs 80% of the time [16]. In this type of intussusception, the terminal ileum invaginates into the colon. Other types of intussusception are small bowel to small bowel and colo-colonic. Most of the pediatric literature on intussusception focuses on the management of ileocolic intussusceptions. Studies demonstrate that spontaneous small bowel to small bowel intussusceptions are quite common and rarely involve a lead point. These will spontaneously reduce over a brief period of time and may be found incidentally on a CT scan without cause for concern [17]. Certain congenital anatomic configurations are thought to predispose patients to intussusception. These configurations include a terminal ileum that inserts anterior onto the cecum, a cecum with immature taenia coli leading to increased flexibility, and lastly underdeveloped function of the colonic longitudinal muscle filaments near the ileocecal valve [9, 18]. Observation of these anatomical variations were seen in postmortem examination of autopsy specimens; it was determined that the process of intussusception occurs when the muscular ileocecal valve invaginates into a flaccid cecum due to lack of mature taenia coli [9, 18]. Another interesting anatomical variation that results in an increased risk of intussusception is an anomaly of intestinal rotation called Waugh syndrome. In this condition, the ascending colon lacks the usual lateral retroperitoneal attachments allowing the ileocecal valve to more freely prolapse and into the rectum [9]. Normally this can lead to an extensive intussusception and without significant intestinal ischemia due to the lack of colonic fixation. It is important to remember this as a possible presentation of malrotation so that the appropriate treatment for an anomaly of intestinal rotation is performed at the time of surgery [9].

Clinical Presentation

Intussusception is a common abdominal pediatric emergency. Parents can describe an acute onset of intermittent abdominal pain. During the episodic pain, children will often move their knees to their chest and demonstrate intense irritability [9]. In between these episodes, the child will frequently return to a normal level of activity, but with progression of the disease, the pain becomes increasingly stronger. It is not uncommon for associated nausea and vomiting to occur with the onset of the pain. Almost 50% of cases will present with the classic "currant jelly" bowel movements caused by the admixture of stool and blood [9]. In patients who undergo successful reduction of an ileocolic or colo-colonic intussusception, a recurrence may occur in 7.5% to 15% of patients within a brief time period following their original event [5]. Patients that have a recurrence of intussusception may present with more subtle signs the second time around, and this is why it is important to remember that a recent episode of intussusception places the patient at

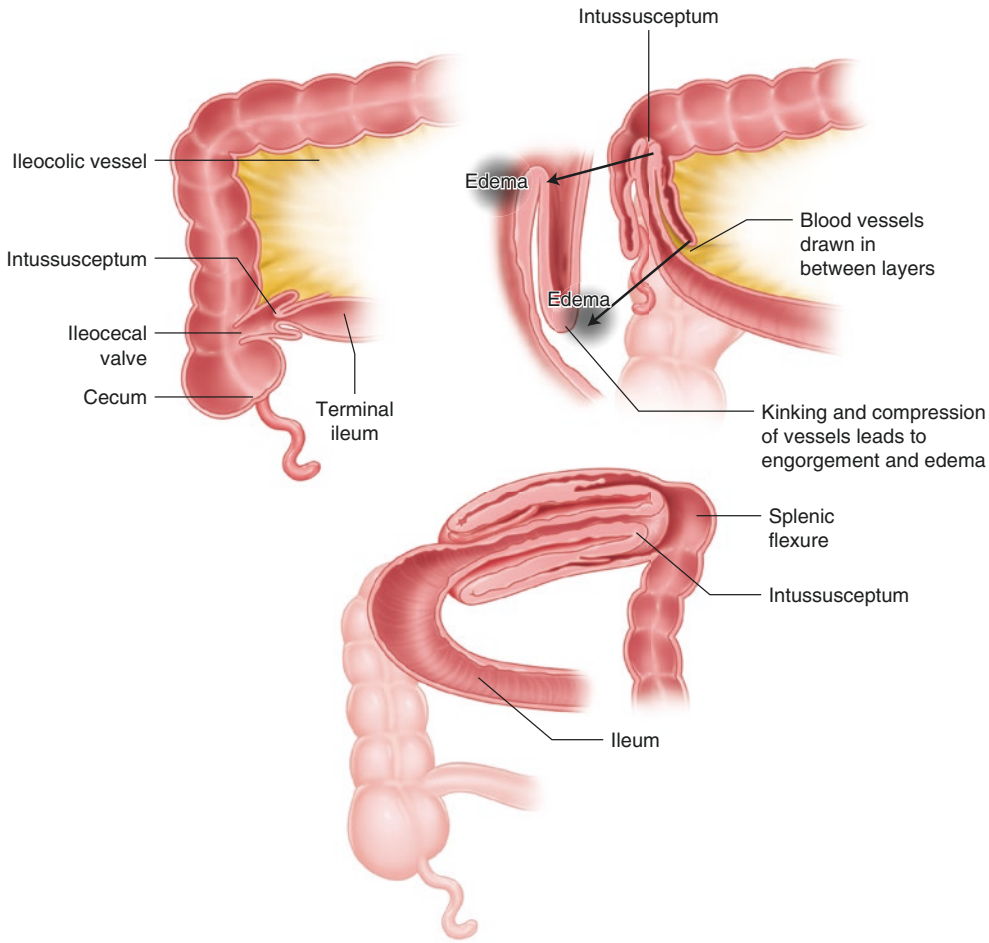

Fig. 47.1 Scheme of intussusception. Reproduced with permission. (This figure was published in Pediatric Surgery, Vo. 2, by Arnold Coran N. Scott Adzick Thomas Krummel Jean-Martin Laberge Robert Shamberger Anthony Caldamone, Intussusception, page 1094, Elsevier/Saunders, 2012)

higher risk of having a recurrent episode [19]. Early recurrence (<24–48 hours) rates range from 0.6 to 2.45% in most studies, and typically, 75% of recurrences will present within 6 months of the original event [19–23]. It is important to always keep a broad differential diagnosis list when initially evaluating a child with abdominal pain.

Diagnostic Evaluation

Suspicion for intussusception will depend to a degree on the child's clinical presentation. If there is a concern for peritonitis, an initial plain film chest or abdominal x-ray (Fig. 47.2) is an efficient diagnostic tool to establish a diagnosis of pneumoperitoneum; otherwise, a plain abdominal film has a 45% sensitivity to diagnosis intussusception [24, 25].

Abdominal ultrasound is a safe and quick diagnostic tool that may differentiate intussusception from numerous other etiologies of abdominal pain. Sonographic intussusception signs (Fig. 47.3) include the target (transverse view), doughnut (transverse view), or pseudokidney (longitudinal view) [11, 15, 16]. For an experienced ultrasonographer, the sensitivity and specificity approaches between 98–100% and 88–100%, respectively [24, 26]. Even in less experienced hands, ultrasound has been found very effective at diagnosing intussusception [27]. Benefits of ultrasound include the ability to differentiate the type of intussusception and identify potential lead points [17]. It is important to remember that up to 17% intussusception cases are transient and self-limiting [28]. Characteristics of transient, non-pathologic episodes of intussusception are that the segment of the involved bowel typically measures <3.5 cm in length and patients are asymptomatic [28].

Observation of decreased Doppler flow on ultrasound raises concern for intestinal necrosis. While color Doppler flow is not a perfect measure of intestinal necrosis, decreased flow is associated with lower rates of successful reduction by enema. The likelihood of reduction with air enema may vary from 94% in patients with visible blood flow to 31% without flow [29]. Nonetheless, in the absence of pneumoperitoneum, a finding of decreased flow on Doppler ultrasound does not preclude an attempt at reduction via contrast enema (see Fig. 47.4).

Fig. 47.2 Abdominal radiograph revealing a curvilinear mass in the right upper quadrant, consistent with possible intussusception

Fig. 47.3 Ultrasound is the primary imaging modality for the diagnosis of intussusception. In this image one can see a cross-sectional slice through the bowel demonstrating the "donut" or "target" signs on this transverse image. A "pseudokidney" sign may be seen on a longitudinal image

Clinical Management

On presentation with intussusception, it is important to evaluate the patient for signs and symptoms of dehydration as losses from both emesis and diarrhea can be profound. Dehydration and electrolyte abnormalities should be aggressively corrected while initiating diagnostic workup clinical stabilization may be necessary prior to any interventions. Occasionally these patients present with such severe electrolyte derangements that they require resuscitation in a pediatric intensive care unit.

Fig. 47.4 Contrast enema of the same patients as in Fig. 47.2, showing the presence of intussusception in the right upper quadrant. One can see the intussusceptum extending into the ascending colon up to the level of the hepatic flexure. The ascending colon is the recipient bowel (intussuscipiens) that contains the intussusceptum

Air or hydrostatic enemas are generally performed under fluoroscopic guidance by radiologists and in most cases are the first-line treatment for intussusception. Recurrence rates following a successful reduction are similar regardless of enema type employed [30]. Pneumoperitoneum, pneumatosis, and true peritonitis are a contraindication to enema reduction requiring prompt surgical intervention, while shock or dehydration is relative contraindications [5]. Aggressive fluid resuscitation may correct dehydration and shock, and then it may be safe to proceed with an attempt at enema reduction. Risk factors associated with unsuccessful of enema reduction are the presence of hematochezia, younger age, concurrent signs of intestinal obstruction, and

extended prodrome of symptoms [5, 31]. The most severe complication of an air enema is perforation of the intestine, which is rare and estimated to occur in 0.16–0.39% of procedures [5]. The risk of perforation is higher in children less than 6 months in age, those with an extended symptom prodrome, and those with unrecognized intestinal necrosis [5, 32]. Perforation may be at the site of intestinal necrosis or distally in the intestinal tract due to elevated pressure from the reduction. Tension pneumoperitoneum is an exceedingly rare complication of bowel perforation during an air enema [32]. This can be identified on physical exam or on ultrasound as extra-intestinal air or a Rigler's sign via fluoroscopy [33]. Treatment of this condition requires immediate cessation of the enema and, if hemodynamic instability is present, needle decompression of the abdomen [5, 33].

To ensure complete reduction of the intussusception, one should see air reflux into the small bowel and the resolution of the mass on imaging [34, 35]. Usually the radiologist will complete an ultrasound immediately after enema to confirm complete reduction. The overall success rate is relatively high between 80 and 95%. Historically, a successful reduction would require that the patient be monitored in a clinical setting for approximately 24 hours as 33% of recurrences occur during that time frame [19]. Recent studies have shown that patients successfully treated with an enema reduction of the intussusception may be safely discharged home after a brief period of observation in the emergency department. It is unclear if certain patients are at greater risk for recurrent intussusception; however, a recent retrospective study of 360 consecutive patients with successful air enema reduction found that age greater than 2 years was the only predictor of early recurrence [36], suggesting that children over 2 years of age might be safely discharged home from the emergency room after a brief period of observation and a successful PO challenge.

The air enema may be repeated if evidence of recurrence or incomplete reduction [34]. Repeated attempts at reductions, even if delayed, have been found to be safe if there is a partial reduction on the initial attempt and the patient continues to be clinically stable [5, 32]. It is hypothesized that the partial reduction of the initial enema allows for restoration of the venous drainage and enables a decrease in edema making subsequent attempts potentially more feasible [32]. Even an attempt at an air reduction enema is recommended first for intussusceptions caused by known lead points if there is no contraindication based on the patient's presentation, allowing emergencies to be handled on an urgent basis via surgery if reduction is successful [32]. For hospitals, without pediatric radiology expertise in enema reductions, a failed attempt at enema reduction for an ileo-colonic intussusception should not always lead directly to surgical intervention. If the radiologist is comfortable with a second repeat attempt at reduction after a delay of 45 to 60 minutes, then this is an option. Otherwise, consideration should be given to transferring the child to a regional children's hospital. There is good evidence that failure at a referring hospital does not preclude a repeat attempt at a children's hospital, and the success rate for a repeat attempt at reduction at the children's hospital should be approximately 60% [37].

For practitioners or families concerned about radiation exposure, it has been found that skilled radiologists are able to exclude intussusception with a fluoroscopy time of only 5–10 seconds [34]. Additionally, the reduction of a straightforward intussusception can occur in a short 14–30 seconds [34]. Air enemas appear to be superior to hydrostatic enemas due to the ease of air movement compared to liquids causing faster reduction rates and thus less radiation time. Another potential benefit to air reduction is the ability to maintain intra-intestinal pressure due to the nature of the valve inhibiting reversal of flow producing a better reduction rate. If a perforation occurs, there is potentially less morbidity with air compared to hydrostatic enemas likely due to decreased fecal contamination [5, 16, 34].

Surgical intervention is considered the first-line therapy when patients present with overt peritonitis on examination or pneumoperitoneum on x-ray [29]. Patients that have a delayed presentation are more likely to require eventual surgical intervention for management [17]. There are differing opinions regarding surgery as the first intervention if there is a pathologic lead point identified on imaging; likely this will be a multidisciplinary discussion between surgery, radiology, and the family about the risk and benefit of air enema reduction and surgery. Surgery can also be considered in same-site recurrent intussusception in the hopes of reducing further recurrences and the potential need for emergent surgical intervention [19].

Conclusion

Intussusception is a common cause for abdominal pain in the pediatric population. Efficient diagnosis and management with enemas have allowed for better outcomes with less invasive procedures for patients. Always keep in mind if there is any concern for a pathologic lead point or if this is a recurrent episode to involve pediatric general surgery.

Meckel's Diverticulum

48

Meghna S. Vaghani and Ashish P. Desai

Introduction

As Charles Mayo described, 'Meckel's diverticulum (MD) is frequently suspected, often looked for, and seldom found' [1].

The first descriptions of MD were by Heladnus in 1598 [2] followed by Levator in 1671 and Ruysch in 1730; much before Meckel's description [3]. Johann Friedrich Meckel is however credited with the first detailed description of the diverticulum and its embryonic origin in 1809 [4, 5].

In 1962, Harper et al. suggested that since 99mTc pertechnetate is concentrated by gastric mucosa, MD containing gastric mucosa should be identifiable scintigraphically using 99mTc pertechnetate [6]. Most MD may in fact be identified intra-operatively due to its varying presentation of intestinal obstruction caused by either band with volvulus or intussusception, umbilical discharge and diverticulitis.

Embryology

During the first few weeks of gestation, the primitive yolk sac divides into the primitive midgut and a smaller yolk sac. An omphalo-mesenteric duct, also known as the vitello-intestinal duct, connects these two structures and usually regresses between the 5th and 7th week of intrauterine life. Failure of regression leads to various presentations of patent vitello-intestinal duct (VI duct). Persistence of the tube only proximally causes MD.

Epidemiology

Common dictum suggests MD is present in around 0.3–2.9% of the population. Whilst these figures offer guidance, incidence of symptomatic MD has been shown to decrease with age. It is thought to be around 4% in the first 3 years of life, and following that, the incidence decreases. The prevalence of MD during postnatal autopsies is 1.23% [7]. The majority of cases of symptomatic or resected MD occur in males, with systematic review data suggesting a male-to-female ratio of 1.5:1 to 4:1 [8].

Associated Anomalies

MD is usually an isolated condition; however patients with Hirschsprung's disease, Down syndrome, oesophageal atresia, duodenal atresia, malrotation and congenital cardiac abnormalities show increased incidence [9].

Gross and Microscopic Anatomy

MD arises on the anti-mesenteric border of the ileum and is approximately 2 inches long. Its distance from I/C valve is variable and is thought to be anywhere from 30 to 120 cm. Hence, during surgery, it is advisable to inspect at least 150 cm of the terminal ileum. It has its own blood supply from the persistent vitelline artery which is a branch of superior mesenteric artery.

Histologically, MD usually resembles the ileum. As it is a true diverticulum, it contains all layers of a normal intestine: mucosa, submucosa, muscularis propria and serosa with its own blood supply. However, it may contain heterotopic mucosa: either gastric or pancreatic tissue. Incidence of gastric mucosa occurs in around 9% of the patients, and pancreatic mucosa is seen in 2.5% of patients [10]. Various studies have also showed the presence of carcinoid, lipoma, leiomyoma or enterolith.

Variations of Patent VI Duct Anomalies

VI duct anomalies occur due to variation in persistence of the VI duct remnant and its attachment to the umbilicus.

Various anomalies are:

1. MD – persistent proximal part of the VI duct.
2. Isolated fibrous band – persistent remnant of whole VI duct.
3. Omphalo-mesenteric fistula – presents as stoma at the umbilicus [11] or prolapse through the umbilicus [12].
4. Enterocyst – persistent middle part of the fistula.
5. Meckel's diverticulum may also have attached fibrous band.

Clinical Features

Most MDs are asymptomatic throughout life. In such cases MD may only be discovered incidentally during other diagnostic or surgical procedures. The clinical features of symptomatic MD can be summarised by the rule of 2: 2% of the population, within 2 feet of the I/C valve, and 2 inches long, two types of heterotopic mucosa [13].

Age-related presentations are further discussed below:

Neonatal

In neonates, presentation is usually due to persistent VI duct presenting as either a discharging sinus at the umbilicus [11] or a prolapsing VI duct remnant [14, 15]. Other presentations may be due to a band with associated volvulus causing partial or complete obstruction. Perforation is rare.

Paediatric Age Group

In the paediatric age group, presentation varies between intestinal obstruction (47%), gastrointestinal (GI) bleeding (25.3%) and diverticulitis (19.5%) [8]. Studies have shown that over 50% of symptomatic patients requiring surgical resection are under the age of 10 [16, 17].

Intestinal Obstruction

Obstruction is the most common presentation in children. Obstruction could be due to various reasons such as volvulus around the MD with a fibrous band, intussusception [18], enterolith, incarceration in Littre's hernia [19] or within umbilical hernia [20].

GI Bleeding

GI bleeding is the second most common presentation in children and the most common below 2 years of age. It is usually a major lower GI bleed, which is fresh and painless or associated with minimal pain. The majority of cases of bleeding are associated with gastric heterotopia [21]. The bleeding is due to a peptic ulcer in the surrounding normal ileal tissue. In cases where the gastric mucosa is absent, bleeding is usually attributable to other causes such as intussusception or gastritis.

Management of a major GI bleed should include assessment and treatment to achieve haemodynamic stability. This includes appropriate monitoring and fluid bolus. This should be followed by trying to differentiate between upper and lower GI bleeding, determining the site of bleeding and the diagnosis.

Children suspected to have MD should be started on H2 blockers such as ranitidine or famotidine after adequate fluid resuscitation. Currently, proton pump inhibitors such as omeprazole or lansoprazole are routinely used. Once the bleeding is controlled, a 99m technetium-pertechnetate scan should be carried out to look for the diagnosis of MD. If diagnosed, they should be resected.

Diverticulitis

Inflammation of the MD may be the presenting sign in 19.5% of children. They are often mistaken as acute appendicitis, and the children are usually older. During surgery, inflamed MD is identified and should be excised.

Adult Age Group

As discussed, the incidence if symptomatic MD decreases with age. If MD does present in adulthood, obstruction and diverticulitis are the more commonly seen [8]. An increased incidence of MD-related cancers is also seen in adults with a mean age of 60.6 years. Furthermore, adjusted risk analysis shows a 70 times higher likelihood of MD malignancy than any other ileal site [22].

Other Presentations

Other rare presentations can be due to development of bezoar in the diverticulum [23] or malignancy. The most common tumour affecting the MD is carcinoid tumour [24, 25]. However, villous adenoma [26] or GI stromal tumour [27] has also been reported.

Management of MD

Investigations

As MD has varied presentations, it is not always possible to diagnose it prior to surgery. The surgeon needs to have high index of suspicion.

The investigations which might raise the possibility of MD are as follows:

1. *Plain X-ray of the abdomen:* Plain X-ray may show evidence of intestinal obstruction. If enterolith is present, it may be visible. If MD has perforated, pneumoperitoneum may be visible.
2. *Scintigraphy:* Harden et al. demonstrated that technetium-99m was concentrated in the gastric mucosa. It can therefore demonstrate the presence of heterotopic gastric mucosa in MD when present. The isotope is selectively taken into gastric, salivary and thyroid tissue and excreted in urine. Hence, false-negative scans may be reported if the diverticulum is overlapped by the urinary bladder. Sensitivity of the scan can be increased by using either pentagastrin or glycogen [28]. These scans have specificity of more than 95% and sensitivity of more than 85%.
3. *Fistulogram:* Patent VI duct may be identified by fistulogram from umbilical fistula.
4. *GI contrast study:* It is unusual to identify MD by barium meal. However, it may be visible in 0.7% cases by small bowel enema.
5. *Angiography:* In adults and older children, bleeding MD may be identified by selective superior mesenteric artery angiography. If the patient is very unstable, it may be possible to temporarily occlude the bleeder by embolising the vessel. The patient should have laparotomy as soon as they are stabilised as embolisation may lead to gangrene and perforation of MD in a few hours' span.
6. *Capsule endoscopy:* Whilst endoscopic patterns for MD have not yet been defined, research suggests that the presence of a double lumen with or without bleeding and/or a diaphragm sign may suggest MD. Localisation in the lower right quadrant is likely MD, though localisations in other areas may need further investigation [29, 30].

Incidental MD

In the event of an incidental MD during laparotomy, the decision to excise will be evaluated based on multiple factors such as cause for the surgery, length and breadth of the MD base and presence or absence of a palpable nodule suggestive of heterotopic mucosa.

Surgical Management

In symptomatic cases, resection of the diverticulum is usually recommended. The whole diverticulum with heterotopic mucosa, if present, should be excised. After the excision, the bowel needs to be anastomosed without causing luminal obstruction. This can be achieved either by diverticulectomy alone if the base is narrow or by resection of the ileum containing the diverticulum with end-to-end anastomosis.

The decision between diverticulectomy and segmental resection is usually evaluated by the surgeon. The MD Resection Index (MDRI) has been proposed as a method for this evaluation and is calculated using the length and width of the diverticulum [31].

This procedure was routinely performed by laparotomy, but with changing practice, laparoscopy, standard three-port or using single-port technique [32], is playing an increasing role. During diagnostic laparoscopies performed for GI bleeding or acute appendicitis, routine examination of the terminal ileum should be carried out for at least 150 cm from the I/C valve to look for MD. The surgeon should start inspecting the ileum systematically from the I/C valve. Two bowel graspers at anti-mesenteric border should grasp intestinal loops, and both sides should be examined. When MD is identified, it can either be excised in situ, or the same can be delivered outside the abdominal cavity via the umbilical port and the resection and anastomosis performed. The intestine can then be reposited inside.

Outcome/Conclusion

Meckel's diverticulectomy has low morbidity and mortality. However, its first presentation may be at any age and is varied with obstruction, diverticulitis, haemorrhage or neoplasm [33]. Hence, the clinician needs to show a high degree of suspicion and look out for this. It is seldom found easily; therefore early diagnosis and proper treatment are essential to manage its varied clinical symptoms. Surgical and laparoscopic techniques have developed over time, and today laparoscopy is increasingly being used in the management of MD.

Appendicitis

49

Megan E. Bouchard, Mark B. Slidell, and Brian A. Jones

Diagnosis of appendicitis is usually not especially difficult.
William Silen – Cope's Early Diagnosis of the Acute Abdomen 1979

I doubt whether there is any disease which has symptoms of such variable degree as appendicitis. Everyone has seen children with negligible symptoms who, at operation, have had gangrene of the appendix. It is these mild cases so easily missed, which eventually make every clinician of experience eat his portion of fricasseed crow.
Willis J. Potts – The Surgeon and the Child 1959

Introduction

Appendicitis, or inflammation of the appendix, is the most common emergent surgical condition in children and accounts for approximately 10% of all pediatric emergency room visits [1]. While some considered it a vestigial organ, the appendix serves as a reservoir for normal intestinal microbiota and has the highest concentration of gut-associated lymphoid tissue in the intestine [1]. Despite its high incidence, appendicitis is the most frequently misdiagnosed surgical condition of the abdomen [2]. To minimize misdiagnosis and standardize care, several algorithms to both diagnose and treat appendicitis have been developed for children.

Classically, appendicitis is subdivided into (1) acute, simple appendicitis; (2) acute, complicated appendicitis; and (3) chronic appendicitis [3]. Simple appendicitis is a process that is confined to the appendix [1, 3]. Complicated, or sometimes referred to as complex, appendicitis instead indicates more advanced pathology including appendiceal perforation, phlegmonous or gangrenous changes, or an associated abscess [1, 3]. Chronic appendicitis is less common and remains a controversial topic [4]. The literature suggests this is a real entity defined by inflammation of the appendix that lasts for weeks, months, or even years [4].

Epidemiology

The annual incidence of appendicitis is estimated at 19–28 per 10,000 children [5]. Appendicitis is more commonly diagnosed in children aged 4–14 years old [5, 6]. Children less than 4 years old have a lower annual incidence of one to six per 10,000 children per year [7]. Overall, the estimated lifetime risk of developing appendicitis is 7–8% [6, 8]. Appendicitis has a male predominance of about 55–60% [8]. The percentage of children who present with complicated appendicitis is estimated at 30%, ranging from 20% to 74% depending on the study [5, 8–11].

Higher rates of complicated appendicitis have been seen in patients with greater than 48 h' duration of symptoms, age less than 5 years old, rural geography, ethnoracial minority, public or self-insurance, obesity, and other chronic diseases [10–12]. Complicated appendicitis is also associated with increased length of stay, complications, and hospital cost [8, 11].

Anatomy and Pathophysiology

The appendix is a blind-ending luminal structure attached to the base of the cecum near the ileocecal valve. The base of the appendix is most commonly located at McBurney's point, which is located one-third the distance from the right anterior superior iliac spine to the umbilicus. The tip of the appendix, however, can be located in various positions including pelvic, subcecal, retroileal, retrocecal, ectopic, and preileal locations. While it is most commonly positioned in the pelvis, the variations in location may affect the presenting symptoms of appendicitis and complicate the diagnosis. The appendicular

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_49

artery, a branch of the ileocecal artery, is the blood supply of the appendix. The appendix is composed of colonic epithelium, with the submucosa containing a high concentration of lymphoid follicles, most especially in children.

Acute appendicitis is caused by obstruction of the lumen of the appendix [13]. Once obstructed, the mucosa continues to secrete mucus and fluid leading to increased pressure within the obstructed lumen [13]. The resident intestinal bacteria continue to grow and recruit neutrophils, which leads to the production of purulent fluid and even higher intraluminal pressure [13]. The high pressure causes obstruction of venous outflow and lymphatic drainage [13]. Ultimately, the arterial blood flow may also become obstructed from the significant edema, leading to transmural appendiceal ischemia [13]. Once the bacteria invade the appendiceal wall, the diseased appendix is then at high risk for perforation [13].

Most commonly caused by fecal stasis or a fecalith, obstruction of the appendix in children may also be caused by lymphoid hyperplasia from systemic infectious illness, granulomatous inflammatory changes with Crohn's disease, thick mucus seen in cystic fibrosis, parasites, or rarely appendiceal neoplasms [5, 6, 9]. Interestingly, a family history of appendicitis is associated with a nearly threefold increased risk of developing appendicitis, suggesting there may also be a genetic component [14].

Presentation and Physical Exam

Presenting Symptoms

Classically, appendicitis begins with the onset of gradual, constant periumbilical pain that eventually migrates and localizes to the right lower quadrant [15]. While the migration of pain is highly specific, it only occurs in approximately half of cases [15]. The periumbilical pain is due to swelling of the appendiceal lumen causing irritation of the visceral peritoneum. The right lower quadrant pain is then due to direct irritation of the parietal peritoneum and ultimately results in somatic pain.

Other common symptoms of acute appendicitis include nausea (81.7%), emesis (67.7%), and anorexia (72.4%) [16]. While most patients are afebrile or simply report a low-grade fever, high fever is uncommon and raises suspicion for perforated appendicitis [17]. In children, the diagnosis of appendicitis can be challenging because they do not always have the classic signs of right lower quadrant pain, fevers, and nausea or anorexia [8, 17]. This is especially true among younger children who may have more difficulty explaining their symptoms and may instead present with irritability, decreased activity, and refusal to eat [8, 17].

In pediatric appendicitis, approximately 50% of patients present with atypical features including normal or increased bowel sounds (64%), absence of rebound pain (52%), lack of migration of pain (50%), lack of guarding (47%), lack of anorexia (40%), and absence of maximal pain in the right lower quadrant (32%) [17]. Given many patients present with these atypical features and the classic symptoms incidentally overlap with presentations of many other common causes of childhood abdominal pain, the diagnosis of pediatric appendicitis can be quite challenging [8, 17].

Physical Exam

On physical exam, it is important to not overlook vitals and the general appearance of the patient. Observations of tachycardia, fever, acute distress, listlessness, and irritability may all be important in establishing the diagnosis. Beyond the complete general physical exam including examination of the lungs, heart, periphery, and ear/nose/throat, the primary exam will be focused on the abdomen.

Beginning with inspection, the abdomen may or may not be distended. If the patient is old enough to participate in the exam, it can be helpful to ask the patient to point to where they feel the most pain. Next, palpate the abdomen in each quadrant, asking the patient to indicate if they experience any pain and where. Observing facial expressions during palpation can also be useful. Classically, patients will exhibit maximal tenderness at McBurney's point, though variations in the location of the appendiceal tip or complications from perforated appendicitis may result in pelvic or diffuse pain. Patients with peritonitis typically lie still and are reluctant to change positions. Gentle percussion or deep palpation with a quick release may elicit rebound tenderness and also indicate peritonitis. Less commonly, a mass may be palpated in the right lower quadrant with more advanced disease.

Classic adjunct maneuvers include the Rovsing, obturator, and psoas signs. The Rovsing sign is positive when palpation of the left lower quadrant results in right lower quadrant pain. The obturator sign is positive when pain is elicited with flexion and internal rotation of the right hip and increases suspicion for pelvic appendicitis. Finally, the psoas sign is positive when the patient is placed in left lateral decubitus position and right hip extension elicits pain; this sign increases suspicion for retrocecal appendicitis. While these physical exam maneuvers may increase the likelihood of appendicitis if positive, labs and imaging are often ordered to differentiate between appendicitis and other diagnoses with similar signs and symptoms.

Diagnosis

Differential Diagnosis

The differential diagnosis for pediatric conditions with overlapping signs and symptoms of appendicitis is broad and var-

ies by sex and age. Other gastrointestinal pathologies include gastroenteritis, Meckel's diverticulitis, intussusception, inflammatory bowel disease, typhlitis, mesenteric adenitis, malignancy, bowel obstruction, and constipation. In girls, it is important to consider pelvic inflammatory disease, ectopic pregnancy, dysmenorrhea, ovarian torsion, and ovarian/paratubal cysts. Other conditions to consider include right lower lobe pneumonia, nephrolithiasis, pyelonephritis, cystitis, pancreatitis, lymphoma, Henoch-Schonlein purpura, and hemolytic-uremic syndrome.

Diagnostics: Laboratory

There is no definitive algorithm for work-up of pediatric abdominal pain concerning for appendicitis, though some diagnostics are important to consider. First, obtaining a complete blood count (CBC) to evaluate the white blood cell count can be helpful. After the first 24 h of symptoms, the CBC may demonstrate a left shift with a predominance of neutrophils and bands [18]. While leukocytosis is a nonspecific marker of inflammation, the increase in neutrophils would increase the concern for infection [18]. It is important to note that leukopenia, rather than leukocytosis, may be present in those who are immunocompromised and may raise the concern for other conditions such as typhlitis [19]. Additionally, a urinalysis should be sent to rule out urinary tract infection and a pregnancy test sent for girls of reproductive age. If the patient reports a significant history of recent emesis and/or diarrhea, obtaining a basic metabolic panel will be helpful in evaluating for electrolyte derangements and acute kidney injury from dehydration. Children with complicated appendicitis will often present with diarrhea secondary to purulent fluid in the abdomen or pelvis causing inflammation of the intestines [20]. In those patients that report pain more in the periumbilical or right upper quadrant regions, it would also be useful to obtain liver function tests and a lipase to rule out hepatobiliary and pancreatic pathology.

Diagnostics: Imaging

Imaging can assist with obtaining a diagnosis, reducing negative appendectomy rates and reducing lengths of stay [21]. In pediatrics, the standard imaging to begin with in diagnosing appendicitis is an abdominal ultrasound, though obtaining quality ultrasound images is user dependent [22]. The advantages of ultrasound are that it is fast, portable, and less expensive than other imaging modalities and delivers no radiation to the child. Nevertheless, visualization of the appendix may be limited by the patient's body habitus, bowel gas, abnormal location of the appendix, or severe pain that hinders abdominal compression with the ultrasound [22]. Despite these limitations, the sensitivity and specificity of diagnosing appendicitis on ultrasound is as high as 90–95% [23].

On ultrasound, an inflamed appendix in children should be greater than 6 mm in diameter and have a wall thickness greater than 3 mm [22, 24]. Other signs that may increase the suspicion for appendicitis include periappendiceal lymphadenopathy and free fluid, hyperechogenic pericecal fat, increased blood flow on Doppler scan, visualization of an appendicolith, and presence of an abscess [22, 24]. On the axial plane, an inflamed appendix will have a target appearance and will be non-compressible [22, 24]. If appendicitis is not visualized, an ultrasound can also assess for other abdominal pathologies including ovarian cysts, ovarian torsion, hepatobiliary pathology, and intussusception.

An abdominal X-ray is not specific or sensitive for diagnosing appendicitis, though may rarely demonstrate a radiopaque appendicolith. Most patients with appendicitis will have a normal-appearing abdominal X-ray [25]. An abdominal X-ray may reveal other causes of abdominal pain that mimic appendicitis, including intussusception, typhlitis, bowel obstruction, ileus, and constipation.

In cases where ultrasound is inconclusive, some hospitals elect to obtain a focused abdominal MRI (magnetic resonance imaging) [26]. Similar to ultrasound, MRI delivers no radiation to the patient, though is not user dependent and provides high-quality images with high sensitivity for appendicitis [26]. Nevertheless, if a focused MRI protocol is not in place at the institution, the scan duration may be quite long, be delayed due to other uses, or require sedation.

Many institutions, especially non-pediatric centers, use abdominal CT (computerized tomography) to diagnose any abdominal pathology. Unlike ultrasound, a CT scan is not dependent on user accuracy. CT can diagnose abdominal pathology other than appendicitis, is fast, and has high sensitivity (94%) and specificity (95%) [16]. Unfortunately, CT imaging does expose the patient to radiation and is much more expensive than ultrasound.

Given all these factors, most pediatric centers would recommend beginning with an abdominal ultrasound to evaluate for appendicitis [8, 22]. Selective use of MRI to follow an inconclusive ultrasound can be effective in establishing the diagnosis with a sensitivity of 100% and specificity of 96% [27]. These findings accompanied with a physical exam consistent with appendicitis lead to a positive predictive value of 83% and a negative predictive value approaching 100% [8, 28]. This work-up pathway has not been shown to increase the risk of perforation or negative appendectomy rates [26]. The time to treatment and length of stay are also unchanged [26].

Scoring Systems to Evaluate for Appendicitis

Another tool that can help in determining the next step in the work-up of a patient with possible appendicitis scoring systems such as the Pediatric Appendicitis Score (PAS) (Table 49.1) [29, 30]. Based on identified signs, symptoms, and laboratory findings, the patient receives a total score from 1 to 10 [29]. The PAS score assesses for tenderness to palpation in the right lower quadrant, anorexia, low-grade fever (>38.0), nausea/emesis, leukocytosis (>10,000/mm^3), left shift (>75% neutrophils), migration of pain to the right lower quadrant, and cough/percussion/heel tapping tenderness in the right lower quadrant. Studies have demonstrated that using the score alone is not sufficient to diagnose appendicitis, but using it in tandem with imaging can risk stratify patients for suspected appendicitis, decrease the time to diagnosis, and limit radiation exposure [8, 29, 30]. In fact, false-negative ultrasound findings decrease with increasing PAS, and conversely false-positive ultrasound findings increase with decrease PAS [30]. There are other validated, risk stratification scoring systems such as the Alvarado score [31] and the Appendicitis Inflammatory Response (AIR) score [32]. All three systems have utility, and differences in the various components of the scoring systems illustrate the challenges in making a confident diagnosis of appendicitis in the emergency setting. None of these systems takes into account two other key factors such as the duration of symptoms or whether the pain is constant or intermittent in nature. We propose that a new scoring system incorporating these factors might have improved diagnostic yield.

In instances where the diagnosis remains unclear, patients can be admitted for observation and serial abdominal exams. In cases of diagnostic uncertainty, antibiotics are generally withheld as antibiotics may effectively teat early appendicitis and mask developing symptoms. Most patients' symptoms will either resolve or progress, and the diagnosis should become clear.

Table 49.1 Comparison of the Pediatric Appendicitis Score (PAS), Alvarado score, and the Appendicitis Inflammatory Response (AIR) score. All three are validated, risk stratification scoring systems, in common use by emergency medicine physicians. The Pediatric Appendicitis Score appears to be the most used system

		Scoring system

When to Consult Surgery or Transfer the Patient to a Center with Pediatric Surgery

Whenever there is a concern for an acute abdomen, surgery should be consulted sooner rather than later. However, if the patient is clinically stable, there is time to begin the diagnostic work-up prior to consultation. Using the PAS tool can be useful to risk-stratify patients and to determine when to consult surgery [29, 30].

For patients with a PAS >6, surgical consultation is warranted, and a discussion with the surgeon regarding whether abdominal imaging is indicated [29, 30]. For patients with a PAS 4–6, it is often helpful to obtain cross-sectional imaging such as an ultrasound or MRI [29, 30]. If the appendix is not visualized on the imaging, then surgical consultation may be reasonable to decide on the disposition of the patient. If the PAS is <4, the patient has a low likelihood of appendicitis and does not necessarily warrant further imaging [29, 30]. This patient is less likely to benefit from a surgical consultation, and other causes of acute abdominal pain should then be considered.

If the patient is being seen in a hospital without pediatric surgery, the provider should consider transferring the patient after establishing the diagnosis or when there is any concern for a possible need for surgical intervention [33, 34].

Management

Initial Management of All Appendicitis Patients

Once the diagnosis of appendicitis is established, the most important first step in management is resuscitation and initiation of antibiotics [6, 8]. Fluid resuscitation may begin prior to completing the work-up, as most patients with appendicitis are dehydrated [6, 8]. The choice of antibiotics varies across institutions. Antibiotics should cover enteric flora including gram-negative and anaerobic bacteria. Providers should also consider the patient's allergy history and their hospital's local antibiogram and resistance patterns.

Surgical Management: Appendectomy

The gold standard treatment for appendicitis is appendectomy, either open or laparoscopic [1, 35]. Both approaches have good outcomes, though patients who undergo laparoscopic appendectomy report less pain, faster discharge, earlier mobilization, and early resolution of ileus [1, 35]. Additionally, laparoscopic appendectomies allow for a better cosmetic result and the ability to easily assess for other intraabdominal pathologies [1, 35]. If the appendix appears normal and no other pathology is identified, most surgeons will still remove the appendix to reduce the diagnostic conundrum if the symptoms persist or return. There are very few contraindications to appendectomy, though patients presenting in septic shock should be resuscitated prior to undergoing surgery. The appendectomy should be performed with some degree of urgency (<24 h from presentation), though does not to be performed emergently (<2 h from presentation) [36].

Several studies support a shift away from the traditional thinking that appendicitis was an emergency and that surgery ought to be performed immediately at the time of diagnosis [37–39]. Children presenting with >48 h of symptoms are more likely to present with complicated appendicitis; however the length of time from diagnosis to the operating room appears to play little to no role in whether the appendix will "perforate" while they await the operating room [37–39]. A study of 230 children which examined the impact of the time from diagnosis to appendectomy supports this change in thinking [38]. Children taken to the operating room at 0–3 h, 4–6 h, or longer than 6 h after diagnosis of appendicitis were not found to have a statistically significant difference in perforation rates or hospital length of stay [39]. Appendectomies that are performed emergently are not associated with decreased rates of perforation or other complications relative to those performed up to 24 h after presentation [37, 38]. Additionally, there is evidence to suggest those children rushed to the operating room may have a higher rate of post-operative surgical site infection in non-perforated patients and that children operated on after overnight fluid resuscitation and antibiotics have a lower risk of post-operative abscess [35, 40]. While in-hospital surgical delay does not appear to increase the risk of finding complicated appendicitis at the time of surgery, delays in patient presentation to the hospital are associated with a 4.9 times increased odds of perforation and a 56% increase on hospital length of stay [40].

After appendectomy, it is important to send the appendix specimen to pathology for review. The diagnosis should be confirmed with histology that may demonstrate acute inflammatory infiltrate, necrosis, thrombosis, and possible transmural infarction in perforated appendicitis. Other pathologies, besides appendicitis, may also be seen. Occasionally, no pathology at all is visualized. The rate of negative appendectomies for pediatric patients is estimated at 3.6%, though is higher for children less than 5 years old and girls older than 10 years old [41]. Patients who undergo diagnostic imaging pre-operatively have lower rates of negative appendectomies, regardless of age or sex [21]. Balancing the risks of perforated appendicitis, a negative appendectomy rate of less than 5% is acceptable at most institutions.

Children with simple appendicitis can be discharged soon after surgery once they demonstrate adequate pain control and oral intake [42]. They do not require further antibiotics. Patients with complicated appendicitis are admitted and maintained on intravenous antibiotics. The total antibiotic duration, intravenous and oral, should be approximately 3–7 days, though varies by patient and provider [43]. Some patients experience post-operative ileus, so their diets are advanced more slowly and occasionally require nasogastric decompression [1]. In patients who are not receiving oral nutrition after 1 week, parenteral nutrition should be considered. Patients with complicated appendicitis are also at high risk for a post-operative inflammatory response and are likely to require ongoing resuscitation with close attention paid to their urine output [1, 6, 8]. Finally, complicated appendicitis significantly increases the risk of development of a post-operative intraabdominal abscess or wound infection [8, 44]. Fever on post-operative day 5 or later should include examination of the incisions and consideration of imaging to rule out a possible intra-abdominal infection. Most patients with complicated appendicitis will have resolution of their symptoms by post-operative day 5. In cases where there is concern for an abscess, waiting until post-operative day 7 before scanning a patient will lead to fewer drainage procedures and decrease the need for additional cross-sectional imaging [45]. Depending on the size and location, well-formed fluid collections can be managed by antibiotics, image-guided drainage, or operative drainage [45].

Nonoperative Management

Patients who present with large well-formed abscesses from perforated appendicitis may benefit from delay in appendectomy [46]. These patients have often had symptoms for several days prior to presentation. Management consists of resuscitation, intravenous antibiotics, and bowel rest (NPO). The abscess is then drained percutaneously if safely accessible and a drain left in place to allow for ongoing drainage [46]. Patients' diets are slowly advanced, and the patient is discharged home on antibiotics with or without the drain in place.

Recently, many researchers have demonstrated resolution of pediatric appendicitis with antibiotics alone [47]. Patients are admitted for observation, intravenous antibiotics, resuscitation, and bowel rest. As their pain improves, patients' diets can be slowly advanced. Once their pain is resolved, they are no longer having fevers, and they are tolerating a regular diet, patients can be discharged home to complete an oral course of antibiotics. However, if patients demonstrate new-onset hemodynamic instability, rising leukocytosis, worsening pain, or persistent fevers after 24 h, the conservative nonoperative management is deemed unsuccessful, and appendectomy should be reconsidered [48]. For patients with perforated appendicitis, conservative management fails in as many as 10–25% of children [48]. Additionally, patients with evidence of an appendicolith are at high risk for failure of conservative management at 72% [49]. In patients with simple appendicitis, conservative management is successful in 72.7–90% of cases in resolving symptoms [50–52]. Conservative management is associated with longer lengths of stay, repeat imaging, and prolonged antibiotics [47].

Interval appendectomy can be offered after conservative management of appendicitis. Interval appendectomies are typically performed 2–3 months after the initial bout of appendicitis. Some proponents of conservative management are beginning to question whether interval appendectomy is necessary [53]. Interval appendectomies decrease the chance of recurrent appendicitis and allow for the evaluation of alternative pathology, such as inflammatory bowel disease or a neoplasm that led to the appendicitis. However, others report the risk of recurrent appendicitis is low enough to avoid subjecting the patient to the anesthesia, surgical risk, and extra cost [53]. As the utility of interval appendectomies and conservative management of appendicitis continue to be debated, patient and family preference will be useful in determining treatment plans. Ultimately, it is important to practice shared decision-making and to recognize patient reported outcomes such as pain, quality of life, disability, general anesthesia avoidance, and acceptance of the risk of recurrent appendicitis [54].

Follow-Up and Post-Operative Complications

After discharge, patients may develop a wound infection (<2% for laparoscopic appendectomy and 3–11% for open appendectomy) or an intraabdominal abscess (5% for simple appendicitis and 15% for complicated appendicitis) [8, 55, 56]. Evidence of cellulitis around the incision sites, fever, or ongoing abdominal pain requires further evaluation and possible diagnostic studies.

While waiting for an interval appendectomy after conservative treatment, approximately 10% of patients will have recurrent appendicitis. For those who do not undergo interval appendectomy, the risk of recurrent appendicitis ranges from 5% to 37% within the first year from the initial appendicitis diagnosis [53, 57]. After that year, the risk returns back to the general population lifetime risk of 7% [1]. However, patients with evidence of appendicolith are at increased risk or recurrence and therefore should undergo interval appendectomy [58].

The majority of patients do very well with timely management of appendicitis. Overall, the mortality rate for pediatric appendicitis is 0.1–1% and most commonly occurs in neonates and infants, where appendicitis is less common and diagnosed later [5, 55].

Gastrointestinal Vascular Anomalies

50

Melania Matcovici, Indre Zaparackaite, and Ashish P. Desai

Introduction

Vascular abnormalities are either present at birth or appear soon after. They are more commonly seen as cutaneous lesions.

The first scientific report of vascular malformations appeared in the literature in the seventeen century. In 1628, *William Harvey* published his major work, *On the Motion of the Heart and Blood in Animals*, where he explained blood circulation. Since then, there was a continuous scientific urge to explore the secrets of abnormal circulation and aberrant vascular communications.

In the nineteen century, a German scientist, *Rudolf Virchow* (1821–1902), the founder of cellular pathology, was the first to suggest that hemangioma is formed of new vessels rather than by passive dilatation of preexisting channels. He also speculated that these tumors appeared antenatally and continued to grow postnatally.

Embryology

The vascular system arises from mesodermal blood islands in the wall of yolk sack. These blood islands are composed of progenitors of blood cells and endothelial progenitor cells. Further development encompasses vasculogenesis (formation of embryonic vessels), migration of angioblasts to the organs, and angiogenesis (the process of growing new vessels). Angiogenesis is regulated by local factors maintaining the subtle balance between the inhibitors (e.g., thrombospondins, endostatin) and stimulators (e.g., vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiopoietins). VEGF is a key regulator in angiogenesis and has been found to be responsible for inducing penetration of the capillary vessels into the avascular epidermis [1]. As an end product, the vessels are composed of a single layer of endothelial cells surrounded by a variable number of layers of vascular smooth muscle cells.

Pathogenesis

The precise pathogenesis of development of vascular lesions is not fully understood. Nevertheless, development process should be considered separately for tumors and malformation.

Vascular Tumors

Vascular tumors are characterized by increased endothelial proliferation. The precise origin of the hemangiomal endothelial cells remains uncertain. Immunophenotypic similarities with placental endothelium suggest a placental origin [2]. The mechanism is believed to be embolization of placental endothelial cells, which enter the fetus from chorionic villi through right-to-left shunts (normal in fetal circulation). This theory was checked in different laboratories, though the results could not be universally confirmed.

In summary, hemangiomas express abnormal proliferation with increased endothelial cell turnover and increased surface markers (VEGF, bFGF) [3].

Vascular Malformations

Conversely, vascular malformations are a product of abnormal morphogenesis. Their endothelial lining is flat, smooth muscle architecture is abnormal, and the expression of surface markers is minimal. Vascular malformations are made up of dysplastic vessels without cellular proliferation, and they have no propensity to regress.

Classification of Vascular Lesions

In the past, the terminology used in association with such abnormalities has been rather confusing, being mainly descriptive and dismissive of the histological origin of the lesions. A binary classification, into *vascular tumors* and *vascular malformations*, was proposed by Mulliken and Glowacki in 1982 [4] and has since been adopted by the International Society for the Study of Vascular Anomalies (ISSVA), established in 1992 (Table 50.1). As more disease entities have been identified and more genetic basis has been discovered, in 2015, the classification was revised and an updated version was issued [5]. The extended detailed version of the classification is available on the ISSVA web site (www.issva.org).

The updated classification is based on the new genetic and histologic information available since 1996 and provides a more clinically relevant and flexible option. It can be used by all medical and surgical specialties.

Table 50.1 International Society for the Study of Vascular Anomalies classification system [6]

Vascular (or vasoproliferative) neoplasms	Vascular malformations
Infantile hemangioma	Slow-flow vascular malformations
Congenital hemangiomas Rapidly involuting congenital hemangioma (RICH) Non-involuting congenital hemangioma (NICH)	Capillary malformation Venous malformation Lymphatic malformation
Kaposiform hemangioendothelioma and tufted angiomas (with or without Kasabach–Merritt syndrome)	Fast-flow vascular malformations
Spindle cell hemangioendothelioma	Arterial malformation
Epithelioid hemangioendothelioma	Arteriovenous malformation
Other rare hemangioendotheliomas (i.e., composite, retiform, and others)	Arteriovenous fistula
Angiosarcoma	Combined vascular malformations (various combinations of the above)
Dermatologic acquired vascular tumors (i.e., pyogenic granuloma)	–

Accessed and used with permission from http://www.issva.org/content.aspx ?page_id=22&club_id=298433&module_id=152904

In order to understand different modalities of investigation and treatment, it is important to appreciate the different origin and behavior of vascular anomalies irrespective of their site.

We describe the main lesions with special emphasis on gastrointestinal (GI) lesions.

Group I: Vascular Tumors

Vascular tumors are divided into the following major groups [5]:

1. Benign:
   - Infantile hemangiomas
   - Congenital hemangiomas (CH):
     - Rapidly involuting congenital hemangiomas (RICH)
     - Non-involuting congenital hemangiomas (NICH)
     - Partially involuting CH (PICH)
   - Tufted angioma
   - Spindle cell hemangioma
   - Epithelioid hemangioma
   - Pyogenic granuloma (or lobular capillary hemangioma)
   - Others
2. Locally aggressive or borderline:
   - Kaposiform hemangioendotheliomas
   - Retiform hemangioendothelioma
   - Papillary intralymphatic angioendothelioma
   - Dabska tumor
   - Composite hemangioendothelioma
   - Kaposi sarcoma
   - Others
3. Malignant:
   - Angiosarcoma
   - Epithelioid hemangioendothelioma
   - Others

Infantile hemangioma is the most common tumor of infancy and childhood with recorded 1–2.6% incidence among Caucasian neonates. By the age of 1, some 4–12% of Caucasian children have hemangioma. The female-to-male ratio is 3:1. Hemangiomas are more common in premature babies [7]. They are usually apparent in the early neonatal period, proliferate until 1 year of age, and then slowly regress until the age of 7 when they end in the involution phase.

The hemangiomas of the GI tract only account for approximately 1% of all GI tumors [8]. They have a tendency toward multiplicity (intestinal hemangiomatosis), and solitary tumors are uncommon. They are often associated with cutaneous hemangiomas. If patients present with five or more cutaneous hemangiomas, the abdominal ultrasound

scan is indicated to look for visceral lesions. When present they are more commonly situated in the liver [9].

Overall, visceral vascular anomalies manifesting gastrointestinal symptoms are rare. Patients may present with GI hemorrhage, anemia, or symptoms of obstruction. An intestinal hemangioma rarely bleeds after the proliferative phase has ended. Therefore, occurrence of gastrointestinal bleeding secondary to hemangiomas after the first year or age 2 is very unlikely.

Eleven to thirty percent of GI hemangiomas may remain asymptomatic [10, 11].

Group II: Vascular Malformations

Although most vascular lesions are sporadic, inheritance has been observed and has thus provided a route to genetic analysis. Sporadic forms usually present as single lesions, but multiple lesions have been observed in familial cases.

Ninety percent of vascular malformations are present at birth. Estimated incidence of vascular anomalies in the general population is approximately 1.5% [12].

Female-to-male ratio is 1:1. These malformations infiltrate the surrounding tissue, never regress, and enlarge with the growth of the patient. Their growth can be worsened over time if not treated. Changes in hemodynamic factors such as arteriovenous shunting or venous stasis especially during puberty or pregnancy can accelerate growth and morbidity.

The "vascular malformations" group can also be subdivided into fast flow (arterial or arteriovenous) and slow flow (capillary, lymphatic, or venous). If fast-flow lesions are localized subcutaneously, they may become more erythematous and may develop a palpable thrill and a bruit.

Vascular malformations of the GI tract are rare in children, but they can be diagnosed at any age, including newborns [13]. They may appear anywhere in the GI tract from the mouth to the anus and may coexist with similar lesions on the skin.

Patients may present with recurrent abdominal pain; GI bleeding; acute or, more often, chronic anemia; intestinal obstruction; volvulus; intussusception; and palpable mass lesion. Sometimes these lesions might be mistaken for inflammatory bowel disease due to mucosal edema, nodularity, and vascular congestion. Bleeding per rectum may also raise differential diagnosis of symptomatic Meckel's diverticulum. Intestinal lesions often represent a diagnostic challenge requiring sophisticated methods of investigation.

Associated Syndromes

Certain syndromes are associated with GI vascular malformations, including:

1. Osler–Weber–Rendu disease (hereditary hemorrhagic telangiectasia)
2. Klippel–Trenaunay syndrome
3. Blue rubber bleb nevus (BRBN) syndrome
4. Proteus syndrome

1. Osler–Weber–Rendu Disease (Hereditary Hemorrhagic Telangiectasia)

This is a genetic disorder inherited in autosomal dominant manner occurring in 1:5000 of the general population. Genetic diagnosis is difficult, but tests are available for the *ENG*, *ACVRL1*, and *MADH4* mutations [14].

The condition typically presents with distinctive small skin and mucosal vascular malformations (telangiectasias) and may appear in the nose, lips, fingers, and along the GI tract. Larger arteriovenous malformations are usually localized in the lungs, liver, brain, and, occasionally, the spine. Though the main clinical problem is usually epistaxis, GI bleeding may also occur, but it is rare in pediatric population. The malformations developing in the liver may eventually lead to portal hypertension, high-output cardiac failure, or encephalopathy. The clinical diagnosis is based on the Curaçao criteria [15], which are:

- Spontaneous recurrent epistaxis
- Multiple telangiectasia in typical locations
- Proven visceral arteriovenous malformations (lung, liver, brain, spine)
- First-degree family member with hereditary hemorrhagic telangiectasia

Management Usually symptomatic treatment of anemia due to GI bleeding is the only required treatment, but in severe cases, argon plasma coagulation or laser therapy may be applied.

2. Klippel–Trenaunay Syndrome

This is a relatively rare condition with approximate incidence of 1:30,000 live births [16]. Historically, it is characterized by a triad of symptoms: capillary skin malformation (port wine stain), varicose veins (especially persistent embryonic lateral vein of Servelle), and bony/soft tissue hypertrophy of the extremity. This hypertrophy is caused by venous and lymphatic malformations localized in the soft tissue but often involving the bony structures. Most commonly, one extremity is affected, usually the leg, but multiple limb involvement is also possible.

The etiology of the syndrome is not entirely clear, but it is believed that most cases happen due to sporadic gene mutation, though some autosomal dominant inheritance cases are

also reported. Mutations in PI3K-AKT gene pathway may play a role in the development of the condition [17].

In association with the classical triad of clinical symptoms, the GI tract may also be affected by vascular malformations. Gastrointestinal tract involvement is observed in up to 20% of cases, usually in the rectum and sigmoid, which can manifest as gastrointestinal bleeding, usually during the first decade of life.

Management Angiographic intervention such as embolization of the bleeding vessel can sometimes be successful. Endoscopic therapy is usually preferred for localized lesions or postoperative residual disease. Endorectal resection extending to the transverse colon has been reported in cases of more extensive disease [18].

3. BRBN Syndrome (Bean Syndrome)

This is a very rare syndrome with slightly over 200 case reports in the literature. It is characterized by cutaneous and visceral venous malformations. These malformations can occur in any tissue but are most prominent in the skin and in the GI tract, the small bowel being the most frequently affected part. Their number can range between several to hundreds. In 2005, Fisherman et al. reported 557 lesions in one patient [19]. Cutaneous lesions are generally small (about 1–2 cm or even smaller), rubbery, compressible, blue to purple nipple-like nodules often found on the face, the upper limbs, and the soles of the feet.

Most cases are sporadic, but some autosomal dominant transmission has also been reported.

A common problem is GI bleeding presenting at early age and continuing throughout life, resulting in chronic anemia requiring repeated blood transfusions. Most patients respond to conservative therapy, which includes iron supplementation, octreotide, and blood transfusions. However, steroids, propranolol, interferon α2a, and sirolimus are sometimes used to decrease angiogenesis. Severe cases may require surgical excision [20]. Sirolimus has been reported to be a successful treatment for BRB [21].

Management A broad spectrum of treatment options is available, from conservative and endoscopic treatment to an aggressive surgical approach. Recently, various endoscopic treatments for gastrointestinal lesions have been suggested including injection of sclerosants [22]. The simple and relatively non-invasive nature of polidocanol injection suggests that it may be the treatment of choice for pediatric and adolescent patients with BRBNS.

4. Proteus Syndrome

This syndrome associates multiple nevus flammeus, body hemihypertrophy, partial achral gigantism, intra-abdominal lipomatosis, pachyderma involving the palmar and plantar aspects of the hand and foot, hypertrophy of vertebral bodies, venous and lymphatic malformations, and epidermal nevi [23].

Imaging of gastrointestinal venous malformations includes plain film. Phleboliths are characteristic of venous malformation and can occasionally be seen on plain film.

Lymphatic Malformations

Lymphatic malformations are relatively rare in the GI tract, especially in children.

The majority of intra-abdominal lymphatic malformations are identified within the mesentery and retroperitoneum. Lesions affecting the bowel are uncommon and account for less than 1% of all lymphatic malformations. Approximately, 70% of those are detected in the small bowel and 30% in the colon [24].

Patients may present with abdominal pain, failure to thrive, palpable cystic mass, intestinal volvulus, bowel obstruction, or intussusception. Differential diagnosis includes intestinal duplication cyst, ovarian cyst, teratoma, Wilms' tumor, and neuroblastoma. In the case of a small bowel lesion, the differential diagnosis of lymphangiomyoma and benign multicystic mesothelioma could be considered. Immunohistochemical analysis can give a clear indication if the lesion was derived from the lymphatic vessels (expected focal positivity of D2–40, a lymphatic endothelial marker).

Management Surgical treatment with complete resection is recommended in all cases due to the high risk of complications related to the increase in the size of the lesion. Sclerotherapy with a variety of sclerosing agents has been reported as a less invasive treatment option, but it has a variable recurrence rate with up to 100% in some series [25].

Primary Intestinal Lymphangiectasia (Waldmann's Disease)

Dilated intestinal channels resulting in lymph leakage into the small bowel lumen and responsible for protein-losing enteropathy leading to lymphopenia, hypoalbuminemia, and hypogammaglobulinemia characterize this disorder. The exact etiology of this condition is unknown, and it is generally diagnosed before 3 years of age. Patients often present with bilateral lower limb lymphoedema, inability to gain weight, and steatorrhea and later develop pleural effusions or ascites. This may be accompanied by abdominal pain. Sometimes the abdominal mass may be palpable, or patients may develop intussusception. Mechanical obstruction of the small intestine may be caused by localized edema leading to intestinal wall thickening and lumen diminution.

Management Diagnostic process can be helped by ultrasound scan, capsule endoscopy, CT, albumin scintigraphy, and sometimes lymphoscintigraphy.

The condition requires long-term medical treatment in the form of reduced dietary fat, medium-chain triglycerides, elemental diet, corticosteroids, and vitamin supplements [26]. In some localized cases, surgical resection may provide satisfactory results [27]. In chronic recurrent conditions, fibrin glue application has been used.

Investigations

The diagnosis of a visceral vascular lesion is often suggested by the patient's age, clinical presentation, and the appearance of associated cutaneous lesions. When investigating a possible GI lesion, aim should be employed toward the following:

- Diagnosis of the main lesion: type, location, relation to the other organs, etc.
- Diagnosis of associated anomalies: syndromes
- Hematological status
- Modalities of imaging

Several imaging modalities can be employed to establish more precisely the type and the location of vascular anomalies. MRI imaging, selective angiography, color Doppler sonography, multiphase CT enterography, and 99mTc-red blood cell (RBC) scintigraphy can all be useful for this purpose [28–31]. The slow-flow veno-lymphatic malformations on MRI scan are typically multispatial and multicystic and may have a partially solid component. Fast-flow arteriovenous malformations demonstrate turbulence, flow voids, and hyperintense signal.

From the imaging point of view, it is important to remember that while young the hemangiomas may behave like arteriovenous malformations and may exhibit the features of fast flow. The slow flow is being established in involution phase.

Currently, ultrasonography and MRI with contrast (T1- and T2-weighed sequences) are the most widely used modalities of initial diagnostic choice. MRI is more sensitive than CT in detecting venous malformations and can show more information regarding bowel wall thickening, fat infiltration, and vessels appearance or identify the presence of any soft tissue masses.

Nuclear scintigraphy can be useful to detect a venous malformation or to demonstrate a bleeding site.

At endoscopy, the whole GI tract should be visualized, if possible, by using different approaches, including rigid or flexible endoscopy, single- or double-balloon enteroscopy, and wireless capsule endoscopy. Each method has its advantages and limitations. Capsule endoscopy, for example, transmits a radio-frequency signal, which allows estimation of the location of the capsule and tracking of it in real time inside the GI tract. Nevertheless, unlike endoscopy it cannot treat pathologies it discovers. Another limitation, specific to the pediatric population, can be the age and size of the patient; these factors can affect tolerance of certain procedures and the accuracy of imaging.

Sometimes, the diagnosis is made during surgery which can be either laparotomy or laparoscopy and enterotomies.

Biopsies should be avoided because of the high risk of bleeding.

Treatment

Even though both hemangiomas and vascular lesions often present with bleeding, principal treatment options are entirely different.

Vascular Tumors

Visceral hemangiomas are at risk of bleeding in the proliferation phase, and the risk diminishes after they enter the involuting phase. In many cases, this could be achieved by using the inhibitors of angiogenesis. For example, extensive intestinal hemangiomatosis can be successfully managed with propranolol, corticosteroids, α-interferon, vincristine, and also thalidomide and somatostatin analog [32].

Vascular Malformations

Sclerotherapy

If amenable, especially if the vascular malformations are located in the anorectal region, direct injection and sclerotherapy can be performed [33].

The principal method of sclerotherapy is injection of water-based or oleous substances into abnormally dilated vessels that can inflict damage to endothelial lining and cause thrombosis, fibrosis, stenosis, and—eventually—scarring. Sclerotherapy for treatment of lymphatic and venous malformations employs a variety of agents, including absolute ethanol, bleomycin, OK-432 (picibanil), and doxycycline [2]. Each agent has a risk profile: Ethanol injections are painful, requiring general anesthesia even in adults, and may cause cardiovascular shock. Bleomycin may cause interstitial pneumonia or pulmonary fibrosis, and treatment with doxycycline may result in tooth discoloration or electrolyte abnormalities.

Medical Therapy

The antiangiogenic treatment is ineffective for vascular malformations. Some complicated vascular anomalies resistant to other treatments can be conservatively treated with sirolimus (especially if they have a lymphatic component), bevacizumab, and estrogen–progesterone combination therapy [15, 34].

Surgical Therapy

Once diagnosed, treatment options are segmental or wedge bowel resection band or suture ligation and argon plasma coagulation or electrocoagulation [35].

Conclusion

GI vascular lesions are rare. Vascular malformations are more common than vascular neoplasms. They require extensive investigations to identify the type and location. Different modalities need to be used to treat the lesions by limited resection or sclerotherapy. Many lesions require lifelong supportive therapy to treat chronic anemia and nutritional deficiencies.

Polyps and Other Tumors of the Gastrointestinal Tract

51

Warren Hyer, Marta Tavares, and Mike Thomson

Introduction

Children and adolescents with gastrointestinal polyps may present symptomatic with rectal bleeding, abdominal pain, or intussusception or alternatively, they may be asymptomatic, having been referred, either because an adult family member has been affected with early-onset colorectal cancer (CRC) or there is a known family history of a polyposis syndrome. Many children fall under the latter category. Managing these children and families requires knowledge of the different polyposis syndromes, their inheritance and genetics, potential for malignant change, and pediatric complications.

Gastrointestinal polyps in children fall into two major categories: hamartomas and adenomas (Table 51.1). Solitary polyps in children are most commonly hamartomas, predominant of the juvenile type, and such polyps are benign. Of the familial syndromes, familial adenomatous polyposis (FAP) is more common than juvenile polyposis or Peutz–Jeghers polyposis.

Table 51.1 Polyps and polyposis syndromes seen in childhood

Adenomatous polyposis syndromes
Familial adenomatous polyposis (FAP)

Peutz–Jeghers syndrome
Inflammatory polyps

PTEN phosphatase and tensin homologue deletion, *MYH* mutY human homologue

Clinical Presentation of Gastrointestinal Polyps

The most common clinical manifestation of a large bowel polyp is painless rectal bleeding. Other symptoms attributed to polyps include abdominal pain, altered bowel habit, and prolapse of polyp or rectum. Diagnosis will be made after full colonoscopy with polypectomy. The clinical presentation, endoscopic appearance, pathological findings, histological description of the polyp, and genetic investigations are all necessary to establish the correct diagnosis of a polyposis syndrome. Once a polyp has been identified at endoscopy, a carefully targeted family history must be taken to enquire if there are family members who have or have had cancer, the site of the cancers, and age of onset (see Table 51.2). Taking such a history to develop a detailed family cancer pedigree may require the expertise of a multidisciplinary familial cancer clinic or polyposis registry [1].

The Single Hamartomatous Polyp: The Juvenile Polyp

With a prevalence of up to 3% of children, the most common presentation of a single hamartomatous (or juvenile) polyp is painless bright red rectal bleeding with blood seen on wiping or mixed in the stool. Seventy percent of juvenile polyps are found in the rectum or rectosigmoid. The rest however are found more proximally, hence the need for pancolonoscopy. Single or solitary juvenile polyps are benign and confer no future risk of malignancy. Presently, it is unknown whether

children who present with a single polyp in childhood may continue to form polyps over time [2].

If a polyp is found to be solitary after full colonoscopy, and there is no relevant family history, endoscopic polypectomy should be sufficient treatment. After polypectomy, parents should be advised that juvenile polyps may be the first feature of a hamartomatous polyposis syndrome, and if new symptoms arise, the child should be reinvestigated. If multiple juvenile polyps are found (>3–5) or there is a positive family history (e.g., colonic polyps or early-onset CRC), a hamartomatous polyposis syndrome should be considered, and an alternative approach should be taken.

Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are a rare group of hereditary autosomal dominant disorders. The polyps themselves are benign, but the polyposis syndromes confer a significant potential for developing CRC and extra colonic cancers. The hamartomatous polyposis syndromes include juvenile polyposis syndrome (JPS), Peutz–Jeghers syndrome (PJS), and phosphatase and tensin (PTEN) hamartoma tumor syndrome, which includes Cowden (CS) and Bannayan–Riley–Ruvalcaba syndrome (BRRS).

Juvenile Polyposis Syndrome

JPS is rare, with an estimated prevalence of 1 in 100,000 individuals presenting with multiple hamartomatous polyps and an increased risk of gastrointestinal malignancies. Affected individuals develop multiple gastrointestinal polyps which are predominantly in the colon, though other areas of the gastrointestinal tract can also be involved. The condition should be considered in any patient with more than five juvenile polyps in the colon, any juvenile polyps found in other parts of the gastrointestinal tract, or if any juvenile polyp is found in a child with a positive family history. Patients present with chronic and acute gastrointestinal bleeding, anemia, prolapsed rectal polyps, abdominal pain, and diarrhea and can develop up to 50–200 polyps in the colon, while in some patients, with generalized juvenile polyposis, polyps can affect the colon, stomach, and small bowel. The total number of polyps needed to make the diagnosis remains controversial, between 3 and 5 [3]. A significant proportion of patients with juvenile polyposis have been reported to have other morphological abnormalities including digital clubbing, polydactyly, macrocephaly, alopecia, cleft lip or palate, congenital heart disease, and mental retardation. A specific variant of JPS called juvenile polyposis of infancy has an onset in infancy presenting with anemia and hemorrhage, diarrhea, protein-losing enteropathy, intussusception, and rectal bleeding. The course in such infants is fulminant, and, even despite colectomy, in severe cases, death occurs before the age of 2 years.

There is little doubt that juvenile polyposis is a premalignant condition. There is a 15% incidence of colorectal carcinoma occurring in patients under the age of 35 years, leading to a cumulative lifetime risk of CRC of 38–68% with a mean age of colonic neoplasia onset between 38 and 44 years [4].

Genetics of Juvenile Polyposis

JPS is a fully penetrant condition with variable expression. Sixty percent of cases are familial and the others occur sporadically. Germline mutations in *SMAD4*, *BMPR1A*, and *ENG1* cause JPS. Approximately 54% of JPS cases will have a detectable mutation [5].

Patients with the *SMAD4* mutation on chromosome 18q21.2 appear to have a higher risk of gastric polyps and hereditary hemorrhagic telangiectasia (HHT). The latter condition is characterized by cutaneous telangiectasia and risk of arteriovenous malformations. Patients found to have the *SMAD4* mutation should be screened for cerebral and pulmonary arteriovenous malformations associated with HHT [6]. *BMPR1A* is located on chromosome 10q22.3 and accounts for another 20% of JPS patients. *ENG1* mutation on gene 9q34.1 has recently been described in JPS patients without HHT.

Screening and Follow-Up

Once the gene mutation has been identified in the index patient, other at-risk family members should be tested. All children of an affected adult will have a 50% chance of inheriting the mutation, and if the family mutation is known, children should undergo genetic screening.

Current guidelines suggest affected children should undergo colonoscopic surveillance every 3 years or earlier if symptoms arise [7]. In those families where the gene mutation is not known, first-degree relatives of patients with JPS should be screened by a single colonoscopy starting at age 12–15 years, even when the subject is asymptomatic (Fig. 51.1).

Full colonoscopy is necessary as right-sided polyps are more common. All polyps should be resected. Annual colonoscopy is performed until all polyps have been resected after which the screening interval is stretched to every 2–3 years. Gastroscopy is commenced from mid-teens. Colectomy is warranted for patients with cancer, dysplasia, or high polyp burden with symptoms that cannot be controlled endoscopically.

PTEN Hamartoma Tumor Syndrome

This group comprises three rare genetic syndromes: Cowden syndrome, BRRS syndrome, and Proteus syndrome (the latter has very few intestinal features). All are associated with a mutation in the PTEN gene located at 10q23.3 [8]. All three syndromes are characterized more by extraintestinal manifestations than intestinal polyposis. The PTEN mutation can be detected in 80% of patients with Cowden, 60% with BRRS, and 50% with Proteus syndrome.

Cowden syndrome rarely presents in childhood. Clinical manifestations include macrocephaly, papillomatous papules, mucocutaneous lesions, facial trichilemmoma, and acral keratosis. It carries a 50% risk of breast cancer in adult women and a 10% lifetime risk of epithelial thyroid cancer. Guidelines presently recommend screening for breast, thyroid, endometrial, and kidney cancer from the age of 18–25 years.

BRRS presents in childhood with gastrointestinal hamartomas, particularly in the ileum and colon, which cause intussusception, rectal bleeding, and hypoalbuminemia. There are additional characteristics including macrocephaly,

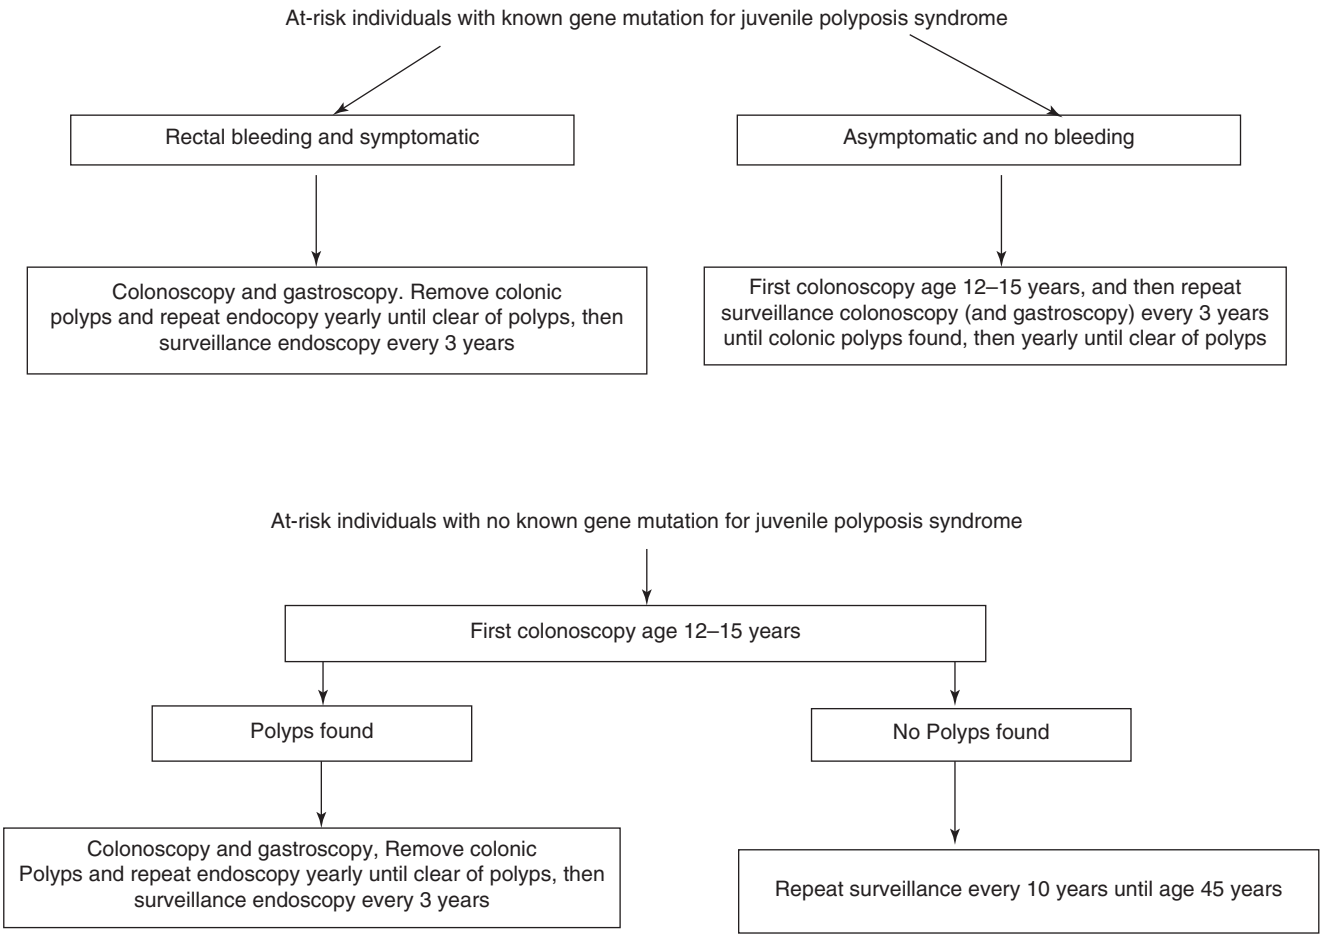

Fig. 51.1 Screening and surveillance algorithm for juvenile polyposis syndrome

developmental delay, abnormal metacarpal and phalanges, pectus excavatum, scoliosis, genital pigmentation, and hemangiomatosis. BRRS presents prior to adolescence, and there is value in genetic testing in early childhood in a family where the mutation has been identified. Patients with BRRS need regular colonoscopy and small bowel surveillance as they are at risk of anemia, intussusception, and hypoalbuminemia from the polyposis. They carry a probable lifetime increased risk of cancer, and surveillance is recommended from age 18–25 years focusing on renal, thyroid, and breast cancer [9].

Peutz–Jeghers Syndrome

Clinical Features and Diagnosis

PJS is a rare autosomal dominant condition with a prevalence of 1 in 50,000 to 1 in 200,000 live births. It is characterized by mucocutaneous pigmentation and the presence of hamartomatous polyps throughout the gastrointestinal tract. Polyps arise primarily in the small bowel and to a lesser extent in the stomach and colon. Polyps are most commonly found in the jejunum and cause bleeding and anemia or intussusception and obstruction from an early age. Presumptive diagnosis can be made in those with a positive family history and typical PJS freckling.

Pigmentation tends to arise in infancy, occurring around the mouth, nostrils, perianal area, fingers, toes, and the dorsal and volar aspects of hands and feet. The primary concern to the pediatrician is the risk of small bowel intussusception causing intestinal obstruction, vomiting, and pain (Fig. 51.2).

Fig. 51.2 Large obstructing duodenal PJS polyp seen at gastroscopy

In addition, intestinal bleeding—with melena, hematemesis, and rectal bleeding—can occur, leading to anemia.

Genetics of PJS

As with other hamartomatous syndromes, PJS has an autosomal dominant pattern of inheritance, and many cases may be sporadic new mutations. The mutated gene *STK11(LKB1)*, located on chromosome 19p 13.3, can be identified in up to 90% of PJS patients [10]. After appropriate genetic counseling and informed consent, testing at-risk family members may be performed early in childhood so that gastrointestinal surveillance can commence before gastrointestinal complications arise.

Screening, Management, and Complications

Individuals at risk of PJS should be evaluated in infancy for pigmented lesions and gastrointestinal symptoms. Asymptomatic at-risk children should undergo genetic testing for the family proband mutation in the STK11/LKB1 mutation if known, soon after infancy, so the family can access medical care early if the child develops symptoms consistent with small bowel obstruction.

The management of a young child with mid-gut PJS polyps is controversial, but recommended guidelines have been published [11]. Children who present with mid-gut intussusception need urgent polypectomy either by laparotomy or laparoscopy and intraoperative enteroscopy (IOE, Fig. 51.3). An IOE is recommended in any patient with PJS undergoing laparotomy, as careful endoscopy via an enterotomy in the small bowel allows identification and removal of polyps, thus avoiding multiple enterotomies and the risk of short bowel syndrome associated with

Fig. 51.3 Intraoperative enteroscopy performed at laparotomy for intussusceptions in a patient with PJS

resection. This technique is superior to palpation and transillumination in identifying polyps, and removal of all detected polyps ("clean sweep") reduces re-laparotomy rate significantly [12].

Endoscopic evaluation of the upper and lower gastrointestinal tract and imaging of the small bowel should be performed from the age of 8 years. Screening should start earlier if symptoms are present before this. Video capsule endoscopy (VCE) has replaced barium enterography as the preferred technique for assessing the small bowel [13]. VCE is more sensitive, preferred by patients, and reduces the lifetime risk from cumulative radiation exposure. An acceptable alternative to VCE is MRI enterography with a close correlation between the two modalities, especially with polyps >15 mm [14]. The advantages and disadvantages of prophylactic polypectomy for asymptomatic patients should be discussed with the family (Fig. 51.5).

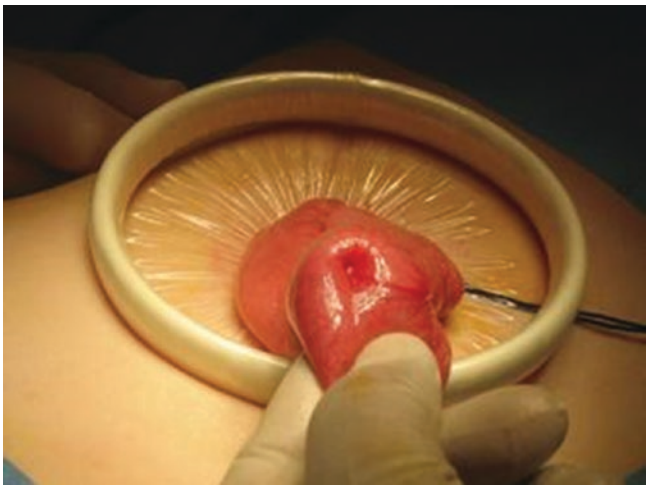

Fig. 51.4 Indentation of the serosal surface of the ileum from intussuscepting PJS polyp

Prophylactic polypectomy of larger small bowel polyps (>1.5 cm) by laparoscopy or double-balloon enteroscopy (DBE) should be performed in order to reduce the incidence of subsequent complications and the requirement for emergency laparotomy. Polypectomy via DBE in the small bowel carries a significant risk of perforation and should be performed only by those who are expert in polypectomy. Muscularis mucosa commonly invaginates into the large pedunculated stalk increasing the risk of perforation at electrocautery (Fig. 51.4). DBE can be combined with laparoscopy to assess perforations that may arise at polypectomy.

The risk of neoplasia is well documented in young adults. A meta-analysis to assess the risk of cancer in PJS identified a relative risk for all cancers in PJS patients (aged 15–64) of 15.2 compared to the normal population, with tumors. Clinicians caring for adolescents with PJS should be aware of unusual symptoms and have a low threshold for investigating potential malignancies. A recommended screening program for PJS patients after adolescence is shown in Table 51.3.

Table 51.3 Suggested program for screening for malignancies in Peutz–Jeghers syndrome after adolescence

General
Annual hemoglobin and liver function tests
Annual clinical examination
Genital tract
Annual examination and testicular US biennial from birth until 12 years
Cervical smear every 3 years from age 25 years
Breast
Monthly self-examination from age 18 years
Annual breast MRI from age 25 to 50, thereafter annual mammography

EGD esophagogastroduodenoscopy, *VCE* video capsule endoscopy, *MRI* magnetic resonance imaging

Adenomatous Polyposis Syndromes

Familial Adenomatous Polyposis

In children, GI adenomas are almost always associated with hereditary adenomatous polyposis syndromes. FAP is characterized by the development of hundreds of adenomas in the colon and rectum as well as several extra colonic manifestations. Almost all affected patients will develop a CRC if not detected and treated at an early stage.

Clinical Features

Patients with FAP typically develop multiple adenomas throughout the large bowel—usually more than 100 and sometimes more than 1000 (Fig. 51.6). Polyps begin to appear in childhood or adolescence and increase in number with age. The standard clinical diagnosis of typical/classical FAP is based on the identification of >100 colorectal adenomatous polyps. By the fifth decade, CRC is almost inevitable if colectomy is not performed. Attenuated FAP (AFAP) is a milder form of the disease which is observed in 8% of cases. It is characterized by fewer adenomas and later presentation [15].

Gastric fundic gland polyps occur in the antrum in 50% of FAP-affected adults, and small bowel adenomas also occur and neither requires intervention. Children under 5 years of age may develop hepatoblastoma, with an increased risk in boys [16]. Adult patients are at increased risk of malignancies of the duodenum and ampulla of Vater, with a lifetime risk of duodenal adenomas of 100%. Duodenal adenomas will progress to malignancy if untreated in 5% of adults and are the second most common malignancy in FAP and AFAP. In addition, FAP is associated with an increased risk of cancers of the thyroid, brain, and pancreas, while papillary carcinoma of the thyroid has been reported in adolescence.

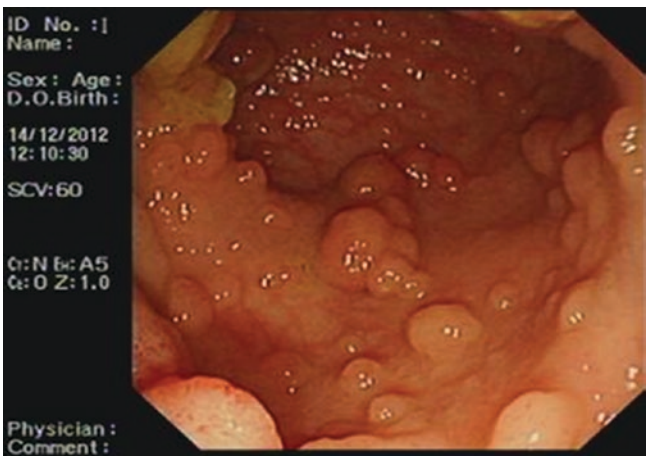

Fig. 51.6 Endoscopic appearance of large adenomatous polyps seen in advanced FAP

Table 51.4 Extracolonic manifestations of FAP in children and young adults

Site	Examples
Bone	Osteomas, mandibular, and maxillary
	Exostosis
	Sclerosis
Dental abnormalities	Impacted or supernumerary teeth
	Unerupted teeth
Connective tissue	Desmoid tumors
	Excessive intra-abdominal adhesions
	Fibroma
	Subcutaneous cysts
Eyes	Congenital hypertrophy of the retinal pigment epithelium
CNS	Glioblastomas, for example, Turcot syndrome
Adenomas	Stomach
	Duodenum
	Small intestine
	Adrenal cortex
	Thyroid gland
Carcinomas	Thyroid gland
	Adrenal gland
Liver	Hepatoblastoma

Extraintestinal manifestations are common (see Table 51.4). Pigmented ocular lesions (previously termed congenital hypertrophy of the retinal epithelium or CHRPE) are found in some but not all cases.

Genetics of FAP

FAP is an autosomal dominant inherited condition caused by a mutation in the adenomatous polyposis coli (APC) gene occurring in 1:10,000 births. In 20–30% of cases, the condition is caused by a spontaneous mutation with no clinical or genetic evidence of FAP in the parents or family.

The gene responsible for FAP, *APC*, is located on chromosome 5q21 and appears to be a tumor suppressor gene [17]. Most mutations are small deletions or insertions which result in the production of a truncated APC protein which then predisposes to adenoma formation. Many mutations have been identified on this large gene, and there is a correlation between the genetic site and severity of clinical manifestation. Mutations between codons 1250 and 1464 (Fig. 51.7), and especially those with a mutation at codon 1309, are associated with a severe form of FAP. Mutations localized at the extreme ends of the gene and in the alternatively spliced part of exon 9 are associated with a mild form of FAP, and an intermediate expression of disease is found in patients with mutations in the remaining parts of the gene. Other phenotype–genotype correlations have been observed [18]. These correlations are not absolute, and there may be considerable intrafamilial variation suggesting that there are other factors involved

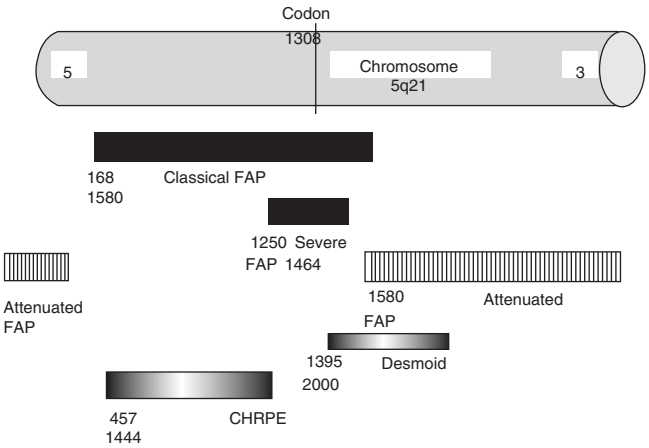

Fig. 51.7 APC protein domains showing FAP genotype–phenotype correlation with codon number. APC adenomatous polyposis coli, FAP familial adenomatous polyposis, CHRPE congenital hypertrophy of the retinal epithelium

in the pathogenesis of the disease. Families need to be aware that the mutation may only be detected in 70–90% of cases.

Diagnosis: Interpretation of the Genetic Test and Clinical Screening in FAP

In order to determine the appropriate screening protocol for a given family, the first step would be to seek which mutation is present in the FAP affected index case. If a mutation cannot be found, the genetic testing is non-informative, and it will not be possible to offer predictive testing to asymptomatic at-risk relatives.

When family-specific mutation is identified, directed DNA diagnostic techniques can be readily used to predict FAP in other family members. The absence of the gene mutation in other family members is considered accurate in excluding FAP, and the subject should be considered to hold an average population risk for the subsequent development of adenomas and cancer. Such genotype negative individuals can be discharged from follow-up.

The presence of the family-specific gene mutation confirms the diagnosis of FAP, and such patients should undergo endoscopic assessment. The diagnosis is confirmed by finding adenomas at colonoscopy (see Fig. 51.2). Teenagers predicted at gene testing to be affected will require a colonoscopy by the age of 14–16, preferably beginning at age 12–14 years [19], to determine polyp density and location, and degree of dysplasia. Upper endoscopic surveillance of the stomach, duodenum, and periampullary region with a side-viewing endoscope can be delayed until after the age 20 years, unless the patient has symptoms such as upper abdominal pain which warrant earlier investigation. In children from families in which the mutation is not known or cannot be identified, the genetic testing is non-informative, and it will not be possible to offer predictive testing to asymptomatic at-risk children. Protocols vary, but current approach is to perform colonoscopy on all first degree relatives from the age of 12–14 years every 3–5 years until adenomas are found. If by the age of 20 years, no adenomas have been identified despite the use of chromoendoscopy, colonoscopy should be performed at five yearly intervals.

No patient should undergo screening for FAP without detailed counseling. The individual being screened must understand the nature of the test and its possible outcomes. Many authorities feel that the child should be involved in the decision-making process and the diagnosis be delayed until the child is old enough to contribute to the screening program, for example, from the age of 12 years onward [20]. Although parents might request testing of a child or infant at a young age, there is value in deferring a test until the child or adolescent can participate in the discussion [21]. Well-informed consent, as a mature minor, prior to predictive testing is the most desirable outcome. There are psychological issues, as well as family, insurance, and employment implications, which may arise in the case of a positive result. These should be discussed prior to testing, and there should be a clear protocol for posttest management [22].

The current advice is to commence endoscopic surveillance from the early teens. Some patients, especially those with a mutation located at codon 1309 in the APC gene, may develop severe polyposis of the colorectum before the age of 10, and therefore, attention must be paid to FAP-related symptoms. These symptoms may include increasing bowel movements, looser stools, mucous discharge, rectal bleeding, abdominal, or back pain. In symptomatic patients, endoscopic investigation may be indicated at any age. Severe dysplasia and even malignancy have been documented in children with FAP under the age of 12 years. Consequently, those children from families in which severe dysplasia or carcinomas have been found at a young age should undergo screening at an earlier age [23]. Some clinicians advocate annual screening for hepatoblastoma with liver palpation, ultrasound, and serum á-fetoprotein levels in at-risk children between the ages of 0 and 6 years although current guidelines suggest this is not required [19].

Management of FAP

Internationally agreed guidelines are currently in place for the management of patients with FAP [24]. The role of colonoscopic surveillance is to assess adenoma burden and determine adenoma distribution especially in the rectum as these impact on surgical options for colectomy. Extra time should be spent in the rectum counting adenomas, especially those

= or >2 mm. If polyps are small or hard to visualize, chromoendoscopy should be considered to improve visibility of polyps.

There is no evidence for accelerated carcinogenesis and therefore no indication that the colonoscopy should be performed every year. The risk of developing cancer in teenage years is as low 0.2% so waiting 1–3 years between colonoscopies would appear safe, so long as families are not lost to follow up [25]. It should be acknowledged there is a phenotypic variation in this age group and the interval between colonoscopies needs to reflect this. Intrafamilial variation is well recognized so relying on family history alone is unsafe. The presence of a gene mutation associated with a more aggressive phenotype (e.g., codon 1309) should not dictate alone the timing of colonoscopy. The presence of symptoms, in particular rectal bleeding and/or anemia, suggests a significant polyp burden and requires an earlier colonoscopy.

Colectomy is currently the only effective therapy that eliminates the inevitable risk of CRC. In the absence of severe dysplasia, colectomy is usually performed in mid- to late teens or early 20s to accommodate work and school schedules. Almost all screen-detected adolescents are asymptomatic and therefore may not be willing to contemplate interruptions in their schooling or effects on relationships. The surgical option, therefore, must not only be carefully timed but also have low morbidity and excellent functional result.

There is no clear evidence to dictate at what polyp size or colonic burden should lead to colectomy and any recommendations remain arbitrary. Current practice is arbitrary recommending colectomy when there are many adenomas >10 mm, >500 of polyps >2 mm, or carpeting of the colon of polyps. The timing of primary preventative surgery may be influenced by knowledge of the mutation site and the likely severity of the polyposis. For example, patients with a deletion at codon 1309 should be offered earlier surgery since this phenotype is characterized by a large number of polyps and a higher risk of cancer [26].

Surgical options are either subtotal colectomy with ileorectal anastomosis (IRA) or restorative proctocolectomy with ileal pouch anal anastomosis (IPAA or pouch procedure). The IRA is a low-risk operation with good functional results and can be performed laparoscopically. There is no pelvic dissection, and therefore, attendant risks of hemorrhage, loss of fertility in women, and damage to adjacent organs such as the ureters are avoided. Complication rates after IRA are low, and postoperative bowel function is almost always good, averaging four semi-formed stools daily. After the IRA, the rectum remains at risk of cancer. Therefore, postoperative six-monthly surveillance of the rectum is mandatory.

An IPAA procedure removes the CRC risk almost completely but is more complicated than an IRA. It carries a higher morbidity and risk of complications. It often requires a temporary loop ileostomy, reoperations and longer hospital stays, night evacuation, and decreased fertility in women [27]. Bowel frequency is generally higher than that for an IRA. The risk of cancer does exist after IPAA as they may develop at the anastomosis or below. The pouch should be examined regularly postoperatively for adenomas [28].

The advantages of an IPAA with a lower risk of cancer must be balanced against the higher operative morbidity. Conversion after an IRA to an ileoanal pouch can be carried out when the patient is older [29]. An IPAA is the treatment of choice if the patient has a large number of rectal adenomas, for example, >20 adenomas, if there is the presence of adenoma with severe dysplasia, a colon with >1000 adenomas, or those with high-risk genotypes (e.g., codon 1309) [30, 31]. In patients with only a few rectal adenomas or with a polyp-free rectum, both options are possible although an IRA may be preferable. The decision can be made on an individual basis, considering preoperative sphincter function, patient compliance, and risk of desmoid.

Desmoid Disease

Desmoids are locally aggressive but non-metastasizing myofibroblastic lesions which occur with disproportionately high frequency in patients with FAP. Putative risk factors include abdominal surgery, positive family history for desmoids, and site of the mutation (mutations beyond codon 1444). In contrast to sporadic desmoid tumors, the majority of the tumors associated with FAP are located in the abdominal wall or intra-abdominally. The tumors can be diagnosed by CT scanning or MRI. Desmoids occur most commonly in the peritoneal cavity (Fig. 51.8) and may infiltrate locally leading to small bowel, ureteric, or vascular obstruction. These lesions may progress rapidly or may resolve spontaneously, their unpredictable nature making them difficult to treat [32]. Attempted surgical resection carries a high morbidity and mortality and usually stimulates further growth. The options for treatment are pharmacological (nonsteroidal anti-inflammatory drugs (NSAIDs) [33] and/or anti-estrogens), chemotherapy, surgical excision, or radiotherapy. Pediatricians treating children with extraintestinal desmoid tumors should consider the possibility of FAP in the family.

Chemoprevention

NSAIDs may be protective against colon cancer by inhibiting prostaglandin synthesis via their effects on cyclooxygenase (COX). Publications have shown a significant reduction in the number of rectal polyps in those patients taking the NSAID sulindac after colectomy. However, despite pro-

Fig. 51.8 Intra-abdominal mass from a desmoid tumor seen in a teenager with FAP

tracted drug use, the adenomas still progressed with case reports of rectal cancer. Sulindac administered before the development of polyps in genotype-positive adolescents did not prevent the development of adenomas.

Cyclo-oxygenase-2 (COX-2) enzyme is induced in inflammatory and neoplastic tissue. Selective COX-2 inhibitors generate fewer gastrointestinal-related side effects compared to the classical non-selective NSAIDs. One of these drugs (celecoxib) was found to reduce the number of colorectal adenomas by 28% [34] and also to reduce the number of duodenal adenomas [35]. Unfortunately, cardiovascular side effects have been reported in patients using selective COX-2 inhibitors. The safety and efficacy of celecoxib as a chemopreventive agent in pediatric population was first studied in a cohort of 18 children of ages 10–14 years with APC gene mutations and/or adenomas with a family history of FAP [36]. Celecoxib at a dose of 16 mg/kg/day, corresponding to an adult dose of 400 mg twice per day, was well tolerated and significantly reduced the number of colorectal polyps by 44.2% at 3 months (p = 0.01), but the cohort was small (n = 18). The largest randomized placebo-controlled chemopreventive study in children using celecoxib (n = 106) suggested the drug was well tolerated and there was a non-significant trend to slower progression of colorectal adenomas in the therapeutic arm compared to placebo [37]. Although NSAIDs cannot replace surgical treatment for colonic FAP, they may play a role in postponing surgery in patients with mild colonic polyposis or patients with rectal polyposis after prior colectomy. Other agents investigated but with so far inconclusive effect on polyp burden include vitamin C, oral calcium, and ornithine decarboxylase inhibitor difluoromethylornithine (DFMO) and eicosapentaenoic acid present in fish oil [38].

Prognosis

Genetic investigations, colonic surveillance, and prophylactic colectomy have impacted favorably on mortality in FAP-affected patients. Studies that evaluated the mortality of patients with FAP reported that surveillance policies and prophylactic colectomy have resulted in a reduction in the number of FAP patients that died from CRC. Currently, a greater proportion of deaths are attributable to extracolonic manifestations of the disease (desmoid tumors, duodenal cancer). Central registration in a family cancer registry and prophylactic examination lead to a reduction of CRC-associated mortality and ensure appropriate follow-up and patient support.

MYH-Associated Polyposis and Lynch Syndrome

MYH-associated polyposis (MAP) is characterized by the presence of adenomatous polyposis of the colorectum and an increased risk of CRC. Patients present with a variable number of polyps but no apparent extracolonic features. This autosomal recessive condition results from a compound heterozygote of the *mutY* human homologue (MYH) gene located on chromosome 1p. MYH polyposis should have no pediatric implications as colonic polyposis typically occurs in patients in their 40s, although cancer and polyps can occur at earlier ages. Surveillance colonoscopy in affected individuals should commence at age 25 years.

Lynch syndrome is an inherited condition with a high penetrance for the development of early CRC caused by an alteration in DNA mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, *PMS2*). With no described pediatric complications, the syndrome is associated with colorectal, endometrial, ovarian, gastric, renal tract, and other cancers. The median age for the development of CRC in Lynch syndrome is approximately 44 years and is uncommon below the age of 25 years. Revised criteria (Amsterdam II or Bethesda criteria) exist to help identify affected families and enable genetic testing for the DNA mismatch repair genes in early adulthood. Once identified as at risk, colonoscopic surveillance should be undertaken from the age of 20 to 25 years.

Other Polyposis Syndromes

Gorlin syndrome is an autosomal dominant condition comprising upper gastrointestinal hamartomas and pink or brown macules in exposed areas such as the face and hands.

Turcot syndrome (also referred to as brain tumor-polyposis syndrome) is characterized by concurrence of a primary brain tumor (most often glioblastoma multiforme) and multiple colorectal adenomas. The number of adenomas is often not high, but many of the reported patients have been adolescents. Patients with a polyposis syndrome and neurological symptoms should undergo thorough neurological examination and investigation for possible brain tumor.

In patients with long-standing inflammatory colitis, inflammatory polyps (pseudopolyps) may develop. Inflammatory polyps are of no significance and have no malignant potential.

The Role of a Polyposis Registry

There are numerous advantages to integrating a family into a cancer/polyposis registry. Polyposis registries are established across the world. A polyposis registry enables registration of polyposis patients and family members accessing counseling and genetic testing and initiation and coordination of screening of family members at risk of a polyposis syndrome. By increasing the rate of diagnosis of FAP and other polyposis syndromes, and enabling earlier diagnosis, there is proven improved survival of patients registered, almost certainly attributable to the improvement in organization and coordination of patient screening [39].

Other Tumors of the GI Tract (Excluding the Stomach and Hepato-biliary)

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are a unique variety of mesenchymal tumors that have recently been described. They are very uncommon among children and adolescents, and their true incidence is not well known due to the small number of described cases.

The overall incidence rates of GIST are reported to range between 6.5 and 14.5 per million per year [40–42]. The UK National Registry of Childhood Tumours showed an annual incidence of 0.02 per million children below the age of 14 years [43].

GISTs were described for the first time in 1990 and probably arise from neural interstitial cells of Cajal. Its molecular oncogenetics derives from mutations in the KIT oncogene (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homologue) that encode for class III receptor tyrosine kinases and platelet-derived growth factor receptor alpha (PDGFRA), which are expressed in GIST patients. About 0–10% of pediatric GISTs have an oncogenic KIT mutation [44–46], and only two patients were reported with a PDGFRA mutation to date [47, 48] which reflects probably other downstream activation pathways other than c-Kit mutation. A small subgroup of syndromic GISTs were found to have common germline mutations encoding the succinate dehydrogenase (SDH) gene [48, 49]. Recently, another molecule, IGF1R (insulin growth factor receptor 1), was found to be significantly expressed in a series of 17 GISTs including one pediatric GIST, both by Western blot analysis and immunohistochemistry, and that it seems to be a new attractive pathway for this complex oncogenic process [50].

Immunohistochemically, these tumors stain positive for vimentin (CD-117, a *c-kit* proto-oncogene protein) and CD-34—and stain negatively for smooth muscle actin [51]. Since the use of CD117 staining in 2002, 82% of mesenquimatous tumors were considered to be GISTs, so its true incidence rose since there, with a proportional decline of smooth muscle tumors cases [52]. Histologically, GISTs are composed either of spindle-shaped cells, epithelioid cells, or a combination of both, being spindle-shaped type slightly more frequent in a large analysis of 99 of 113 pediatric cases [53].

GISTs can present as sporadic or inherited cases, and the latter can be inherited through familial autosomal dominant fashion or as syndromic tumors, named as the Carney triad.

Carney Triad

GIST can occur rarely in association with other tumor syndromes. The association of gastric leiomyosarcoma, extra-adrenal paraganglioma, and pulmonary chondroma was first described in 1977 and subsequently named the Carney triad [54]. It affects predominantly females, and it has been described as a chronic benign-course tumor that comprises recently also adrenocortical tumors and esophageal leiomyoma [55–57]. Neither KIT, PDGFRA, nor SDH mutations were found in patients with the Carney triad. In 2002, Carney and Stratakis distinguished an inherited tumor syndrome comprising GIST and paragangliomas which have common germline mutations encoding SDH subunits B, C, and D, and it was termed Carney–Stratakis dyad [58].

Familial

Familial GIST cases are very rare, and they are autosomal dominant inherited. They differ from Carney dyad as they are heritable germline KIT mutation tumors. Occurrence of

multiple tumors can be observed both in syndromic [59–64] and in sporadic GIST. Familial GISTs do not have female predominance, and the main location is the small intestine, in contrast to sporadic GIST where the stomach is the main affected place [61, 65]. Other phenotypic characteristics associated with familial GIST include mastocytosis [66], dysphagia [67, 68], cutaneous hyperpigmentation or urticaria pigmentosa [59, 61, 64, 69, 70], and recurrent small intestinal diverticular perforation [68]. Familial GIST does not develop early in life, as the youngest patient in a GIST family described to this date had symptoms at 18 years old [70].

Sporadic

A considerable number of articles describing children and adolescents with sporadic GIST have been published [71–73]. Sporadic GISTs have been described in newborns [72–75], but the majority of cases become symptomatic in the second decade of life. There is a strong female predominance with a male-to-female ratio of 1:2.5.

The majority of pediatric GISTs are located in the stomach (mainly in the antrum) [45, 72–74, 76–80], but it can be found virtually in every digestive tube segment as well as mesentery, omentum, and abdominal wall [81–84].

Clinical presentations vary from upper gastrointestinal bleeding with anemia and anemia-related symptoms to nonspecific symptoms such as loss of appetite, poor feeding, abdominal pain, abdominal distension, nausea, vomiting, constipation, epigastric discomfort, diarrhea, and intestinal obstruction [53]. Sometimes they are incidentally discovered in a routine abdominal examination as a palpable mass, suggestive for a more advanced stage of the disease, or at ultrasound [53].

GISTs generally have a nodular growth pattern, with frequent submucosal spreading. Surface ulceration may result in acute or chronic bleeding which promotes clinical investigation (Fig. 51.9). Gastrointestinal contrast series denote solitary or multiple nodular round filling defects. Even without metastases on presentation, submucosal spreading can occur, so endosonography can be a very useful diagnostic resource [44, 80, 85–87]. Other image tools include abdominal and thoracic CT or MRI to perform disease staging. Metastases on diagnosis are not frequent, but they may occur in the liver (most commonly), lymph nodes, peritoneum, and mesentery. Even without metastasis on diagnosis, these are very frequent places for recurrent disease [47, 72, 76, 77, 87].

Fluorodeoxyglucose positron emission tomography (FDG-PET) seems to be a sensitive diagnostic tool, particularly to monitor treatment response. The final diagnosis is based on histology and immunohistochemistry. Tissue samples can be obtained either by biopsy or by tumor resection, which in many cases of small localized disease, is usually the only procedure needed [88].

Fig. 51.9 GIST in the stomach. GISTs gastrointestinal stromal tumors

There are no algorithms for children GIST workup as well as for the treatment. As in adults, total resection with microscopic free margins is the gold standard treatment. Adjunctive therapy from conventional cytotoxic chemotherapy had no positive results. Localized disease is usually cured by surgery, and it can be performed more than once in recurrent disease or in incomplete primary resection. Metastases should undergo surgical treatment as lymph node dissection and resection of hepatic-affected areas [88].

Recently, there are increasing cases of children treated with RTK inhibitors (imatinib and sunitinib), based on adult experience. They may be considered in high-risk patient such as metastatic diffuse disease or when the primary tumor cannot be fully resected. Despite the fact that there are no randomized trials in children or consensus on imatinib dosage, a starting dose of 400 mg/m^2 once daily might be suggested with a maximum dose of 400 mg bid = 2 times daily [53].

In children, prognosis depends on the results from surgery of the main tumor lesion and the presence of metastatic lesions, especially if they are not amenable to complete resection [44, 76, 77, 89–91]. Recurrences are frequent and may occur many years following diagnosis, but it seems that mortality from GIST is low, despite tumor recurrence and development of metastases.

In summary, the pathogenesis, clinical course, and prognosis of GIST in children are currently insufficient due to the small number of reported cases. Future research based upon controlled randomized trials should be encouraged to inform about optimal management in this particular population.

Gastrointestinal Autonomic Nerve Tumors

Gastrointestinal autonomic nerve tumors (GANT) are variants of GIST. Diagnosis is based on electron microscopic studies showing neural differentiation in contrast to GIST, and the number of pediatric patients with GANT is limited to a few cases [92–97].

Inflammatory Pseudotumors

Inflammatory pseudotumors are solid tumors composed of spindle cells, myofibroblasts, plasma cells, and histiocytes that can occur in every organ system during childhood [51, 98, 99]. Lung is the most common location, whereas occurrence in the gastrointestinal tract is rare, the majority involving the stomach [100] (Fig. 51.10). They are commonly described as plasma cell granulomas or inflammatory myofibroblastic tumors. Abdominal pain is the most common presenting symptom but may also present with dysphagia, intestinal obstruction, and iron-deficient anemia. It affects mostly girls, as reported in the literature [98].

Like the majority of gastrointestinal tract tumors in childhood, complete surgical resection is the treatment of choice. Sporadic trials of nonsteroidal and steroidal anti-inflammatory medications have been reported for the treatment of large and unresectable masses. Its success rate seems to be variable [101]. Recurrence rates are reported between 18% and 40% and are more common in extrapulmonary lesions. Multiple recurrences are associated with a higher rate of malignant transformation with an overall mortality of 5–7% [51, 102, 103].

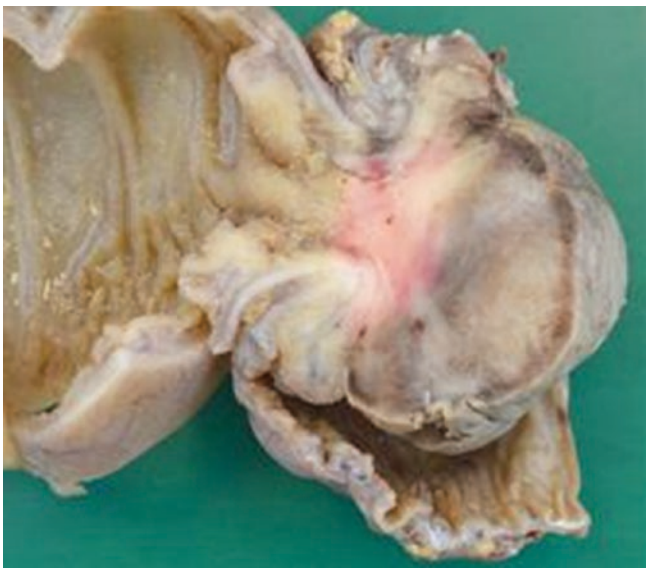

Fig. 51.10 Inflammatory pseudotumor

Sarcomas

Soft tissue sarcomas account for 7% of all childhood malignancies, and only 2% of this group have digestive involvement [104, 105]. Sarcomas are smooth muscle-derived neoplasms that occur anywhere along the gastrointestinal tract, more often involving the stomach and small intestine (leiomyomas) (Fig. 51.11). In the stomach, these can be confused with the appearance of an umbilicated lesion typical of an ectopic pancreas. The malignant form (leiomyosarcoma) is more common in the jejunum [106, 107]. The definition of malignancy usually is based on mitotic index at histologic examination (more than ten mitoses per high-powered field), but in children, it is not common to see a high mitotic index that enables the adult classification of leiomyosarcoma [51]. Nearly 40% of these present with less than five mitoses per high-powered field, so pathologic features must also include tumor size, cellular atypia, tumor necrosis, and myxoid change [108].

Clinical presentation occurs early on life, with over half of the leiomyosarcomas occurring in the newborn period, but they can present throughout childhood and adolescence. The clinical signs vary from an incidental mass finding to active GI bleeding associated with anemia signs or acute perforation. They can also be the cause of recurrent intussusception [109–112]. Rare presentations include cough and dysphagia (if esophageal location) and oral cavity swelling [113, 114].

Symptomatic lesions may also present concurrently in patients with neurofibromatosis and in children with human

Fig. 51.11 Leiomyoma of the stomach

immunodeficiency virus (HIV) [115–117]. The goal of treatment is complete resection as pediatric leiomyosarcomas are less likely to be found with metastases at diagnosis [118], and the use of adjuvant chemotherapy and radiotherapy remains experimental. Long-term outcomes for leiomyosarcomas are related with the histologic type of the tumor and with successful surgical excision.

Carcinoid Tumors

Carcinoid tumors in children are quite rare, and their true incidence is unknown. The occurrence of carcinoid tumors in children was recently reported as approximately 0.1% of all pediatric cancers [71, 119]. These tumors are more prevalent in school-aged children, but younger patients have been reported. An overall female-to-male ratio of 3:1 has been noted [119]. Despite their rarity, carcinoid tumors have been described in all portions of the gastrointestinal tract from the stomach to the rectum. The most common location is the appendix, followed by involvement of the small intestine and rarely the colon and rectum [120]. Reports have also documented the presence of carcinoid tumors in gastrointestinal duplication cysts and Meckel's diverticulum [121–123]. The diagnosis is often made through the incidental pathologic findings within an appendectomy specimen. However, these tumors may present with clinical signs of hematochezia or anemia from chronic gastrointestinal blood loss, right-lower quadrant abdominal pain, and small bowel obstruction-associated signs [119, 121, 124]. The vast majority of carcinoid tumors are benign. Occasionally, they may be locally invasive, especially if originating from the colon or small intestine. Few reports have noted their malignant transformation in children, with metastasis to the liver, lung, and bone [119]. Serotonin hypersecretion signs known as carcinoid syndrome with cutaneous flushing, diarrhea, asthma-like respiratory distress, and right-sided cardiac failure are quite rare [121, 124, 125].

Incidental gastrointestinal carcinoid tumors which are less than 2.0 cm in diameter and without evidence of metastasis are successfully treated with complete resection, which should include tumor-free margins. For those with evidence of serosal penetration or local extension, a bowel resection with associated mesenteric resection is required, along with abdominal surveillance for metastatic disease [51]. Patients with tumors exceeding 2.0 cm in size should undergo thorough evaluation for possible metastases to the liver, lung, and bone. Serum 5-hydroxyindoleacetic acid (5-HIAA) levels may act as a serologic marker of disease, but are not present in all metastatic cases. Serum chromogranin A is more reliable as a marker and does not require metastases for this to be an abnormal result. Abdominal and thoracic CT or MRI and 99m-technetium bone scan should be considered in patients with metastatic disease and/or bone pain. Children with metastatic disease often respond poorly to cytotoxic chemotherapy, but they can benefit from the administration of octreotide for symptomatic relief [119].

Gastroenteropancreatic Neuroendocrine Tumors

Pediatric gastroenteropancreatic neuroendocrine tumors (GEP-NETs) have traditionally been classified into two groups: carcinoids, which are subdivided by their origin into tumors of the *foregut* (lung, thymus, stomach, duodenum); *mid-gut* (jejunum, ileum, appendix, right colon), and *hindgut* (left colon, rectum); which were previously discussed; and pancreatic tumors [126]. A more useful classification was proposed by the World Health Organization in 2000: well-differentiated NETs, which show benign behavior and well-differentiated neuroendocrine carcinomas, which are characterized by low-grade malignancy and poorly differentiated NEC of high-grade malignancy [127].

These tumors can be *functional* or *nonfunctional*. Functional tumors have clinical symptoms caused by hypersecretion of hormones such as gastrin, while nonfunctional tumors can produce clinically silent hormones such as pancreatic polypeptide. The functional tumors are named according to the hormone responsible for the clinical syndrome, such as gastrinoma causing Zollinger–Ellison syndrome and insulinoma causing hypoglycemic syndrome. NETs can either be sporadic or occur as part of familial syndromes such as multiple endocrine neoplasia (MEN) I and II, von Hippel–Lindau (VHL) syndrome, and neurofibromatosis type I (NF-I) [128].

GEP-NETs are very rare in children. Tumors with gastroenteropancreatic hormone production include amine precursor uptake and decarboxylation tumors (APUDomas), extrapancreatic gastrinomas, and vasoactive intestinal polypeptide tumors [129, 130]. Pancreatic NETs account for approximately 30% of pancreatic tumors in patients younger than 20 years. While insulinomas are the most common in adults, gastrinomas are more common in children and affect more frequently the stomach. Hypersecretion of gastrin by gastrinomas causes recurrent or ectopic peptic ulcers (Zollinger–Ellison syndrome) or malabsorption diarrhea [128]. Non-gastrinoma neuroendocrine tumors can occur in any part of the pancreas [131]. Metastases are present in 60–80% of patients at initial diagnosis of gastrinoma, with the liver and lymph nodes being the most common sites of metastatic disease [132]. There is limited information in the pediatric literature regarding the imaging findings of NETs

as well as treatment options. PET scan with octreotide labeling may help in diagnosis. Prognosis of this rare entity depends on disease extension and presence of metastatic disease. A recent study from a European registry showed an overall survival of 100% when complete surgical resection was performed in patients with localized neuroendocrine neoplasm (NEN) in contrast to poor survival rate associated with metastatic disease [133].

Adenocarcinoma

Progression to adenocarcinoma from polyposis syndromes such as FAP and the HNPCC is dealt with the above.

Colorectal cancer's prevalence in children is very low with fewer than 500 pediatric cases reported in the literature and a few articles dealing with this as reviews [134–138]. Compared to adults who have no predetermining diseases, in children, there is usually preexisting polyposis or, rarely, colitis.

Pathogenesis

Colorectal carcinoma is due to sequential genetic mutations, commonly known as the adenoma–carcinoma sequence. Progress to malignancy happens due to the coexistence of four or more genetic problems which can include mutational activation of oncogenes and inactivation of tumor suppressor genes.

Pathology

Colonic carcinoma in children is usually cecal or right-side colonic disease, with 50% in the ascending and transverse colon. If colonic cancer penetrates the bowel wall, it can spread to regional lymphatics and subsequently to distant lymph nodes and metastasize to the liver, lungs, and vertebrae. Cases are staged according to the degree of local spread and presence or absence of transmural penetration, the degree of lymph node involvement, and the presence of distant metastases. In a review of younger cases with colonic cancer, 82% of these cases had either distant metastases, lymph node involvement, or transmural penetrating disease, significantly higher than adult cases.

In adults, the CRC is that of a moderate to well-differentiated adenocarcinoma. In children, this is a more aggressive type, with more proportion of tumors with mucinous (30%) and signet-ring (10%) histological appearances, hence with a poorer prognosis—this probably leads to the poorer prognosis at presentation in children (Fig. 51.12).

Clinical Presentation

Abdominal pain is the main presenting symptom in the majority of cases—other symptoms include weight loss, intussusception, vomiting, rectal bleeding, and altered bowel habit. The site of the lesion is important with constipation, obstruction, and bleeding more common with left-sided disease and, more commonly in childhood, right-sided disease which may not present with obstruction until the cancer is larger and a mass is palpable.

Diagnosis is by most usefully achieved by ileocolonoscopy in the majority (Fig. 51.13), although the lesion

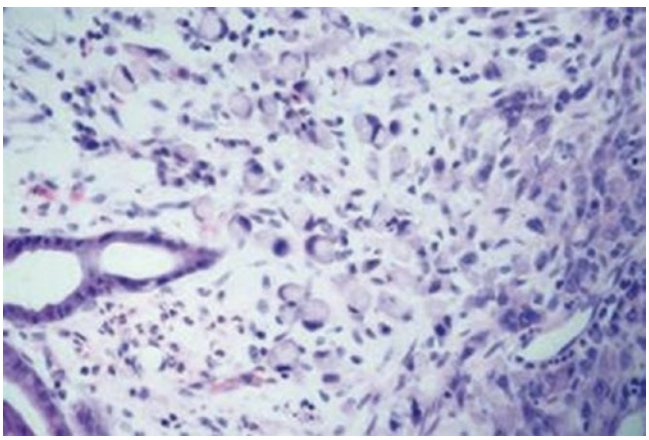

Fig. 51.12 Histological appearance of signet-ring adenocarcinoma

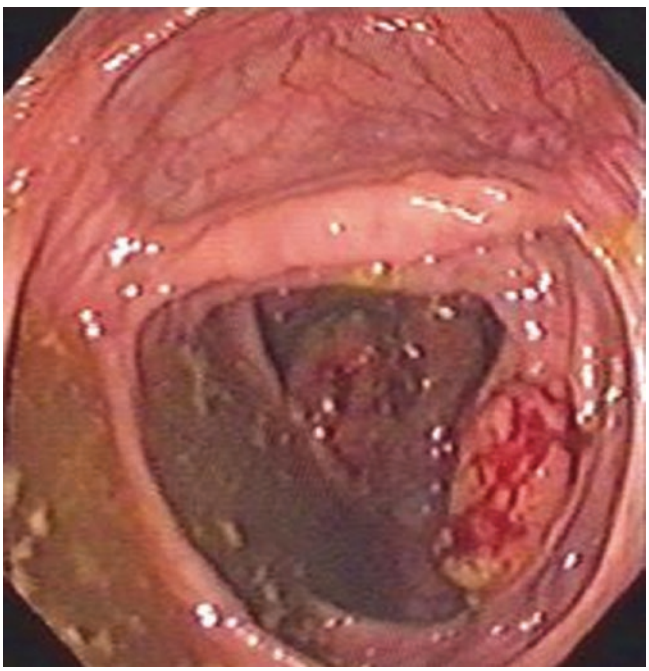

Fig. 51.13 Colonoscopic appearance of rectosigmoid adenocarcinoma

can also be identified by other diagnostic techniques including wireless capsule endoscopy, ultrasound, CT colonography, or MRI. Although serological markers such as carcinoembryonic antigen (CEA) are available, their role in establishing this rare diagnosis in children has not been fully evaluated.

Treatment/Prognosis

Surgery is the most effective treatment for colonic carcinoma, with complete resection of the primary lesion and regional lymph nodes being the main aim; however, total clearance and resection are often not possible in children due to the advanced stage at presentation. Chemotherapy for metastatic disease has poor results, and the role of radiotherapy or combination therapies grouping childhood cases is hampered by limited numbers presenting precluding viable randomized studies.

Sadly the prognosis for children with colon cancer is poor with 5-year survival rates of 10–20% [134–141]. These poor results are due to a combination of aggressive phenotype and delayed presentation.

Lymphoma

Epidemiology and Classification

In the developed world, lymphoma accounts for 10% of all cancers in children under 15 years of age—however, it is an unusual GI condition and would need a predisposing condition in most cases, for example, celiac disease or isolation by distance (IBD). Nevertheless, cases occur without these prerequisites [142, 143].

Etiology

Non-Hodgkin's lymphoma (NHL) usually presents in association with immunodeficiency syndromes—inherited (e.g., ataxic-telangiectasia, severe combined immunodeficiency (SCID)) and acquired (e.g., HIV infection)—and also with immunosuppressive drug regimens such as those encountered after liver transplant [144]. Epstein–Barr virus (EBV) may play a role in disease pathogenesis especially in Burkitt's lymphoma, although malaria coinfection may be important in promoting B-cell activation as part of the process. Other conditions that give rise to chronic mucosal inflammation have also been linked to lymphoma including *Helicobacter pylori*. T-cell NHL is associated with celiac disease, while both lymphoma and adenocarcinoma are associated both with Crohn's disease where the lesion is typically in the small bowel and with ulcerative colitis [142, 143].

Pathology

Intra-abdominal NHL in children typically is of an undifferentiated histological type—only around 50% have a primary intestinal origin—and the most common intestinal primary sites are the distal ileum, cecum, and appendix. Bone marrow involvement occurs in up to 40% of undifferentiated lymphoma, while central nervous system involvement is uncommon. In Burkitt's lymphoma, 60% can have abdominal disease.

Clinical Presentation

Disease may present with nonspecific symptoms such as abdominal distension, nausea, vomiting, altered bowel habit, and abdominal pain. Lymphoma in the GI tract is typically localized to the distal ileum and cecum and would present as a mass or occasionally as an ileo-cecal intussusception manifesting with obstructive symptoms or bleeding.

Endoscopy is important in diagnosis (Fig. 51.14), and when the tumor is suspected but is outside the reach of conventional endoscopes, then wireless capsule endoscopy (Fig. 51.15) and balloon enteroscopy can be useful tools in identifying lesions and then if necessary biopsy of these lesions and tattooing, thereby accurately localizing them in case of the absence of serosal abnormality for future surgical

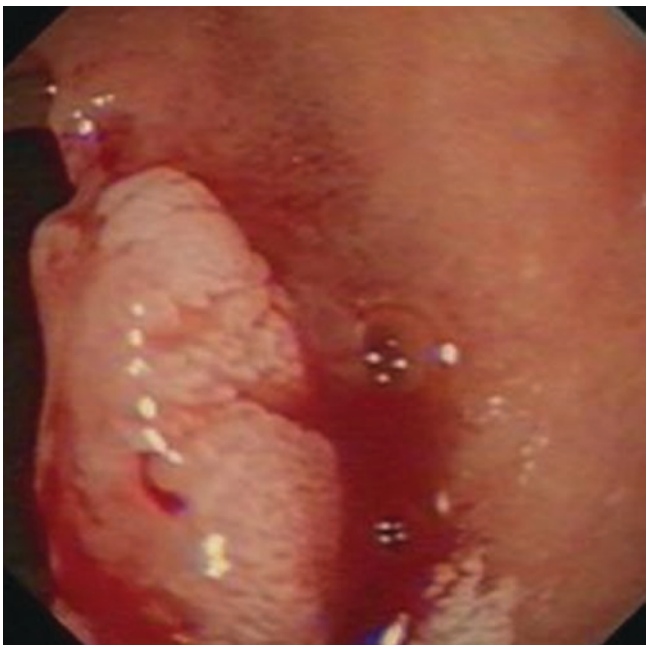

Fig. 51.14 Endoscopic appearance of small bowel lymphoma

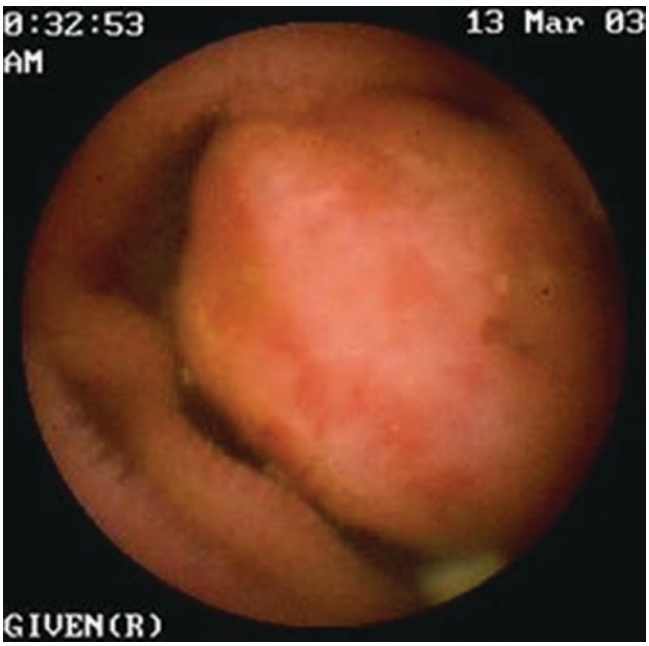

Fig. 51.15 Lymphoma in the mid-small bowel identified by wireless capsule endoscopy

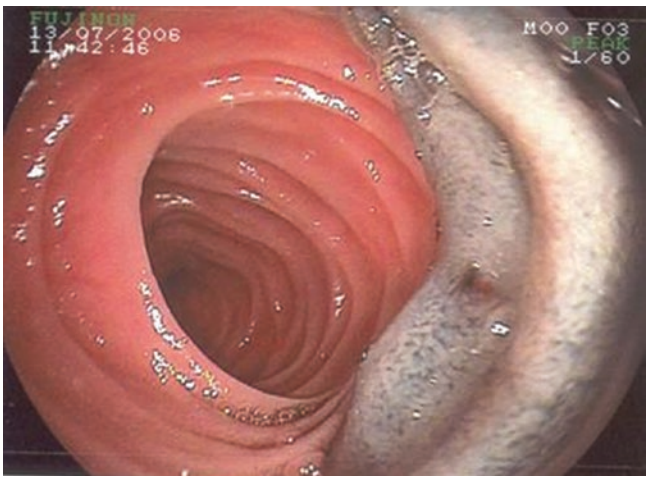

Fig. 51.16 Biopsy and then tattooing for identification of the exact site of a small bowel tumor by double-balloon enteroscopy prior to surgery

resection (Fig. 51.16). The diagnosis of NHL depends on histological examination with immunophenotyping and cytogenetics. Staging of disease with chest and abdominal imaging, lumbar puncture, and bone marrow examination is also required and may allow treatment to start if there is a delay in undertaking a laparotomy.

Treatment and Outcome

Surgical resection of local disease is indicated where it is possible, although such fully resectable disease accounts for only 60–75% of cases [144]. The high mortality associated with intestinal perforation in more advanced disease has led to debate as to the role of partial resection as opposed to simple biopsy to establish histological type. Subsequent chemotherapy is required in all cases. For more localized disease, the overall outcome is relatively good. In 30% of childhood, NHL cases with localized disease cure rates as high as 95% have been reported following combined surgical resection and combination chemotherapy [144].

Abbreviations

CDI	*Clostridium difficile* infection
FMT	Fecal microbiota transplantation
GVHD	Graft-versus-host disease
IBD	Inflammatory bowel disease
IBS	Irritable bowel syndrome
MDRI	Multidrug-resistant organism infections
SAEs	Serious adverse events

Introduction

Humans are inhabited by a huge number of microbes, most of them being located in the gastrointestinal tract: the intestinal microbiota. This is not a simple reserve of microorganisms; it should be considered a real organ instead [1, 2]. Plenty of research is ongoing on this matter, but its composition is not yet fully known. *Bacteroidetes* and *Firmicutes* are the most represented phyla, having on their side archaea, viruses, fungi, and protozoa [3].

Gut microbiome is involved in a large number of physiologic functions including modulation of local and systemic immunity, regulation of metabolic pathways, and development of a barrier against exogenous agents. A solid scientific evidence suggests that dysregulation of intestinal microbiome homeostasis can lead to development of both digestive and extradigestive diseases, ranging from gastrointestinal infections to inflammatory bowel disease (IBD), colon cancer, metabolic syndrome, irritable bowel syndrome (IBS), and allergies [4].

Theoretically the reconstitution of a "healthy" intestinal microbiota represents a valid approach for the management of diseases related to microbiota dysregulation. Antibiotics, probiotics, and prebiotics are currently the most widely used therapeutic options in children. In adults, fecal microbiota transplantation (FMT) has already demonstrated undoubted efficacy in the management of recurrent *Clostridium difficile* infection (CDI), and it is already considered a therapeutic strategy for other diseases associated with intestinal microbiota imbalance [5]. At the moment there is paucity of data on FMT in children and the associated microbiome changes.

It is well known that microbiome of a child, especially in the very young, differs from that of an adult, both in terms of initial colonization of the infant gut and in terms of dynamic microbiome development over the years, until the stage for a relatively stable microbiome in the healthy adult [6].

Fecal Microbiota Transplantation in Children

FMT is the infusion of feces from a healthy donor to a sick recipient for the treatment of a specific pathology, in order to modify the microbial composition and reduce gut dysbiosis [5]. Transfer of human fecal product modifies microbiome composition shifting it toward the healthy donor, increasing recipient fecal microbial biodiversity, short-chain fatty acid, and secondary bile acid synthesis [7]. These changes can persist up to 6 months following FMT [8].

In children, especially in the very young age, the intestinal microbiome is known to differ from that of adults. Very little data has been published in recent years characterizing associated microbiome changes with FMT in pediatric populations. Microbiome changes have been reported in a

20- month-old boy [9], with decreased diversity of the microbiome prior to FMT—abundance of *Proteobacteria*— and increased diversity after FMT, increasing of *Bacteroidetes*, similarly to what has been already described in adults [7]. In a case series of older children with CDI and with or without IBD, increased microbiome diversity after FMT has also been described [10].

In general, microbial signatures demonstrating decreased gut microbiota and phyla diversity have been shown to predispose individuals to CDI [5].

Anyhow, the administration of FMT products requires a rigorous screening process in order to minimize the risk of donor-derived infection (DDI). Consensus recommendations have been published for adults and also for children, jointly by the North American (NASPGHAN) and the European (ESPGHAN) Society for Pediatric Gastroenterology, Hepatology and Nutrition [11]. A combination of screening questionnaires (to exclude high-risk donors), donor serologic testing for transmissible pathogens (e.g., syphilis and HIV), and donor stool tests to reduce the risk of DDI (e.g., stool enteric pathogen culture, CDI testing, and *Norovirus* and *Adenovirus*) are requested. Institution-specific protocols are also available in FMT centers.

Pediatric Fecal Microbiota Transplantation: Clinical Indications

Clostridium difficile, more recently termed *Clostridioides difficile*, is a spore-bearing gram-positive anaerobic organism responsible for significant morbidity and mortality among children and adults. In children, the incidence of CDI has significantly increased in the last 20 years. Some studies have reported an almost twofold increase in pediatric CDI hospitalizations between 2001 and 2006, and a 12.5-fold increase in overall CDI incidence per 100,000 children [12].

Risk factors for CDI include antibiotic use in the previous 4 weeks, solid organ transplant, and the presence of gastrostomy or jejunostomy (G or J) tube. CDI diagnosis is often challenging because of high carrier rates for *Clostridioides difficile* in children less than 2 years of age [11].

Recurrence following CDI occurs in 11–20% of pediatric patients [12]. Management of recurrent CDI is not well studied in children, with evidence mostly inferred from adult studies. FMT has been shown to be more effective than antibiotics for recurrent CDI in adults. Cammarota et al. [13] showed a cure rate of 90% in patients treated with FMT compared with 26% rate in those treated with vancomycin. van Nood et al. [14] showed a resolution rate of 81% after FMT compared with 31% after vancomycin alone. However no randomized controlled trials (RCT) in children have been performed yet. There is also paucity of pediatric large case series up to now. A multicenter retrospective cohort study by Nicholson et al. on 372 children—between the ages of 11 months and 23 years old—affected by recurrent CDI [15], reported that FMT was effective in 81% cases, demonstrating CDI resolution at 2 months following a single FMT. It has to be noted that 32% of patients in this cohort had IBD. Multiple case series and reports have shown therapeutic success of FMT in pediatric RCDI, regardless of the mode of delivery.

Nonetheless, there is very limited data on FMT treatment in pediatric IBD, and no RCT is available to date. The evidence in pediatrics is limited to case series and individual reports. In a report of ten children, IBD clinical remission was described in three of eight UC patients and two of two Crohn's disease (CD) patients after eight doses of FMT [16]. In a prospective study, Goyal et al. [17] reported a clinical response in 57 and 28% at 1 and 6 months after a single FMT in 21 IBD patients. Although responders showed an increase in diversity of microbiome 1 month after FMT, at 6 months these changes returned to baseline conditions. Other reports are available in literature demonstrating similar efficacy and transient response.

A separate mention needs to be done for very young children who represent a unique population, both given their dynamic microbiome profiles and their peculiar and changing physical size. The youngest reported child receiving FMT for CDI is a 13-month-old infant [18]; few other reports of cases under the age of 3 years have also been published. All cases were successful, but in this population, clinicians should be very careful about the choice of patient for FMT, given the high rate of asymptomatic carriage of *Clostridium difficile* in very young children, as largely specified by the joint NASPGHAN and ESPGHAN recommendations [11].

FMT has also been explored as a therapeutic strategy for the management of IBS and chronic idiopathic constipation. Available data are limited to the adult population and small numbers.

FMT has been successfully used in multiple reports to decolonize adult patients with multidrug-resistant organism (MDRO) infections, including vancomycin-resistant *Enterococcus* and *Klebsiella pneumoniae*. However, data regarding the overall efficacy of FMT in this setting remains limited, and no pediatric data is available so far.

FMT has been proposed as a mechanism to restore gut microbial diversity and decrease complications following hematopoietic stem cell transplant and GVHD. However, there are no pediatric data to date, and while the prospect of FMT for refractory gut GVHD remains promising, additional investigation is needed.

Potential therapeutic applications of FMT have been further explored in the treatment of a wide range of illnesses, including allergic colitis and behavioral and gastrointestinal manifestations of autism spectrum disorder [19, 20], but no robust conclusion can be designed in these two fields of interest.

Up to now, the only indication for which FMT can be used without an investigational new drug application from the Food and Drug Administration is CDI. When children with CDI may need FMT, guidelines may be the following: *(i)* in recurring or relapsing CDI, with at least three episodes of mild–moderate infection and failing a 6–8-week vancomycin taper or at least two episodes of severe CDI resulting in hospitalization and associated with significant morbidity; *(ii)* in moderate CDI not responding to standard therapy for at least a week; and *(iii)* in severe CDI with no response to standard therapy after 48 h. Children with CDI who may need FMT most often are affected by mild–moderate recurring or relapsing CDI.

Pediatric Fecal Microbiota Transplantation Safety Profile

Although the long-term safety of FMT has not yet been established, serious adverse events (SAEs) are overall rare. Among children, a multicenter retrospective cohort study of 335 patients receiving FMT for CDI demonstrated SAEs in 4.7% of subjects in the 3-month period after FMT [15]. Among children, data on the safety of FMT among immunocompromised hosts are scant, and no AE has been reported on four immunocompromised pediatric patients [12]. In general, while available studies to date suggest that FMT is safe and effective among immunocompromised individuals, additional studies are needed to characterize the safety and efficacy of FMT among immunocompromised children.

Conclusions and Future Perspectives

Up to now the only indication for which FMT can be used without an investigational new drug application is CDI also in pediatric populations. Nevertheless, while studies about FMT in children hold a great promise for the treatment of recurrent CDI, and possibly IBD, some concerns should be raised specifically pertaining to pediatric FMT. The first concern is about the stool donor: most studies on FMT in children have used an adult donor, even if it is well known that children, especially if in the first years of their lives, have a developing gut microbiome that correlates with development of the immune system and other physiological functions [21]. It should be further explored whether the transfer of an adult microbiome to a developing microbiome in a child may predispose to altering immune aging and developing immune-related complications [22] (Fig. 52.1). Currently there have been no studies with long-term follow-up of FMT in children to provide answers. Technical aspects for FMT in children are also unanswered. The optimal amount of stool to be used for children of varying sizes and best mode of delivery still needs to be addressed. Moreover, different donor screening protocols for infection should be used for FMT in children, who are less likely than adults to have been exposed to such infections as cytomegalovirus.

In conclusion, it is already known that FMT is an effective treatment for recurrent CDI in adults. In children data is still limited, but initial reports seem encouraging that FMT is effective for recurrent CDI as well. FMT seems to be safe at least in the short term in pediatric IBD. Nevertheless, clinicians approaching FMT in a child should keep clear in mind that manipulation of the intestinal microbiome has the potential to have implications on both gastrointestinal and non-gastrointestinal sites, especially when manipulating the developing microbiome of a child that is particularly vulnerable. Further studies are awaited on pediatric populations in the near future.

Prebiotics in Pediatrics

53

Francesco Savino

Introduction

The concept of prebiotics was first suggested by Gibson and Roberfroid in 1995 in their scientific publication *Dietary modulation of the human colonic microbiota: Introducing the concept of prebiotics*. In the decades that followed, scientific discussions about prebiotics tended to focus on identifying substances that targeted health-promoting groups of bacteria in the gut, in particular bifidobacteria and lactobacilli [1–3].

Although the original term was approximately defined, subsequent publications suggested that the fructans, namely, oligofructose and inulin, fructo-oligosaccharides (FOS), and lactulose, and the galactan, galacto-oligosaccharides (GOS), were the only established prebiotics at that time [4]. Early research mainly focused on those few substances (Table 53.1).

However, by the early 2000s, the development of the next generation of rationally selected prebiotics had been proposed [5]. Researchers suggested that resistant starch (RS), milk oligosaccharides and pectin, and other fiber components had prebiotic potential [6, 7]. These have now been classified as new prebiotics [5] (Table 53.2).

Research on the development of intestinal microflora in newborn infants showed that it was strictly related to the feeding method they received [8].

Breastfed infants, unlike bottle-fed ones, were shown to have an intestinal ecosystem that was characterized by a strong prevalence of bifidobacteria and lactobacilli [9, 10].

There are numerous substances present in human milk, and data have been published that show that one of the main components, oligosaccharides, has a clear prebiotic effect. They are only partially digested in the small intestine, and when they reach the colon, they selectively stimulate the development of bifidogenic flora. Studies have also confirmed that human milk oligosaccharides were the first prebiotics in humans. This has been recently proved both by the characterization of oligosaccharides in the feces of breastfed infants and by studying intestinal microflora using new molecular analysis techniques [11].

The oligosaccharide content and concentration in breast milk is a dynamic process, just like other macronutrients, and it has been impossible for the industry to mimic nature. However, even if the composition cannot be faithfully replicated, the effect and function can be imitated. Human milk promotes growth of specific gut microorganisms, mainly of

Table 53.1 Confirmed prebiotics

Prebiotics	Food source
Galacto-oligosaccharides (GOS) Fructo-oligosaccharides (FOS) Inulin	Legumes, chickpeas, beans, and lentils Asparagus, garlic, and leeks Chicory, artichokes, onions, wheat, and bananas
Lactulose	Synthetic disaccharide

Table 53.2 New prebiotics

Prebiotics	Food source
Polyphenols	Cloves, dried herbs, green tea, and beans
Pectin	Cell wall components of fruit, asparagus, garlic, and leeks
Resistant starch	Potato, corn, and tapioca
Soy	Soybeans
Cellulose	Component of plant cell walls
β-Glucans	Soluble fibers found in oats and barley cereals
Mannose	Many fruits and vegetables
Xylo-oligosaccharides, arabinoxylo-oligosaccharides	Wheat bran
Maltose, malto-oligosaccharides	Products broken down from starch
Isomaltulose	Honey, sucrose, and sugarcane juice
Raffinose oligosaccharides	Beans, lentils, and peas

the *Lactobacillus* and *Bifidobacterium* species, and they have also become the preferred target organisms when it comes to evaluating the effects of prebiotics [12].

The addition of two oligosaccharides to infant formulas based on cows' milk, galacto-oligosaccharides and inulin, has been shown to have a bifidogenic effect and to stimulate the growth of bifidi and lactobacilli. That is why they are added to infant formulas [13, 14] (Table 53.3).

The most abundant human milk oligosaccharide (HMO) in most mothers' breast milk is 2'-fucosyllactose (2'-FL). This molecule has recently been synthesized and shown to be structurally identical to the human milk. 2'-FL HMO is now available in some commercial infant formulas. Preclinical research has demonstrated that HMOs, and specifically 2'-FL, are more than just prebiotics. They have multiple functions, including immune stimulation, gut health, and cognition benefits [15–18].

Animal studies of *Il10* $^{-/-}$ mice have shown that post-weaning administration of specific oligosaccharides can shift the composition of the gut microbiota and reduce chronic inflammation. The expansion of *Ruminococcus gnavus* sets a positive microbial environment that lowers intestinal inflammation but at the cost of pro-inflammatory Gram-negative bacteria [19–21].

As our knowledge about the influence of prebiotics on the microbiota continues to grow, there have been continued discussions about the need to enlarge the definition. Recently, Bindels et al. proposed that a prebiotic should be defined as "a nondigestible compound that, through its metabolization by microorganisms in the gut, modulates composition and/or activity of the gut microbiota, thus conferring a beneficial physiological effect on the host" [22]. Their proposed definition identifies the ingredient as the causative agent for changes in the microbiota. It also excludes the restrictive language related to selectivity and specificity while maintaining the need to identify a beneficial physiological effect. This helps pave the way for investigations into bacteria that have not been historically studied, such as bifidobacteria and lactobacilli. For example, butyrate-producing bacteria, such as *Faecalibacterium prausnitzii* and *Akkermansia muciniphila*, which is a mucin-degrading bacterium, have both been associated with beneficial health effects, including reduced inflammation and improved gut barrier function, respectively [6, 22].

More recently, new methods have been developed to investigate gut microbiota, such as next-generation sequencing. These methods have revealed more complex outcomes from prebiotic administration, with quite different and sometimes unexpected members of the microbiota being enriched by these supplements. In particular, several putatively beneficial autochthonous gut strains, including *Faecalibacterium prausnitzii* and *Akkermansia muciniphila*, have been shown to respond to specific prebiotics [23–28].

Consuming other substances, such as resistant starch and various soluble and insoluble fibers or human milk oligosaccharides, may also enrich other, as yet unidentified, strains of the gut microbiota. This may occur directly or via cross-feeding [29, 30]. However, there have been a lack of sequencing studies on the clinical application of quite a lot of the new prebiotics.

Taking into account these new observations, Bindels et al. have proposed enlarged definitions for prebiotics, as detailed above. So have Bird et al. [6, 22], who have further proposed that prebiotics should be viewed as "undigested dietary carbohydrates" that are fermented by colonic bacteria and create short-chain fatty acids as end products.

The current scientific definition of a prebiotic was reviewed by a panel of experts in microbiology, nutrition, and clinical research that was convened by the International Scientific Association for Probiotics and Prebiotics in 2016. The present consensus definition is "a substrate that is selectively utilized by host microorganisms conferring a health benefit." This notion is based on three inner parts: a substance, a physiological effect, and a mechanism [4, 31, 32] (Table 53.4).

Table 53.3 Prebiotics in infant formulas

Prebiotics	
Galacto-oligosaccharides (GOS)	GOS
Fructo-oligosaccharides (FOS)	FOS
2'-Fucosyllactose (2'-FL)	2' FL

Possible Effects of Prebiotics

If we are to understand how prebiotics work, and more importantly how to use them to influence the microbiota and improve health, we need to realize that the microorganisms that live in the gut are part of complex functional ecosystems.

Microbes play several roles within these ecosystems, including converting incoming dietary carbohydrates and degrading proteins into metabolites. These can then have a

Table 53.4 Prebiotic effects and outcomes

Effects	Outcomes
Immune modulation Improve bowel function Increase absorption of mineral	Reduce type 2 T helper responses, atopy Constipation, infantile colic Calcium=> improve bone health
Metabolic regulation	Favoring gluconeogenesis and lipid biosynthesis
Decrease protein fermentation	Reduce toxic metabolites
Provide nutrients for colonocytes	Stimulates proliferation of colonocytes

positive or negative effect upon the health of the host (Fig. 53.1) [33–35].

The prebiotics that are currently available are predominantly based on carbohydrates, but other substances might exert prebiotic effects, such as polyphenols and polyunsaturated fatty acids [32]. One example of a polyphenol is water-insoluble cocoa fraction. A gut model showed that this substantially increased bifidobacteria, lactobacilli, and butyrate production [36].

Carbohydrates with a low molecular weight are very well taken up by microorganisms such as bifidobacteria, which have a wide range of enzymes, namely, cell-associated and extracellular glycosidases. Bifidobacteria also have specific transport systems, allowing them to rapidly assimilate low-molecular-weight sugars [37].

Other bacteria, such as members of the *Bacteroides* genus, are adept at breaking down high-molecular-weight polysaccharides [38].

Some microorganisms might be regarded as keystone species, as they have the ability to initiate digestion of particular substrates [39]. One example is the *Ruminococcus* species, which can promote the degradation of resistant starch [40].

After they have been liberated, low-molecular-weight dextrins are then metabolized by the microbial community. The pathway from a polysaccharide to a short-chain fatty acid (SCFA) is, therefore, a complex and indirect network of metabolism. We know that acetate and lactate, which are the main metabolic end products of bifidobacteria and lactic acid bacteria, are also used by other microorganisms to produce, for example, propionate [41] and butyrate [42].

Some of the ecological networks that are involved in the metabolism of carbohydrates have been clarified [43, 44], but the extent to which they operate in the gut is not completely known at the present time (Fig. 53.1).

Immune Modulation

Some data have shown that those prebiotic interventions can reduce type 2 T helper cell responses and therefore affect allergies, although the precise mechanisms are uncertain.

The most helpful data have come from studies of infants. For example, GOS and long-chain FOS were administered in infant formula in a double-blind, randomized, placebo-controlled trial of 259 infants. The probiotic formula was associated with a reduced incidence of atopic dermatitis, wheezing, and urticaria, and the levels were more than 50% lower in this group than the controls who received a non-prebiotic formula [45–47].

Consuming prebiotics can improve immunity functions by increasing the population of protective microorganisms. Prebiotics can also induce the expression of immunity molecules, especially cytokines [48].

A prospective, double-blind, placebo-controlled trial, which has not been replicated yet, looked at healthy term-born infants at risk of atopy, who were fed with hypoal-

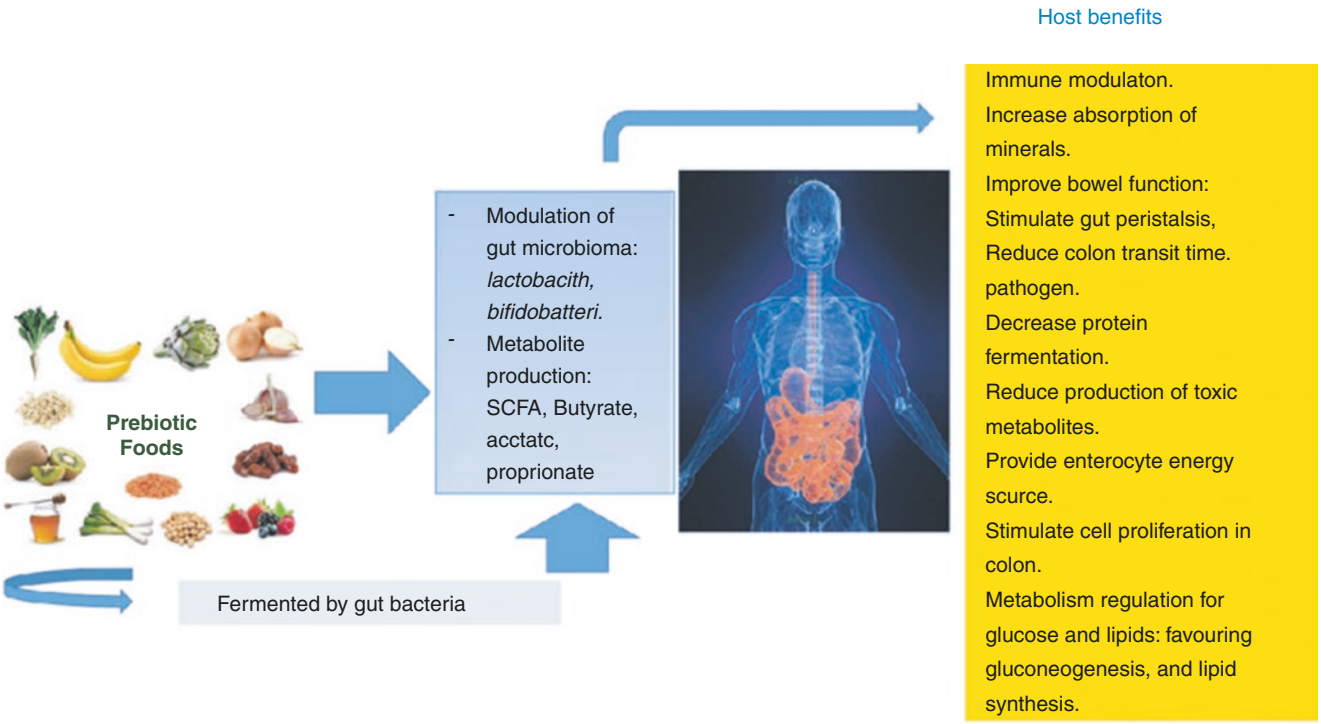

Fig. 53.1 Functions of prebiotics

lergenic formula supplemented with prebiotics for 6 months. The authors reported that they had a greater than fivefold reduction in the prevalence of allergies 5 years after they received the formula [49].

Improved Bowel Function

Improvements in bowel function have often been ascribed to simple fecal bulking, because individuals consume more dietary fiber [50]. However, animal studies have shown that the SCFAs produced by fermenting prebiotics can regulate gut hormones and that these, in turn, modulate the local motor responses of the gut [51].

The humectant water-binding capacity of prebiotic carbohydrates also soften stools, making their passage easier [52].

There are surprisingly few studies on the effect of prebiotics on bowel function, although those randomized trials that have been carried out have consistently reported improvements in stool consistency and the frequency of defecation [53, 54].

A systematic review and meta-analysis indicated that short-chain β-fructan supplements had a positive effect on bowel function, by significantly increasing the frequency of bowel movements and reducing constipation [55].

Increased Mineral Absorption

Minerals are mainly absorbed in active transport mechanisms in the small intestine, and increasing calcium could have a substantial, positive effect on bone mineral and good health. We know that when prebiotics are fermented this leads to the production of SCFAs, which reduces luminal pH. This can increase calcium solubility and, therefore, absorption [56]. One problem with proving that this process works is that many of the calcium salts in supplements and food have pH-dependent solubility and limited availability. Depending on the starting pH, the solubility of calcium can actually increase as the pH increases [57]. One study showed that when young adolescents consumed a mixture of FOS and inulin or GOS, this showed marked increases in the amount of calcium absorbed and mineralized in their bones [58].

Prebiotics in Infant Formulas

Prebiotics are commonly used to supplement infant formula. These include prebiotic oligosaccharides that stimulate *Bifidobacterium* growth and aim to mimic the high levels of these commensal bacteria in the guts of breastfed infants. Studies suggest that probiotic supplements may be beneficial in preventing and managing disease, by reducing the risk of necrotizing enterocolitis in preterm infants and treating minor digestive symptoms, such as constipation and infantile colic [15–21, 59–61].

Bourewicz et al. used Illumina HiSeq sequencing of polymerase chain reaction amplified 16S rRNA gene fragments to investigate the composition of fecal microbiota in infants aged 2–12 weeks who were receiving either breastmilk, infant formulas fortified with prebiotics, or mixed feeding. They showed that formulas supplemented with either GOS (0.24–0.50 g/100 ml) or GOS and FOS (9:1 ratio, total 0.6 g/100 ml) had a strong bifidogenic effect when compared to traditional formulas. They also resulted in altered patterns of microbial colonization within the infants' developing gastrointestinal tracts [62].

Possibly the strongest support for using prebiotics comes from prebiotic infant formulae. Such products are now routinely supplemented with mixtures of GOS and fructans [63, 64], and this 9:1 ratio blend of prebiotics has been shown to reduce respiratory tract infections to the levels found in breastfed infants [13, 65, 66]. There is less evidence that prebiotics with preclinical trial data, specifically those that have focused on 2'-FL, are more than just a prebiotic and have multiple functions, including immune, gut, and cognition benefits [15–18].

A Cochrane review [67] that examined the dietary treatment of infantile colic included a study that compared a partially hydrolyzed, lower-lactose, whey-based formula containing prebiotics, namely, oligosaccharide GOS and FOS, with a standard formula with simethicone. The trial comprised 267 infants, and it found that both groups experienced a decrease in colic episodes, which was a secondary outcome after seven days. The partially hydrolyzed formula fell from a mean of 5.99 ± 1.84 episodes to 2.47 episodes ±1.94, while the standard formula fell from 5.41 ± 1.88 episodes to 3.72 ± 1.98. After 2 weeks, the difference between the two groups was significant, with a mean of 1.76 ± 1.60 episodes for the partially hydrolyzed group and 3.32 ± 2.06 episodes for the standard formula. The authors confirmed there were no adverse effects in either group [60].

Conclusions

Prebiotics are substrates that are selectively used by host microorganisms and confer health benefits. They provide a defense against pathogens, as well as immune modulation; favor mineral absorption; and improve bowel function, metabolic effects, and satiety [68]. Pediatric researchers have shown a particular interest in their relationship with overall human health in recent years.

Our understanding of how prebiotic fibers influence the gastrointestinal microbiota, including those considered

prebiotics, is emerging. However, more research is needed to discover if modulating the composition and function of the human gastrointestinal microbiota leads to health benefits.

Larger prospective studies are needed to determine the associations between prebiotic supplements and disease. These should be well-controlled clinical studies, ideally randomized controlled trials, that study single ingredients and use crossover designs with washout periods. They should assess the impact of fiber on the gastrointestinal bacterial taxa and also focus on microbial metabolites and other physiological measures of health, such as body composition, blood cholesterol, glycemia, and gut inflammation. Where possible, the use of new methods to study gut microbiota will further strengthen these investigations.

Probiotics in Pediatric Gastroenterology

54

Hania Szajewska

Introduction

A balanced gut microbiota is crucial for health. Conversely, dysbiosis, which refers to altered gut microbiota diversity and composition (i.e., changes at the level of phylum, genus, or species) [1], contributes to the development of gastrointestinal and extraintestinal diseases, such as irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), necrotizing enterocolitis (NEC), allergy, obesity, type 1 diabetes, and autism (in addition to other factors such as genes or environmental factors) [2, 3]. However, the exact microbiota changes remain a matter of debate. It also remains to be determined whether the gut microbiota alterations are a cause or a consequence of these disorders. For none of the diseases has a specific "microbiota signature" been identified. The lack of standardized methods for microbiota evaluation may be responsible for inconsistences among studies. However, efforts to standardize operating procedures designed to ensure the robustness of data in the microbiota field are being made [4]. Still, the association between a low diversity of gut microbiota, which may be considered a marker of dysbiosis, and disease has been documented in several studies. From a functional point of view, low gut microbiota diversity affects the gut-liver axis and is associated with the potential for reduced butyrate-producing bacteria, increased mucus degradation, reduced hydrogen and methane production combined with increased hydrogen sulfide formation, and increased hepatic oxidative stress, inflammation, and fibrogenesis [5, 6].

Targeting the gut microbiota with probiotics, prebiotics, synbiotics, postbiotics, and fecal microbiota transplants could potentially benefit human health and treat or reduce the risk of diseases. These interventions are currently gaining worldwide popularity and are increasingly being used in the pediatric population.

In this chapter, current evidence based on the findings from the latest meta-analyses of randomized controlled trials (RCTs) on the efficacy of probiotics in pediatric gastroenterology are summarized. If available, recent recommendations made by recognized scientific societies such as the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN), the American Gastroenterology Association (AGA), and the European Crohn's and Colitis Organization (ECCO) are presented. To identify relevant data, searches of MEDLINE and the Cochrane Library databases were performed in July 2020 to locate publications preferentially published in English in the last 5 years.

Definition and Mechanismss of Probiotics

A consensus definition developed by the International Scientific Association for Probiotics and Prebiotics (ISAPP) defines probiotics as "live microorganisms that, when administered in adequate amounts, confer a health benefit on the host" [7]. Commonly used probiotics are bacteria from the genus *Lactobacillus* or *Bifidobacterium*, as well as a yeast, *Saccharomyces boulardii*. Each microorganism should be defined by its genus, species, and strain designations. Of note, the genus of *Lactobacillus* has been recently reclassified into 25 genera, which includes 23 novel genera [8]. For example, the new name for *Lactobacillus rhamnosus* is *Lacticaseibacillus rhamnosus*. However, the abbreviations of microorganisms remained the same (i.e., *L. rhamnosus*). Species names and strain designations did not change [8].

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_54

Besides traditional probiotics, next-generation probiotics are currently under investigations, including *Roseburia* spp., *Akkermansia* spp., *Propionibacterium* spp., and *Faecalibacterium* spp., genetically modified organisms for delivering molecules in situ and live biotherapeutic products [9, 10].

As probiotics cover a range of living microorganisms, potential mechanisms of action differ. Possible main mechanisms include [11]:

- Production of metabolites such as short-chain fatty acids, the majority of which are acetate, propionate, and butyrate.
- Modulation of the composition and/or activity of the host microbiota (e.g., through colonization).
- Enhancement of epithelial barrier integrity.
- Modulation of the host immune system.
- Adherence to the mucosa and epithelium, with inhibition of pathogen adhesion and/or growth.
- Production of enzymes (e.g., lactase to promote lactose digestion).
- Production of bacteriocins.

Some of these mechanisms are shared by many microorganisms [7, 12]; however, some (e.g., immunological, production of specific bio-actives) are strain-specific mechanisms [7]. Considering the latter, when evaluating the health benefits and safety of probiotics, the focus should be on individual probiotic strains, not on probiotics in general. The effects of probiotics are strain- or combination-specific, not species-specific [13]. The efficacy is also disease-specific [14]. The clinical effects and safety of any single probiotic or combination of probiotics should not be extrapolated to other probiotics or conditions. Lastly, while some subjects respond to probiotic interventions, others do not [15]. Thus, it is likely that the response to probiotics is subject-specific.

For a guide on how to choose a probiotic, see Table 54.1. For a summary of the clinical effects of probiotics in children, see Table 54.2.

Many factors may contribute to the effects of probiotics, including diet, baseline microbiota, dose, matrix, manufacturing conditions, use of concomitant medications (e.g., gut microbiota modifiers such as antibiotics, proton pump inhibitors), and, in case of infectious diarrhea, etiology/vaccination status. Some recent studies have suggested, based on findings in animal and human experiments, that probiotic administration (at least the combination of 11 strains used by the investigators) does not consistently change the gut microbiota composition and that individual responses to probiotic administration differ. It was also suggested that probiotic effects, including the lack of an effect, may differ depending on the indigenous microbiota and gene expression profiles [16, 17].

Table 54.1 How to choose a probiotic (based on reference [9])

Genus, species, strain	Only probiotic strains for which identity and genetic stability have been demonstrated should be used Example of an identification: *Lacticaseibacillus* [formerly known as *Lactobacillus*] (genus) *L. rhamnosus* (species) GG (strain) ATCC 53103 (microbiological culture deposition)
Multi-strain vs. single-strain products	A multi-strain probiotic per se does not guarantee more benefit. For each product, the effect must be documented in well-designed RCTs
Expiration date	The manufacturer should guarantee: The *minimum* number of live cells throughout the shelf-life of the product The *maximum* number of live cells at the time of manufacturing (no guarantee on the viability by the end of shelf-life)
Storage needs	Storage needs recommended by the manufacturers must be followed
Dose	One dose cannot be assumed to be effective for all strains A larger dose is not always better It is prudent to use the treatment regimen proven to be effective in well-designed and executed RCTs for the same indication
Quality	Each formulation is subject to different regulatory processes and quality control processes
Evidence	See Table 54.2

ATCC American Type Culture Collection, *RCTs* randomized controlled trials

Management of Conditions with Probiotics

Treatment of Acute Gastroenteritis

The key treatment of acute gastroenteritis is oral rehydration with low osmolarity oral rehydration solution (ORS) [18, 19]. However, despite being effective, inexpensive, and widely available, ORS remains underused. Insufficient acceptability of ORS by caregivers and physicians may be due to the lack of an effect on the duration of diarrhea or stool output [19].

Until 2020, many, if not all, professional societies and group of experts advocated the use of probiotics with documented efficacy for the management of acute gastroenteritis [19–22]. Currently, the recommendations differ, possibly reflecting negative (null) studies questioning the efficacy of some strains with previous positive recommendations [23, 24].

In 2020, the ESPGHAN Working Group (WG) on Probiotics identified 16 systematic reviews and meta-analyses published since 2010, which included more than 150 RCTs. The WG made weak (also known as conditional) recommendations *for* (in descending order in terms of the number of trials evaluating any given strain) the following: *S.*

Table 54.2 Effects of probiotics in children. ESPGHAN and AGA recommendations

Condition	Society	Recommendation
Treatment of acute gastroenteritis	ESPGHAN 2020	Conditional (weak) recommendation *for*: *S. boulardii* (250–750 mg/day, for 5–7 days) (low to very low certainty of evidence) *L. rhamnosus* GG (ε10^{10} CFU/day, typically 5–7 day) (very low certainty of evidence) *L. reuteri* DSM 17938 (1×10^8 to 2×10^8 to 4×10^8 CFU/day, for 5 days) (low to very low certainty of evidence) *L. rhamnosus* 19070–2 and *L. reuteri* DSM 12246 (2×10^{10} CFU of each strain/d, for 5 days) (very low certainty of evidence) Strong recommendation *against*: *L. helveticus* R0052 and *L. rhamnosus* R0011 (moderate certainty of evidence) Weak recommendation *against*: *Bacillus clausii* O/C, SIN, N/R, and T (very low certainty of evidence)
	AGA 2020	Against the use of probiotics in children with acute infectious gastroenteritis in North America (conditional recommendation, moderate quality of evidence)
Prevention of AAD	ESPGHAN 2016	Strong recommendation *for*: *L. rhamnosus* GG (moderate quality of evidence) *S. boulardii* (moderate quality of evidence)
	AGA 2020	Not addressed
Prevention of *C. difficile* diarrhea	ESPGHAN 2016	*S. boulardii* (moderate quality of evidence)
	AGA 2020	*S. boulardii* A two-strain combination of *L. acidophilus* CL 1285 *and L. casei* LBC80R A three-strain combination of *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus*, and *B. bifidum*[a] A four-strain combination of *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus*, *B. bifidum*, and *Streptococcus salivarius* subsp. *thermophilus*[a]
Prevention of NEC	ESPGHAN 2020	Conditional recommendation *for*: *L. rhamnosus* GG ATCC53103 (at a dose ranging from 1×10^9 CFU to 6×10^9 CFU) (low certainty of evidence) *B. infantis* Bb-02, *B. lactis* Bb-12, and *Str. thermophilus* TH-4 at 3.0 to 3.5×10^8 CFU (of each strain) (low certainty of evidence) No recommendation *for* or *against*: *L. reuteri* DSM 17938 (very low certainty of evidence) *B. bifidum NCDO 1453 and L. acidophilus NCDO 1748* (very low certainty of evidence) Conditional recommendation *against*: *B. breve BBG-001* *S. boulardii*
	AGA 2020	Combination of *Lactobacillus* spp. and *Bifidobacterium* spp.: *L. rhamnosus* ATCC 53103 and *B. longum* subsp. infantis[a] *L. casei* and *B. breve*[a] *L. rhamnosus*, *L. acidophilus*, *L. casei*, *B. longum* subsp. *infantis*, *B. bifidum*, and *B. longum* subsp. *longum*[a] *L. acidophilus* and *B. longum* subsp. *infantis*[a] *L. acidophilus* and *B. bifidum*[a] *L. rhamnosus* ATCC 53103 and *B. longum* Reuter ATCC BAA-999 *L. acidophilus*, *B. bifidum*, *B. animalis* subsp. *lactis*, and *B. longum* subsp. *longum*[a] *B. animalis* subsp. *lactis* (including DSM 15954) *L. reuteri* (DSM 17938 or ATCC 55730) *L. rhamnosus* (ATCC 53103 or ATCA07FA or LCR 35)
H. pylori infection	ESPGHAN and NASPGHAN 2017	Not recommended
Crohn's disease	ESPGHAN 2018	Not recommended
	AGA 2020	*Against* the use of probiotics, unless in the context of a clinical trial

(continued)

Table 54.2 (continued)

Condition	Society	Recommendation
Ulcerative colitis	ESPGHAN and ECCO 2018	A mixture of eight strains[b] or *Escherichia coli* Nissle 1917
	AGA 2020	*Against* the use of probiotics, unless in the context of a clinical trial
Pouchitis	ESPGHAN 2018	A mixture of eight strains[b]
	AGA 2020	A mixture of eight strains[b]
Functional abdominal pain disorders, including IBS	ESPGHAN or NASPGHAN	No addressed
	AGA 2020	IBS. Only in the context of a clinical trial
Infantile colic	ESPGHAN or NASPGHAN or AGA	Not addressed
Functional constipation	ESPGHAN and NASPGHAN 2014	Not recommended

AAD antibiotic-associated diarrhea, *AGA* American Gastroenterology Association, *CFU* colony-forming units, *ECCO* European Crohn's and Colitis Organization, *ESPGHAN* European Society for Paediatric Gastroenterology, Hepatology and Nutrition, *NASPGHAN* North American Society for Pediatric Gastroenterology, Hepatology and Nutrition, *NEC* necrotizing enterocolitis

[a]No strain specification was given for any of the strains

[b]*L. paracasei* DSM 24733, *L. plantarum* DSM 24730, *L. acidophilus* DSM 24735, *L. delbrueckii* subspecies *bulgaricus* DSM 24734, *B. longum* DSM 24736, *B. infantis* DSM 24737, *B. breve* DSM 24732, and *Str. thermophilus* DSM 247]

boulardii (low to very low certainty of evidence), *L. rhamnosus GG* (very low certainty of evidence), *L. reuteri* DSM 17938 (low to very low certainty of evidence), *L. rhamnosus* 19070-2, and *L. reuteri* DSM 12246 (very low certainty of evidence). The WG made a strong recommendation *against L. helveticus* R0052 and *L. rhamnosus* R0011 (moderate certainty of evidence) and a weak (conditional) recommendation *against Bacillus clausii* strains O/C, SIN, N/R, and T (very low certainty of evidence) [25].

In contrast, also in 2020, the AGA, based on the evaluation of 89 trials, made a conditional recommendation *against* the use of probiotics in children from North America with acute infectious gastroenteritis (moderate quality of evidence) [13]. The rationale for the negative AGA recommendation was that the majority of the studies were performed outside North America. Moreover, two large, high-quality null trials, performed in Canada and the USA, questioned the efficacy of probiotics, or more specifically the probiotics evaluated in these studies, for the management of children with acute gastroenteritis [23, 26].

Of note, the interpretation of a conditional recommendation *for* and a conditional recommendation *against* is similar. For clinicians, it means that different choices will be appropriate for different people. Clinicians should help each patient make decisions consistent with the patient's preferences. For patients, it means that the majority of individuals in this situation would want the suggested course of action, but many would not [27].

Prevention of Antibiotic-Associated Diarrhea

One of the potential mechanisms of antibiotic-associated diarrhea (AAD) is a direct effect of the antibiotics on the intestinal mucosa, resulting in alterations in the gut microbiota composition and the overgrowth of pathogens. *Clostridioides*, formerly known as *Clostridium difficile* (*C. difficile*), is the most common infectious cause of AAD [28]. However, other pathogens such as *Staphylococcus*, *Candida*, *Enterobacteriaceae*, and *Klebsiella* may be involved [29]. Other mechanisms include a decrease in the metabolism of the non-digested carbohydrates and primary bile acids and the reduced production of short-chain fatty acids [29]. The clinical manifestations of AAD range from mild diarrhea to colitis or fulminant pseudomembranous colitis.

Evidence from several meta-analyses has consistently shown that most of the tested probiotics significantly reduce the risk of AAD, including a 2019 Cochrane review [30]. The latter identified 33 RCTs involving 6352 participants and indicated a statistically significant reduction in the incidence of AAD in the probiotics groups compared with the control groups (8% vs. 19%, respectively, relative risk 0.45, 95% confidence interval 0.36 to 0.56), with a number needed to treat of 9 (95% CI 7 to 13). Single-strain meta-analyses found that, compared with placebo or no intervention, probiotics such as *S. boulardii* [31] or *L. rhamnosus* GG [32] reduced the risk of AAD.

For preventing AAD, in 2016, the ESPGHAN WG on Probiotics recommended using *L. rhamnosus* GG (moderate quality of evidence, strong recommendation) or *S. boulardii* (moderate quality of evidence, strong recommendation). Other strains or combinations of strains have been tested, but sufficient evidence is still lacking. If the use of probiotics for preventing *C. difficile*-associated diarrhea is considered, the ESPGHAN WG suggested using *S. boulardii* (low quality of evidence, conditional recommendation) [33].

In contrast, the AGA (2020) did not formulate any recommendations with regard to the use of probiotics for preventing AAD. However, the AGA conditionally recommended (based on low quality of evidence) certain probiotics for the prevention of *C. difficile* infection in children receiving antibiotic treatment. These include *S. boulardii*; or the two-strain combination of *L. acidophilus* CL 1285 *and L. casei* LBC80R; or the three-strain combination of *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus*, and *B. bifidum*; or the four-strain combination of *L. acidophilus*, *L. delbrueckii* subsp. *bulgaricus*, *B bifidum*, and *Streptococcus salivarius* subsp. *thermophilus* [13]. No strain specification was given for the

three-strain and four-strain combinations which may contribute to confusion for implementation of these recommendations.

Prevention of Necrotizing Enterocolitis

NEC is one of the most severe and life-threatening gastrointestinal diseases to occur in preterm infants, particularly those with a birth weight <1000 g. The factors involved in the pathogenesis of NEC include formula feeding rather than breastfeeding, intestinal hypoxia–ischemia, and colonization of the gut with pathogenic microbiota [34]. A number of previous meta-analyses consistently showed that the administration of probiotics to infants was associated with a reduced risk for NEC or death [35–37]. In 2020, both ESPGHAN [38] and AGA [13] published their recommendations on the use of probiotics for preventing NEC. While both were based on pair-wise systematic reviews and network meta-analyses [39], their conclusions differ. The only probiotic strain that was recommended by both societies is *L. rhamnosus* GG ATCC 53103. With regard to *L. reuteri* DSM 17938, the ESPGHAN did not formulate a recommendation for or against it, while the AGA conditionally recommends it. For details and specific recommendations from both societies, see Table 54.3.

Table 54.3 Probiotics for preventing NEC. Comparison of ESPGHAN and AGA recommendations

	ESPGHAN 2020	AGA 2020
Target population	Preterm infants	Preterm infants (less than 37 weeks GA), low-birth-weight infants
Intervention	Probiotics	Probiotics
Comparison	Placebo/no probiotics	Placebo/no probiotics
Outcomes	NEC, sepsis, and all-cause mortality	NEC, sepsis, and all-cause mortality
Recommendations formulated based on system atic reviews	Probiotic strain-specific systematic review and NMA	Probiotic strain-specific systematic review and NMA
Number of RCTs evaluated	51 RCTs, *n* = 11,231	63 RCTs, *n* = 15,712
Members of the guideline development group	Experts in the fields of neonatology, pediatric gastroenterology, and nutrition	Guideline panel: gastroenterologists Technical report: methodologists
Target audience	Not specified	North America
General recommendation	Only strain-specific recommendations were formulated	We suggest using a combination of *Lactobacillus* spp. and *Bifidobacterium* spp. for the prevention of NEC over no and other probiotics
Recommendations *for*	*L. rhamnosus* GG ATCC 53103	*L. rhamnosus* (ATCC 53103 or ATC A07FA or LCR 35)
	B. infantis Bb-02 + *B. lactis* Bb-12 + *Str. thermophilus*	*L. rhamnosus* ATCC 53103 and *B. longum* subsp. *infantis*
		L. casei and *B. breve*

		L. reuteri (DSM 17938 or ATCC 55730)
		L. rhamnosus (ATCC 53103 or ATC A07FA or LCR 35)

(continued)

Helicobacter pylori Infection

Unsatisfactory *H. pylori* eradication rates and therapy-associated side effects remain a problem. A number of systematic reviews and meta-analyses, focusing mainly on adults, have shown that probiotic supplementation improves eradication rates and/or reduces side effects of anti-*H. pylori* treatment [40, 41]. For pediatric patients, a 2017 systematic review and a network meta-analysis involving 29 trials (17 probiotic regimens, 3122 participants) showed that compared with the control groups, children in the probiotic groups experienced an increased eradication rate and reduced the risk of total side effects associated with *H. pylori* eradication therapy [42]. A single-strain meta-analyses found that compared with placebo or no intervention, *S. boulardii* given along with standard triple therapy significantly reduced the risk of overall *H. pylori* therapy-related adverse effects and increased the eradication rate [43]. However, data in children for *S. boulardii* were limited [44]. While in both analyses the addition of probiotics to standard triple therapy significantly increased the eradication rate, it was still below the desired level (≥90%) of success.

According to 2017 ESPGHAN/NASPGHAN *H. pylori* guidelines [45], the routine addition of either single or combination probiotics to eradication therapy to reduce side

Table 54.3 (continued)

effects and/or improve eradication rates is currently not recommended. This is in contrast to the recommendations in adults [46].

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) consists mainly of two distinct disorders: Crohn's disease and ulcerative colitis. A recent systematic review concluded that there is increasing evidence for differences in abundances of some bacteria in patients with IBD compared with controls [47], contributing to the initiation and maintenance of inflammation. However, the findings were not consistent, at least partially due to different methods used to analyze the microbiota.

A 2020 Cochrane review concluded that low certainty of evidence suggests that probiotics may induce clinical remission in patients with active ulcerative colitis when compared to placebo [48]. However, specific strain(s) were not identified. Another 2020 Cochrane review concluded that evidence is vague with regard to the efficacy or safety of probiotics, when compared with placebo, for induction of remission in patients with Crohn's disease [49].

In line with 2018 evidence-based guidelines by the ECCO and ESPGHAN, a mixture of eight strains [*L. paracasei* DSM 24733, *L. plantarum* DSM 24730, *L. acidophilus* DSM 24735, *L. delbrueckii* subspecies *bulgaricus* DSM 24734, *B. longum* DSM 24736, *B. infantis* DSM 24737, *B. breve* DSM 24732, and *Str. thermophilus* DSM 24731] or *Escherichia coli* Nissle 1917 may be considered as an effective treatment for maintenance in patients with mild ulcerative colitis as an adjuvant therapy or in those intolerant to 5-ASA; however, this recommendation is based on limited evidence [50].

In line with 2018 guidelines of the ESPGHAN Porto IBD Group [51], there is limited evidence in favor of using the mixture of eight strains (as above) or *L. reuteri* ATCC 55730 as an adjuvant to standard therapy for induction of remission in mild-to-moderate pediatric ulcerative colitis. The mixture of eight strains has also shown efficacy for maintaining remission and possibly preventing pouchitis in adults [48], but data in children are lacking [51].

For Crohn's disease, according to the same 2018 ESPGHAN guidelines, there is not enough evidence to suggest that probiotics are beneficial for the induction or maintenance of remission of Crohn's disease in children [51].

The AGA (2020), both in patients with ulcerative colitis and Crohn's disease, recommends *against* the use of probiotics, unless in the context of a clinical trial [13]. However, in adults and children with pouchitis, the AGA conditionally recommends the use of the eight-strain combination [*L. paracasei* subsp. *paracasei* DSM 24733, *L. plantarum* DSM 24730, *L. acidophilus* DSM 24735, *L. delbrueckii* subsp. *bulgaricus* DSM 24734, *B. longum* subsp. *longum* DSM 24736, *B. breve* DSM 24732, *B. longum* subsp. *infantis* DSM 24737, and *S. salivarius* subsp. *thermophilus* DSM 24731] over no or other probiotics.

Functional Gastrointestinal Disorders

Functional gastrointestinal disorders (FGDs) account for a substantial number of referrals to gastroenterology clinics. Management remains difficult, prompting interest in new and safe treatment options.

Treating Infantile Colic

Evidence suggests that the gut microbiota in subjects with infantile colic differs from that in an unaffected population, and first-pass meconium is associated with subsequent infantile colic [52]. In colicky infants, dysbiosis may affect gut motor function and gas production, leading to abdominal pain/colic [53].

A 2018 individual participant data meta-analysis, which included data from four RCTs involving 345 infants with colic, documented that the administration of *L. reuteri* DSM 17938 at a dose 1×10^8 colony-forming units (CFU) is likely to reduce crying and/or fussing time in breastfed infants with infantile colic, but its role in formula-fed infants is less clear [54]. Other meta-analyses have confirmed these findings [55, 56]. Whether the type of feeding matters is uncertain, as the incidence of infantile colic is similar among breastfed and formula-fed infants [57]. Data on other probiotics, either positive or negative, are too limited to allow one to draw reliable conclusions [58–61].

Preventing Infantile Colic

A 2019 Cochrane review identified six RCTs (involving 1886 infants) which compared probiotics with placebo for preventing infantile colic [62]. The pooled results of three RCTs in which LGG and two multi-strain products (one included four strains of lactobacilla and three strains of bifidobacteria and *Str. thermophilus* DSM 24731 and another included *L. rhamnosus* GG, LC705, *B. breve* Bb99, and *Propionibacterium freudenreichii* ssp. *shermanii*) were

assessed found a similar occurrence of new cases of colic in the probiotics and placebo groups. The pooled results of three other RCTs found, in the probiotics group compared with the placebo group, reduced duration in crying time at study end (MD −32.6 min/day, 95% CI −55.6 to −9.5). However, one of the included studies evaluated a prebiotic formula with added probiotic strains; thus, this was a synbiotic intervention. At the strain level, the effect was particularly evident for *L. reuteri* DSM 17938 administered at a dose of 1×10^8 CFU to newborns each day for 90 days [63]. Other probiotics were also studied; however, evidence is limited [64].

Functional Abdominal Pain Disorders

Functional abdominal pain disorders (FAPDs), particularly IBS, are evidently associated with gut microbiota dysbiosis [65]. However, no clear microbiota signature has been identified. It also remains to be determined whether the gut microbiota alterations are a cause or a consequence of the disease. As most data have been obtained in adults [65], it remains unclear whether the findings can be extrapolated to children.

A 2018 systematic review concluded that there is insufficient evidence for the use of probiotics in children with FAPDs [66]. Only *L. rhamnosus* GG (three RCTs) reduced the frequency and intensity of abdominal pain in children with IBS. In children with IBS, a multicenter, crossover RCT using a mixture of eight probiotic strains (*Str. thermophilus* BT01, *B. breve* BB02, *B. longum* BL03, *B. infantis* BI04, *L. acidophilus* BA05, *L. plantarum* BP06, *L. paracasei* BP07, *L. delbrueckii* subsp. *bulgaricus* BD08) was found to be safe and more effective than placebo in ameliorating symptoms and improving quality of life [67]. Evidence on *L. reuteri* DSM 17938 (five RCTs using different methods of pain assessment) for treating FAPDs is inconsistent. Compared with placebo, *L. reuteri* DSM 17938 improved abdominal pain in three RCTs [68–70], reduced functional disability but not abdominal pain in one RCT [71], and was no better than placebo in one trial [72]. Mixtures of *B. infantis*, *B. breve*, and *B. longum* (one RCT) or *B. lactis* (one RCT) were not effective in children with FAPDs [66].

There are no specific recommendations from ESPGHAN or NASPGHAN. The AGA 2020 guidelines noted with regard to IBS that there are many studies; however, significant heterogeneity in study design, outcomes, and probiotics used resulted in no recommendations for the use of probiotics in symptomatic children and adults with IBS (except in the context of a clinical trial).

Functional Constipation

Functional constipation is a frustrating symptom affecting 3% of children worldwide. Treatment is often difficult and long-lasting. Moreover, more than 30% of the children dislike the taste of the conventional laxatives available. Some studies suggest differences in gut microbiota in patients with versus without functional constipation. However, no firm conclusions can be made due to inconsistent findings and methods used in studies [73].

A 2017 systematic review of RCTs identified seven RCTs with a total of 515 participants performed in children with functional constipation [74]. Pooled results of two RCTs showed no significant difference between the *L. rhamnosus casei* Lcr35 and placebo groups with respect to treatment success. Other probiotics studied in single trials only included *L. rhamnosus* GG; *L. reuteri* DSM 17938; *B. lactis* DN-173 010 [and yogurt starter cultures: *L. delbrueckii* ssp. *bulgaricus* (CNCM I-1632 and I-1519), *Str. thermophilus* CNCM I-1630, and *Lactococcus cremoris* (CNCM I-1631)]; *B. longum* [and yogurt starters, *L delbrueckii* subspecies *bulgaricus* and *Str. thermophilus* from the YF-L812 commercial culture]; and a mixture of seven strains (*L. casei* PXN 37, *L. rhamnosus* PXN 54, *Str. thermophilus* PXN 66, *B. breve* PXN 25, *L. acidophilus* PXN 35, *B. infantis* PXN 27, and *L. bulgaricus* PXN 39). There was no significant difference between the probiotic and control groups with respect to treatment success [74]. Similar conclusions were reached by the authors of a 2018 systematic review [66]. The findings of both systematic reviews support current ESPGHAN/NASPGHAN recommendations that probiotics should not be used in the treatment of functional constipation in children [75].

Cystic Fibrosis

Cystic fibrosis (CF) is a common, severe, autosomal recessive genetic disease caused by mutations in the CF transmembrane conductance regulator (CFTR) gene. There is evidence from metagenomics and metabolomics studies that the CFTR gene mutation contributes to gut dysbiosis [76]. Frequent use of antibiotics is an additional risk factor contributing to dysbiosis in children with CF.

A 2020 Cochrane review [77] of probiotics for people with CF included 12 RCTs (among them, 8 RCTs included children only). Probiotics (as a group) might have some limited health benefits. Compared with placebo, there was reduced fecal calprotectin in the probiotic groups. For clinical outcomes, there were a reduced number of pulmonary exacerbations in those receiving probiotics compared with placebo after 12 months, albeit this difference was of borderline significance. There was no strong effect of probiotic treatment on weight, lung function, or hospitalizations. Similar conclusions were reached by the authors of earlier systematic reviews focusing on children only [78, 79]. However, so far, CF guidelines have not been updated to recommend the use of any of the studied probiotics in patients

with CF. Among others, specific probiotic strains, doses, and durations of treatment need to be established.

Other Diseases

A number of RCTs have evaluated various probiotics for preventing or treating other diseases. Both positive and negative (null) studies have been published. With few exceptions (e.g., pancreatitis), for most of these diseases, explicit *for* or *against* recommendations have not been formulated. Different choices may be appropriate for different patients. Clinicians should help each patient make decisions consistent with their preferences. Among others, the other conditions for which probiotics have been studied include:

- Celiac disease (e.g., *B. infantis* NLS in adults [80], *B. longum* CECT 7347 in children [81], *B. breve* BR03 and *B. breve* B632 [82, 83].
- Non-celiac gluten sensitivity (e.g., *B. longum* ES1 [84].
- Type 1 diabetes (e.g., *L. rhamnosus* GG and *B. lactis* Bb12) [85].
- Small bowel bacteria overgrowth (inconsistent results) [86, 87].
- Pancreatitis (in adults, a multispecies probiotic preparation increased mortality from mesenteric ischemia) [88]; the use of probiotics is not recommended).
- Non-alcoholic fatty liver disease (e.g., *L. rhamnosus* GG [89]; a mixture of *L. acidophilus* ATCC B3208, *B. lactis* DSMZ 32269, and *B. bifidum* ATCC SD6576; *L. rhamnosus* DSMZ 21690 [90]; a mix of eight strains (*Streptococcus thermophilus*, bifidobacteria [*B. breve*, *B. infantis*, *B. longum*], *Lactobacillus acidophilus*, *L. plantarum*, *L. paracasei*, and *L. delbrueckii* subsp. *bulgaricus*)).
- Autism spectrum disorders (e.g., *L. plantarum* PS128 [91].
- Caries (e.g., *L. rhamnosus* GG [92].
- Eczema (various *Lactobacillus* and *Bifidobacteria* species [93].

Safety of Probiotics

A 2018 systematic review found that more than a third of the 384 trials evaluated did not provide information on harms, and only 2% adequately reported adverse events [94]. While uncertainty remains due to a lack and/or inadequate reporting of harms, overall, probiotics are considered safe for use in otherwise healthy populations. Caution should be exercised with regard to all probiotics, including *S. boulardii* [95] and *L. rhamnosus* GG [96], in specific patient groups. Risk factors for adverse events include immunosuppression, prematurity, critical illness, presence of structural heart disease, hospitalization, presence of a central venous catheter, and the potential for translocation of probiotics across the bowel wall [97, 98]. The effects of long-term administration of probiotics remain largely unknown. If probiotics are to be given early in life, for a prolonged time, safety and quality issues need special attention.

Quality of Probiotics

There is also a concern with regard to the quality of products targeting the microbiota, probiotics in particular. This issue was recently reviewed by the ESPGHAN Working Group on Probiotics [99]. The Working Group suggested a more stringent quality control process to ensure "that the probiotic content as mentioned on the label meets the actual content throughout the shelf life of the product, while no contamination is present." Probiotic product quality through an independent third party would be desirable [100]. However, at present, there is no general standardization of regulatory framework, and it may differ between countries.

Conclusions

Interventions modifying the gut have the potential to prevent gastrointestinal and extraintestinal diseases. Despite the evidence to support the use of specific interventions in some clinical situations, further studies confirming the effect(s) and defining the type, dose, and timing of probiotics are still often required. As not all interventions within the group of probiotics are equal, the efficacy as well as safety should be established individually for each specific intervention. The use of interventions targeting the gut microbiota with no documented health benefits should be discouraged.

Postbiotics

55

Seppo Salminen and Hania Szajewska

Introduction

Interest in gut microbiota for health regulation has rapidly increased. Understanding their mechanisms, effects, and regulation is important for developments in their application, as a balanced microbiome is related to health, while an imbalanced microbiome or dysbiosis is related to many health problems. These microbiota are found within the gastrointestinal tract, but they have a wider impact. Therefore, the development of microbiota-modifying products, both foods, supplements, and pharmaceuticals, has increased. In this context, knowledge of the biotic family is of importance. Previously, the International Scientific Association for Probiotics and Prebiotics (ISAPP) consensus panel defined three members of this family: probiotics, prebiotics, and synbiotics [1–3]. Recently, the family was completed with postbiotics [4, 5]. Descriptions of the consensus terms are presented in Fig. 55.1.

In this chapter, recent developments on postbiotics are presented, and current evidence on the efficacy and safety of postbiotics for pediatric population is summarized. To obtain evidence on the health benefits of postbiotics in children, the Cochrane Central Register of Controlled Trials and MEDLINE databases were searched in July 2020 for randomized controlled trials (RCTs) or meta-analyses that compared postbiotics with placebo or no therapy.

Definition and Mechanisms of Action of Postbiotics

The concept that non-living microorganisms could promote or preserve health is not new, and several terms have been used to describe such substances (e.g., paraprobiotics, parapsychobiotics, ghost probiotics, or metabiotics). However, in recent years, the term "postbiotic" has been used most often. A consensus definition was established by ISAPP to enable the use of a single, well-defined, and widely understood term rather than different terms. According to this definition, a postbiotic is "a preparation of inanimate microorganisms and/or their components that confers a health benefit on the target host" [4]. Effective postbiotics must contain inactivated microbial cells with or without metabolites or cell components that contribute to observed health benefits. Purified compounds synthesized by microorganisms, such as antibiotics, are not considered postbiotics. Compared with probiotics, postbiotics offer several advantages. First, they are safe. Postbiotics can be reasonably expected to have a better safety profile than probiotics because they have lost the capacity to replicate and thus cannot cause bacteremia, a risk (albeit extremely rare) of probiotic administration. Still, postbiotics cannot be presumed to be safe based solely on the safety profile of the progenitor microorganism, and a safety assessment of any postbiotic is needed prior to use. Second, postbiotics have inherent stability, both during industrial processes and storage. An example of the safety assessment of a potential probiotic, *Bacteroides xylanisolvens*, was reported by the European Food Safety Authority [6, 7]. Maintaining the stability of live microorganisms is a technological challenge, but inanimate microorganisms can readily be used to create products with a long shelf life. Postbiotics may also be more suited than probiotics to geographic regions that do not have reliable cold chains or whose ambient temperature may cause problems for the storage of live microorganisms [4, 5].

https://doi.org/10.1007/978-3-030-80068-0_55

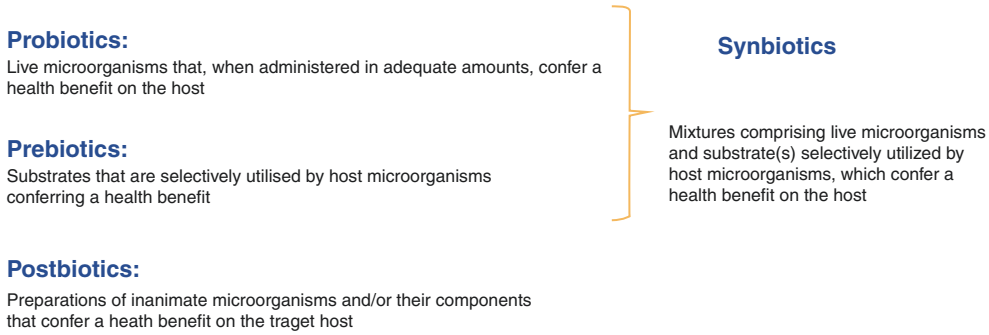

Fig. 55.1 Definitions of the members of the Biotic family: probiotics, prebiotics, synbiotics and postbiotics

The mechanisms of action for postbiotics remain unclear. Moreover, the potential mechanisms of action differ, as postbiotics derive from a range of living microorganisms. Recently, ISAPP experts proposed five main mechanisms of postbiotics, as discussed in detail elsewhere. These mechanisms include modulation of the resident microbiota, enhancement of epithelial barrier functions, modulation of local and systemic immune responses [4], modulation of systemic metabolic responses, and systemic signaling via the nervous system [4, 5].

The Science of Inactivated Probiotics and Other Microorganisms

Although probiotics are defined as live when administered, all probiotic preparations include dead and injured microorganisms. The potential impact of these non-viable bacterial cells and their components on probiotic functionality has attracted some attention, but it has been mostly neglected [5]. Fermented foods, such as yogurt, may contain a significant number of non-viable microbial cells, particularly after prolonged storage but also after processing with methods such as pasteurization or baking (e.g., sourdough bread).

Fermented foods have long been a significant part of the human diet and nutrition. Fermentation has a significant impact on the physical properties and potential health effects of many foods, especially milk and plant-based foods. It is most often mediated by lactic acid bacteria, and the results produce a range of cellular structures and metabolites that are associated with human health, including various cell surface components (inactivated artificially or naturally); short-chain fatty acids (SCFAs), such as lactic and acetic acids; and other metabolites. SCFAs have a number of roles in human health, including fighting pathogens and nurturing intestinal epithelial cells. The effector molecules of microorganisms in fermented food have been considered to be similar to those of probiotics, but fermentation products may have different effects.

Bacterial lysates of common bacterial respiratory pathogens have been used for decades to prevent pediatric respiratory diseases via general immune-stimulating mechanisms, which have been postulated but are not yet well understood.

Postbiotics can be based on current inactivated probiotics or novel microorganisms. Such organisms include, for example, *Akkermansia muciniphila*, *Eubacterium hallii*, *Streptococcus*, and *Faecalibacterium* species as well as some fructophilic lactic acid bacteria. Certain yeasts have also been reported as potential sources of postbiotics [5, 6, 8, 9]. To date, only one larger study in adults has been conducted with non-viable *B. bifidum* HI-MIMBb75 cells to examine their potential to alleviate irritable bowel syndrome (IBS) and its symptoms [10]. Further studies need to be conducted to confirm the results.

Postbiotics in Children

Fermented Formulas

Fermented formulas (i.e., those fermented with lactic acid-producing bacteria during the production process and not containing significant amounts of viable bacteria in the final product) are available in some countries. In 2007, the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) Committee on Nutrition reviewed evidence on fermented infant formulas published until April 2006. As only two randomized controlled trials (RCTs), which included 933 infants, were identified, the committee concluded that no conclusions could be drawn regarding the use and effects of fermented formulas for infants [11]. A 2015 systematic review updated this review with new evidence [12]. Five RCTs, which evaluated fermented infant formulas containing *Bifidobacterium breve* C50 and *Streptococcus thermophilus* with a sample of 1326 infants, met the inclusion criteria. Overall, the limited available evidence suggested that the use of fermented milk formula does not offer clear additional benefits compared to standard infant formula. At the same time, no negative health effects have been documented. A more recent study evaluated the effects of a newly developed fermented infant formula combining short-chain galacto-oligosaccharides (scGOS) and long-chain fructo-oligosaccharides (lcFOS) with

Lactofidus™. The 50% fermented formula with scGOS/lcFOS was well tolerated and associated with lower overall crying time, a lower incidence of infantile colic, and a stool-softening effect in healthy term infants. However, as fermented formula was supplemented with scGOS/lcFOS, it is unclear which modification (i.e., the fermented formula or prebiotic oligosaccharides) was responsible for the effects [13].

Data on the use of fermented formulas in preterm infants are limited to one RCT, which evaluated the effect of a formula fermented by *B. breve* and *Str. thermophilus*. In infants fed fermented preterm formula, compared with standard preterm formula, there was a reduced incidence of abdominal distension as well as significantly lower fecal calprotectin levels [14].

Prevention and Treatment of Common Infectious Diseases

A 2020 systematic review [15] (search date: March 2019) evaluated evidence on the use of postbiotics to prevent and treat common infectious diseases among children younger than 5 years. Seven RCTs involving a total of 1740 children met the inclusion criteria. In therapeutic trials, compared with the placebo, supplementation with heat-killed *Lactobacillus acidophilus* LB reduced the duration of diarrhea (four RCTs; $n = 224$; mean difference [MD], −20.31 h; 95% CI −27.06 to −13.57). For preventive trials, the pooled results from two RCTs ($n = 537$) showed that, compared with the placebo, heat-inactivated *L. paracasei* CBA L74 reduced the risk of diarrhea (relative risk [RR] 0.51; 95% CI 0.37–0.71), pharyngitis (RR 0.31; 95% CI 0.12–0.83), and laryngitis (RR 0.44; 95% CI 0.29–0.67). The authors concluded that there is only limited evidence to recommend the use of specific postbiotics for treating pediatric diarrhea and preventing common infectious diseases among children. Further trials are needed to evaluate the effects of different postbiotics.

Two additional studies were identified. The first RCT investigated the effect of micronutrients (including zinc) with or without heat-inactivated *L. acidophilus* compared to a placebo in 75 infants aged 6–12 months who are at high risk for diarrhea-related mortality (defined as at least one episode of diarrhea in the preceding 2 weeks). The prevalence of diarrhea was 26% in the micronutrient with *L. acidophilus* group, 15% in the micronutrient group, and 26% in the placebo group. The difference between the micronutrient with LAB group and placebo group was not significant. It was concluded that the intervention with heat-inactivated *L. acidophilus* had a negative effect in these children [16]. The second trial investigated the effect of heat-inactivated *L. casei* GG compared with viable *L. casei* GG in children with acute rotavirus diarrhea. The clinical recovery from rotavirus diarrhea was equal in both groups [17].

Cow's Milk Allergy Management

Kirjavainen et al. [18] compared the effect of an extensively hydrolyzed whey formula (EHWF) supplemented with live or killed *Lactobacillus* GG (LGG) and non-supplemented EHWF among 35 infants (mean age, 5.5 months) with atopic eczema and cow's milk allergy. The authors reported significant reductions in scoring atopic dermatitis (SCORAD) scores in the EHWF group, EHWF/viable LGG group, and EHWF/heat-inactivated LGG group (baseline vs. end of a 1-month intervention). Compared with the EHWF group, the decrease in SCORAD scores was significantly higher in the EHWF/viable LGG group ($P = 0.02$). However, this study performed only a post hoc analysis. No adverse events were reported in the EHWF group or EHWF/viable LGG group. However, compared with these two groups, administration of EHWF/heat-inactivated LGG resulted in a significantly higher risk of diarrhea ($P = 0.05$).

Non-clinical Outcomes

A number of studies evaluated additional non-clinical effects [17, 19–22]. For example, the use of fermented formula reduced fecal pH values. However, whether fecal pH reduction is beneficial has not been well established. The same applies to other stool parameters, such as fecal IgA levels and bifidobacteria levels.

Postbiotics in Adults

In adults, data on postbiotics are limited. However, orally administered, inactivated lactic acid bacteria were found to have efficacy for eradication of *Helicobacter pylori* (inactivated culture of *L. acidophilus*) [23] and reduction of IBS symptoms in an observational study (inactivated *Lactobacillus* LB) [24]. More recently, it was shown to have efficacy in an RCT (heat-inactivated *Bifidobacterium bifidum* MIMBb75) [25], for chronic unexplained diarrhea (heat-killed *Lactobacillus acidophilus* LB) [26], and for suppression of the negative impacts of stress (heat-inactivated, washed *Lactobacillus gasseri* CP2305) [27]. These results are not directly applicable to pediatric populations, but they reveal directions for future research.

Conclusions

As the term "postbiotics" is new, the applications of postbiotics to infant nutrition and pediatric gastroenterology are still developing. While there have been some promising results, overall, there is limited evidence to suggest that post-

biotics have health benefits for pediatric conditions. As yet, no clear recommendations for or against the use of postbiotics in pediatrics can be formulated. The effects of postbiotic supplementation have been studied mainly in fermented infant formulas. Overall, the safety and potential harms of postbiotic interventions remain poorly understood. Further multicenter studies are necessary to determine the effects and safety of different postbiotics.

Maesha Deheragoda

Normal Liver Development

The liver commences development between the 3rd and the 4th weeks of gestation. Development commences as an outpouching, called the liver diverticulum, which arises from the ventral endodermal layer of the distal foregut [1]. The endodermal cells in the cranial part of the diverticulum penetrate the septum transversum to become the hepatocytes and intrahepatic biliary system. The septum transversum is the mesodermal plate separating the thoracic and abdominal cavities and will form the connective tissue of the hepatic stroma and the capsule. Hepatocytes proliferate within the septum transversum and become organized into cords around developing sinusoids, which are derived from vitelline vein branches that perforate the septum transversum. The septum transversum eventually separates from the endoderm-derived hepatocytes and becomes the diaphragm.

The caudal part of the hepatic diverticulum that did not invade the septum transversum becomes the gallbladder, cystic duct and common bile duct by the 5th week of gestation [2]. The intrahepatic bile ducts begin developing between the 5th and 9th weeks of gestation and arise from the limiting plates of the forming hepatoblast cords in the mesenchyme, adjacent to the portal vein branches. Hepatoblasts flatten to become the ductal plate – a continuous layer of biliary-type cuboidal cells. By remodelling to form discrete tubular spaces at around 12 weeks of gestation, the intrahepatic bile duct system will develop. This process starts around the hepatic hilum and progresses towards the periphery of the liver, completing at around 6 weeks postnatally [3, 4]. SOX9 appears to be a key component coordinating the timing of biliary development, with Notch, Wnt, TGF-β, Hippo-Yap and FGF signalling pathways forming downstream signalling pathways [5, 6]. HNF6 and HNF1β appear to be involved in remodelling of the ductal plate [7]. Failure of remodelling results in ductal plate malformation, seen in congenital malformations of the intrahepatic biliary tree [8]. Antigen expression on bile canaliculi, spaces lined by specialized membranes into which hepatocyte bile is exported, is seen at 14–20 weeks of age [9]. Hepatocellular bile acid synthesis begins at 5–9 weeks and bile secretion in the 12th week [10]. However, the exchange of biliary solutes across the placenta is important in foetal life as the canalicular transport and hepatic excretion are still immature.

The liver receives a dual blood supply through the portal vein (which supplies venous blood from the intestines, pancreas and spleen) and an arterial supply from the hepatic artery. During initial stages, the blood flow into the sinusoids of the developing liver comes via the two vitelline veins and the right and left umbilical veins, until the 5th week when the right umbilical vein involutes and the left umbilical vein becomes the main blood supply from the placenta [11]. The venous pattern of the liver is dependent on involution of parts of the venous system and joining of the umbilical veins and vitelline venous system. In the 7th week, the portal vein is already formed from the anastomosing channels of the vitelline veins. Intrahepatic branches of the vitelline vein become the portal venous system. The intrahepatic segments of the portal vein and its branches become surrounded by mesenchyme and will become the portal tracts. Progressive branching of the right and left portal vein branches within the liver creates the terminal portal venules and inlet venules which open into the sinusoids. The sinusoidal blood drains into the centrilobular venules and eventually through the hepatic veins into the inferior vena cava (which is formed from the proximal end of the right vitelline vein). The umbilical vein gives branches to the left liver and drains into the ductus venosus, a structure that connects it to the inferior vena cava [12]. The hepatic artery arises from the celiac axis. At the porta hepatis, it divides into right and left hepatic arteries. These undergo branching to form terminal hepatic arterioles, which communicate with the hepatic sinusoids [11].

The umbilical circulation closes at birth, with cessation of umbilical venous flow by 20 days. The reduction in venous flow results in collapse of the ductus venosus, within a week of postnatal life. The umbilical vein becomes the ligamentum teres and the ductus venosus becomes the ligamentum venosum. Development of the arterial system mirrors that of the bile ducts and reaches maturity at 15 years of age [13].

Innervation of the liver appears in the later stages of embryonic development, continues to mature postpartum and comprises sympathetic and parasympathetic fibres [14], which enter through the porta hepatis. The capsule is supplied by a few branches of the lower intercostal nerves.

Liver haematopoietic activity starts from the 6th week, and by the 12th week, the liver is the main site of haematopoiesis, until the third trimester of intrauterine life [11]. It diminishes slowly after birth [15]. The liver at birth will have periportal deposits of iron, and these gradually disappear at 3–4 months of age. Residual periportal iron after 4 months of age may reflect poor growth but can also be seen in certain disorders if present in larger quantities – for example, cystic fibrosis, alpha-1 antitrypsin deficiency, urea cycle disorders, citrin deficiency, mitochondriopathies, peroxisomal disorders, congenital disorders of glycosylation and tyrosinaemia, to name a few. Periportal copper-binding protein may also be seen as a physiological finding up to 4 months of age. Intrahepatic haematopoiesis can be seen physiologically within the liver up to 12 months of age. Beyond this point, it may indicate the presence of a haematological disorder, particularly when also associated with immature myeloid forms.

Coordinated growth of the embryonal liver is dependent on a large number of growth factors such as hepatocyte growth factor (HGF), transforming growth factor beta (TGF-β), tumour necrosis factor alpha (TNF-α) and factors involved in the Wnt-signalling pathway [16]. The topic is beyond the scope of this chapter and covered in several excellent reviews [16–19].

Normal Liver Macroanatomy

The liver is the largest visceral organ and continues to grow until around 15 years of age, doubling in size in the first year of life. In adulthood, it will weigh ten times greater than its weight at birth. The liver is divided into right and left lobes and two small central quadrate and caudate lobes. The liver is covered by the visceral peritoneum, except for the 'bare area' on the posterior surface, which is in direct contact with the diaphragm. At the porta hepatis, the hepatic artery and portal vein enter the liver, and the common hepatic duct exits the liver. The liver is connected to the diaphragm and to the anterior wall of the abdomen by five ligaments: the falciform, the coronary and two lateral (triangular) ligaments, the fifth being a fibrous cord (the round ligament) corresponding to the obliterated umbilical vein.

For the purpose of facilitating surgical resections and radiological interpretation, the liver macroanatomy can be subdivided into eight segments based on the intrahepatic distribution of the portal and hepatic veins [20]. The liver is divided into two functional lobes of similar sizes, separated on the liver surface by an imaginary line going through the inferior vena cava sulcus and the middle of the gallbladder fossa. The right lobe is further divided into posterior and anterior sectors and the left lobe into medial and lateral parts. Eight segments, with almost independent blood supply, are thus formed as follows: (I) caudate lobe, (II) superior subsegment of the left lateral segment, (III) inferior subsegment of the left lateral segment, (IV) left medial segment, (V) inferior subsegment of the right anterior segment, (VI) inferior subsegment of the right posterior segment, (VII) superior subsegment of the right posterior segment and (VIII) superior subsegment of the right anterior segment [20]. Segments II, III and IV are drained by the left hepatic vein; the middle hepatic vein drains blood from segments IV, V and VIII; and the right hepatic vein drains segments V–VIII. The inferior hepatic vein drains the caudate lobe (segment I) directly into the inferior vena cava.

Liver Microanatomy and Considerations When Interpreting Histological Findings in Paediatric Liver Biopsies

The terms 'lobule' and 'acinus' are often used by pathologists to describe the distribution of changes, which may in turn give clues about the underlying aetiology. Some scoring systems such as the modified Ishak scoring system also rely on the use of these systems to describe and score patterns of injury [21]. The lobule is a hexagonal structure which places the hepatic venule in the centre and the portal tracts at the corners [22] (Fig. 56.1). The hepatic acinus is a subdivision of the lobule into triangles, with the portal venule at the apex and the portal tracts at the base [23] (Fig. 56.1). The acinus is divided into three zones: zone 1, which is located in the vicinity of the portal tract; the mid-zone (zone 2); and zone 3, situated close to the terminal hepatic venule (Fig. 56.1). The concept of the liver acinus is also useful when considering functional heterogeneity that exists along the portocentral axis. Periportal hepatocytes have a higher capacity for gluconeogenesis and fatty acid metabolism and those in perivenous areas have a higher capacity for detoxification [24]. Gene expression levels can vary across the acinus or can be restricted to particular parts of the acinus. For example, glutamine synthetase, an enzyme involved in ammonia metabolism, is normally restricted to acinar zone 3 and under control of the Wnt/beta-catenin signalling pathway [25].

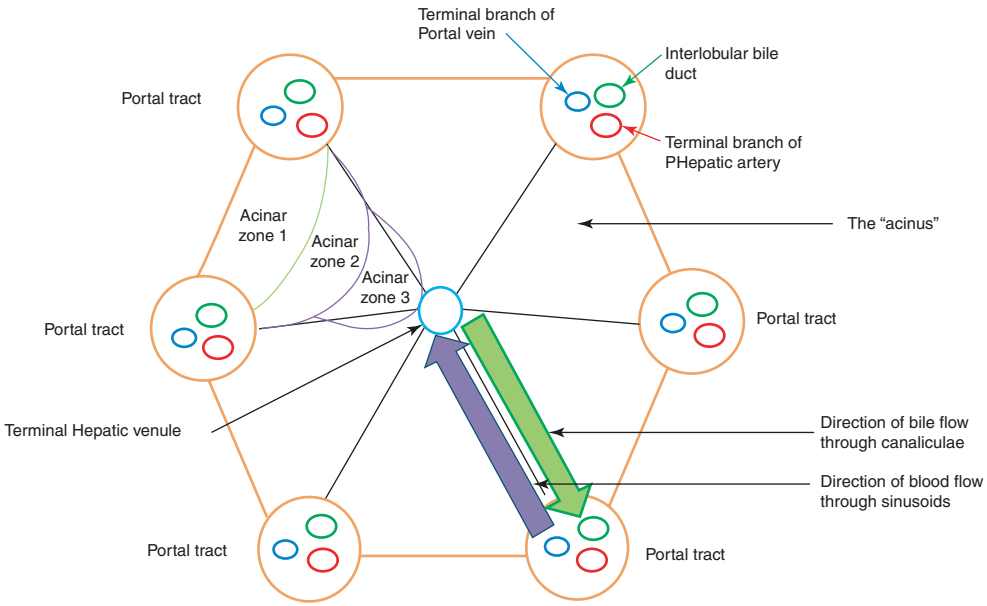

Fig. 56.1 Schematic diagram of the structural and functional components and anatomical relationships of the hepatic lobule (orange hexagonal outline) and the acinus

Non-physiological changes in the immunohistochemical expression pattern of glutamine synthetase are useful when diagnosing disorders of vascular flow or tumours [26]. Enzymes can also change in level according to changes in the hormonal or metabolic state.

Under light microscopy, hepatocytes are polygonal in shape with an approximate diameter of 25 μm. The cell membrane can be divided into three aspects, with different characteristics: a basolateral aspect facing the sinusoidal lumen, a canalicular aspect, which delimits the canalicular space and the lateral aspect between the other two. The nucleus is centrally located. Most hepatocytes are mononuclear, although binuclear hepatocytes are often found. In the neonate and up to 1 year of age, multinucleate hepatocytes can also be seen – often referred to as 'giant cells'. The hepatocyte cytoplasm is abundant and eosinophilic. Periportal hepatocytes in children and adolescents show physiologically vacuolated nuclei. Hepatocytes are arranged in cell cords of variable thickness to around 5 months of age, when they form two-cell-thick cords. At approximately 5 years of age, they adopt the adult pattern of one-cell-thick cords.

Terminal portal tracts show a 1:1 pairing of hepatic arteries and terminal bile ducts. There are approximately two artery/bile duct pairs per single portal vein [27]. There remains a connection of bile ducts with the hepatic parenchyma through bile ductules. Ductules are lined by bile duct epithelial cells (cholangiocytes) derived from the ductal plate. The canals of Hering are an extension of the ductules that penetrate the interface between the portal tract and hepatic cords, with one half of the circumference composed of bile duct epithelial cells and the other half comprising hepatocytes. They may penetrate into the lobule up to a third of the way towards the terminal hepatic venule [28]. The Canals of Hering are thought to contain resident hepatic stem/progenitor cells throughout life [29]. Biliary stem/progenitor cells are thought to be located within peribiliary glands along larger intrahepatic bile ducts [30]. Any significant injury to either bile ducts or hepatocytes at the interface is accompanied by proliferation of the canals of Hering – ductular compartment – leading to a ductular reaction [11].

The bile canaliculi drain bile across the lobule towards acinar zone 1 (see Fig. 56.1) and connect to the bile ducts through the canals of Hering. Downstream propulsion of bile is provided by a combination of a contractile subapical hepatocellular actin network and the fluid pressure generated by active secretion of biliary solutes and fluid [31]. These membranes are highly specialized structures involved in bile transport into the canalicular space and contain proteins involved in bile transport and/or membrane function. Tight junctions also exist between hepatocytes and probably play a role in maintenance of specialized membrane function. Defects in bile acid transporters and tight junction proteins can lead to familial intrahepatic cholestatic liver disorders.

The hepatic sinusoids are specialized vascular channels passing between hepatocyte cords, optimizing contact between the blood contents and the parenchymal elements of the liver. They are lined by fenestrated endothelium. Kupffer cells – specialized liver macrophages – are present on the internal sinusoidal surface [3]. Approximately two thirds of the intrahepatic blood supply is from the portal venules and the remaining third from the hepatic arterial blood supply. Flow of blood into the sinusoids is controlled by sphincters in arteriolar walls and inlets and outlets of sinusoids. The composition of blood within the sinusoids can be arterial, venous or a mixture of the two, depending on sphincteric activity and the distance of the sinusoid from

the portal tract [32]. The space between the endothelial cells and the hepatocytes is defined as the space of Disse, which contains the hepatic stellate cells (Ito cells). They store retinoids, can contract affecting the sinusoidal calibre and can produce extracellular matrix participating to fibrogenesis when activated. Blood from the sinusoids enters the terminal hepatic venule and enters the inferior vena cava via the hepatic veins.

A knowledge of the development of the liver combined with timings of physiological changes described above will aid accurate diagnosis of the paediatric liver biopsy.

Diagnostic Procedures in Paediatric Hepatology

57

Andreas Panayiotou, Annamaria Deganello, and Maria E. Sellars

Imaging of Cholestatic Jaundice

Neonatal

Neonatal jaundice that persists longer than 2 weeks demands clinical, laboratory and radiological investigation, as early diagnosis of surgically treatable conditions leads to favourable outcomes. The role of radiology in the work-up of conjugated hyperbilirubinemia is to make a distinction between obstructive cholestasis due to structural biliary anomalies and non-obstructive conditions such as genetic, metabolic, endocrine or infective disorders, in which imaging investigations are often normal at presentation.

High-resolution ultrasonography is the imaging modality of choice in the screening of these patients and provides the radiologist with a non-invasive, non-ionizing tool, independent of liver function tests.

The ultrasound approach to these patients needs to be systematic, with thorough examination of the liver parenchyma, gallbladder, bile ducts, portal venous system, spleen and pancreas. In particular, the examiner should concentrate on the intra- and extrahepatic bile ducts, in order to detect dilatation. The common bile duct (CBD) should not exceed a calibre of 1 mm in neonates, 2 mm in infants up to 1 year of age, 4 mm in older children and 7 mm in adolescents [1, 2]. The gallbladder needs to be evaluated in its length (normal range between 1.5 and 3 cm) and shape and for the presence of gallstones, inspissated bile and irregular, thickened walls. Evaluation of portal vein patency and direction of flow, presence of collaterals as well as splenic length and ascites is needed to assess signs of portal hypertension. Finally, the size and echogenicity of the pancreas and the calibre of the pancreatic duct (which needs to be <1–2 mm) should also be recorded [3, 4].

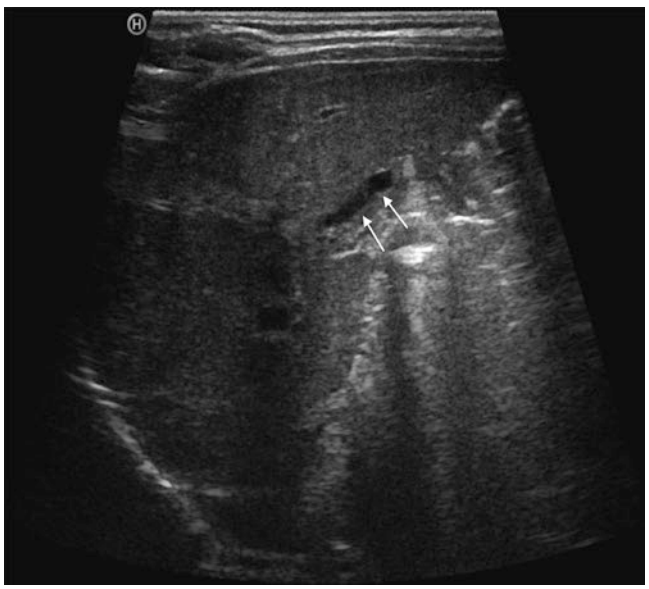

Fig. 57.1 B-mode US of the liver of a patient with biliary atresia shows an abnormal small gallbladder (1.2 cm in length) with irregular walls (*arrows*)

The absence of dilated ducts, a small abnormal gallbladder with irregular walls and hyperechoic fibrous tissue at the porta hepatis (triangular cord sign) are suggestive but not pathognomonic features of extrahepatic biliary atresia (Fig. 57.1). Signs of biliary atresia splenic malformation (BASM) syndrome also need to be sought, such as polysplenia, situs ambiguous, interrupted IVC, pre-duodenal portal vein, anomalous hepatic artery supply and intestinal malrotation (Fig. 57.2); these patients may require MRI supplemented by angiographic sequences for detailed vascular delineation, crucial for pre-operative planning. Infants with biliary atresia can present with end-stage liver disease, and

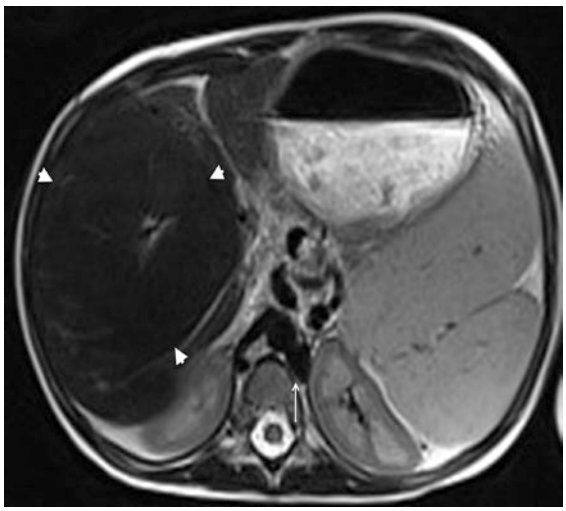

Fig. 57.2 T2W MRI image of a patient with BASM. The liver is cirrhotic with a large central regenerative nodule (central plate hypertrophy, *arrowheads*) and atrophied left lobe and posterior segments of the right lobe. There is polysplenia and interrupted IVC with hemi-azygous continuation (*arrow*)

therefore initial US can detect coarse nodular liver parenchyma, retrograde flow in the portal vein, ascites, varices and splenomegaly. In biliary atresia, hepatic scintigraphy will show normal uptake of radiotracer in the liver but failure of biliary excretion after 24 h (Fig. 57.3); however, neonatal hepatitis could also show absent bowel activity due to poor hepatocellular function. Therefore phenobarbital is administered prior to the procedure to enhance hepatocellular function. Confirmation of diagnosis is normally achieved with liver biopsy, which will differentiate between biliary atresia and neonatal hepatitis, which is a diagnosis of exclusion.

When dilated ducts are detected, the differential will include choledochal malformation, inspissated bile syndrome and Caroli with congenital hepatic fibrosis. In these instances, the patient needs further evaluation to define the anatomy; historically, this was achieved by means of direct percutaneous cholangiography (PTC) or endoscopic retrograde cholangiopancreatography (ERCP), but the implementation of MR imaging with heavily T2w cholangiography

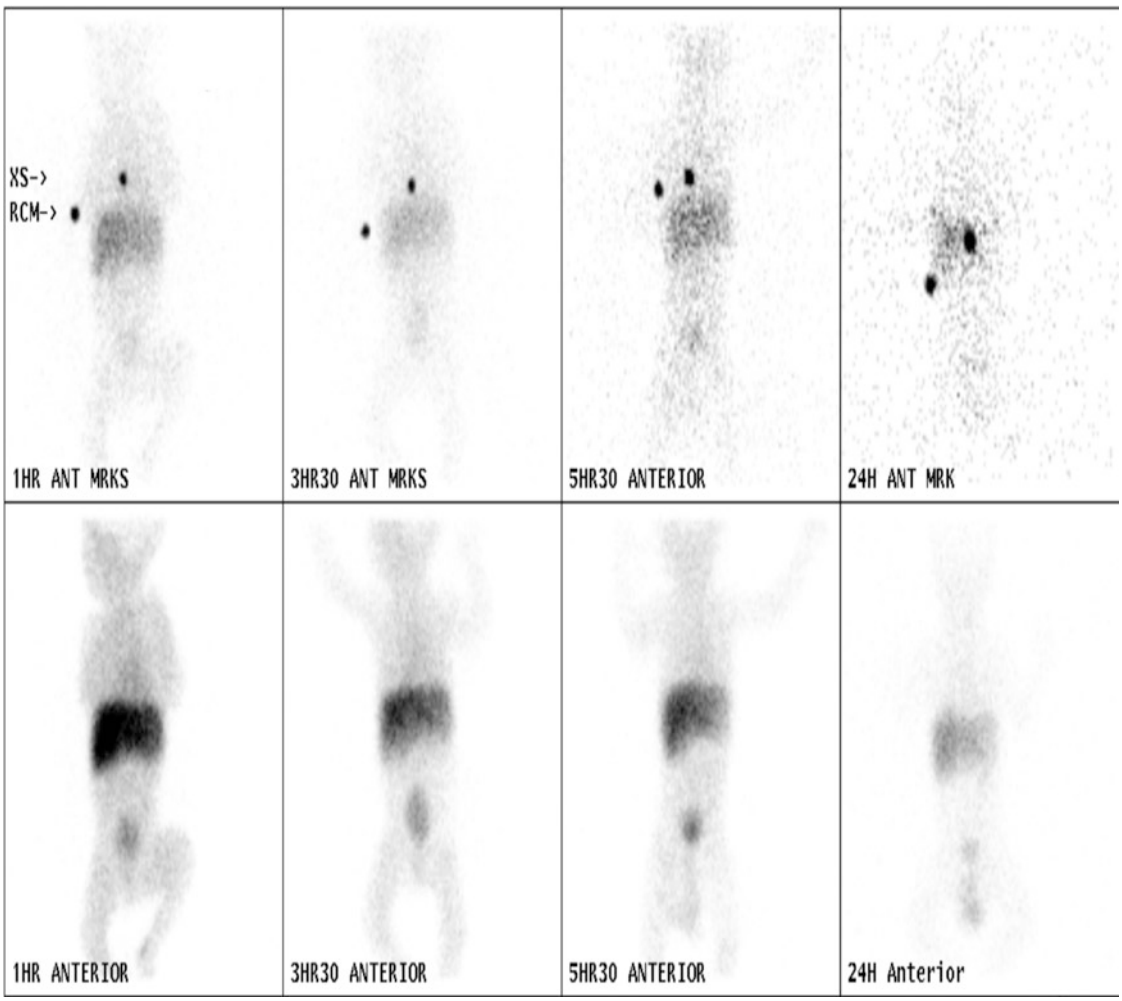

Fig. 57.3 Nuclear medicine hepatobiliary function study demonstrates accumulation of radiotracer in the liver with no evidence of uptake in the intra- or extrahepatic biliary tree. There is no radiolabelled bile seen within the bowel at the 24-h delayed planar image. Normal physiologic uptake is seen within the urinary bladder

sequences has allowed the radiologist to achieve the diagnosis confidently and in a non-invasive way [5].

Magnetic resonance cholangiopancreatography (MRCP) can in fact classify the different types of choledochal malformations and reveal anomalies of the pancreatico-biliary junction (more often associated with type I cysts) with possible complications, such as calculi within a long common channel (Fig. 57.4).

In case of Caroli, MRCP will show multifocal cystic dilatation of the intrahepatic bile ducts, possibly containing filling defects, representing calculi; MR can demonstrate non-invasively that these cysts communicate with the biliary tree, thus excluding autosomal dominant cystic liver disease and biliary hamartomas (Fig. 57.5). A specific MR finding of Caroli is the "central dot sign", a portal vein branch protruding into the lumen of a dilated duct, which enhances with gadolinium [6].

ERCP is not routinely indicated but may still be required in doubtful cases or as a therapeutic option in those patents where MRCP has identified an obstructed biliary system due to inspissated bile or choledocholithiasis or in a very select case of suspected biliary atresia before laparotomy.

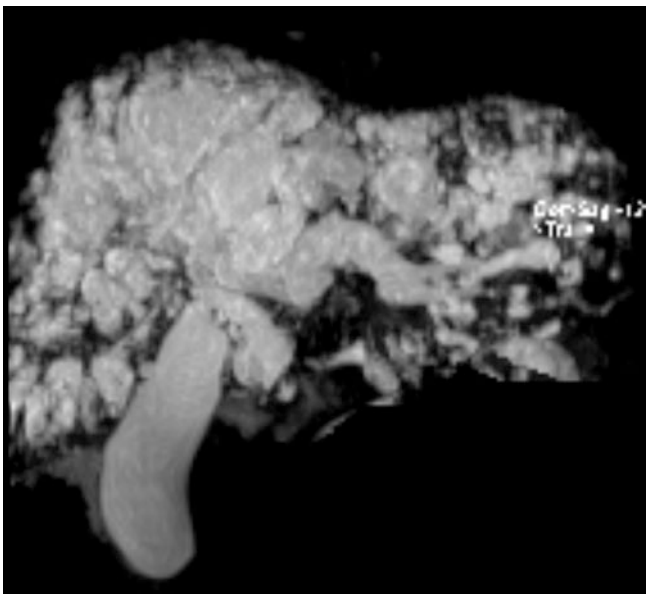

Fig. 57.5 Coronal maximum intensity projection (MIP) MRCP shows numerous cystically dilated intrahepatic bile ducts that communicate with the biliary tree. The common and main hepatic bile ducts are markedly dilated

Older Children

Jaundice in older children can be caused by hepatocellular disease (acute or chronic) and obstructive causes, and imaging investigations can distinguish these entities and often establish the aetiology of many chronic conditions and acquired or developmental biliary disorders.

Fig. 57.4 MRCP MIP reconstruction of the biliary tree showing a type of choledochal malformation with an impacted calculus within a long common channel (*arrow*)

Ultrasound findings in acute hepatitis are normally non-specific, with US demonstrating hypoechoic parenchyma, increased periportal reflectivity due to oedema and thickened gallbladder walls.

In the context of chronic liver disease, radiology can confirm the clinical diagnosis demonstrating coarse, heterogeneous liver parenchyma and abnormal liver architecture as well as signs of portal hypertension (Figs. 57.6 and 57.7).

Medical causes of jaundice or liver disease in older children include Wilson's disease, cystic fibrosis, glycogen storage disorder, tyrosinaemia and alpha-1 antitrypsin deficiency. In all these conditions, US will show non-specific changes with hyperechoic liver parenchyma; however, these patients are prone to develop focal liver lesions (such as adenomas and, importantly, hepatocellular carcinomas), and in this instance, US is extremely useful as a non-invasive, radiation-free surveillance test. In addition, some of these conditions have specific imaging features, such as multiple small nodules with low signal intensity in T2 on MR in Wilson's disease and focal biliary cirrhosis with periportal fibrosis seen on US and MR in cystic fibrosis.

Calculi, benign strictures (as seen in primary sclerosing cholangitis, PSC) and neoplasms (which will be discussed separately) are all obstructive causes of jaundice in older children.

Calculi are seen in US as hyperechoic foci with posterior acoustic shadowing, mobile when detected within the gallbladder; these are seen as signal voids on MR. Inspissated bile is again hyperechoic in US but does not cause posterior shadowing.

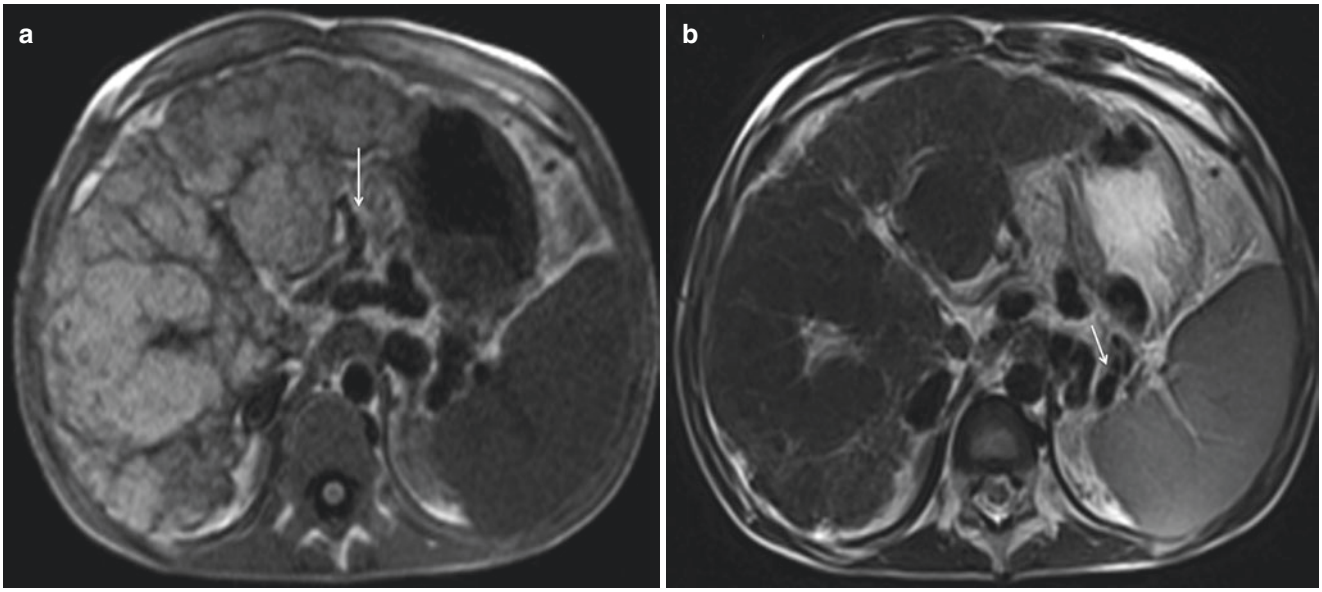

Fig. 57.6 MRI T1W (**a**) and T2W (**b**) images of a cirrhotic liver with markedly abnormal contour and varying size-regenerative nodules throughout. The portal vein is occluded, and there are numerous short gastric and splenic varices (*arrows*)

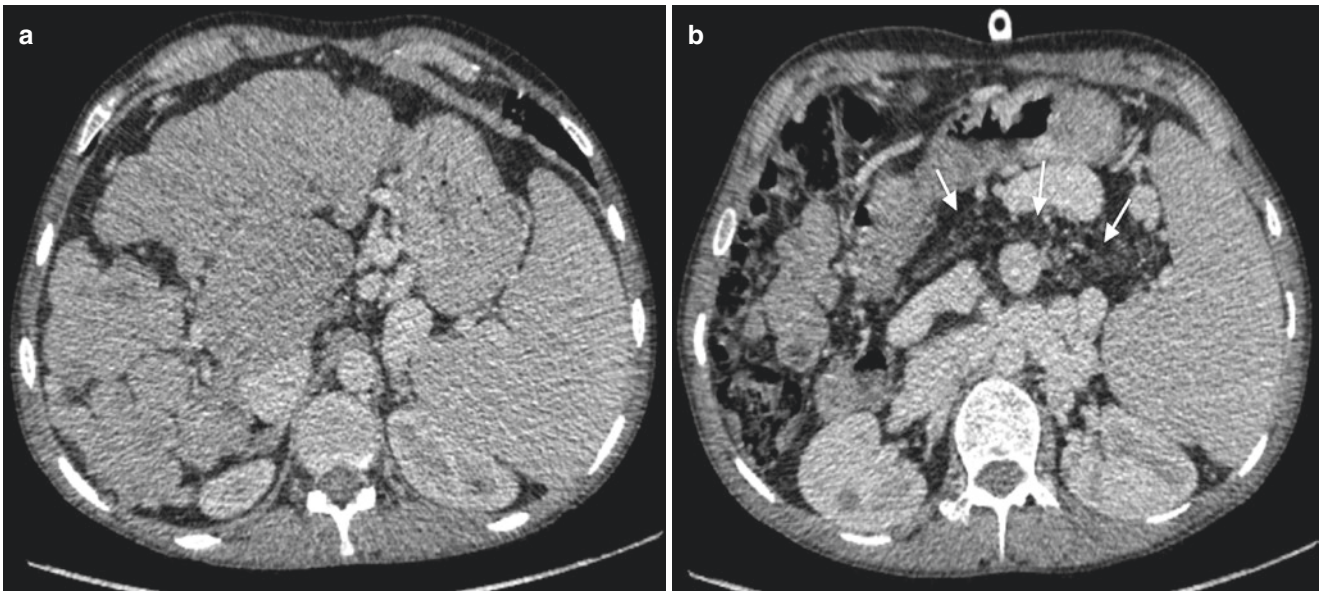

Fig. 57.7 CT of a patient with cystic fibrosis and chronic liver disease. (**a**) Nodular cirrhotic liver and signs of portal hypertension, splenomegaly and varices. (**b**) Fatty infiltration of the pancreas (arrows)

Primary sclerosing cholangitis (PSC) is characterized by inflammation and fibrosis of the biliary tree, which results in cholestasis with progression to secondary biliary cirrhosis and hepatic failure. Histologically, the intrahepatic bile ducts are surrounded by cuffs of inflammatory cells and fibrosis, which results in segmental dilatation of the peripheral ducts alternated with narrow or obliterated segments, reflected in the imaging findings. The radiological diagnosis of PSC is often challenging and needs confirmatory clinical, biochemical and histologic findings. Traditionally, ERCP and PTC have been used as standard imaging procedures for the radiological diagnosis of PSC; however, MRCP has nowadays replaced these techniques.

Ultrasound remains the first-line investigation in these patients and shows segmental duct dilatation, irregular thickened walls of the CBD (Fig. 57.8), lymph nodes at the porta hepatis and heterogeneous reflectivity of the liver parenchyma (depending on the stage of disease). In established chronic liver disease, there is coarse echotexture with nodularity and relative atrophy of the right lobe with hypertrophy of the caudate and lateral segment of the left lobe.

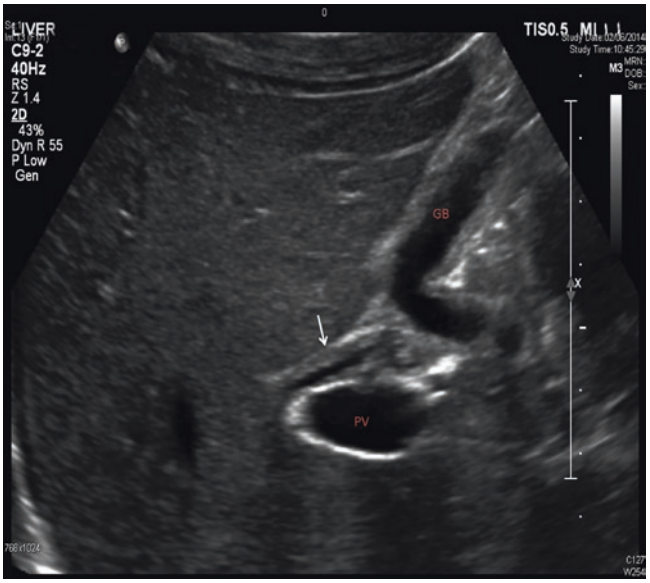

Fig. 57.8 US of the liver of a patient with PSC shows thickened wall of the common bile duct (*arrow*). *PV* portal vein, *GB* gallbladder

MRCP can depict ductal irregularity, stricturing, focal dilatation, beading and pruning affecting the intra- or extrahepatic biliary tree (Fig. 57.9). Post-contrast dynamic MR sequences should also be included to look for enhancement of thickened walls of the extrahepatic ducts and cholangiocarcinoma.

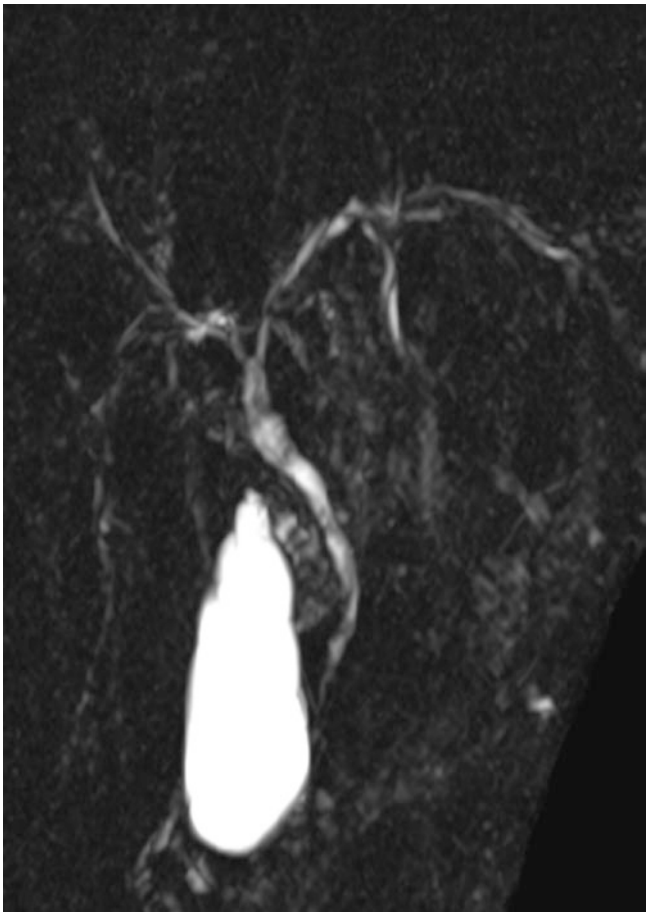

Fig. 57.9 MRCP MIP reconstruction of the biliary tree showing irregularity of the walls of the intra- and extrahepatic bile ducts, with focal structuring, in keeping with PSC. *MIP* maximum intensity projection

Congenital and Acquired Vascular Disorders

Portal Hypertension

The aetiology of portal hypertension can be classified as cirrhotic and non-cirrhotic. The latter can be prehepatic (portal vein thrombosis), intrahepatic (portal vein sclerosis, congenital hepatic fibrosis, steatosis, nodular regenerative hyperplasia, veno-occlusive disease) or suprahepatic (Budd-Chiari). Depending on the aetiology, different radiological findings will be present. Liver function tests may be normal, and the diagnosis of portal hypertension relies on demonstration of splenomegaly and formation of portosystemic collaterals.

In cirrhosis, prehepatic and pre-sinusoidal portal hypertension, the role of radiology is to determine the extent of involvement of the portal venous system, as this would influence the therapeutic options, which include surgical portosystemic shunt, Rex bypass, transjugular intrahepatic portosystemic shunt (TIPS) and ultimately liver transplantation.

The radiological approach to children with portal hypertension starts again from US with Doppler, which can detect low velocity, retrograde or absent flow in the main portal vein and intrahepatic divisions. A patent umbilical vein, splenomegaly, with varices and ascites can also be easily seen on US, however, cross-sectional imaging is used as a "roadmap" for the evaluation of the portal system and collaterals pathways. CT and MRV can also demonstrate cavernous transformation of the portal vein, seen as a typical "beaded" appearance at the porta hepatis, which consists of venous channels within and around a previously stenosed or occluded portal vein [7]. This can occur within a few weeks after a thrombotic event, even in the case of partial recanalization of the thrombosed segment, and can extend to the intrahepatic branches. Cystic and pericholecystic dilated veins can also be seen. CT performed in the arterial phase often shows patchy areas of high density at the periphery of the liver parenchyma, and this is due to a peripheral increase of the arterial inflow to supply the areas not reached by the cavernous portal vein.

Intra- and Extrahepatic Vascular Shunts

Intrahepatic communications between portal vein, hepatic artery and hepatic veins are rare, and the most common,

although often difficult to demonstrate, are small arterioportal shunts seen in cirrhotic livers. Large connections include portosystemic shunts (intra- and extrahepatic), arterioportal shunts and arteriovenous shunts/malformations.

The origin of portosystemic shunts is still controversial and congenital, genetic (such as trisomy 21) and acquired causes (such as in cirrhosis and post-traumatic) have been postulated [8]. These shunts have been historically classified into intrahepatic and extrahepatic; however, some authors discourage this classification and suggest to use an anatomical classification, which is aimed to establish the origin of the shunt (main portal vein, its tributaries or intrahepatic branches) and its systemic termination, the type of communication (end to side or side-to-side) and the number of connections. A distinction should be made between these shunts and a persistence of the ductus venosus [9].

The aim of radiology is to detect the shunts, delineate the anatomy, and assist planning and monitoring of interventional/surgical corrections and follow-up. Doppler US is the modality of choice to achieve this: direct communication between a portal branch and hepatic vein or the ductus venosus can be readily demonstrated, often due to enlargement and tortuosity of the vessels involved; the flow is usually continuous but triphasic flow can be seen in the portal branch. In case of the main portal vein-IVC connections, there is low velocity flow or non-visible intrahepatic portal vein, and the liver is usually decreased in size. Cross-sectional imaging is performed routinely to confirm the diagnosis and define the anatomy prior to intervention or surgery; in addition, shunts between the splenic vein or superior mesenteric vein and the IVC may be easily missed on US. CT and MR are also useful to characterize focal liver lesions, often found in associations with these shunts.

Angiography is often part of the work-up of these children, either as a therapeutic option or prior to surgery to detect non-visible portal vein/portal vein branches. A balloon occlusion catheter is placed in the shunt and pressures are measured before and after occlusion to evaluate how closure will be tolerated. In addition, angiography can investigate if there is continuity between left and right intrahepatic portal venous radicles, crucial to establish feasibility of Rex shunt.

Arterioportal shunts may be congenital (in Rendu-Osler disease) or acquired (post-traumatic, post-liver biopsy, cirrhosis). On CT, small arterioportal shunts in cirrhosis appear as small, wedge-shaped, peripheral areas of increased attenuation with early portal venous filling in the arterial phase and uniform attenuation in the portal venous phase. In the presence of large arterioportal shunts or fistulas, there is early and marked enhancement of the main portal vein or segmental branches during the arterial phase. At Doppler US, large shunts will manifest with pulsatility of the portal vein flow [10].

Connections between the hepatic artery and systemic veins are rare and can be seen in congenital arteriovenous malformations (AVM), HCC and large haemangioendotheliomas; on Doppler US, altered waveforms of the hepatic vein can be seen in severe AVM, whereas CT will show asymmetrical, early filling of the hepatic vein.

Budd-Chiari Syndrome

Budd-Chiari syndrome is the clinical manifestation of hepatic venous outflow obstruction at any level of the hepatic veins, IVC or right atrium; this could be primary, caused by an endoluminal thrombus or membrane or secondary, when the occlusion is due to non-vascular material or from extrinsic compression. On US, there is narrowing and lack of visualization or thrombosis of the hepatic veins/IVC, with absent or monophasic flow at colour Doppler. There is enlargement of the caudate lobe, ascites and signs of portal hypertension with retrograde flow in the portal vein and splenomegaly.

On cross-sectional imaging in the acute setting, occlusion of the hepatic veins with severe ascites is the typical finding. There is patchy, decreased peripheral enhancement of the liver due to portal and sinusoidal stasis and higher enhancement of the central parenchyma and caudate lobe, which compresses the IVC (Fig. 57.10). In subacute Budd-Chiari syndrome, portal vein thrombosis can develop as the result of reduced portal flow caused by blockage of the outflow. Finally, in chronic stages, multiple regenerative nodules can be seen, and on MR these are bright on T1-weighted images and strongly hypervascular on post-gadolinium sequences. The nodules are predominantly isointense or hypointense relative to the liver on T2-weighted images [11].

Imaging of Transplant Liver

Liver transplantation is the treatment of choice for children with end-stage acute or chronic liver failure in which other therapies have failed or are not available. The successful development of novel surgical techniques of segmental, split, auxiliary and living donor transplantation, together with advances in organ preservation, immunosuppressive therapy and adequate choice of donor organ, has led to reduced rate of complications. However, these new surgical techniques have also brought with them new potential complications: in living-related transplants, for example, when the vascular pedicle may be too short, an autologous iliac artery conduit can be used, leading to a potential higher risk of vascular complications.

Early recognition is crucial to the successful management of these complications, and a multimodality imaging

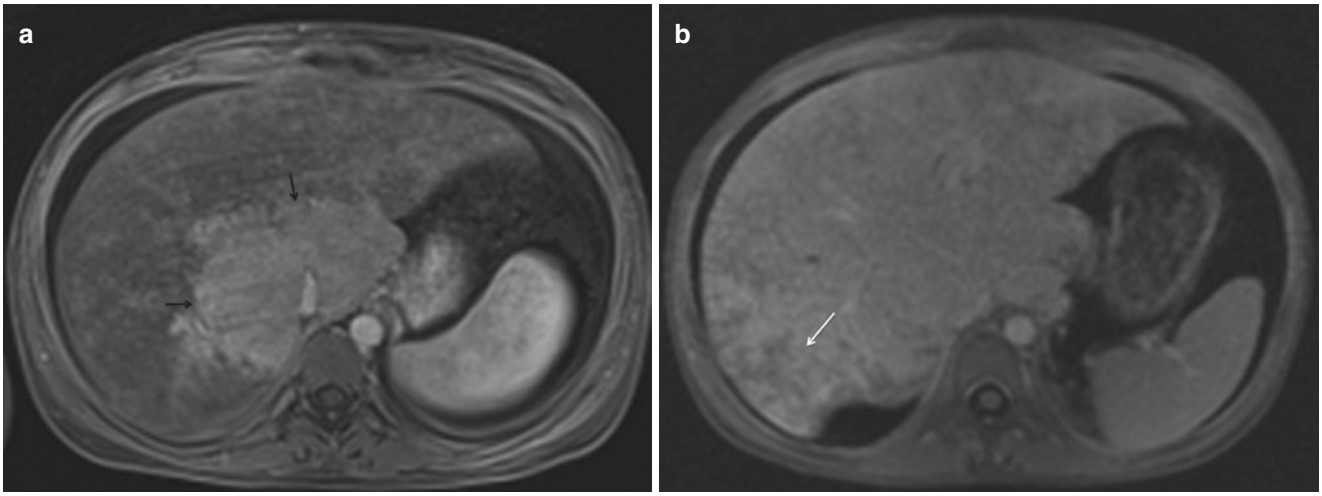

Fig. 57.10 MRI post-gadolinium T1W images of a patient with Budd-Chiari. In the acute phase (**a**), there is significant enlargement of the caudate lobe (*black arrows*), which enhances normally versus the poorly vascularized peripheral parenchyma. The IVC is compressed by the caudate lobe. In the subacute phase (**b**), there are signs of paraseptal necrosis (*white arrow*) with preserved central enhancement

approach is most effective to achieve the diagnosis, except in case of graft rejection, in which radiology has no role.

Serial ultrasound is the screening modality of choice immediately postoperatively and can be easily performed at the patient's bedside; however, ultrasound has inherent limitations, and, even though the use of ultrasound contrast agents can improve its sensitivity, it depends on the expertise of the operator, and cross-sectional imaging is often necessary in inconclusive cases. Conventional angiography is now limited to those cases in which endovascular treatment is required.

We will illustrate the imaging appearances of the main, most common complications following liver transplant.

Hepatic Artery

A normal hepatic artery waveform shows a rapid systolic peak followed by a continuous diastolic flow; the resistive index (RI) should range between 0.5 and 0.8, except in the immediate postoperative period (<72 h), in which the RI can be higher. An increased RI is associated with older donor age and prolonged ischemia time.

Hepatic artery thrombosis is a feared complication and a major cause of graft loss due to fulminant hepatic necrosis; in the long term, this complication can also lead to ischaemic cholangiopathy, as the hepatic artery is the only arterial supply to the bile ducts in liver grafts. Children are particularly at risk, due to hepatic artery size discrepancy between recipient and donor.

On colour and Doppler US, complete loss of arterial signal at the porta hepatis and within the liver suggests hepatic artery thrombosis. A tardus parvus waveform (prolonged systolic acceleration time and low flow velocity with RI < 0.5) at the porta hepatis or in the intrahepatic arteries indicates significant impairment of hepatic arterial perfusion, usually as a result of either arterial stenosis (uncommon) or thrombosis with collateral arteries (Fig. 57.11): collateral vessels from the Roux loop may form rapidly following hepatic artery thrombosis; therefore surveillance with Doppler US in the immediate postoperative days is vital. Conversely, false-positive results can be found in case of hepatic oedema or systemic hypotension [12]. In case of inconclusive findings on US but still high clinical suspicion of hepatic arterial insufficiency, a CT angiogram with thin-slices acquisition should be performed, which will show abrupt interruption of the hepatic artery and ischaemic/necrotic parenchyma in case of thrombosis and focal narrowing with decreased hepatic perfusion in case of stenosis. Ischaemic lesions can liquefy and complicate with infection and abscess formation.

The role of conventional angiography is mostly therapeutic rather than diagnostic, with thrombolysis, angioplasty or stenting (depending on the findings) to allow early revascularization.

Portal Vein

Portal vein complications are relatively rare and normally result from technical problems, such as difference in calibre between donor and recipient, narrow native portal vein (e.g. in biliary atresia) and stretching at the anastomotic site or other factors including previous thrombosis, hypercoagulable states and increased resistance due to inferior vena cava (IVC) strictures.

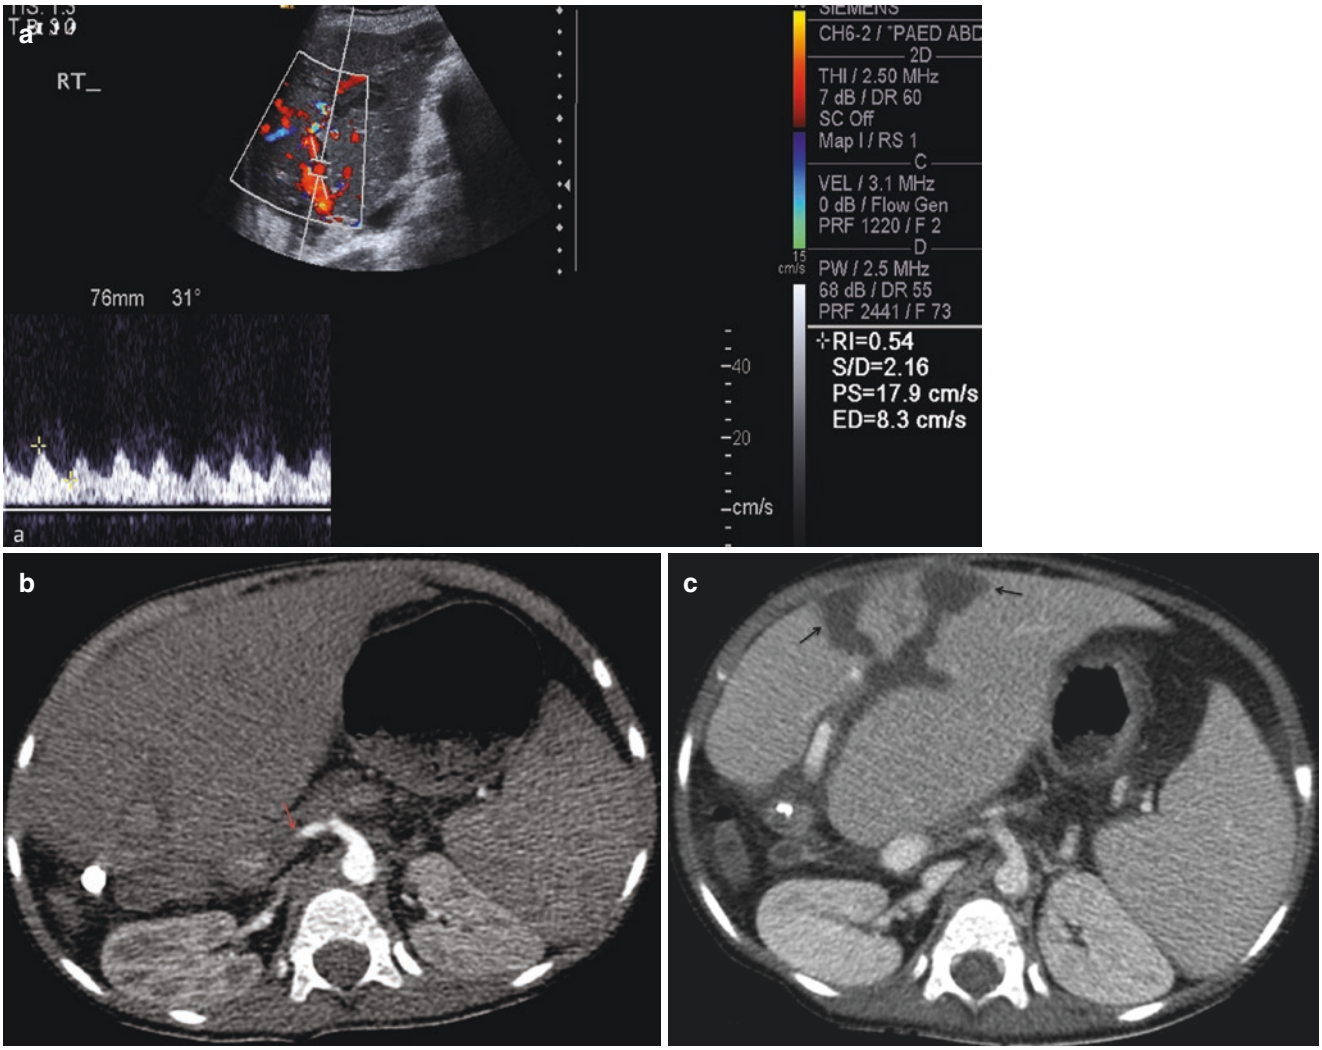

Fig. 57.11 Doppler US scan of a left lateral segment transplant liver. There is a pulsus tardus parvus in a collateral of the hepatic artery with a prolonged acceleration time and reduced peak systolic velocity (17.9 cm/s). (**b**) CT angiogram confirms the finding of a thrombosed hepatic artery (*red arrow*). (**c**) A follow-up CT scan performed 1 month later shows low-attenuation lesions within the parenchyma, in keeping with bile lakes (*black arrows*)

On US, a normal portal vein has smooth walls and an anechoic lumen and on colour and Doppler images shows antegrade/hepatopetal monophasic flow, except in the early postoperative period, where it can show high velocity and turbulent flow.

Portal vein thrombosis manifests with echogenic intraluminal thrombus and lack of flow on colour and Doppler trace, and absent portal vein enhancement is seen on CEUS (Fig. 57.12), in which case either thrombolysis or, more frequently, surgery with thrombectomy or venous graft is performed.

Portal vein stenosis has a later onset and can present with signs of portal hypertension. B-mode US shows focal severe narrowing of the portal vein at the anastomotic site with post-stenotic dilatation; on colour and Doppler images, there is focal aliasing at the stenotic site with an increase of the velocity of three- to fourfold compared to the pre-stenotic segment [12, 13]. These findings can be confirmed with CT or, usually for the late-onset complications, with MR angiography (Fig. 57.13). Symptomatic patients are normally treated with balloon angioplasty or stenting (Fig. 57.14).

IVC

Venous outflow obstruction is a rare complication secondary to either stenosis, thrombosis of the suprahepatic IVC or caval kinking from organ rotation.

The normal Doppler trace of the hepatic vein and IVC is triphasic due to pressure variations during the cardiac cycle;

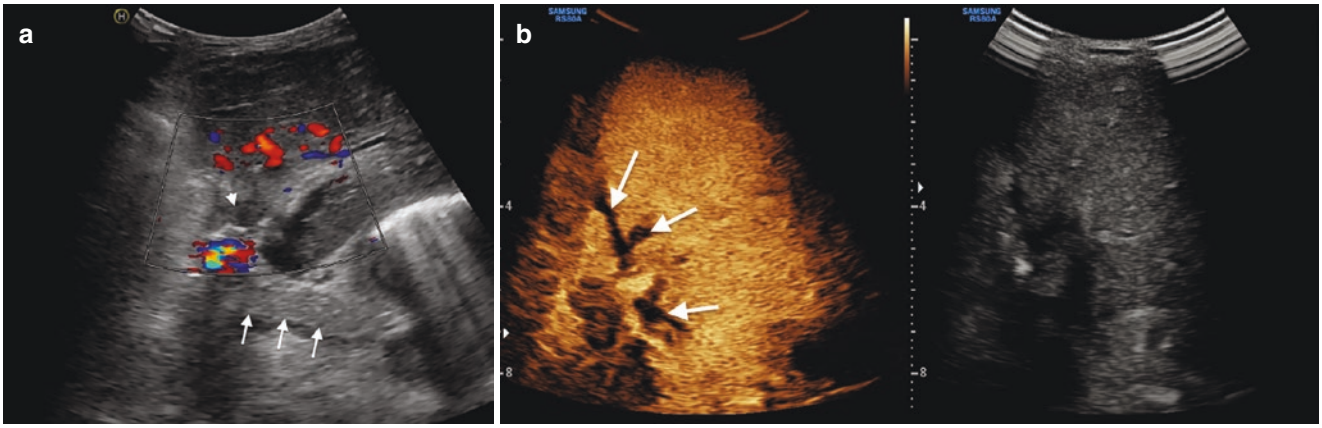

Fig. 57.12 (**a**) US shows an echogenic thrombus within the extrahepatic portal vein (*arrows*), with extension into the intrahepatic portal veins and absent flow on colour Doppler (*arrowhead*). (**b**) CEUS shows the absence of enhancement of the portal vein and branches (*arrows*)

a monophasic waveform is a sensitive but non-specific sign of stenosis, and a triphasic or biphasic waveform can exclude a substantial stenosis. Like the portal vein, stenosis can be seen on US as a focal stricture with impaired flow and prestenotic dilatation of the hepatic vein, whereas echogenic thrombus and complete absence of flow are direct signs of thrombosis. CT or MR is normally needed to confirm US findings or make the diagnosis where US is inconclusive. Cross-sectional imaging can also show signs of Budd-Chiari syndrome with the typical mosaic pattern of perfusion.

Biliary Disorders

Biliary complications are relatively frequent and are a common cause of graft dysfunction; these can often present with ischaemic liver injury as well as cholestasis and cholangitis and include anastomotic strictures, fistulas, stone formation with obstruction, diffuse cholangiopathy and bile leaks.

A Roux-en-Y choledochojejunostomy is the most commonly performed anastomosis to achieve biliary drainage, although an end-to-end choledochal anastomosis may be performed in older children recipient of a whole graft.

US serves as a surveillance test to detect bile duct dilatation, although this is a variable feature, as mild dilatation can be present in the absence of significant obstruction and therefore clinical and laboratory correlation is needed.

MRCP is the modality of choice to investigate cholangiopathy and biliary strictures, the most common biliary complication (Fig. 57.15). This can be due to either fibrotic proliferation and narrowing of the lumen or ischaemic cholangiopathy; multiplanar MR provides anatomical details and helps in planning percutaneous, endoscopic or surgical treatments.

Bile leaks normally occur early and can form perihepatic collections, which are drained percutaneously; treatment options include placement of a stent or biliary reconstruction. Intrahepatic bile leaks are normally secondary to ductal ischaemia.

Liver Masses

Radiological Approach to the Child with a Focal Liver Lesion

The diagnostic approach to children with chronic liver disease or a suspected liver mass should be tailored to the clinical scenario, including the age of the child and serum alpha-fetoprotein (AFP) levels. Not all malignancies produce AFP; however, if serum AFP is elevated, a benign lesion is unlikely. US is the modality of choice in the screening of these children, because of its lack of ionizing radiation and no need for sedation. Some tumours, such as haemangioendothelioma, have typical features on US and Doppler scan and may not require further characterization; however, the vast majority of liver masses need cross-sectional investigation [14, 15]. Contrast Enhanced Ultrasound (CEUS) is a useful and evolving technique for assessing focal liver lesions and has the potential to not only differentiate benign from malignant liver lesions but also establish a diagnosis in benign lesions such as focal nodular hyperplasia, without the need for further cross-sectional imaging [16, 17].

When performing a CT in children, efforts should be made to minimize radiation exposure, and unnecessary phases should be avoided (such as non-contrast scans); when the aim of the scan is surgical planning, a single post-contrast phase should be performed.

If multi-phase post-contrast imaging is required, then MRI should be performed instead of CT. The limiting factor here is the need for sedation in young children; therefore each scan should be performed starting from the most valuable sequences to achieve a definitive diagnosis.

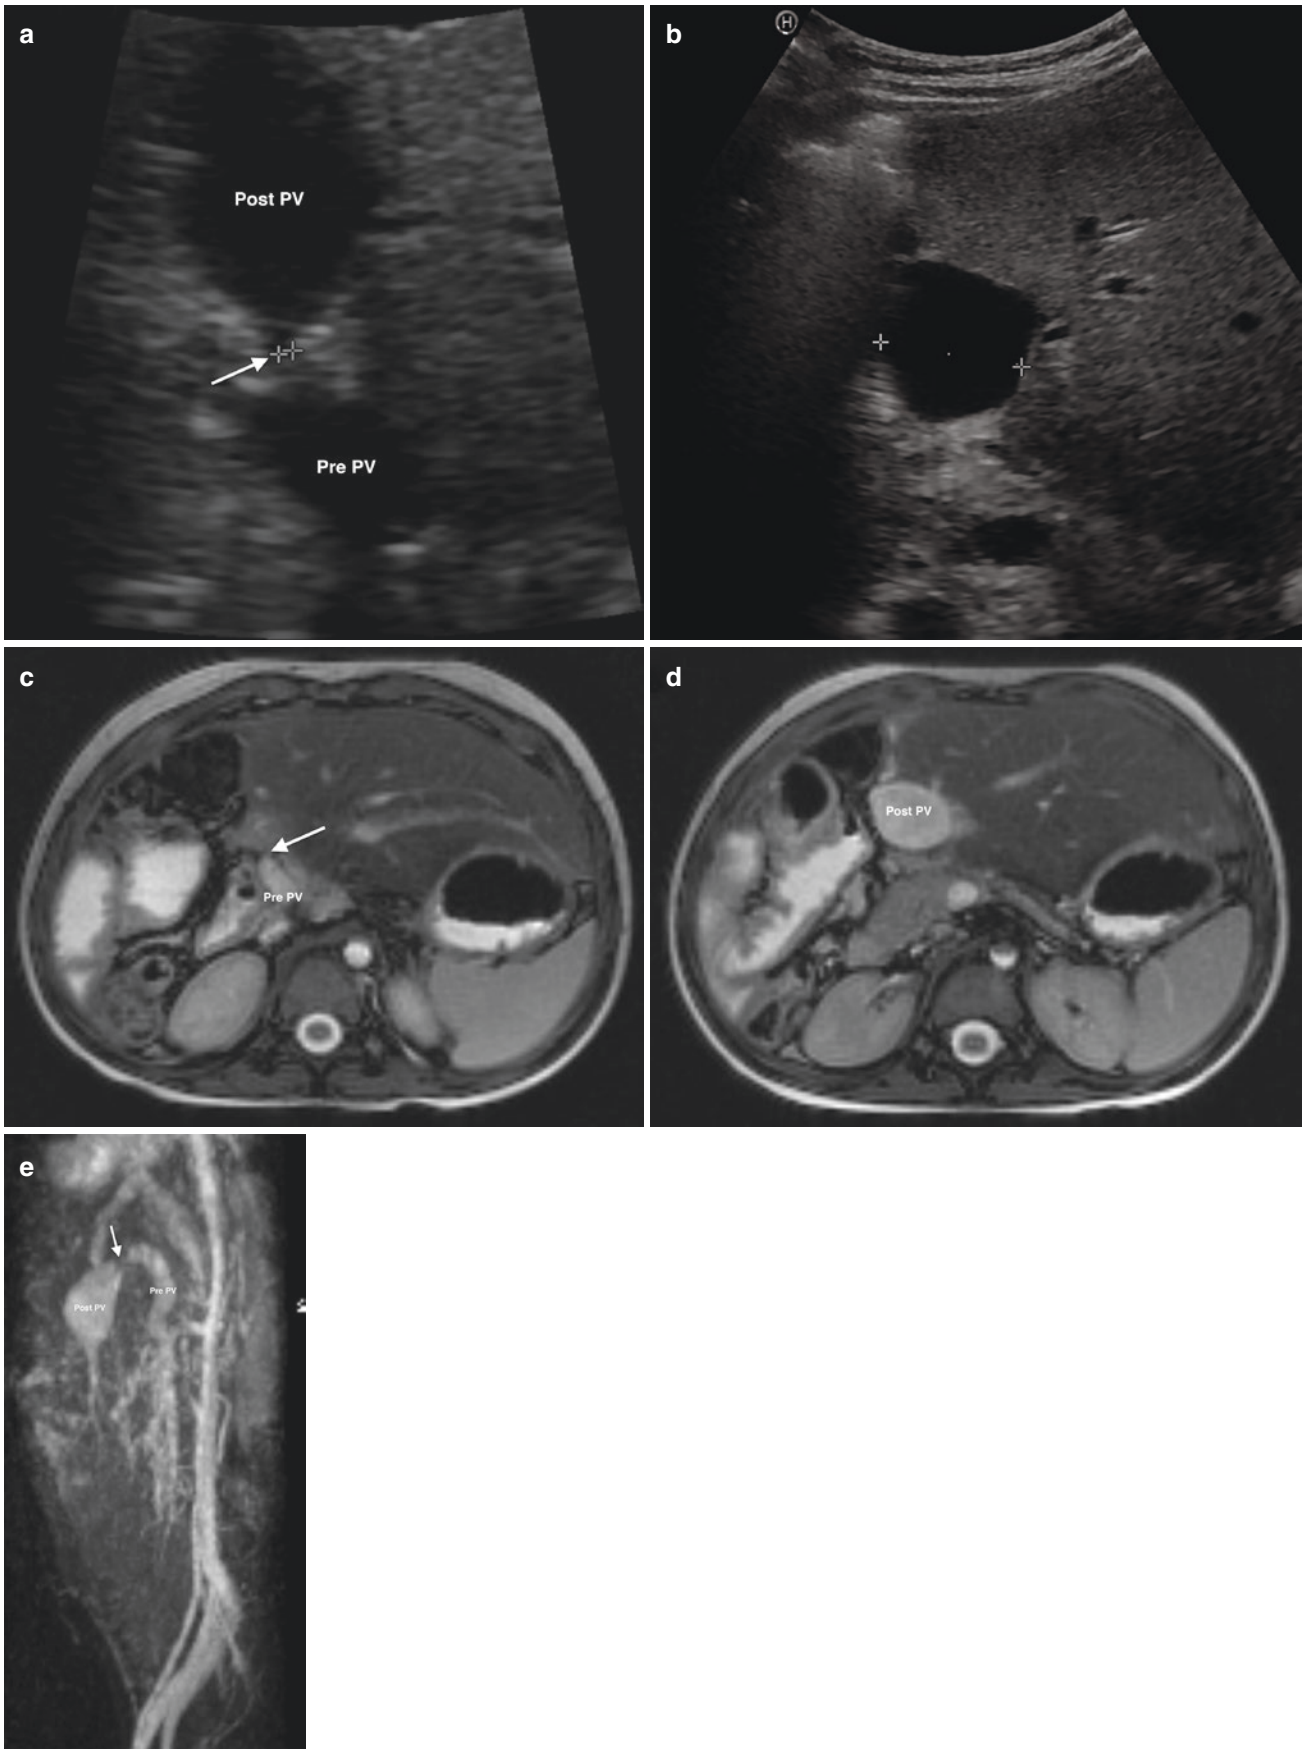

Fig. 57.13 B-mode US of a post-liver transplant patient. (**a**) Anastomotic stricture of the portal vein (*arrow*, 1 mm) (**b**) with post-stenotic dilatation. (**c**) T2W MRI demonstrates the anastomotic stricture (*arrow*) and (**d**) post-anastomosis stricture dilatation. (**e**) MRV MIP sagittal image shows the PV stricture (*arrow*) and post-anastomosis stricture dilatation. Pre-anastomosis portal vein *Pre PV*, post-anastomosis portal vein *Post PV*

Fig. 57.14 Percutaneous transhepatic portal venogram. (**a**) Post-anastomosis stricture dilatation of the portal vein (*arrow*). (**b**) Balloon angioplasty of the PV stricture (*arrows*). (**c**) Post-balloon dilatation of the PV anastomosis stricture (*arrows*)

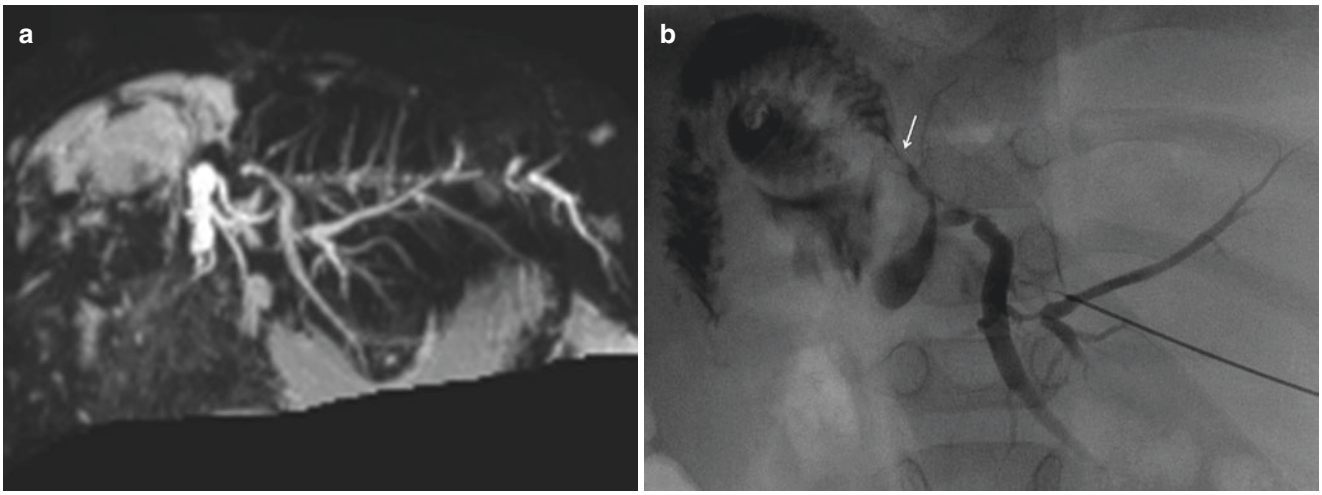

Fig. 57.15 (**a**) MRCP MIP reconstruction of the biliary tree in a left lateral segment transplant liver shows signs of cholangiopathy with an anastomotic stricture of the biliary enterostomy. (**b**) PTC image confirming the MRCP findings of a stricture (*white arrow*). The patient underwent balloon dilatation of the stricture. *MIP* maximum intensity projection

If, at the end of the diagnostic pathway, there is still uncertainty on the nature of a lesion, then imaging-guided (either US or CT) biopsy should be performed.

Benign Tumours

Infantile Hepatic Hemangiomas

Infantile hepatic hemangioma (IHH) is a vascular neoplasm and represents the most common benign tumour in children; the lesions can be either single or multifocal, and its margins may be sharp or ill-defined. In the first 6 months of life, these tumours show progressive growth, followed by spontaneous involution. On antenatal US scan, a hypoechoic liver mass can be detected, sometime together with foetal hydrops and cardiomegaly, which correlate with worse prognosis.

Multifocal lesions are small and uniform in appearance, usually hypoechoic on US within a markedly enlarged liver. Large lesions can have heterogeneous appearance in all modalities, due to central haemorrhage, necrosis, fibrosis and calcification, and prominent vascular channels will be seen on colour Doppler. On CEUS, peripheral nodular enhancement is seen on the arterial phase with centripetal homogenous or incomplete enhancement on venous and late phases (Fig. 57.16).

On cross-sectional imaging, there are signs of high flow, with enlargement of the hepatic artery and veins (due to the presence of arteriovenous shunting) and possibly tapering of the aorta below the origin of the coeliac axis. Like CEUS, similar enhancement characteristics are seen as CT and MRI: peripheral nodular enhancement with "filling in" on the delayed phase. On MR, the lesions have characteristic hyperintense signal on T2W images (Fig. 57.17).

Angiography is now reserved for those cases in which arteriovenous shunts require embolization of the feeding arteries.

Mesenchymal Hamartoma

Mesenchymal hamartomas typically present as solitary tumours of the liver in infants and small children; most commonly, they involve the right lobe of the liver, and the vast majority of these contain cysts, even though they can be either predominantly cystic or solid. The gross pathologic appearance will influence imaging findings: cystic portions are avascular with thin or thick septa, and solid components are hypovascular compared to the normal liver parenchyma. The cysts will be anechoic on US and have high signal on T2W MRI and either low signal (clear cyst contents) or high signal (mucoid contents) on T1W images (Fig. 57.18). CEUS will show enhancement of the wall and septa, which persists on delayed phases.

Focal Nodular Hyperplasia (FNH)

FNH is a benign epithelial liver tumour, uncommonly seen in young children. The tumour is composed of well-differentiated hepatocytes forming nodules divided by

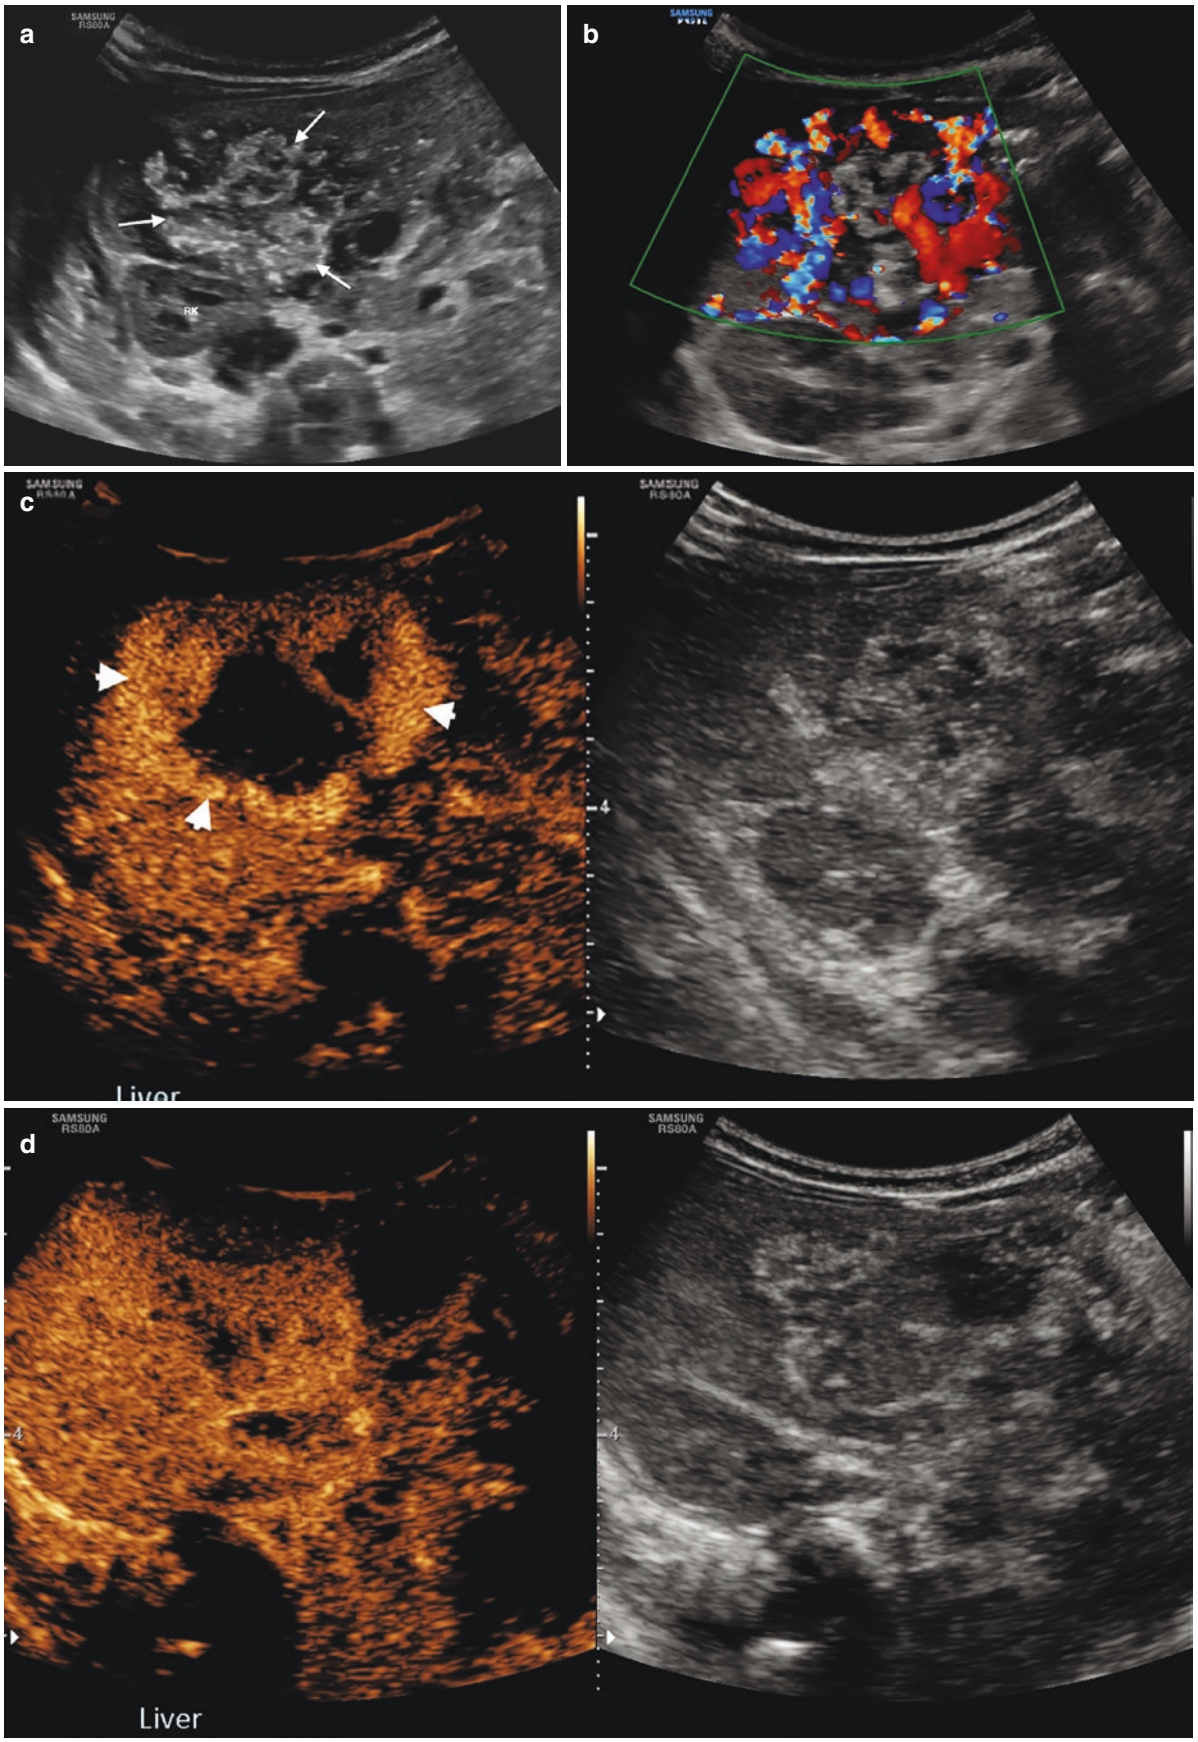

Fig. 57.16 Conventional ultrasound of an infantile hepatic hemangioma (IHH). (**a**) Mixed echogenic mass with solid and cystic components and calcifications with on B-mode ultrasound (arrows). (**b**) Prominent vascular channels are seen on colour Doppler US. CEUS in a different patient demonstrates (**c**) peripheral enhancement on the arterial phase (*arrowheads*) and (**d**) incomplete centripetal enhancement on the venous phase. *RK* right kidney

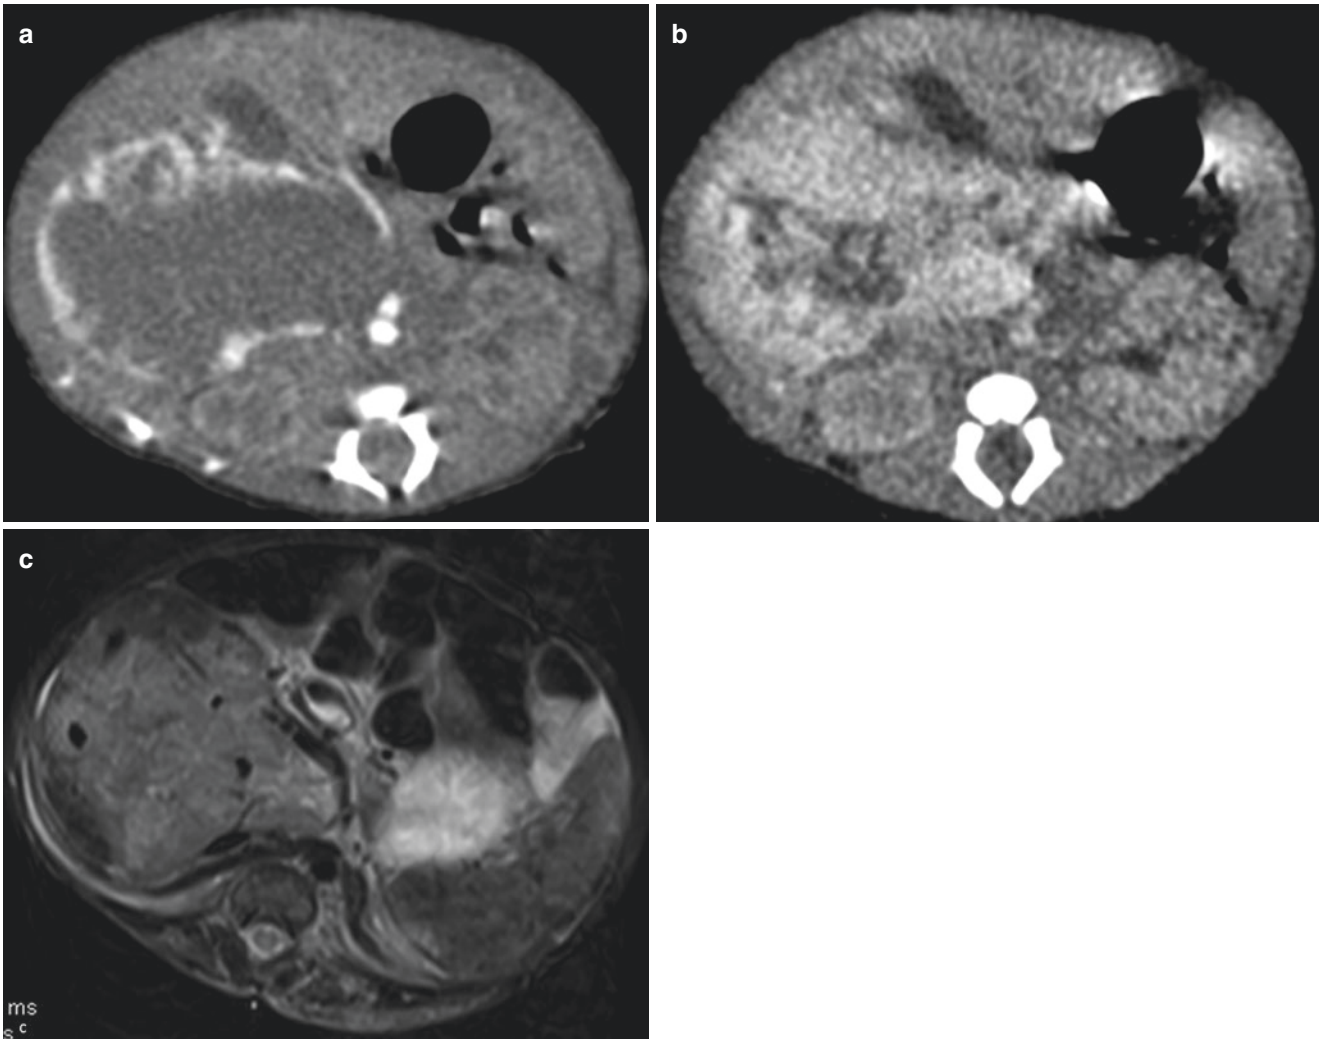

Fig. 57.17 (**a**) CT scan performed in the arterial phase in a new-born baby shows a large IHH in the right lobe of the liver with peripheral enhancement. (**b**) In the portal venous phase, there is centripetal enhancement of the mass. (**c**) A T2W MR image shows the lesion as hyperintense compared to normal liver parenchyma

fibrous septa, which form a characteristic vascular central scar with a stellate shape. It is usually a solitary, well-circumscribed, encapsulated mass but can be multifocal. On US it appears as a homogeneous lesion of variable echogenicity, usually isoechoic compared to normal liver. Central vascularity can be detected at colour Doppler, and CEUS will show a typical pattern of centrifugal, spoke-wheel arterial enhancement followed by uniform enhancement with the rest of the parenchyma in the portal venous and late phases (Fig. 57.19) [17]. This can be confirmed at post-contrast cross-sectional imaging; on MR, similar enhancement characteristics are seen, and the central scar is normally bright in T2W images (Fig. 57.20). In equivocal cases, hepato-specific agents (such as Teslascan or Primovist) show tumour uptake that persists for hours or even several days.

Hepatocellular Adenoma

Hepatocellular adenoma (or hepatic adenoma) is a rare benign neoplasm composed of hepatocytes with increased intracellular fat and glycogen, often prone to intralesional haemorrhage and necrosis. The majority of hepatic adenomas present as solitary well-circumscribed lesions, although in children with glycogen storage disease they can be multifocal.

Hepatic adenomas without haemorrhage will be homogeneous with the rest of the liver in all imaging modalities. Following administration of contrast in CT or MR, the lesions typically display increased enhancement in the arterial phase and uniform enhancement with the rest of the liver in the portal venous and delayed phases; if there is haemorrhage, the lesion will enhance heterogeneously. Similar

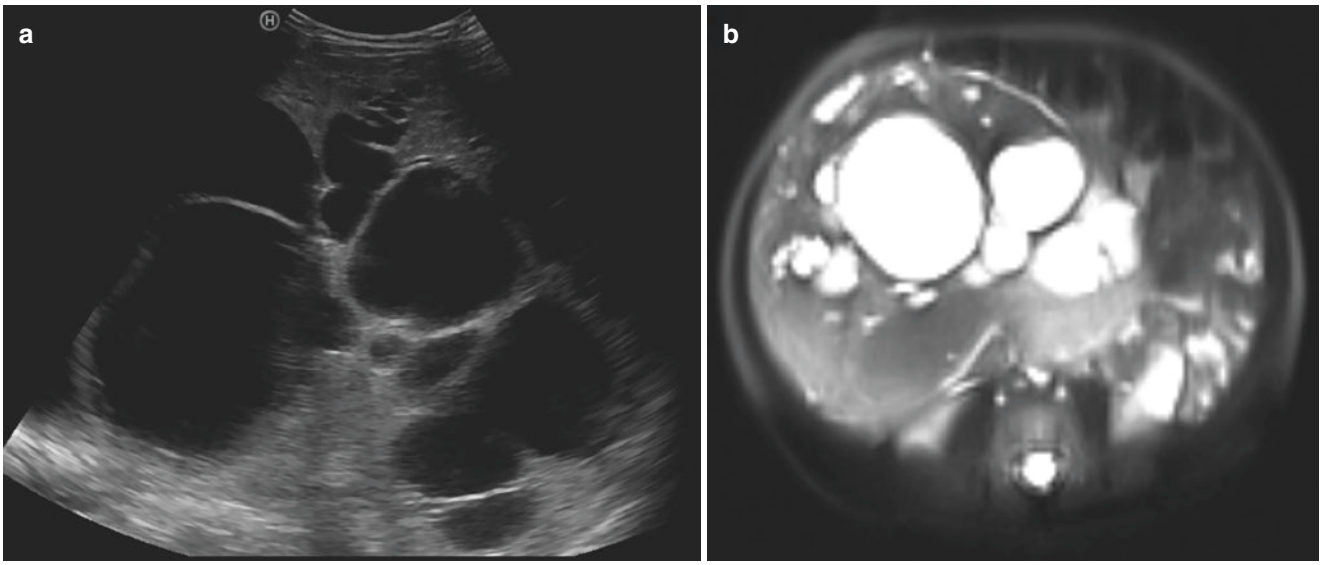

Fig. 57.18 (**a**) US shows a multicystic mass with anechoic cysts and thin intervening septa. (**b**) A T2W MR image shows the lesion with multiple hyperintense cysts

enhancement characteristics are seen on CEUS with mixed or centripetal arterial enhancement, isoenhancing with the liver parenchyma on the venous phase, and without washout on the early and late phase. Lesions with high-fat content will show on MR high signal intensity on T1W and T2W images, with signal dropout on opposed-phase or fat-suppressed sequences.

Nodular Regenerative Hyperplasia (NRH)

NRH is characterized by regenerative nodules surrounded by atrophic liver without a fibrotic component. Various types of small-vessel blood flow alterations are seen in association with NRH, including lymphoproliferative disorders, autoimmune disorders and Budd-Chiari syndrome, and with the use of various medications (steroids, chemotherapeutic agents). The nodules, usually multiple with the tendency to coalesce, are composed of hepatocytes like the surrounding liver; therefore they can be difficult to distinguish from the adjacent parenchyma in all modalities, even after contrast administration.

Malignant Tumours

Hepatoblastoma

Hepatoblastoma is the most common primary hepatic tumour in children, occurring predominantly in children below the age of 5 years. These tumours normally present as large masses often containing haemorrhagic and necrotic areas and speckled or amorphous calcifications; in 90% of the cases, AFP serum levels are elevated. At imaging, hepatoblastomas present as large, well-circumscribed masses with septa; epithelial tumours have a homogeneous appearance, whereas mixed epithelial and mesenchymal tumours are more heterogeneous with variable osteoid, cartilaginous and fibrous components. The primary role of radiology is to assess the tumour for resectability (sections involved, involvement of the caudate, vessel invasion) and staging (the lung being the most common site for metastases): hepatoblastoma should be evaluated using the PRETEXT classification as this will establish treatment regimen [18]. On post-contrast cross-sectional imaging and CEUS, hepatoblastomas can show early avid, inhomogeneous enhancement and early washout (Fig. 57.21); vascular invasion is better demonstrated on contrast-enhanced scans.

Hepatocellular Carcinoma

The main differential diagnosis of hepatoblastoma is hepatocellular carcinoma; HCC however is rare under the age of 5 years, and 50% of cases have a pre-existing liver disease, such as biliary atresia, familial intrahepatic cholestasis, glycogen storage disease type I, tyrosinaemia, Wilson's disease and alpha-1 antitrypsin deficiency.

Unlike in adults, small HCCs are unusual in children, and lesions can have variable appearance on US, with a hypoechoic halo if the tumour has a capsule. Large tumours may contain areas of haemorrhage and necrosis.

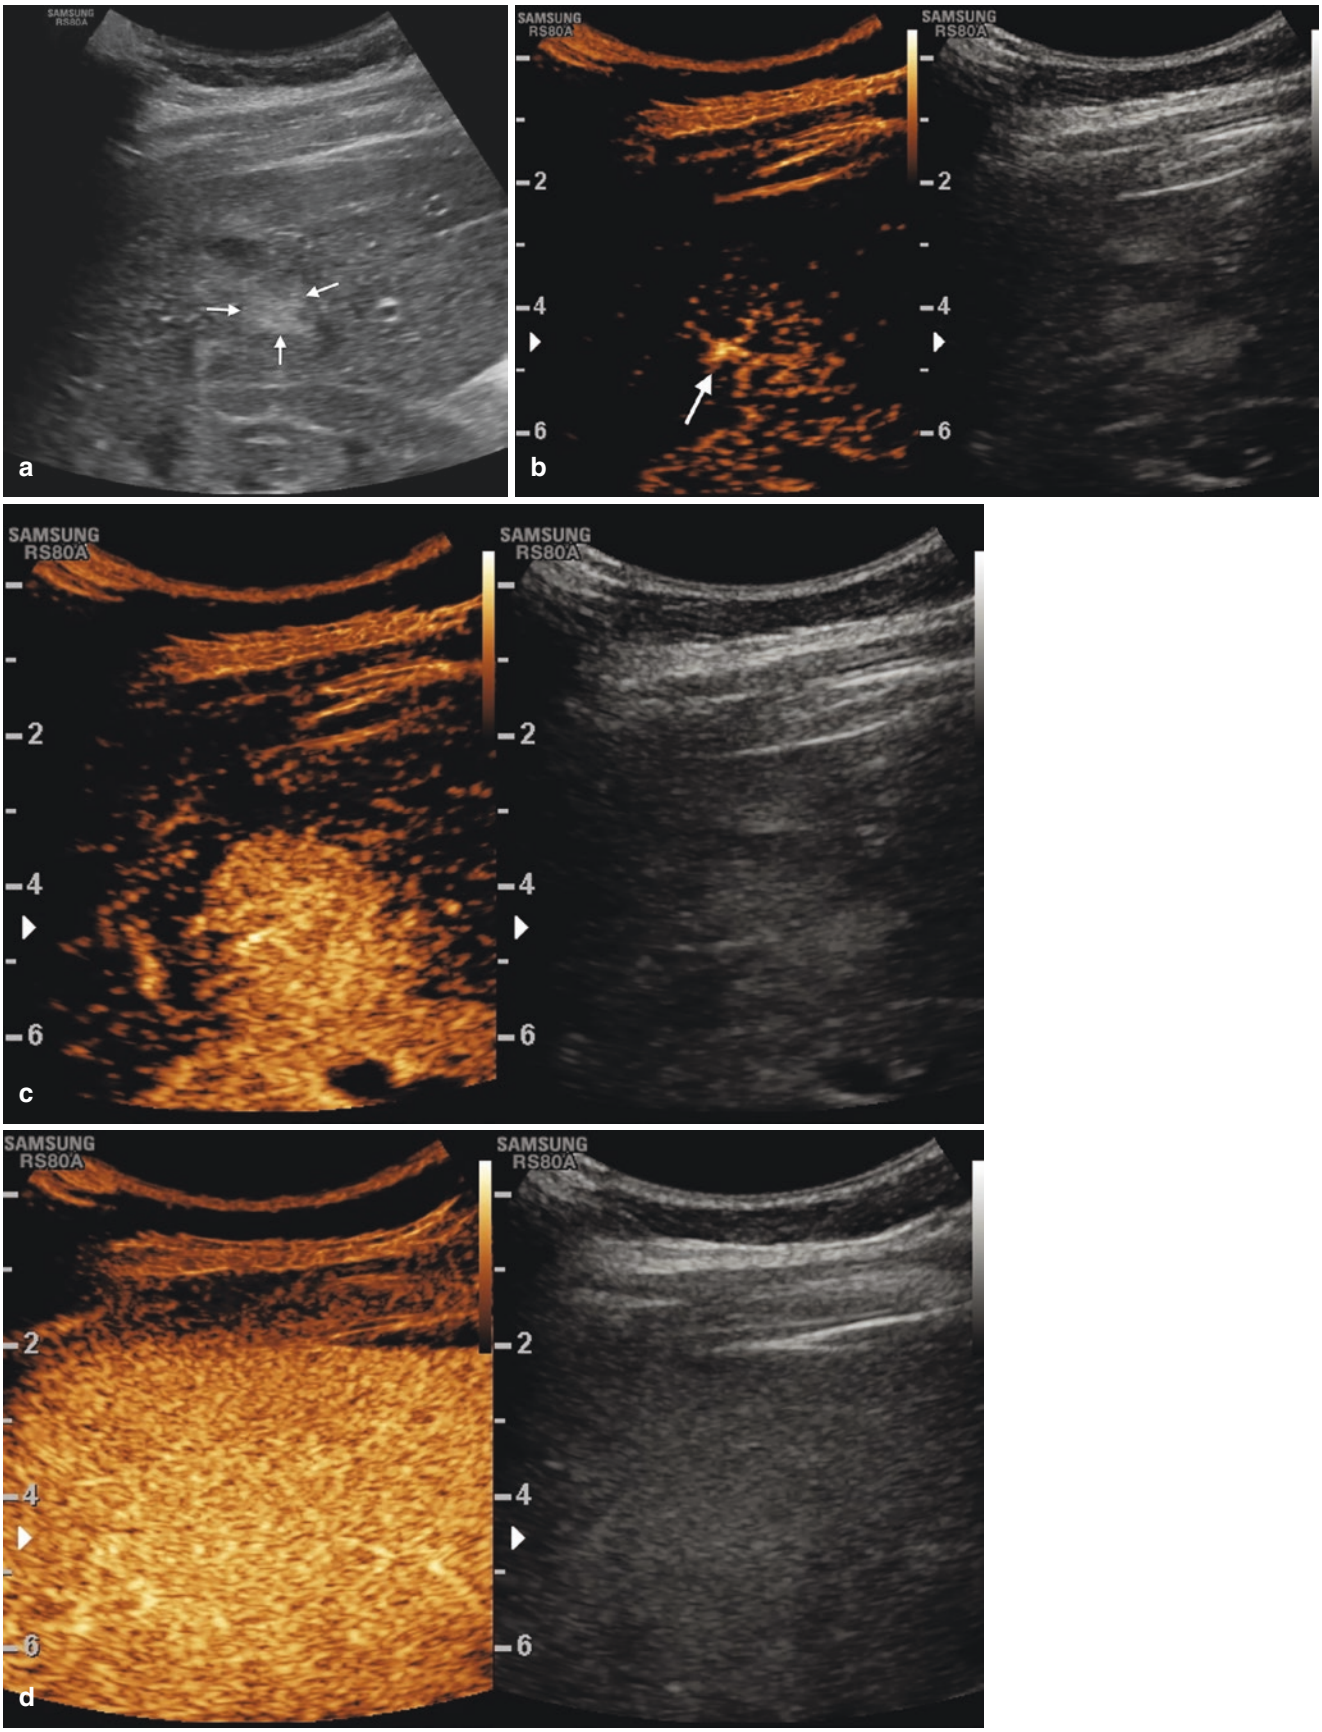

Fig. 57.19 Conventional US of an FNH. (**a**) B-mode shows a well-defined slightly hyperechoic mass (*arrows*). CEUS (**b**) early arterial phase (16 s) demonstrates a spoke-wheel pattern (*arrow*). (**c**) Late arterial phase (25 s) shows centrifugal homogeneous enhancement (**d**) venous (50 s), and (**e**) late phase (67 s) shows isoenhancement with the surrounding liver parenchyma with no evidence of washout

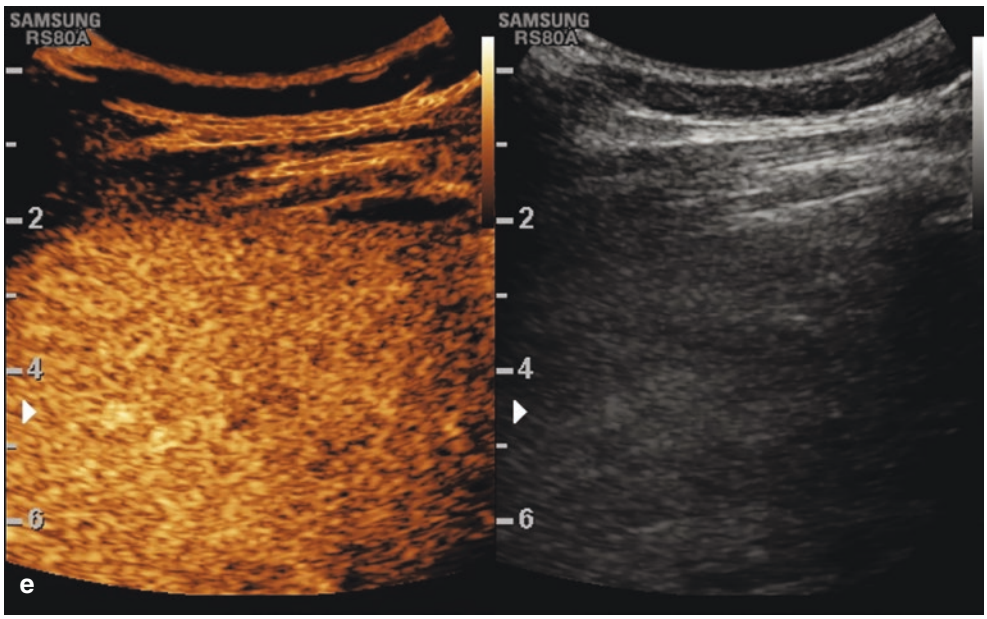
Fig. 57.19 (continued)



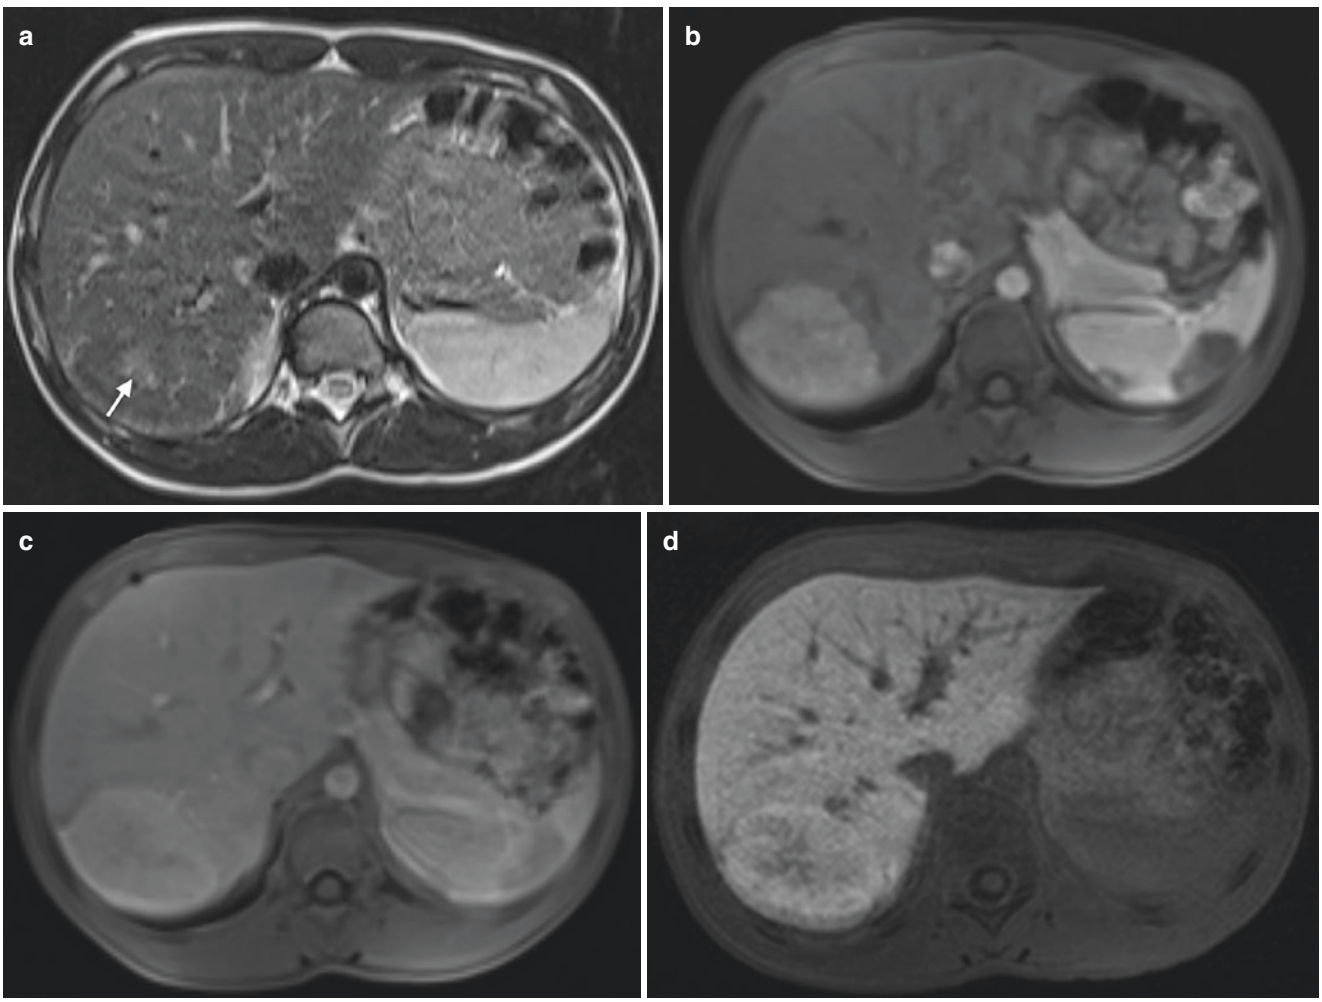


Fig. 57.20 MRI of an FNH. (**a**) A T2W image shows a mildly hyperintense central scar (arrow). Post-contrast T1W FS (**b**) arterial phase shows homogeneous intense enhancement. (**c**) Iso- to mildly hyperintense on the venous phase. (**d**) No evidence of washout on the hepatobiliary phase

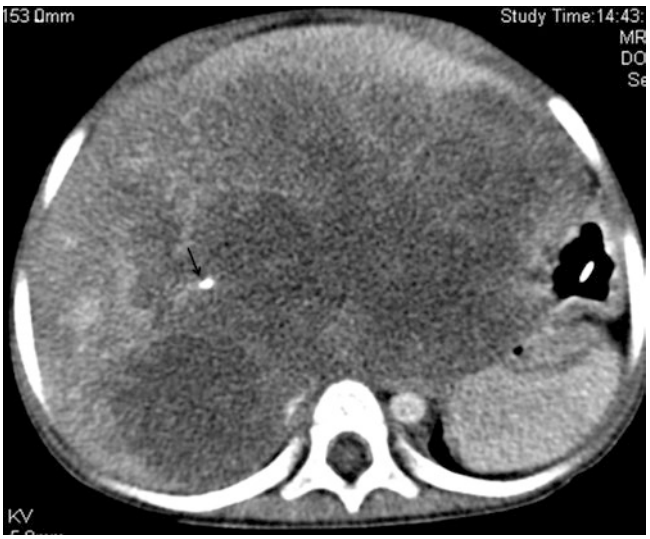

Fig. 57.21 A CT scan performed on the portal venous phase shows a large, poorly enhancing hepatoblastoma involving the whole of the liver; note intralesional calcification (*arrow*)

On post-contrast cross-sectional imaging and CEUS, HCC typically shows early arterial enhancement with washout in the portal venous and delayed phases; portal and hepatic venous invasion may be identified.

Fibrolamellar Carcinoma

Fibrolamellar carcinoma is a slow-growing tumour that occurs in adolescents and young adults. The tumours are normally well demarcated and contain numerous fibrous septa which may separate the tumour into lobules and form a central scar-like structure; haemorrhage and necrosis are rare but calcifications can be observed. US shows a solitary heterogeneous mass; post-contrast CT and MR show avid enhancement in the arterial phase with often lack of enhancement of the central scar. On MR, the scar is typically hypointense in T1 W and T2W images, in contrast with the scar seen in FNH, which is normally hyperintense in T2W images. CEUS may have value in demonstrating similar enhancement characteristic like CT and MR imaging and a central non-enhancing scar in all phases, but there is only limited published evidence to support this [19].

Undifferentiated Embryonal Sarcoma (UES)

UES is a rare tumour that usually presents between 6 and 10 years of age; AFP levels are usually normal and the presentation is non-specific. The tumours show very aggressive local growth with invasion of the diaphragm and lung. These tumours typically show a predominantly solid appearance on US but cystic appearance on CT and MR, due to its prominent myxoid stroma, which contains water. These tumours are usually well-demarcated by a fibrous pseudocapsule, which generally show marked enhancement on post-contrast images.

Angiosarcoma

Angiosarcoma is a rare vascular tumour that can occur in young girls and in children with a previous diagnosis of IHH.

US can show either multiple nodules or a large mass of variable echogenicity. On post-contrast imaging, the lesion often show decreased, heterogeneous enhancement compared to the normal liver with occasionally central or ring enhancement. Haemorrhage or necrosis can be observed.

Embryonal Rhabdomyosarcoma

Rhabdomyosarcoma can rarely arise from the biliary tree, and this form is almost exclusively seen in young children; it spreads by intraluminal extension and causes significant cholestasis. At imaging, a mass can be seen usually at the porta hepatis, with intrahepatic biliary duct dilatation and normal-sized or, if affected by the tumour, enlarged extrahepatic duct (Fig. 57.22). Portal vein displacement without invasion is common. Like other malignant liver lesions, post-contrast enhancement with early washout can be seen on CEUS.

Imaging of Liver Trauma in Children

CT remains the gold standard in the evaluation of blunt abdominal traumas in children; however, due to the risks related to radiation exposure, CT must be reserved for those children in whom there is a high index of suspicion and should be performed following IV injection of contrast, possibly with split-bolus technique. When indicated, CT can provide rapid information regarding intra-abdominal injuries and can guide patient's management towards operative or conservative. Even though US would be preferable to CT given its non-invasive nature and the lack of radiation, published data regarding the use of FAST (Focused Abdominal Sonography for Trauma) in children are not supportive of its use. Conversely, there are encouraging data regarding the use of CEUS in the setting of paediatric trauma, and in many centres, this imaging modality is routinely used, if not at presentation, certainly as the main follow-up examination [20].

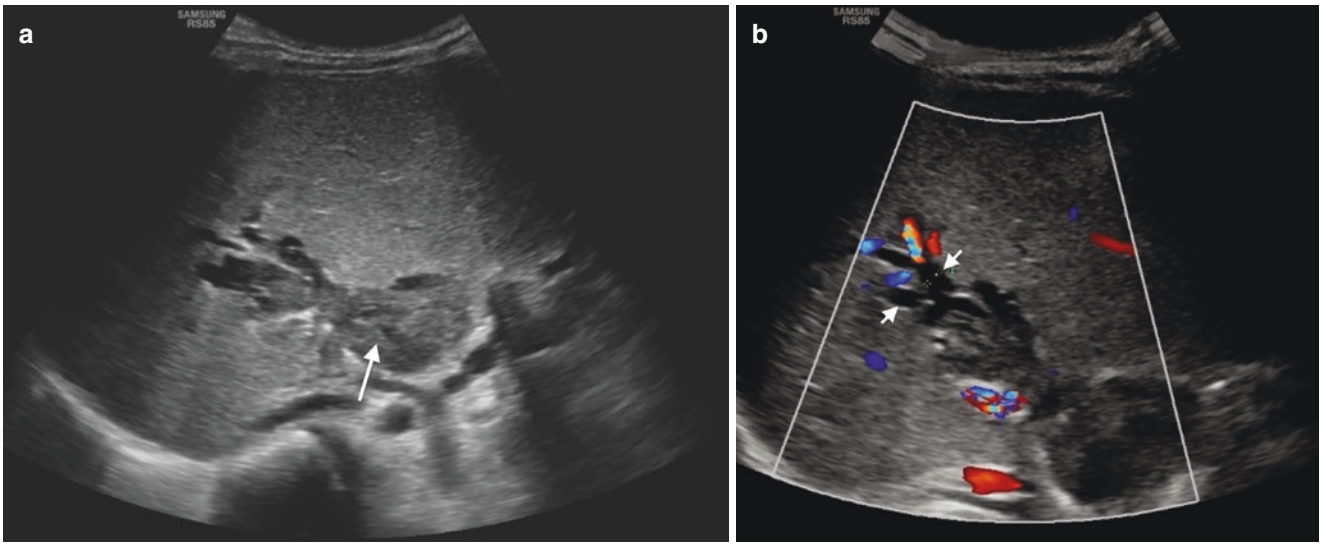

Fig. 57.22 B-mode ultrasound image of a patient with rhabdomyosarcoma relapse demonstrates (**a**) markedly thickened and expanded bile duct (*arrow*). (**b**) Distal intra-hepatic biliary dilatation (*arrows*)

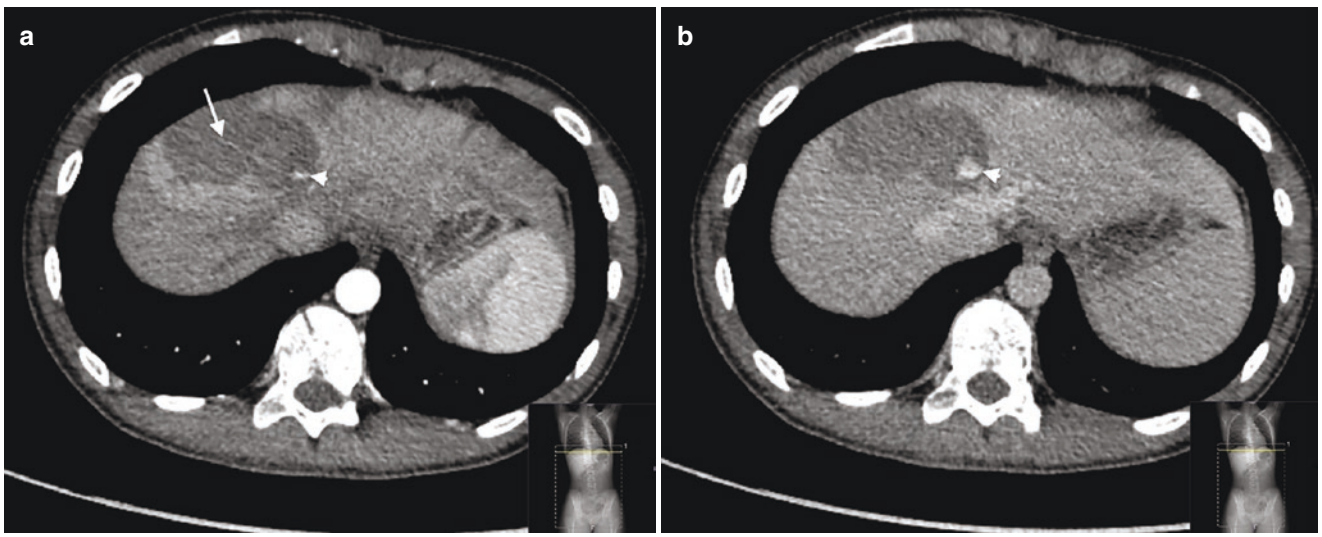

Fig. 57.23 A dual-phase CT scan performed on patient following major trauma shows a large liver contusion (*arrow*, **a**) and active bleeding. (**a**) Extraluminal blush of contrast-enhanced blood in the arterial phase (*arrowhead*). (**b**) Expansion of the hyperattenuating focus on the venous phase (*arrowhead*)

The liver is the second most commonly injured organ in paediatric abdominal trauma (the spleen being the commonest site of injury); the role of the radiologist in this setting is to establish the extent of the injury (in terms of lobes and segments involved and vascular injury) and possible associated complications, such as ongoing haemorrhage (Fig. 57.23). When active bleeding is demonstrated on CT, the patient will proceed to have an angiography with selective embolization of the bleeding vessel (Fig. 57.24). At follow-up, normally between days 5 and 7 of trauma, potentially dangerous complications like pseudoaneurysm of the hepatic artery, hematomas and bile leaks should be actively sought (Fig. 57.25).

CEUS has a higher diagnostic accuracy than conventional US and is comparable to CT for the assessment of liver trauma. It can be used to demonstrate traumatic injuries to the liver, especially at follow-up, to evaluate their extent and complications such as a haematoma, pseudoaneurysm and biloma (Figs. 57.26 and 57.27) [21].

Fig. 57.24 (**a**) Conventional angiography demonstrates selective cannulation of a hepatic artery branch and extraluminal extravasation of contrast (*arrow*) consistent with active bleeding. (**b**) Post-coil embolization (*arrow*) image shows cessation of bleeding

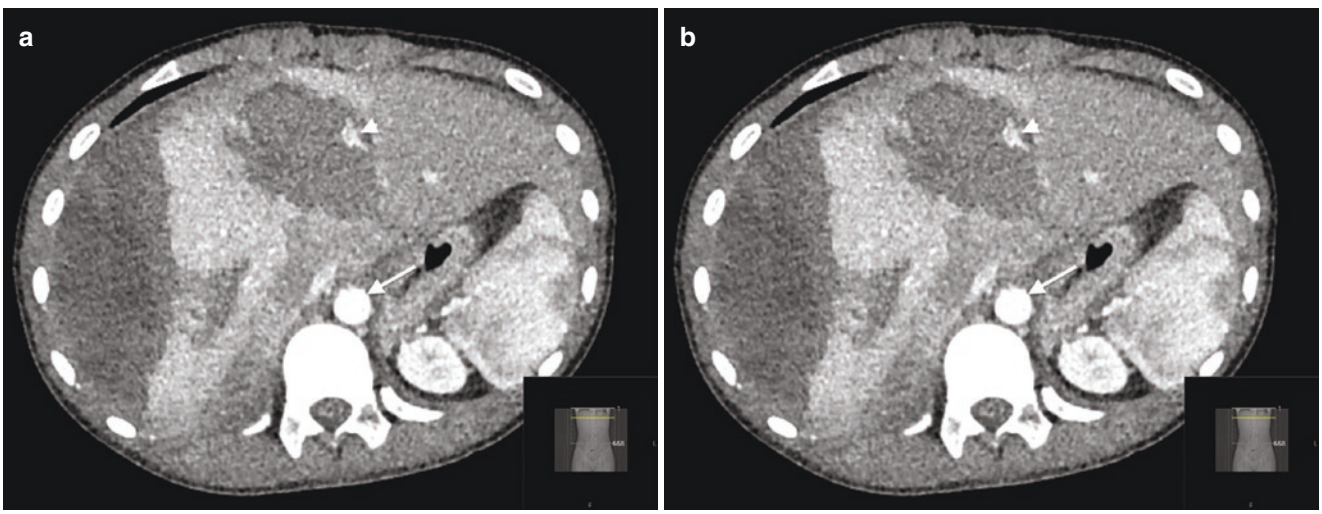

Fig. 57.25 A dual-phase CT scan performed 5 days following a liver trauma demonstrates a pseudoaneurysm. (**a**) Roundish extravasation of contrast-enhanced blood (*arrowhead*) in the arterial phase and has a similar density as the aorta (*arrow*). (**b**) Portal venous phase shows no expansion or change in morphology (*arrowhead*) and has a similar density as the aorta (*arrow*)

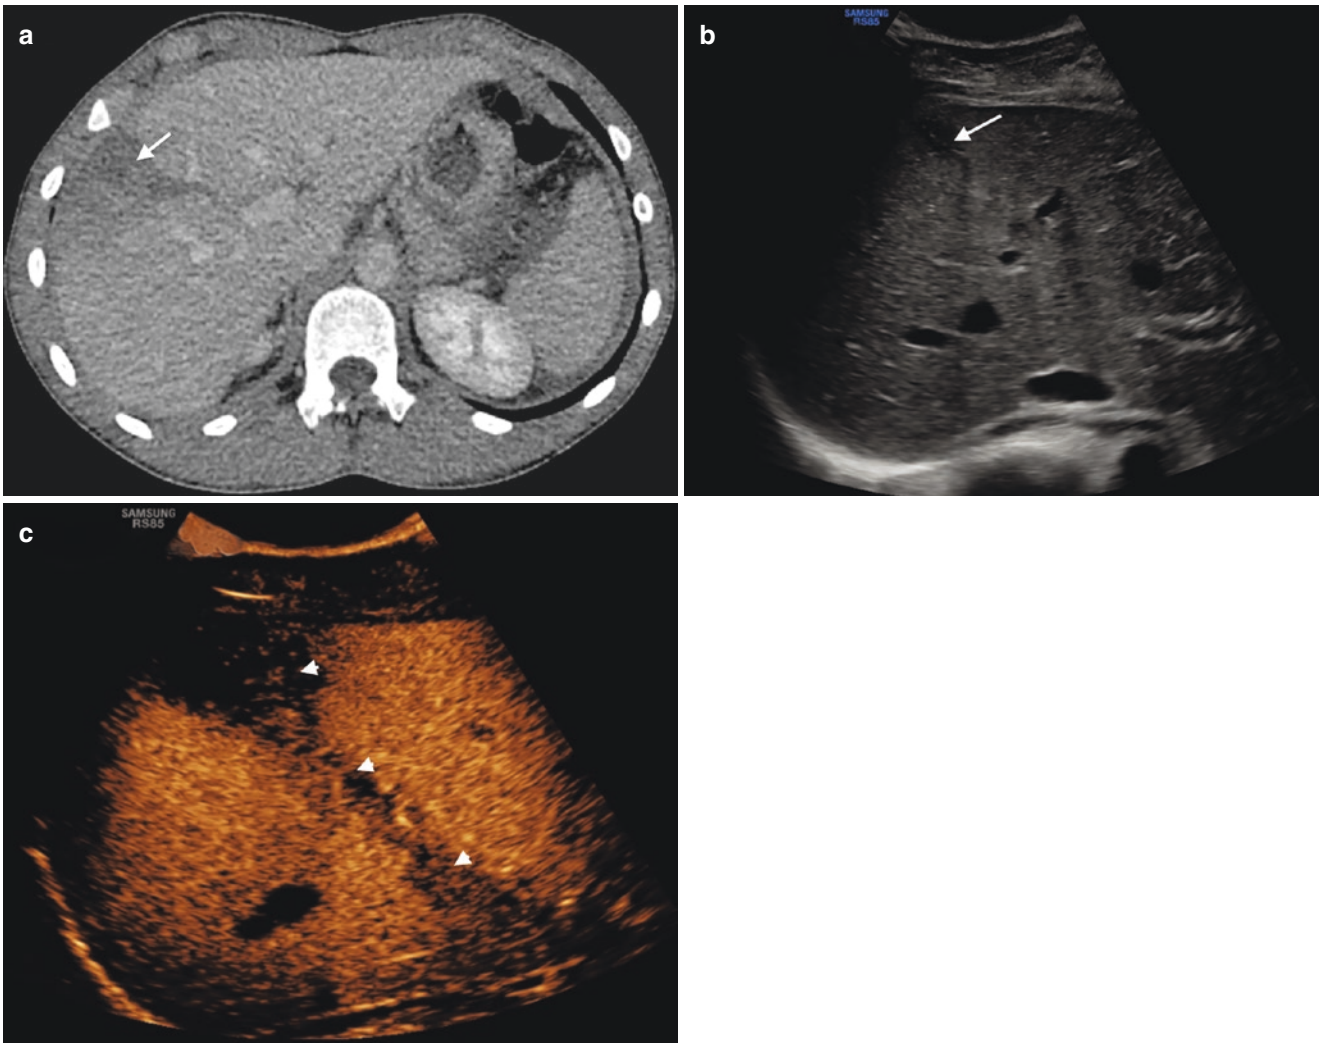

Fig. 57.26 (**a**) Axial CT image of the liver demonstrates a liver contusion/laceration that extends to the hilum (*arrow*). (**b**) Follow-up B-mode image of the liver shows a small focal hypoechoic area in the periphery of the right liver lobe (*arrow*). (**c**) Corresponding CEUS demonstrates the actual extent of the liver contusion and liver laceration (*arrowheads*)

Imaging of Pancreas

Acute and chronic pancreatitis are a significant cause of morbidity and mortality in children; the most common causes of pancreatitis in children are trauma, structural anomalies, multisystem and metabolic disease, drugs and autoimmune disease.

US is the first-line examination of the pancreas and can exclude extra-pancreatic disease; change in pancreatic parenchyma echogenicity is a variable feature, as well as swelling of the gland. US can easily detect dilatation of the pancreatic duct and peripancreatic fatty infiltration, free fluid and collections. In chronic pancreatitis, calcifications can be demonstrated.

MRI with MRCP is the most useful imaging modality to evaluate the severity of pancreatitis and establish further management; in addition, underlying structural anomalies such as abnormal pancreatico-biliary junction and choledochal cysts can also be diagnosed.

Autoimmune pancreatitis shows some specific features: the enlarged pancreas is in fact associated with irregular narrowing of the pancreatic duct, delayed contrast enhancement and a capsule-like rim which is more evident in the early post-contrast images on CT or MR; this corresponds to a fibrosing process extending to the peripancreatic fat.

Pancreatic involvement in children with CF is more frequent than liver disease, with plugging of pancreatic ducts due to inspissated secretions resulting in exocrine insuffi-

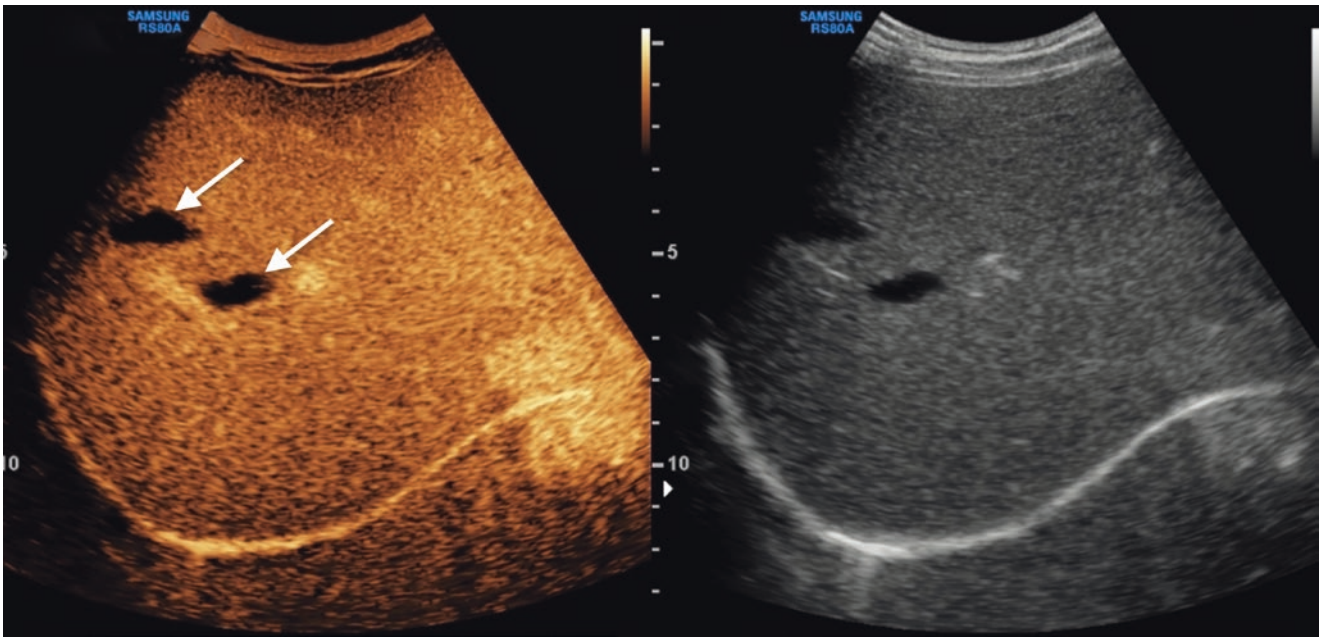

Fig. 57.27 CEUS (left) and B-mode (right) ultrasound images show well-defined anechoic and non-enhanced lesion in the liver parenchyma consistent with post-traumatic bilomas (*arrows*)

ciency. US shows an enlarged or atrophied pancreas with increased echogenicity due to fat deposition; cysts can be present, probably related to the obstruction of ducts.

Infantile Cholestasis: Approach and Diagnostic Algorithm

58

Narmeen I. Khan and Ruba K. Azzam

Introduction

Clinical jaundice in the first 2 weeks after birth is a common finding, occurring in 2.4–15% of newborns [1]. Often benign, it resolves spontaneously by 2 weeks of age but may persist as long as 3 weeks in a breastfed but otherwise healthy infant. Any jaundice beyond 2 weeks is considered abnormal and requires evaluation with a fractionated serum bilirubin level [2].

Cholestasis, defined as a decrease in bile formation or flow secondary to hepatocellular or obstructive cholestasis, respectively, stems from a variety of etiologies including genetic, metabolic, infectious, and toxin-mediated causes (Table 58.1). Hepatocellular cholestasis is secondary to reduced bile formation, such as due to sepsis or toxins. Obstructive cholestasis is due to either intra- or extrahepatic obstruction, a product of either anatomic or functional obstruction of the biliary system such as with biliary atresia (BA) and Alagille syndrome [3].

Cholestasis is defined as a conjugated/direct hyperbilirubinemia greater than 1 mg/dL if total serum bilirubin is at or below 5 mg/dL or direct bilirubin fraction >20% of total bilirubin when the total is higher than 5 mg/dL. Histologically, bile pigment is present in hepatocytes and bile ducts. Physiologically, the accumulation of substances normally excreted in bile is present in blood and extrahepatic tissues [4].

BA is the most common cause of cholestasis in the neonatal period, accounting for approximately 20–35% of infantile cholestasis [5, 6] and with a wide range of reported incidence rates worldwide. Historically, idiopathic neonatal hepatitis (INH) accounted for the majority of neonatal cholestasis, whereas today, its histologic finding of giant cell transformation is known to be nonspecific and attributable to multiple infectious, metabolic, and genetic disorders [6, 7]. Less than 5% of infantile cholestasis is secondary to congenital infections.

Immaturity of the neonatal liver in bile synthesis, transport, and metabolism renders itself more susceptible to cholestasis. The physiologic development of hepatic function matures in late gestation and over the first few months after birth. This immaturity contributes to a decreased capacity to synthesize and transport bile acids and affects the metabolism, detoxification, and excretion of drugs, xenobiotics, and bile [8–10].

Differential Diagnoses

Conjugated hyperbilirubinemia portends a hepatobiliary pathology that requires further evaluation in a time-sensitive manner. Greater than 95% of neonatal cholestasis cases result from a short list of disorders. Some of these are briefly discussed in this chapter (Table 58.1).

Obstructive

The most common forms of obstructive cholestasis in infancy are BA and choledochal cysts. BA is a fibro-inflammatory disease of the biliary tree. The etiology of BA continues to be researched. It is the most common etiology of chronic cholestasis in infants and children and is the most common indication for pediatric liver transplantation [11]. Affecting 1 in 8000 to 12,000 live births worldwide, there are two major etiologies: perinatal/acquired, accounting for more than 80% of cases, and the rest of BA cases are congenital/embryonic.

Typically, BA presents with jaundice and acholic stools in a well-appearing infant. Physical findings, other than icterus, may not be present in the first few weeks of life especially in the acquired cases. Early detection and timely referral to the pediatric gastroenterologist are crucial since timely surgical intervention with Kasai hepatoportoenterostomy gives the best outcomes if done by experienced surgeons between 45 and 60 days of age [12]. The Roux-en-Y loop of jejunum is anastomosed to the hilum of the liver, creating a conduit for biliary drainage. Patients are usually placed on a high-calorie diet to circumvent malabsorption especially in the case of an unsuccessful surgical outcome, ursodeoxycholic acid, fat-soluble vitamins, as well as antibiotic prophylaxis against ascending cholangitis [11]. Early diagnosis and treatment, in the first 45–60 days of life, improve transplant-free survival to upwards of 75%–90% [13–15]. However, if Kasai fails to clear cholestasis, the 3-year transplant-free survival rate is only 20% [11].

Total bilirubin levels 3 months post-Kasai can indicate prognosis with only 16% 2-year survival with the native liver if the total bilirubin is greater than 6 mg/dL compared to 84% if the total bilirubin level is less than 2 mg/dL [16]. Choledochal cysts are congenital conditions involving cystic dilation of the intra- and/or extrahepatic bile ducts. With type determined by location, these often present with jaundice and are treated surgically within the first year of life. A few cases present beyond this age and into adulthood as well.

Hepatocellular

Hepatocellular cholestasis was historically attributed to idiopathic neonatal hepatitis (INH) which is a prolonged conjugated hyperbilirubinemia with no known etiology. However, in recent years, advanced diagnostic capabilities have made INH a rare diagnosis of exclusion, requiring thorough evaluation for congenitally acquired pathogens (rubella, toxoplasmosis, cytomegalovirus, herpes, human immunodeficiency virus, and syphilis), as well as bacterial infections (gram-negative and gram-positive organisms) as seen in infants with urinary tract infections presenting with jaundice (Table 58.1). Panhypopituitarism should also be considered as a potential cause for unexplained neonatal hepatitis and must be ruled out because a delay in diagnosis may lead to progressive liver disease but also significant endocrinopathies and neurologic disturbances [12]. Once all infectious, genetic, metabolic, and endocrine causes have been ruled out, confirmation of the disease is achieved via a liver biopsy, which demonstrates widespread transformation of multinucleated giant cells, lobular cholestasis in a predominantly canalicular pattern, and hypoplastic bile ducts [17]. The vast majority of these cases resolve spontaneously over a few months [18].

Genetic and Metabolic

Different genetic and metabolic diseases present as neonatal cholestasis, including but not limited to, Alagille syndrome, alpha-1 antitrypsin (α1-AT) deficiency, galactosemia, tyrosinemia, progressive familial intrahepatic cholestasis (PFIC), as well as a variety of other extremely rare metabolic disorders (Table 58.1).

Alagille syndrome is an autosomal dominant multisystemic disease with variable penetrance. It results from mutations of the *Jagged 1* or *NOTCH2* genes responsible for encoding cell surface proteins that interact with Notch receptors during embryogenesis. Presentation is widely variable from being completely asymptomatic to having one or more of the following: chronic cholestasis due to paucity of the interlobular bile ducts, abnormal triangular facies, posterior embryotoxon, butterfly-like vertebral arch defects, and cardiovascular malformations. Patients are also at increased risk for vascular malformations intrahepatically and cerebrovascularly. In infants, prognosis varies with some patients becoming asymptomatic with age, whereas others gradually developing cirrhosis. Supplementation of medium-chain triglycerides, essential fatty acids, and fat-soluble vitamins is emphasized. In extreme cases of cirrhosis, portal hypertension, or severe pruritus, liver transplantation may become indicated [19].

Alpha-1 antitrypsin (α1-AT) deficiency is an autosomal recessive condition that occurs in 1 in 1600 to 2000 live births and is extremely rare in the non-Caucasian population. It results from the intracellular hepatic accumulation of a misfolded α1-AT (a protease inhibitor, PI) protein leading to liver injury [20]. Diagnosis is based on the serum levels of α1-AT and the phenotype, leading to varying degrees of liver, lung (in the form of emphysema), and, less often, skin manifestations. Normal genotype is PI*MM and is associated with normal levels and function of α1-AT. Only those genotypes, such as PI*ZZ, associated with pathologic polymerization of α1-AT within the endoplasmic reticulum of hepatocytes, produce significant liver disease. Neonatal cholestasis is the typical presentation; however, it is highly variable given that only 8–10% of individuals with the PI*ZZ genotype develops any clinically significant liver disease during the first 20 years of life. Two studies indicate that 80% of patients presenting with neonatal cholestasis secondary to α1-ATdeficiency, PI*ZZ, are healthy and free of chronic disease by the age of 18 years [21]. Cirrhosis, portal hypertension, and hepatocellular carcinoma are other hepatic manifestations in older patients.

Yet another autosomal recessive disorder is progressive familial intrahepatic cholestasis (PFIC), a heterogeneous condition associated with the disruption of bile formation [22]. It is divided into at least four subtypes; newer subtypes are being studied further, most of which may have an early presentation in the first year of life. Type I, known as Byler or FIC1 disease, is associated with a mutation in the P-type ATPase FIC gene (*ATP8B1*). FIC1 is expressed in several epithelial tissues including the liver, pancreas, and small intestine. Patients usually present with recurrent cholestasis leading to growth retardation, severe itching, and rickets, among other symptoms, and may progress to cirrhosis if left untreated [23].

FIC1 disease can have extrahepatic manifestations as well, such as recurrent pancreatitis, diarrhea, cough, wheezing, and sensorineural hearing loss. PFIC type II is caused by a mutation in *ABCB11*, the gene coding for the bile salt export pump (BSEP). This defect leads to impaired bile acid transport from the hepatocytes into the bile canaliculi. The gene is liver-specific, and the clinical presentation is similar to that of PFIC type I, though cholestasis is non-relapsing, severe, and progressive. Patients usually suffer from severe pruritus, rickets, growth retardation, and early development of cirrhosis. They are at high risk for early development of hepatocellular carcinoma [23].

PFIC type III results from a gene mutation in *ABCB4* which leads to the defect in MDR3, a member of the ATP-binding cassette family of transporters that serves as a phospholipid flippase. This leads to reduced biliary phospholipid secretion, impairing the balance of the cholesterol saturation index, which leads to crystallization of cholesterol and lithogenicity of bile, ultimately resulting in bile duct injury. Presentation in the neonate is rare, and the spectrum of hepatic manifestations includes cholesterol cholelithiasis, intrahepatic cholestasis of pregnancy, and biliary cirrhosis [23].

PFIC type IV
Inborn errors of bile acid synthesis
ARC syndrome
Lymphedema-cholestasis (Aagenaes syndrome)

PFIC progressive familial intrahepatic cholestasis, *ARC* arthrogryposis-renal dysfunction-cholestasis

PFIC type IV is due to a mutation in *TJP2* which encodes for tight junction protein 2 (TJP2). The expression of this protein has been found to be essential to the hepatobiliary integrity, given that canalicular and cholangiocytic membranes are exposed to high concentrations of detergent bile acids [23]. Deficiency in TJP2 leads to leakage of bile components through the paracellular space and into the liver parenchyma, ultimately causing liver injury [23, 24]. PFIC types I, II, and IV are characterized by low to normal serum γ-glutamyl transpeptidase (GGT) levels, unlike type III which presents with high GGT levels (Table 58.2).

Galactosemia and tyrosinemia are two inborn errors of metabolism that result in liver disease. Galactosemia is an autosomal recessive disorder resulting in the inability to digest galactose. It results from deficiency of three different enzymes, the most common and severe type is due to the absence of galactose-1-phosphate uridyltransferase (GALT). Although most states screen for galactosemia, many infants become symptomatic prior to the availability of these results. The typical presentation includes jaundice, lethargy, hypotonia, poor feeding, and hepatomegaly. The diagnosis is confirmed by a deficiency or complete absence of GALT activity in red blood cells. Of note, receipt of a blood transfusion prior to newborn screen may alter results and prevent timely diagnosis. Although dietary restriction of galactose can reverse the hepatic dysfunction, chronic and progressive neurologic impairments and infertility may occur in these patients despite lifelong dietary compliance [3, 12, 25].

Tyrosinemia is an inborn error of metabolism in the tyrosine catabolism pathway, most commonly due to fumarylacetoacetate hydrolase (FAH) deficiency, which results in the accumulation of toxic metabolites such as succinylacetone. It is characterized by acute liver failure and severe renal tubular dysfunction that present in the first weeks or months of life. It can also present as a chronic liver disease. Evaluation includes quantitative measurement of plasma amino acids and urine succinylacetone levels. Dietary

restriction of tyrosine and phenylalanine, as well as early initiation of nitisinone, a potent inhibitor of the enzyme 4-hydroxyphenylpyruvate dioxygenase, is the mainstay of treatment [3, 12].

Lab Evaluation

One must distinguish between direct/conjugated and indirect/unconjugated hyperbilirubinemia in order to properly manage jaundiced infants. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) published guidelines in 2004 and in 2017 for the evaluation of cholestasis in infants [2, 12]. The group recommended that any infant noted to be jaundiced at 2 weeks of age should be evaluated for cholestasis with measurement of total and direct serum bilirubin. Breastfed infants with an otherwise normal history (no dark urine or light stools) and unremarkable physical examination, however, may be asked to return at 3 weeks of age for further evaluation; if jaundice persists beyond 3 weeks, these infants require further evaluation as well [2]. Multiple studies have supported that early diagnosis, despite the etiology, will lead to better clinical outcomes, especially in BA as discussed earlier.

An algorithm for the evaluation of cholestatic infants is presented in Fig. 58.1.

A thorough history and physical examination can help guide the preliminary steps of the diagnostic process. For example, acholic stools and dark urine are indicators of cholestasis. A study in Taiwan suggested that providing parents with a stool card as a means of "mass screening" was efficacious in early diagnosis of BA [12, 26]. Parents may report a history of easy bleeding or bruising due to a coagulopathy from vitamin K malabsorption and/or liver failure. A complete family history may reveal consanguinity or an inherited genetic disorder. A thorough obstetrical history will identify congenital infections, anatomic abnormalities detected in prenatal ultrasounds, and ABO incompatibility, which, in about 3% of infants, results in intrahepatic cholestasis that resolves spontaneously within a month [27].

Additionally, a complete physical examination may reveal identifying clinical features. Population studies have shown BA to be more common in females of normal birth weight, versus INH, common in low birth weight or premature males. Alagille syndrome may present with both abnormal facies (usually seen beyond the first year of life) and a cardiac murmur. Congenital BA may be associated with structural heart disease, situs inversus, or dextrocardia besides other intra-abdominal anomalies that radiologic evaluation will reveal. Splenomegaly may be found in patients with portal hypertension, storage disorders, or hemolytic diseases [12].

Infants with cholestasis in the setting of sepsis, metabolic diseases, or congenital infections are usually ill-appearing (Fig. 58.1). Congenitally infected newborns are usually small for their gestational age and may have microcephaly, purpuric rash, or chorioretinitis, among other findings.

Confirmation of cholestasis with an elevated fractionated serum bilirubin level requires a concurrent baseline assessment of hepatic function (serum albumin, glucose, prothrombin time/INR, and ammonia) to determine the next step in evaluation (Fig. 58.1). Of note, parenteral administration of vitamin K is recommended in the setting of prolonged INR and should normalize coagulation studies if the synthetic hepatic function is preserved. The alpha-1 antitrypsin (α1-AT) level and phenotype need to be checked early in the diagnostic process, as the histologic differentiation between BA and α1-ATdeficiency is very difficult in neonates (Fig. 58.1). More recently, the serum matrix metalloproteinase-7 (MMP-7) level has been a useful noninvasive tool to distinguish BA from other causes of cholestasis, with sensitivity of 97% and specificity of 83% in one study [28]. The MMP-7 level reflects severity of liver fibrosis and has also been shown to predict the need for liver transplantation in BA patients post-Kasai [28].

Although elevation in alkaline phosphatase (ALP) can be indicative of biliary obstruction, it is non-specific as it is also produced by bone, small bowel, and kidneys. Gamma-glutamyl transpeptidase (GGT) is more sensitive in identifying biliary disease. Low levels of GGT in the setting of cholestasis suggest a short list of hepatobiliary diseases including PFIC types I, II, and IV, arthrogryposis-renal dysfunction-cholestasis syndrome (ARC), and inborn errors of bile acid synthesis (Table 58.2).

Metabolic acidosis on an electrolyte panel or blood gas sample could hint towards a metabolic disease, especially in the setting of other abnormalities like hypoglycemia, hyperammonemia, and lactic acidosis with or without ketonuria. Blood and urine cultures should be drawn when clinically indicated. Septicemia leads to downregulation of biliary transporters, biliary stasis, and hepatic parenchymal injury from circulating endotoxins.

Radiological Evaluation

Ultrasonography is the initial imaging study of choice to assess hepatic size, echogenicity, as well as anatomic anomalies. It also assesses the presence and size of the gallbladder, biliary stones, or sludge. Ultrasound can identify signs of obstruction or dilatation of the biliary tree; extrahepatic anomalies like polysplenia, asplenia, or situs inversus; as well as the different positional variants of the portal vein and hepatic artery. Signs of BA include a small or absent gall-

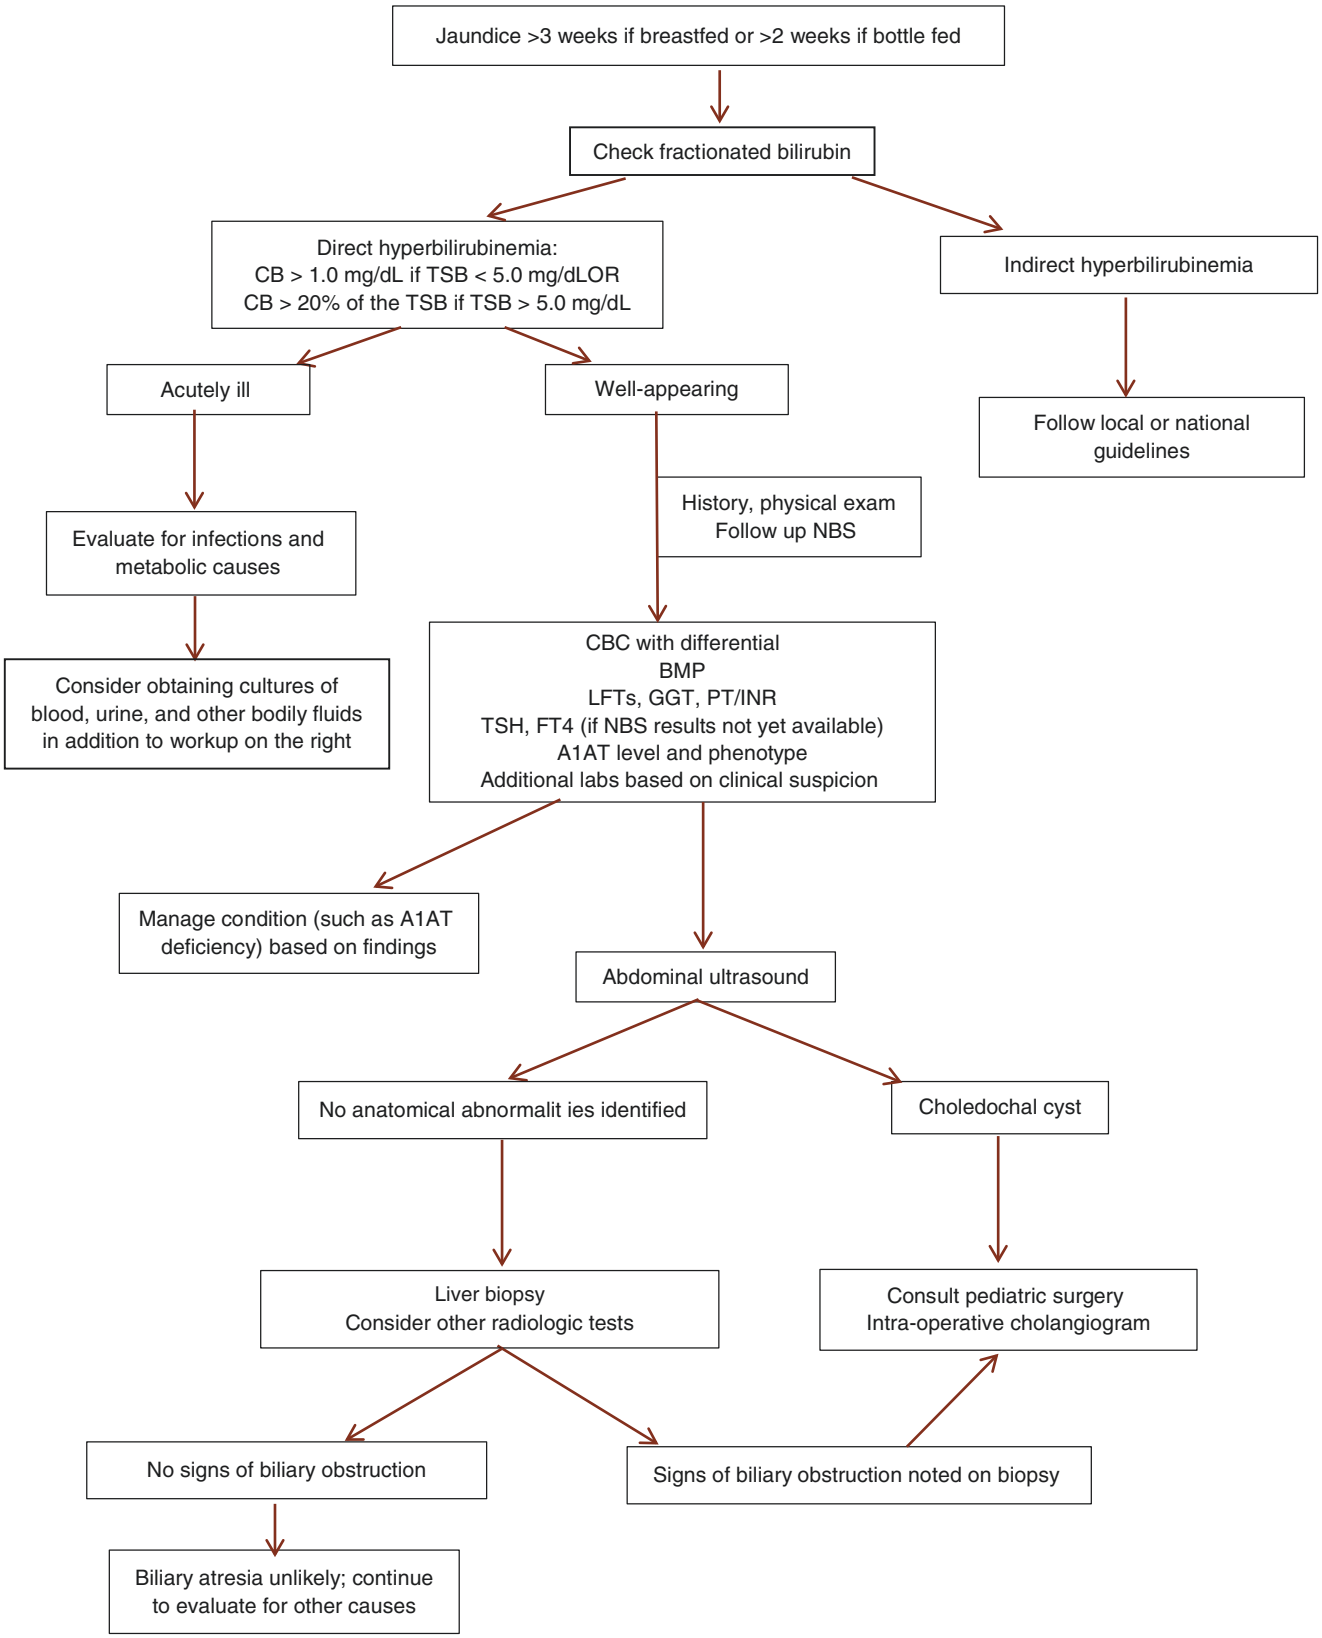

Fig. 58.1 Algorithm for evaluating infants with jaundice

bladder as well as a "triangular cord sign," noted as triangular echogenicity of the anterior wall of the right portal vein on transverse or longitudinal view. Although the use of ultrasound is limited by operator dependence, it is still recommended over computed tomography (CT) which has significant radiation side effects. More recently, transient elastography through elastic shear wave propagation has been found to be a more sensitive and specific noninvasive means to detect severe fibrosis and cirrhosis, such as that seen in BA [29].

Magnetic resonance cholangiography (MRCP), performed with T2-weighted turbo spin-echo sequences, is noninvasive and not operator-dependent but requires sedation. MRCP can evaluate structural anomalies in detail. The addition of gadolinium enhancement for its T2-shortening effect may allow for a more definitive determination of the presence or absence of the duct in infants with cholestasis, especially when conventional MRCP is indeterminate [25].

The ability to differentiate extrahepatic biliary obstruction from non-obstructive causes has been done with hepatobiliary scintigraphy (HIDA) using technetium Tc99m iminodiacetic acid analogues. The addition of phenobarbital for 3–5 days before the test increases its yield but may delay the time to diagnosis.

Endoscopic retrograde cholangiopancreatography (ERCP) is also considered a safe and reliable diagnostic method in cholestatic infants. Its sensitivity and specificity in the diagnosis of extrahepatic causes of cholestasis are superior to other available diagnostic methods when performed by a skilled and experienced endoscopist. In the case of BA and choledochal cysts, the high negative predictive value and specificity of ERCP are superior in diagnosing structural abnormalities of the bile ducts [30].

Following labs and imaging, liver biopsy continues to be an important diagnostic tool, with accuracy reported as high as 90–95% in BA. Timing is important as those performed prematurely will not demonstrate the typical histopathologic features of BA requiring serial investigations and repeat biopsy at 6 weeks of age. Liver biopsy can also be diagnostic of other conditions via electron microscopy, immunohistochemical, or biochemical staining.

The most invasive means of imaging is an intraoperative cholangiogram, the gold standard test to study the patency of the biliary system. Considered the gold standard for diagnosing BA, this study is often elected by surgeons when the diagnosis remains elusive despite imaging studies and liver biopsy [23].

Treatment

Treatment varies widely based upon the cause of cholestasis and will not be explored with further depth in this chapter.

Conclusions

Although the causes of neonatal cholestasis can be many, some of which are benign, prompt and thorough evaluation is indicated to avoid poor outcomes. Fractionated bilirubin must be obtained by 3 weeks of age for infants with prolonged newborn jaundice.

Biliary Atresia and Choledochal Malformations

Elke Zani-Ruttenstock and Mark Davenport

Biliary Atresia

Introduction

In 1891, John Thompson, a physician from Edinburgh, described in detail the clinical features and postmortem findings of an infant with what he labelled as "congenital biliary obstruction" [1]. His drawing clearly showed an absence of a common hepatic duct and a collapsed empty gallbladder. Further reports during the early part of the twentieth-century prompted surgeons to explore the biliary tree to try and identify a blockage and perhaps a proximal bile-containing duct to anastomose to. This led to the concept that biliary atresia (BA) was either "correctable" or "uncorrectable" depending on operative findings. With increasing experience it became evident that the latter was much more common and hence survivors were exceptional. Although the use of these terms is nowadays anachronistic (because you can "correct" the uncorrectable!), it perhaps best illustrates the hopeless prognosis of these unfortunate infants.

Figure 59.1 illustrates the various types of BA and is based upon the most proximal level of obstruction. Thus, over 95% are type 3 where there is no visible bile duct in the porta hepatis (hence "uncorrectable"). It does not imply anything about causation (see later).

A more radical approach to the technique was pioneered in Sendai, Japan, during the 1950s and 1960s by Morio Kasai (1922–2008) to the problem of "uncorrectability" [2, 3]. He advocated a more radical approach to the biliary dissection and simply transected at the most proximal point in the porta hepatis. The porta, even if there were no visible ducts, was then anastomosed to a Roux loop (portoenterostomy). Transection exposes residual microscopic bile duct remnants within the fibrous tissue, which retain communication with the intrahepatic duct system (still often very abnormal). Hence bile flow actually occurs to a varying degree, but in perhaps the majority enough to lose their jaundice (see later for results and outcome), postoperative outcome significantly improved.

For the first time, KPE enabled a much larger cohort of long-term survivors, initially in Japan [3] but later from the 1970s in Europe and North America. It wasn't a cure though, and even survivors displayed many complications related to liver fibrosis and cirrhosis.

Thomas Starzl in 1963 attempted the first liver transplant in humans in a child born with BA [4]. Sadly, the child died of operative bleeding related to severe portal hypertension. This prompted a number of units around the world to set up transplantation programmes, but in the absence of effective immunosuppression, they were all terminated by the end of the 1960s. With the discovery of cyclosporine at the beginning of the 1980s, transplantation once more became a viable option, and from this the current strategy of an initial attempt to restore (some might say resurrect) bile flow with a KPE followed by liver transplantation if this fails evolved.

Variants of Biliary Atresia

BA is not a single disease; rather it should be thought of as a phenotype resulting from a number of different and entirely separate aetiologies leading to the final common phenotype of biliary inflammation, luminal obliteration and fibrosis [5].

We have been able to define clinically at least four broad groups (Fig. 59.2).

1. *Syndromic Biliary Atresia*

While BA is usually an isolated abnormality found in otherwise normal term infants, there are a group of infants

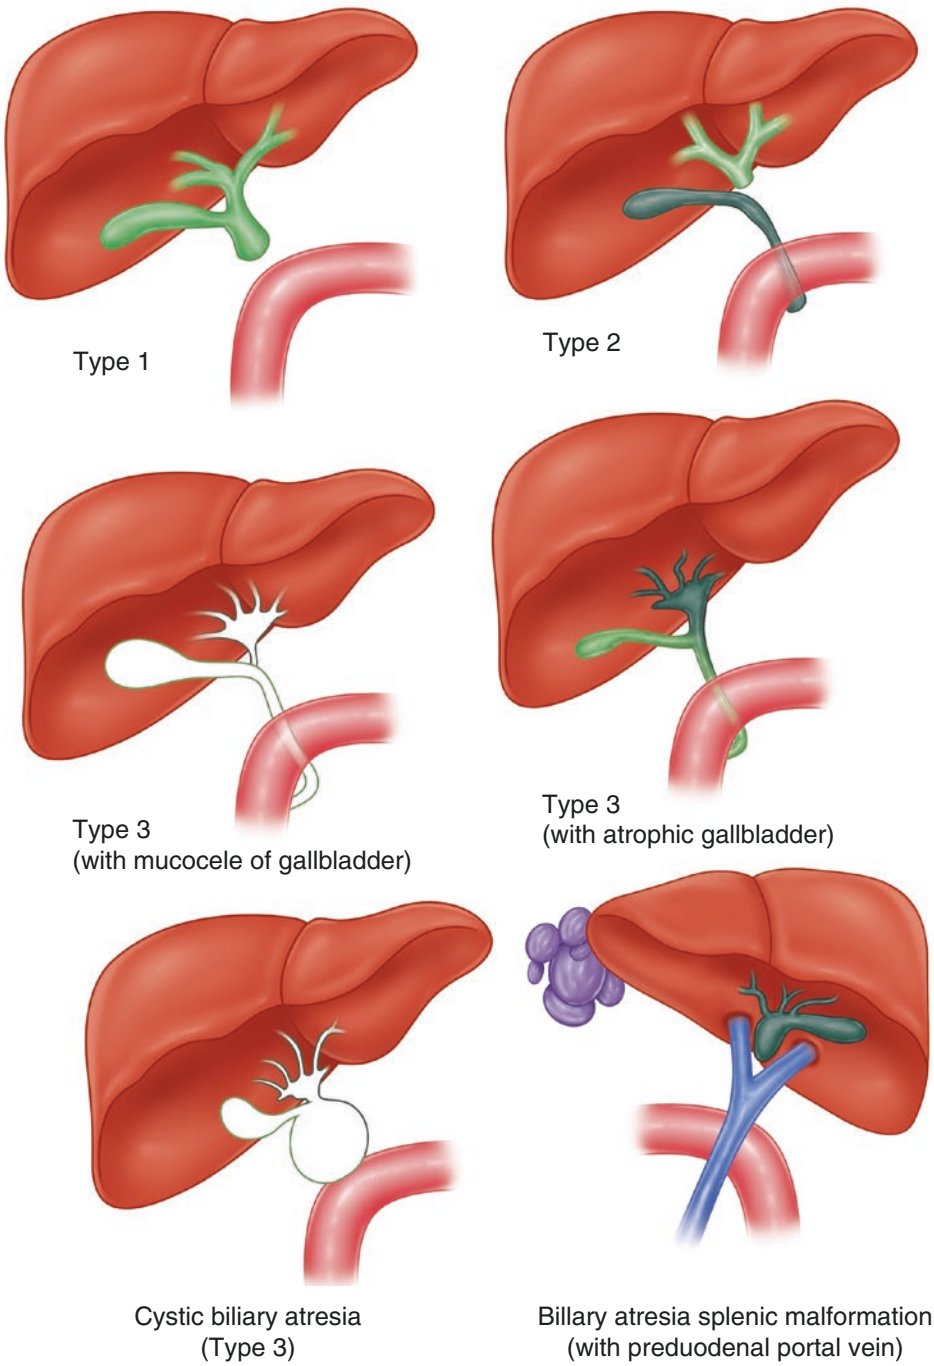

Fig. 59.1 Schematic illustration of biliary atresia. (Based on Japanese Association of Pediatric Surgeons classification)

(about 10–15% in European and North American series, but <2% in Asian series) with other non-biliary anomalies and a poorer prognosis. We have termed this specific constellation of anomalies the biliary atresia with splenic malformation (BASM) syndrome [6, 7]. All will have a splenic malformation, usually polysplenia (~80%) but occasionally asplenia or double spleens, and about half will have situs inversus and congenital heart abnormalities. Other anomalies are evident at laparotomy including preduodenal portal vein, absence of the inferior vena cava and malrotation. Most infants with this syndromic form of BA are female. It is speculated that such cases may result from some fundamental derangement of extrahepatic bile duct (and other systems) development within the embryological phase (<6 weeks of gestation). A large-scale North American study recently identified deleterious mutations in the *PKD1-L-1* gene using whole-exome sequencing in about 10% of subjects with BASM [8]. Other candidate genes have also been suggested such as *CFC-1* and

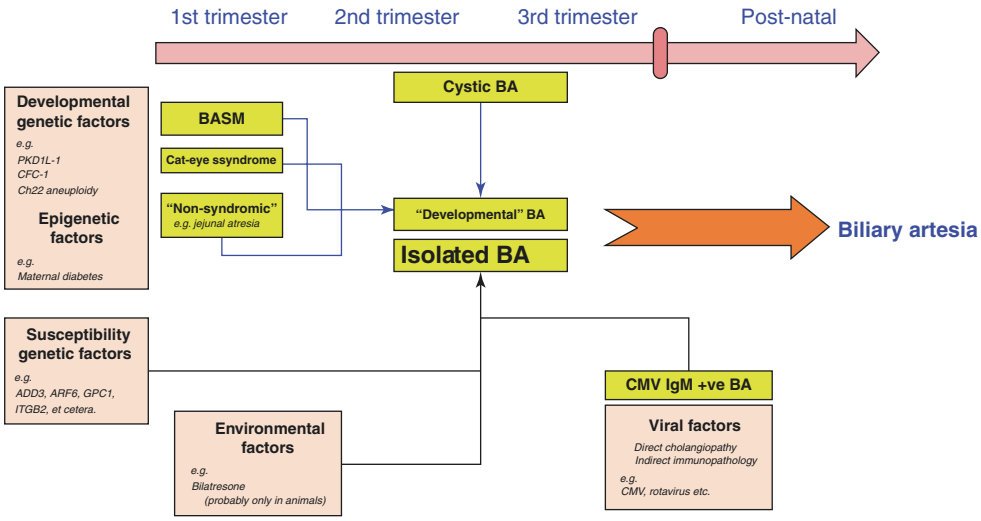

Fig. 59.2 Variants of biliary atresia. Key: Variants ; Proposed aetiological factors

FOXA2 [9]. There is also an association with an abnormal first-trimester intrauterine environment such as that found in maternal diabetes and thyrotoxicosis [7].

2. *Cystic Biliary Atresia (CBA)*

In about 5% of cases, there is an obvious cyst (sometimes containing bile) within an otherwise obliterated biliary tree. In recent years it has been possible to detect this cystic change on antenatal ultrasound scans as early as the 18th week of gestation [10, 11]. CBA should not be confused with cystic choledochal malformation, which can be indistinguishable on ultrasound and MR scans [12]. Discrimination may be made clinically as CBA will invariably have conjugated jaundice, pale stools, etc. and at laparotomy as the cholangiogram will show the abnormal and primitive intrahepatic duct structure.

3. *Isolated Biliary Atresia (IBA)*

This is the typical BA variant accounting for about 80–90% of cases [13]. They have no other significant features and usually display an obliterated biliary tree at laparotomy (usually type 3). Real evidence of what has caused BA in this group is minimal and remains open to speculation. However, some recent evidence towards a developmental pathogenesis was presented by a review of early liver biochemistry (day 1 and day 2 of life) in infants later shown to have BA. This showed that all had elevated direct/conjugated bilirubin by 24 h implying biliary obstruction at the time of birth [14] (Fig. 59.3).

4. *Cytomegalovirus (CMV) IgM+ve Biliary Atresia*

Although there is a range of possible hepatotropic cholangiopathic viruses (e.g. Reovirus type 3, rotavirus), it has been difficult to definitively ascribe clinical consequences to infection. We have recently discriminated infants with CMV IgM+ve antibodies from their IgM−ve fellows clinically, histologically and in their response to treatment [15]. These made up 10% of our clinical series and were more commonly seen in infants from a non-Caucasian ethnicity. Clinically they were older at diagnosis and came to KPE later. Biochemically, they had higher bilirubin and AST levels, with larger spleens as measured on ultrasound than comparable IgM−ve BA infants. The histological appearance within the liver was characterised with an obvious mononuclear cell infiltrate consisting of largely CD4+ Th1+ T cells [16]. These infants also appeared to have the worse response to KPE and also appeared particularly susceptible to death during early childhood [15, 17] (Fig. 59.4). Of all the clinical groups described, this is the group that appears to fulfil most of the requirements to support an immune-destructive pathogenesis following viral triggering.

Epidemiology

Population-based studies reporting incidence and outcomes of BA are scarce. There is marked variation in incidence across the globe ranging from about 1 in 5–10,000 live births in Taiwan [18, 19] and Japan [20] to about 1 in 15–20,000 in mainland Europe [21–24], England and Wales [13] and North America [25].

Furthermore, there is marked geographical variation of the specific variants mentioned above. The incidence of BASM varies widely, being rarely reported in Asian series but accounting for about 10% of European and North American series. By contrast, the incidence of CMV IgM+ve BA also varies from 10% to 20% in European series [15] to perhaps up to 50% reported in some series from China [26].

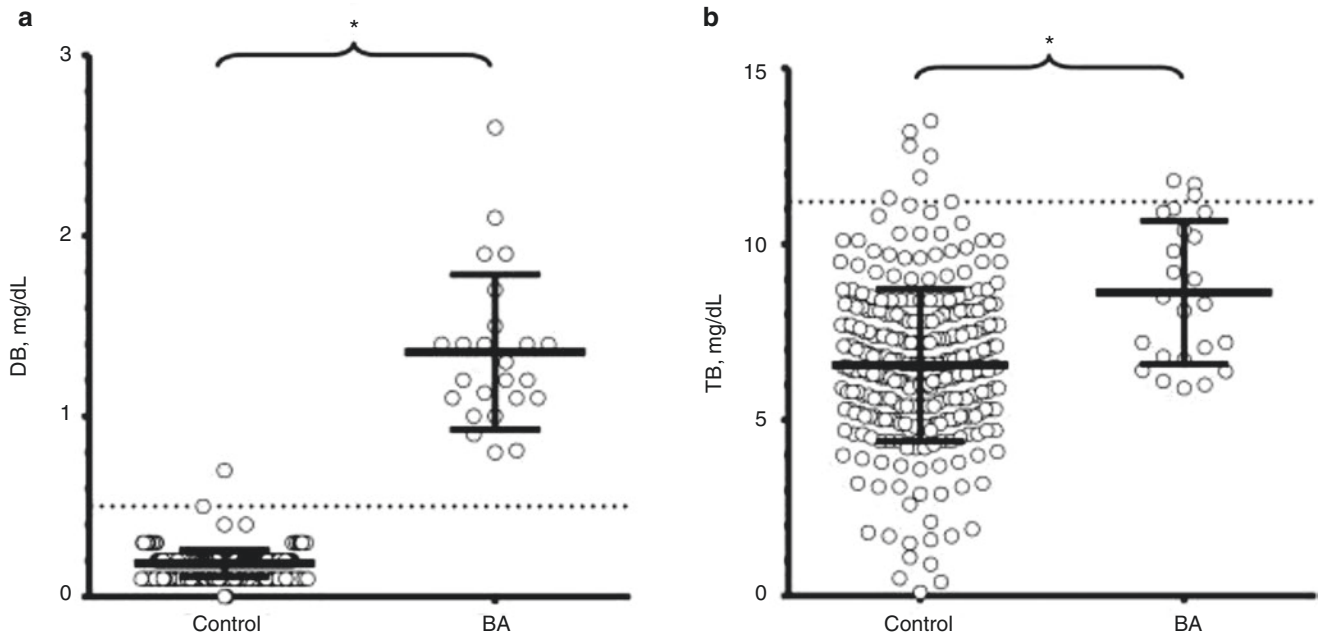

Fig. 59.3 Infants with BA have elevated direct bilirubin (DB), but not total bilirubin (TB), levels at 24–48 h of life (HoL). Shown are the mean DB (**a**) and TB (**b**) levels for controls ($n = 300$; collection time, 39 +/− 5.6 HoL) versus patients with BA ($n = 24$; collection time, 34 +/− 6.2 HoL). The dashed lines indicate the upper limits of normal (**a**, 0.5 mg/dL) or the approximate phototherapy level at 34 HoL (**b**, 11.2 mg/dL). *$P < 0.0001$

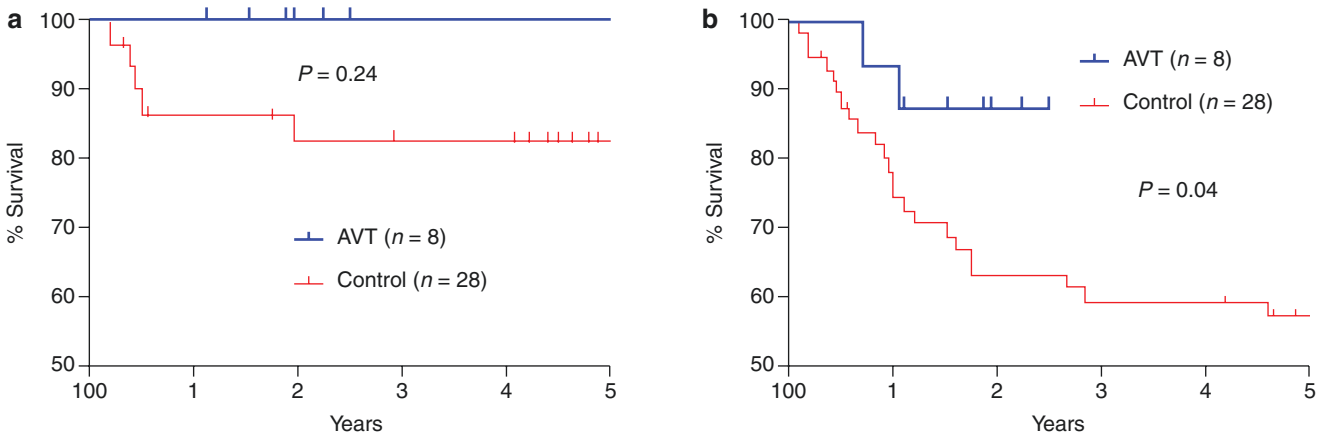

Fig. 59.4 Actuarial native liver survival (**a**) and actuarial survival (**b**) of infants with CMV IgM+ve biliary atresia. NB Both groups (controls and AVT) were treated with Kasai portoenterostomy with (AVT) or without (control) anti-viral therapy (AVT). (Reproduced with permission from Parolini et al. [17])

A number of small series suggested seasonality for BA [18, 27], though these were far from definitive and larger national series failed to observe any predilection for a particular season [13, 20, 21].

Clinical Features

The key features of BA are persistent conjugated jaundice, acholic stools and dark urine in an otherwise healthy term infant (Fig. 59.5). The latter feature is caused by excess conjugated (i.e. water-soluble) bilirubin passing into the urine causing its colour to darken. Such alternative pathways of bilirubin excretion are more developed or at least preserved in the newborn, and very high levels of bilirubin (>300 μmol/L or >17 mg/dL) are exceptional. Sometimes jaundice will be difficult to discern in infants of Asian or Afro-Caribbean origin leading to delays in diagnosis and treatment. The median time to referral was 47 days in white versus 52 days in non-white infants in one UK study [28]. Furthermore, all of those "missed" and referred beyond 100 days were non-white.

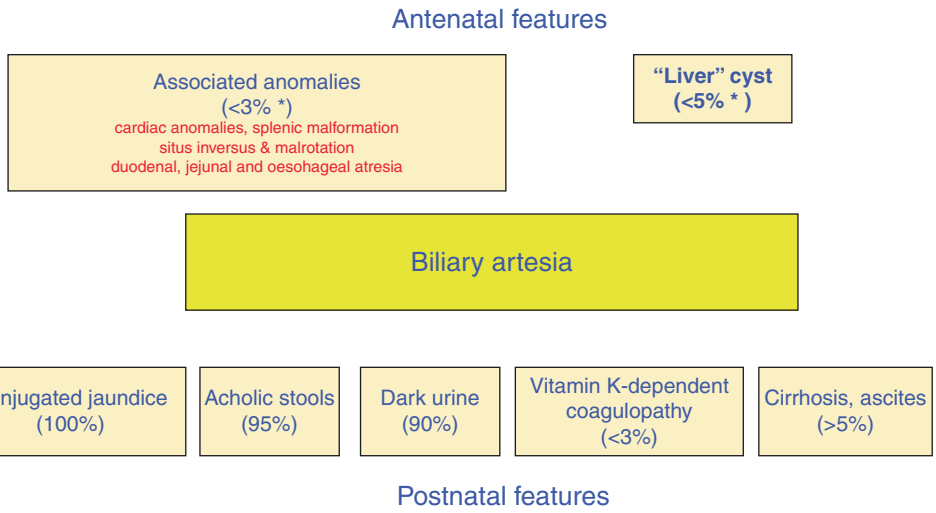

Fig. 59.5 Modes of presentation of biliary atresia. (NB the percentages reflect the mode of presentation not the actual proportion)

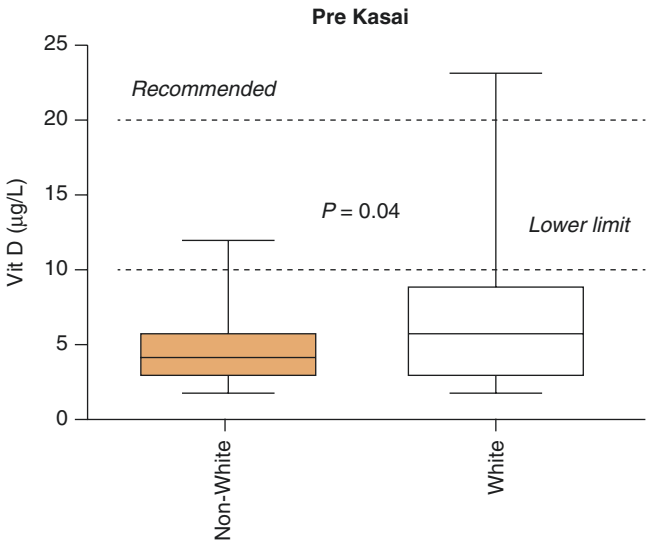

Fig. 59.6 Decreased pre-operative vitamin D levels in non-white compared to white infants with biliary atresia. (Reproduced with permission from Ng et al. [29])

Sometimes the antenatal ultrasound scan will be abnormal showing a sub-hepatic cyst, and one should then be suspicious of CBA [10]. There is no difference in gestational age or birth weight between all the BA variants with all of them presenting with failure to thrive by the time they are admitted. Fat malabsorption is the presumed mechanism, and this will also cause deficiency of the fat-soluble vitamins D, A, E and K. Low vitamin D levels are almost invariable even in those infants presenting early [29], and this is exacerbated in those of Asian family origin, presumably reflecting low maternal stores (Fig. 59.6). Vitamin K deficiency is possible, and a proportion will present with a bleeding tendency, perhaps from the umbilical stump or more catastrophically with an intracranial haemorrhage. Marked elevation of the INR or prothrombin time will be seen in those presenting late. Some syndromic cases will present early (or even antenatally) because of other abnormalities associated with BASM (e.g. cardiac anomalies, malrotation or situs inversus) [30].

Diagnosis

The diagnostic workup in our institution includes a detailed ultrasound of the liver, liver biochemistry and a percutaneous liver biopsy [12]. Using this, more than 90% will have an accurate diagnosis before laparotomy.

Ultrasonography

The ultrasound (US) examination is a key part of the diagnostic protocol as it usually excludes other surgical diagnoses (e.g. choledochal malformation, inspissated bile syndrome, etc.). All of these are being characterised by intrahepatic or common bile duct dilatation. US may be suggestive of BA as a diagnosis – by showing a shrunken, atrophic gallbladder with no evidence of filling between feeds. In about 20% of cases, a "normal gallbladder" is described – these usually turn out to have a mucocele of the gallbladder together with a relatively preserved common bile duct (CBD) and an absent common hepatic duct (CHD) (Fig. 59.1).

Laboratory Findings

Liver biochemistry will show a conjugated jaundice (typically >100 µmol/L), modestly raised transaminases (>100 µmol/L) as well as significantly raised γ-glutamyl transpeptidase (GGT > 200 IU/L). Serum protein and albumin levels should be normal. However, none of these are specific and by themselves are not diagnostic.

Percutaneous Liver Biopsy

In the authors' unit, the pre-laparotomy diagnosis of BA is usually made by percutaneous liver biopsy showing histological features characteristic of "large duct obstruction" such as bile duct proliferation, portal oedema and absence of sinusoidal fibrosis. It is less accurate the younger the infant and it does require an experienced and confident liver pathologist.

Aspartate Aminotransferase-to-Platelet Ratio Index (APRi)

The aspartate aminotransferase-to-platelet ratio index (APRi) can be used as a surrogate of liver fibrosis in many liver diseases, including BA. We have reported that this correlates significantly with age at surgery and was much higher in CMV-IgM+ve BA [31]. Macroscopic cirrhosis evident at laparotomy could also be predicted using a cut-off value of 1.2, with reasonable sensitivity (75%) and specificity (84%) in a large cohort of infants from our unit [31].

The usual differential diagnoses of conjugated jaundice include TORCH infections (e.g. toxoplasma, rubella, CMV, hepatitis, etc.), genetic conditions (e.g. α-1 antitrypsin deficiency, Alagille's syndrome (abnormal "elfin" facies, butterfly vertebrae, pulmonary stenosis), progressive familial intrahepatic cholestasis (PFIC) disorders), metabolic conditions (e.g. cystic fibrosis, galactosemia), parenteral nutrition and neonatal hepatitis.

Miscellaneous Diagnostic Techniques

Some centres rely on more functional tests *looking for* an absence of bile in the intestine such as duodenal intubation and aspiration or hepatobiliary radionuclide scans using a variety of technetium-labelled iminodiacetic acid derivatives (HIDA) [32]. The use of endoscopic retrograde cholangiopancreatography (ERCP) is possible in infants, but its use is typically confined to large specialist centres [33]. Similarly, magnetic resonance cholangiopancreatography (MRCP) is still not detailed enough to confidently diagnose BA.

The "acid test" for many remains operative visualisation (which could be laparoscopic) supplemented by on-table cholangiography where possible.

The surgical differential is less common and includes obstructed choledochal malformation, which usually shows obvious dilated intra- and extrahepatic biliary dilatation, inspissated bile syndrome which usually occurs in the preterm with a precipitating event such as dehydration or haemolysis and spontaneous perforation of the bile duct which usually shows US evidence of bile ascites and a sub-hepatic collection evident on US [12].

Screening

Some countries have adopted a population screening programme for BA [34, 35]. The most well-developed has been that of Taiwan [36, 37], where mothers are issued with colour-coded cards and asked to compare it with their infant's stool. Recognition of pale stool prompts further investigation and referral. This has certainly shortened their time to surgery – the median age at KPE is now <50 days and is currently one of the lowest nationally. The key achievement, we believe, has been the marked reduction in late-presenting infants who had already developed cirrhosis [38].

The simplest solution to early diagnosis remains education however. It is clear from so many histories that it is often the parents who recognise that persisting jaundice in their infants is not normal but then are falsely reassured by health visitors and their community doctors who fail to inquire about pale stools or dark urine (never mind looking at them) and fail to do the appropriate blood test (split bilirubin for conjugated and unconjugated fractions). The statutory community check in the UK occurs at 6 weeks of age and is far too late to make a difference in when these affected infants come to surgery.

Kasai Portoenterostomy

The aim of surgery is to excise all extrahepatic biliary remnants allowing a wide portoenterostomy onto a portal plate, denuded of all such tissue (Fig. 59.7a, b). In most cases, this will expose sufficient transected microscopic bile ductules which retain connections with the primitive intrahepatic bile ductule system to allow restoration of at least a degree of biliary drainage. This should be the object for all three types of BA.

A short right upper quadrant muscle-cutting incision (or laparoscopy) should be performed initially to confirm the suspected diagnosis or, if the gallbladder is shown to contain bile, to proceed to on-table cholangiography.

There are then two surgical strategies to expose the porta hepatis: one involving division of at least the left-sided suspensory ligaments and then eversion of the liver onto the abdominal wall. The other retains the liver in the abdominal cavity but usually requires dissection and slinging of the right and left portal veins to allow full exposure of the biliary remnants. A simple portoenterostomy using a retrocolic Roux loop (about 40 cm) completes the reconstruction (Fig. 59.8). Older techniques involving stomas in the Roux loop have been abandoned by virtually all centres.

Both the dissection and reconstruction in the open KPE can be replicated laparoscopically. However, most centres that pioneered this technique have subsequently reverted to open KPE as outcomes in terms of native liver survival rates and actuarial survival rates are unfavourable compared to conventional surgery [39, 40]. A recent study from Hong Kong confirmed the superiority of the open approach reporting 10-year native liver survival rates of

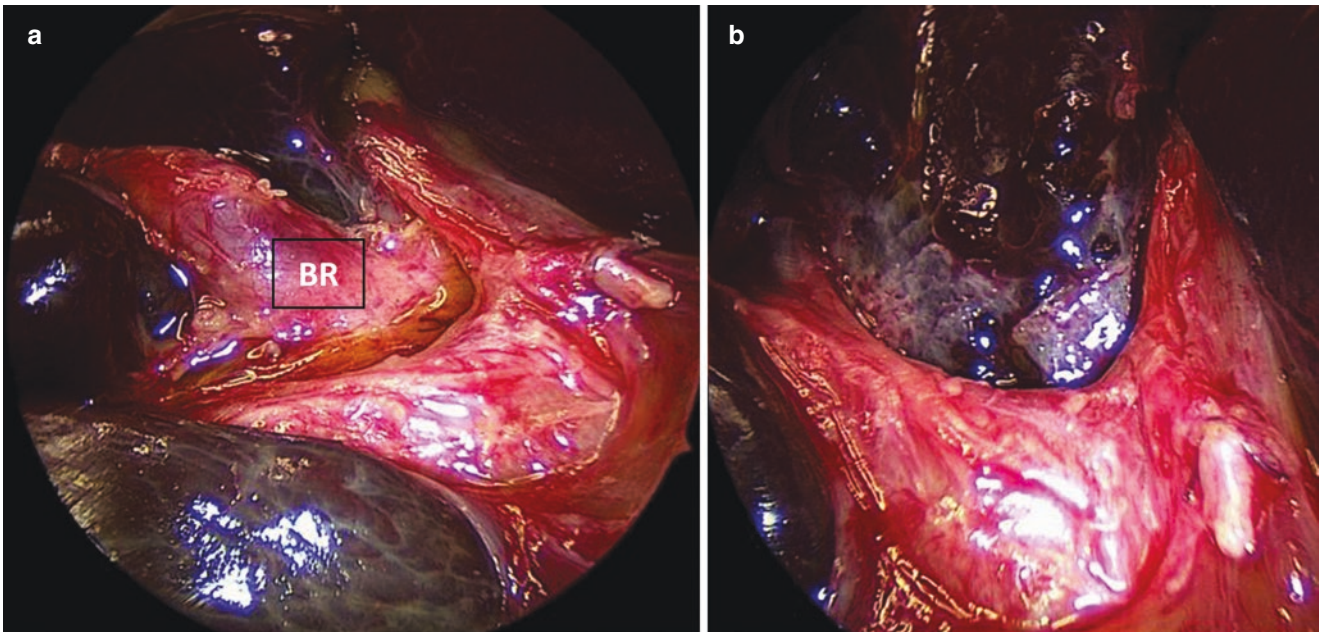

Fig. 59.7 Close-up of porta hepatis during Kasai portoenterostomy. (**a**) Hypertrophied proximal biliary remnant (BR) being separated from vascular structures of liver. (**b**) Same view following resection of BR, showing denuded portal plate

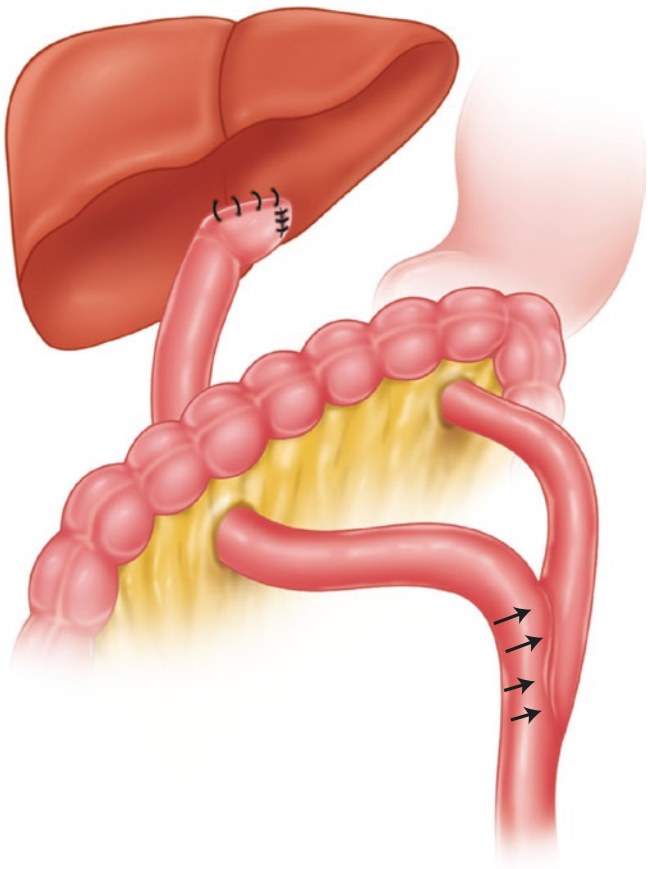

Fig. 59.8 Schematic illustration of retrocolic Roux-en-Y loop, typically measured at 40 cm from portoenterostomy to jejunojejunostomy

85% for the open and 45% for the laparoscopic KPE [41]. The portal dissection, the key to wide excisional surgery, is not improved by being performed laparoscopically, and the reconstruction remains technically challenging. There is obviously a better scar, though the infants remain in hospital for the same length of time and perhaps an adhesion-free abdominal cavity for the transplant surgeon, although even the latter has been challenged by a study from Germany [42].

Surgeons in Juntendo, Tokyo, have adopted a different approach to these issues by limiting the scale of the portal dissection and consciously limiting the transection to a basic oval shape – allowing at least some remnant to remain [43].

Postoperative Management

Intravenous fluids and nasogastric aspiration are continued until return of bowel function (about 3–4 days). Careful monitoring of blood glucose, electrolytes and INR is important in the early phase. Liver biochemistry (including bilirubin) may well worsen in the first week, but by about the fourth week, there should be a definite fall in bilirubin and consistently pigmented stools in those who will do well. Strict attention to nutritional needs is important, and all infants need regular fat-soluble vitamin supplementation. Medium-chain triglyceride (MCT)-based formula milk (e.g. Caprilon®; SHS, Liverpool, UK) is advocated to maximise calorie input and facilitate lipid absorption.

Adjuvant Therapy for Biliary Atresia

As the aetiology of BA remains ill-defined and numbers are relatively few, adjuvant treatment has been largely based on pragmatism and trial and error.

Corticosteroids

Systematic analysis (level 1A evidence) [44] of the few randomised placebo-controlled trial data [45–47] and larger single-centre cohort studies [48] have suggested that postoperative high-dose steroids do have a significant effect on clearance of jaundice with a 10–15% increase in jaundice clearance. This is particularly so in infants <70 days at KPE [49]. We have recently shown that other biochemical markers indicating more specific liver injury (i.e. AST, APRi) are also affected by high-dose steroids at least in the first 6 months post KPE, implying an actual effect on the underlying pathology of the disease process and not just perhaps on degree of restored bile flow [48].

Ursodeoxycholic Acid

The use of oral ursodeoxycholic acid (UDCA) remains popular and may be beneficial but only if surgery has already restored bile flow to a significant degree. Willot et al. from Lille in France assessed the effect of UDCA on liver function in children >1 year post-Kasai portoenterostomy and showed that it improved biochemical liver function in stable children [50]. It may also have an extra beneficial effect in BA because of its immunosuppressive properties as it has been shown to decrease proliferation of and cytokine production by mononuclear cells in vitro [51].

Anti-viral Therapy

CMV IgM+ve BA seems to have an even worse prognosis than CMV IgM−ve BA [15], and for the past few years, we have begun to treat the viral component of this variant. Admittedly this has been on an *ad hoc* basis with variation of the anti-viral agent ranging from IV ganciclovir to oral valganciclovir. However, we have noted a dramatic improvement in the outcome with increased clearance of jaundice and reduction in the medium term for liver transplantation [17] (Fig. 59.4).

Miscellaneous

The benefit of long-term prophylactic antibiotics, bile acid sequestrants (e.g. colestyramine) or probiotics remains unproven. Newer modalities such as immunoglobulin, FXR agonists (e.g. obeticholic acid) and ileal bile acid transporter (IBAT) antagonists (e.g. maralixibat) remain unproven but are now coming into consideration.

Complications

About 20–30% of infants will show no effect from KPE, their stools will remain pale and their bilirubin levels will continue to rise. These infants will inexorably develop cirrhosis and end-stage liver disease with severe failure to thrive, ascites, splenomegaly, deepening jaundice and often bleeding from varices. Such infants need expedited liver transplantation, often before their first birthday. It is important to recognise these infants early and not offer false hope that they will somehow turn a corner – they won't.

Other specific complications deserve a more detailed coverage.

Cholangitis

Re-establishment of bile drainage exposes the child to the risk of ascending cholangitis, which occurs most commonly in the year following primary surgery in about 40–50% of children. Paradoxically, it only occurs in children with some degree of bile flow, not in those with early failure as described above. The usual organisms are enteric in origin (e.g. *Escherichia coli*, *Pseudomonas*, *Klebsiella* spp.).

Clinically, an episode is characterised by fever, acholic stools and a change in biochemical liver function (rising bilirubin and AST levels). The diagnosis may uncommonly be confirmed by blood culture or rarely by percutaneous liver biopsy, but the key component is antibiotic treatment on suspicion not confirmation. Intravenous broad-spectrum antibiotics are effective against Gram-negative organisms (e.g. piperacillin and tazobactam, gentamicin). Most will respond within 24 h, and liver function is usually restored fairly quickly. Some children sustain repeated cholangitis, and they should be treated by prolonged courses of intravenous antibiotics via an indwelling vascular device. If however, it is clear that there are other features of end-stage liver disease, and then they too should be considered for transplant.

Occasionally, cholangitis occurs as a late event in otherwise normal children or adolescents, who have good liver function and have cleared their jaundice [52]. The Roux loop may be at fault here with partial obstruction leading to bile stasis. A combination of radio-isotope scans and percutaneous cholangiography may aid the diagnostic process, and operative Roux loop revision may be required. We have used an enteroscope to investigate these patients and provide radiological and endoscopic visualisation of the proximal Roux loop [53].

Portal Hypertension

Increased portal venous pressure has been shown in about 70% all infants at the time of Kasai operation [54]. However, subsequent portal hypertension depends on both the degree of established fibrosis and, most importantly, the response to surgery. There is a relationship with biochemical liver function and variceal development, and in those who fail and need early transplantation, about 30% will have had a significant variceal bleed.

Infants and children with bleeding oesophageal varices need rapid access to high-quality paediatric facilities with

the resources and expertise to manage them appropriately. Injection or banding is not a technique for the occasional paediatric endoscopist. Restoration of circulating blood volume and pharmacotherapy (e.g. 2 mL/h of 500 μg octreotide in 40 mL of saline) should precede endoscopy and achieve a measure of stabilisation. Sometimes a modified Sengstaken tube needs to be placed to achieve control of bleeding [55]. Invariably in children this can only be done under general anaesthesia but can be life-saving. The definitive treatment in older children is endoscopic variceal banding, although injection sclerotherapy retains a role in treating the varices in infants.

In common with other large centres, we therefore recommend that for each child with BA there is the opportunity to enter a programme of endoscopic surveillance to try and pre-empt variceal bleeding [56]. In this respect, there may be a role for selection based on haematological, biochemical or ultrasound variables to assign risk. One-multinational study suggested that APRi and CPR (clinical prediction rule) [57] appeared to be superior in this respect to simple univariate indices (e.g. platelets, bilirubin) or ultrasound dimensions (e.g. spleen size or resistance index).

The key variceal signs that should prompt *prophylactic* endoscopic treatment are the presence of significant red *wales* in grade II/III oesophageal varices and obvious (usually lesser curve) gastric varices [56]. Liver transplantation needs to be actively considered as definitive treatment for portal hypertension where liver function is poor and the child is already significantly jaundiced.

Ascites

This is related to portal hypertension in part, but there are other contributory factors including hypoalbuminaemia and hyponatraemia. It also predisposes to spontaneous, bacterial peritonitis. Conventional treatment includes a low-salt diet, fluid restriction and the use of diuretics particularly spironolactone. It is often seen in settings of malnutrition and end-stage liver disease, and a nutritional supplementation is important to try and increase calorie and protein intake.

Outcome Following Kasai Portoenterostomy

There are many factors, which will influence surgical outcome in BA. Some are unalterable (e.g. degree of cirrhosis at presentation, absence of, or paucity of bile ductules at the level of section), and some are subject to change (e.g. efficacy of the KPE due to surgical inexperience, poor choice of technique, complications postoperatively due to inexperienced unit, untreated cholangitis, etc.). In large centres with experienced surgeons, about 50–60% of all infants should clear their jaundice and achieve a normal (<20 μmol/L or <1.5 mg/dL) bilirubin [58]. These should do well and have a good quality of long-term survival with their native liver, though the need for transplantation is ever present and the plateau is never flat.

There is no doubt that increasing age at KPE is associated with increasing liver fibrosis and cirrhosis although the actual rates of progression differ according to underlying cause [59]. There is a marked relationship with age at surgery, for instance, with cystic BA and BASM, but it is less evident in isolated BA. So, it is not really possible to use age as a simplistic predictor in individual cases as even in those coming to surgery at >100 days may still have a response to KPE [60]. Still there may be a role for those with the signs of evident cirrhosis (e.g. ascites, heterogeneity of the liver appearance on US) for consideration of transplantation as the primary procedure. This remains an uncommon choice though in the UK and Europe, with <5% of all infants in our series, for instance [58]. By contrast, it seems to becoming a much more prevalent option in certain states in the USA (e.g. California) [61].

In England and Wales, we have adopted a policy of centralisation of surgeons and resources. So for a country of 56 million, there are only three recognised centres to treat this condition, all with surgical facilities including transplantation. This policy was adopted because previous audits of outcome had shown a significant difference depending on centre experience with the less experienced centres showing very poor outcomes [62]. Subsequent studies confirmed an improvement in overall national outcome [58, 63]. Our current outcome statistics show clearance 60–65% of infants coming to KPE at a median now of 48 days. With this at 5 years, we achieve a native liver survival of about 50% and overall survival of 93% (unpublished data; Fig. 59.9a, b). This policy has been successfully replicated by some (typically) Northern European countries [64].

Congenital Choledocal Malformation

Introduction

The German anatomist Abraham Vater recognised the ampullary nature of the junction of biliary and pancreatic ducts which since then has carried his name. Subsequently he also described what appeared to be a choledochal cyst in a pamphlet published in 1723 [65]. Further examples of this, the classical choledochal cyst, were described, but still barely 90 cases had been recorded by 1959, when Alonso-Lej et al. attempted a simple classification into three types [66]. Even as recently as 1975, Flanagan could only identify details of 955 cases from the literature [67].

Choledochal malformation (CM) (of which only some can be described as choledochal "cysts") may be characterised as, … "an abnormal dilatation of the biliary tract, in the

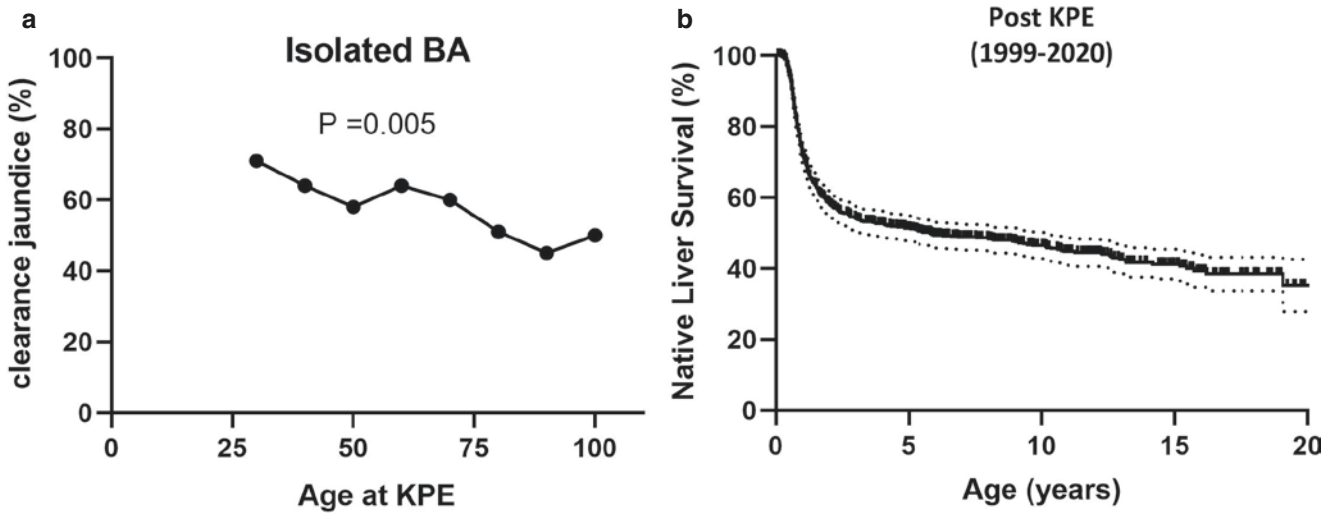

Fig. 59.9 Outcome of biliary atresia in England and Wales since centralisation (1999–2019). (**a**) Age cohort analysis: clearance of jaundice by age at Kasai portoenterostomy. Each point represents individual probability for age-defined cohort (e.g. <30d: 31–40d; 41–50d, etc.). The joining line represents overall influence of age. A "falling line" implies negative influence of clearance on increasing age. Note – NO cut-off! ($n = 613$). (Taken from England and Wales Biliary Atresia database). (**b**) Actuarial native liver survival curve (median (±95% CI)) for biliary atresia ($n = 867$)

absence of any acute obstruction". This allows us to exclude the dilated CBD secondary to choledocholithiasis and strictures secondary to chronic pancreatitis, for instance. Similarly, while many CMs present with jaundice and biliary obstruction, it is obvious that previously their function was unimpaired for much of the subject's life in the presence of clear morphological change.

Aetiology

Most CMs appear in some way to be of congenital origin though the actual mechanism itself is obscure.

There are two competing hypotheses:

1. *Pancreatic Reflux*

An intrinsic part of most examples of CM complex is an abnormal pancreatobiliary junction. Normally the pancreatic and bile ducts open separately within the wall of the duodenum at the ampulla of Vater achieving biological separation of bile and pancreatic juice. In most patients with CM, duct confluence occurs within the head of the pancreas, outside the duodenal wall resulting in a common channel that allows free intraductal mixing of both types of secretion [68, 69].

Donald Babbitt, an American radiologist, proposed that this reflux of presumably activated pancreatic juice could damage the wall of the bile duct causing weakness and then dilatation [70]. There are a number of experimental animal models which have tried to replicate the effects of pancreatic enzymes on bile ducts [71, 72], but there has been little actual documented change in the dimensions of the biliary system.

2. *Distal Bile Duct Stenosis*

Almost 25% of CMs can now be detected antenatally on the maternal US. Most of the infants are not actually jaundiced at birth – though some are and here need to be urgently discriminated from cystic biliary atresia. In all of these, the morphological type is a cystic malformation, and in these, though there might be a common channel, there is minimal amylase in bile (implying no reflux) and often a very definite abrupt change and stenotic distal bile duct segment. Furthermore, animal models involving ligation of the distal bile duct [73] produce obvious cystic change.

To try and resolve some of these questions, we performed a series of studies looking at the relationship between age at presentation, modes of clinical presentation, bile duct pressure (as measured at operation), levels of amylase in the bile (as a marker of reflux) and the histological appearance of the resected choledochus [69, 74, 75]. This showed there is a remarkable inverse relationship between pressure and amylase – the higher the pressure, the lower the amylase and that increasing histological epithelial injury and damage are found in those with higher pressures and very obviously not with high amylase levels (Fig. 59.10).

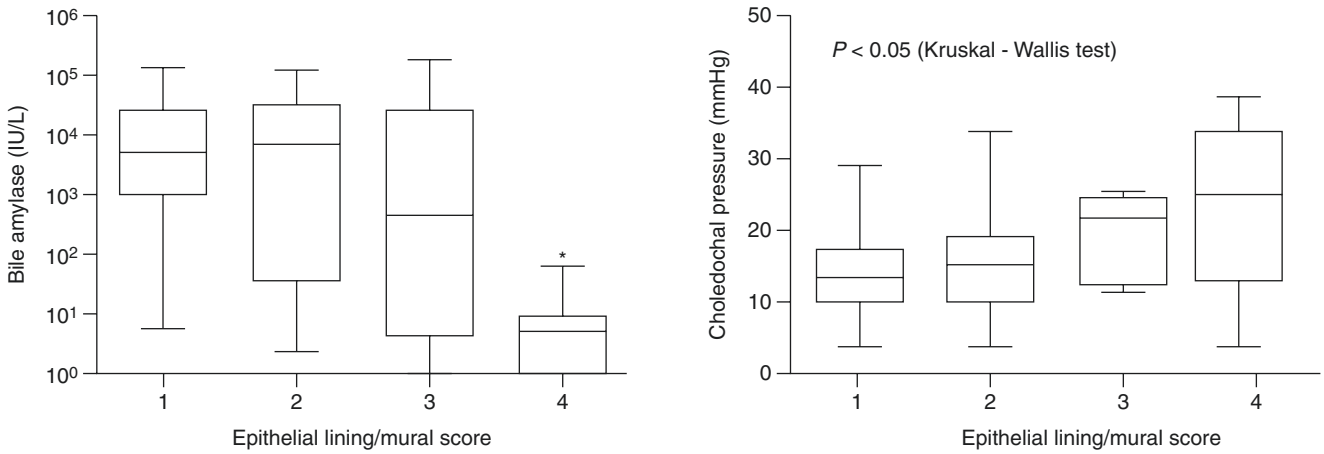

Fig. 59.10 Relationship between biliary amylase, choledochal pressure and epithelial histology. Levels of biliary amylase (**a**) (as a surrogate of pancreatic reflux) and in situ choledochal pressure (**b**) in 73 children with choledochal malformation. The Y axis (epithelial lining/mural score) uses a semiquantitative score for biliary epithelium where 0 = normal, 1 = minimal focal hyperplasia and chronic inflammation, 2 = mild chronic inflammation, 3 = pronounced hyperplasia and moderate chronic inflammation and 4 = epithelial loss, bile impregnation and biliary necrosis. (Extracted from Ref. [59])

Classification

The original Alonso-Lej classification (types 1, 2 and 3) [66] has been modified most notably by Takuji Todani, a Japanese surgeon, by adding the concept of multiple dilatation (type 4) and isolated intrahepatic dilatation (type 5) [76]. The King's College Hospital classification (Fig. 59.11), which has been in use for over 30 years, simplifies the Todani classification into types 1C and 1F (depending on the predominant appearance as cystic or fusiform) and limits type 4 to the combination of intra- and extrahepatic dilatation but again incorporating a cystic or fusiform morphology [77]. This classification has been the basis of our attempts to define pathophysiological characteristics to each type [75, 77–79]. Other workers have emulated this simpler approach.

We also prefer to use the generic term *choledochal malformation*, rather than the very specific term choledochal cyst, since not many of the described dilatations actually appear as a "cystic" (i.e. spherical or globular) entity. The principal variants of extrahepatic dilatation (type 1) making up about 80% of all cases are either *cystic CM (type 1c)* or *fusiform CM (type 1f)*. The former typically has a natural demarcation at either end (Fig. 59.12a), while the latter is much smaller in diameter but merges imperceptibly with a common channel distally or the bifurcation proximally. The only other common variant (*type 4*) is either of the foregoing extrahepatic dilatation (*4c or 4f*) together with significant intrahepatic biliary dilatation – sometimes this is because of actual obstruction with a swift return to normal calibre after surgery, but in others it may appear as an intrinsic feature of the condition (Fig. 59.12b) [79]. Of the remaining variants, *types 2 and 3* are rarely seen in children. The former can be likened to a diverticulum of the CBD, the latter a localised dilatation of the CDB as it transits the wall of the duodenum (a.k.a. choledochocele). *Type 5 CM* refers to usually solitary intrahepatic biliary cystic lesions. Most of these are detected incidentally and can be left alone.

Jacques Caroli, a French gastroenterologist and prolific author, described a number of intrahepatic biliary pathologies which carry his name [80, 81]. The term Caroli disease is usually applied to ectasia or segmental dilatation of the larger intrahepatic ducts (typically the left hepatic duct system) without any other extrahepatic manifestation and is usually sporadic. Caroli syndrome describes a condition in which there are multiple, discrete small yet saccular dilatations of the intrahepatic bile ducts with almost invariably hepatic fibrosis and usually renal disease. This is generally inherited in an autosomal recessive manner [82–84], and there is a large overlap with congenital hepatic fibrosis, polycystic kidney disease (both autosomal dominant and recessive types), etc.

Epidemiology

CMs can present at any point in the life cycle from an antenatal scan to the postmortem table, which makes the true incidence hard to define. If biliary atresia is used as a guide for a condition where the incidence is known (e.g. 1 in 17,000 in the UK) and the ratio of the two conditions presenting in infancy is taken from a specialist hepatobiliary unit, then an approximate figure of about 1 in 100,000 live births may be suggested [85]. Nevertheless, the incidence is much higher in Asian populations, and virtually all of the large series of this has been reported from Japan [86, 87] and now increasingly China [88, 89] with very few series from

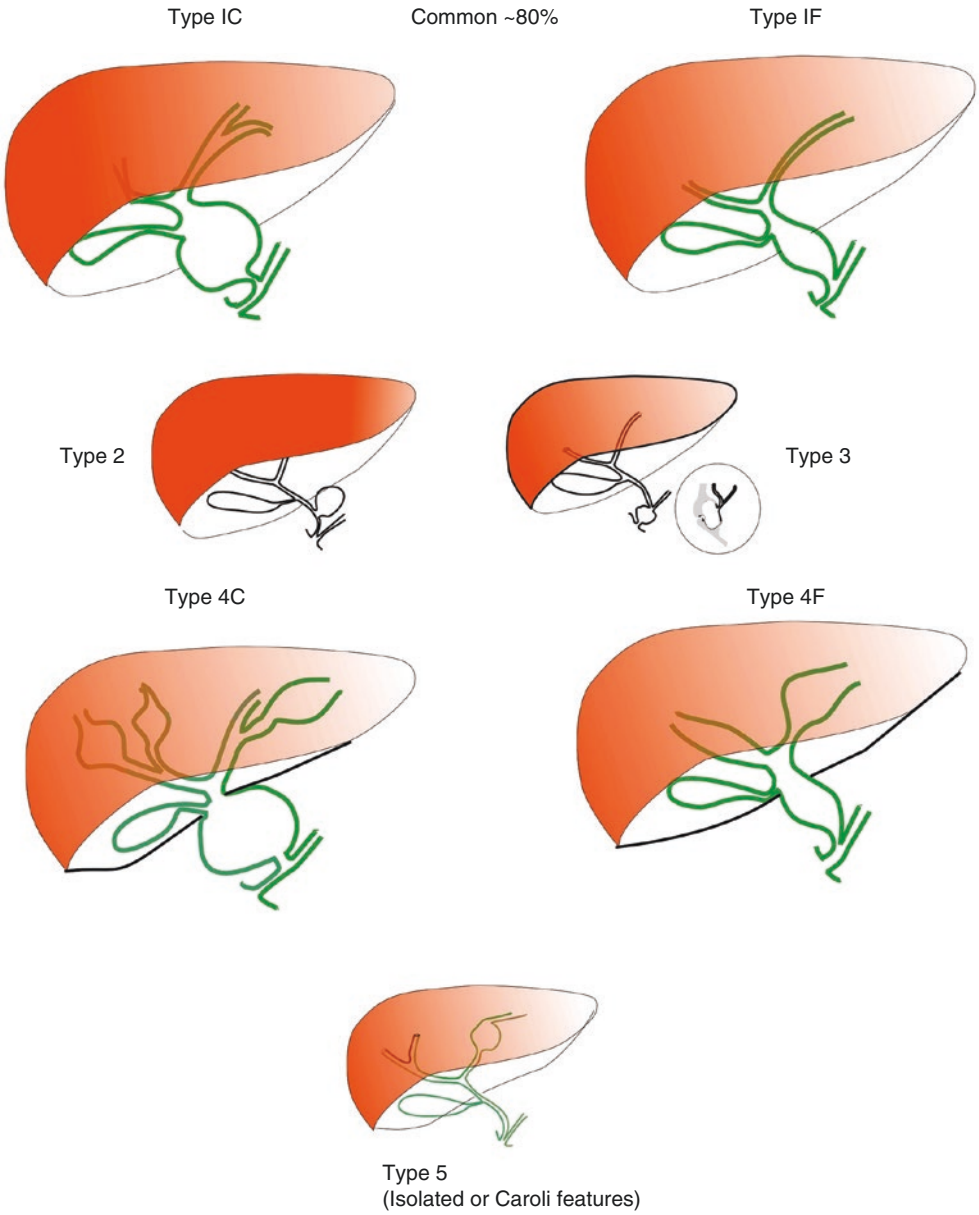

Fig. 59.11 King's College Hospital classification for choledochal malformation

North America [90, 91] or Europe [92]. There is a marked female predominance (4:1) [92], but not much in the way of an identifiable hereditary element. However, isolated examples of familial occurrence in siblings and twins have been reported [93, 94].

Clinical Features

CM can present at any age, but more than 90% will present within the first decade [92]. Clinical manifestations do differ according to the age of onset. Typical presenting symptoms in the newborn mimic biliary atresia and specifically cystic biliary atresia with obstructive jaundice, acholic stools and hepatomegaly, depending on the degree of obstruction. These sometimes have advanced liver fibrosis depending on the length of the period of obstruction. As described above, some will present with an abnormal antenatal ultrasound scan although it will quickly clear their neonatal jaundice.

Older infants and toddlers then tend to present with jaundice and may well be found to have an upper abdominal mass, and most turn out to have a type 1c CM. If obstructive features are ignored, then chronic liver disease may result, and cirrhosis is possible though seemingly not as common as in some older series [92].

Recurrent abdominal pain becomes a feature later on and may be due to an obstructed high-pressure system or actual recurrent pancreatitis. This is usually pathologically mild, oedematous and short-lived and associated with hyperamylasemia. This scenario is usually associated with the type 1f

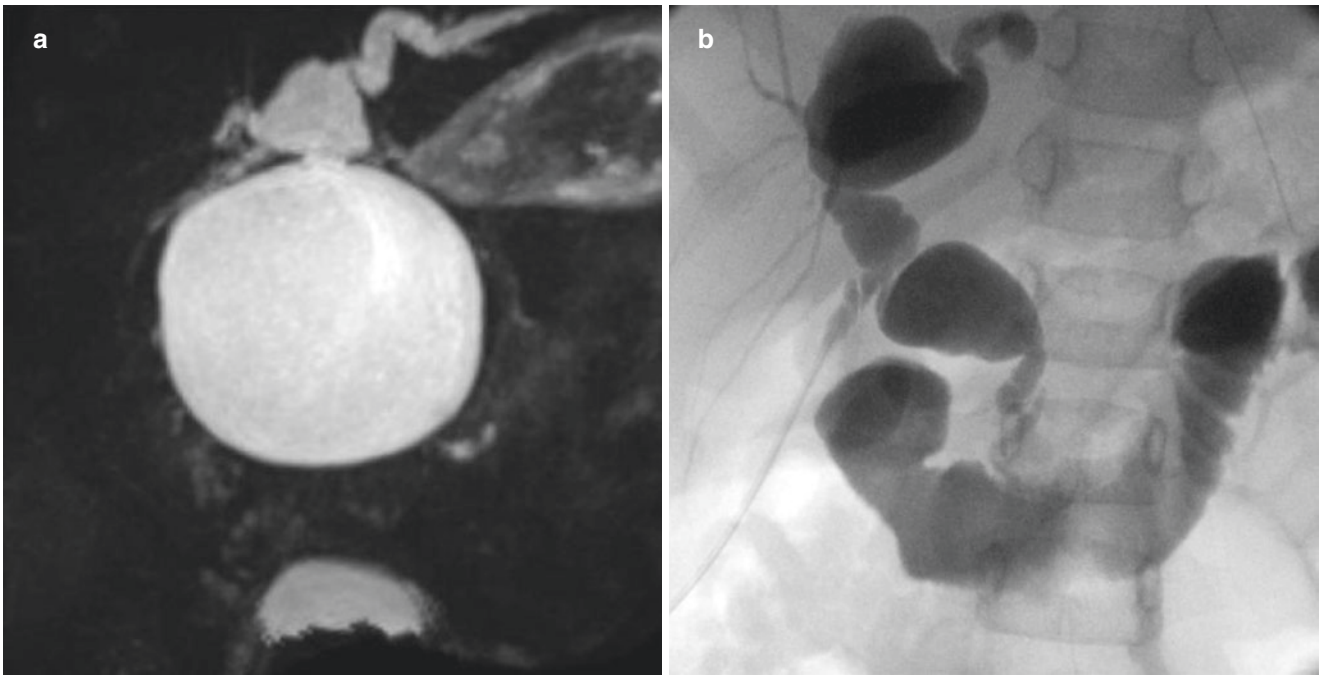

Fig. 59.12 Types of choledochal malformation. (**a**) MR scan (T2 weighted) showing "classical" type 1c choledochal malformation (CM) with a degree of left intrahepatic dilatation. Infant presented antenatally with abnormal maternal ultrasound scan. Note clear demarcation of dilatation both proximally and distally. (**b**) Operative cholangiogram of type 4 choledochal malformation with fusiform extrahepatic appearance and marked segmental dilatation of intrahepatic left hepatic duct. The distal duct gradually tapers towards a common channel (filled with debris) inserting into the third part of the duodenum. A 4-year-old child who presented with acute pancreatitis

CM. Sometimes investigation shows a common channel, presenting features of pancreatitis but not much in the way of biliary dilatation. This has been termed a *forme fruste* CM or more simply common channel syndrome (Fig. 59.13).

Perforation of a high-pressure system is perhaps surprisingly uncommon (<5%), and in these the clinical scenario may mimic spontaneous biliary perforation in infancy [95, 96] or appendicitis in the older child. Bile leakage is usually confined to the retroperitoneum and tracks down the paracolic gutter.

There is a risk of carcinomatous change in long-standing CM which will manifest later in adulthood and exceptionally rarely in adolescence. Up to 10% of adult series have established malignant change at laparotomy [78, 97, 98]. In a Japanese series of 94 patients (adults and children) with excised choledochal malformation, four later developed malignancy. The age at detection ranged from 27 to 65 years with the malignancy arising both in the liver and the head of the pancreas [97]. Similarly, Lee et al. described 80 patients with biliary malignancies from a large Korean multicentre series of 808 adults [98]. Of these most ($n = 74$) were evident at initial presentation and laparotomy while six presented 4 years after their previous choledochal excision. What is not known is what the real long-term risk is in those who have

Fig. 59.13 Common channel syndrome. An 8-year-old girl with long history of recurrent acute pancreatitis requiring an ERCP to diagnose a common channel, with presumed reflux of the bile into the pancreatic duct. She was cured by disconnection of biliary and pancreatic ducts and Roux loop hepaticojejunostomy biliary reconstruction

had their definitive excisional surgery in childhood. We tried to identify these on the basis of the histological characteristics of the excised biliary tract (including Ki67 expression), levels of CA19-9 and amylase in bile but there were no consistent features [99].

Diagnosis

A choledochal cyst was first diagnosed antenatally using ultrasound by Dewbury et al. from Southampton in the UK in 1980 [100]. Since then, up to 25% of CM (in the UK at least) are diagnosed antenatally from as early as 15 weeks' gestation, and these are almost invariably types 1c or 5 CM [101]. CM may be confused with duodenal atresia, cystic biliary atresia, ovarian cyst, duplication cyst and mesenteric cyst. In this scenario, it is most important to exclude the possibility of cystic BA who requires urgent Kasai portoenterostomy [11]. If there is clinical doubt, then a dynamic radio-isotope scan (e.g. technetium^{99}-labelled iminodiacetic acid, HIDA scan) will confirm the non-obstructing CM, where surgery can be deferred to about 3–4 months.

Postnatally, US is the initial diagnostic modality of choice, allowing for precise measurements of intra-/extrahepatic duct dilatation and identification of stones/sludge. MRCP has superceded the use of CT and for the most part ERCP for pre-operative anatomical delineation of the pancreaticobiliary tract. Three-dimensional reconstruction images are easily obtained, although sedation may be required in infants and small children.

Functional assessment of CM may be shown using a dynamic radio-isotope scan which can show baseline parenchymal hepatocyte uptake together with the pattern and degree of bile excretion – important if not considering surgery. This may also be useful in diagnosing choledochal perforation. ERCP may still be required when there is diagnostic uncertainty over the nature of the pancreaticobiliary junction and common channel, particularly in those with minimal biliary dilatation and often with a presenting feature of pancreatitis.

Biochemical liver function tests may be normal or show evidence of biliary obstruction. Amylase levels may be elevated during episodes of abdominal pain suggestive of actual pancreatitis. A prolonged INR secondary to cholestasis should be corrected with intravenous vitamin K.

Surgical Management

Open surgery is still very much the standard in most centres. For the common types (type 1c, type 1f and type 4), this consists of excision of the dilated part of the extrahepatic biliary tree, clearance of debris and stones from any dilated intrahepatic ducts (best achieved with on-table cholangioscopy), clearance of any common channel debris (± transduodenal sphincteroplasty) and a reconstruction end-to-side hepaticojejunostomy using a long (40–50 cm) Roux loop. Despite often quite alarming intrahepatic dilatation in type 4 CM, the usual best course is simply excision of the extrahepatic segment with a fastidious approach to ensuring segmental drainage and cautious follow-up. Most ducts will reduce in size, particularly in children which in itself suggests the primary aetiological role of elevated intrabiliary pressure [77, 79].

The first laparoscopic cystectomy and reconstruction of a 6-year-old female with a type 1c malformation was reported by Farello et al. in 1995 from Schio, Italy [102], and has become an option in some parts of the world. The largest series are either from China or Vietnam and now number well over 200 children in each [88, 103]. The technical skills required are high, and a large throughput is important in minimising complications. The standard Roux loop reconstruction is usually carried out by extracting the small bowel through an enlarged umbilical incision though the hepaticojejunostomy is performed intracorporeally. A controversial innovation has been to discard the hepaticojejunostomy because it is difficult and perform a hepaticoduodenostomy which is easier instead [104]. This short cut may be expedient, but the long-term effects of this may be poorer. Cholangitis and biliary gastritis are both significantly more common using this so-called "physiological" alternative [105]. The other alternative, only available in certain centres of course, is robotic surgery which may facilitate the bile duct anastomosis [106], though even here the postoperative stay is no different to those treated more conventionally.

Excision of the diverticulum is probably all that is needed in the rare type 2 CM as long as normal unobstructed distal bile flow can be demonstrated radiologically [107]. Large choledochoceles (type 3 CM) can be removed transduodenally, whereas smaller choledochoceles can be treated by sphincteroplasty or endoscopic sphincterotomy, although admittedly most reported experience is in adults [108].

Most type 5 CMs are isolated, asymptomatic and picked up incidentally with US. They can probably best be treated conservatively with serial US to try and detect any complications such as stone formation [101]. In those with symptomatic or complicated Caroli-like intrahepatic dilatation, resection should be considered particularly if unilobar. The treatment of Caroli's syndrome may be complicated, and occasionally liver transplantation may be considered.

Postoperative Management

Intravenous fluids and nasogastric aspiration are continued until return of bowel function, usually on day 2 or 3 after the operation. Oral feeding is recommenced after the fluid from the nasogastric tube becomes clear.

Complications

Complications are uncommon but may include bleeding, adhesive small bowel obstruction, anastomotic leakage and leakage from the pancreatic duct. Anastomotic leakage may be treated conservatively, particularly if this has followed a difficult and challenging anastomosis. Abdominal drainage is key, and if there is no obstruction to a functioning Roux loop, then it will settle. Pancreatic leaks are less common but more challenging, particularly if the ampullary sphincter is still intact. Consideration should be given to endoscopic ERCP and stenting if a conservative trial of abdominal drainage, intravenous antibiotics, nasogastric decompression and parenteral nutrition fails.

Anastomotic stricture usually followed by recurrent cholangitis and intrahepatic stone formation are late complications [109]. Cholangitis implies a mechanical problem and should be aggressively investigated. Strictures or persistent intrahepatic dilatation can be treated by radiological intervention with surgery reserved for failure. Recurrent pancreatitis implies obstructive problems with the retained common channel. MRCP, but more likely ERCP, should be diagnostic and, in the latter's case, may be therapeutic with endoscopic channel clearing or stenting.

Definitions

Ciliopathies

Ciliopathies are a heterogeneous group of disorders due to cilia abnormalities.

Ciliopathies are multisystemic disorders often sharing common features, such as polydactyly, mental retardation, retinal defects, kidney cysts and fibrocystic liver disease. Multisystemic ciliopathies are described at the end of this chapter.

Fibrocystic Liver Diseases

Congenital hepatic fibrosis (CHF), Caroli's disease (CD), and Caroli's syndrome (CS) are fibrocystic liver diseases and the most common liver manifestations of ciliopathies [1–5]. Their presentation can be only the liver disease or can be associated with a syndrome. Their common feature is the presence of *ductal plate malformation (DPM)*: an abnormal embryonal development of the ductal plate due to impaired ciliary function.

Fibrocystic liver diseases are summarized in Table 60.1. Choledochal cysts may be considered part of the "fibrocystic liver disease" spectrum, because extensive fibrosis and other signs of CHF may be seen on biopsy [6]. The differential of intrahepatic cysts is summarized in Table 60.2 [7–9].

Hepatorenal Fibrocystic Disorders

When the phenotype of the ciliopathy combines only hepatic and renal manifestations, these conditions are also referred to as the *hepatorenal fibrocystic disorders* (HRFCD). The most frequent HRFCD are autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD).

Pathophysiology

Liver Development Overview

In vertebrates, the early liver bud develops when a few cells from the endoderm delaminate into the adjacent mesenchyme. The early liver cells are called hepatoblasts. They are bipotential precursors which eventually adopt either a hepatocyte fate or a cholangiocyte fate (Fig. 60.1) [10]. As such they express markers of both lineages during development, some of which can be reactivated in certain disease states [11]. Hepatoblasts contribute to intrahepatic biliary development at the ductal plate, a process which is orchestrated by intrahepatic vascular development and which is of importance in understanding fibrocystic liver disease [12].

The Ductal Plate

The ductal plate is the embryonic precursor of the intrahepatic bile ducts. It is first detected by 6 to 7 gestational weeks and consists of a double layer of cuboidal, biliary-type epithelium that surrounds the developing portal veins. This layer develops from the transformation of hepatoblasts and yields an anastomosing tubular network of biliary ducts through a process called ductal plate remodeling (Fig. 60.1) [13–16].

Ductal plate remodeling begins by 11 weeks of gestation and, in normal conditions, is complete in early post-natal life. It is a process of negative selection of non-functional

Table 60.1 Fibrocystic liver diseases with ductal plate malformation

Disease	Characteristics	Symptoms	Diagnosis	Associated syndromes	Treatment
Congenital hepatic fibrosis (CHF)	Abundant fibrous tissue between portal tracts and ductal plate malformation Rare: latent disease	Portal hypertension: hypersplenism, thrombocytopenia, hepatosplenomegaly Rare: Cholangitis	US Liver biopsy	Ciliopathies	Supportive with management of portal hypertension Porto-systemic shunt Liver transplantation
Caroli's syndrome (CS)	CHF Saccular dilatation of the intrahepatic ducts	Cholangitis Cholestasis, pruritus Abdominal pain Signs of portal hypertension	US MRCP	Ciliopathies Risk of CCA	Antibiotics for cholangitis Liver transplantation
Caroli's disease (CD)	No signs of CHF Saccular or fusiform cystic dilatation to 5 cm of larger and proximal intrahepatic biliary ducts Inheritance unclear but familial cases	Cholestasis Cholangitis No portal hypertension	US MRCP Liver biopsy	Extrahepatic bile duct dilatation Choledochal cyst Risk of CCA	Antibiotics for cholangitis Partial hepatectomy Liver transplantation
Autosomal dominant polycystic liver disease (PCLD)	> 20 round and smooth cysts Non-communicating Development of cyst associated with hormonal features Woman > men **Gene: *SEC63*, *PRKCSH*** **→ *Abnormalities of cAMP pathway*** [1]	Asymptomatic Abdominal mass Pain Cyst infection, bleeding Biliary obstruction No portal hypertension Rare liver failure	US MRCP Liver biopsy	Distinct form associated with ADPKD	Somatostatin analogues (Inhibition of cAMP pathway) Surgical resection Rarely liver transplantation
von Meyenburg complex	Bile duct hamartomas Benign pathology Multiple/unique round uniform cysts 0.1–0.3 cm, Localized close to portal tracts	Asymptomatic, usually found in liver biopsy for other indications Rare portal hypertension	Incidental MRCP Liver biopsy	ADPKD ARPKD Risk of CCA	None
Choledochal cyst	Dilatation of common bile duct +/− intrahepatic and extrahepatic biliary tree Classification based on location Type I-IV: No parenchyma hepatic involvement Type V: Multiple cyst dilatation intrahepatic → Caroli's disease 8–53% cases	Conjugated hyperbilirubinemia Jaundice abdominal pain Acute complication: perforation, bleeding, infection, lithiasis Long-term complication: biliary cirrhosis and hypertension	US MRCP	CHF Risk of CCA	Surgical resection Choledo-enterostomy

CCA cholangiocarcinoma, *US* ultrasonography, *MRCP* magnetic resonance cholangiopancreatography

Table 60.2 Other causes of biliary cysts

Disease	Characteristic	Symptoms	Diagnosis	Treatment
Solitary hepatic cyst, non-communicating	Delimited No communication with biliary duct Right lobe No associated cysts in viscera	Asymptomatic Complications: infection, perforation, obstruction, neoplastic degeneration	Clinical and MRCP Avoid biopsy →infectious risk	Surgery [69]: laparoscopic fenestration or total resection or hepatectomy
Obstructive bile duct dilatation	Stones inside ducts or stricture of ducts from extrabiliary cause (neoplasia; pancreatitis)	Asymptomatic Complication: cholestasis, cholangitis, perforation Signs of primary disease causing obstruction	Clinical MRCP US Signs of primary disease	Surgery Treatment of primary disease

US ultrasonography, *MRCP* magnetic resonance cholangiopancreatography

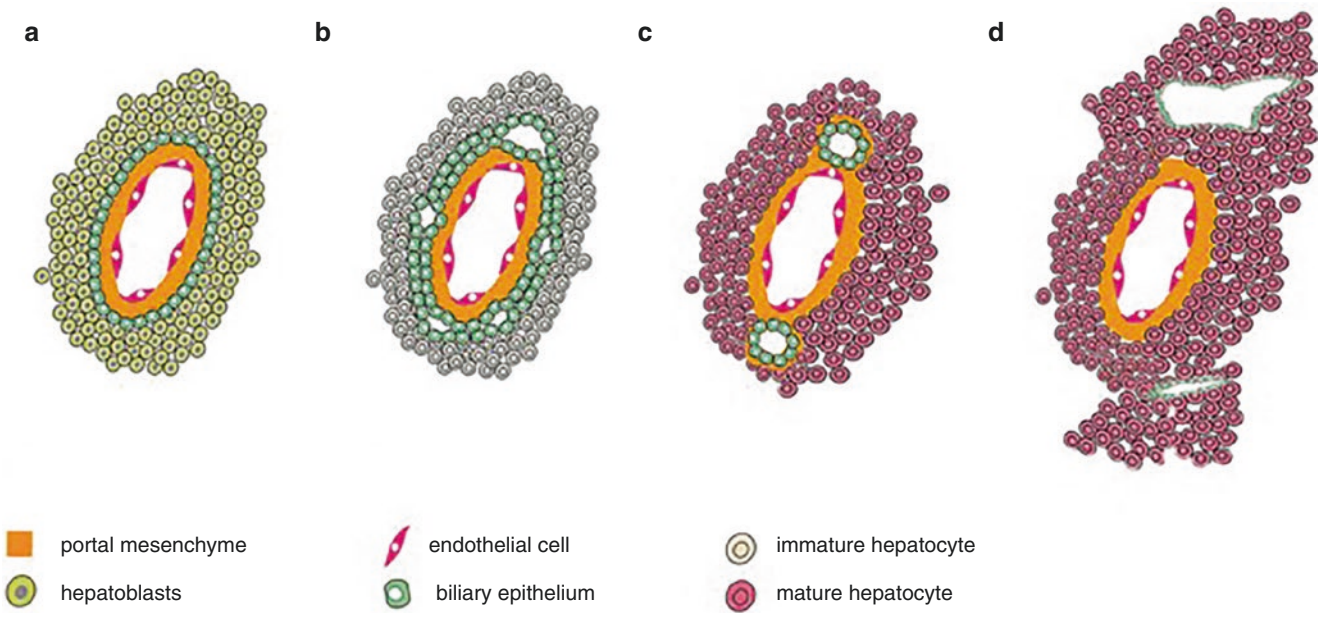

Fig. 60.1 Biliary development and the ductal plate malformation. (**a**) At 14 weeks of gestation, hepatoblasts in contact with portal vein mesenchyme adopt a biliary epithelial fate. (**b**) At 17 weeks of gestation, biliary layer duplicates and focal dilatation within the layer leads to bile ducts formation. (**c**) At birth, bile duct development is nearly completed, and the bilayer has involuted. Liver cells are either hepatocytes or hepatoblasts. (**d**) Ductal plate malformation: abnormal ductal plate remodeling leads to saccular, biliary dilatations. (Modified from [10])

ductal plate elements which involute in a centripetal fashion from the hilum toward the liver periphery [13, 15, 17]. The remodeling phase is characterized by a high rate of mesenchymal proliferation, resulting in the separation of the developing bile ducts from the liver parenchyma (Fig. 60.1) [13, 17]. Meanwhile, hepatocytes and intrahepatic biliary epithelial cells undergo apoptosis at a higher rate than normal under the control of apoptosis-related proteins: C-myc protein and fas antigen stimulate cell death, while Bcl-2 protein inhibits apoptosis [14]. It is possible that an imbalance between proliferation and apoptosis impedes normal ductal plate remodeling, thereby yielding the ductal plate malformation [13, 14]. Remodeling is under the control of a number of genetic and molecular factors that make it vulnerable to maldevelopment. Among these factors are signaling molecules from the portal venous mesenchyme, from adjacent hepatoblasts, from involuting bile ducts, and from hormones such as estrogens [18].

The Ductal Plate Malformation

The term "ductal plate malformation" (DPM) was first used by Mogens Jorgen Jorgensen in 1977 to describe an unusual histologic configuration of the liver of children with polycystic disease. He first described extensive fibrosis and increased number of bile ducts within the fibrotic regions, now recognized as the cardinal features of the DPM [19]. It is now understood that the DPM occurs when certain ductal plate remnants fail to involute. What is not understood is why the size of the bile ducts affected by the DPM varies between diseases: small ducts are affected in CHF, while larger ducts are dysmorphic in Caroli's disease. Figure 60.2 illustrates the DPM and related diseases along a centrifugal axis from the hilum to the subcapsular region. In case of complete lack of remodeling of the ductal plate, the DPM appears like a circular lumen surrounding a central fibrovascular axis. Alternatively, incomplete remodeling results either in a ring of interrupted ducts around a fibrovascular axis or a polypoid projection of biliary epithelium in a dilated duct [20, 21]. Mouse models suggest that DPM occurs as a result of impaired differentiation of biliary precursor cells, failure of maturation of primitive ducts, and defective duct expansion. Interestingly, the same mice models reveal impaired cell polarity and disruption of cholangiocyte ciliogenesis pointing to cilia-mediated cholangiocyte polarity in bile duct (mal)development [22].

There are two groups of diseases in which the DPM is a dominant feature, although it is unclear whether they share a common etiology. The first is characterized by inflammation and destruction of intrahepatic bile ducts with some degree of fibrosis, as seen in biliary atresia. The second is the pattern typically seen in fibrocystic diseases: extensive fibrosis with ectasia and hyperplasia of intrahepatic bile ducts (Fig. 60.2) [16]. Our purpose is to focus on the latter group.

Cavernous Transformation of the Portal Vein

The DPM is often associated with abnormalities in portal vein branching. During normal development, the portal vein

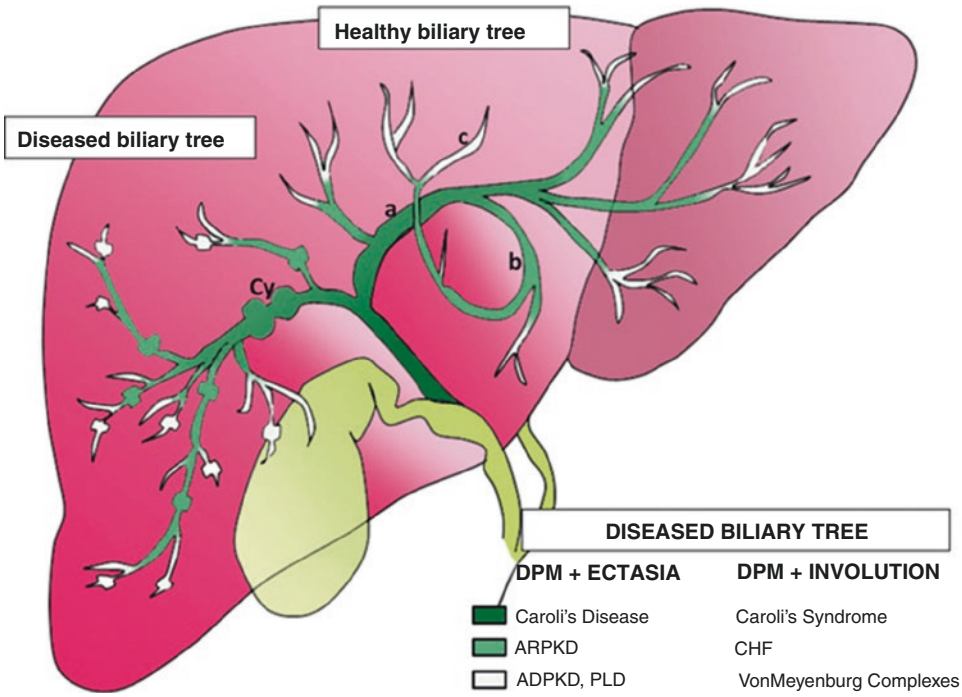

Fig. 60.2 Schematic of intrahepatic biliary tree and level of DPM. For reasons still unknown, defects in ductal plate remodeling impact the biliary tree at different levels. In addition, the remodeling defect yields one of two phenotypes: predominantly fibrotic lesions and dilated biliary structures. Caroli's syndrome is an example of how the two phenotypes might overlap. (Inspired from [20]). *Abbreviations:* Cy kyst. (a) Large biliary ducts. (b) Medium ducts. (c) Small ducts. DPM ductal plate malformation, CHF congenital hepatic fibrosis, ARPKD autosomal recessive polycystic kidney disease, ADPKD autosomal dominant polycystic kidney disease, PLD polycystic liver disease

invades the early liver parenchyma in a centrifugal branching pattern from the hilum to the periphery. This branching pattern determines the lobular architecture of the liver. Therefore, it follows that alterations of vascular development and intrahepatic bile ducts go hand in hand [16, 23, 24]. In the case of DPM, branching is abnormal, thereby leading to the "pollard willow formation," characterized by clusters of unseparated venous tracts [16, 20, 23]. Extrahepatic cavernous transformation of the portal vein occurs in 50–70% of patients with CHF and Caroli's disease and contributes to portal hypertension, one of the main clinical features of CHF patients [23, 24]. Congenital absence of the portal vein has rarely been reported in association with CHF [25–28]. How the extrahepatic portal vein abnormalities are related to the intrahepatic alterations is unclear.

Fibrosis

CHF is a developmental disorder due to DPM of the small, interlobular bile ducts, during which persistence of embryonic remnants stimulates the development of fibrosis. Portal fibrosis is the major histological finding in CHF. The development of fibrosis is a multifactorial process involving hepatic stellate cells, myofibroblasts, and macrophages. Known molecular mediators include transforming growth factor-β1 (TGF-β1) and connective tissue growth factor (CTGF) [29]. CTGF is known to promote fibrosis [29]. In CHF, CTGF is retained in the extracellular matrix, thereby maintaining a local stimulus for fibrosis. How fibrosis develops in ciliopathies is developed further in the section below on animal models.

Hepatic stellate cells (HSCs) constitute approximately 5–8% of liver cells. They are located in the space of Disse, between sinusoidal endothelial cells and liver parenchymal cells [30, 31]. Activated stellate cells express tissue inhibitors of metalloproteinases 1 and 2 (TIMP 1 and 2) [32–34]. These factors have two roles in fibrogenesis: they exert a direct inhibitory action on metalloproteinases which leads to extracellular matrix accumulation, and they confer anti-apoptotic proliferative signals to activated stellate cells [32, 35]. Finally, stellate cells respond to nearby injury by transforming into myofibroblasts [30] which secrete extracellular matrix (ECM) components leading to scarring [30, 31].

Myofibroblasts are only present in the injured liver and are classically believed to derive from portal fibroblasts or hepatic stellate cells. They are responsible for producing the extracellular matrix which leads to fibrosis [31, 36]. In CHF, parenchymal fibrosis is minimal compared to portal fibrosis. Therefore, it is possible that in CHF, myofibroblasts derive from periductal fibroblasts rather than from parenchymal stellate cells [29].

Finally, *macrophages* have also been recognized as important regulators of liver fibrosis. They are located close to myofibroblasts and interact with the latter and with HSCs [37–40]. They also act independently, by producing their own metalloproteinases and TIMP. They contribute to the phagocytosis of cellular debris and to the secretion of cytokines and immunoregulatory mediators [37, 40, 41].

In summary, portal fibrosis is a major feature of CHF. In response to abnormal ductal plate remodeling, portal fibroblasts transform into myofibroblasts and interact with macrophages which secrete the inflammatory cytokines that trigger fibrosis. At this time, however, the underlying molecular and cellular mechanisms are not clear.

Cilia in Development

Abnormal primary cilia are now understood to be one of the main mechanisms causing DPM. The term *ciliopathies* refers to a heterogeneous group of disorders involving anomalies in primary cilia. Primary cilia are highly conserved organelles used to detect various extracellular stimuli [42]. Although their existence has been known since the nineteenth century, their role in disease is still incompletely understood.

In the liver, cholangiocytes are the only cells with primary cilia [43, 44]. Normal ciliary function is necessary for biliary development. Cholangiocyte cilia are important receptors of mechanical and osmotic signals. They respond by modulating intracellular levels of cAMP and calcium in response to bile flow. This function depends on polycystin 1 and 2 (PC-1 and PC-2) that form a functional complex. PC-1 is a ciliary protein with a large extracellular domain that senses cilia bending. It then transfers this signal to PC-2 which triggers a rise in intracellular calcium which in turn regulates cellular proliferation. PC-1 exerts a regulatory role on growth, such that when its function is impaired or its level of expression diminished, the break is lifted and excess proliferation ensues [45]. Cholangiocyte cilia also detect osmotic changes in the bile via the transient receptor potential cation channel subfamily V member 4 (TRPV4) protein which participates in the regulation of bicarbonate-dependent bile secretion [43, 44, 46–49].

Structural and functional defects of primary cilia result in decreased intracellular calcium and increased cAMP, causing cholangiocyte hyperproliferation and abnormal cell-matrix interactions [43, 47, 50–52]. Estrogens and IGF-1 also contribute to cholangiocyte proliferation, and cystic cells have been shown to overexpress estrogen and IGF-1 receptors. Cell cycle dysregulation also contributes to cholangiocyte proliferation [18, 51].

Excessive cholangiocyte proliferation leads to the development of cysts. Evidence suggests that cAMP signaling dysregulation plays a principal role in cystogenesis. In addition, it appears that the mTOR signaling cascade is involved in cyst growth, since it is upregulated in the epithelium lining the cysts. Finally, cystic cholangiocytes display an abnormal ion transporter pattern leading to increased fluid secretion in the cysts [51, 53–55].

As summarized in Fig. 60.3, cyst expansion in ciliopathies is related to structural and functional defects of the cilia, leading to cholangiocyte proliferation and cyst formation. This process is enhanced by other factors, such as abnormal cell-matrix interactions, cell cycle dysregulation, overexpression of estrogen, and IGF-1 and increased fluid secretion in the cysts.

Evidence suggests that biliary precursors are vulnerable to developmental hits that can impair remodeling. One such scenario is that of somatic mutations occurring during development [56, 57]. A mutation in a single allele of a developmentally key transcription factor such as HNF6 prior to ductal plate formation may lead to impaired ciliogenesis and thus cyst development. Other intracellular mechanisms which can theoretically lead to DPM include loss of heterozygosity, glycosylation defects, and post-translational modification leading to faulty transcription factor binding [58].

Among other developmental steps prone to anomalies, the local growth factor milieu is another variable in a complex web of events. It is probably because the number of genes and signaling pathways are so numerous and the possible combinations of developmental accidents almost infinite that biliary development is so vulnerable to malformations and that there is so much overlap between phenotypes among the ciliopathies and fibrocystic diseases. To help make sense of this wide range of phenotypes, it has been suggested that DPMs can be categorized in one of three ways: perturbations in differentiation of biliary precursors, impaired maturation of radially asymmetrical primitive ductules, and abnormal (excessive) ductular expansion.

Animal Models of Ciliopathies

Much of what is understood today about cystogenesis, fibrosis, and ciliopathies is through animal studies. Animal studies help elucidate mechanisms of pathogenesis and factors of disease progression, identify possible outcomes, and develop treatment strategies.

Although different parameters have been identified leading to cholangiocyte proliferation and cyst development, until recently there was no clear mechanistic studies to

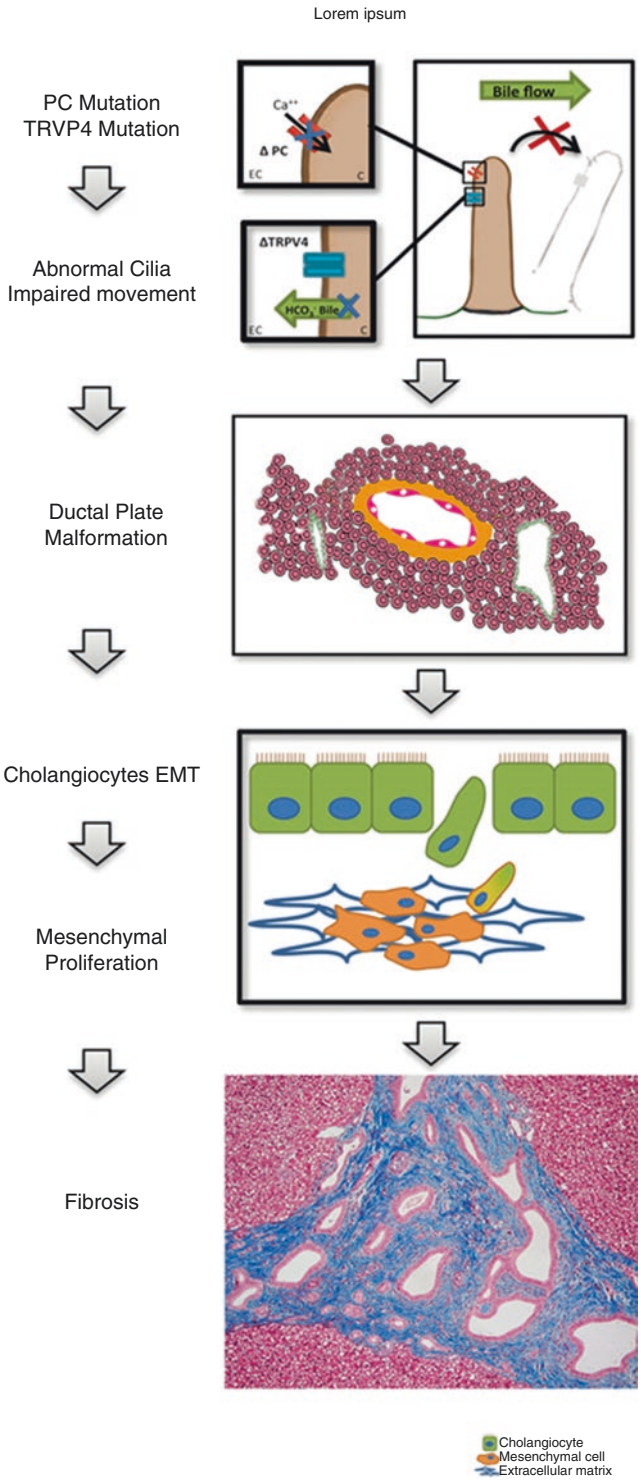

Fig. 60.3 Schematic description of molecular and cellular mechanisms in the hepatic manifestations of ciliopathies. Mutations in polycystin (PC) lead to impaired calcium transport into cilia and thus impaired movement. In case of TRPV4 mutation, osmotic changes in bile cannot be sensed, and a dysregulation of bicarbonate-dependent bile secretion occurs. Structural and functional defects of the cilia lead to ductal plate malformation. Cholangiocytes undergo an epithelial to mesenchymal transition and proliferate in the mesenchyme contributing to fibrosis. *Abbreviations:* PC polycystin, TRPV4 transient receptor potential cation channel subfamily V member 4, EC extracellular, C cytosol

explain the link between cyst formation and fibrosis. Recent studies in rats have shown that abnormal cystic cholangiocytes can undergo an epithelial to mesenchymal transition and secrete extracellular matrix molecules contributing to the development of fibrosis (Fig. 60.3) [59].

The PCK rat carries a splicing mutation in polycystic kidney and hepatic disease 1 gene (Pkhd1), an ortholog of polycystic kidney and hepatic disease 1(PKHD1). Defects in ciliary structure of cholangiocytes lead to abnormalities of biliary tree differentiation and bile duct dilatation, mimicking Caroli's disease. Besides the histological findings described above, macroscopic findings include cholangitis with intestinal metaplasia and hepatic fibrosis [41, 59, 60].

Besides PKHD1 orthologs, other models displaying both polycystic kidney and liver diseases that have include mice with mutations in the genes encoding for cystin, Bicc1, Inversin and Polaris proteins [42].

Animal studies offer insight in the role of signaling pathways in the pathogenesis of liver and kidney ciliopathies. More specifically, receptor tyrosine kinase (RTK) and cyclic AMP (cAMP) pathways are activated in the Cy and PCK rats and in the pcy and jck mice. Furthermore, decreased activation of cAMP pathway seems to improve evolution in PCK and pcy mice. Other signaling pathways explored in rodent models of PCK include intracellular Ca^{2+}, PPAR-γ, MCP-1, and STAT3 that are also targeted in the same rodent models leading to further understanding of disease progression mechanisms in these diseases [61]. Finally, mTOR inhibitions also improve the outcomes of Cy rats, PCK rats, Pkdw $^{WS25/-}$ mice, and Pkd2 $^{flox/-}$ mice.

Congenital Hepatic Fibrosis, Caroli's Syndrome, and Caroli's Disease

CHF, CS, and CD are the most common liver manifestations of ciliopathies in children. Rarely these entities present only with liver involvement, but more often, they are part of syndromic associations which will be described in the next section.

Clinical Features

CHF usually presents between 5 and 7 years of age. Familial cases exist, highlighting the importance of a thorough family history [62–65]. CHF can present in one of four ways [46, 64–66]. First, the most frequent presentation is *portal hypertension* with firm hepatomegaly and splenomegaly [62, 64, 67–69]. Thrombocytopenia and hypersplenism are often present. Occasionally, anemia reveals occult variceal bleeding. The mode of presentation may be an acute gastrointestinal bleed in a previously healthy child. In 30 to 70% of patients that present within the first decade of life, recurrent hematemesis or melena caused by variceal bleeding is frequent, whereas ascites is uncommon [66]. In most patients without an associated syndrome, growth and development are normal. Serum aminotransferase and bilirubin levels are generally within the normal range at diagnosis and remain (near-)normal throughout follow-up. No progression to liver failure has been reported [63]. Complications of portal hypertension such as hepatopulmonary syndrome and portopulmonary hypertension have been described [63, 66].

The second presentation, frequently associated with CD/CS, is *recurrent bacterial cholangitis*. Symptoms include intermittent abdominal pain and pruritus from chronic cholestasis. In this case, serum levels of gamma-glutamyl transferase (GGT), alkaline phosphatase, and bilirubin are elevated. Bacterial cholangitis can progress to septicemia and lead to the development of hepatic abscesses. Recurrent cholangitis may lead to liver failure and failure to thrive in children [66]. Third, patients can present occasionally with *both portal hypertension* and *cholangitis*.

Finally, the disease can be *latent* and revealed by an incidental, clinical, biological, or radiological finding such as hepatomegaly or cytopenias [70–72].

CS/CD can present earlier and later in life. For example, prenatal diagnosis of CS/CD is typically made on the basis of extrahepatic signs of a ciliopathy rather than on the liver alone (Table 60.3) [73–75]. Another mode of presentation is cholangiocarcinoma given the increased risk in the CD/CS population due to bile stasis and chronic inflammation. In the long run, CD and CS are associated with an increased risk of cholangiocarcinoma, thought to be. Cholangiocarcinoma has been reported to occur in 5 to 10% of patients with CD and CS. It has also been reported in patients with isolated CHF, albeit rarely. The average age at appearance is >40 years (range of 33–75 years), and the risk increases with age. It occurs more often in the monolobar form of the disease and has very poor 1-year survival rates [76–79].

Diagnosis

Radiology

Diagnosis should first be suspected on clinical findings. Ultrasonography is a useful, first-line tool for the diagnosis of CHF. Findings are typically heterogeneous liver parenchyma, foci of hyperechogenicity, and images compatible with biliary cysts. The left lobe may appear enlarged and the right lobe atrophic. Splenomegaly and Doppler may be suggestive of portal hypertension and cavernous transformation of the portal vein, although esophagogastroduodenoscopy is the gold standard in the assessment of portal hypertensive complications. Dilatations of the proximal bile ducts and the presence of intrahepatic stones suggest Caroli's syndrome

Table 60.3 Phenotype and epidemiology of ciliopathies. There is no clear genotype-phenotype correlation

[65, 66, 80]. In case of ARPKD, kidneys appear hyperechoic on ultrasound with cysts. Since the risk of ERCP-related complications is high, MR cholangiography (MRCP) is best to evaluate biliary disease using 3D reconstructions (Fig. 60.4). Likewise, MR angiography or CT angiography can further characterize vascular findings. US and MR elastography are increasingly used to evaluate fibrosis especially for ARPDK [81–85].

Histology

Liver biopsy is the gold standard to confirm diagnosis, although not always necessary. CHF is characterized by the presence of persistent ductal plate structures of the interlobular bile ducts. Large bands of fibrous tissues link enlarged portal tracts with mild inflammatory cell infiltrates (Fig. 60.4). Within the fibrous bands, branching small interlobar bile ducts lined by normal, cuboidal epithelium are irregularly dilated and may contain bile. The hepatic parenchyma and architecture between portal tracts and centrilobular veins remain normal. There is hypoplasia of portal vein branches and compensatory increased arterial profiles. Caroli's disease is characterized by saccular or fusiform cystic dilatation of larger and proximal, intrahepatic, and extrahepatic ducts without signs of fibrosis. Caroli's syndrome combines the histological features of CHF and Caroli's disease [6, 62, 64, 65, 67, 69, 86, 87].

Management

Treatment of CHF and CD/CS used to be mostly symptomatic and is mainly directed toward the management of complications, such as recurrent episodes of cholangitis and portal hypertension.

The management of portal hypertension is reviewed elsewhere in this volume. Progress has been made toward a pharmacologic approach of patients with polycystic liver disease, aiming to reduce liver volume and to improve quality of life. Long-acting release (LAR) somatostatin analogues such as lanreotide, pasireotide, and octreotide have proven effective in decreasing liver cyst volume in such patients. However, when treatment was interrupted, liver volume increased again. Furthermore, side effects of somatostatin analogues, especially gastrointestinal symptoms, cholelithiasis, and

liver cyst infection, lead to treatment interruption in a number of patients. Ursodeoxycholic acid does not seem to affect liver volume in patients with polycystic liver disease [88–93].

Intrahepatic cholelithiasis is managed with ursodeoxycholic acid and with endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy. Partial hepatectomy for recurrent cholelithiasis has yielded satisfactory results [94–96]. In the case of monolobar CD, partial hepatectomy has also been shown to prevent recurrent, life-threatening cholangitis, with acceptable morbidity [76, 77, 97].

Liver Replacement

Liver transplantation is the only definite cure for CHF and CD/CS. It is indicated in refractory portal hypertension, severe growth failure, recurrent cholangitis, decompensated cirrhosis, and liver failure.

The short-term and long-term outcome of liver transplantation in patients with CHF and Caroli's disease is satisfactory overall. Outcomes for CD/CS reach the current average outcomes of liver transplantation for other indications [65, 76, 77, 97–100].

In patients with polycystic kidney disease requiring renal transplantation, combined liver and kidney transplantation yields better results compared to kidney transplantation alone. It has been shown that the outcome of patients with PKD mostly depends on the severity of liver disease and that major complications, such as sepsis, are more frequent in patients with advanced liver disease. Combined liver and kidney transplantation seems to be the treatment of choice for these patients, since nephrotoxic drugs for isolated liver transplantation prior to kidney transplantation can accelerate renal demise [66, 101–103].

Targeting Fibrosis

Although the prospect of antifibrotic agents is attractive and may prove life-saving or at least postpone liver transplantation for some indications, there is no data to show an effect on the fibrosis of fibrocystic diseases. Fibrocystic diseases differ from other secondary causes of fibrosis in several ways: (1) destruction of abnormal cholangiocytes triggers an inflammatory cascade and (2) peribiliary fibroblasts rather than contribute to the extracellular matrix deposition. Therefore, no extrapolation can be made from evidence garnered in other causes of cirrhosis.

Ciliopathies and Associated Syndromes

Ciliopathies with a prevalence greater than 1:150000 are described below, and ciliopathies with low prevalence are outlined in Table 60.3 [104–116]. A practical approach to diagnose liver involvement in case of hepatorenal fibrocystic disease is suggested, and the crucial role of genetic testing is highlighted at the end of this section.

Autosomal Recessive Polycystic Kidney Disease (ARPKD)

ARPKD is the most frequent ciliopathy in childhood, affecting in 1:20,000 live births. It is characterized by progressive cystic degeneration of the kidneys and CHF. As its name suggests, transmission is recessive [108, 111]. Eighty percent of patients have mutation in polycystic kidney and hepatic disease 1 (PKHD1) gene. For the rest, a variation of PKHD1 genes (increase of the number of copies or second locus mutations) have been identified. DAZ-interacting zinc finger protein 1-like (DZIP1L) mutation has been reported in moderate ARPKD [112, 114].

Presentation All patients diagnosed with ARPKD have CHF from birth on microscopic examination, but only 50% have hepatomegaly. CD and CS were also described in association with ARPKD. Most of the patients are born with nephromegaly from dilated collecting ducts which can present as a palpable flank mass. Thirty percent of patients die at birth from pulmonary hypoplasia (Potter's syndrome). There is a marked variability of phenotypes even among siblings [113].

Renal Disease The course and the severity of renal disease and liver disease are unrelated. In the infant or neonate, presentation is usually renal, while CHF is typically asymptomatic early in life. Renal disease can present as a simple urinary concentration defect or more often as severe cystic kidney disease leading to hypertension and renal failure. End-stage renal disease affects about 30% of children under 10 years. For neonates surviving the first month of life, the 5-year survival rate is about 90%. Most patients presenting as neonates will require kidney transplantation before 20 years of age.

Liver Disease Improvement in the management of renal complications has led to an increased awareness of the liver-related morbidity and mortality due to CHF. In addition to liver and kidney disease, intracranial and splenic aneurysms have been

described, as has cardiac involvement [117, 118]. Diagnosis and management of liver disease are described before (Section Management) (Sect. 5 [115] and Sect. 6 [117–130].

Autosomal Dominant Polycystic Kidney Disease (ADPKD)

Across all age groups, the most common hepatorenal fibrocystic disease is ADPKD, with an incidence of 1:1000. Liver involvement usually presents as polycystic liver disease, while CHF and CD or CS are rarely described. As its name suggests, transmission is dominant. The most common mutations are PKHD1 and polycystic kidney and hepatic disease 2 (PKHD2). All other mutations are related to the function of polycystin-1 [122, 123]. Kidney cysts develop progressively from the whole tubule. Onset is slow such that diagnosis is usually made in adulthood, with young women being the most severely affected [124, 125]. Other organs may also develop cysts: pancreas, intestinal epithelium, arachnoid mater, and seminal vesicles. Cardiac valvular disease and cerebral aneurysms have also been described. Affected patients are usually asymptomatic in childhood. On occasion, an incidental finding of cysts in the fetus, young child, or adolescent can lead to the misleading suspicion of ARPKD. Most often, in childhood, the incidental finding of a cyst should orient toward ADPKD, especially if hypertension is present. Some very rare cases of end-stage renal disease are described in childhood [131–134].

Nephronophthisis

Nephronophthisis is the most frequent genetic cause of end-stage kidney disease in children and may be associated with liver disease. Nephronophthisis is classified according to age at presentation: infantile, juvenile, and adolescent. In all cases renal involvement leads to end-stage renal disease requiring kidney transplantation. Most commonly, it is the adolescent form caused by mutations in nephrocystin 3 gene (NPHP3) which presents with liver disease characterized by bile duct proliferation and portal fibrosis [134–137]. This characteristic histology should encourage clinicians to search for NPHP3 mutations and examine renal function. Tapetoretinal abnormalities constitute another sign favoring the diagnosis [138]. Mutations in eight other genes have been identified in the adolescent and juvenile form nephrocystin 1,3–8 (NPHP1, NPHP3–NPHP8) but have not been associated with liver abnormalities except for an occasional biochemical abnormality. In NPHP2 and NPHP3, both presenting in infancy, liver involvement varies from mild to CHF [139–142].

Meckel Gruber Syndrome

Meckel syndrome is a rare autosomal recessive lethal ciliopathy composed of four cardinal features: occipital encephalocele, bilateral cystic kidneys, CHF (100%), and polydactyly. The incidence is 1:140,000 and is increased in the Finnish population (1:1000) [143–146].

Joubert and Coach Syndromes

Joubert syndrome (JS) is a recessive disorder with occurrence of 1:100,000 and characterized by brainstem and cerebellar malformation, ataxia, developmental impairment, alternance of hyperpnea and hypopnea, abnormal eye and tongue movements, and hypotonia and by an array of neurological, retinal, renal, or skeletal anomalies. The key feature of JS is molar tooth sign (cerebellar peduncles and deep interpeduncular fossa on cerebral MRI). The most frequent liver abnormality associated with JS is CHF and elevated serum aminotransferase levels. Cholangitis is very rare. Mutation in the transmembrane 67 (TMEM67) gene is strongly associated with liver involvement.

COACH syndrome includes *c*erebellar vermis hypo/aplasia, *o*ligophrenia, *a*taxia, *c*oloboma, and *h*epatic fibrosis. This very rare syndrome combines the presence of CHF and the classical neurologic signs of JS. Mutations in transmembrane protein meckelin (MKS3), a centriole protein necessary for ciliary function and for primary cilium formation, are present in more than 50% of COACH syndrome cases and are uncommon in JS patient without liver involvement [147–152].

Practical Approach

All patients with known cystic renal disease should be evaluated for liver involvement. Liver fibrosis begins early in life in patients with ARPKD and ADPKD. In the absence of signs or symptoms, it is not recommended to perform a liver biopsy. Portal hypertension should be sought at each visit. Annual liver function tests and annual liver ultrasonography are recommended. An MR cholangiogram should be performed once to understand biliary morphology, even when there are no significant findings on US. Although liver biopsy is the gold standard for diagnosis, it is not always indicated if it does not immediately alter management. Conversely, since the association between renal and liver diseases is so frequent, all patients diagnosed with CHF or CD/CS should be evaluated for renal cystic disease. Screening for malignant transformation is not indicated in children, because onset occurs generally in the fifth decade. Improved management of children with chronic liver disease means that more

patients with fibrocystic liver diseases are reaching adulthood with their native livers and therefore that adult gastroenterologists will be the ones to diagnose malignancy in these patients [153].

Genetics

Genetic testing is recommended for diagnosis, management, and prognosis [154]. If the clinical picture is suggestive of a given phenotype and the differential diagnosis narrow, known candidate genes can be tested to provide a definitive diagnosis, and genetic counseling should be offered to patients and relatives. Some associations between gene mutation and ciliopathies are strong as described in Table 60.3. But it can happen that the mutated gene does not correspond to the described phenotype of the ciliopathy. Indeed, there is phenotypic overlap across genotypes, something highlighted in Table 60.3. When the differential diagnosis is broader, casting a wider net to identify the ciliopathy is easily achievable through next-generation sequencing (NGS). Given the complexity of these analyses and the inherent difficulty of interpretation, clinical genetic expertise is advisable. According to the identified variant and the specific mode of inheritance, familial segregation analysis may be indicated.

Conclusion and Future Perspectives

Ciliopathies often present with liver disease due to associated ductal plate malformation. Associated renal disease is frequent and should be sought. Liver involvement must be recognized as it may progress to life-threatening complications (portal hypertension or cholangitis) and possibly warrant liver transplantation. An increasing number of disease causing mutations are identified, and sequencing is part of the diagnostic workup of these diseases. However, there is no clear genotype-phenotype correlation. In particular, it is unclear why some ciliopathies present with distal DPM, while others show abnormalities of the large, proximal bile ducts.

Acknowledgments We gratefully acknowledge Mrs. Sylvia Udry-Moulin and Dr. Véronique Raies-Dauve for their helpful assistance with the illustrations, Dr. Anooshiravani-Dumont for providing illustrative imaging, and Dr. Rougemont for sharing examples of histology.

Disclosure of Interest The authors declare that they have no conflicts of interest.

Familial Intrahepatic Cholestasis

61

Tassos Grammatikopoulos

Abbreviations

BSEP	Bile salt export pump
CLDN1	Claudin-1
CLDN2	Claudin-2
FHC	Familial hypercholanaemia
FIC	Familial intrahepatic cholestasis syndrome
FXR	Farnesoid X-activated receptor
GGT	Gamma-glutamyltransferase
HCC	Hepatocellular carcinoma
IE	Ileal exclusion
LT	Liver transplantation
MDR3	Multidrug resistance protein 3
MYO5B	Myosin 5B
PEBD	Partial external biliary diversion
SPAD	Single pass albumin dialysis
TJP2	Tight junction protein 2
UDCA	Ursodeoxycholic acid
USP53	Ubiquitin-specific peptidase 53
ZO	Zona occludens

Introduction

Two main mechanisms of cholestasis have been so far identified, which can be either hepatocellular or obstructive in origin affecting the biliary structures. Hepatocellular cholestasis is considered to be due to alterations in bile formation and transportation of bile salts and other components of bile at the cellular level involving multiple mechanisms. Obstructive cholestasis on the other hand is due to bile duct injury either at extra- and/or intrahepatic level.

To date, seven major types of familial intrahepatic cholestasis have been identified, associated with mutations in genes encoding proteins involved in the hepatocellular transport and structure. These are FIC1 deficiency, bile salt export pump (BSEP) deficiency, multidrug resistance protein 3 (MDR3) deficiency, tight junction protein 2 (TJP2) deficiency, farnesoid X-activated receptor (FXR) disease, myosin 5B (MYO5B) disease and ubiquitin-specific protease 53 (USP53)-associated liver disease. The inheritance pattern in each case is autosomal recessive. Presentation is usually within the first year of life for the more severe forms either in a recurrent, such as FIC1 and MYO5B, or progressive form such as BSEP, TJP2 and MDR3 deficiency. Irregularities in bile formation and transportation can lead to disturbance in the enterohepatic circulation with bile salt retention and cholestasis. Cholestatic syndromes can affect solely the liver but also can have multi-organ involvement (Table 61.1).

FIC1 Deficiency

Familial intrahepatic cholestasis protein 1 (FIC1) deficiency is an autosomal recessive condition with a wide phenotypic spectrum extending from mild recurrent to severe liver disease. FIC1 deficiency was initially called Byler's disease, after the Amish family in which it was first described. Furthermore, the term Byler's bile has been used as the description of coarsely granular canalicular bile seen in FIC1 deficiency on transmission electron microscopy.

It is characterised by hepatocellular cholestasis with low serum levels of γ-glutamyltransferase (GGT) activity and normal cholesterol levels. Presentation can be early on in life with recurrent cholestatic episodes and eventually progress to cirrhosis [1, 2]. Less severe disease can however present in adulthood. Presenting features consist of cholestasis, low serum albumin, epistaxis and splenomegaly.

Table 61.1 Seven major types of familial cholestatic syndromes with respective organ involvement and disease severity

Disease name	Aliases	Gene	Protein	Features
FIC1 deficiency	Byler's disease, PFIC1	*ATP8B1*	FIC1	Multisystem disorder Wide range of severity
BSEP deficiency	Byler's syndrome, PFIC2	*ABCB11*	BSEP	Liver only affected Spectrum of severity
MDR3 deficiency	PFIC3	*ABCB4*	MDR3	Liver only affected Wide range of severity
TJP2 deficiency	PFIC4	*TJP2*	TJP2	Multisystem disorder Wide range of severity
FXR liver disease	Farnesoid X-activated receptor associated liver disease PFIC5	*NR1H4*	FXR	Rapid-onset progressive liver disease
MYO5B liver disease	PFIC6	*MYO5B*	MYO5B	GI and liver disease Variable range of severity
USP53-associated liver disease	PFIC7	*USP53*	USP53	Multisystem disorder Mild disease severity

FIC1 is the protein encoded by the gene *ATP8B1* [3–5], which is located at chromosome 18q21-q22. FIC1 (or ATP8B1) is a P-type ATPase, which is one of several aminophospholipid flippases present in different membranes. Its role in the liver, largely based on a mouse model, is in maintaining the gradient of phosphatidylethanolamine and phosphatidylserine towards the inner leaflet of the cell membrane. A transmembrane balance of lipids appears to be required in the presence of the high bile salt concentration in the canaliculus [6]. The normal canalicular membrane requires a high degree of detergent resistance in order to prevent damage from the detergent effect of bile itself. Paulusma et al. showed that by ex vivo infusion of bile acids in the knockout mouse, the extraction of aminophospholipids was greatly increased. In the human liver, several proteins are not present, or are in reduced quantities, in the canalicular membrane of patients with FIC1 deficiency. This observation still does not account for the cholestasis, as no transporter critical to bile formation has been identified to be absent. It appears more likely that these proteins are malfunctioning in an altered lipid environment of the canalicular membrane. As FIC1 deficiency is primarily characterised by cholestasis, studies have attributed this phenotype to a defective farnesoid X-activated receptor (FXR) signalling pathway [7, 8]. Other groups however suggested that impaired FXR activity is secondary to cholestasis and not responsible for the phenotype [9]. The activity of FXR and its target genes remained uninterrupted in FIC1-depleted Caco-2 cells, created using small hairpin RNA and small interfering RNA, respectively, suggestive of an unimpaired FXR signalling mechanism in FIC1-deficient patients [10, 11]. In view of a proportion of phenotypically FIC1-like patients in whom no mutations were identified, a study looked into promoter and 5′ untranslated (5′-UTR) regions affecting gene regulation in human liver and small intestine tissue by 5′ rapid amplification of cDNA ends. Expression levels of *ATP8B1* transcripts were determined by quantitative reverse-transcription PCR and compared with the non-variable part of *ATP8B1*. Twelve different splicing variants and four novel untranslated exons located up to 71 kb upstream of the previously published exon 1 were identified in both tissue types. A number of transcription start sites were identified, and the proximal promoter upstream of the major transcription start sites was also proven to be an essential regulatory element responsible for 70% of total *ATP8B1* transcriptional activity. In vitro the main promoter was shown to drive constitutive *ATP8B1* gene expression independent of bile acids [12].

Altered gene expression demonstrated in extrahepatic sites may be contributory to the multisystemic nature of this cholestatic syndrome. Other disease features include diarrhoea, malabsorption of fat-soluble vitamins, hearing loss, pancreatitis, renal tubular acidosis, delayed puberty and growth failure. The multisystem nature of the disease is supported by the widespread expression of the *ATP8B1* gene including the liver, pancreas, kidney and more widely in the small intestine [5].

Liver histology changes consist of cholestasis with bile plugs and periportal biliary metaplasia of hepatocytes in the absence of ductular proliferation in the portal tracks (Figs. 61.1, 61.2, and 61.3).

Early-onset patients, without treatment, usually progress to end-stage liver disease by early adulthood. The first-line treatment includes antipruritic agents such as ursodeoxycholic acid (UDCA) [13], fat-soluble vitamin supplementation and nutritional support. Failure of medical treatment would lead to the first-line surgical treatment, which is currently partial external biliary diversion (PEBD), a technique that diverts an unknown proportion of bile externally. The consequences of this procedure certainly include interruption of the enterohepatic circulation of bile acids [14–17]. An external stoma can also be formed by using the appendix creating a cholecystoappendicectomy as reported by Rebhandl et al. [18]. Another alternative is ileal exclusion (IE), which has also been performed in cases with previous cholecystectomy or as rescue treatment [2, 15, 19, 20].

Liver transplantation (LT) is the next treatment option for these patients [16], but some extrahepatic symptoms will not

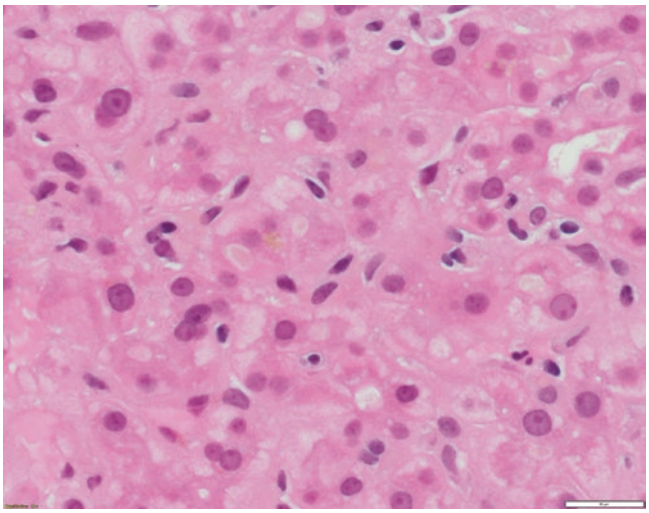

Fig. 61.1 Liver biopsy from a 20-year-old patient with ATP8B1 disease/FIC1. Hepatocytes are small and without anisocytosis. There is canalicular cholestasis. Of note, there is pale staining bile within the canaliculi. [H&E ×400 magnification]

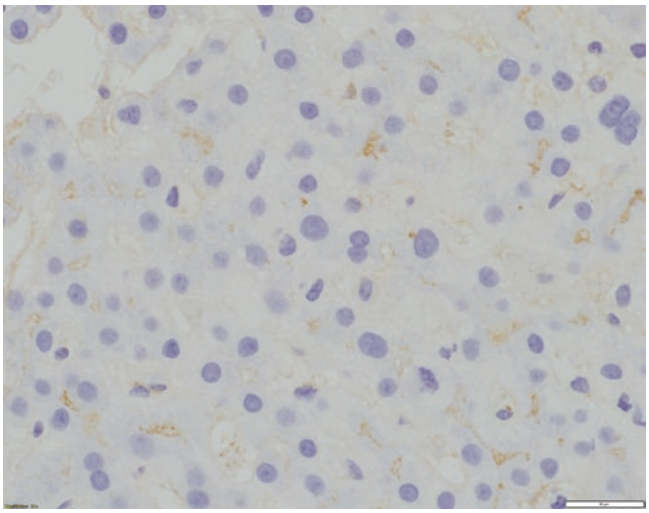

Fig. 61.2 Absence of canalicular GGT expression. ×400 magnification

improve, such as growth, and some may even become aggravated, such as diarrhoea [14], liver steatosis or kidney disease. Some of these patients may end up requiring multi-organ transplantation including liver, small bowel, kidney and pancreas (personal data).

BSEP Deficiency

The major bile salt transporter of the canalicular membrane level is the BSEP, which is encoded by the gene *ABCB11* [21]. The clinical condition associated with bile salt transport deficiency was previously known as "Byler's syndrome". The phenotype of BSEP-deficient patients can also vary from a mild

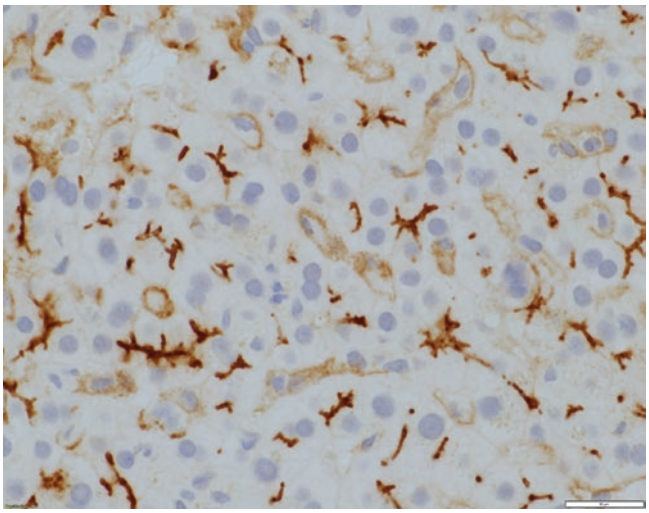

Fig. 61.3 Evident canalicular expression of CD10 [×400 magnification]

(BRIC) to a more severe type requiring liver transplantation [22–24]. *ABCB11*, expressed only in the liver, encodes BSEP, a member of the ATP-binding cassette (ABC) family of transporters responsible for the transport of bile acids across the canalicular membrane. The locus for *ABCB11* is at chromosome 2q24 with the most common European mutations being D482G (c.1445A > G) and E297G (c.890A > G) [21, 23]. BSEP deficiency leads to accumulation of bile salts within hepatocytes and has a subsequent effect on hepatocellular function. As anticipated, it has also been shown to have significant affinity for some of the main bile salts in human bile, such as glycocholate, taurocholate and chenodeoxycholate [25].

Severe BSEP deficiency presents within the first year of life, and, although variable, it is usually a non-relapsing severe progressive cholestasis and pruritus leading to fibrosis. Birth weight can be below normal range especially in the non-D482G > E patients [22]. Serum bilirubin levels are not necessarily reflective of the degree of cholestasis as bilirubin is transported separately from bile salts. Like FIC1 deficiency, BSEP-deficient patients demonstrate low γ-glutamyltransferase (GGT) activity but with a trend to higher cholesterol, significantly raised transaminases (>threefold higher compared to FIC1 deficiency), alpha-fetoprotein and serum bile acid concentrations. Other biochemical indices include fat-soluble vitamin deficiencies manifesting with coagulopathy and rickets. Gallstones have been reported in up to 32% of patients [22]. Serum bile acid profiles demonstrate a high cholic acid-to-chenodeoxycholic acid ratio as reported in FIC1 patients. Reduced biliary bile salt concentration in BSEP patients is similar to that in PFIC1 and in direct contrast to MDR3 deficiency patients [3, 26, 27].

Severe phenotypes have been associated with mutations leading to protein truncation or failure of protein production.

In a series by Strautnieks et al., missense mutations were identified in 79% of patients, many affecting protein processing and trafficking or protein structure [28]. Previous reports of *ABCB11* missense mutations and single nucleotide polymorphisms showed pre-mRNA splicing subsequently causing reduction in mRNA levels in a significant number of cases. These defects at the protein or mRNA level can have a detrimental impact in BSEP function [28].

Liver histology features consist of increased lobular inflammation and portal fibrosis, giant cell transformation of hepatocytes and neonatal hepatitis with finely filamentous bile. The absence of liver immunohistochemistry for BSEP can assist in the diagnostic process [23, 29] (Fig. 61.4). Immunohistochemically detectable BSEP expression does not exclude functional BSEP deficiency [30]. In a previous series, 28% of BSEP patients analysed exhibited some degree of BSEP staining, and in a small minority expression was even considered normal [23].

Hepatocellular carcinoma (HCC) or cholangiocarcinoma has been reported in a number of children on the background of severe neonatal hepatitis [31, 32] or proven BSEP deficiency [23, 32]. The risk appears to be higher in patients with two protein-truncating mutations (38% vs. 10%) compared to other genotypes. The exact mechanism of malignancy remains unclear, though further insight to the development of these tumours has been gained recently [33].

Treatment options for BSEP deficiency include antipruritic agents such as UDCA, rifampicin, liver enzyme inducers (phenobarbitone), nutritional support and fat-soluble vitamin supplementation, where indicated. Partial external biliary diversion, ileal exclusion and liver transplantation are all recommended surgical treatment options [16, 20, 34, 35]. Hepatocellular malignancy remains an indication for early liver transplantation in BSEP patients. Patients with biallelic truncating mutations warrant close monitoring with liver ultrasonography and serum alpha-fetoprotein levels. Overall, in terms of prognosis, patients with D482G mutation developed portal hypertension less frequently, developed fibrosis at an older age and underwent liver transplantation at an older age as well [22].

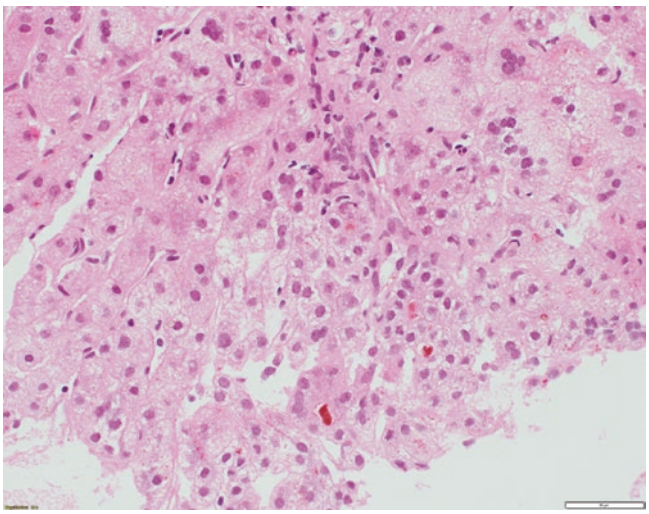

Fig. 61.4 Liver biopsy from a 7-month-old patient with ABCB11 disease/BSEP deficiency. There is bridging fibrosis and partial nodular transformation of the parenchyma (not shown). Hepatocytes show giant cell change and canalicular cholestasis. Lobular inflammation is present. BSEP immunostaining shows the absence of canalicular expression, whilst canalicular GGT expression is preserved (not shown) [H&E stained slide at ×200 magnification]

Recurrence of symptoms after LT has been described in BSEP-deficient patients, in contrast to other FIC syndromes. Jara et al. reported recurrence of cholestasis and pruritus following LT in BSEP patients with no evidence of cellular rejection on liver biopsy in 2009 [36]. In the same year, BSEP antibodies in the serum and at the hepatocyte canalicular membrane of a single patient who underwent two liver transplants were described [37]. The mechanism of action is thought to be that anti-BSEP antibodies form, which bind to an epitope in the intracanalicular domain of BSEP and subsequently block the function of the bile acid transporter. A multicentre series of six patients with recurrence of disease [38] was reported in 2010. In all of these patients, treatment was extremely problematic, four underwent a repeat LT and various management protocols were suggested. All reports have identified mutations (splice site, missense, truncating) leading to the absence of BSEP protein expression on immunostaining. Modifications in immunosuppression, plasmapheresis, intravenous immunoglobulin courses and single pass albumin dialysis were used in isolation or jointly with limited effect on patients' symptoms. Following the identification of BSEP antibodies in post-LT BSEP deficiency patients with cholestasis in the absence of rejection, an antibody-based treatment was suggested as potentially beneficial. Two cases of patients with BSEP deficiency that, following LT, had demonstrated evidence of functional BSEP deficiency treated successfully with two repeated 4-week courses of anti-CD20 monoclonal antibodies were subsequently reported [39, 40].

TJP2 Deficiency

Since in one third of patients with normal-GGT cholestasis mutations in either *ABCB11* or *ATP8B1* have not been identified [26], a cohort of 33 cholestatic children with relatively low serum GGT levels were studied recently by Sambrotta et al. [41]. From eight consanguineous families with novel protein-truncating mutations in the tight junction protein-2 gene (*TJP2*), located in chromosome 9q21.11, 12 patients were identified. The phenotype of these patients consists of early presentation within the first couple of months of life with low serum GGT, and nine of

them underwent liver transplantation by their first decade of life. Patients can develop portal hypertension, persistent pruritus and malabsorption. A single patient died at 13 months. Liver immunohistochemical findings consist of lack of TJP2 and reduced staining of claudin-1 (CLDN1) with normal distribution of claudin-2 (CLDN2), both proteins essential to cellular tight junctions (Figs. 61.5, 61.6, and 61.7). On transmission electron microscopy, elongation of the tight junctions with sparsity of the zona occludens (ZO) is also seen. Extrahepatic involvement is present in some cases and consists of chronic respiratory disease or neurological complications such as subdural haematomas. Mutations in the *TJP2* gene have been previously associated with familial hypercholanaemia (FHC), a nonprogressive cholestatic disorder, described in the Amish population [42]. In that report, out of all 17 individuals with FHC screened, 11 patients in eight families were found homozygous for an incompletely penetrant missense mutation in *TJP2,* with alterations in the cellular bile acid concentration gradient. Mutations in the *TJP2* gene are also known to cause intrahepatic cholestasis of pregnancy (ICP) [43], BRIC [44], cirrhosis in adults and hepatocellular carcinoma [43, 45, 46] and deafness [47, 48].

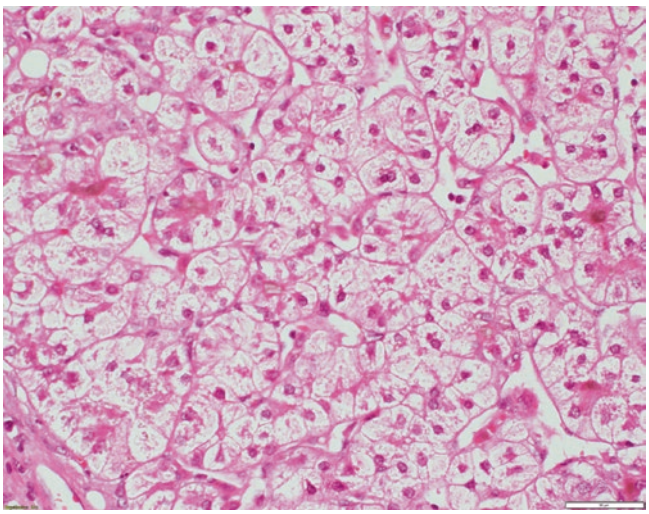

Fig. 61.5 Liver biopsy from a 4-year-old patient with TJP2 disease. There is extensive bridging fibrosis (not shown). Hepatocytes are oedematous and show rosetting. Canalicular cholestasis is present. [H&E ×200 magnification]

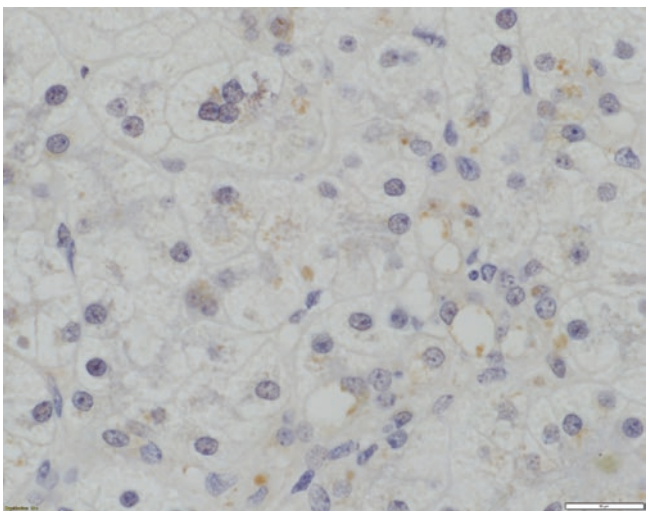

Fig. 61.6 Absence of canalicular TJP2 expression. [×400 magnification]

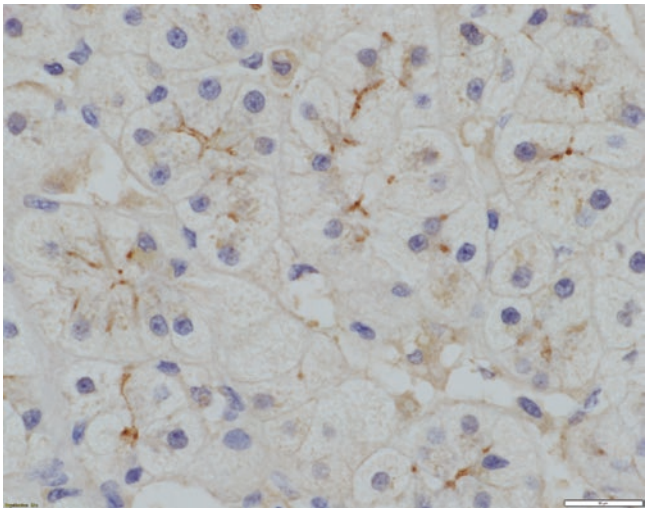

Fig. 61.7 With expression of canalicular BSEP [×400 magnification]

Treatment consists of supportive choleretic agents, fat-soluble vitamin supplementation, nutritional support, partial external biliary diversion (PEBD) and subsequently liver transplantation. No liver malignancy has been so far described in this newly defined PFIC group.

MDR3 Deficiency

This type of FIC is caused by a variety of mutations in the ATP-binding cassette subfamily B member 4 (*ABCB4*), the gene encoding multidrug resistance protein 3 (MDR3) [49]. It is also inherited in an autosomal recessive pattern. *ABCB4* has been mapped to the 7q21-36 region, and it codes for a floppase responsible for phosphatidylcholine [50] translocation across the canalicular membrane. Defective PC translocation leads to a lack of PC in bile. The absence of PC inhibits the chaperoning of bile acids through micelle formation, leading to damage to the biliary epithelium and cholangiopathy. Biliary phospholipid levels are significantly reduced, and biliary bile salt-to-phospholipid and cholesterol-to-phospholipid ratios are significantly higher in affected individuals when compared with wild-type bile [51].

MDR3 deficiency causes a spectrum of liver diseases such as cholesterol cholelithiasis, adult biliary cirrhosis, low-phospholipid-associated cholelithiasis syndrome (LPAC), transient neonatal cholestasis, intrahepatic cholestasis of pregnancy (ICP) and drug-induced cholestasis [52–58]. In severe MDR3 deficiency, symptoms can manifest within the first year, but not usually as neonatal jaundice, and gradually progress towards liver cirrhosis and end-stage liver disease within the first few years of life [1, 59, 60]. Patients with a single affected copy of the gene can develop symptoms under particular circumstances, such as pregnancy, whilst otherwise they may remain asymptomatic [61, 62].

Liver histology demonstrates expansion of portal tracts, bile duct proliferation, bile plugs and portal fibrosis with mixed inflammatory infiltrate (Fig. 61.8). Cytokeratin immunostaining can be confirmatory of the ductular proliferation, and MDR3 immunohistochemistry can be absent or markedly reduced at the canalicular membrane in affected individuals [63].

MDR3 deficiency is differentiated from the other three FIC types at a biochemical level by an elevated serum of γ-glutamyltransferase (GGT). Biochemical profile also consists of normal serum cholesterol and moderately raised concentration of serum primary bile salts [27].

The first-line management, as in the other FIC types, is with UDCA and other antipruritic and choleretic agents. UDCA seems to be very effective in milder cases, and it may also prevent disease progression in these cases. Liver transplantation remains the treatment of choice for the nonresponders.

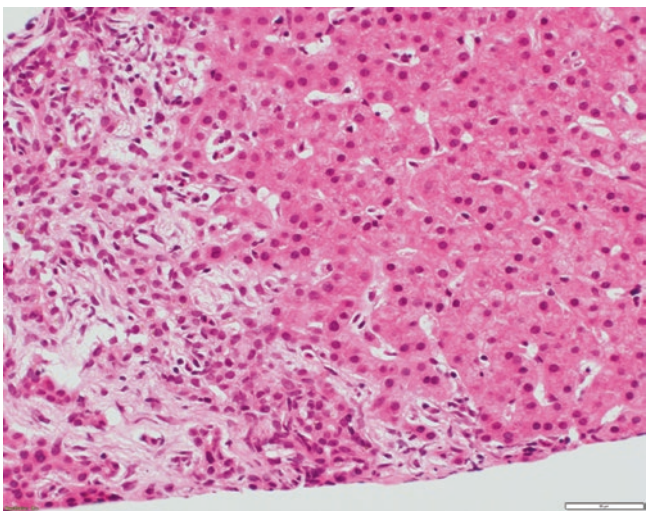

Fig. 61.8 Liver biopsy from a 1-year-old child with MDR3 deficiency/ABCB4 disease. There is a cholangiopathy manifested by cholangiocyte disarray and vacuolation. Immunohistochemistry demonstrated an absence of canalicular MDR3 expression (not shown) [H&E ×200 magnification]

Farnesoid X-activated receptor

Another molecule regulating bile acid homeostasis is the farnesoid X-activated receptor (FXR). FXR belongs to a subclass of metabolic receptors within the intracellular ligand-activated nuclear receptor (NR). FXR is encoded by the nuclear receptor subfamily 1, group H, member 4 *(NR1H4)* gene, located in chromosome 12q23.1 [64, 65]. Bile acids are ligands for the nuclear hormone receptor FXR, which together with its heterodimeric partner, the RXR, acts as a transcription factor for several bile salt transporters, including the hepatic BSEP and the ileal bile acid binding protein (I-BABP) [66, 67]. The expression of short heterodimeric protein (SHP)-1 in the liver, which acts as a transcriptional repressor, is itself regulated by FXR and can downregulate the expression of several genes including Ntcp and cholesterol-7a-hydroxylase CYP7A1, which is a rate-limiting enzyme in bile salt synthesis [68]. Conversion of cholesterol to bile salts by CYP7A1 is stimulated by the oxysterol-activated liver X receptor (LXR). Bile salts have a negative effect on their synthesis by activation of the FXR-dependent short heterodimeric protein 1 (SHP-1), which in turn suppresses *CYP7A1* and 8B1 transcription. The activation of FXR by bile salt production stimulates the transcription of Mrp2, Bsep and OATP8 [69, 70]. Bile salt synthesis is also regulated by a feedback mechanism between FXR and other nuclear receptors including RXR, LXR and LRH-1.

FXR is expressed in the liver, intestine and kidney, and its activation has been shown to be activated by both conjugated and free bile salts such as chenodeoxycholate, deoxycholate, lithocholate and cholate [67]. There are similarities in the activation of FXR by bile salts in hepatocytes and terminal ileum enterocytes which in essence controls the entire enterohepatic circulation of bile salts [71]. The presence of bile salts in the terminal ileum activates FXR which reduces bile salt uptake and promotes their secretion via the basolateral membrane reducing the intracellular concentration and increasing their excretion via the faecal route [72, 73]. FXR has been shown to activate an endocrine feedback mechanism via the fibroblast growth factor 19 (FGF19). FGF19 is secreted from the ileum to the portal venous system whereby once it reaches the liver it supresses bile salt production by activation of the FGF receptor 4 [74]. FGF19 can also activate hepatic glycogen synthesis and inhibits gluconeogenesis [75, 76].

Gomez-Ospina et al. reported the first small series of four individual patients from two unrelated families with homozygous loss-of-function variants in *NR1H4* [65]. All patients presented at a very early age. Three presented with neonatal cholestasis and one presented with ascites, pleural effusions and intraventricular haemorrhage at birth. At the time of initial evaluation, all patients had conjugated hyperbilirubinemia, raised liver transaminases, low-to-normal GGT activity

and refractory to vitamin K coagulopathy. Two patients underwent successfully LT, one died on the waiting list for LT and another patient died at 5 weeks of age from an acute vascular event. Chen et al. identified one patient with a single heterozygous nonsense variant in *NR1H4* from a large cohort of children with early-onset normal GGT activity cholestasis [64]. Their patient underwent biliary surgery and T-tube drainage for refractory to medical treatment cholestasis with minimal effect. Subsequently, this case developed cirrhosis and ascites. So far, the phenotype of patients affected with FXR-associated liver disease seems of early-onset cholestasis leading to cirrhosis and LT.

Liver histology can show ductular reaction, giant cell transformation with hepatocyte ballooning and intralobular cholestasis. Biopsy material from explanted livers had features of micronodular cirrhosis and fibrosis. Liver immunohistochemistry showed lack of canalicular BSEP expression with preservation of MDR3.

More recently, FXR agonists, such as the bile salt derivative obeticholic acid, have been shown to improve alkaline phosphatase (ALP), a disease marker in primary biliary cirrhosis [77, 78], but with minimal effect on pruritus. In recent years, there have been studies suggestive of FXR's potential therapeutic role also in lipid and glucose metabolism [79, 80], immunomodulation in inflammatory bowel disease [81, 82] and colorectal cancer [83].

Further reports are required to expand our knowledge of the disease, understand genotype-phenotype associations and investigate potential therapeutic options.

Myosin 5B Cholestasis

MYO5B is a motor protein-mediating membrane transport and recycling in polarised cells, found in all epithelia [84] and encoded by the gene *MYO5B,* located in 18q21.1. MYO5B binds selected small guanosine triphosphatase (GTPase) rab proteins, including the trans-Golgi network (TGN)-associated and the recycling endosome-associated rab11a and rab8, and has been implicated in protein trafficking across the apical plasma membrane [85].

Functional deficiency or loss of MYO5B results in aberrant cell polarity and is the major cause of microvillus inclusion disease (MVID), an autosomal recessive disorder causing watery diarrhoea presenting in early infancy that requires parenteral nutrition. The condition can also lead to intestinal failure and small bowel transplantation [86, 87]. Loss of the motor function causes the formation of inclusions and retention in brush border enzymes that lead to early-onset watery diarrhoea and failure to thrive [88].

Cholestasis when reported in patients with MVID is often considered identical to the typical intestinal failure-associated liver disease phenotype. More recently though, there has been a clearer distinction in this type of cholestatic syndrome, now called MVID-associated cholestasis [89, 90]. Recent evidence shows that the effects of mutations on *MYO5B* (OMIM 606540) are not limited to the small intestine but can also involve other organs such as the stomach, colon, pancreas and more importantly the liver [84]. Interestingly, a small group of children can present with MVID-like disease, but although they recover from their gastrointestinal disease with histologically normal small intestine, they suffer from recurrent cholestasis and troublesome pruritus [91].

Patients can present with cholestasis and pruritus at an early age but some at a much later stage. The biochemical profile is that of low GGT activity with preserved synthetic function and evidence of cholestasis with raised bilirubin or serum bile acids and limited parenchymal inflammation (AST/ALT) and gallstones. The difference in the disease phenotype between MVID- and MYO5B-associated cholestasis has not been yet clearly defined though, and further functional studies are required.

It has been recognised that deficiency of MYO5B impairs the BSEP in the canalicular membrane contributing to cholestasis [92]. BSEP is a liver-specific transporter and crucial to bile acid transport at the canalicular membrane [93]. An alternative mechanism for the cholestasis in these patients has also been attributed to impairment of MYO5B/RAB11A interaction [92, 94, 95]. The degree of jaundice or cholestasis can be variable amongst patients with MYO5B-associated cholestasis but somewhat comparable to other low-GGT cholestatic syndromes such as FIC1 and BSEP deficiency [5, 96]. There are often clinical similarities between their MYO5B cohort and patients with other low-/normal-GGT cholestatic syndromes but also differences in their histological/immunostaining findings. Liver histology findings are those of mild and nonspecific portal inflammation with minimal, focal lobular cholestasis and fibrosis. BSEP expression has been variable amongst different case series from preserved and localised to the canalicular membrane to distortion with low GGT expression mainly identified in periportal areas [94].

Croft et al. reported a unique case, where the patient presented with severe gastrointestinal symptoms, typical of MVID, which resolved over childhood. The GI histology showed MYO5B expression at the microvillus brush border, and ultrastructural studies confirmed the absence of microvillus inclusions, with intact normal-sized microvilli in the brush border [91, 96]. This case subsequently developed cholestasis and pruritus. Perry et al. reported some atypical cases of MVID in whom one patient had transient intestinal failure but was on full enteral feeds at time of reporting [97]. Both these reports highlight the clinical diversity of GI involvement in patients with MYO5B cholestasis in whom a convincing pathophysiologic explanation remains to be established.

The clinical progression of the disease demonstrates a variable response to medicinal antipruritic agents and surgical interventions. Some centres reported good response to medicinal agents (bile acid modifiers); others explored the potential role of surgical interruption of the enterohepatic circulation (external or internal biliary diversion) and nasobiliary drainage with limited effect on pruritus and quality of life and a minority progress to LT [98–100]. The clinical progression of the disease demonstrates a variable response to medicinal antipruritic agents (UDCA, cholestyramine, rifampicin, naltrexone, chlorphenamine) and surgical interventions. Some patients require biliary diversion with limited effect on pruritus and quality of life, but only two reported cases so far progressed to LT. Despite the various treatment modalities, patients do not become completely asymptomatic. Clinical trials currently underway in other cholestatic conditions interfering with the bile acid homeostasis may have a beneficial effect on children with *MYO5B*-associated cholestasis.

The long-term prognosis of patients with *MYO5B*-associated liver disease should be addressed with caution on the basis of the uncertainty whether these patients will remain free of GI symptoms in the future and their liver disease outcome in adulthood.

Ubiquitin-Specific Peptidase 53-Associated Liver Disease

In the last 2 years, another type of progressive familial intrahepatic cholestasis with normal GGT has been described in association with variants in the ubiquitin-specific peptidase 53 gene [101–104]. To date, there have been three case series reported describing a limited number of patients with *USP53*-related cholestasis.

The *USP53* gene, located in chromosome 4q26, encodes a non-protease protein homologue of the ubiquitin-specific peptidase family [105] important for the regulation of protein degradation, but due to lack of a histidine residue, this function is lost [106]. The USP53 protein is expressed in the kidney, inner ear, liver and brain. USP53, a tight junction (TJ) protein, co-localises and interacts at the cellular TJs with other tight junction proteins 1 and 2 (TJP1 and TJP2). In a mouse model, Usp53 is interacting with TJs and more specifically with TJP2. The missense variant c.682T > A; p.Cys288Ser seems though to not alter the co-localisation with TJP2, and it has been reported to cause progressive hearing loss [107].

The biallelic variants described so far include mostly homozygous or compound heterozygous forms with variations though amongst reports. Bull et al. and Alhebbi et al. reported in all but one homozygous changes in *USP53* variants causing loss of function unlike the series by Zhang et al. where all cases were compound heterozygous in variants causing either nonsense, frameshifting, canonical splicing or missense changes. In view of the limited cases reported, it remains challenging to extract meaningful phenotype-genotype associations and more so about the long-term prognosis.

Clinical presentation can include relapsing normal-GGT cholestasis varying from early infancy to adolescence, pruritus and signs of fat-soluble vitamin deficiency such as hypocalcaemia, tetany and intracranial bleeding due to vitamin D and K deficiency, respectively. Hypertrophic cardiomyopathy, heart failure, hypothyroidism, unilateral kidney enlargement, developmental/speech delay and hearing loss requiring cochlear implants have also been reported. The biochemical profile of patients with *USP53*-associated liver disease consists of high serum bilirubin and ALP, mildly elevated ALT/AST and normal GGT [101–104].

Liver histopathology shows hepatocyte giant cell changes, canalicular and hepatocellular cholestasis with mild lobular activity and in a single case [101] cholangiopathy with florid duct proliferation and inflammation. Of interest, there is also porto-septal and porto-portal fibrosis and parenchymal nodularity hinting towards the chronic nature of the liver disease.

Immunohistochemistry confirms canalicular protein GGT and BSEP expression in a pan-lobular distribution in all patients. TJP2 can be expressed albeit decreased and less crisp with challenges in USP53 immunostaining from reports [102, 104]. In ultrastructural studies, Bull et al. reported variations in bile retention (granular or finely filamentous) with preservation of tight junctions, but changes in TJ's length and orientation were described by Zhang et al.

Patients reportedly respond well to UDCA and/or cholestyramine and rifampicin with relapse in pruritus after temporarily stopping treatment.

In the majority of patients with *USP53*-associated cholestasis, the disease phenotype may be relatively mild albeit relapsing, but one patient has already undergone LT. There is also variability in onset of hearing deficit, and further reports will enhance our knowledge and understating of this newly described condition.

Conclusion

Over the last few years, our understanding of paediatric cholestatic disorders has significantly improved. Through the latest gene sequencing techniques (targeted resequencing and/or whole exome sequencing) and careful patient selection, we have managed to identify causative genes for cholestatic syndromes in most patients and highlight the mechanism of action of the encoded proteins at a cellular level. This enables physicians to characterise and treat these patients more efficiently. A number of clinical trials are cur-

rently underway in some of the above-mentioned cholestatic conditions interfering with the bile acid homeostasis, and yet there is to be established the application of possible gene therapies. Whether such treatment options would be beneficial to children with FIC1, BSEP deficiency or other cholestatic syndromes requires further interrogation. Additionally, new clinical challenges are appearing such as recurrence of BSEP deficiency after liver transplantation.

Alagille Syndrome

62

Shannon M. Vandriel and Binita M. Kamath

Introduction

Alagille syndrome (ALGS) is an autosomal dominant phenotypically heterogeneous disorder. The defining clinical features of ALGS as described by Daniel Alagille include cholestatic liver disease classically with bile duct paucity, cardiac disease, posterior embryotoxon, butterfly vertebrae, and characteristic facial features [1]. The diagnostic criteria have since been expanded to encompass vascular and renal anomalies [2, 3]. ALGS stems from heterozygous mutations in one of two genes in the Notch signaling pathway: *JAGGED1* (*JAG1*) mutations are reported in up to 94% of clinically diagnosed cases, and mutations in the *NOTCH2* receptor are found in 2.5% [4]. *De novo* mutations account for approximately 60% of ALGS cases.

Historically, the prevalence of ALGS has been estimated to be approximately 1 in 70,000 live births. However, advances in molecular diagnostics have revealed that the true burden of ALGS is likely closer one in 30,000 [5]. This increase in prevalence is partially attributable to the growing availability and use of genetic testing and capturing individuals who present with partial or subclinical disease expression. There is remarkable variability in both disease severity and organ system involvement among ALGS patients, even within families harboring the same pathogenic variant. The following sections will describe the hallmark features of ALGS and provide evidence-based management considerations and strategies.

Clinical Manifestations

Hepatic

The majority of ALGS patients who are symptomatic with liver disease present in the first year of life with cholestasis, classically with conjugated hyperbilirubinemia and high γ-glutamyltransferase (GGT). During childhood, elevations of serum bilirubin up to 30 times normal and serum bile salt elevations of 100 times normal are common. Cholesterol levels can be staggering and may exceed 1000–2000 mg/dL. However, this high level of plasma cholesterol is largely associated with lipoprotein-X [10]. Lipoprotein-X is in the low-density lipid range and resists oxidation, thereby protecting against atherosclerosis. Thus, the hypercholesterolemia of ALGS does not appear to carry an increased risk of cardiovascular disease [6, 11]. Hepatic synthetic function is usually well preserved in ALGS.

Physical examination findings in children with ALGS and liver disease include hepatomegaly early on and splenomegaly in the majority over time. The pruritus seen is among the most severe of any liver disease. It rarely is present before 3–5 months of age but is seen in most children by the second year of life, even in some who are anicteric. Multiple xanthomas are common sequelae of severe cholestasis associated with ALGS and correlate with a serum cholesterol level greater than 500 mg/dL. Xanthomas typically form on the extensor surfaces of the fingers, the palmar creases, the nape of the neck, the ears, the buttocks, and around the inguinal creases (Fig. 62.1a, b). Xanthomas are disfiguring and occasionally interfere with fine motor function when they occur on the fingers and feet.

Bile duct paucity is the histopathologic hallmark of ALGS and is defined as a ratio of interlobular bile ducts to portal tract ≤0.5 in at least five portal tracts (normal ratio 0.9–1.8). Other histological features of ALGS include giant cell transformation and, occasionally, biliary obstruction in patients with a biliary atresia (BA) phenotype. Notably, bile duct

Fig. 62.1 (**a, b**) Xanthomas on the hands of a child with Alagille syndrome

paucity is not always present in early infancy and has been reported to increase in frequency with age [6].

Large regenerative hepatic nodules are observed in up to 30% of ALGS patients and are postulated to occur in response to abnormal vascular perfusion of the liver [7, 8]. These lesions are typically solitary and centrally located close to the right portal vein. On radiological evaluation, these lesions have normal hepatic vessels and are relatively stable on follow-up imaging studies, with a mean interval of 33 months [8]. There is general consensus that the mechanisms leading to hepatic nodules in ALGS are reactive in nature as opposed to neoplastic.

Hepatocellular carcinoma (HCC) is considered a rare complication of ALGS. A recent case series and review of the literature described 21 children with ALGS who developed HCC [9]. The median age of HCC diagnoses was 4 years old (range 1–16 years), with the youngest case reported being a 1.5-year-old child. Cirrhosis was reported in all cases except for one at the time of HCC diagnosis. Although ALGS patients are not considered a high-risk group for HCC, monitoring of serum alpha-fetoprotein levels and an ultrasound examination is recommended every 12 months.

There is considerable variation in the clinical course and ultimate prognosis of liver disease in ALGS. For those children with significant hepatic involvement in infancy, the clinical picture is dominated by cholestasis and follows a severe course in the first 5 years of life, after which it appears to improve for many patients. This spontaneous improvement is poorly understood but well documented. In approximately 10–20%, the cholestasis persists unabated or progresses to end-stage liver disease (ESLD) with the onset of portal hypertension later in childhood. It is difficult to predict early on which ALGS children with cholestasis in early childhood will eventually require liver transplantation (LT) and which will spontaneously improve. There are no known genotypic or radiologic predictors of liver disease progression in ALGS. A review of laboratory data of ALGS patients showed that bilirubin and cholesterol levels before the age of 5 may aid in distinguishing patients at high and low risk of problematic cholestasis in later childhood. More specifically, mean levels of total bilirubin (TB) >6.5 mg/dL (111μmol/L), conjugated bilirubin (CB) >4.5 mg/dL (77μmol/L), and cholesterol >520 mg/dL (13.3 mmol/L) are strongly associated with severe liver disease in later life, whereas levels lower than this are associated with a more favorable hepatic

outcome [10]. These data may assist the clinician in predicting which children might go on to resolve their cholestasis and therefore avoid unnecessary LT in young children with ALGS.

The overall hepatic prognosis in ALGS was previously regarded as favorable, with reportedly only 20–30% requiring LT [6, 11]. However, these data represent mixed cohorts of children with ALGS and those with and without significant liver disease. Recently, Kamath et al. recently reported on the outcomes of 293 ALGS patients with cholestasis in a prospective observational multicenter North American study [12]. Native liver survival in ALGS probands with cholestasis was only 24% at 18.5 years. As described above, in early childhood, LT in ALGS typically occurs due to complications of cholestasis, and this study revealed an additional burden of liver disease in later childhood due to fibrosis and portal hypertension [6, 11, 13].

Cardiac

Cardiac anomalies are a hallmark feature of ALGS, with a reported prevalence of 94% [14]. The extent and pattern of cardiac involvement is highly variable, ranging from an asymptomatic murmur or peripheral pulmonary artery stenosis (PPS) to more complex intracardiac anomalies such as tetralogy of Fallot with or without pulmonary atresia. PSS accounts for approximately 73% of reported cardiac anomalies in ALGS and can lead to pressure or volume overload of the right ventricle (RV), RV hypertrophy, and, in severe cases, right-sided heart failure. The most common serious intracardiac defect is tetralogy of Fallot (TOF), which occurs in 7–12% [6, 14]. Approximately 40% of patients with ALGS demonstrating TOF have pulmonary atresia, representing a more severe phenotype. Cardiac disease accounts for nearly all of the early deaths in ALGS. Patients with intracardiac disease have approximately a 40% rate of survival to 6 years of life, compared with a 95% survival rate in patients with ALGS without intracardiac lesions [6].

Characteristic Facies

Individuals with ALGS often have a characteristic facial appearance that may include a high forehead with frontal bossing, deep-set eyes with moderate hypertelorism, saddle or straight nose with a bulbous tip, and/or pointed chin (Fig. 62.2). Together, these features give the face an inverted triangle appearance. This facial appearance is one of the most penetrant findings in ALGS and is reported in up to 90% of patients with a *JAG1* variant [6]. In early infancy, characteristic ALGS facial features may be difficult to recognize; however, this feature becomes increasingly evident

Fig. 62.2 Facial features of Alagille syndrome

with age. In one study, a series of photographs from patients with ALGS and patients with other known early-onset liver diseases were evaluated by clinical dysmorphologists to determine the diagnostic sensitivity and specificity of ALGS facies. The study authors found clinical dysmorphologists were able to correctly identify ALGS facial features in 79% of pediatric cases [15]. Interestingly, in adults, ALGS facial features were more difficult to identify and were correctly identified in only 67% of cases. The author's clinical experience is consistent with this finding, which suggests the forehead becomes less prominent after puberty, while the protruding chin is more noticeable, thus losing the overall triangle appearance. Recognition of ALGS-specific facies may aid in diagnoses, particularly in adult ALGS patients who present with idiopathic cardiac or renal disease and little or no hepatic involvement.

It should be noted that the presence of ALGS facial features might be less evident among individuals with ALGS and Vietnamese heritage [16]. When evaluated by North American dysmorphologists, characteristic ALGS facies was only identified correctly in 24% of Vietnamese children with ALGS and a *JAG1* variant. A higher sensitivity was reported by the referring pediatric gastroenterologist in Vietnam, who identified ALGS facies in 61% of children. Furthermore, a notably lower incidence of characteristic facial features has been described in ALGS patients with a *NOTCH2* variant (20%) in comparison to those with a *JAG1* variant (79%) [17]. These findings were recently confirmed in a congress abstract by the Global Alagille Alliance (GALA) Study Group, which describes the largest cohort of *NOTCH2*-associated ALGS to date [18]. These data indicate that

clinicians should evaluate these patient populations for other extrahepatic involvement instead of relying on the characteristic facies.

Ophthalmologic

The ocular abnormalities of patients with ALGS do not generally affect vision but are important as diagnostic tools. A large and varied number of ocular abnormalities have been described, though posterior embryotoxon is the most important diagnostically. Posterior embryotoxon is a prominent, centrally positioned Schwalbe's ring (or line) at the point at which the corneal endothelium and the uveal trabecular meshwork join and is visible on slit-lamp examination. Posterior embryotoxon occurs in 56–88% of patients with ALGS and was also detected in 22% of children evaluated in a general ophthalmology clinic [19]. Posterior embryotoxon is seen in other multisystem disorders such as chromosome 22q deletion, as well. The Axenfeld anomaly, seen in 13% of patients with ALGS, is a prominent Schwalbe's ring with attached iris strands and is associated with glaucoma. Optic disk drusen identified using ocular ultrasonography has been described in ALGS patients with high prevalence, but this test is not routinely performed [20].

Skeletal Involvement

Vertebral abnormalities are described in the initial reports of this syndrome. The most characteristic finding is the sagittal cleft or butterfly vertebrae, which is found in 33–87% of patients with ALGS [1, 13, 21, 22]. This relatively uncommon anomaly may occur in normal individuals and is also seen in other multisystem abnormalities, such as 22q deletion syndrome and VATER (vertebral defects, anal atresia, tracheoesophageal fistula, radial and renal defect) syndrome. The affected vertebral bodies are split sagittally into paired hemivertebrae because of a failure of the fusion of the anterior arches of the vertebrae. The mildly affected vertebrae have a central lucency. A fully affected vertebra has a pair of separate triangular hemivertebrae whose apices face each other like the wings of a butterfly. Generally, these anomalies are asymptomatic and of no clinical significance. Other associated skeletal abnormalities include an abnormal narrowing of the adjusted interpedicular space in the lumbar spine, a pointed anterior process of C1, spina bifida occulta, fusion of the adjacent vertebrae, hemivertebrae, the absence of the 12th rib, and the presence of a bony connection between ribs. In addition, supernumerary digital flexion creases have been described in one-third of patients [23].

Severe metabolic bone disease with osteoporosis and pathologic fractures is common in patients with ALGS. Recurrent fractures, particularly of the femur, have been cited as an indication for LT. Preliminary survey data suggests that there is a propensity toward pathologic lower extremity long bone fractures in ALGS [24]. A number of factors may contribute to osteopenia and fractures, including severe chronic malnutrition, vitamin D and vitamin K deficiency, chronic hepatic, and renal disease. It is not yet known whether there is an intrinsic defect in cortical or trabecular structure of the bones in patients with ALGS. Olsen evaluated bone status in prepubertal children with ALGS and identified significant deficits in bone size and bone mass that were related to fat absorption but not dietary intake [25]. In a study from the Childhood Liver Disease Research Network (ChiLDReN), 49 ALGS patients and 99 children with other inherited chronic liver diseases underwent dual-energy X-ray absorptiometry (DXA) scans [26]. In ALGS, DXA measures were found to be low but improved after adjustment for weight and height. Of note, DXA Z-scores in the ALGS population correlated negatively with measures of cholestasis including TB and serum bile acid levels. These data support multifactorial influences on bone density in ALGS, with possible contribution of impaired Notch signaling.

ALGS patients are frequently found to have short stature, and this is likely multifactorial in origin, resulting from cholestasis and malabsorption, congenital heart disease, and genetic predisposition. A validated growth curve for ALGS individuals is not yet available.

Renal Involvement

Renal involvement in ALGS has been widely reported on an individual case basis or as part of a larger report on general features of ALGS. The prevalence of renal involvement in larger series ranges from 40% to 70% such that it has been proposed that renal anomalies now be considered a disease-defining criterion in ALGS. In a large retrospective study, there was a prevalence of 39% of renal anomalies or disease. The most common renal involvement was renal dysplasia (59%), followed by renal tubular acidosis (10%), vesicoureteric reflux (8%), and urinary obstruction (8%) [3]. Hypertension in patients with ALGS can be of cardiac, vascular, or renal etiology.

Functional and structural evaluation of the kidneys should be undertaken in all patients. Renal function should be reassessed during the evaluation for LT (see Management below).

Vascular Involvement

Cerebrovascular anomalies are a well-known feature of ALGS and are a significant contributor to morbidity and

early mortality [2]. Three distinct clinical phenotypes have emerged in ALGS, including (1) cerebral aneurysms, (2) syndromic moyamoya, and (3) anomalies of the internal carotid artery. The main clinical complication of these anomalies in ALGS is stroke, either ischemic or hemorrhagic. Ischemic stroke is typically associated with moyamoya, while cerebral aneurysms represent the most common cause of hemorrhagic stroke among patients with ALGS. The presence of a vasculopathies in ALGS is consistent with the intrinsic role of the Notch signaling pathway in vascular formation and morphogenesis.

Retrospective studies in small cohorts of ALGS patients have reported wide ranges for the prevalence of cerebrovascular anomalies [2]. In one study, Emerick et al. retrospectively reviewed neuroimaging reports in 26 children with ALGS and identified anomalies in 38% of patients [27]. In this series, 100% of symptomatic ALGS patients and 23% of clinically asymptomatic patients had vascular anomalies detected by imaging studies. However, most concerning, cerebral angiography failed to detect any vascular anomaly in two asymptomatic patients, who both subsequently suffered fatal intracranial events several years after their baseline screening. These findings suggest the progression of underlying cerebrovascular disease. A more recent retrospective analysis by Carpenter et al. evaluated arterial and venous abnormalities in 19 children and young adults with ALGS [28]. The study authors reported cerebral arterial disease in 32% ($N = 6/19$) of ALGS patients, while venous anomalies were present in 21% ($N = 4/19$). Like Emerick et al., most patients were clinically asymptomatic at the time of neurovascular imaging, suggesting a high prevalence of silent cerebral vasculopathies.

It is now recognized that vasculopathies in ALGS extend beyond the central nervous system (CNS). Reported systemic vascular abnormalities include aortic aneurysms and coarctations and celiac, hepatic, and renal arterial anomalies. In a large retrospective chart review of 268 patients with ALGS, 25 patients had vascular complications (9%), including three patients with aortic aneurysms, two with aortic coarctations, and one patient with bilateral renal artery stenosis [2]. The frequency of intra-abdominal vascular anomalies has particular significance for LT in ALGS [29].

Bleeding Tendency in ALGS

Intracranial bleeding events are a concerning and potentially life-threatening complication of ALGS. Clinical series have reported cerebrovascular events in up to 16% of ALGS patients, with 30–50% of events resulting in mortality [2, 21]. Bleeding events in ALGS do not follow a distinct or predictable pattern and may occur spontaneously or with minimal trauma. An increased susceptibility to systemic bleeding events has also been observed in ALGS and appears to be unrelated to coagulopathy. In a retrospective chart review of 174 ALGS patients, 22% ($n = 38/174$) of individuals had one or more bleeding episodes, in the absence of coagulopathy [30]. The majority of the reported bleeding events occurred spontaneously or during a surgical or other invasive procedure. Concerningly, bleeding events accounted for 14% of deaths in the cohort.

The underlying processes responsible for the heightened risk of spontaneous bleeding, particularly intracranial bleeding, among individuals with ALGS remain unclear. Impaired integrity of blood vessels due to an underlying developmental defect, particularly within the CNS, has been cited as a possible explanation. Moreover, as discussed in the preceding section, underlying cerebral vascular anomalies, including cerebral aneurysms, are known to contribute to some cases [31–33].

Infections and Immune Dysregulation

It has been suggested that some individuals with ALGS may exhibit an immune-deficient phenotype characterized by recurrent episodes of otitis media with effusion (OME) and upper respiratory tract infections (URTIs). Serious, recurrent bacterial infections have not been reported in ALGS. Recurrent OME and URTIs have been described in up to 35% of children with ALGS, and it is hypothesized that this stems from an intrinsic defect in Notch signaling, specifically in CD46-Jagged1 interactions [13, 34]. CD46 is a complement and immune regulator that plays a critical role in mediating NOTCH expression during T cell activation. CD46 also mediates innate and adaptive immune responses. In a small case series, Shamouna et al. demonstrated increased Jagged1 expression on resting T cells in four immune-deficient ALGS patients. Furthermore, CD4+ T cells in these patients failed to elicit an efficient Th1 response to sustain induction of interferon (IFN)-γ production, both in vitro and in vivo. Similar findings have been described in CD46-deficient patients. The study authors also speculate that the molecular mechanisms leading to immune defects in ALGS may predispose patients to asthma, eczema, and food allergies [35, 36]. However, further studies are needed to understand how dysfunction in Notch signaling contributes to immune dysregulation in children with ALGS and the clinical significance of this problem.

Hearing Loss

Children with ALGS are at greater risk for both conductive and sensorineural hearing loss (SNHL). ALGS-specific features may be a contributing factor to OME (as described

above) and conductive hearing loss. Structural anomalies in the middle and inner ear have been described in ALGS, including partial or a complete absence of the bony and membranous structures of the posterior semicircular canals and hypoplasia of the anterior semicircular canals [37–39]. In one series, Teng and colleagues conducted hearing tests in 44 children with ALGS, of whom 13 had hearing loss in at least one ear [40]. Conductive hearing loss (27% of left ears, 30% of right ears) was the most common hearing impairment, followed by mixed hearing loss (14% of left ears, 9% of right ears) and SNHL (4% of left ears, 11% of right ears). More recently, in large multicenter cohort, Kamath et al. investigated audiological manifestations in 110 children with ALGS and cholestatic liver disease. Air conduction testing was performed and revealed 38% (n = 42) of participations failed at least one frequency in one or both ears [12]. Tympanometry was subsequently performed in those who failed the air conduction test and identified 67% (n = 28/42) of participants failed in one or both ears. These data indicate a high prevalence of hearing impairment among ALGS patients and the need for ongoing surveillance and hearing screening.

Arthritis

The number of reported cases of arthritis in ALGS has increased in recent years and may be more common than initially appreciated. In 1993, Jacobs and colleagues reported the first case of a child with ALGS and severe, refractory juvenile idiopathic arthritis (JIA) [41]. Two subsequent case reports have also described JIA in a child and an adult with ALGS [42, 43]. More recently, in an international, multicenter study, Ferrara et al. described ten children with ALGS and features of JIA [44]. The median age of onset was 6.5 years (range 2–10 years), and the median number of joints with active arthritis was 2 (IQR 0–4). The most commonly affected joints were the knees (90%) and ankles (70%), followed by the small joints of the hands or feet (50%). Notably, only 33% (n = 2/6) of ALGS children had positive antinuclear antibody (ANA) titers. The study authors pooled together all ALGS cases from their seven centers with and without JIA and reported a combined prevalence rate of 5% (n = 10/195). Strikingly, the estimated prevalence rate of JIA is 1 in 1000 children (<0.1%), suggesting that children with ALGS have a 50-fold increased risk of developing arthritis compared to the general pediatric population [44, 45].

The underlying mechanisms involved in the pathogenesis of arthritis in ALGS patients remain elusive. However, a growing body of evidence has demonstrated that Notch signaling is activated in autoimmune and inflammatory-related diseases, such as rheumatoid arthritis (RA) and osteoarthritis [46]. For instance, Jiao and colleagues found that Th cells in individuals with active RA expressed significantly higher levels of Notch2, Notch3, and Notch4 at the mRNA and protein level in comparison to health controls [47]. Further evidence demonstrating a link between the Notch pathway and inflammation is shown by Park et al., who found pharmacologic inhibition of Notch signaling modulates disease activity in experimental inflammatory arthritis [48]. Collectively, these studies suggest that mutations in genes encoding components of the Notch signaling pathway, including *JAG1* and *NOTCH2*, could lead to arthritis in ALGS. Future clinical studies will be necessary to determine whether the type of arthritis observed in ALGS is similar to JIA or is an extension of the ALGS phenotype.

Genetics of ALGS

ALGS is inherited in an autosomal dominant manner, with highly variable expressivity. It is a genetically heterogeneous disorder and may be caused by mutations in either *JAG1* (seen in 94% of clinically defined probands) or *NOTCH2* (seen in approximately 2.5%) [4, 17, 49, 50]. Jagged1 is a cell surface protein that serves as a ligand for the four Notch receptors (Notch1, 2, 3, and 4), and together these proteins begin the cascade of events that turn on the Notch signaling pathway. The Notch signaling pathway is involved in the determination of cell fate and as such plays a crucial role in normal development.

Gene Identification and Mutation Analysis

JAG1 was identified as the cause of ALGS in 1997 [49]. To date, more than 430 *JAG1* mutations have been identified in patients with ALGS. Utilizing current screening techniques, the mutation detection rate is 94% [4]. The frequency of sporadic mutations (i.e., new in the proband) is approximately 60–70%. Approximately, 75% of ALGS patients have *JAG1* protein-truncating (frameshift or nonsense or splice-site) mutations [4]. Approximately 7% have gene deletions. Missense mutations are identified in 15%. Haploinsufficiency, a decrease in the amount of the normal protein, is hypothesized to be the mechanism causing ALGS. ALGS associated with *NOTCH2* mutations was described in 2006. Thus far, 23 patients with unique *NOTCH2* mutations have been described [4, 17, 50].

A small fraction (3–5%) of ALGS individuals have deletions of chromosome 20p. Genome-wide single-nucleotide polymorphism (SNP) analysis of 25 patients with ALGS revealed 21 deletions ranging from 95 kb to 14.62 Mb [51]. Patients with deletions greater than a critical 5.4 Mb region had additional phenotypic features not usually associated with ALGS such as developmental delay and hearing loss.

Genotype–Phenotype Correlations

JAG1 Mutations

Although the ALGS phenotype is highly variable, there is no apparent correlation with *JAG1* genotype in the majority of patients. A study of 53 *JAG1* mutation-positive relatives of a cohort of ALGS probands demonstrated that only 53% met the clinical criteria for a diagnosis of ALGS, including 11 of 53 with obvious clinical features that would easily have led to a diagnosis of ALGS and 17 of 53 (32%) who had mild features that would have only been apparent on targeted evaluation following the diagnosis of a proband in their family (i.e., discovery of elevation of liver enzymes or posterior embryotoxon in an asymptomatic individual) [52]. This underscores the variable clinical consequences associated with a *JAG1* mutation and suggests the presence of genetic modifiers.

NOTCH2 Mutations

While the phenotype of *JAG1*-associated ALGS has been reasonably well characterized, *NOTCH2*-associated disease has only been reported in a small number of individuals. Pathogenic or likely pathogenic *NOTCH2* variants have been reported in 23 children with ALGS with complete or partial features of the classic phenotype [4]. Recently, in a congress abstract, the GALA Study Group described 19 ALGS patients with *NOTCH2*-associated disease, the largest comprehensive analysis to date. In comparison to *JAG1*-ALGS patients ($N = 755$), *NOTCH2*-ALGS were significantly less likely to have characteristic facies (53% vs. 88%, $p < 0.001$), an ECHO-confirmed cardiac anomaly (58% vs. 93%, $p = 0.001$), posterior embryotoxon (14% vs. 53%, $p = 0.004$), or butterfly vertebrae (0% vs. 44%, $p = 0.001$) [18]. Notably, 10- and 18-year native liver survival rates in patients presenting with neonatal cholestasis were comparable between the two variant groups (59% and 74%; 48% and 62%, respectively; log-rank $p = 0.31$). These data suggest that reliance on classical clinical phenotypic definitions of ALGS may miss patients with *NOTCH2*-related disease and that genetic testing is crucial for diagnosis.

Diagnostic Considerations

Clinical Diagnostics

The majority of infants with ALGS are evaluated for conjugated hyperbilirubinemia in the first weeks or months of life. ALGS is occasionally misdiagnosed as BA because of the overlap of biochemical, scintigraphic, histologic, and cholangiographic features. Serum bilirubin, bile acid, and GGT levels typically are elevated in both of these disorders. Ultrasound findings in both conditions may reveal small or apparently absent gallbladders. Excretion of nuclear tracer (diisopropylacetanilido iminodiacetic acid, DISIDA) into the duodenum excludes BA, but non-excretion of tracer is also possible in ALGS. There was no excretion of scintiscan in 61% of 36 infants with ALGS [6].

Although a liver biopsy is not mandatory to diagnose ALGS, it remains an important step in differentiating between ALGS and BA in infants with high-GGT cholestasis. In BA, bile duct proliferation is the typical histologic lesion. In ALGS, paucity is evident in 60% of infants younger than 6 months but in 95% of older patients [6]. Unfortunately, there may be a normal number of ducts early in the course of BA and also in some patients with ALGS, and bile duct proliferation occasionally occurs in infants with ALGS. Giant cell hepatitis is also seen in both disorders. Finally, it should be noted that bile duct paucity, if present, is not diagnostic of ALGS and other diagnoses should be considered (e.g., alpha-1-antitrypsin deficiency, cystic fibrosis, cytomegalovirus infection, etc.).

An operative cholangiogram is considered the gold standard procedure to evaluate the extrahepatic and intrahepatic biliary tree; however, this can also be misleading in ALGS. The extra- and intrahepatic ducts are extremely small in patients with ALGS, and the cholangiogram commonly does not demonstrate communication proximally. In 37% of 19 cholangiograms in infants with ALGS, there was no opacification of the proximal extrahepatic ducts, and, in another 37%, the proximal extrahepatic tree was abnormally small [6]. The intrahepatic ducts were normal in only 10% of 19 infants with ALGS, small or hypoplastic in 16%, and not visualized in 74%. Therefore, even the apparent gold standard test to differentiate ALGS and BA can be misleading.

Clinical features in extrahepatic organ systems may help in the diagnostic evaluation. The list of abnormalities identified in the "major" organ systems and the list of other affected organs have grown appreciably. Thus, an echocardiogram, slit-lamp examination, renal ultrasound, and spinal X-ray are essential diagnostic tests when ALGS is suspected. It should be noted that several of the ALGS-defining features are present in normal individuals or other conditions. Heart murmurs are present in 6% of all newborns, posterior embryotoxon appears in 22% of the general population, and butterfly vertebrae are seen in 11% of patients with 22q11 deletion. Furthermore, the facial features of ALGS patients are subtle during the first months of life making this an unreliable diagnostic tool in infancy.

With the advent of molecular testing for ALGS and the broader appreciation of the phenotypic variability, the diagnostic criteria for ALGS have been modified. To make a

clinical diagnosis for an index case (proband) in the family, the original Alagille criteria hold, modified only so as no longer to require histology and expanded to include renal and vascular involvement. Thus, ALGS can be diagnosed clinically on the basis of cholestasis with at least three features from the list of characteristic Alagille facies, consistent cardiac disease, posterior embryotoxon, butterfly vertebrae, typical ALGS renal disease, and a structural vascular anomaly. In families with one definite clinically defined proband, other members with only two features should be considered as having ALGS.

Molecular Diagnostics

Molecular diagnostics is now widely commercially available for *JAG1* and *NOTCH2*. For practical reasons and cost-effectiveness, simultaneous testing of both genes is now carried out by readily available next-generation sequencing (NGS) panels. A molecular diagnosis can assist in an atypical ALGS case and is also useful for genetic counseling and prenatal diagnosis. *JAG1* sequencing identifies mutations in individuals with clinically defined ALGS in the majority of cases (>95%) [4].

Once a *JAG1* mutation is identified in a proband, it is simple to test parents and other relatives for the identified mutation. Mutations are inherited from an affected parent in 30–50% of patients, whereas the mutations appear de novo in 60–70% [4]. If a parental mutation is identified, there is a 50% risk for each future offspring to inherit the *JAG1* mutation. However, it should be emphasized that expressivity of the disorder is highly variable, and it is not currently possible to predict disease severity in a new baby.

Prenatal genetic testing for ALGS is possible if a parental mutation has been identified. This requires amniocentesis or chorionic villous sampling and assessment for a known *JAG1* mutation. Preimplantation genetic diagnosis has also been successfully performed in ALGS. It is imperative to carefully counsel parents undergoing any type of prenatal testing since there are no genotype–phenotype correlations in ALGS, so it is not possible to make predictions about a child's clinical course based on the type or presence of a mutation.

Management

Management of Cholestasis

Patients with ALGS present significant management challenges due to profound cholestasis and complex multisystem disease [53]. A sequential and additive approach to medical cholestasis therapy in ALGS is most appropriate. The most commonly used agents are listed in Table 62.1 with common side effects and described below.

The pruritus associated with ALGS cholestatic liver disease can be severe and may occur even without jaundice. Pruritus is often debilitating, disturbing sleep, daily activities, and cognitive development. Conservative management of pruritus entails taking care to keep the skin hydrated with emollients, trimming the fingernails, and taking short baths or showers to limit drying of the skin. Bile flow may be stimulated with choleretics, and ursodiol is the most commonly used agent. The use of ursodiol has been studied in ALGS children with improvement in pruritus, xanthomas, and biochemical markers of cholestasis [12, 39–41]. Therapy with antihistamines may provide some symptomatic relief but is rarely effective alone. Bile-acid-binding resins, such as cholestyramine, can be effective but more often are not palatable. They are also difficult to administer since they must be given 2 h apart from other medications. Colesevelam may be better tolerated but has not been studied in pediatrics. It should be noted that colesevelam is a very potent bile-acid-binding resin and may severely deplete the concentration of free luminal bile acids resulting in risk of fat-soluble vitamin deficiency, and these levels should therefore be monitored. Rifampin has been comparatively well studied in ALGS [54, 55]. Yerushalmi et al. studied 24 children with severe cholestasis, of whom 6 had AGS, and 92% of the cohort showed a response in improving pruritus [55]. Although rifampin is associated with elevation of serum transaminases, none of these studies reported clinical or biochemical adverse events. Naltrexone has been shown to be effective against pruritus in cholestatic adults [56, 57]. Based on limited experience, it can be useful in the pruritus of ALGS children as well [58].

Table 62.1 Medications for cholestasis in Alagille syndrome

Medication	Dose	Most frequent side effects
Choleretics		
Ursodeoxycholic acid (Actigall)	10–20 mg/kg/day, divided in two doses	Diarrhea, abdominal pain
Others		
Rifampin	10 mg/kg/day, divided in two doses (maximum dose 600 mg/day)	Red discoloration of urine, idiosyncratic hypersensitivity, reactions, hepatitis
Sertraline (Zoloft)	75–100 mg/day (maximum dose of 200 mg/daily)	Restlessness, loss of appetite
Naltrexone	1–2 mg/kg orally once daily (maximum dose of 50 mg/day)	Nausea, abdominal pain
Bile-salt binding agents		
Cholestyramine	240 mg/kg/day, divided into three doses; maximum dose of 8 g/day	Constipation, abdominal pain

Emerging data also exist for the use of sertraline in cholestatic pruritus, but its use is not widespread [59].

Newer agents that inhibit apical sodium-dependent transport of bile acids (ASBT inhibitors or inhibitors of bile acid transport (IBAT)) act at the enterocyte and interrupt the enterohepatic circulation. These drugs reduce the total bile acid pool size, effecting a chemical biliary diversion [60, 61]. Currently, two drugs in this class are under study for pruritus in children with cholestasis, maralixibat and odevixibat. At this time, there are more data available for maralixibat in ALGS. Maralixibat has been evaluated in phase 2 trials in patients with ALGS. The ITCH trial evaluated 37 patients with ALGS in a placebo-controlled randomized trial [62]. Although the prespecified primary endpoints were not met in this study, a reduction in pruritus, as measured by caregivers via the validated itch-reported outcome instrument (ItchRO), was more common in the maralixibat-treated group as compared to the placebo group. Maralixibat was well tolerated with comparable adverse events between groups. The ICONIC trial evaluated 31 patients with ALGS in a multicentered trial using a randomized drug-withdrawal study design (these data have only been presented in abstract form, to date) [63]. Serum bile acid levels and pruritus scores fell on maralixibat treatment; however, during the randomized drug-withdrawal period, bile acid levels in the placebo group returned to baseline, and subjects had significantly higher pruritus scores with improvement in both of these parameters on restarting the drug [63]. These preliminary studies show that IBAT inhibitors hold promise as future treatments for pruritus that may potentially also prove to be hepatoprotective.

Surgical biliary diversion has been successful in a number of patients, though it does not appear to be as effective for ALGS as it is for progressive familial intrahepatic cholestasis (PFIC) [64–66]. Wang et al. evaluated the efficacy of non-transplant surgical interventions in 58 children with severe cholestasis, including 20 participants with ALGS [67]. The median age of surgical diversion was 30 months (Q1/Q3 = 26/86 months, range = 2–218 months, mean = 65 months), and the leading indication was severe pruritus (100%), followed by xanthomata (50%) and progression of liver disease (25%). Among the ALGS patients, 15 underwent partial external biliary diversion (PEBD), which led to a significant decrease in total serum cholesterol (695 ± 465 vs. 457 ± 319 mg/dL; preop vs. 12–24 months postop, respectively; $p = 0.0001$). Surprisingly though, there was not a significant decrease in serum TB (ALGS: 0 = 5.3 ± 5.4, 24 mos. = 4.9 ± 4.1 mg/dL). Ileal exclusion (IE) was performed in five ALGS patients, and none of these patients experienced relief of their xanthomata over 24 months postoperatively. External biliary diversion appears to be more effective than internal approaches though the impact on quality of life of a stoma limits the acceptability of this approach with many families.

Hepatoportoenterostomy is not indicated in children with ALGS and is associated with adverse clinical outcomes. In a limited retrospective study comparing ALGS patients to matched BA patients after Kasai procedures, the ALGS cohort had a significantly higher rate of LT (47 vs. 14%) and sustained higher mortality [68]. These data suggest that the Kasai procedure is not a marker for severe underlying liver disease but that the Kasai procedure itself has a detrimental effect on outcome. Similar negative outcomes were observed in a recent systematic review and meta-analysis [69].

Xanthomas do not require specific treatment unless they interfere with vision, feeding, or motor development which is exceptionally rare. As the hypercholesterolemia of ALGS is not atherogenic, dietary modifications or medical therapy is not necessary.

Nutritional

Failure to thrive and malnutrition need to be addressed aggressively and early on in life. There is significant malabsorption of long-chain fat; therefore, formulas supplemented with medium-chain triglycerides may have some nutritional advantage. Many patients are unable to eat enough to provide the substantial quantities of energy required for growth and development, and nasogastric or gastrostomy tube feedings can provide necessary supplementation.

Fat-soluble vitamin deficiency is present in most patients with significant ALGS cholestasis. Oral or parenteral supplementation is necessary for prevention of vitamin deficiencies and their sequelae. Standard multivitamin preparations may not provide the correct ratio of fat-soluble vitamins, unless they have been specifically formulated for cholestasis (e.g., DEKAs). If such cholestasis-specific preparations are not available, vitamins are best administered as individual supplements tailored to the specific needs of the patient. Close monitoring (every 3–6 months) of fat-soluble vitamin levels is crucial to avoid complications of vitamin deficiencies, particularly in the first years of life.

Liver Transplantation

LT is an effective therapeutic modality for ALGS patients and is indicated in 20–50% of all pediatric cases, and this varies according the heterogeneity of the cohort being reported. Clinical indications for LT in ALGS can be categorized into two groups: (1) those with one or a combination of complications related to chronic cholestasis, including refractory pruritus and disfiguring xanthomas, failure to thrive, fat-soluble vitamin deficiency, and/or recurrent pathological fractures, and (2) those with biliary cirrhosis and/or evidence of portal hypertension. The burden of extrahepatic comorbidities in

ALGS, including cardiac, renal, and vascular involvement, is important determinant of transplant outcomes in terms of both morbidity and mortality. As such, a multifaceted, multidisciplinary team-based approach is recommended.

A thorough and in-depth assessment of the cardiovascular system is a key part of the transplant candidate evaluation in children with ALGS, and special attention should be paid to the functional capacity of the right ventricle. Cardiac evaluations should include a chest X-ray, electrocardiogram (ECG), and two-dimensional echocardiogram (ECHO). However, a limitation of these testing modalities is they can underappreciate the peripheral branches of the pulmonary arteries and the degree of right ventricular hypertrophy in this population. Therefore, the King's College Group suggests a cardiac catheterization and dynamic stress test with dobutamine (DSE) to simulate perioperative conditions in the LT evaluation of ALGS patients [70]. This approach induces peripheral vasodilatation and increases cardiac output, thereby mirroring the conditions of graft reperfusion. If the transplant candidate achieves a cardiac output of more than a 40% during DSE, the patient's cardiac reserve is considered sufficient for transplantation.

Given the high rate of renal involvement in ALGS, a detailed evaluation of the kidneys is indicated in all transplant candidates, including a measured glomerular filtration rate (GFR) and in some institutions serum cystatin C. Furthermore, to prevent subsequent renal injury during the posttransplant course, the authors advocate for the use of a renal-sparing protocol in all ALGS transplant recipients, regardless of pretransplant renal function.

Living-related liver transplantation (LRLT) in ALGS requires careful thought and consideration. Although 60% of ALGS cases result from de novo mutations, the possibility of a first-degree relative harboring the same pathogenic variant as the proband needs to be entertained. Therefore, targeted genetic testing of *JAG1* and *NOTCH2* is recommended for any biological relatives of an ALGS patient considering becoming a living-related donor. Indications for LT in ALGS are not typically emergent, and the time scale for predictive genetic testing for prospective donors is rapid, approximately 2–4 weeks. On a cautionary note, Gurkan reported two instances in which apparently unaffected parents underwent donor operations that were unsuccessful because of bile duct paucity discovered intraoperatively [71]. These case examples underscore the importance of genetic testing in all. Therefore, the recommendation in North America is for potential donors to undergo screening for the known mutation in the proband and for them generally not to be used as donors if positive for the mutation.

Liver Transplant Outcomes

Overall patient and graft survival rates for children with ALGS are now comparable with other indications for pediatric LT [72, 73]. Marked improvements in survival rates over the past decade are attributed to careful candidate selection, better perioperative management of systemic disease features, and revised immunosuppression protocols.

In the largest series to date, Arnon and colleagues analyzed outcomes of 461 children with ALGS over a 21-year period [74]. They reported 1- and 5-year patient survival rates of 83% and 78.4% and 1- and 5-year graft survival rates of 75% and 62%, respectively. The study authors also compared posttransplant outcomes between children with ALGS and those with BA. Both 1- and 5-year patient and graft survival rates were lower in ALGS patients in comparison to BA (83% and 78% patient survival, 83% and 70% graft survival, respectively). Reduced posttransplant survival in ALGS may be partially explained by the multisystem nature of the syndrome and a greater burden of comorbidities. However, the United Network for Organ Sharing (UNOS) database does not capture characteristic features of ALGS such as cardiac, renal, or vascular involvement, limiting further interpretation of these findings.

A concerning observation among several large ALGS series is the high incidence of early posttransplant mortality (<30 days post-LT). In the previously described UNOS study by Arnon et al., pediatric LT recipients with ALGS were far more likely to experience early death in comparison to children with BA (9.6% vs. 4.8%, $P = 0.01$) [29]. Recipient characteristics associated with early mortality included higher mean pretransplant creatinine levels, cold ischemic time >12 h, and prior transplantation. A clustering of deaths in the immediate posttransplant period was also demonstrated in another Alagille-transplant study [73]. In contrast, the study authors did not identify any pretransplant variables associated with early mortality. However, complications, including biliary, vascular, renal, and CNS during the first 6 months following LT, were proportionally higher among children with ALGS, and these were prognostic markers for increased mortality.

Cardiac Anomalies

Management of the cardiac involvement in ALGS is clearly lesion specific. In a large, though now older, ALGS series, cardiac surgery was performed in infancy in 11% [6]. The mortality rates were 33% for those with TOF and 75% for those with TOF with pulmonary atresia. The survival of patients with ALGS with these lesions is markedly lower than for patients (with these lesions) without ALGS. This may be a result, in part, of the common presence of significant stenoses in the distal pulmonary artery or other systemic manifestations of the syndrome. Nonsurgical invasive techniques have been used successfully for patients with ALGS, including valvuloplasty, balloon dilatation, and stent implantation. Heart–lung transplantation has been performed in

combination with LT in a child with ALGS as a rare occurrence [75].

Other Extrahepatic Diseases

As with the cardiac involvement in ALGS, other extrahepatic diseases must be managed according to standard of care. Currently, there are no established guidelines for the screening and management of cerebral vasculopathies in ALGS, and prospective studies are lacking. Considering the potentially fatal consequences of cerebrovascular abnormalities, the authors recommend all individuals with ALGS undergone a screening MRI/MRA at approximately 8 years of age, when sedation is no longer required. Furthermore, children with ALGS need to be managed with a heightened sense of awareness and urgency in the setting of acute head trauma or any new neurologic signs of symptoms. In the setting of any major surgery, such as LT, all children with ALGS should undergo an MRI/MRA of the head and vascular imaging of the abdomen, typically CT angiography to identify vascular anomalies.

Prognosis of Alagille Syndrome

Overall mortality is difficult to ascertain in ALGS since the organ involvement is variable and so reported mortality rates reflect the nature of the underlying cohort. Cardiac, hepatic, and vascular diseases account for the majority of deaths in ALGS. The presence of a complex intracardiac anomaly is the only predictor of an excessive early mortality rate, and cardiac anomalies account for the majority of deaths in early childhood. Overall, vascular and bleeding events accounted for most of the mortality in one large series of ALGS: 34% [2]. Quiros-Tejeira reported a 72% survival rate in 43 patients at a mean follow-up of 8.9 years in a population in which 47% underwent LT [13]. Emerick estimated the 20-year survival rate in 92 patients to be 75% overall, 80% for those not requiring LT, and 60% for those requiring transplantation [6]. However, both of these case series are more than 20 years old. In the most recent assessment of outcomes in a prospectively followed cholestatic cohort of 293 ALGS patients, native liver survival was only 24% at 18.5 years, and during the study period only 11 patients died [12].

Conclusion

To conclude, ALGS is a complex condition in which the molecular basis is well understood, but the absence of identified genotype–phenotype correlations and the broad variability poses management challenges. Renal and vascular involvement should be included in the diagnostic criteria. The discovery of two disease genes and a broader phenotype, which includes individuals with *no* liver disease, suggests that a redefinition of this syndrome is warranted based on molecular defects, possibly reserving the term ALGS for those with liver disease and associated features, as Daniel Alagille originally intended. The most exciting management advance in ALGS is the promise of IBAT inhibitors which will likely revolutionize the treatment of pruritus and hopefully reduce the need for surgical biliary diversion and perhaps even LT.

Chronic Hepatitis B

Introduction

Hepatitis B virus (HBV) infection remains a global health burden with estimated 250 million people chronically infected worldwide. Nevertheless, since HBV vaccine has become available for more than 25 years and many countries introduced vaccination programs as a prevention strategy on a regular basis for young infants, significant reduction of the incidence of acute hepatitis B in children and adolescents has been observed. Unprotected, approximately 90% of HBV-infected infants and 20–25% of those infected in preschool age will develop chronic infection decreasing to a chronicity rate of around 5% for adolescents and adults [1–3]. Despite a rather benign spontaneous course of the disease during childhood and adolescence, there is a considerable lifetime risk of progressive liver disease, liver cirrhosis, and the development of a hepatocellular carcinoma (HCC), which may eventually reduce life expectancy. Thus, careful long-term monitoring has to be performed, and appropriate treatment options, which unfortunately are not entirely curative at present, have to be considered.

Pathogenesis of Chronic HBV Infection

HBV belongs to a DNA virus family called hepadnaviruses. It contains a partially double-stranded DNA genome with about 3200 nucleotides. The minus strand covers four overlapping open reading frames (ORFs): S, for the surface gene encoding three envelope proteins (hepatitis B surface antigen, HBsAg); C, for the core gene encoding the core protein (hepatitis B core antigen, HBcAg); X, for the regulatory X gene; and P, for the polymerase gene encoding the viral DNA polymerase. By using multiple start codons, HBV is able to encode more than one protein from an ORF. After hepatocyte entry by the NCTP-receptor, the viral envelope is

S. Guandalini, A. Dhawan (eds.), *Textbook of Pediatric Gastroenterology, Hepatology and Nutrition*,
https://doi.org/10.1007/978-3-030-80068-0_63

removed, and the nucleocapsid reaches the nucleus, where the double strand will be completed and converted into a covalently closed circular DNA (cccDNA). This is an important step, because the majority of cccDNA is then organized into nucleosomes forming the viral minichromosome, which is serving as template for the synthesis of the viral mRNA. The transcripts are translated into the viral proteins, and simultaneously reverse transcription leads to the synthesis of a complete minus strand of HBV DNA. The plus strand can then be synthesized again, and the molecule circularizes. Thus, the replication of HBV is similar to that of a retrovirus. The proteins are synthesized and assembled at the endoplasmatic reticulum and eventually discharged by vesicular transport as a Dane particle which contains the complete virus. The cccDNA plays a key role in viral persistence, viral reactivation after treatment withdrawal, and drug resistance. It accumulates in the nucleus of the hepatocyte as a stable minichromosome organized by histone and nonhistone viral and cellular proteins [4, 5]. Persistent HBV replication is associated with a high frequency of integration of HBV sequences into the human host liver cell genome. Enhanced DNA replication and DNA damage occurring during chronic inflammation with cycles of cell death and regeneration increase the availability of DNA ends in host genomic DNA and promote the process of viral integration [6]. Furthermore, it is presumed that certain altered cells are susceptible to the development of additional genetic and epigenetic changes that may lead to the development of malignant cell transformation and HCC.

For the understanding of the different phases during the course of the chronic disease, it is important to realize that the virus itself is not primarily pathogenic to the hepatocyte. The mechanism of cell death is generally accepted to be the result of a cytotoxic T-lymphocyte-mediated immune response of the host to the virus. Additionally, it has been shown that some HBV proteins may be able to induce apoptosis. During the transition from the immune-tolerant to the immune-active phase, a shift from the hepatitis e antigen (HBeAg)-specific Th2 cell tolerance to Th1 cell activation may recognize HBV-related epitopes on hepatocytes resulting in secretion of cytokines such as interleukin (IL)-2 and tumor necrosis factor alpha (TNF-α) and thus activating inflammation [7].

Epidemiology

Overall, the number of infected people is decreasing. Nevertheless, there are still high endemic countries in Asia, Africa, and some parts of South America with an HBsAg prevalence of more than 8%. The Arabian region, parts of the Eastern hemisphere, and Greenland show an HBV prevalence of 2–7%, and in the Western countries the rate is below 2% [8, 9]]. Global immunization programs have been established in many countries, and the HBV infection rate has declined worldwide. Vertical transmission has become the main route of infection; nevertheless, in some areas, HBV may also be a predominant disease in adolescents and adults due to high-risk sexual behavior and drug abuse [10]. Unfortunately, up to 2–15% of perinatal HBV infection of antibody against HBeAg (anti-HBe)- and HBeAg-positive mothers cannot be prevented by active and passive immunization due to intrauterine infection, vaccine failure, or HBsAg escape mutants [11, 12]. Thus, passive and active immunization has to be started immediately after birth in all newborns from HBsAg-positive mothers. HBeAg-positive mothers can be considered to receive treatment with the nucleoside analogues telbivudine and tenofovir in late pregnancy to decrease viral load [13, 14]. After complete immunization, there are no objections against breastfeeding. In countries with blood donor screening and serum testing, parenteral transmission does no longer play a significant role. The HBsAg prevalence in children is estimated between 0.02% and 0.03% in Western countries and the USA, 0.14% in Brazil, and 0.5% in Taiwan after immunization [1, 15]. Given HBsAg prevalence in pregnant women of 0.4% in Western Europe and an HBV transmission rate of 5–10% despite complete vaccination, 20–40 newborns in 100,000 births may be infected and become a chronic carrier state.

Ten HBV genotypes (A–J) have been documented showing a distinct distribution. Genotypes A and D are predominant in North America, Europe, and India, and genotypes B and C are mostly found in Asian countries. To date, routine determination of genotype is not yet recommended because treatment options are not adjusted to genotypes. Nevertheless, since there is line of evidence that genotypes C and D may be associated with more aggressive liver disease, this might become significant during the long-term follow-up [16].

Diagnostics

Chronic hepatitis B infection is defined as a repeatedly positive HBsAg test result within 6 months. Apart from the aminotransferases, HBeAg, anti-HBe, anti-HBcIgG, and quantitative HBV DNA have to be determined to confirm chronic hepatitis B and to classify the present stage. Additionally, antibody against delta virus (anti-HDV) should be tested to exclude concomitant hepatitis D. It is recommended to perform an ultrasound examination including liver stiffness assessment for baseline findings. Since chronic hepatitis B usually is a mild disease in terms of inflammation in childhood, histological examination by liver biopsy is not mandatory. However, in subjects who are suspicious of progressive liver disease or cirrhosis or if an impact on therapeutic decisions is identifiable, liver biopsy may be a reasonable completion.

Natural History

There are four natural stages of chronic hepatitis B infection: immune tolerance stage, immune reactive or immune clearance stage, inactive HBsAg carrier stage, and reactivation stage. The immune-tolerant phase is also named chronic hepatitis B infection and the immune-active phase chronic hepatitis B. As fifth and last stage, viral elimination with antibody against HBsAg (anti-HBs) seroconversion, which is a rather rare event occurring not more than 0.5% annually in children, could be denominated [7, 17]. Figure 63.1 illustrates the different phases of chronic hepatitis B.

Children who have HBV infection acquired perinatally or in the first months have an initial tolerance stage which is characterized by the presence of HBsAg, HBeAg, and extremely high HBV DNA levels (10^{7-9} virions/ml) and normal aminotransferases. The duration of the immune-tolerant phase is not predictable and may last 1–4 decades. Asian patients use to have a longer immune-tolerant stage. T helper (Th) cell immune tolerance is generated by HBeAg functioning as an immunoregulatory protein mostly already transplacentally transmitted. This kind of induced immune tolerance may explain the high chronicity rate and the younger the individuals are when they get infected. Usually, only minimal inflammatory activity is detectable in the liver tissue in this phase. Even in adult patients, no severe progression is expected during the immune-tolerant stage [18]. Although antiviral therapy is still not recommended for immune-tolerant subjects, they should be carefully monitored to duly recognize progression to immune-active phase.

With time, a nonspecific increase of inflammatory activity or a decrease of HBeAg serum concentration, which may be due to emerging mutants in the core promotor or precore region resulting in a lower HBeAg production, may activate HBeAg-specific T cell clones. In this immune reactive phase, HBeAg remains positive, and aminotransferases rise. HBV DNA remains high or stays at a little lower level. During this time, progression to liver fibrosis or cirrhosis may occur. However, liver cirrhosis rate is not expected to exceed 3–5% until reaching adulthood [19–21]. In the immune reactive phase treatment has to be considered.

A key event in the natural course of chronic hepatitis B is the HBeAg/anti-HBe seroconversion which occurs unpredictably for the single individual during the immune-active phase. Anti-HBe seroconversion is associated with a significant decrease of viral replication and normalization of aminotransferases reflecting the biochemical and histological remission of inflammatory activity. In some studies, the annual seroconversion rate depends on the route of infection and the ethnic origin. Whereas the mean seroconversion rate in non-Asian children ranges between 8% and 15%, seroconversion in Asian children was considerably lower with approximately 5% per year [7, 20]. Anti-HBe seroconversion is followed by the inactive HBsAg carrier state with persistently normal aminotransferases and a low viral load. Viral replication is considered low when HBV DNA serum concentrations remain below 2000 IU/ml. Some carriers may be lucky and develop anti-HBs antibodies indicating viral elimination and cure of the disease. The estimated incidence of this rare event in children is 0.05–0.8% per year in endemic areas with predominantly perinatal HBV transmission [7, 15].

Approximately 20–30% of inactive HBsAg carriers will experience spontaneous reactivation during long-term follow-up. Those episodes may cause progressive liver damage. The reactivation phase is characterized by the presence of anti-HBe and elevated aminotransferases. HBV DNA levels rise over 2000 IU/ml. This status is also named HBeAg-

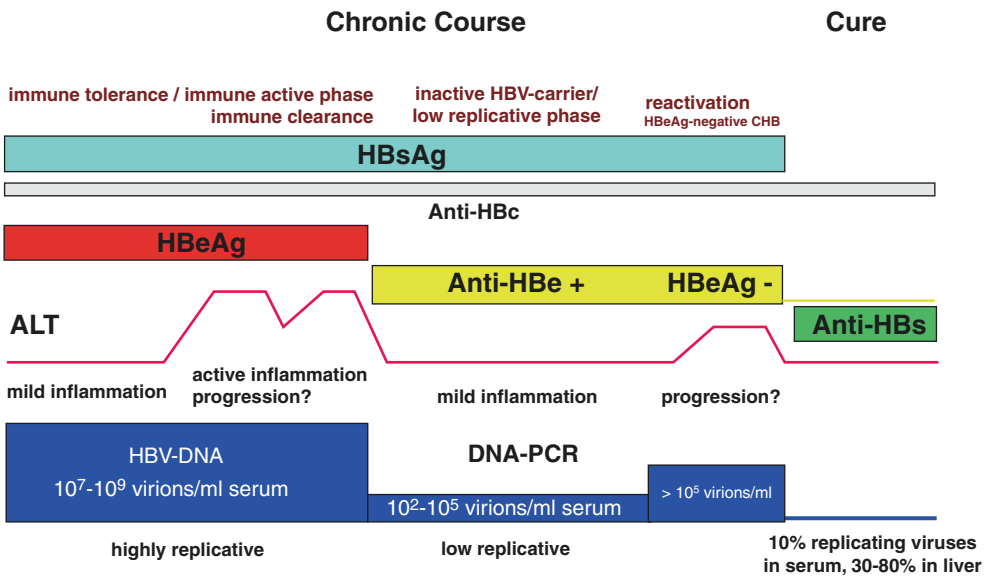

Fig. 63.1 Illustration of the different phases of chronic hepatitis B. *HBV-DNA* hepatitis B virus deoxyribonucleic acid, *DNA-PCR* deoxyribonucleic acid polymerase chain reaction, *HBV* hepatitis B virus, *HBsAg* hepatitis B surface antigen, *Anti-HBc* antibody against HBcAg, *ALT* alanine aminotransferase, *HBeAg* hepatitis e antigen, *Anti-HBs* antibody against HBsAg

negative hepatitis B. However, reactivation rarely occurs during childhood and adolescents.

Another particular condition warrants mention: occult HBV infection. It is defined as the existence of HBV DNA in serum among HBsAg-negative patients and can be classified into seropositive and seronegative with respect to the presence of anti-HBs or antibody against HBcAg (anti-HBc) antibodies. Possible explanations are low levels of viral replication activity or the emergence of HBV variants in the a-determinant of the S-gene. Occult hepatitis B is most common in endemic regions and seems rare with 1.4% [22]. However, prevalence may rise considerably in immunized children from HBsAg-positive mothers. One study reported a prevalence of 28% in this special group [23].

Long-Term Prognosis

Individuals with chronic HBV infection are at risk to develop long-term sequelae such as end-stage liver disease including liver cirrhosis, hepatic failure, and HCC. Progression strongly correlates with the disease activity in terms of viral replication level, inflammatory activity, HBsAg levels, HBV genotypes, and HBeAg/anti-HBe status. Strong risk factors for developing liver cirrhosis and HCC are higher age, male, presence of HBeAg, HBV DNA levels $>10^4$ copies/ml, HBsAg serum concentrations $>10^3$ IU/ml, and alanine aminotransferase (ALT) > 45 IU/l [24, 25]. Progression to liver cirrhosis in children is under 5% until adulthood, and data of the Asian region report 0.01–0.003% of individuals with chronic hepatitis B to be expected developing HCC in childhood [26, 27]. In general, anti-HBe seroconversion significantly reduces the risk of developing HCC. The time at which anti-HBe seroconversion occurs is important. A study in adults investigating the 15-year cumulative incidences of HBeAg-negative hepatitis demonstrated that cirrhosis and HCC increased with increasing age of HBeAg seroconversion [28]. The lowest risk was observed in patients with anti-HBe seroconversion under the age of 30 (cirrhosis 7%, HCC 2.1%) and highest in individuals older than 40 years (cirrhosis 42.9%, HCC 7.7%). The hazard ratio for HBeAg-negative hepatitis, cirrhosis, and HCC was 2.95, 17.6, and 5.22, respectively, in the older compared with the younger group. The authors concluded that patients with HBeAg seroconversion before age 30 have an excellent prognosis, whereas patients with delayed HBeAg seroconversion after age 40 have significantly higher incidences of HBeAg-negative hepatitis, cirrhosis, and HCC. An additional precondition is persistently normal ALT levels [29]. Since children have a high probability to experience anti-HBe seroconversion until adulthood, the overall risk of developing severe liver disease in later life seems limited. Nevertheless, there remain a considerable number of patients with immune tolerance or inflammatory activity that needs careful and professional monitoring.

Relevance of Genotypes and Mutants

During the replication cycle, HBV polymerase is acting as a reverse transcriptase without proofreading function. Therefore, mutant viral genomes are regularly emerging in a considerable number particularly during the high replicative status. Peculiar requirements such as replication modalities, selection pressure, and changing immunological conditions may select variants and strongly influence the predominant HBV quasispecies in an infected individual. Generally, a change of the primarily determined genotype is possible during long-term course and ranges between 2.8% and 19% usually associated with anti-HBe seroconversion [26, 30]. It is not yet known if there is any clinical impact at all. In adults, genotype C infection rather than genotype B is associated with a delayed anti-HBe seroconversion and a higher risk of developing HCC. Genotype D tends to proceed more severely and shows delayed anti-HBe seroconversion compared with genotype A. Precore and basic core promotor (BCP) mutants are frequently associated with HBeAg-negative hepatitis, and HBsAg escape mutants are now increasingly observed in association with primarily vaccinated children. The typical precore point mutant is the G1896A stop codon preventing the production of HBeAg. It emerges typically around the time of anti-HBe seroconversion and may be associated with a decreased risk of developing HCC compared with the wild type. But it can also be found in patients with HBeAg-negative hepatitis. Depending on European or Asian regions, precore mutants have been detected between 8% and 50% in HBeAg-negative children. The BCP mutants A1762T/G1764A prevail to be associated with an increased risk for HCC. But, finally, the data remain controversial [7, 16, 31, 32].

Treatment

Since there is no definite curative medical treatment available to date, it has to be defined what the aim of antiviral treatment should be in dependence on age group and phase of chronic hepatitis B. There is no doubt that one major goal is to reduce the risk of progressive liver disease and long-term sequelae such as liver cirrhosis, hepatic decompensation, and HCC and eventually to achieve the same life expectancy compared with healthy individuals of the same age. Unfortunately, anti-HBs seroconversion can only be reached in 5–10% at the most under current medical treatment strategies. Thus, the most important task in the treatment of children and adolescents is to achieve anti-HBe

seroconversion at the earliest possible time associated with suppressed viral replication and decreased liver inflammation followed by persistent presence of anti-HBe, undetectable HBV DNA, and preferably aminotransferase values less than half of the upper limit of normal. Children with HBeAg-positive hepatitis should be monitored every 6 months with physical examination, measurement of laboratory parameters such as aminotransferases, hepatitis B serology, alpha-fetoprotein, and ultrasound of the liver. After anti-HBe seroconversion, follow-up visits can be performed for lifetime on an annual basis [15, 17, 33].

The decision to treat should be based on age, phase of HBV infection determined by ALT level, HBeAg/anti-HBe status, liver histology, coexisting diseases, and expectable compliance. The response rate in patients in the immune-tolerant phase is very low. Thus, treatment of children with normal aminotransferases is not recommended. Recently published clinical trials in immune-tolerant children and adults combining a nucleoside analogue and peg-alpha interferon did not achieve a higher anti-HBe seroconversion rate compared to the control group [34, 35]. However, treatment should be considered when aminotransferases rise and transition to the immune-active phase is recognized. Children and adolescents who have persistently elevated ALT levels for more than 6 months should be offered treatment. Currently, seven treatment options are approved for hepatitis B in adults, including two formulations of conventional and pegylated interferon as an immunomodulatory therapy and five nucleos(t)ide analogues (lamivudine, adefovir dipivoxil, entecavir, telbivudine, and tenofovir disoproxil) with strong reduction of viral replication. Approval for children and adolescents depends on the region. Large trials have been performed in children for lamivudine, adefovir, entecavir, and tenofovir. Entecavir has been authorized from 2 years onward, and adefovir and tenofovir disoproxil have been approved for subjects older than 12 years of age in the USA and Europe [36–38]. Predictors of response may be increased ALT levels, relatively low HBV DNA levels, and infection with genotype A or B. The main problem of all clinical trials with nucleos(t)ide analogues is the duration of medical treatment of not more than 96 weeks. Although a high proportion of treated patients will experience a significant decrease of viral load, the anti-HBe seroconversion rate cannot be expected to exceed 25%. After ceasing treatment, a reactivation of viral replication to baseline levels can be observed. A 24-week course of alpha interferon yields an approximately 10% higher anti-HBe seroconversion rate. Anti-HBs seroconversion rate is limited to single cases with nucleos(t)ide analogues and may range between 6% and 10% in patients with alpha interferon. There is no doubt that these results are dissatisfying with respect to our primary goal of anti-HBe seroconversion. Another interesting fact is that alpha interferon treatment only accelerates anti-HBe seroconversion in successfully treated individuals but does not enhance the absolute number of responders [39]. Extending the treatment with nucleos(t)ide analogues for several years will result in an anti-HBe seroconversion rate of 40–50% [33]. However, there are no long-term data in children with regard to side effects. In the case of anti-HBe seroconversion, treatment should be maintained for 12 months, because the treatment-induced anti-HBe-positive status may be instable and reactivation may occur [40, 41].

In view of the present data and experience, there is a remarkable counseling conflict between the choice of drug and the duration of treatment, given that anti-HBe seroconversion remains the essential goal. Antiviral drug resistance is a major limitation to the long-term success of antiviral treatment. For this reason, lamivudine with a 5-year resistance rate of 70% has been considered obsolete just as adefovir which does often not sufficiently suppress viral replication. Nevertheless, at least for smaller children, lamivudine can be used as an approved drug for a limited time. Telbivudine has also a considerable resistance risk and is not approved. Entecavir and tenofovir do not show significant resistances after years of treatment. Tenofovir disoproxil may be associated with an increase in serum creatinine levels after 3–5 years of therapy. Decrease of bone mineral density has also been reported. These side effects might occur less frequent with the new tenofovir alafenamide. Oral treatment with nucleos(t)ide analogues is quite comfortable but needs a real true commitment to the treatment, and alpha interferon may have sometimes restrictive side effects but with the advantage of a defined duration.

Thus, the decision which treatment option to choose is not that easy and has to be achieved in agreement with the patient and the parents. Alpha interferon is particularly appropriate for those children and adolescents who are reluctant to commit to a long duration of treatment and are not in the pubertal growth spurt. Nowadays, peg-alpha interferon should be recommended for 48 weeks. Nucleos(t)ide analogues are most appropriate for patients with contraindications to interferon, after liver transplantation with an anti-HBc-positive donor or under immune suppressive treatment. It is most important that they are willing to commit to a treatment for several, probably 3–5, years, maybe longer. Entecavir and tenofovir have the best profile in terms of safety, efficacy, and drug resistance. For younger patients, entecavir seems actually the preferable option.

Children and adolescents with a HBeAg-negative hepatitis should be treated with a nucleos(t)ide analogue if ALT levels are elevated, and HBV DNA concentration is above 20,000 IU/ml to prevent progressive liver disease [42]. During long-term treatment with nucleos(t)ide analogues, HBV DNA, HBeAg/anti-HBe status, and aminotransferase levels should be monitored every 3 months. Very low or negative HBV DNA concentrations are important preconditions to avoid drug resistance.

Prevention

Vaccination is the most effective procedure in order to prevent infection with the HBV. Active and passive immunization is well established in newborns of HBsAg-positive mothers. The first injections have to be administered within 12–24 h after birth to achieve a seroprotective response in 90–95% when two monthly follow-up active vaccinations are completed. Very-low-birth-weight preterm infants should receive a total of four doses. HBeAg-positive mothers can be treated with a nucleoside analogue (telbivudine, tenofovir) during the last trimester of pregnancy to reduce the risk of vertical transmission [14].

In many countries, routine active HBV vaccination is implemented in the vaccination schedule of all infants. Postvaccination testing for a protective anti-HBs concentration (> 100 IU/l) is not routinely recommended. If indicated, the best time would be approximately 2–3 months after the last vaccination. Revaccination is indicated in subjects with an anti-HBs titer <10 IU/l. In the majority of nonresponders, three more vaccinations will induce protective response. According to present experiences, protective anti-HBs response will be maintained for more than 15 years [13, 41].

Chronic Hepatitis C

Introduction

Hepatitis C virus (HCV) infection is a frequent course of chronic liver disease, and approximately 71 million people are estimated to be chronically infected worldwide. The number of chronically infected children up to the age of 15 is estimated with approximately 13 million. Unfortunately, to date, no preventive vaccination could be developed. Despite a normally benign course of the disease during childhood and adolescence, there is a considerable lifetime risk of progressive liver disease, liver cirrhosis, and the development of a HCC, which may eventually reduce life expectancy. Remarkable advances have been made in therapeutic approaches so far, and considerable rates of cure have been yielded with the former interferon-based treatment standard of care. In the last years, interferon-free treatment regimen using direct-antiviral agents (DAA) has become the new standard of care, yielding excellent results for viral elimination. DAAs are now also available for children and adolescents.

Pathogenesis of Chronic Hepatitis C Infection

HCV is a positive-stranded RNA virus within the *Flaviviridiae* family. It forms its own genus *Hepacivirus*, and there are six main genotypes. The viral genome encodes nine proteins including its own RNA polymerase. Because of the high error rate of the virus-specific RNA polymerase, many variants may be produced. So-called quasispecies represent the high variability of the virus which allows a survival advantage to the virus. Replication of HCV starts with the binding to hepatocytes and entry which is a rather complex procedure. RNA is released into the cytoplasm and translated in the rough endoplasmatic reticulum. A 3000-amino-acid-long polypeptide arises and is then cleaved into ten different products. Membranous replication vesicles are induced, and HCV assembly is accomplished and released with the help of very-low-density lipoprotein (VLDL) synthesis. Chronic hepatitis C in children is associated with a variety of histological patterns, mostly considered as mild and slow progressive. Nevertheless, significant fibrosis or cirrhosis may occur but is not expected to exceed 4% until reaching adulthood. Need for liver transplantation is very rare as is the development of HCC [43]. Little information is available about the host response to the virus. Cluster of differentiation 4 (CD4) + lymphocytes seem to be involved. Infants with the rs 12,979,860 CC genotype for the IL28B polymorphism tend to experience a higher spontaneous viral elimination [44–46].

Epidemiology

The prevalence of HCV infection in children in developed countries ranges between 0.1% and 0.4%. For adults, prevalence rates are 0.4–3% in North America and Western Europe and higher in Eastern Europe and Middle East. Egypt has the highest prevalence with 9%, almost exclusively genotype 4 [47, 48]. Central and East Asia and North Africa are estimated to have a prevalence between 3.6% and 3.8% [49]. During the last 15 years, the predominant route of viral hepatitis C transmission has become vertical infection. Contamination through blood products is exceedingly rare in developed countries but may remain an issue in developing countries. The rate of perinatal transmission from an HCV-RNA-positive mother ranges from 2% to 5%. Out of this group, a considerable number of infants received the infection probably already in utero [50]. Concomitant HIV infection may increase the risk of HCV transmission. Breastfeeding does not promote viral transmission and is allowed. The HCV prevalence in pregnant women from North America and Central Europe was reported between 0.16% and 0.53%. Assumed a perinatal transmission rate of 2–4%, 8–10 newborns in 100,000 births per year may be infected and become chronically infected during the first year of life. Viral clearance in vertically infected children seems to be dependent on the genotype and was reported to range from 2.4% to 25%. In contrast, children infected with genotype 3 had a higher

spontaneous clearance rate compared to individuals with genotype 1. Beyond the age of 5 years, spontaneous viral elimination becomes less likely [51, 52]. In view of the fact that more and more patients can be cured with DAAs, it is expected that the prevalence of chronic hepatitis C infection will decrease significantly within the next 5 years.

Diagnosis

Serologic testing for anti-HCV antibodies is the appropriate screening test for HCV. The next diagnostic step is the determination of quantitative HCV RNA and the genotype. The most prevalent genotype in pediatric trials performed in Western countries was genotype 1 (ca. 74%) followed by genotype 3 (ca. 14%) and 2 (ca. 9%). Genotype 4 had the lowest prevalence (ca. 3%) [53]. It is useful to perform an ultrasound examination including liver stiffness assessment for the baseline report. As chronic hepatitis C usually is a histologically mild disease with low inflammatory activity in childhood, liver biopsy is not mandatory. However, in subjects, who are suspicious of progressive liver disease or cirrhosis or if there is an impact on therapeutic decisions, liver biopsy may be a reasonable measure [53].

Several studies have demonstrated that certain host polymorphisms (e.g., CC) located upstream of the IL28B (interferon lambda 3) gene are associated with a higher sustained viral response rate to combination treatment with peg-alpha interferon and ribavirin. There is also an association with spontaneous clearance of HCV. So far, the determination of IL28B polymorphisms has not been used routinely and is becoming far less important in the treatment with DAAs.

Natural History

Normally, HCV infection is asymptomatic. Histological findings are usually mild, and the risk of severe complications until the infected individuals are reaching adulthood is low. Not more than 5% of children and adolescents will have evidence of advanced liver fibrosis or cirrhosis. Liver transplantation units from the USA have been reported on 133 transplanted children due to chronic hepatitis C during a time span of 13 years. In a lifetime, the risk of developing liver cirrhosis is about 20%, and the risk of HCC based on liver cirrhosis is estimated to be 2–5% [45]. These data are from adults, and there are no long-term follow-up studies in vertically infected patients. Natural history is also affected by other medical and social factors. Overweight children with liver steatosis are at greater risk for progressive liver disease. Risky behaviors and alcohol misuse worsen the long-term prognosis. Similar course and progression of hepatitis C were reported in former pediatric patients with successfully treated malignant disease after three decades of observation with about 20% spontaneous clearance and up to 5% liver cirrhosis. During the chronic course, ALT levels may be normal or intermittently elevated. Only few patients show persistent markedly elevated aminotransferases. Also the HCV RNA serum concentration may considerably fluctuate but without immediate prognostic relevance. Spontaneous resolution beyond the preschool age is quite rare and may occur in up to 10% of adolescents [45, 48, 54]. Some extrahepatic manifestations may be associated with chronic hepatitis C such as glomerulonephritis and possibly cognitive deficits or developmental delay [55]. However, in adult patients, the clinical effects of reported symptoms such as fatigue, depression, or marginal poorer learning efficiency were rather limited [56]. In conclusion, early acquired chronic hepatitis C is a clinically and histologically silent and hidden condition. Nevertheless, it may become insidious. Although the rate of developing liver cirrhosis until adulthood is low, activation beyond the second decade of life is likely. A large Danish study in adults revealed that in patients with chronic HCV infection, the 8-year risk of liver-related death was 5.5% compared with 2.0% in individuals who cleared the infection [57]. However, patients who have eventually proceeded to compensated liver cirrhosis have a dubious prognosis. In a follow-up study of cirrhotic patients over more than 10 years, HCC developed in 32%, and the annual mortality rate was 4% [58]. Thus, the literal aim of therapeutic interventions in children and adolescents is not the treatment of an ongoing liver disease but the prevention of a future one by early eradication of the infection.

Treatment

The primary goal of HCV therapy is to cure the infection, which is reflected by persistently negative HCV RNA in serum and normalized aminotransferases. Sustained viral response (SVR) is defined as an undetectable HCV RNA level 24 weeks after cessation of treatment. The interferon-based treatment regimens included the combination of pegylated alpha interferon with ribavirin and a protease inhibitor. They were the approved and established standard of care in adults until the year 2014. With these regimens, considerable sustained viral response rates could be achieved ranging from more than 65% for genotype 1 to over 80% for genotype 2 and 3 patients [59]. Then, the interferon-free era started with the introduction of direct antiviral agents (DAA) focusing on genotypes 1 and 4 [60]. Genotypes 2 and 3 were also treated in different combinations over 12 to 24 weeks. The most important substance was sofosbuvir. However, more and more combinations were tested and approved, and numerous drugs were on the market only for a few years [61]. Table 63.1 summarizes the currently mostly used preparations with respect to the approval status in adults and children.

Table 63.1 Direct antiviral agents for the treatment of chronic hepatitis C

Substances	Registered trade name	Genotype	Trials in children	Approved >12 years of age [a]	Approved >3 years of age [a]
Sofosbuvir/Ledipasvir	Harvoni	1, 4	Yes	Yes	Yes
Ribavirin/Sofosbuvir [a]	Ribavirin, Sovaldi	2, 3	Yes	Yes	Yes
Ritonavir/Ombitasvir/Dasabuvir/ Ribavirin [a]	Viekirax, Exviera	1, 4	Yes	Not intended	Not intended
Daclatasvir/Sofosbuvir [b]	Daklinza, Sovaldi		Yes	Not intended	Not intended
Grazoprevir/Elbasvir	Zepatier	1, 4	Yes	In question	In question
Sofosbuvir/Velpatasvir	Epclusa	1–6	Yes	Yes	Yes, > 6 years
Sofosbuvir/Velpatasvir/Voxilaprevir [c]	Vosevi	1–6	Yes	Not intended	Not intended
Glecaprevir/Pibrentasvir [c]	Maviret	1–6	Yes	Yes	Yes

[a] Approval by FDA and EMA
[b] No longer in use in adults
[c] Duration of treatment 8 weeks in non-cirrhotic patients

Experiences with the treatment of children with chronic hepatitis C started in the early 1990s. Nineteen studies using recombinant alpha interferon were published between 1992 and 2003. A meta-analysis of trials with alpha interferon monotherapy showed a wide range of viral response (0–76%). Based on an increasing number of trials in adults, ribavirin was also added to alpha interferon treatment trials for children. Between the years 2000 and 2005, six studies were published showing a sustained viral response rate from 27% to 64% [52]. It became clear that genotype-2- and genotype-3-infected individuals responded much better. Alpha interferon-2b in combination with ribavirin was then approved by the FDA. Trials with peg-alpha interferon and ribavirin followed in the next years, and both peg-alpha interferon-2b and peg-alpha interferon-2a have been approved by FDA and EMA 2008/2009 and 2011/2012 in combination with ribavirin for children. Peg-alpha interferon and ribavirin therapies in treatment-naïve children and adolescents yield a sustained viral response rate in approximately 50% of adequately treated genotype-1-infected patients. Thus, this option could theoretically be offered to all interested individuals. In patients infected with genotype 2 or 3, treatment for 24 weeks has a response rate of more than 90% [62–64]. It could be used in children from 3 years and peg-alpha interferon-2a from 5 years onward, but it is also no longer recommended. Since spontaneous viral elimination in vertically infected subjects may occur within the first 3 to 4 years, the start of therapy was agreed after the age of three.

Treatment management of children with chronic hepatitis C infection is formed by the attitude of the medical attendant regarding the need of therapeutic intervention with respect to a generally slow progressive disease. In general, also for children and adolescents, interferon-based treatment options are considered obsolete, despite approval. Adverse events during treatment were frequent, and the duration was 24 to 48 weeks in dependence on the genotype. Under the aspect of health prevention for a long lifetime, all children with a measureable level of HCV RNA should be treated. The level neither of aminotransferases nor of HCV RNA predicts the long-term outcome of the disease. Also, liver histology is not a helpful entry criterion for indicating treatment, because children generally do not have severe lesions. With the development of the new DAAs, there is no reason not to treat children and adolescents after diagnosis of chronic hepatitis C from 3 years of age onward [65, 66]. The drugs are well tolerated and have only an exceptionally low rate of side effects.

Three groups of DAAs were differentiated in three groups: NS3/4A protease inhibitors, NS5a inhibitors, and polymerase inhibitors. Protease inhibitors have the ending "previr," NS5a inhibitors have the ending "asvir," and polymerase inhibitors are ending with "buvir." Sofosbuvir is one of the most potent polymerase inhibitors. It is important to combine at least two of different groups to avoid developing rapid drug resistance.

For the pediatric population, several clinical trials have been performed. Due to the approval regulations, the first groups included were between 13 and 18 years of age, followed by the younger ages. The combination of sofosbuvir and ledipasvir is approved from 3 years onward and suitable for the treatment of genotypes 1 and 4. It is administered for 12 weeks [67–69]. For genotypes 2 and 3, sofosbuvir and ribavirin are approved. Genotype 2 has to be treated for 12 weeks and genotype 3 for 24 weeks [70, 71], which can now be considered second line. The most recent approval is the combination of glecaprevir and pibrentasvir, which is pangenotypic (genotypes 1–6) and has the additional advantage of an 8-week treatment duration [72]. With Sofobuvir/Velpatasvir there are now two pangenotypic active drugs available. This panel seems sufficient to successfully addressing the pediatric chronic HCV infections. The overall sustained viral response rate was extremely high and achieved in most of the trials 100%. That was also true for individuals who were treatment experienced with a previous interferon-based therapy. Relapses were observed only in few isolated cases. It is recommended to determine HCV RNA 4 weeks after the start of treatment. Most patients are already negative at that time. The most important checkpoint is SVR

24, 24 weeks after cessation of treatment, as HCV RNA negativity is associated with long-term elimination. The safety and tolerability profile of the DAAs is also excellent. The vast majority of adverse events were mild and unrelated to the medication. Headache, fatigue, or signs of upper respiratory tract infections were registered up to about 15% [72]. In adult trials, there was no difference to the side effects of the placebo arm. Treatment does not appear to have an impact on growth and development.

Overall, early treatment of the pediatric population with chronic hepatitis C will decrease the pool of infected individuals and not only alleviate the development of a progressive liver disease but also prevent further transmission in the hope to eradicate the disease in this age group.
