Preface

It was our great pleasure to compile this book as an up-to-date review on the various hybrid imaging modalities that may be employed for the purpose of cardiac imaging. We both spent quite some time together in front of those hybrid systems and later analyzing and integrating data—sharing frustrations but predominately enjoying the wealth of information such systems are capable of generating.

After discussion of generic aspects of hybrid imaging, SPECT/CT, PET/CT, and PET/MRI are each considered in depth. In addition, information is provided on upcoming technologies, such as dedicated so-called fast cardiac cameras (CZT detector technology) and novel probes and radiotracers. We tried to address a wide variety of topics, including important technological aspects, possible applications, imaging protocols, and peculiarities of the available modalities. Last but not least, an estimation of the cost efficiency of dedicated and hybrid imaging devices in cardiology is provided and possible scenarios with respect to health care economics are described.

The editors would like to thank all the chapter authors for their competent inspiring contributions. We appreciate the support by Springer and sincerely hope that this book might support the interdisciplinary community working in this fascinating field.

Generic Aspects of Hybrid Imaging

Hybrid Imaging and Healthcare Economics

1

Danilo Neglia, Valentina Lorenzoni,
and Giuseppe Turchetti

Owing to the rapid technological advancement in cardiovascular diagnostic imaging, many non-invasive diagnostic tests are currently available which either evaluate cardiac anatomy or function or both. Although these tests are relatively non-invasive, they still pose a burden to the individual patient, the healthcare system, and society at large, because they are associated with significant patient time, costs, radiation exposure, and the risk of adverse events. Nevertheless, physicians often request multiple tests in order to increase their confidence in the diagnosis and treatment plan of patients. In order to minimize risks and burden to patients, radiation exposure, and healthcare costs, diagnostic algorithms have been developed which define a sequence of tests, where the choice of each imaging modality is determined by patient characteristics and the results of previously performed diagnostic tests. Imaging algorithms recommended by guidelines vary widely, demonstrating variability in clinical practice and attesting to the uncertainty about which imaging algorithm is optimal in terms of both costs and outcomes, i.e. is cost-effective.

In many clinical scenarios one of the reasons for multiple imaging testing is the need to complement anatomical information, best provided by some modalities, with functional information best provided by others. In this respect the introduction of “hybrid” imaging, i.e. the combination and/or fusion of two imaging modalities, has been considered a relevant advancement [1]. The term “hybrid imaging” is generally applied for the combination of images providing additional anatomical and

functional information beyond that achievable with either imaging modality alone, possibly leading to a more effective management of the patient. Different imaging datasets can be used from various modalities such as Coronary CT angiography (CTCA), single photon-emission CT (SPECT), positron emission tomography (PET), and cardiac magnetic resonance imaging (CMR). Images may be acquired on a hybrid scanner or by separate stand-alone devices with manual, software-based co-registration of both datasets for fusion. For some clinical indications and in some sites with appropriate infrastructure and tracer availability single session hybrid imaging may be a good option since it gives obvious potential benefits for the patients. For some other clinical indications and sites, however, the use of stand-alone scanners in sequence may be more efficient because it allows to keep some flexibility with regard to scanner occupation, to apply best imaging protocols for each modality and because of the difficulty in predicting a priori which patients would benefit from the dual scanning. Furthermore, most advanced scanners, such as high-end CT systems allowing imaging of the entire heart region within a single heartbeat, are currently not offered in hybrid configurations. Therefore, the practical approach for overall clinical effectiveness and the minimization of the cost and radiation dose may be sequential scanning, facilitated by software tools for automatic image registration and fusion [2].

At present, no health-economic evaluation of cardiac “hybrid” imaging is available which takes into account all these factors, i.e. its clinical effectiveness as well as direct and indirect costs, to demonstrate whether and in which patients it may be more cost-effective than a traditional imaging approach [2, 3]. However, there are increasing evidences that applying the “hybrid” imaging concept, i.e. the appropriate combination and fusion of anatomical and functional imaging modalities, may be useful in terms of costs and outcomes in some clinical scenarios.

1.1 Hybrid Imaging in Stable CAD (SCAD): CTCA and MPI

In the evaluation of patients with known or suspected stable coronary artery disease (CAD) the use of an anatomical-functional “hybrid” imaging approach is promising from both a clinical and healthcare economics perspective.

CTCA permits direct visualization of both the lumen and the walls of the coronary arteries and thus is a robust tool for identifying the presence and extent of CAD and for providing prognostic information. From the diagnostic endpoint, numerous studies have confirmed the high negative predictive value (NPV) and sensitivity of CTCA which thus can reliably “rule out” the presence of anatomical disease. On the other hand, however, the positive predictive value (PPV) and specificity of this modality are typically lower, in particular to detect functionally significant coronary lesions [4]. For this reason and for pathophysiologic considerations, i.e. the concept that an anatomic coronary lesion does not necessarily imply a “functionally significant” disease, a purely anatomical CTCA-guided diagnostic strategy is suboptimal to “rule in” patients requiring invasive coronary angiography (ICA) as potential candidates to revascularization. Functional measurements such as FFR_{CT} have been

recently developed to complement traditional CTCA imaging even if they have not yet gained widespread clinical use. In a multicentre, prospective study of stable symptomatic patients with suspected CAD, an evaluation strategy based on use of CTCA selectively augmented by FFR_{CT} was associated with a high rate (60%) of cancellation of planned invasive catheterization a significantly lower rate of ICA showing no obstructive CAD with significantly lower resource utilization and cost as compared with standard care [5]. These findings suggest that the combination of anatomic and functional imaging data may safely reduce the use of invasive catheterization and costs of care in selected patients undergoing evaluation for suspected CAD without no negative effect on clinical outcome.

Following a similar concept CTCA can be complemented with functional myocardial perfusion imaging (MPI). Traditional MPI includes SPECT, PET, and CMR. These modalities identify stress-induced wall motion abnormalities or regional myocardial perfusion defects and abnormal flow reserve. They have an established role in identifying patients with flow-limiting coronary stenoses or, in the case of angiographically normal coronary vessels, functional coronary/microvascular disease. In pooled analyses, the sensitivity and specificity of MPI to diagnose functionally significant obstructive CAD (documented by invasive FFR) is typically between 70 and 90% and 75 and 94%, respectively [4]. However, in real-world practice MPI has a lower accuracy for a number of reasons such as suboptimal quality of protocols and images and lower prevalence of obstructive disease in current populations which increase the likelihood of false negative and false positive studies decreasing sensitivity and specificity [6]. A hybrid approach combining MPI and CTCA has the advantage of fusing the anatomic CTCA derived data with functional MPI perfusion data. In doing so, this dual-modality approach is expected to improve diagnostic performance for detecting obstructive CAD by overcoming many of the drawbacks relative to stand-alone CTCA and MPI. Among MPI modalities SPECT and PET enable acquisition of three-dimensional datasets of the entire heart as for CTCA, which substantially facilitates the process of image fusion and, thus, renders these modalities ideal for fused hybrid imaging. A number of studies have demonstrated the added diagnostic accuracy of hybrid SPECT/CTCA and PET/CTCA for the diagnosis of hemodynamically significant CAD. Hybrid imaging has been shown to be particularly useful for enhancing specificity and PPV of CTCA [7], although significant improvement of diagnostic accuracy has been reported also compared with PET or SPECT alone [8–11]. The integration of anatomical information by CTCA with the functional information by SPECT or PET also allows for accurate localization of the coronary lesion responsible for downstream myocardial perfusion deficit. In almost 1 patient over 5 hybrid imaging may lead to complete reassignment of the ischemic territory to the culprit lesion of a different vessel than originally suggested [12]. This potentially translates into a better guide to patient management and downstream resources utilization. In single centre and multicentre studies in patients with suspected stable CAD, a matched finding (i.e., in fused hybrid images, a significantly obstructed coronary vessel at CTCA subtending a perfusion defect on SPECT or PET) was associated with a relatively high rate of revascularization as compared with mismatched or discordant

findings [12, 13]. When used as a gatekeeper to invasive procedures, hybrid imaging had a strong impact on downstream resources utilization as 100% of patients with a match, but only 13% of patients without match were referred for catheterization, and 91% were revascularized [14]. As a result, the positive diagnostic yield of invasive coronary angiography may be higher than 90% comparing favourably to the yield of less than 40% recently reported in large populations [15]. However, not all patients may benefit from hybrid imaging and in routine practice a logical approach would be sequential testing after an initial equivocal test [1, 2]. For example, in patients with a low-to-moderate pre-test probability (PTP) of CAD, it is rational to perform CTCA first as its excellent NPV allows for definite exclusion of obstructive disease. On the other hand, a tailored approach may allow immediate assessment by additional MPI of the functional relevance of an intermediate stenosis documented at CTCA or may assist in differentiating artifact-driven stenosis from true coronary luminal diameter narrowing.

Routine implementation of a hybrid anatomic-functional approach, either performed on hybrid scanners or on sequential stand-alone modalities, would necessitate evaluation of costs, potential harms (including radiation doses), and benefits. The addition of a second imaging exam would increase upfront costs which should be balanced against its effect on reduction of downstream testing and procedures. The potential harm associated with radiation doses (which with current technology and protocols may be reduced below 5 mSv) must be balanced against the risk of avoidable or inappropriate invasive procedures. Finally, and most importantly, it should be assessed whether diagnostic benefits may translate into improvement of long-term patient outcome. Integration of CTCA and SPECT or PET perfusion imaging allows to identify patients at higher future risk of adverse events [16, 17] but how this risk can be favourably modified by hybrid imaging-guided management has not yet been established. In stable CAD populations revascularizations have failed to confer a prognostic superiority compared to optimal medical therapy [18]. Unfortunately, a large randomized outcome based cost-effectiveness study where a tailored CTCA/MPI hybrid approach guiding invasive procedures is compared with standard care is not yet available.

1.2 Health-Economic Implications

In symptomatic patients with suspected SCAD available guidelines recommend using stress imaging and CTCA according to the PTP of disease [19] or CTCA as the first-line investigation in all patients [20]. Additional non-invasive testing is also considered in case of uncertain results of the first test [19, 20]. By their nature guidelines consider whether a test is appropriate for various clinical scenarios, but not their cost. The costs of an expensive non-invasive imaging strategy may be justified if it implies a reduction of downstream unnecessary utilization of further non-invasive or invasive procedures while maintaining or improving outcomes. Since the cost dimension is considered one of the relevant factors currently influencing clinical choices, cost-effectiveness studies of imaging-guided strategies in stable CAD have gained increasing attention [21].

Nevertheless, available health-economic studies [22–24] are controversial with no single modality consistently emerging as superior to all others and across all patient subgroups. The PROMISE study was a large pragmatic randomized controlled trial where CTCA or functional testing, including stress SPECT or ECHO, were compared as alternative diagnostic strategies to select patients for ICA [25]. The most remarkable finding, similar to the results of the EVINCI study which also included stress PET and CMR [6], was the better diagnostic performance of CTCA over functional testing. This translated into a higher positive diagnostic yield of ICA in the CTCA-guided arm than in the stress-imaging arm (71% vs 48%). However, the mean costs were similar for the two strategies at 90 days (\$2494 versus \$2240) and at 3 years follow-up, with more revascularizations and catheterizations performed with CTCA use. In another cost-effectiveness analysis, based on simulation models using published effectiveness and costs data, integrated anatomical-functional imaging strategies were also assessed [26]. In patients with intermediate-low PTP of CAD, CTCA followed by any cardiac stress-imaging test was cost-effective as compared with single imaging strategies. In particular in the USA and the Netherlands the optimal cost-effective strategy, i.e. that which provided the lower cost for one Quality Adjusted Life Year gain (around 20,000 \$/QALY) began with CTCA, followed by cardiac stress imaging if the CTCA demonstrated at least a 50% stenosis in at least one coronary artery and ended with ICA if the stress test was positive. The cost-effectiveness of different strategies varied somewhat among different countries and according to patients' characteristics such as gender and PTP of disease. In any case it is suggested that CTCA is cost-effective as an initial gatekeeper test under varying assumptions in patients with a low-to-intermediate PTP of CAD [27] but integration with functional imaging may help to avoid that an overreliance on coronary anatomy might result in an excessive use of ICA and revascularization procedures, as seen in the SPARC registry [28] and the PROMISE trial [29]. However, it must be taken into account that in contemporary populations referred to cardiac imaging, cardiac event rates with optimal medical therapy, even in patients with established CAD, are quite low [18, 25, 30] thus it is not known whether any imaging strategy will reduce cardiac events in a cost-effective manner when compared with appropriate risk factor modification. For patients with higher risk, direct ICA might be a cost-effective initial strategy but, due to the overestimation of disease probability by current clinical predictive models [6, 31, 32] in real-world practice an integrated CTCA and stress-imaging strategy as gatekeeper to ICA could remain cost-effective in the majority of patients.

In this respect, the health-economic analysis of the EVINCI study provided additional evidence [33]. EVINCI was a multicentre, multinational European, non-randomized controlled clinical trial comparing all available non-invasive imaging modalities for the diagnosis of obstructive CAD in patients with stable chest pain symptoms, intermediate PTP and without prior evidence of disease [6]. Cost-effectiveness analysis was performed in 350 patients (209 males, mean age 59 ± 9 years) undergoing both CTCA and stress imaging prior to ICA. According to Guidelines [19], combined strategies were built with CTCA as first test followed by one stress imaging in case of uncertain CTCA results or with one stress imaging as first test followed by CTCA in case of uncertain stress-test results. Any test was

defined uncertain by core-labs whether the image quality was judged as suboptimal or the stress protocols were inadequate (submaximal stress, therapy not withdrawn). The diagnostic endpoint was obstructive CAD defined as >50% stenosis at quantitative ICA in at least one major coronary vessel. Effectiveness was defined as the percentage of correct diagnosis and costs were calculated using country-specific reimbursements. Incremental cost-effectiveness ratios (ICERs) were obtained using per-patient data and considering “no-imaging” as reference. The prevalence of obstructive CAD was 28%. Strategies using stand-alone CTCA, a specific stress test, their combinations (CTCA first or stress test first) or direct referral to ICA were compared. Combined non-invasive strategies including CTCA-ECHO, CTCA-CMR, CTCA-PET, CTCA-SPECT and direct referral to ICA were all cost-effective and dominated stand-alone stress imaging or the other combinations. Stand-alone CTCA had lower induced costs but only a marginal improvement in effectiveness as compared with “no-imaging.” Costs saving per one additional correct diagnosis over 100 patients ranged from -969 €/cd for CTCA-CMR to -1490 €/cd for CTCA-PET, -3092 €/cd for CTCA-SPECT, and

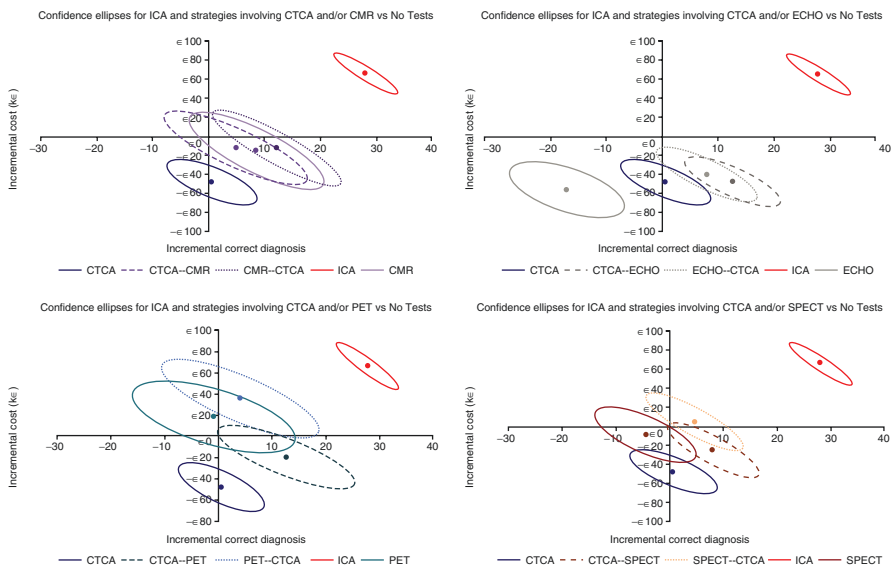

Fig. 1.1 The differences in mean cost and in mean effectiveness (with relative contour plots representing confidence intervals of the distribution generated from bootstrap analysis) are shown. The distribution plot for ICA (continuous red line) is located in the upper right quadrant thus indicating higher effectiveness at the price of higher costs. The distribution plot for stress ECHO is located in the lower left quadrant demonstrating reduction of costs but also lower diagnostic effectiveness while uncertainty exists for all other self-standing tests. For combined strategies, the distribution plots for CTCA-CMR, CTCA-ECHO, CTCA-PET, and CTCA-SPECT (dotted lines) are consistently located in the lower right quadrants indicating gain in effectiveness with reduced costs with some uncertainty. (Adapted from Lorenzoni V et al., The European Journal of Health Economics (with permission))

−3776 €/cd €/cd for CTCA-ECHO. Direct referral to ICA was cost-effective but with additional costs (+2362 €/cd) (Fig. 1.1).

When concordance of imaging results with early revascularization was also considered as an alternative measure of effectiveness, combined strategies with CTCA as gatekeeper followed by either stress CMR, ECHO, PET, or SPECT were all cost-effective as compared with “no-imaging” and dominated stand-alone or other combined strategies, despite some uncertainty. Direct referral to ICA was cost-effective requiring additional costs (+6876 €/correct prediction of revascularization). In general, whether the combination of CTCA with stress imaging would have been used as gatekeeper to catheterization, the positive yield of ICA for the diagnosis of obstructive CAD would have increased from 28 to 57% and the rate of revascularizations performed from 19% up to 40% (Fig. 1.2).

In summary, no outcome based comparative cost-effectiveness study of cardiac “hybrid” imaging in stable CAD is currently available. However, there is some evidence that a “hybrid” strategy, i.e. an appropriate sequential combination and fusion of anatomical imaging by CTCA with perfusion imaging in particular by SPECT or PET, is associated with higher diagnostic efficacy, better guide to invasive procedures and treatment and overall reduced costs as compared with self-standing single non-invasive tests. In the common practice, however, the evaluation of the health-economic impact will be difficult since it depends on multiple variables related to the patient

Fig. 1.2 The diagnostic and therapeutic yield of invasive angiography, if indicated on the basis of non-invasive imaging strategies (without distinction among stress modalities). For comparison, the same figures are obtained whether all patients would have been referred directly to ICA. (Adapted from Lorenzoni V et al., *The European Journal of Health Economics* (with permission))

population (all comers vs selected patients), the estimation of the costs (hybrid technology vs sequential self-standing modalities, differences in regional tariffs), and the estimation of the benefits (diagnosis vs outcome vs potential additional risks).

1.3 Hybrid PET-MRI and Health-Economics Implications

Integrated PET/MRI scanners are available since 2010 and many promising fields of application in cardiology have been developed including suspected coronary artery disease, acute myocardial infarction, heart failure, inflammatory heart diseases such as myocarditis and cardiac sarcoidosis, as well as cardiac tumours. However, it is recognized that large studies are still needed to demonstrate added value in comparison with current standards of care [3]. PET-MRI is an expensive modality that requires proximity to a cyclotron, specialists trained in PET and MRI for patient preparation, image acquisition, post-processing, analysis, and reporting. Simultaneous PET-MR imaging may improve patient workflow and patient experience of a single scan. However, health-economic analyses have to clarify where integrated scanners demonstrate a competitive advantage and where sequential PET and MR acquisition with post hoc image fusion with software is a good alternative. With the current evidence available, clinical PET-MR may be well suited to conditions such as cardiac masses and suspected cardiac sarcoidosis where hybrid imaging offers precise co-registration and fusion of complementary information that may provide incremental value. Once clear clinical indications and pathways are developed, these will need to be recognized as cost-effective for healthcare systems with a defined route for reimbursement [34].

Industry Perspective on Hybrid Cardiac Imaging

2

Thomas Krüwel

2.1 Introduction

Coronary artery disease is one of the major causes of morbidity and mortality in the Western civilization, although large progress was made as cardiovascular disease mortality rates declined dramatically in the last decades [1–3]. Besides changes of lifestyle and medical treatment, surgical revascularization of coronary arteries accounts for a big deal of the declining numbers. However, before surgical treatment, proof of myocardial ischemia is mandatory according to recent guidelines [4]. Thus, there is a need for safe, reliable, robust, fast and cost-effective procedures to detect and assess the extent of coronary artery disease.

Non-invasive cardiac imaging has witnessed huge advances in the last decades, especially for coronary artery disease where it is currently used for diagnosis, risk assessment and decision making for appropriate treatment strategies [3, 5]. As a result, the number of non-invasive cardiac imaging examinations increased over the last years which lead to an increased request of high-end devices for computed tomography (CT) and nuclear cardiology [5].

In nuclear cardiology, positron emission tomography (PET) imaging is referred as the gold standard as it is by nature a quantitative non-invasive method and allows the absolute assessment of myocardial blood flow. Additionally, PET perfusion tracers, such as Ammonia N13, have a relatively high extraction rate and a short physical half-life which allows absolute quantification. However, due to the short half-lives of the available perfusion tracer an onsite cyclotron is needed for cardiac PET imaging today. This requires large investments in equipment and infrastructure which limits the sites who can perform myocardial perfusion PET imaging.

e-mail: thomas.kruewel@ge.com

Single photon emission computed tomography (SPECT) imaging is still the workhorse in nuclear medicine due to the commercial availability of ^{99m}Tc by Mo/Tc generators. For myocardial perfusion, two ^{99m}Tc -based tracers sestamibi (CardioLite, Du Pont) and tetrofosmin (Myoview, GE Healthcare) are available.

Myocardial perfusion SPECT imaging advanced to the most frequently used nuclear medicine test with annually 6.3 million exams in the USA [2]. Conventional SPECT imaging involves prolonged procedure times which compromise cost-effectiveness and overall diagnostic quality. Therefore, the latest development aimed to decrease required imaging time and increase patient throughput at equivalent or better levels of spatial resolution and contrast [6].

2.2 Ultra-Fast Cardiac Cameras Based on CZT Technology

Most recent advances in myocardial SPECT imaging were made in the development of dedicated ultra-fast cardiac cameras based on semiconductor technology of cadmium zinc tellurium (CZT) detectors. In comparison to conventional sodium iodine (NaI) detectors, CZT detectors do not contain a scintillation crystal and the radiation is converted to electrical signals directly without intermediate conversion steps. Although being integral part of conventional NaI detectors and well established for many decades, the intermediate conversion steps are responsible for significant data degradation, especially the energy resolution, and thus clinical limitations. The use of CZT detectors with direct conversion technology, converts the radiation directly, circumvents these shortcomings and recovers lost spatial and energy resolution and eliminates much of the bulk of the systems.

In conventional NaI detectors, gamma rays are absorbed and converted to ultraviolet (UV) photons. The UV photons are directed to photomultiplier tubes (PMT) by light guides and optical coupling compounds (Fig. 2.1a). The detector facing side of the PMT is equipped with a photocathode, which absorbs the UV photons and releases electrons by the photoelectric effect. These electrons are accelerated and multiplied by high voltage stages and collected on the input of a sensitive signal amplifier. This process is defined as indirect conversion. In comparison to that, in the direct conversion process as happening in CZT detectors, incident gamma rays are absorbed which directly results in an electric charge (Fig. 2.1b). This direct process happens without any steps of UV light production, transport and conversion. The 140 keV gamma photon produces 33,000 electron-hole pairs. An applied electric field causes the charges to move and induces signals on the anodes. These signals are further amplified for further readout processing. This results in a better energy resolution, as it only depends on the amplifier noise and is no longer determined by a step with low statistics. In addition to the significantly improved energy resolution, the system resolution was improved due to pixilation of the detector with 2.46 mm by 2.46 mm pixels leading to reduced uncertainty of the intrinsic resolution to the boundaries of the pixel.

The CZT detector has a very compact structure with a crystal dimension of 4 cm by 4 cm by 5 mm or 7.25 mm, respectively. In comparison, a conventional

Fig. 2.1 Comparison of indirect and direct conversion in nuclear medicine event detection. (a) With NaI detector technology, an emitted photon is absorbed by the scintillator (i.e. NaI crystal) and a small light signal is emitted. An array of photomultiplier tubes (PMTs) collects and amplifies the light, which is then converted to 500 photo-electrons. The location of the event (location of the photon emission) is approximately calculated. (b) With the CZT detector technology a photon is directly converted into 30,000 photo-electrons. This eliminates the analog noise or signal noise. The location of the event is accurately identified, including the energy of the photon

detector with a PMT has a vertical dimension of 7 cm, which corresponds to a reduction of size of a factor of 10. This specific design allows the packaging of multiple detectors tightly together or to develop imaging systems with improved proximity, i.e. closer to the body. This allows many detectors to be packed together in a single system which opens a completely new possibility in cardiac imaging. Figure 2.2 shows the components of a complete CZT imaging module including CZT crystal, ASIC electronics, heat sink and digital board. The fully assembled CZT detector module including cover and connectors is depicted in Fig. 2.3.

The advantages of the CZT detector in terms of energy and spatial resolution as well its extremely compact structure makes them well suited for the use in dedicated cardiac cameras. Today, two dedicated cardiac systems based on CZT technology with fundamentally different setup are commercially available. The D-SPECT camera of Spectrum Dynamics is equipped with 6 or 9 rotating detector columns with a parallel hole collimator. Each detector column consists of 4 CZT detector modules summing up to a total of 24–36 detector modules [7].

The Discovery NM 530c of GE Healthcare is equipped with 19 stationary detectors based on pinhole collimation. Each detector consists of four CZT modules summing up to a total of 76 detector modules build in the Discovery NM 530c [6, 7].

Fig. 2.3 Fully assembled CZT detector module

2.3 Pinhole Imaging

Pinhole imaging has been used historically in nuclear medicine for specialized imaging with high resolution due to the magnification of the projection of the specimen. The improvement in spatial resolution, however, comes by the cost of a reduced sensitivity [8]. In cardiac imaging, increased spatial resolution has not highest relevance due to the blurring effects of the moving heart in the cardiac cycle. However, the combination of pinhole collimation with high resolution CZT detectors provides a new means to achieve a net gain in performance without the tradeoff between spatial resolution and sensitivity. The pinhole imaging allows the high resolution of the CZT detector to be converted to high sensitivity without degrading resolution which is more valuable for cardiac imaging. The high sensitivity can then be used to optimize workflow and patient throughput, while the conserved resolution preserves the clinical character and quality of conventional images and the diagnostic protocols [6, 9, 10]. Furthermore, the multiple detectors acquire the full set of views needed for tomographic reconstruction simultaneously and without any detector motion at all (Fig. 2.4a). This capability reduces systematic error from all sources of motion blurring, including both, the detector motion and even the cardiac motion itself. Figure 2.4b shows the multi-pinhole collimator focusing the heart with each pinhole.

The principle how the combination of CZT and pinhole collimation to achieve high sensitivity and conserve resolution is depicted in Fig. 2.5. In conventional NaI imaging the pinhole resolution decreases, i.e. improves with increasing magnification factor. Thus, optimization for high resolution is achieved by moving the detectors away from the pinhole in order to increase the magnification factor. However, the small pixels with the reduced pixel size of the CZT detectors facilitate a new

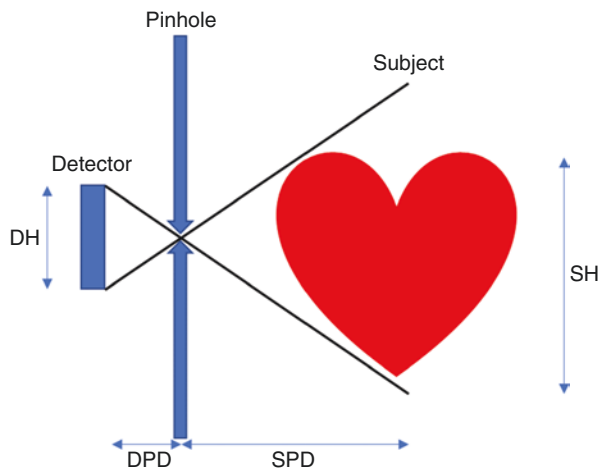

Fig. 2.4 Multi-pinhole imaging. **(a)** Scheme of the geometry of the stationary detector. No movement of the detector occurs during acquisition. **(b)** Multi-pinhole collimator of the Discovery NM 530c

Fig. 2.5 Principle of CZT-based pinhole imaging. Due to the high resolution of the CZT detector, the detector can be closer to the pinhole than the specimen yielding a magnification factor <1 . Magnification is calculated as DH/SH or DPD/SPD . DH detector height, SH source height, DPD detector to pinhole distance, SPD source to pinhole distance

counterintuitive strategy to optimize for high efficiency. In this case, the detector is moved towards the pinhole. The detector surface area needed to image the object is rapidly reduced. The number of pixels in the image is preserved by use of smaller pixels. In order to preserve the resolution, the pinhole size is reduced in accordance with the small pixel size.

In comparison to a conventional gamma camera with low energy high resolution (LEHR) collimator pinhole imaging based on CZT detectors adds up to a five times higher system efficiency.

2.4 Hybrid Imaging for Dedicated Cardiac SPECT Cameras

The new design of the CZT-based dedicated cardiac cameras was reported highly efficient in multiple studies. In comparison to conventional double-head gamma cameras the new systems yield images with higher contrast and spatial resolution, acquired in shorter time and/or with reduced radiation doses to the patient [1, 7, 11–15]. As with conventional gamma cameras, inferior wall artifacts due to soft tissue attenuation are common. The specificity can be improved by two position imaging (supine and prone), however, attenuation correction should be applied if it is available. The CT data used for attenuation correction are embedded in the reconstruction algorithm which leads to more accurate voxel values and has the potential to provide absolute radiotracer concentrations enabling a possible flow quantification with existing tracers [3]. For the dedicated cardiac camera Discovery NM 530c there is already a straightforward approach to include external CT data for attenuation correction.

Besides attenuation correction, hybrid imaging strategies for cardiac imaging are typically synergistic and provide more information than either dataset alone, leading to improved sensitivity and specificity [16–18]. This is because both, the functional consequences of coronary stenosis on myocardial perfusion and metabolism and the morphological coronary artery disease are relevant. Additionally, other entities such as microvascular or endothelial dysfunction have been recognized to contribute significantly to disease pathology [5]. To achieve this, coronary artery calcification (CAC) or coronary CT angiography (CCTA) datasets are fused SPECT or PET myocardial perfusion imaging data.

CAC can be readily compared with an attenuation correction CT because a native CT scan without contrast enhancement is required. CAC adds high clinical value as it provides an estimate of coronary atherosclerotic plaque burden and correlates strongly with the overall amount of coronary plaque. The assessment of the presence of subclinical coronary atherosclerosis with CAC, which cannot be detected by MPI, provides an opportunity to identify asymptomatic patients who are at risk for developing long-term coronary artery disease. Thus, the combination of SPECT and CAC results in a significant improvement in sensitivity and specificity for the diagnosis of angiographically significant coronary artery disease compared to SPECT alone [3, 5, 19, 20].

CCTA provides an accurate morphological assessment of coronary artery anatomy and has the ability to exclude CAD through its very high sensitivity. However, CCTA is a purely anatomical imaging modality and does not offer information on the functional relevance of the coronary lesion. Therefore, the combination and fusion of SPECT and CCTA datasets significantly improve diagnostic accuracy compared to SPECT alone or SPECT and CCTA side-by-side analysis [3, 16, 21–23].

There are many clinical evidences that hybrid imaging adds a strong clinical benefit to myocardial perfusion imaging. This can be performed in two different ways, either by using hybrid SPECT or PET/CT systems or by consecutive SPECT and CT exams on two different systems and a dedicated post-processing. Today, commercially available hybrid SPECT systems are equipped with a CT-subsystem

with a up to 2 cm detector (up to 16 rows) and PET/CT systems with a up to 4 cm detector (up to 64 rows). The in details described dedicated cardiac cameras are available as stand-alone systems only by today.

CT scans for attenuation correction and landmarking can be performed on a non-diagnostic CT scanner. CAC requires at least a diagnostic quality CT scanner and CCTA a state-of-the-art CT with at least 4 cm detector with ultra-fast tube rotation. One may ask why not every hybrid system may be equipped with a modern state-of-the-art 64 row CT, as it would enable convenient and straightforward hybrid imaging. The reason for this is of pure economic nature because every system has to be operated profitable. According to Kaufmann et al. [16], not every patient would benefit from CCTA at all and the prescription of additional CCTA has always be carefully considered, especially regarding dose exposure. If such a CT would be connected to a dedicated cardiac camera, it would be occupied with low utilization. Having a dedicated cardiac camera and a high-end CT, both systems can be operated profitable at optimal capacity utilization as patients that do not need myocardial perfusion imaging can receive their CT exam in the meantime. For those scenarios powerful post-processing was developed to easily register and fuse functional myocardial perfusion with CT data. For attenuation correction, however, an (ultra-)low dose CT combined to a cardiac camera would provide a benefit because SPECT and CT images would be inherently aligned. Although registration of SPECT and CT cardiac datasets is software assisted and a manageable region of interest, registration has to be carefully examined that no potential mismatch occurs. Here, a hybrid system could be beneficial for an improved clinical hybrid workflow.

The field of nuclear cardiac imaging underwent huge improvements by the development of CZT-based dedicated cardiac cameras. The addition of CAC or CCTA to myocardial perfusion imaging improves the diagnostic confidence of the report. Multiple post-processing tools are available to perform registration and fusion of SPECT and CT data to create meaningful SPECT/CT dataset.

Global and Regional Peculiarities: The IAEA Perspective

3

Diana Paez, Maurizio Dondi, Joao V. Vitola, Pedro Prado,
and Leslee J. Shaw

3.1 Introduction

The International Atomic Energy Agency (IAEA) is an independent, intergovernmental organization within the United Nations, with the mandate to accelerate and broaden the contribution of nuclear applications to peace, health and prosperity.

Cardiovascular disease (CVD) is a major contributor to premature morbidity and mortality worldwide. Low- and middle-income countries (LMICs) are particularly affected by cardiovascular diseases (CVDs), as more than 75% of all CVDs deaths occur in these countries [1]. Global prognostic figures are alarming, as an estimated 23.6 million people will die each year due to CVDs by 2030. For this reason, target 3.4 of the Sustainable Development Goals (SDGs) of the agenda of the United Nations (UN) aims at reducing premature mortality due to Non-Communicable Diseases (NCDs) by 30% by 2030 [2], also shared by the European Union [3]. In that context, among other applications, the promotion of nuclear medicine techniques for detection and guided treatment of CVD is a core target of the Division of Human Health inside the IAEA [4].

Medical imaging has revolutionized health care in the past decades as it has enabled the delivery of individual, patient-tailored disease management. The diagnostic and prognostic value of myocardial perfusion imaging (MPI) in CAD is very well established [5].

Within the IAEA, numerous initiatives have been developed or are underway to promote quality imaging practices through regional and global clinical research, educational and training programs. These programs emphasize the importance of worldwide standards for instrumentation, protocols, appropriate use, and high-quality image interpretation and reporting practices [6, 7].

As we look into the future, the IAEA plays an important role in the development of clinical evidence and guidance documents to synthesize available data into optimal testing strategies of care [7–11].

Over the past two decades, the practice of nuclear medicine, including nuclear cardiology applications, has undergone dramatic evolution with the introduction of hybrid systems, which couple a CT scanner with either a PET or a SPECT scanner, that are now in routine clinical practice [5, 12–15]. In nuclear cardiology, the coupled CT scanner is commonly used for attenuation correction [16] but, if equipped with adequate software and an adequate number of slices, can be used to evaluate coronary artery calcium and/or perform coronary CT angiographic studies [17]. An advantage of these systems is that they provide, in one imaging study, comprehensive cardiac evaluation of anatomic information from the CT scan and physiologic information from the PET or SPECT scans [18].

The introduction of hybrid imaging into healthcare systems worldwide has implications about availability of adequate budget and human resources capacity. Both remain the main constraints in LMICs, IAEA Member States, where financial resources are often inadequate and human resources scant.

This chapter will try to discuss global and regional heterogeneity of hybrid imaging as applied in cardiology in IAEA Member States.

3.2 Health Expenditures

According to the World Health Organization (WHO), global public expense for health care (i.e., as a percentage of the gross national product) varies between 4.4 and 16.8%. In 2015, about 7.2 trillion US\$ or on average 10% of global Gross Domestic Product (GDP) were spent on health [19]. Although projections for the future are fraught with challenges, it is conceivable that diagnostic imaging will encumber a significant proportion of that budget. Figure 3.1 represents the current heterogeneity in health care expenditures as a percentage of GDP.

The IAEA has collected data on nuclear medicine practices around the world through its Nuclear Medicine Database (NUMDAB) [20]. According to those records, the average age of equipment is more than 6 years for all types of gamma-cameras in LMICs. However, some systems have been operational for more than 30 years and in many cases planar cameras are still in use in almost all regions in the world, with Africa and Middle East running the oldest machines.

Fig. 3.1 Annual percentage of health care expenditures by country as percentage of GDP. (From: World Health Organization, Global Health Observatory data)

3.3 The Challenge of Introducing Newer Technologies

In general, we have witnessed a delay in introduction of hybrid systems, either SPECT/CT or PET/CT, in LIMCs. Among the possible factors that could explain it is the heterogeneity of investments in newer technologies, impacting nuclear medicine equipment renewal around the globe.

The introduction of newer technologies into health care practices requires a careful assessment of the impact at the medical, societal, and economical level. This is usually done with Health Technology Assessment (HTA), a branch of health care research employing specific methodologies [21] to assess the impact of any new practice in health care, e.g. a new antibiotic, a new surgical procedure, a new screening program, a new expensive technology, etc. LMICs have special needs regarding this approach as financial resources are often limited.

Indeed, economics play an important role in decision-making and a careful assessment of the diagnostic efficacy of a technology is strongly required.

3.4 Diagnostic Efficacy and Cost Effectiveness

Diagnostic imaging efficacy measures may be thought of as arranged in an hierarchical manner [22, 23] (Fig. 3.2).

At the most micro, or local, level, we are concerned with the physical imaging process itself. Efficacy evaluation at the initial level, Level 1, are more related to technical and physical characteristics of diagnostic imaging such as better

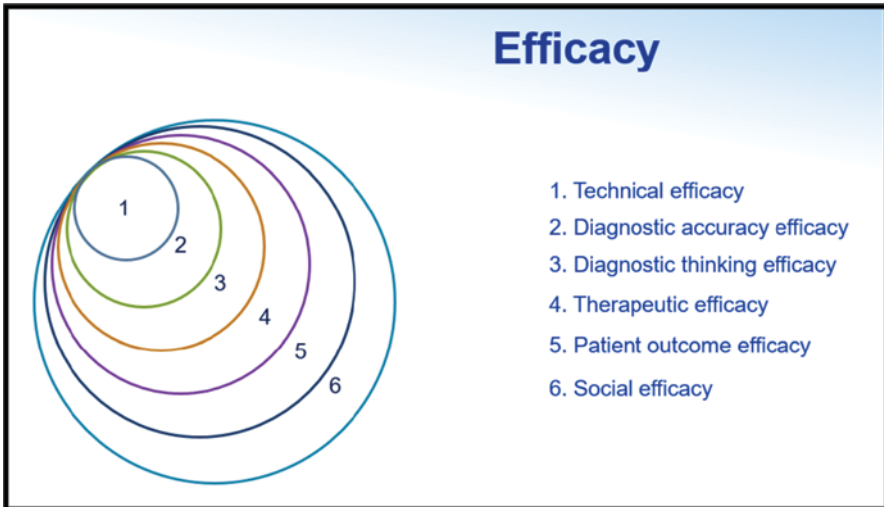

Fig. 3.2 The six levels of efficacy. (Modified, from ref. [22])

resolution or better image quality. At level 2, we are considering parameters such as sensitivity, specificity, diagnostic accuracy; negative and positive predictive values and the actual impact of the interpretation skills of readers. Most clinical research is carried out at this level.

At level 3, we deal with the effect of test results and the way imaging information may have an impact on the differential diagnosis. This usually requires a prospective randomized trial, with its ethical and practical implications [24, 25] to attribute some portion of any improved patient condition to the use of an imaging test (or not).

Level 4 concerns comparison of intended therapeutic intents before the diagnostic examination is obtained with the treatment carried out after test results and the way imaging information changed the management.

Level 5 “patient outcome efficacy” reflects whether there is any impact on patient’s outcome, i.e. his/her well-being. In other words, efficacy at this level requires that a technology diverts therapeutic choices in such a way that patients’ conditions improve.

Level 6 or “societal efficacy” goes beyond the question of individual risks and benefits and is the level that defines the broadest level of efficacy. Efficacy at this level is required by policy makers when they must choose allocation of resources. It means that the costs borne by society for use of a given examination are acceptable, and diagnostic imaging examination is efficacious to the extent that it is an efficient use of societal resources to provide medical benefits to society.

With regard to hybrid imaging, the key issue is that the more global, “systems” view of efficacy forces one to consider standards that go beyond quality or accuracy of hybrid studies to examine the ultimate value or benefit to society that is derived from those examinations.

This hierarchical model can be applied with equal ease to nearly all diagnostic technologies, not just diagnostic imaging, and a key feature of this model is the understanding that for an imaging procedure to be efficacious at a higher level in this hierarchy, it must be efficacious at lower levels. However, the reverse is not true.

In general, assessing the impact of diagnostic imaging studies on patient outcome remains a challenging task, as imaging usually is just one step within the overall management strategy which involves many decisions and other types of clinical information to drive decision-making.

3.5 Economic Evidence on the Use of Nuclear Cardiology

Projected annual costs associated with cardiovascular disease (CVD) continue to grow largely due to the enormous burden of the disease that impacts nearly half of all adults [26]. The resources required to care for this population at risk and living with CVD is equally hefty including costs associated with the diagnostic evaluation and treatment. For example, in the USA, CVD is associated with ~40% of total healthcare expenditures including costs associated with drug treatment [27]. For cardiac imaging, diagnostic procedural growth and utilization volume also contribute to rising costs associated with CVD [28].

Comparing the costs of a given procedure remains an important consideration for creating efficiency within the patient's evaluation and to improve selectivity and optimize the use of lower cost procedures. For nuclear cardiology procedures, the overall costs are generally higher than that of exercise electrocardiography (ECG) due to the need for more expensive equipment, isotopes, and experienced technologists; all increasing the overall cost of the test. However, around the world costs for nuclear cardiology vary when compared to the use of echocardiography, magnetic resonance imaging, or for computed tomographic imaging. So, although we will discuss the cost efficiency and effectiveness, it remains important for readers of this chapter to take the published evidence and apply it within their own healthcare system and local costs.

The total cost of a procedure should include the upfront as well as downstream or follow-up costs. This would sum across a given period of follow-up or at a minimum to include the episode of care. As well, to be comprehensive, cost analyses should also include indirect as well as direct healthcare costs. Indirect costs are those encumbered by the patient including out-of-pocket expenses, such as payments for a procedure, travel costs, or that due to missing a day of work. There is a predictable relationship between cost and patient risk whereby higher risk patients have higher rates of downstream testing. This makes sense as the patient with an abnormal SPECT-myocardial perfusion imaging will be more likely to proceed to invasive coronary angiography and potentially undergo coronary revascularization.

A brief review of the mathematical calculations required for economic modeling can help guide the reader toward a greater understanding of the literature. Cost effectiveness is defined using an incremental or comparative analysis of the differences in cost divided by the differences in outcomes. The result is the term incremental cost effectiveness ratio or ICER. $ICER = (\Delta \text{ cost} / \Delta \text{ outcome})$. Traditionally, the ICER calculation would include the denominator of life years saved or, in some cases, quality-adjusted life years saved. However, many other variants of this are also considered acceptable such as the cost per case detected of coronary artery disease. One challenge with the ICER is that they are often derived using decision models or simulations which rely on many assumptions and apply data inputs from varied resources. Thus, for any cost effectiveness analysis, the reader should take care to evaluate the appropriateness of the cost and outcomes as well as any assumptions made in the modeling process. All these factors may influence the results. For example, the assumption that all patients with abnormal tests proceed to invasive coronary angiography would increase overall costs and is generally not the pattern observed in clinical practice.

The calculation of an ICER can be used to compare optimal selection between two comparative diagnostic strategies and can be used to set local or national policies for a given procedural use. The use of the ICER to guide clinical application provides support for policy changes based on both clinical outcome and economic data to set appropriate standards for imaging utilization.

For nuclear cardiology, cost effectiveness analysis provides a comparison of cost and outcomes with other tests and under which circumstances a given patient indication is optimal. Moreover, the ICER allows policy and decision makers to evaluate the price of one additional outcome from switching from a given standard approach to a novel strategy. If the cost per life year saved is low enough, then the decision is considered favorable. The threshold for economic favorability in the USA has been historically set at <\$50,000 per life year saved but may be set lower or higher based on a given countries economy and available resources for healthcare [29].

Several notable examples exist in the nuclear cardiology literature of cost effectiveness analysis [30–33]. One example compared 4637 patients undergoing SPECT-MPI with 4884 undergoing exercise echocardiography [31]. The results revealed that SPECT-MPI was more cost effective with an ICER of \$32 thousand dollars per life year saved when compared with exercise echocardiography. The analysis revealed that prompt revascularization of patients with abnormal MPI studies improved life expectancy by nearly 3.0 years when compared with echocardiography. Overall, SPECT-MPI was more cost effective than echocardiography among higher likelihood patients including the elderly, diabetics, and those undergoing pharmacologic stress imaging. However, exercise echocardiography had a more favorable ICER (i.e., <\$20,000 per life year saved) among lower risk patients, such as those with an intermediate Duke treadmill score. This analysis supports the value

of understanding patient risk to guide cost effectiveness analysis and optimal allocation of resources.

Importantly, for economic calculations, if there are no differences in outcome, then the calculation is one of cost savings or cost minimization. When differences in outcome exist between two comparative cohorts, then any identified cost savings may impact patient outcome and cause harm. Several notable examples exist in the nuclear cardiology literature when comparative outcomes were similar, yet sizeable cost savings were achieved [34–37]. In one older comparison, 3-year rates of coronary artery disease death and myocardial infarction were similar between an analysis comparing SPECT-MPI as a frontline procedure versus direct invasive coronary angiography [34]. Given the similar outcomes, differences in cost can identify a similarly safe but less expensive diagnostic strategy of care. Direct coronary angiographic costs ranged from \$2900 to \$4600 for low to high clinical risk subgroup as compared to \$2400 to \$3000 for SPECT-MPI patient risk groups ($p < 0.001$); decidedly less costly. Overall a nearly 30% cost savings for SPECT-MPI as the optimal frontline diagnostic procedure when compared with direct coronary angiography. A major driver of the lower cost is the low rate of invasive coronary angiography among patients with normal SPECT-MPI findings. These findings illustrate the importance of SPECT-MPI as a gatekeeper to invasive coronary angiography as an important means to elicit cost savings. A similar analysis was published from a multicenter registry from Europe supporting the use of SPECT-MPI as associated with sizeable cost savings in the evaluation of patients with stable chest pain [38].

A summary of these findings reveals a robust evidence base on the economic evidence of SPECT-MPI. As regards the combination of MPI with coronary calcium or CT angiographic findings done directly with hybrid imaging systems, although specific data is not available, for either SPECT/CT or PET/CT, it remains likely that the combination may improve the timeliness of diagnosis and result in prompt efficient diagnostic care pathway. It can be anticipated that such a pathway would result in more selective use of invasive coronary angiography including improved referral of patients with obstructive coronary artery disease and provocative ischemia.

3.6 The Program in Human Health of the IAEA to Support Nuclear Medicine and Hybrid Imaging

The goal of the IAEA programme in Human Health is to enhance the capabilities in Member States to address needs related to prevention, diagnosis, and treatment of diseases through the application of nuclear techniques. This mandate arises from

Article II of the IAEA's Statute: "The Agency shall seek to accelerate and enlarge the contribution of atomic energy to peace, health and prosperity throughout the world."

To accomplish its Mission, the Division of Human Health run four sub-programs: Nuclear Medicine and Diagnostic Imaging (NMDI); Radiation Oncology and Cancer Treatment; Quality Assurance and Metrology in Radiation Medicine; and Nutrition for Improved Health. The sub-program in Nuclear Medicine and Diagnostic Imaging, run by the NMDI Section, has a long-term objective on enhancing Member States' capability to address health needs by the use nuclear techniques in both imaging and therapeutic applications.

Different activities are run under this subprogram: Coordinated Research Projects (CRPs); Expert Meetings to advise the Agency on specific topics; scientific publications; guidance documents; and educational website [39] and databases [20] Many projects run under Nuclear Medicine have been oriented towards the clinical applications of standard and emerging technologies in Nuclear Medicine such as SPECT/CT, PET/CT for diseases related to two of the major causes of death: cancer and cardiovascular diseases. Focus is also given to therapeutic applications wherein the primary objective is to make available fundamental radiopharmaceuticals for routine clinical use in developing countries [40], and to develop, evaluate, and standardize new diagnostic and therapeutic radiopharmaceuticals for the effective use in diagnostic and therapeutic nuclear medicine procedures. Finally, the section manages projects related to quality improvement and implementation of quality systems in the clinical practice of nuclear medicine [41].

Besides those activities, NMDI also provides support to projects of international technical cooperation managed by the Technical Cooperation Department [42, 43] whose technical cooperation program (TCP) helps Member States to establish effective strategic partnerships with countries and development organizations. It also examines how collaborative efforts may help to meet the requirements of the United Nations' Agenda 2030 and the Sustainable Development Goals [44], of which Human Health is an integral part.

The IAEA's technical cooperation TCP supports national development priorities and needs and is the main mechanism through which the IAEA supports Member States, including support to achieve their identified SDGs. The Agency's TCP is delivered in four regions: Africa, Asia and the Pacific, Europe (and countries in Central Asia), and Latin America and the Caribbean. These needs are identified from national development plans, sectoral strategies, regional profiles, and other relevant programming strategies, such as the 2030 Agenda, including the SDGs, and United Nations Development Assistance Frameworks (UNDAFs), through the Country Programme Framework (CPF).

Fig. 3.3 Technical cooperation program disbursements (actuals) by technical field for 2019. (Source: Technical Cooperation report, IAEA 2019)

In 2019 the technical cooperation fund (TCF) has supported projects in 147 recipient countries and territories including 25 least develop countries, for a total budget of Euro 86 million, of which 25% pertain to the health area (Fig. 3.3).

3.7 Human Resources Capacity Building

Projects covering hybrid imaging supported by the IAEA may include procurement of machinery which in some cases could be SPECT/CT systems, while procurement of PET/CT scanners requires substantial cost-sharing from the recipient country. However, considering the magnitude of the financial investments, all projects must become self-sustainable once the Agency completes its commitments. Therefore, the IAEA puts a lot of energy into human resources capacity building and education and training remains an integral part of the assistance provided to Member States.

In the last years, supported by 134 TCP projects, more than 350 NM practitioners coming from 75 different countries were placed for fellowships (Fig. 3.4a) focused on hybrid imaging (both SPECT/CT and PET/CT) which may last from a few months, when the objective of the training is acquiring new skills or

Fig. 3.4 The distribution of fellows for hybrid imaging fellowships by home country (upper half, **a**) and host country (lower half, **b**) in the last 10 years, is shown in this map. (Source: PCMF database, IAEA)

strengthening existing ones, up to 3–4 years in case of medical doctors requiring certification of specialty. The aggregate number of years of training of these fellows, hosted in 45 countries (Fig. 3.4b), has been about 68 years. A breakdown of those numbers shows that 70% of those fellowships were focused on PET/CT and only

Fig. 3.5 Participants to regional training courses by place of origin. (Source: PCMF database, IAEA)

30% on SPECT/CT, probably reflecting the greater complexity of the former and the greater need in LMICs.

In addition to this, other educational activities are being supported, such as regional training courses (RTCs) on all aspects of NM clinical practice. Limiting our analysis to hybrid imaging for all its applications, we have found that, in the last 10 years, 55 RTCs have been organized and financially supported, with 1167 participants from 103 different countries of origin (Fig. 3.5). Again, a breakdown of the numbers shows that the clear majority (almost 74%) attended RTCs on PET/CT applications.

Educational activities in nuclear cardiology have always been a priority for NMDI, in consideration of the burden of CVD in the developing world, the importance of NC applications in diagnosing and managing CVDs, as well as requests from Member States. Overall, for training in nuclear cardiology at large, the IAEA has supported more than 1000 practitioners for both fellowships and RTCs. More specifically for hybrid imaging in cardiology, the IAEA has supported 55 fellows from 18 home countries who have been placed in 24 different host countries, and 5 RTCs with 104 participants.

3.8 The Growth of Hybrid Imaging in Developing World

The IAEA maintains a worldwide database [20] where information from more than 1300 centers is collected. Currently, more than 1300 centers are counted (Fig. 3.6).

Fig. 3.6 Distribution of censored centers worldwide. (Source: NUMDAB)

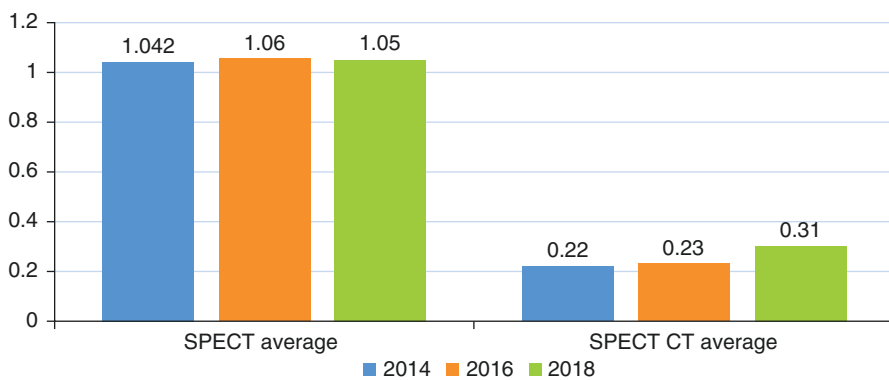

Fig. 3.7 Relative growth of SPECT and SPECT/CT scanners worldwide as counted on NUMDAB database

Through that instrument, information has been collected on the relative overall growth of SPECT/CT and PET/CT and we see that while the average number of SPECT scanners/center has not significantly increased and remained at about 1.05–1.06 scanners per center, the presence of SPECT/CT devices on average has increased from 0.22 to 0.31 per center (Fig. 3.7), a relative increase of about 50%.

Unlike stand-alone SPECT scanners which remain common, we have observed that stand-alone PET scanners are being outnumbered by hybrid PET/CT machines, similar to the developed world (Fig. 3.8).

Fig. 3.8 Rate of growth of PET and PET/CT scanners in LMICs. (Source: NUMDAB)

3.9 Assessment of the Utilization of Hybrid Imaging Worldwide

A recently performed survey among physicians practicing nuclear medicine/nuclear cardiology to evaluate the current utilization of hybrid imaging (PET/CT and SPECT/CT) allowed to collect data from 80 countries in both high-income countries (HIC, $n = 16$) and low- and middle-income countries (LMIC, $n = 64$) representing all the regions of the world. This survey, together with data already available at the IAEA/NUMDAB, allowed for an assessment of the availability of hybrid imaging technology worldwide and showed that these are available at country level in all world regions (Fig. 3.9).

As seen on Fig. 3.9, both technologies are widely available in the Americas (North and Latin America), in Europe, Asia, and Oceania. The figure shows, however, a heterogeneous availability in Africa region with only five countries where both types of scanners are available. Furthermore, in this region, while 11 countries have at least one of the two, and more specifically only SPECT/CT, many others, particularly sub-Saharan countries, have none.

According to this survey, the practice of nuclear cardiology (NC), using any form of equipment, hybrid or not, is either non-existent or practiced at a very low volume in more than 50% of centers in LMIC (<50 patients/month/center). By comparison, nearly 50% of the centers in HIC perform at least 100 patients per month, a clear demonstration of the contrast between LMIC and HIC regarding NC utilization in general.

When those performing NC procedures in HIC and LMIC were queried about the use of SPECT/CT for NC procedures, it was observed that, while 37.5% of the studies are done using this technology in HIC, contrasting to only 21.7% in LMIC (Fig. 3.10). No NC studies are done using SPECT/CT in 43.3% of centers in LMIC, which could be expected due to the limited availability of the technology, but this was also reported in 30.4% of centers in HIC.

Fig. 3.9 Availability of hybrid technology (PET/CT and/or SPECT/CT) worldwide, integrating information from the survey and data from IAEA database/NUMDAB [20]

Fig. 3.10 Percentage of nuclear cardiology studies using SPECT/CT in high-income countries (a) and low- and middle-income countries (b)

As one of the explanations for the low utilization could be that, although practicing NC, some centers might not be equipped with SPECT/CT, we examined in greater detail this question from only the centers with SPECT/CT available and asked whether they use it for NC (Fig. 3.11).

Notably, when available for myocardial perfusion imaging, 67% of the participants are using their SPECT/CT for attenuation correction (AC), for assessing

Fig. 3.11 Use of SPECT/CT for AC and/or CACS in high-income countries (a) and low- and middle-income countries (b)

coronary artery calcium score (CACS) or a combination of both. In HIC, the combination of both is more frequent compared to LMIC (23 vs 15%). These data reveal that despite SPECT/CT availability at their center, 33% of the participants to this survey are not using hybrid imaging at all for NC and this holds true for both HIC and LMIC (Fig. 3.11).

Regarding CACS evaluation, it could also be observed in Fig. 3.11 that, despite its demonstrated prognostic value [45], only 25 and 20% in HIC and LMIC of those doing NC studies using SPECT/CT are also performing CACS.

One interesting question that could be raised is why hybrid systems, even when available, are not being used fully for attenuation correction (AC) and/or CACS which could benefit patient care? Possible explanations could be related to reimbursement issues; lack of training/knowledge from either referring physicians or nuclear physicians/cardiologists; workload or time required for oncologic procedures using this equipment.

Regarding PET/CT, the survey has shown that 79.3% of participants from HIC and 63.2% from those in LMIC do have PET/CT technology available. Nevertheless, only 22.4% of those in HIC and 10.9% in LMIC PET/CT (Fig. 3.12) use it for multiple NC applications, including myocardial perfusion and others (i.e. sarcoid, viability, endocarditis).

Finally, when participants were inquired about the progress of PET/CT for NC applications at their centers, their answers showed that an increase was observed by 64.5% of participants in HIC as opposed to only 47.5% of those in LMIC (Fig. 3.13).

The same question was asked about the progress of SPECT-CT over the last 5 years and approximately 50% of the participants in both HIC and LMIC have observed no significant change in utilization (Fig. 3.14).

Indeed, a decrease was observed by 9.7% of those in HIC vs 16.4% of those in LMIC. Some reasons for this may be related to: (a) limited availability of technology within the country resulting in overload of existing scanners for oncologic indications, (b) non-availability of perfusion agents for PET/CT in LMICs, (c)

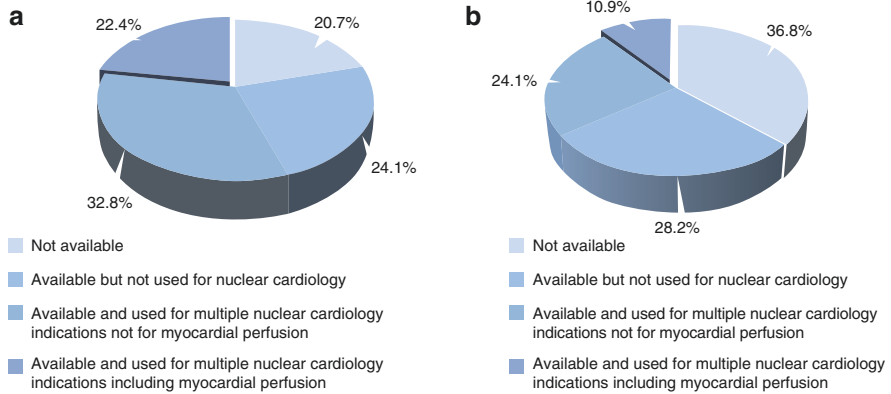

Fig. 3.12 Availability and utilization of PET/CT in high-income countries (a) and low- and middle-income countries (b)

Fig. 3.13 Progress of PET/CT for NC applications in the past 5 years

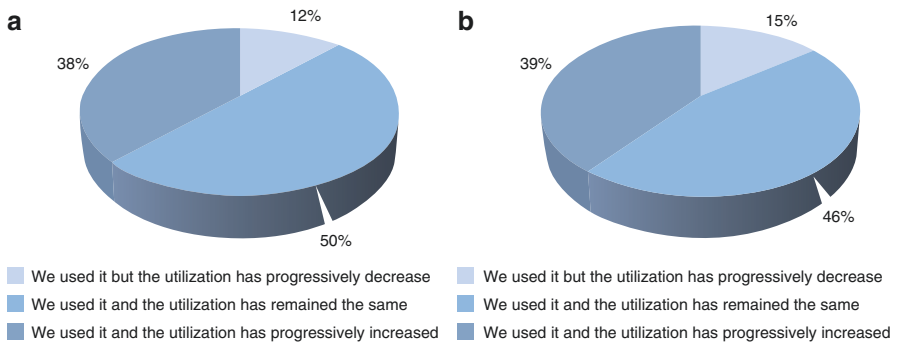

Fig. 3.14 Progress of SPECT/CT for NC applications in the past 5 years

reimbursement issues in some countries, frequently limited to oncologic applications, and/or (d) lack of knowledge/training.

In conclusion, hybrid imaging is growing worldwide and even more so for PET/CT, notably also in LMICs and the developed world. However, its application in NC is not yet so widespread and, while this finding might be related to the very limited availability of that instrumentation which is mainly employed for oncologic applications in LMICs, explanations for HICs require further analysis.

4.1 Coronary Dominancy and Variations

The dominancy of coronary artery distribution is typically defined according to the origin of posterior descending artery [1]. From large number registry of The National Cardiovascular Database Cath Percutaneous Coronary Intervention Registry, Parikh et al. reported that right dominant coronary was found in 169,809 out of 207,926 patients (about 80%), while 20,974 (10%) were found to be left dominant [2]. The variation analysis using CTA (64 slice-CT) reported that 76% showed right dominant and left dominant was only 9.1% out of 700 patients [3]. These findings were similar to the results of Parikh et al's study. Individual coronary anatomy shows significantly wide variation in second branch level, while the dominancy of major coronary tree can be categorized in several patterns. It is occasionally necessary to presume individual coronary path in interpretation of nuclear cardiology. Image interpretation of myocardial perfusion SPECT usually requires nuclear cardiologist to focus on branch distribution of left ventricle which is mainly supplied by left coronary artery (LCA), while right coronary artery (RCA) is mostly dominant vessel in the whole heart. The distribution of distal branch from

left circumferential artery (LCX) and RCA is one of the challenges for nuclear cardiologist to determine culprit vessel in regional ischemia or infarction on inferior to postero-lateral wall.

Territorial analysis in the coronary artery is challenging due to the difficulty of comprehension of dominance in its microvascular level. Several studies suggest to employ coronary CTA based myocardial segmentation (alternatively, called voronoi-based segmentation) [4]. Validation analysis was conducted both in and ex vivo [5–7]. The algorithm is based on segmentation on the area of epicardial surface, and has the limitation of incapability in endomyocardial segmentation, including the papillary muscle level. However, to date, nuclear cardiology has access to only territorial interpretation by default territory presets which can be discrepant from individual coronary dominance and path. Sample illustration of 2D bull's eye output from 3D coronary CTA with typical coronary dominance is shown in Fig. 4.1. The assessment of coronary dominance can be more intuitive, and the territorial difference among cases is obvious in these 2D output when compared to default coronary territory presets.

Fig. 4.1 Sample illustrations of 2D bull's eye output from 3D coronary CTA with typical coronary dominance are shown. Left upper shows balanced distribution in left ventricle, upper right shows left descending artery dominant. Lower left shows right coronary artery dominant which covers whole inferior wall with posterior descending artery, and atrioventricular nodal branch. Lower right shows left circumflex artery dominant which distributes whole inferior wall, and RCA is hypoplastic which was not reachable posterior intraventricular groove

4.2 Calcium Scoring and Assessment of Plaque and Stenosis

Coronary calcium surrogates the pathophysiology of the various causes including atherosclerosis and inflammation. Cumulative evidence suggests that the coronary atherosclerosis is associated with adverse cardiac events and increases mortality [8]. Calculation of coronary calcification had been initially established by Agatston et al. [9]. The initial calcium scoring was done by mostly 4–16 slice-CT which had significant limitation for time resolution and radiation exposure. In the era of high-speed, 320 row-detector CT with reduced radiation exposure, it has become more common to use CT as a part of preventive medicine [10, 11]. The main process of measuring coronary calcium is to use region of interest on coronary calcification along major coronary arteries. Using thresholds (mostly 130HU), volume over CT value was calculated as total Agatston score [12]. This step of calcium scoring is similar among most vendors. The illustrative images for measurement of coronary calcium are shown in Fig. 4.2. Risk management using non-contrast enhanced CT has become the established stratification for low-intermediate risk groups combined with conventional non-invasive risk analysis such as MESA database [13]. As a limitation, extensive coronary calcification can frequently hinder reliable analysis of coronary artery in contrast enhanced scan. However, severe coronary calcification is known to be closely associated with significant coronary obstruction. For its simplicity, the novel approaches for calcium scoring have been attempted in the various opportunities to use CT scan, i.e. lung screening or attenuation correction [14–16]. The weakness of this method is that is no longer available after revascularization including stenting or bypass surgery, device implantation, and chest surgery due to trauma or disease. Vessel specific calcium scoring or

Fig. 4.2 Illustrative figure for coronary calcium scoring is shown. After manual ROI setting, CT value over 130 Hounsfield Units are automatically extracted, and total volume is generated as total Agatston score. Figure shows significant coronary calcification in left descending artery which is calculated as 360

analysis avoiding stent is available in almost all vendors, while those separated analysis remain unclear for its clinical value. Recently, a novel analysis beyond conventional CAC scoring has revealed to investigate the distribution of calcification among vessels in addition to summed value for whole coronary artery calcification [17].

Coronary atherosclerosis represents the course of the development of coronary atherosclerotic change, including soft plaque, and remodelling, and calcification. Despite the incomplete comprehension of the true mechanism due to multifaceted nature of plaque progression, the imaging modalities have successfully managed to visualise those pathological features [18]. The existence of mixed plaque is mostly observed as coexisting with calcified and soft plaque and occasionally contains a certain pattern of calcification on vessel wall with internal low-dense plaque, which is called “napkin ring sign.” These findings can be visually identified in clinical routine. However, the measurement of CT value in the cross-sectional reconstruction is necessary for precise plaque evaluation [19]. Although a number of studies have demonstrated CTA analysis for prediction of plaque characteristics, wide variation of CT values for plaque composition are observed. Plaque is usually categorized as Hounsfield Units (lipid rich plaque as <30 or 50 , fibrotic plaque as over $70-90$) [19, 20]. The so-called ‘vulnerable plaque’ can be defined as high-risk plaque feature, including specific findings, i.e. spotty calcification, soft plaque, and positive remodelling [21, 22]. Figure 4.3 shows the representative case of routine coronary analysis using volume rendering, curved planar reconstruction images of mild and severe atherosclerosis, and typical high-risk plaque.

Fig. 4.3 Coronary CT analysis with volume rendering 3D, curved planar reformatted images (CPR), and cross-sectional images are shown. Left shows 3D volume rendering image for whole heart. Middle-left shows CPR for RCA with minimum coronary atherosclerosis. Middle-right shows severe atherosclerosis with obstructive proximal LAD. Right upper and lower show cross-sectional view images for high-risk plaque feature. Upper shows calcified vessel with internal low attenuation plaque (napkin ring like), and lower shows positive remodeling, lipid rich plaque (attenuation lower than 50HU), and spotty calcification

Basically, CTA has a strong feature for high negative predictive value ($> 95\%$), while positive predictive value remains moderate [23]. Namely, the evaluation of organic stenosis is not clinically useful for prediction of flow-limiting coronary atherosclerosis. The assessment and/or decision-making in coronary revascularization has been based on the degree of luminal stenosis for decades. In 1980's, Quantitative Coronary Angiography (QCA) has been used in catheterization laboratory [24]. Various measuring methods (i.e. Caliper, Densitometry) have failed to overcome beyond the limitation of conventional visual estimation. This issue has not been resolved for decades, and FAME trial finally proved poor predictability of evaluating luminal stenosis for beneficial effect of coronary revascularization [25]. At present, functional assessment by fractional flow reserve (FFR) with the use of vasodilator stress during invasive coronary angiography has been common and required procedure for intermediate stenosis. Similar as above, the limitation of CTA has been incapability of detecting significant flow-limiting coronary artery disease, which can be frequently identified as transient regional ischemia for rest/stress myocardial perfusion SPECT or PET. Thus, functional and physiological evaluation has emerged as clinical needs for CTA, while it has provided anatomical information. Trans attenuation gradient (TAG) has been employed as potential method to detect flow-limiting coronary stenosis using routine CTA [26]. However, the latest studies revealed the significant diagnostic limitation of TAG for detecting functional flow-limiting coronary stenosis [27].

FFRct has emerged as powerful no-invasive FFR prediction tool, employing super computing technology with novel algorithm called computational fluid dynamics [28]. Initial studies demonstrated promising results to predict functional stenosis [29]. The large clinical trials, PROMISE trial, and ADVANCE registry have followed, and PROMISE trial demonstrated the threshold of FFRct = 0.8 significantly improved in predicting revascularization and cardiac mortality. From ADVANCE registry, 1-year outcome revealed that FFRct higher than 0.8 showed lower rates of cardiac events, and long-term prognostic value of FFRct is expected [30]. However, it should be noted that in PROMISE trial, 67% patients was available to analysis for decision making, namely more than 30% subjects needs further analysis. This result indicated that there are frequent inappropriate candidates in clinical routine for FFRct.

4.3 Myocardial CT Perfusion by Dynamic CTA

The evolution of machine enable us to perform dynamic study during administration of contrast agent. CT perfusion has emerged as novel technique to detect stress induced hypo-attenuation as regional ischemia. Large clinical trials for stress myocardial CT perfusion such as CORE64, and CORE320 have demonstrated the promising results for predicting myocardial ischemia [31, 32].

Dynamic CT with reduced radiation exposure has been challenging. CT perfusion study needs both rest and stress scan in order to differentiate stress inducible hypo-attenuation from fixed perfusion defect which indicates myocardial infarction. Despite additional radiation exposure and time extension, the latest generation of

multi-slice CT scanner allows us to perform with lower tube voltage and faster volume scan [33, 34]. This innovation has shown potential of significant usability for CTA as one-stop shop due to have dynamic 4D myocardial perfusion and late enhancement. Stress CT perfusion is limited for pharmacological vasodilation for detecting inducible ischemia. Pharmacological agents for CTP are mainly Dipyridamole, Adenosine, Dobutamine, and Regadenoson, and each has advantage and limitation in terms of cost-effectiveness or required procedure. Current problem is that CT perfusion scan with rest and stress usually take at least about 30 min including 15 min of contrast wash-out either rest/stress or stress/rest, and it may reduce examination throughput in the clinical routine. Moreover, extra equipment is required for automatic syringe for pharmacological stress, extra venous line for infusion, and continuous ECG monitoring.

Here, some facilities has attempted to evaluate intracoronary dynamic flow by 4D-CT as another strategy to identify flow-limiting coronary stenosis [35–37]. The basic concept is development of post-processing to multiply scanned images to animate dynamic series. Using commercially available, dedicated tool (motion coherence image processing by Physiodynamics®, ZIO station®, Ziosoft, Tokyo, Japan), scanned data are interpolated by multiplying neighboring phases up to 90–100 dynamic image datasets. Animated cine is available for visual interpretation with various reconstruction images such as volume rendering, multiplanar reconstruction, slab-maximum intensity projection images, or cross-sectional views [35, 37]. Automated volumetric tracking tool for 4D-CT enable continuous measurement of luminal CT attenuation. Figure 4.4 shows the sample dynamic image series of volume rendering and curved planar reformat combined image series of dynamic perfusion PET (Munich Heart, Munich, Germany). Wall motion kinetics is also available for analysis, and the feasibility of CT derived myocardial strain is increasingly investigated [37, 38].

4.4 Hybrid Analysis and Image Fusion (SPECT or PET and CTA)

In most clinical facilities, both coronary CTA and nuclear cardiology are available for cardiac examination. CTA and nuclear cardiology are routinely performed to detect coronary atherosclerosis or myocardial perfusion abnormality. Mostly, CTA is used as a first line non-invasive tool, and abnormal findings may drive candidates for myocardial perfusion imaging, or CTA may be performed later to rule out when SPECT shows mild abnormal which possibly be artifact. In real-world clinical decision making, the EVINCI study has demonstrated that hybrid interpretation by CTA and SPECT was recognized as a reliable approach for patient management [39]. A picture archiving and communication system (PACS) is available for most radiological image data, and side-by-sided image interpretation using PACS is available and easy in most facilities. Image fusion of CTA and

Fig. 4.4 Serial images for dynamic CTA is shown. Dynamic 4D images of whole heart and coronary flow is visualised using motion coherence image processing technique. This technique is based on image interpolation of scanned images up to four times. Dynamic images were made from 20 scans of diastole phase with low tube voltage. Volume rendering and CPR are also available for measurement of intracoronary or intramyocardium time density. Lower panel shows dynamic scan for myocardial perfusion with N-13 ammonia PET

nuclear cardiology is known as most persuasive approach to manifest the colocalization of regional myocardial ischemia and culprit vessel [40]. However, the image fusion of different modalities can be occasionally challenging due to the frequent misalignments and the discrepancy of temporal resolution among modalities. Figure 4.5 shows the schematic presentation of image fusion by CTA and PET or SPECT scan. Cardiac PET usually show high myocardial uptake with sufficient contrast. In advanced PET machine with time of flight technique, both ventricles are mostly visual and easy to merge one modality to another and confirm registration. Figure 4.6 shows the image fusion of CTA and ^{13}N ammonia PET. Image fusion can demonstrate regional flow reserve with the help of CTA based segmentation in addition to conventional fusion analysis of coronary path and regional ischemia [41]. On contrast, as shown in lower panel of figure 4.5, cardiac SPECT with conventional anger gamma camera shows lower contrast and blur myocardial contour. Consequently, it should be difficult to confirm image registration. Nevertheless, hybrid analysis by image fusion can bring convincing assessment for challenging case. Figure 4.7 shows CTA and SPECT for a patient with post-status of bypass surgery. Significant regional ischemia was identified in antero-lateral wall, while CTA revealed no stenosis or obstruction in bypass grafts. CTA-SPECT fusion showed that the ischemia was localized in distal region of narrowed native diagonal branch.

Fig. 4.5 The figure shows comparison of image fusion for CTA and PET or SPECT. Panels show transaxial view of each modality. Upper shows ^{13}N ammonia PET, CTA, and image fusion. Lower shows $^{99\text{m}}\text{Tc}$ sestamibi SPECT, CTA, and image fusion. Using high-resolution PET, image fusion to CTA is obviously feasible due to both RV and LV are visual, while it is occasionally challenging due to lower contrast and blur contour in SPECT images

Fig. 4.6 Territorial analysis derived from 3D image fusion of CTA and PET is shown. CPR images show significant atherosclerosis in proximal LAD and suspect of obstructive. PET flow reserve map shows impaired flow response in anterior wall, while relative perfusion is normal from rest/stress static images. In default territorial map shows relatively impaired flow reserve in LAD territory (1.89). However, it shows 1.68 from patient based territorial flow analysis

Fig. 4.7 3D fusion image of CTA and SPECT in a patient post status of bypass surgery is shown. SPECT shows regional ischemia in mid-anterolateral wall, while CTA shows no significant stenosis or obstruction in bypass grafts. Image fusion demonstrates the ischemia is corresponding for distal site of native diagonal branches

4.5 Future Direction and Visions

In view of the current trend, FFR_{ct} has a potential as a standard decision-making tool in clinical routine. Recent investigation has demonstrated the usability of CTA, FFR_{ct}, and CT perfusion in single cardiac CT session, optimizing CTA for the standard imaging technique of detecting organic, functional stenosis, and perfusion abnormality [42]. This promising development will enable us to perform anatomical and functional assessments within a single modality.

However, myocardial perfusion imaging provides different clinical information and the established evidence. Moreover, myocardial perfusion study with nuclear cardiology has substantial advantage in obtaining valuable information, including ischaemic burden, size of infarction, viability, stress induced functional impairment, wall motion abnormality, and transient stunning. Of note, the COURAGE nuclear substudy demonstrated that the reduction in ischaemic burden by coronary intervention was directly linked to better prognosis [43]. These clinical evidences are quite valuable information and CTA has not provided yet.

Non-invasive imaging technique including simple test such as calcium scan, or advanced hybrid assessment of coronary atherosclerosis and endothelial dysfunction will remain as primal strategy and provide significant incremental value in clinical decision-making.

Hybrid Imaging of the Autonomic Cardiac Nervous System

5

Walter Noordzij, Lars Stegger, and Riemer H. J. A. Slart

5.1 Introduction

Cardiac autonomic innervation is an integrative part of the physiology of the heart. Myocardial innervation plays an important role in adapting the cardiac function in daily life. Autonomic cardiac innervation is linked to the pathophysiology of several cardiovascular diseases. Arrhythmias are connected to regional as well to global alterations of the electrophysiological function, influenced by autonomic innervations. The cardiac sympathetic innervation system seems to be more sensible to ischemia as compared with myocytes, and may represent an important cause for the development of arrhythmias. Derangements in autonomic function have also been detected in heart failure [1], and appear to have a significant prognostic value [2, 3]. Also, the ability to predict potential lethal ventricular arrhythmias will be important for accurate selection of patient that really need an implantable cardioverter defibrillator (ICD). Non-invasive imaging methods are needed to evaluate the cardiac autonomic function. A number of imaging techniques, including radiopharmaceuticals are available now, applicable on SPECT and PET cameras.

To improve quality, better delineation of the heart, accurate matching of molecular properties and morphology, SPECT and PET are equipped these days with a CT component. This chapter focuses on SPECT/CT and PET/CT application for visualizing and measurement of the cardiac innervation *in vivo*, using specific SPECT and PET radiopharmaceuticals.

5.2 Cardiac Sympathetic Nervous System Imaging

The autonomous nervous system, consisting of the sympathetic and parasympathetic branches, plays a very important role in cardiac functioning. Sympathetic activation leads to an adjustment of cardiac output (e.g., increased heart rate, conduction, and contractility), vessel tone with improved perfusion in brain and muscle, decreased perfusion in the gastrointestinal system, and cardiac metabolism in order to adapt to requirements of mental and physical activity (“fight or flight”) [4]. Sympathetic innervation pertains both to pacemaker cells and normal cardiomyocytes. Both, adrenergic nerves and receptors can be found in abundance in the whole heart. The parasympathetic branch of the autonomous nervous system has an antagonistic effect and adjusts the cardiovascular system to resting conditions with a decrease in heart rate, myocardial contractility, and a redistribution of blood to the gastrointestinal system, e.g. after a meal. While a high density of receptors for the neurotransmitter acetylcholine can be found in the heart, nerve fibers of the parasympathetic function supply the sinus and atrioventricular nodes but also the cardiomyocytes [5]. For both branches, the presynaptic and postsynaptic sides of innervation can be imaged. For the sympathetic branch, radiotracers that mimic the physiological neurotransmitter noradrenalin have been developed for both conventional planar and tomographic (SPECT) scintigraphy and PET [6]. Also, ligands for the relevant receptors are available (see below). The same can be said about the parasympathetic system. Especially with PET, biokinetic modelling can be used together with dynamic data acquisition (and blood sampling) for quantification of physiological properties such as the distribution volume of a neurotransmitter or the density of receptors. Depending on the model and the sophistication of the employed technique biokinetic modelling can require dual or multiple injections of cold and hot substances. In addition, analysis of metabolites may be required. Biokinetic modelling provides meaningful quantitative and not only qualitative/regional information. This is especially relevant in diseases that lead to global and not regional changes of innervation.

5.3 SPECT and PET Tracers

5.3.1 Presynaptic

Several tracers for cardiac sympathetic innervation imaging have been introduced, with iodine-123 labelled metaiodobenzylguanidine (^{123}I -MIBG) being widely used in conventional nuclear medicine, and carbon-11 labelled meta-hydroxy-ephedrine

Table 5.1 SPECT and PET radiopharmaceuticals for the autonomic cardiac nervous system

Name	Target	Category	Advantage	Disadvantage
¹²³ I-MIBG	Presynaptic NE transport	Transporter substrate	– Availability – Experience	– SPECT – Semi-quantitative
¹¹ C-mHED	Presynaptic NE transport	Transporter substrate	– Quantification – Most PET experience	Cyclotron dependent
¹¹ C-epinephrine	Presynaptic NE transport	Transporter substrate	– Quantification – True neurotransmitter	– Cyclotron dependent – Peripheral metabolism
¹¹ C-phenylephrine	Presynaptic NE transport	Transporter substrate	Quantification	– Synthetic catecholamine – Rapid myocardial washout
¹⁸ F-LMI1195	Presynaptic NE transport	Transporter substrate	– Transportable – Quantification – High quality	– Not commercial available – Higher radiation dose
¹¹ C-CGP12177	Post-synaptic beta-adrenoceptor	Receptor antagonist	Quantification	– Cyclotron dependent – Production complicated
¹¹ C-CGP12388	Post-synaptic beta-adrenoceptor	Receptor antagonist	Quantification	Cyclotron dependent
¹¹ C-MQNB	Post-synaptic muscarinic receptor	Receptor antagonist	– Quantification – Highly specific	– Cyclotron dependent – Multiple injection protocols

(¹¹C-mHED) within positron emission tomography (PET) (Table 5.1). In addition to ¹¹C-mHED, amongst others also ¹¹C-ephedrine, ¹¹C-epinephrine, ¹¹C-phenylephrine and—more recently—fluorine-18 labelled *N*-[3-bromo-4-(3-fluoropropoxy)-benzyl]-guanidine (¹⁸F-LMI1195) have been studied. All tracers visualize presynaptic sympathetic innervation.

¹²³I-MIBG is actually an analogue of norepinephrine, as it results from chemical modification of the false neurotransmitter analogue guanethidine. Therefore, its uptake mechanism is similarly to that of norepinephrine (Fig. 5.1). The uptake occurs mainly by a specific uptake system (“uptake-1”) and to a much lesser extent, by a non-specific uptake system (passive diffusion, “uptake-2”). Like norepinephrine, ¹²³I-MIBG is stored in presynaptic nerve terminals granules. Unlike norepinephrine, ¹²³I-MIBG is not bound to receptors on the myocyte membrane, in the case of sympathetic de-innervation, and will not undergo catabolization by monoamine oxidase (MOA). In healthy subjects ¹²³I-MIBG is retained in these granules and will not undergo washout into the synaptic cleft [7, 8].

Carbon-11 labelled meta-hydroxy-ephedrine (¹¹C-mHED) is the main PET tracer in cardiac sympathetic innervation imaging. ¹¹C-mHED is derived from the

Fig. 5.1 Schema of myocardial adrenergic neuronal terminals. It shows the schematic representation of myocardial adrenergic neuronal terminals and demonstrates the chemical structure of the tree main tracers $^{11}\text{C-HED}$, $^{123}\text{I-MIBG}$, and $^{18}\text{F-LMI-1195}$. Abbreviations: *NET* neuroendocrine transporter, via the uptake-1 mechanism, *AR* adrenergic receptor, *NE* norepinephrine. (Acknowledgement: David Vallez Garcia for preparing this illustration)

false norepinephrine analogue *metaraminol*, which is taken up by the presynaptic nerve terminals similarly to norepinephrine (through the “uptake-1” mechanism) [9, 10]. Like $^{123}\text{I-MIBG}$, $^{11}\text{C-mHED}$ is not metabolized by catechol-*O*-methyl transferase or oxidatively deaminated by MOA. However, $^{11}\text{C-mHED}$ rapidly leaks out of the presynaptic vesicles and diffuses into the interstitial space and will dynamically recycle into the neurons again [11]. In the case of sympathetic de-innervation, there is an increase in spillover of $^{11}\text{C-mHED}$ from the nerve terminal, leading to a decreased reuptake [12]. $^{11}\text{C-epinephrine}$ has high affinity for uptake-1 as well [13], and shows higher vesicular packaging and breakdown by MAO. The higher vesicular packaging can be considered as an advantage, since it results in a lower washout rate of the tracer [14]. Especially this breakdown results in radioactive metabolites, with the necessity for correction in quantification of tracer uptake. Unlike norepinephrine, these tracers have no postsynaptic effect when released into the synaptic cleft.

The two most important advantages of PET over conventional nuclear medicine techniques are the better spatial resolution, and the possibility of absolute quantification of tracer uptake. The uptake of $^{11}\text{C-mHED}$ is expressed by the retention index, which is defined as the myocardial activity divided by the integral of the

time-activity curve in plasma [15]. Since myocardial perfusion determines the retention of ^{11}C -mHED, a nitrogen-13 labelled ammonia (^{13}N -ammonia) PET has to be acquired just before ^{11}C -mHED acquisition. Myocardial ^{11}C -mHED uptake in control subjects is homogeneous, characterized by intense accumulation in all myocardial segments [16]. Therefore, the PET tracer ^{11}C -mHED is an attractive non-invasive method for quantification of cardiac sympathetic innervation. The major disadvantage of these ^{11}C -labelled PET tracers is the necessity of an on-site cyclotron. This may become less of a problem with the introduction of ^{18}F -LMI1195, which is actually an analogue to ^{123}I -MIBG [17] (Fig. 5.1).

Head-to-head comparisons of ^{123}I -MIBG and ^{11}C -mHED have not been extensively studied, so far. One study in patients with left ventricular dysfunction showed that defect size (defined as $<60\%$ of maximum) determined by ^{123}I -MIBG and ^{11}C -mHED is closely correlated: $r = 0.88$ [18]. ^{123}I -MIBG scintigraphy underestimates tracer uptake in inferior to inferoapical (or even inferolateral) wall segments. This is probably not a consequence from heart failure, since the same distribution is found in healthy controls [19]. At present, the explanation for this defect has not been fully elucidated, but may be caused by the so-called liver-heart artifact and filtered back projection algorithm. In short, it is likely that ^{11}C -mHED outperforms ^{123}I -MIBG. Despite the advantage of ^{11}C -mHED over ^{123}I -MIBG in tracer uptake quantification, ^{11}C -mHED does not provide in washout kinetics, in contrast to ^{123}I -MIBG. At present, direct comparison between ^{123}I -MIBG and ^{18}F -LMI1195 have not been performed in clinical setting.

5.3.2 Post-synaptic

Several postsynaptic receptor ligands have been labeled and proposed as PET tracers for cardiac quantification and imaging (Table 5.1). However, the clinical use of receptor-targeted tracers is limited to a relative low number of studies. High specific binding, high affinity, and hydrophilicity, which avoids binding to internalized inactive receptors, lack of pharmacologic effects and, finally, a simple and reliable tracer synthesis are requirements that must be met for a widespread application of receptor ligands for myocardial PET. ^{11}C -CGP12177, a hydrophilic non-selective β -adrenoreceptor antagonist, is still the most widely used tracer for adrenergic receptor imaging [20–23]. ^{11}C -CGP12388 is a non-subtype-selective β -adrenergic receptor antagonist and an isopropyl analog of CGP 12177. CGP12388 can be labeled easier than CGP12177 via a one-step procedure using 2- ^{11}C acetone [24]. It is equally hydrophilic compared to ^{11}C -CGP12177 and the biodistribution and retention of CGP12388 is reported to be similar to ^{11}C -CGP12177 [25]. β -adrenoceptor density with ^{11}C -CGP12177 PET in patients showed a decreased β -adrenoceptor density in vivo in a group of patients with heart failure due to idiopathic dilated cardiomyopathy [26].

Caldwell and colleagues evaluated in 13 patients with ischemic congestive heart failure and 25 aged-matched healthy volunteers the presynaptic function with ^{11}C -mHED and the post-synaptic function with ^{11}C -CGP12177 [20]. They

demonstrated a mismatch between pre- and postsynaptic left ventricular sympathetic function is present in patients with severe CHF and may be more marked in those with adverse outcomes. A more recent ^{11}C -CGP12177 PET study found out that in the remote non-infarcted region in patients, β -adrenoceptor downregulation was observed, which was related to deterioration of local myocardial systolic function [27]. In patients with syndrome X [28] and asthma [29], i.e. patients with normal left ventricular function, myocardial β -adrenoceptor density was found to be equal to that in normal volunteers, which is in agreement with the general hypothesis that β -adrenoceptor downregulation is only associated with heart failure. Interestingly, myocardial β -adrenoceptor downregulation was also observed in patients with arrhythmogenic right ventricular cardiomyopathy [30]. Although these patients have no heart failure, some evidence suggests that their local synaptic catecholamine levels are increased, which apparently causes downregulation of β -adrenoceptor similar to that in patients with heart failure [31]. So far, production methods of beta-receptor PET-ligands were very complex, hampering their widespread use. Because of the potential clinical importance of cardiac β -adrenergic receptor imaging with PET, radiopharmaceuticals should be developed for PET sites without proper production facilities. To this end new radiopharmaceuticals need to be developed which are labelled with ^{18}F instead of ^{11}C , as ^{18}F has a longer half-life (110 min) and can be transported to sites within a range of 4 h transport time, which is routinely done on a commercial basis for ^{18}F -FDG. Future perspectives may include the development of ^{18}F -labeled subtype-selective β -adrenoceptor ligands to obtain more information about the pathophysiological role of the different subpopulations in vivo. Subtype-selective ligands are being developed for the β_1 -adrenoceptor as well as the β_2 -adrenoceptor but thus far no suitable ligands have been produced and evaluated in clinical studies. Furthermore, noradrenaline uptake-1 mechanism and β -adrenoceptor density are reduced in the myocardium of patients with chronic LV dysfunction and evidence of hibernating myocardium [32].

5.4 Principles in Analysis, Quantification, and Software

The quantification of ^{123}I -MIBG uptake is a longstanding and a relatively straightforward method: uptake signals from two regions drawn in planar images result in the so-called heart-to-mediastinum ratio (H/M). Usually two measurements are performed, one after 1.5 and one after 4 h, which also yields the diagnostic information of tracer washout [33]. However, although planar imaging is logistically and technically easy to perform, PET offers, through better spatial resolution and sensitivity, access to the regional tracer distribution. PET imaging, however, needs kinetic analysis and is now used basically in all modern medical imaging modalities. From a conceptual point of view, 2–3 general approaches are used: the use of compartmental models, their simplifications, and non-compartmental parameters [34]. It requires a good understanding of the different compartments where the tracer is

distributed such as blood, extracellular, and intracellular compartments, where the tracer is bound. Regarding innervations tracers, the cellular compartments would be the axoplasm and the vesicles. For ^{11}C -mHED, a simplified parameter is available and is the so-called retention (also called retention fraction, retention index or fractional uptake rate). This parameter is calculated by the activity found at a defined time point (e.g. 30–40 min p.i.) and divided by the integral of the arterial input function which is usually derived from the dynamic images. As the tracer uptake of ^{11}C -mHED in the myocardium is very stable in the first hour p.i. this parameter is in a practical setting highly reliable. Generic software packages and well as commercially available software packages are available to quantify the autonomic heart function with PET [34].

5.5 Clinical Applications

5.5.1 ANS and Myocardial Ischemia and Infarction and Heart Failure (CMP)/Heart Transplantation

Autonomic nerve system innervation and function is altered following an acute myocardial infarction (AMI). Excessive cardiac SNS activation is a hallmark of progressive heart failure [35–37]. A compensatory increase in adrenergic drive causes desensitization/downregulation of the uptake-1 mechanism due to excess NE in the synaptic cleft. The downregulation of uptake-1 exposes the heart and postsynaptic adrenergic receptors to greater concentrations of NE, which in turn causes desensitization/downregulation of β -adrenergic receptors, cardiac remodeling, and worsening of HF and prognosis.

Cardiac transplantation leads to sympathetic nerve system denervation (SNS) due to surgical transection of innervating postganglionic nerves at the base of the heart. Indeed, denervation leads to altered SNS cardiac responsiveness, contributing to exercise intolerance and altered coronary blood flow regulation to stress [38, 39]. Based on imaging studies, it is now well known that sympathetic reinnervation may occur later after transplantation; that presence and extent of reinnervation are determined not only by time after transplantation but also by other factors related to age, surgery, and rejection.

PET imaging with ^{11}C -HED has been extensively used to non-invasively characterize cardiac denervation and reinnervation process, and the cardiac physiological responses to reinnervation [38–40].

Longitudinal studies using ^{11}C -HED confirmed these findings and reported a reinnervation pattern that initially occurs in the anteroseptal wall in a basal to distal fashion, followed by lateral wall reinnervation, and lastly inferior wall and apical reinnervation [40]. However, the heart does not become fully reinnervated over time and some patients remain denervated late after surgery (15 years).

Studies evaluating postsynaptic SNS and PNS receptor density in transplant patients with PET are lacking.

5.5.2 Long QT, Brugada, ARVD Detection

The often genetically determined myocardial diseases LongQT-syndrome, Brugada-syndrome and arrhythmogenic right-ventricular cardiomyopathy/dysplasia (ARVC/D) may cause life-threatening arrhythmias that become apparent by syncope and cardiac arrest and are a leading cause of sudden cardiac death in young persons.

Long QT-Syndrome (LQTS). As the name implies, this disease is characterized by an abnormal repolarization phase after cardiac excitation with a characteristic elongation of the QT interval. This change in repolarization makes cardiomyocytes prone to arrhythmias. Long QT is caused by aberrant functioning of different ion channels so that there are different subforms of the disease, most of them inherited, although this syndrome can also be acquired, e.g. if drugs interact with these channels or in cases of low potassium due to malnutrition. The most common variants of inherited Long QT syndrome are caused by mutations in the genes *KCNQ1* (LQT1, most common, affecting the slow delayed potassium rectifier channel), *KCNH2* (LQT2, second most common, affecting the rapid delayed potassium channel), and *SCN5A* (LQT3, affecting the sodium channel). It is known that sympathetic innervation can influence ion channels and cardiac arrhythmias typically occur in times of elevated stress, e.g. during physical exercise or other forms of stress such as sudden noise, for LQT1 and 2 but during rest in LQT3 subforms [41]. The fact that beta-blockers are effective treatment points to a relevant contribution of sympathetic innervation. ^{123}I -MIBG SPECT showed reduced regional tracer uptake in those patients with high QT times, with a previous episode of torsade de pointes tachycardia, ventricular fibrillation or syncope [42], corroborated by Chevalier et al. [43]. No correlation of ^{123}I -MIBG defects were found with LQT genetic subtype by Kies et al. [44]. With ^{11}C -mHED PET also regional uptake deficits were shown by Mazzadi et al. [45]. Zumhagen et al. using the same tracer showed a higher washout rate in LQTS patients, especially in patients with long QT intervals and patients with symptoms [46], but not a higher tracer retention. This is compatible with an earlier study by Calkins et al. [47] that has also not shown a different tracer retention. All in all, there is evidence that sympathetic innervation imbalance is playing a role in this disease.

Brugada syndrome (BrS). BrS is also caused by aberrant ion channels in the heart and can occur in patients without apparent structural abnormalities [48]. The most common involved gene is *SCN5A* that is also affected in the LQT3 subform of the Long QT syndrome, coding for a sodium channel. Other subforms may affect other ion channels. It may become apparent by a typical aberration visible in ECG (ST-segment elevation in V1-V3 leads with coved morphology, called type I form), however, the change may be hidden in normal ECG. The antiarrhythmic agent Ajmalin can be used to reveal the typical ECG changes. Arrhythmias may arise from the right ventricular outflow tract [49]. Clinical symptoms are syncope, cardiac arrest that may result in sudden cardiac death. It is noteworthy that unlike in Long QT syndrome cardiac arrhythmias are triggered during resting conditions and not typically during exercise, conditions in which not the sympathetic but the parasympathetic branch of the autonomous nervous system is active. Regional uptake

deficits in the LV myocardium were revealed by Agostini et al. and corroborated by Wichter et al. using ^{123}I -MIBG SPECT [50, 51], albeit not correlated to clinical characteristics of the disease. Kawaguchi and coworkers were able to show a correlation of more significant uptake deficits with type I ECG patients, considered patients with a higher risk [52]. A dual-tracer PET study addressing the presynaptic and postsynaptic sides of the sympathetic innervation (radiotracers ^{11}C -mHED and ^{11}C -CGP-12177) showed increased presynaptic catecholamine recycling without reduction in beta-receptor densities [53].

ARVC/D. Mutations in genes, in most cases coding for desmosomes that link cells together [54], lead to a cardiomyopathy located mainly in the right ventricular wall, although the left ventricular myocardium may be also affected, so that it may be better to talk of arrhythmogenic cardiomyopathy (ACM) in general [55]. Functional imaging with echocardiography or MRI can find hypokinesia and fatty or fibrofatty replacement of cardiomyocytes and formation of aneurysms and in later stages global impairment of ventricular function [56]. In addition, arrhythmias can arise from these abnormally structured parts of the heart wall with remaining conducting myocardium within scar formations similar to the situation in the post-infarct myocardium. Arrhythmias typically occur during times of elevated sympathetic drive during exercise. Beta-blockers are one of the established treatments pointing also to an involvement of the sympathetic nervous system in this disease. Imaging of the sympathetic function in the LV myocardium has been performed with ^{123}I -MIBG SPECT by Wichter et al., showing the presynaptic side [57]. A large proportion of patients showed regional uptake deficits correlating with the presumed origin of tachycardia. This regional reduction in uptake has prognostic implications with a higher rate of tachyarrhythmias [58]. The density of receptors (postsynaptic side) were also shown to be reduced by the same group using PET and ^{11}C -CGP-12177 as the radiotracer [31].

All these inherited diseases may overlap, e.g. genetic alterations are affecting gene locations underlying more than one disease, e.g. patients may have electrical changes of Brugada syndrome and structural changes of ARVC. Also, cardiac arrhythmias may be associated with other genetic aberrations such as deafness.

As seen from the above examples, there is not (yet) relevant published data on hybrid imaging of autonomous cardiac innervation in LQTS, BrS and ARVC/D investigating both molecular and anatomic and functional data at the same time. The role of hybrid imaging with SPECT-CT, PET-CT, and PET-MRI for the investigation of the autonomic nervous system in these diseases can be found in a molecular assessment by the SPECT and PET components as shown above and by a structural and functional analysis of the heart by the CT and MRI components. MRI has become the modality of choice for most evaluations of cardiac anatomy and function [59] including the assessment of the right ventricular outflow tract [60] relevant in the above diseases. In addition, spatially and temporally (PET-MRI) aligned data sets of molecular and function-anatomic images may help in PET and SPECT uptake quantification in left ventricular and, with potential worth, right ventricular myocardium by means of motion and partial volume corrections.

The value of imaging of anatomic and functional changes is especially obvious for ARVC/D since this cardiomyopathy is frequently associated with typical

anatomical and functional changes to the (in most cases right ventricular) myocardium. MRI is the most relevant modality to assess both anatomical changes/function loss and fibrosis at the same time and newer MRI techniques such as strain analysis with additional potential [54, 56]. However, also in the “channelopathies” LQTS and BrS with primarily electrical changes, anatomical and functional changes can occur. As an example Papavassiliu et al. have found a dilatation of the right ventricular outflow tract in patients with BrS and obvious, non-hidden ECG changes [61]. Gray and colleagues have also found equivalent changes with MRI [62]. Bastiaenen et al. have identified myocardial fibrosis with MRI in patients with BrS [63]. Structural and functional abnormalities measured with MRI are correlated with the SCN5A mutation status [64, 65]. The aberrant QT intervals in LQTS lead to regionally different changes in diastolic function as shown with MRI by Brado et al. [66].

Limited resolution of SPECT and PET and cardiac motion caused by cardiac contraction and respiration lead to image blurring and impaired uptake quantification. Complementary CT and MRI data with a much higher spatial resolution than SPECT and PET can delineate cardiac anatomy more exactly. This information may be used to correct for partial volume effects [67]. Hybrid PET-MRI systems are especially suited to depict motion since MRI imaging over a longer time does not increase radiation burden and can be acquired concurrently with PET [68].

5.5.3 Predicting Ventricular Arrhythmias and Sudden Cardiac Death with ANS Imaging

Selective denervation of myocardial tissue is a key feature in the development of ventricular arrhythmia, in patients with ischemic as well as patients with non-ischemic cardiomyopathies. In addition, even patients without structural or functional heart disease or genetic susceptibility may develop ventricular arrhythmia: idiopathic ventricular fibrillation. Several studies have been performed in these different patient groups [2, 69, 70]. The common features from the results of both PET and MIBG studies are: (1) decreasing cardiac tracer accumulation is linearly correlated with patient survival, (2) the presence of disturbed innervation increases the risk on ventricular arrhythmia, and (3) the risk on ventricular arrhythmia is also determined by the defect size (defined as <60% uptake from maximum). Despite the established higher risk of ventricular arrhythmia with decreasing myocardial tracer uptake, low late HMR could not be identified as an independent prognostic factor from a meta-analysis of 600+ heart failure patients [71]. However, defect size was identified as the only independent prognostic factor for the development of ventricular arrhythmia in ischemic cardiomyopathy patients, based on a prospective multicenter center [72]. This finding could not be confirmed in (non-) ischemic cardiomyopathy patients treated with prophylactic ICD implantation, despite that univariate analysis revealed large late ^{123}I -MIBG sized defect as an independent prognostic predictor of appropriate ICD discharge and sudden cardiac death [73]. Comparable results were shown in the PAREPET study: defect size was identified as the only independent predictive factor for sudden cardiac death [74]. At present, little is known about the role of cardiac sympathetic innervation imaging in

determining cost-effectiveness of ICD implantation in patients with ischemic cardiomyopathy. Not all patients will develop ventricular arrhythmia. In fact, approximately 30% of all patients will benefit from prophylactic ICD implantation. At present, low late HMR has not been able to identify those patients with improved survival after ICD treatment [75].

5.5.4 ANS and Cardiac Resynchronization

Cardiac resynchronization therapy (CRT) can improve cardiac performance in patients with advanced heart failure and LV dyssynchrony. The immediate effect is an improvement in hemodynamics by restoring in-sync contraction of all portions of the ventricular wall. Secondary effects such as an improvement in neural function also play an important role. However, a significant proportion of patients (30–40%) does not benefit from this therapy and the contributing pathomechanisms in success and non-success are not clear [76]. Identification of the regional distribution of viable myocardium and scar tissue can explain part of the failed therapy and can be measured by SPECT, PET, and MRI. Also, the amount of dyssynchrony, conveniently assessed from the same images [77, 78], can predict the potential for improvement. Alterations of the autonomous nervous system present in heart failure and restoration of sympathetic function by CRT may also contribute to a successful treatment (Fig. 5.2). It is known that ^{123}I -MIBG scintigraphy can predict hard adverse events such as life-threatening arrhythmias and cardiac death in patients

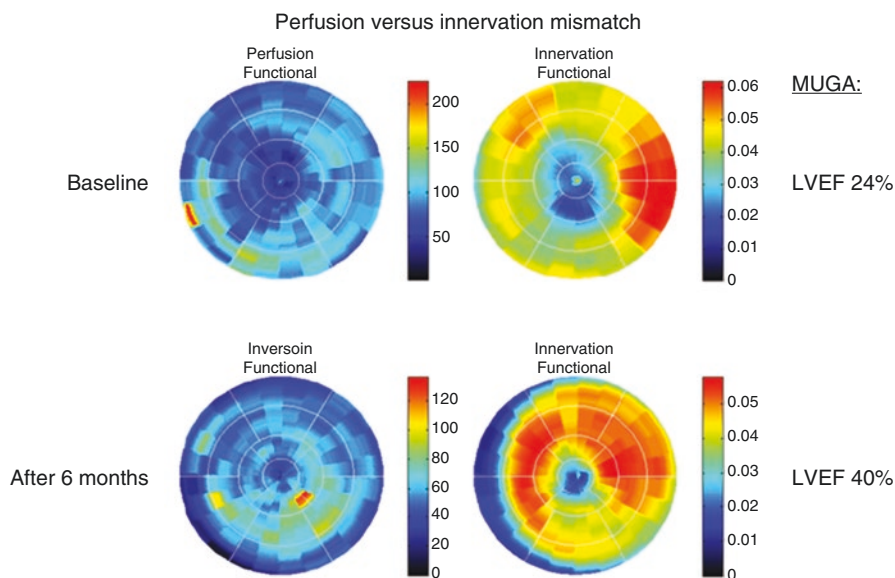

Fig. 5.2 Left polar maps indicate myocardial perfusion (^{13}N -ammonia), right polar maps indicate sympathetic innervation, using ^{11}C -mHED. Patient who showed response to the CRT scanned after 6 months. Mean ^{11}C -mHED increased from 0.035 to 0.041 mL/min/mL after CRT application, combined with improvement of LVEF. (From book Springer Verlag: Alexanderson et al. [79])

with heart failure (lower myocardial tracer uptake means higher risk) [2]. Martignani et al. have investigated the presynaptic sympathetic function with PET and ^{11}C -mHED. Responders to CRT have shown a higher tracer uptake before and after CRT and also an improvement in homogeneity of tracer uptake [80]. Therefore, patients with a structurally preserved sympathetic nervous system benefit better from CRT. Capitanio et al. used the same technique to evaluate whether improved hemodynamics after CRT is accompanied by improved sympathetic innervation [81]. PET images were acquired before, 1 week after and 3 months after initiation of CRT. Results showed that overall uptake did not change significantly but that homogeneity and therefore regional neuronal dysfunction improved over time (measured 3 months after therapy initiation) and not immediately after CRT. Also, radiotracer retention in arterial blood decreased over time, possibly owing to a global improvement of sympathetic function also in other organs. Both factors can be measured separately but are mixed in planar MIBG imaging using the heart-to-mediastinum (blood pool) ratio, showing that planar MIBG imaging is inferior to PET. It remains difficult to predict success from the baseline images alone [82].

5.5.5 ANS and Cardiac Amyloidosis

Patients with amyloidosis have an increased risk of developing cardiac sympathetic innervation abnormalities, in the absence of myocardial perfusion disturbances [83]. Especially patients with transthyretin-related amyloidosis (ATTR type) and patients with immunoglobulin light chain-derived amyloidosis (AL type) may suffer from amyloid infiltration into the conductive system [84]. Specifically, patients with the hereditary form of ATTR (hATTR) frequently develop polyneuropathy and cardiac sympathetic innervation abnormalities. On the other hand, the typical restrictive cardiomyopathy occurs more often in wild-type ATTR amyloidosis (wtATTR) patients.

Despite limitation of nuclear medicine modalities for the visualization of actual amyloid infiltrations, semi-quantitative HMR analysis is assumed to represent amyloid deposits in the sympathetic nerve system [85]. However, ^{123}I -MIBG scintigraphy is not able to discriminate ATTR from AL type amyloidosis [85].

Low late HMR has important implications for amyloidosis patients, since low late HMR is associated with decreased survival. Late HMR is an independent prognostic factor for all-cause mortality. Reported mortality rate was 42% in amyloidosis patients with late HMR <1.60 , whereas 7% in patients with late HMR ≥ 1.60 (hazard ratio (HR) 7.2, $p < 0.001$) [86]. Liver transplantation, which is the only curative option in ATTR patients, may even improve survival in patients with late HMR <1.60 . Furthermore, late HMR after liver transplantation may seem to be of prognostic importance. Although low late HMR has a larger area under the receiver-operating curve (AUC) than clinical parameters and heart rate variability (AUC: 0.79 versus 0.66 and 0.52, respectively) in, this did not result to be of value in multivariate analysis (AUC 0.80 versus 0.79 for reference model, respectively) [87].

Little is known about the contribution of low late HMR to cardiovascular outcome measurements. Although decrease in late HMR stops after liver transplantation, these patients have a higher risk of developing ventricular arrhythmia [88]. At present it is unclear whether continuous amyloid infiltration despite liver transplantation may play an additional role in the prognosis of these patients.

5.5.6 ANS and DM

The long-term complications of DM include microvascular damage of the eyes, kidneys, and nerves, and macrovascular complications including ischemic heart disease, stroke, and peripheral vascular disease. Coronary artery disease (CAD) is the leading cause of morbidity and death in individuals with DM type 2 [89]. The 10-year mortality rate in patients with known CAD and diabetes exceeds 70%.

Another important complication of DM is diabetic neuropathy. Diabetic neuropathies are a heterogeneous group of diabetic complications that affect different parts of peripheral nervous system. Its pathophysiology is likely to be multifactorial, involving alterations in metabolism, micro- and macrovascular dysfunction, deficiency of neurohormonal growth factor, and autoimmune nerve damage [90]. Cardiac autonomic neuropathy (CAN) is one of the most important neuropathies for patients with DM, because it is related with poor cardiac outcome. The prevalence of CAN in type 2 diabetic patients is estimated to be around 20–30% of patients. CAN is particularly associated with an increased risk of silent myocardial infarction and associated with poor outcome related to ventricular arrhythmias and sudden cardiac death [91, 92]. This is contributing to significant cardiovascular morbidity and mortality [93]. CAN results from damage to the autonomic nerve fibers innervating the heart and blood vessels, which causes abnormalities in heart rate control and impairs vascular dynamics. It was estimated that the 5-year mortality rate is five times higher in diabetic patients with CAN than without CAN [90, 94]. Early diagnosis and recognition of CAN are crucial as it may impact on the clinical decision-making of these patients. However, all these tests are indirect assessments of the autonomic nervous system and are less sensitive than direct assessments by cardiac sympathetic adrenergic imaging with SPECT or PET [95–97]. At present, several studies using ^{123}I -MIBG imaging have demonstrated the presence of global and regional abnormalities in sympathetic innervation in diabetic patients [98–102]. Nagamachi and colleagues subsequently evaluated the prognostic value of cardiac ^{123}I -MIBG imaging by retrospectively evaluating 144 type 2 diabetic patients for the occurrence of cardiac events (arrhythmia, heart failure, or acute myocardial infarction), and all-cause mortality [99]. After a mean follow-up period of 7.2 ± 3.2 years, 17 (11.8%) patients experienced a cardiac event, of which 7 died. Previous data have suggested that ^{123}I -MIBG scintigraphy may be more sensitive than HRV for detection of CAN in diabetic subjects [97, 103]. Langer and colleagues investigated CAN according to HRV and ^{123}I -MIBG scintigraphy in 23 normal subjects and 65 asymptomatic patients with diabetes type 2 and silent myocardial ischemia [104]. The authors showed that ^{123}I -MIBG

uptake was largely reduced in diabetic patients, especially in those with clinically detectable CAN; in particular diffuse abnormalities in ^{123}I -MIBG uptake were observed in patients with silent myocardial ischemia. While HRV and other traditional parameters provide an impression of global innervation abnormalities, ^{123}I -MIBG scintigraphy with SPECT provides information on regional innervation. The findings in the study from Scholte indicated that regional abnormalities occur often in patients with asymptomatic diabetes [105].

Regional abnormalities in cardiac sympathetic innervation with ^{11}C -mHED PET imaging in 29 diabetic patients compared with 10 healthy subjects have been studied by Stevens and coworkers [96]. The diabetic patients were categorized into the presence of mild or severe diabetic autonomic neuropathy. Using the absolute difference in myocardial tracer uptake, the extent of regional sympathetic denervation was expressed as the percentage of the left ventricle (LV) in all subjects with diabetes. The study showed that the extent of regional sympathetic denervation was significantly larger in patients with severe autonomic neuropathy compared with patients with mild autonomic neuropathy ($48 \pm 19\%$ vs $6 \pm 5\%$, $p < 0.01$). The role of ^{123}I -MIBG scintigraphy in predicting heart failure (HF) progression in patients with and without DM has been worked out in a substudy of the ADMIRE-HF study [2, 106]. In this international multicenter study, the prognostic value of ^{123}I -MIBG cardiac imaging in 961 subjects with NYHA class II-II heart failure and left ventricular ejection fraction (LVEF) $< 35\%$ have been evaluated. Progression of HF, defined as an increase in NYHA class (from II to III/IV or from III to IV) was observed in 22% of patients with DM compared to 14% in those without DM ($p = 0.005$). In patients with DM the late H/M ratio was lower than in those without DM, and only 21% of patients with DM in the study had a late H/M ratio ≥ 1.6 . This is consistent with cardiac autonomic neuropathy in patients with HF in general, regardless of the presence of DM. Moreover, in heart failure patients with H/M ratio < 1.6 , DM was associated with an three times increased risk of HF progression over 2 years compared to those with DM with normal ^{123}I -MIBG uptake (RR, 2.99; $p < 0.001$).

5.6 Conclusion and Future Perspectives

5.6.1 Potential Novel Tracers

The PAREPET trial identified a prognostic value of regional heterogeneous ^{11}C -mHED uptake (denervation) and ^{11}C -mHED/ ^{13}N -ammonia mismatch (perfused and denervated) for subsequent ventricular arrhythmia manifesting as sudden cardiac death or Implantable Cardioverter Defibrillator (ICD) discharge [74]. The regional abnormalities reported in this study suggest a benefit for PET imaging, in which spatial resolution permits more thorough evaluation of segment innervation. Small-scale trials suggest that postsynaptic β -adrenoceptor imaging may be used to identify patients who will most benefit from targeted β -blocker therapy with carvedilol [23]. These trials demonstrate the potential for sympathetic neuronal

imaging in advanced management of cardiac patients, identify at-risk patients, and guide therapeutic interventions in a sophisticated manner.

There remain challenges with the routine application of currently available radiotracers of the sympathetic nervous system. The complex kinetics of neuronal agents, including some combination of reuptake, vesicular storage, metabolism, active release, and passive diffusion limits the true quantification of sympathetic neuronal integrity. While retention indices, heart to background ratios, or washout rates provide rudimentary data, the accuracy, repeatability, and reproducibility of these measurements can be questionable. Development of novel neuronal tracers with more favorable kinetics, such as the phenethylguanidine series, may overcome some of these challenges and provide more concrete measurements for clinical practice. Second, the majority of PET tracers currently available are labeled with carbon-11, necessitating on-site production for clinical application. Continued development of [^{18}F]-labeled alternatives, particularly ^{18}F -LMI1195 (Fig. 5.3), would overcome these rollout issues to generate a wider clinical relevance. Third,

Fig. 5.3 Case example of a patient with a history myocardial infarction of the inferior wall who underwent F-18 flubromenguane (^{18}F -LMI1195) PET/MRI. Red arrows depict late gadolinium enhancement in MRI as a sign of scarring (upper row), while blue arrows point at decreased tracer uptake in PET indicating denervated areas (bottom row). Overlay of PET and MRI is demonstrated in the middle row. Note that scarring and denervation can also be seen in the inferior part of the right ventricle. (Reprinted with permission from Rischpler C et al. “Cardiac PET/MRI: Current Clinical Status and Future Perspectives.”, *Semin Nucl Med.* 2020 May;50(3):260–269)

imaging of β -adrenoceptors is complicated by application in a patient population that is frequently treated with chronic β -adrenoceptor blockade. This complication underscores the value of developing novel tracers targeting intracellular second messengers and response elements of the signal cascade. Continued research and development with radiotracers targeting adenylate cyclase, cAMP, PKA, regulatory proteins, other specific downstream targets not only overcome the complication of β -blockade, but also may provide invaluable information on compensatory cardiac function under medical therapy. Alternatively, future tracer development may be targeted upstream of adrenergic signaling, aiming at systems and receptors that modulate sympathetic activity in the heart, such as the renin-angiotensin system or the parasympathetic nervous system. Further development of tracers targeting angiotensin receptors, muscarinic and nicotinic acetylcholine receptors, and other targets could contribute to a more complete picture of autonomic regulation of myocardial contractility.

Taken together, while great strides have been made with sympathetic neuronal tracers, many opportunities for molecular imaging remain to be confronted.

5.6.2 Role of PET/MR

The newest hybrid system on the market is the PET-MRT device that combines a PET and an MRI component in one enclosure. One advantage for imaging of the autonomous nervous system of the heart with PET-MRI compared to PET-CT is the superior information gained from MRI. MRI has become the de-facto standard for anatomic and functional assessment of the heart, except for non-invasive coronary angiography that is still in the realm of CT. MRI can also depict tissue properties of the myocardium such as edema and fibrosis, making it a very versatile multimodality imaging technique. Since MRI does not operate with ionizing radiation, PET-MRI causes significantly less radiation exposure than PET-CT, especially when PET-CT is conducted with contrast-enhanced full-dose diagnostic CT. Therefore, longitudinal studies with PET-MRI are easier to justify. The unique feature of this combined system is its ability to image the same field of view with PET and MRI at the same time, allowing for perfect spatial and temporal alignment. This can be an advantage when a physiological intervention, e.g. pharmacological or physical stress, is applied during data acquisition. Only with concurrent imaging the same physiological state is imaged with both MRI and PET. Concurrent PET-MRI acquisition also opens a door to MR-based PET image improvement via partial volume and motion correction. Last but not least, total imaging time is significantly less when both time-consuming MRI and (dynamic) PET can be acquired at the same time. Also, biokinetic modelling of PET data may be improved with MRI, either by using MRI vessel data for partial volume correction of the arterial input function or by using an MRI-derived parameter (e.g., first pass tracer distribution, quantitative perfusion) within the mathematical framework of PET quantification.

5.6.3 New Clinical Trial

Large trials are necessary for future implementation of cardiac sympathetic imaging into different guidelines. Recently, the PAREPET II trial ([ClinicalTrial.gov Identifier: NCT03493516](https://clinicaltrials.gov/ct2/show/study/NCT03493516)) started recruiting patients. This prospective study will use ^{18}F -LMI1195 for the quantification of denervated area of the left ventricle. The aim of the study is to better identify those patients with coronary artery disease who will benefit from ICD implantation for primary prevention of ventricular arrhythmia and sudden cardiac death. Furthermore, this study aims to identify those patients in whom ICD implantation can be safely withheld. A total of 302 patients are expected to be enrolled before January 2023. First results are expected in 2024.

5.6.4 Clinical Implementation

Before cardiac sympathetic imaging will be incorporated within clinical guidelines, not only large clinical trials will be pivotal, but also consensus in standardization of both image acquisition and analysis is warranted [107]. In general, the use of medium energy collimators is preferred over low energy collimators. In recent years, conversion algorithms showed to adequately overcome the difference in acquired HMR [108, 109]. In addition, meta-analyses of the results from previous studies by means of these conversion factors have been recently published. Recalculation of standardized HMR from previously published ^{123}I -MIBG HMR values in patients with chronic heart failure resulted in a 2-year mortality risk model [110]. Despite good correlation with actual cardiac mortality, the model underestimated mortality in patients with highest risk of cardiac death.

Finally, dedicated software applications for analysis of both PET and ^{123}I -MIBG based data for quantification of cardiac sympathetic function are still lacking. Introduction of these software packages would fast-forward the clinical implementation of this imaging modality.

5.7 Conclusion

Imaging cardiac sympathetic innervation has a large potential in clinical decision-making. This potential lies mainly in identifying those patients that would benefit from prophylactic ICD implantation, in predicting of response to CRT, and novel drug-driven indications. Incorporation of sympathetic innervation imaging into clinical guidelines relies on standardization of both imaging acquisition and data analysis.

Dyssynchrony is the term applied to disorganized ventricular contraction and is typified by regional variation in the timing of contraction of left ventricular (LV) segments. While minor variations in the timing of regional segmental contraction exist in normal hearts, pathologic dyssynchrony is defined by limits not encountered in normal subjects. Thus, dyssynchrony is best considered along a continuum of severity, rather than as a binary phenomenon. The term dyssynchrony has been applied to both electrical and mechanical aberrations. Electrical dyssynchrony is most commonly recognized by a wide QRS duration [1, 2], which is a strong predictor of clinical improvement after cardiac resynchronization therapy (CRT) [1–4]. In contrast, mechanical dyssynchrony can present itself as (a) atrioventricular dyssynchrony: between the atrium and the ventricle, as seen in heart blocks, (b) interventricular dyssynchrony: between left and right ventricle, and (c) intraventricular dyssynchrony: within various segments of the LV or left ventricular mechanical dyssynchrony (LVMD). Additionally, LVD can be both systolic and diastolic, with growing evidence of prognostic value of the latter [5]. Studies have shown that LVD is more significantly correlated with cardiac hemodynamic than interventricular dyssynchrony [6], and is a strong predictor of heart failure (HF) progression [7–9]. Clearly, electrical and mechanical dyssynchrony can co-exist,

thickening and myocardial count density during a cardiac cycle [12]. This can be appreciated as a “brighter” myocardium (secondary to higher count density) during systole in gated SPECT. In phase analysis the myocardial count data from a cardiac cycle is subjected to Fourier first harmonic transformation to obtain a count activity curve, which represents the timing of myocardial thickening on gated SPECT. For gated SPECT, with a typical 8 or 16 frame gating, Fourier first harmonic transformation improves the temporal resolution, allowing for comparison of timing of contraction between various myocardial voxels. The time during a cardiac cycle when the count density of a voxel increases above the mean count density of that voxel is used to delineate the onset of mechanical contraction (OMC). Thus OMC represents the phase (time in degree) when a myocardial voxel begins contracting (Fig. 6.2a) [13, 14]. The OMC data is acquired for numerous voxels (>600) and displayed as a histogram, wherein the x -axis represents the phase (time in degrees; 0–360°) and y -axis represents the frequency of OMC at that phase (Fig. 6.2b). In addition to degrees, phase analysis results can also be presented as milliseconds and percentage of cardiac cycle (%R-R). Similar principles can also be applied to derive the peak of contraction of a myocardial voxel, and software approaches variably utilize the onset or peak of regional contraction to derive dyssynchrony parameters. The most

Fig. 6.2 Phase analysis by gated myocardial perfusion SPECT. (a) Example of a time-activity curve for a single myocardial sample volume generated by 16-bin gating. The data points (filled triangle) are then fitted to a continuous curve, using a Fourier transform. Based on the partial volume effect, this time-activity curve represents the thickening curve of this particular myocardial sample during a cardiac cycle. The point at which the continuous thickening curve intersects with the average count density of this voxel (horizontal line) is considered the onset of mechanical contraction (OMC) for this region. The software computes the OMC for all LV myocardial samples collected (>600) and then displays the composite result as a phase histogram and phase polar map (b). The phase histogram shows the percentage of myocardium contracting (y -axis) at each point in the cardiac cycle (x -axis). The phase polar map is a bull’s-eye representation of the left ventricle, showing the sequence of mechanical activation, using a color-coded scheme. This is an example of synchronous LV contraction with a narrow and highly peaked histogram and a uniform color on the phase polar map. (Adapted from Friehting M, Chen J, Saba S, et al. A prospective pilot study to evaluate the relationship between acute change in left ventricular synchrony after cardiac resynchronization therapy and patient outcome using a single-injection gated SPECT protocol. *Circ Cardiovasc Imaging* 2011;4 (5):533; with permission) [56]

commonly utilized and validated indices of LVD from gated SPECT are the phase histogram bandwidth (HBW), the range of degree of the cardiac cycle that encompasses 95% of the phase distribution, and the PSD, which is the standard deviation of the phase distribution. Entropy% reflects the similarity in the contraction onset times in the LV and is calculated by $[f_i * \log(f_i)] / \text{Log}(n)$, where f is the frequency in the i th bin and n is the number of bins [15]. These values of global LVD from gated SPECT have been validated against 2D [16, 17] and 3D echocardiography [18, 19], as well speckle tracking echocardiography [20]. Several commercial software packages have been developed to make the LV perfusion interpretations more standardized including QPS-QGS from Cedars Sinai Medical Centre (California, USA) [21], Corridor4DM SPECT from Invia Medical Solutions (Eclipse Systems, Branford, USA) [22], and Emory Toolbox from Emory University (Georgia, USA) [23]. Recent studies have shown a considerable variability among measures of LVD by different software [15, 24]. Thus, software specific values should be used to interpret presence or absence of LVD. Phase histograms from patients with and without LVD are shown in Fig. 6.3. Averaging of the phase value of each voxel within a specific standard myocardial segment [25] allows for assessment of

Fig. 6.3 Representative phase histograms and polar maps from two patients (a) without and (b) with left ventricular dyssynchrony

Fig. 6.4 Phase polar map depicting segmental phase values in a patient with left bundle branch block. Mean segmental phase (in degrees) is calculated for each of the standard 17 left ventricular segments by averaging the peak phases of all the voxels that form a segment. The onset of mechanical contraction is earlier (92–170°) in septal segments than in lateral segments (180–200°)

segmental phase [25] (Fig. 6.4). These phase analysis values expressed with a 17-segment model allow for comparison of regional differences in myocardial contraction. An alternative approach to detect wall motion and LVD uses an estimation of endo- and epicardial borders localized in gradient operators and information on the LV shape, location, and continuity of the LV wall. A midline between endo- and epicardium is set, and perpendicular normal vectors are placed between the corresponding sectors in end-diastolic and end-systolic borders. Regional LV motion is detected as a change in vector length in each corresponding sector. The time to peak motion is calculated throughout the cardiac cycle for each segment and a phase histogram is then produced based on that information [26].

6.2 Dyssynchrony as a Guide for Cardiac Resynchronization Therapy

In patients with HF, dyssynchrony promotes ventricular remodeling which worsens systolic function, HF symptoms and, increases morbidity and mortality [27–29]. Cardiac Resynchronization Therapy (CRT) via implantation of a biventricular pacemaker has been shown to promote synchronous ventricular contraction [30–32] and reversal of LV remodeling [33, 34]. Though, population based studies have shown that among patients with drug refractory HF, resynchronization therapy confers a mortality benefit, especially in the presence of dyssynchrony [35–38], symptomatic improvement from CRT is noted only in 50% of the patients receiving this invasive therapy [39]. Although patients with electrical dyssynchrony (LBBB or a wide QRS) have been shown to derive the greatest benefit from CRT in clinical trials [40], some studies have reported either modest no correlation between electrical dyssynchrony and response to CRT [41, 42]. While the presence of mechanical

dyssynchrony seems to be essential for clinical improvement following CRT [43], CRT response is a complex phenomenon and is influenced by several other parameters, such as myocardial scar burden, regional (segmental) differences in myocardial contractility, and the location of the LV lead in relation to latest contracting segments and myocardial scar. Furthermore, anatomical abnormalities attributable to congenital heart diseases or previous surgical intervention can cause technical challenges in the CRT lead placement [44]. Routine Gated SPECT allows for identification of all of these important determinants of CRT response and can thus theoretically aid in improving the efficacy of CRT.

The influence of myocardial scar on clinical response to CRT is well established. Among patients with ischemic cardiomyopathy, CRT non-responders had a significantly greater scar burden when compared to CRT responders (50% vs 28% of left ventricular myocardium) [45]. Additionally, non-responders had a greater number of severely infarcted segments and a greater density of scar near the LV lead. Similarly, among patients with ischemic cardiomyopathy, LV lead location in regions of transmural scar on SPECT was associated with the lack of clinical improvement after CRT [46], and placement of LV lead at or near myocardial scar, and ischemic myocardium was associated with greater mortality and HF hospitalization [47]. This impact of myocardial scar on CRT response was further evaluated in a larger population of 620 patients, with HF, severely reduced left ventricular EF and QRS duration >120 ms [48]. In this study, patients with a summed rest score (SRS) >27 (corresponding to approximately 40% of the left ventricular myocardium) on rest-redistribution thallium 201 chloride (TI-201) myocardial perfusion SPECT, experienced a lack of functional improvement and poorer survival after CRT [48]. These studies suggest that a high global myocardial scar burden (~40% of the left ventricle) and regional scar at the site of the LV lead preclude a favorable response to CRT and should be accounted for when evaluating candidacy for CRT and response.

Assessment of regional or segmental phase by gated SPECT allows for the identification of the site of latest activation (SOLA), and this can be used to guide implantation of LV lead of a biventricular pacemaker [25, 49, 50]. SOLA guided LV lead placement has been shown to result in a greater response from CRT, along with reverse LV remodeling [51]. Contemporary CRT with biventricular pacing from the right ventricle and coronary sinus limits the implanter's options of positioning the left ventricular lead, which is often empirically positioned in the lateral LV wall [52]. It is thus likely that the septal and lateral positioning of the CRT leads specifically ameliorates the inherent septal to lateral wall delay seen in LBBB, thus resulting in the greatest benefit from CRT among those with HF and LBBB. A study applying phase analysis of gated SPECT among patients with non-ischemic cardiomyopathy has shown that benefit from CRT is greater among patients with a wide QRS duration (>150 ms) when compared to those with QRS duration between 120 and 150 ms [25]. This association was not observed in

patients with ischemic cardiomyopathy when the site of latest activation was at the scar, irrespective of QRS duration. In a retrospective study of HF patients undergoing gated SPECT, it was noted that among patients with non-LBBB QRS morphology, approximately 50% had a myocardial activation pattern mimicking those with LBBB (septal to lateral wall delay) [53]. This observation may explain the variable CRT response observed in patients with non-LBBB types of QRS morphology and argues for a formal assessment of dyssynchrony patterns in these patients before prescribing CRT. A small, randomized controlled trial has shown better CRT response among patients in whom the placement of left ventricular lead was guided by SOLA on speckle tracking echocardiography [54]. SOLA guided lead implantation resulted in resynchronization in 72% of the patients as opposed to only 48% in whom biventricular pacemaker was implanted without imaging guidance. These findings support the identification of SOLA in a viable segment of myocardium to guide optimal left ventricular lead placement for CRT response. An approach of identifying SOLA, myocardial scar burden and an ideal site of LV lead placement from a single gated SPECT has been recently reported [55]. This approach allows for fusion of gated SPECT images with coronary sinus venogram, allowing the operator to guide the LV lead towards an optimal location on the left ventricle, i.e. viable or non-scarred myocardium with SOLA. The combined value of identifying LVD, myocardial scar burden, and LV lead concordance with SOLA has been systematically studied in patients undergoing CRT. In a prospective study of 44 CRT candidates, SPECT was performed before and immediately after activation of the left ventricular lead, using a novel “single-injection” ^{99m}Tc -protocol [56]. An algorithm incorporating the presence of LVD at baseline, scar burden of <40%, and concordance of left ventricular lead with SOLA was shown to predict acute improvement or no change in LV synchrony with 72% sensitivity, 93% specificity, 96% positive predictive value (PPV), and 96% negative predictive value (NPV) for acute deterioration in synchrony (Fig. 6.5). Patients who had acute improvement or no change in LV synchrony following CRT had lower composite outcome of death, heart failure hospitalization, and ventricular arrhythmia compared to those who had acute deterioration [56].

These recent findings from observational and prospective studies may explain the lack of symptomatic or functional improvement in a substantial proportion of patients selected for CRT using clinical criteria. Our contemporary knowledge base suggests that CRT response is a complex phenomenon and that attempts to predict CRT response using just a few dyssynchrony parameters may be overly simplistic. The available literature strongly supports an in-depth assessment of several parameters (presence and pattern of dyssynchrony, location and extent of scar, site of latest activation) to identify myocardial substrate that is amenable to improvement after CRT. The “U-shaped” LV conduction pattern detected with MPI SPECT, MRI or echocardiography has been shown to be predictive for reverse remodeling and good CRT response [57–59].

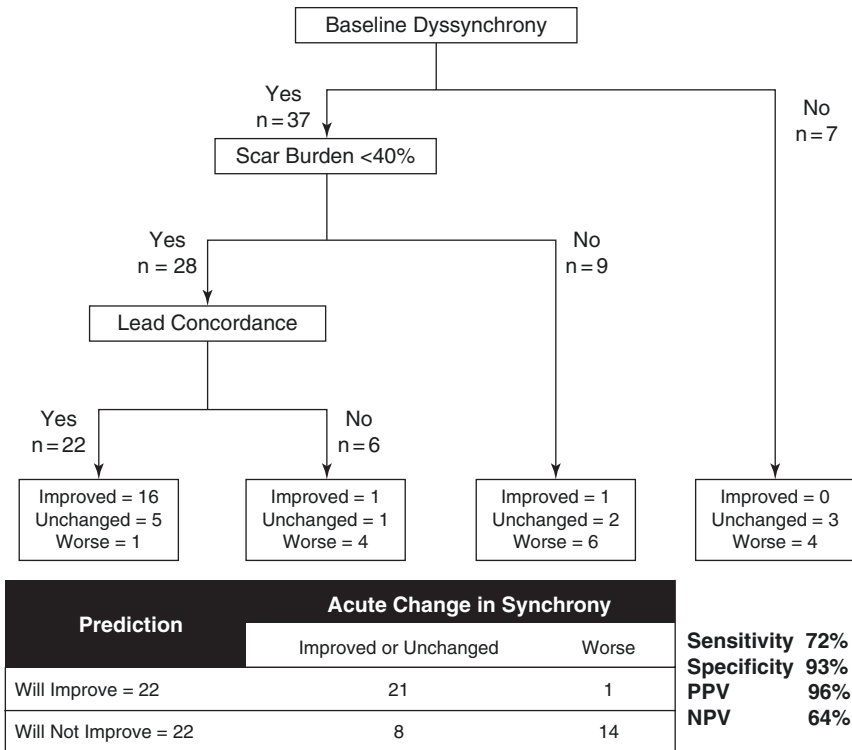

Fig. 6.5 Algorithm for predicting acute change in synchrony from gated SPECT. (Adapted from Friehling M, Chen J, Saba S, et al. A prospective pilot study to evaluate the relationship between acute change in left ventricular synchrony after cardiac resynchronization therapy and patient outcome using a single-injection gated SPECT protocol. *Circ Cardiovasc Imaging* 2011;4 (5):536; with permission) [56]

6.3 Dyssynchrony as a Guide for Implantable Cardioverter Defibrillator

Implantable cardioverter defibrillators (ICDs) are an established preventive therapy in symptomatic HF patients with low LV ejection fraction (<35%), particularly with ischemic cardiomyopathy, and confers a mortality benefit [60, 61]. Recent data suggests that the incidence of ICD shock in a real-world scenario to be only 4% and that of an appropriate ICD therapy (shock or antitachycardia pacing) to be about 14% [62, 63], indicating that only a fraction of patients with an ICD receive appropriate therapy. ICD implantation is expensive, with a relatively high cost per life-year saved [64]. Additionally, inappropriate ICD shocks are associated with a poor outcome [65]. These observations underscore the need for more selective criteria than LV ejection fraction for ICD implantation. Among patients with ischemic and

nonischemic cardiomyopathy and a primary prevention ICD, a greater severity of dyssynchrony by phase analysis of gated SPECT was associated with a greater occurrence of death and ICD shocks [66]. Similarly, among patients with biventricular pacemakers, a combination of lower LV ejection fraction, greater burden of myocardial scar, and a greater severity of dyssynchrony were associated with ventricular tachyarrhythmia [67]. These observational studies suggest that the genesis of ventricular tachyarrhythmia in HF is a complex process with an interplay of numerous factors, and that LV ejection fraction is a poor surrogate of arrhythmogenic myocardial substrate.

The interaction between dyssynchrony and myocardial substrate in predicting ventricular tachyarrhythmia has been recently reported in a population with primary prevention ICD. In 183 patients with ischemic and nonischemic cardiomyopathy, dyssynchrony was determined from by gated SPECT performed prior to ICD implantation [3], and was noted to be present in majority of the patients, with LV scar burden being the only independent predictor of dyssynchrony. Over an average follow-up of 12 months, ventricular tachyarrhythmia occurred in 48 patients (26%). Ninety-eight percent of patients who experienced VT had dyssynchrony prior to ICD implantation. Only one patient without dyssynchrony experienced VT (negative predictive value of 98%). The presence of LV dyssynchrony and a scar burden of >6% of the LV myocardium predicted ventricular tachyarrhythmia in 83% of the patients, and thus identified patients at the highest risk of ventricular tachyarrhythmia. On the contrary, lack of dyssynchrony was associated with an excellent prognosis, free of ventricular tachyarrhythmia, and thus identified HF patients with reduced ejection fraction at the lowest risk of an arrhythmic event. A diagrammatic representation of the interplay between dyssynchrony and arrhythmogenic myocardial substrate is shown in Fig. 6.6. Among patients with biventricular pacemakers ($n = 43$), in whom gated SPECT was performed both before and immediately after activation of biventricular pacing [3, 56], complete amelioration of dyssynchrony with CRT was associated with the absence of any ventricular arrhythmia on follow-up (Fig. 6.7). Persistent or new LVD after CRT are associated with similar rates of ventricular tachyarrhythmia after CRT (Fig. 6.7). It is likely that CRT exerts its anti-arrhythmic effects by reducing dyssynchrony, which is supported by similar observations from clinical trials [68]. Contrary to this benefit, CRT may also induce dyssynchrony in previously “synchronous” ventricles and make them prone to ventricular tachyarrhythmia. The potential adverse effect of CRT has also been reported in patients undergoing an upgrade from an ICD to a biventricular pacemaker/ICD [69]. A greater frequency of sustained ventricular tachyarrhythmia (16% vs. 7%), non-sustained ventricular tachyarrhythmia VT (59% vs. 2.3%), and ventricular fibrillation (25% vs. 5%) were reported following CRT despite an improvement in left ventricular EF, though presence or resolution of LVD was not studied. These findings collectively suggest a critical role of dyssynchrony in arrhythmogenesis, and its utility in guiding ICD therapy. Furthermore, these observational studies provide consistent evidence that presence of dyssynchrony is probably essential for benefit from CRT and, that CRT can also result in worsening outcomes, possibly via induction of LVD.

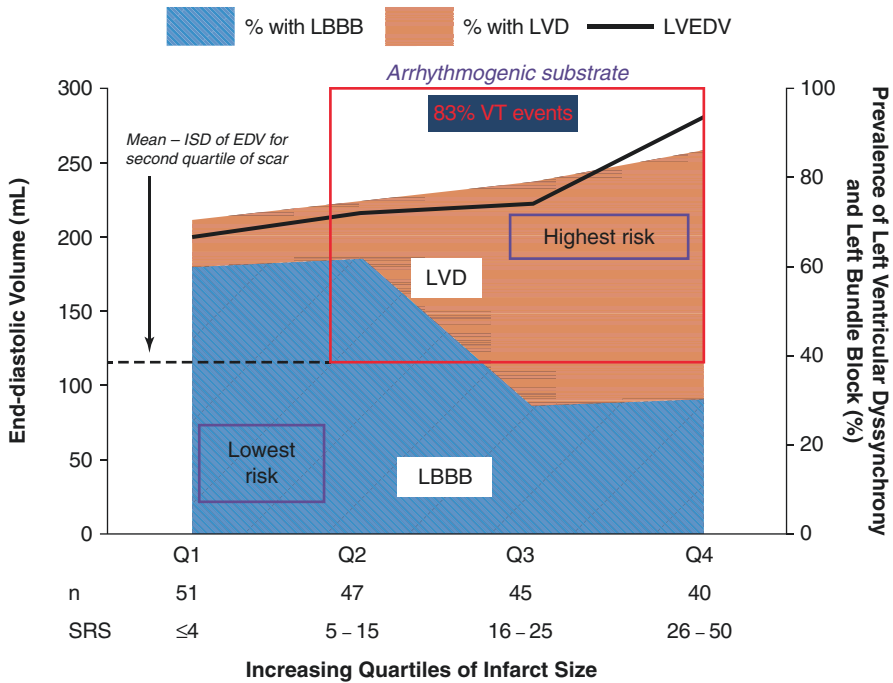

Fig. 6.6 A schematic representation of the interplay of myocardial dyssynchrony, scar and left ventricular remodeling in the generation of ventricular tachyarrhythmia. Relationship between Left Ventricular Dyssynchrony and Scar burden in the Genesis of Ventricular Tachyarrhythmia. *Journal of Nuclear Cardiology*. 2017; with permission) [3]

6.4 Value of Dyssynchrony in Ischemic Heart Disease

Reports have suggested diagnostic and prognostic value of LVD in coronary artery disease (CAD). A retrospective study of patients with CAD reported that electrical and mechanical LVD (by phase analysis) by gated SPECT provides incremental prognostic value for all-cause mortality and cardiac death which was additive to assessment by LV ejection fraction alone [70]. In another study of 1310 patients with CAD (at least one vessel stenosis $\geq 50\%$), both systolic and diastolic LVD was measured by phase analysis of gated SPECT, and both were noted to be present in approximately 18% of the population [71]. Both systolic and diastolic LVD were associated with increased cardiovascular mortality, and diastolic LVD was noted to provide incremental predictive value to clinical history, electrical dyssynchrony, and left ventricular function. In a Tl-201 based dipyridamole-stress and 4-h rest/redistribution study, LVD was reported to be significantly greater with stress imaging among patients with ischemia [72]. There was a significant improvement in synchrony on the post-stress image (synchrony reserve) in patients with a normal perfusion and those with infarcted myocardium without significant ischemia despite

Fig. 6.7 Relationship between ventricular tachyarrhythmia and acute change in dyssynchrony after biventricular pacing. *VT* ventricular tachyarrhythmia, *LVD* left ventricular dyssynchrony, *Pre* before activation of cardiac resynchronization device, *Post* after activation of cardiac resynchronization device. (Reproduced from Malhotra S, Pasupula DK, Sharma RK et al. Relationship between Left Ventricular Dyssynchrony and Scar burden in the Genesis of Ventricular Tachyarrhythmia. *Journal of Nuclear Cardiology*. 2017; with permission) [3]

a much greater degree of resting LVD. Early post-stress LVD has also been noted to correctly identify patients with multi-vessel coronary artery disease [73]. In a retrospective study of 144 patients who underwent stress/rest TI-2101 SPECT, patients with multi-vessel CAD on angiography had significantly more global dyssynchrony than the patients with <70% coronary stenosis. Additionally, patients with multi-vessel CAD showed significantly more global and territorial dyssynchrony on stress images than on rest. A combination of visual assessment and dyssynchrony allowed for more patients with 3-vessel CAD to be correctly classified as having multi-vessel disease. In a PET based study of patients with ischemic cardiomyopathy and low EF, changes in LVD between rest and vasodilator stress were identified using Rubidium-82 PET [74]. Among normally perfused ventricles, LVD decreased following stress (improvement in synchrony), while development of ischemia with stress resulted in an increase in LVD and was associated with all-cause mortality. Change in LVD with vasodilator stress was further studied in a population of 195 patients with largely preserved EF, undergoing Rubidium-82 PET for assessment of coronary artery disease [75]. Rest and stress myocardial blood flow (MBF) was calculated, along with MBF heterogeneity, which was determined as the ratio of the standard deviation of segmental MBF values to the average MBF value from 14 of the standard LV segments. A large proportion of patients with LVD at rest continued to remain dyssynchrony with stress. However, there was a reduction in LVD after stress in a small proportion of patients who had significantly higher coronary flow reserve, stress MBF and a lower coronary vascular resistance when compared to those who continued to have LVD after stress (Fig. 6.8). This study also reported a

Fig. 6.8 Relationship between left ventricular dyssynchrony (LVD) and myocardial blood flow (MBF). Representation of the continuum of LVD and its relation to MBF in a population with coronary artery disease. Values of histogram bandwidth (HBW) and MBF are taken from Van Tosh et al. [88]. The population is stratified by the presence of LVD at rest or with stress. MBF (a) and histogram bandwidth (HBW) (b) data are graphed across LVD. “Synchrony reserve” applies to reduction in LVD after stress among patients with baseline LVD, that could result in complete resolution of LVD in a subset of the population. Abnormally high HBW characterizes patients with fixed LVD, despite improvement in HBW after stress. (Reproduced from Malhotra S and Canty JM, Jr. Vasodilator stress and left ventricular asynchrony. *J Nucl Cardiol* 2017;24:53–6; with permission) [76]

strong relationship between a stress-induced reduction in MBF heterogeneity with improvement in LVD (receiver operating characteristic area under the curve = 84%). This reduction in LVD with stress raises the possibility of a “synchrony reserve,” [76] that could explain the improvement in ejection fraction (EF reserve) with vasodilator stress [77]. The association between LVD and ischemia is further substantiated by studies reporting improvement in LVD indices with anti-ischemia therapy. In a retrospective study of 230 patients who underwent serial rest/stress myocardial

perfusion SPECT before and after coronary revascularization, there was a significant reduction in LVD indices after revascularization [78] (Fig. 6.9). In addition, there was a trend toward greater improvement in synchrony among those with greater ischemic burden ($\geq 10\%$ vs. $<10\%$ ischemic myocardium). Improvement in LVD with medical antianginal therapy was reported in a prospective study of 32 patients with reversible perfusion defects on myocardial perfusion SPECT [79]. Serial phase analysis from gated SPECT before and 4-weeks after ranolazine therapy showed a significant reduction in all LVD indices, suggesting improvement in ventricular synchrony with medical therapy for myocardial ischemia. It is worth investigating whether the improvement in synchrony that occurs as a result of ischemia resolution also results in improved outcomes.

6.5 Technical Considerations in the Assessment of Dyssynchrony by SPECT

In single center settings, phase analysis of gated SPECT is a reproducible technique for assessment of dyssynchrony [80]. However the reproducibility of SPECT-derived dyssynchrony measurements have not been tested in a multi-center setting. Echocardiography-based measures of dyssynchrony have been found to be poorly reproducible in a multi-center trial [81]. One has to be mindful of certain technical and software considerations that may result in erroneous measures of dyssynchrony and adversely affect clinical decision making. Determination of dyssynchrony by phase analysis relies on assessment of the timing of contraction or relaxation of the myocardium. Gating artifacts have been shown to affect the assessment of myocardial thickening [82, 83]. Since phase analysis uses count density as a surrogate of myocardial thickening, gating errors can confound the measurement of dyssynchrony. Atrial arrhythmia or frequent premature ventricular beats offset the gating of tomographic images that use the R-wave on the ECG to determine the beginning of a cardiac cycle. This results in a count drop off in the “diastolic” frames of the cardiac cycle and has been shown to spuriously reduce the severity of dyssynchrony [84], which is more pronounced with a greater severity of gating artifact (Fig. 6.10). This is clinically relevant since patients in whom assessment of dyssynchrony is desired (HF and low EF) often suffer from arrhythmia. In such patients with a high likelihood of dyssynchronous LV contraction, phase analysis may label inherently dyssynchronous ventricles as being non-dyssynchronous. While the use of a narrow beat-acceptance window could minimize gating artifact, there will be a significant increase in the imaging time that could impact laboratory throughput. List-mode image acquisition can allow for gating correction and potentially reduce gating artifacts. Furthermore, there is significant discordance in indices of dyssynchrony determined by different SPECT processing software. These differences were recently studied by Nakajima et al. among 69 (36 male and 33 female) normal subjects, without any perfusion defects or regional wall motion abnormalities [15, 24]. SPECT perfusion images were processed using Emory Cardiac Toolbox, Quantitative Gated SPECT, Heart Function View (HFV) and cardioREPO (cREPO) software, using standard software settings, and measures of volume, function, and dyssynchrony were determined from each of the software. Statistically significant differences were noted for the phase analysis parameters, with ECTb and cREPO software reporting the highest PSD and HBW (Fig. 6.11). Statistically significant, though weak, correlations were observed between the phase analysis values from different software – PSD only significantly correlated between cREPO and HFV ($r = 0.36, p = 0.003$) and, HBW correlated between ECTb-cREPO ($r = 0.38, p = 0.001$) and cREPO-HFV ($r = 0.33, p = 0.006$). PSD values positively correlated with EDV (coefficient range for PSD: 0.12–0.37), and both PSD (correlation coefficient range: -0.24 to -0.53) and HBW (-0.46 to -0.55 , only for QGS and HFV, respectively) negatively correlated with LVEF. These differences likely stem from the software specific techniques for delineating LV boundaries, that vary among different software, and can be considered similar to the differences noted in the measures of left ventricular volumes and function [85]. There are additional differences in how software programs perform phase parameters. Quantitative Gated SPECT (Cedars Sinai, Los Angeles, CA)

Fig. 6.10 Prevalence and influence of gating error on phase standard deviation (PSD). Bars represent frequency of gating error at each level of severity. Each bar is stratified by Emory Cardiac Toolbox’s report of gating error (green, none or minor; yellow, moderate; and red, severe). Overlain is PSD for each group (mean ± SE). (Reproduced from Ludwig DR, Friebling M, Schwartzman D, et al. On the Importance of Image Gating for the Assay of Left Ventricular Mechanical Dyssynchrony Using SPECT. J Nucl Med 2012;53:1892–6; with permission) [84]

Fig. 6.11 Histogram bandwidth values from gated myocardial perfusion SPECT obtained from four different software. *ECTb* Emory Cardiac Toolbox, *QGS* Quantitative Gated SPECT, *HFV* Heart Function View, *cREPO* cardioREPO. (Adapted from Malhotra S and Soman P. Software-dependent processing variability in SPECT functional parameters: Clinical implications. J Nucl Cardiol 2017 Apr;24 (2):622–624; with permission) [89]

excludes myocardial regions with the lowest 5% of phase amplitude in the derivation of the phase bandwidth [4], and therefore can be expected to produce values of phase bandwidth that are different from Emory Cardiac Toolbox [86, 87]. Due to these software specific differences in assessment of dyssynchrony, software specific cut-offs should be utilized when identifying the presence or absence of dyssynchrony, and the same software be used when performing serial evaluations.

Novel Techniques: Solid-State Detectors, Dose Reduction (SPECT/CT)

7

Piotr J. Slomka, Robert J. H. Miller, Lien-Hsin Hu,
and Daniel S. Berman

7.1 Introduction

Myocardial perfusion imaging (MPI) with single photon emission tomography (SPECT) is widely used for the diagnosis and management of patients with known or suspected coronary artery disease (CAD), providing crucial information regarding both myocardial perfusion and function. Since being introduced in the 1970s SPECT camera system designs have undergone several incremental improvements. More recently, however, there has been an evolutionary leap with dedicated cardiac SPECT camera systems which utilize solid-state crystals and novel collimator designs, such as multi-pinhole and locally focusing collimators configured specifically for cardiac imaging [1]. These innovations have facilitated dramatic reductions in both imaging time and radiation dose, while maintaining high diagnostic accuracy. These features are related to simultaneous improvement in sensitivity (five to eight times higher) [2, 3], (due to the collimator and imaging geometry) and

image resolution (up to two times higher) [3], (due to the improved energy resolution of the new crystals). Additionally, the physical space requirements for solid-state camera systems have been significantly reduced because photomultiplier tubes are no longer required. New scanners can also be coupled with diagnostic quality CT systems-suitable for calcium scanning or coronary CT angiography. With the growing clinical experience using solid-state SPECT camera systems there is also emerging evidence demonstrating comparable or superior, diagnostic and prognostic utility.

This review summarizes the current solid-state SPECT and SPECT/CT technology and clinical applications, including emerging techniques for myocardial blood flow quantitation. We will also discuss imaging protocols, potential imaging pitfalls and review the validation efforts for this new technology regarding diagnosis and prognosis.

7.2 Technology

Several technologic advancements are responsible for the improved imaging characteristics of solid-state SPECT camera systems. No single change can be attributed to the significant improvements in both photon sensitivity and spatial resolution realized with these systems. This section will review these advances within the context of the overall camera system.

7.2.1 Solid-State Detectors

The radiation detectors are made of Cadmium-Zinc-Telluride (CZT) crystals which are more expensive than NaI(Tl) crystal detectors but have important imaging advantages. CZT detectors have improved energy response which reduces the scatter component of measured data by 30% [4], and superior intrinsic spatial resolution compared to conventional Anger cameras. Removing the need for photomultiplier tubes has resulted in more compact detector size which has facilitated more efficient camera designs with innovative imaging geometries and high-sensitivity collimation. Solid-state detectors can also be combined with scintillation crystals to indirectly detect photons. In these detectors, thallium-doped cesium iodide CsI(Tl) scintillation crystals are coupled with photodiodes (instead of photomultipliers) [5]. CsI(Tl) has superior spectral light response characteristics compared to NaI(Tl) when used with silicon photodiodes.

Solid-state detectors are integrated with innovative collimator designs which increase photon sensitivity in the myocardial region. The high-sensitivity characteristics of solid-state SPECT cameras are often mistakenly attributed to the CZT crystal. Although the density of CZT is higher than NaI(Tl) (5.8 vs. 3.7 g/cm³), due to cost considerations CZT detectors are thinner (~5 mm) than typical NaI(Tl) crystals (9.5 mm), such that the intrinsic detection efficiency of these systems is comparable to conventional Anger detectors.

7.3 Dedicated Cardiac Systems

7.3.1 Detectors

CZT SPECT camera systems specifically designed for cardiac use are commercially available from two vendors. One system (Spectrum Dynamics, D-SPECT) uses pixelated CZT detector arrays. Nine vertical columns are arranged in a 90° gantry geometry. Each column consists of 1024 CZT elements ($2.46 \times 2.46 \times 5$ mm thick), arranged in a 16×64 element array with an overall size of 40×160 mm. Since CZT crystals are expensive, the vendor offers a system with six detector columns, creating a trade-off between cost and image quality. The other camera design (GE Healthcare, Discovery NM 530c) features a curved array of 19 CZT pixelated detector arrays coupled to pinhole collimators with geometry optimized for cardiac imaging. Each detector array consists of four detectors, each with 246 CZT detector elements ($2.46 \times 2.46 \times 5$ mm thick) arranged in 16×16 elements.

The indirect solid-state detector has been utilized in traditional 2- or 3-detector configurations (Digirad), allowing for a more compact design than conventional Anger cameras. Each detector head contains an array of 768 ($6.1 \times 6.1 \times 6$ mm thick) CsI(Tl) crystals coupled to individual silicon photodiodes that convert the crystal scintillations to electrical pulses, which are then processed digitally.

7.3.2 Dedicated Cardiac Collimators and Geometries

The improved sensitivity of solid-state SPECT cameras is achieved by novel collimator designs and dedicated cardiac imaging configurations. Increasing photon sensitivity is important since a conventional Anger cameras detect $<0.01\%$ of incoming photons [6]. Diagrams of these novel collimator technologies, for cardiac solid-state cameras and a general-purpose solid-state camera are shown in Fig. 7.1.

The D-SPECT features one small high-sensitivity tungsten collimator for each detector column (as described above). These collimators can be positioned close to the patient's body which increases the number of photons detected and improves spatial resolution. The collimators are square, parallel holes with dimensions of 2.26×2.26 mm and wall thickness of 0.2 mm matched to the dimensions of a single detector element. The hole dimensions are larger than conventional high-resolution collimators, resulting in higher sensitivity at the expense of image resolution. However, the loss in spatial resolution resulting from this design is more than compensated for by the use of pixelated CZT detectors and software-based resolution recovery [2]. During acquisition, each of the nine detectors is focused on the heart and rotates over 45° , with a rotation time of 3 s. Patients are positioned on a chair rather than on a bed, increasing patient comfort. Patients are typically imaged in both semi-supine and upright positions.

The Discovery NM 530/570c camera systems utilize pinhole collimation. The design includes 19 pinhole collimators with multiple focal depths and one hole (4.75 mm in diameter) in each collimator. The CZT detectors and

Fig. 7.1 Diagrams of three novel collimator designs used in solid-state camera systems. Panel (a) shows an example of high-sensitivity parallel collimators, as used in the D-SPECT camera system. The collimators are square with parallel holes, each coupled to a single detector. Panel (b) shows a multi-pinhole collimator design, as used in the Discovery NM 530c camera system. Panel (c) shows the collimator design of the new general-purpose Veriton for 3D body contouring. Images courtesy of Spectrum Dynamics and GE Healthcare

collimators do not move and photons are acquired simultaneously through all the pinholes. Simultaneously acquired pinhole views allow consistent tomographic sampling, reducing motion artifacts. Patients are typically imaged in both supine and prone positions, with their arms placed above their head. Higher sensitivity is achieved by the wider acceptance angle of photons with multi-pinhole collimation and the cardio-centric acquisition which limits photon detection to the myocardial region.

7.4 SPECT/CT

MPI can benefit from CT-based attenuation correction (CTAC) using either dedicated hybrid SPECT/CT systems or separate scanners, with many new systems offered in hybrid SPECT/CT configurations. Some systems offer basic CT capabilities with relatively slow rotating gantry CT systems—suitable only for AC of SPECT. However, an increasing number of scanners are equipped with more advanced CT components, capable of diagnostic quality cardiac imaging. In addition, it has been shown that separately acquired coronary artery calcium (CAC) scans can be used for AC of SPECT MPI studies [7]. The use of separately obtained CT for AC is supported by vendors for routine clinical use [8, 9]. CTAC using either separate systems [9] or hybrid SPECT/CT systems [10] can improve diagnostic accuracy of SPECT MPI compared to single-position non-corrected imaging.

SPECT/CT scanners provide new opportunity to enhance MPI data with additional CT information. Non-contrast CT can be used to quantify CAC, a specific

marker of coronary atherosclerosis. The CAC scan is simple to perform, low-cost, acquired without intravenous contrast, and associated with low radiation exposure [11–13]. To date, evidence has consistently shown that CAC predicts cardiovascular events beyond standard risk factors [14–26]. With complementary information regarding both ischemia (MPI) and atherosclerosis (CT), hybrid SPECT/CT imaging can outperform SPECT MPI alone. We have demonstrated the complementary role of CAC with PET and proposed a logistic-regression based score for PET + CAC, which increased the diagnostic performance [27, 28]. Additionally, several studies have shown that MPI and CAC provide an independent and complementary prediction of cardiac risk [29, 30, 31]. This widely available combination of MPI and CT provides a new opportunity to enhance MPI with additional diagnostic and prognostic information.

The scans performed for CTAC maps are acquired with a lower radiation dose than standard CAC scans and are obtained without ECG-gating. Nevertheless, it is possible to extract useful CAC information from these maps. We reported high agreement between visual estimation of calcium from CTAC and CAC scores from standard CAC scans in a multicenter study [32]. Protocols have also been proposed for modified CTAC acquisitions, optimized for quantification of CAC without increasing radiation dose [33]. Investigators at Yale University have demonstrated that visual identification of CAC on CTAC scans improves the diagnostic accuracy of SPECT/CT [34]. Although these reports are encouraging, logistically such additional assessments increase the overall complexity of SPECT MPI reporting and require additional expertise, which may not always be available. Software tools will be required which will automatically extract and integrate CTAC scan information, including CAC, with SPECT MPI results.

While CAC is a dominant parameter available from the non-contrast CT, there are additional markers of patient-specific cardiovascular conditions which have prognostic value [35, 36], and can potentially be assessed from CTAC scans. Epicardial fat tissue on non-contrast CT which can be measured in a fully automated fashion, as established, is one such additional CT marker [37]. Other potentially important cardiovascular markers include calcification of the thoracic aorta and heart valves [38], liver density [39], pulmonary artery dilatation and heart anatomy [40]. This information is currently not routinely utilized during cardiac SPECT/CT but could be part of a comprehensive assessment, enhancing the utility of SPECT/CT.

While functional testing with myocardial perfusion SPECT is well established, cardiac computed tomography angiography (CCTA) has emerged as a promising diagnostic and prognostic technique [41]. Hybrid SPECT/CT systems with 64-slice CT scanner systems are capable of obtaining both scans. CCTA-guided contour and vascular territory adjustment of SPECT MPI can improve quantitative diagnostic accuracy for left circumflex and right coronary artery lesions [42]. Similarly the diagnostic accuracy of visual analysis of SPECT MPI can improve by integrating CCTA data [43]. In addition, CCTA may help exclude hemodynamically significant CAD in patients with intermediate to high pretest likelihood of CAD or abnormal SPECT MPI [44]. Accurate registration of the data from SPECT and CCTA, even if

obtained on the same system, is complicated by the potential mismatch in cardiac image phase. However, image registration can be refined using an automated registration scheme, with correction for the cardiac phase disparities [45].

7.5 Solid-State SPECT/CT Systems

Hybrid SPECT/CT solid-state systems are not yet in widespread clinical use. Initially only multi-pinhole solid-state camera systems (GE 570c) were offered with a hybrid diagnostic CT configuration; however, there are only a few such systems operating worldwide. In the last 2 years, general-purpose solid-state SPECT cameras coupled with diagnostic quality CT scanners—capable of coronary calcium scoring—have been introduced by two vendors. While these systems are designed for general imaging use, they can also be used effectively for MPI. Spectrum Dynamics introduced the Veriton-CT system with 8 CZT modules within each of 12 detector blocks, each with individual detector arms with swivel motion, which allow precise and close 3D contouring around the patient during imaging. The field-of-view length is 320 mm and can be focused for single organ acquisitions or used for whole torso scanning. The optimized collimator design results in higher volumetric sensitivity (0.0192%) compared to dual-head camera systems with conventional collimators (<0.01%). Additionally, with image resolution recovery this system achieves high spatial resolution (4.3 mm). Initial clinical studies of the prototype design with detector design similar to Veriton demonstrate potential improvements in image quality compared to a conventional camera [46]. The Veriton-CT system is configured with up to 128-slice CT camera, allowing both calcium scoring and CT angiography studies. GE introduced a general-purpose solid-state camera, the Discovery NM/CT 870 CZT, equipped with conventional collimators. This camera system offers similar photon sensitivity to the conventional Anger system (as the collimation system is the same) but allows better energy resolution and image resolution due to the CZT detectors and has demonstrated improved image quality in early clinical implementation [46, 47].

7.6 Reconstruction Including Resolution Recovery and Anatomical Constraints

In parallel with improvements in technical aspects of SPECT scanner hardware, enhanced image reconstruction techniques have been implemented. New reconstruction algorithms include modeling of the collimators and detectors, as well as resolution recovery. Most systems compensate for spatial resolution losses by using iterative reconstruction. The aggressive resolution recovery is needed to compensate for the effects of high-sensitivity collimation, which reduces spatial resolution by accepting photons from a wider angle. Therefore, software modeling the collimator response during reconstruction is a critical component needed to achieve the simultaneous increase in spatial resolution and count sensitivity with the solid-state SPECT camera systems.

Further improvements in spatial resolution can be achieved by using iterative reconstruction with myocardial anatomical priors, which constrain the shape and thickness of myocardial walls to fit within an expected range. This approach can further improve image quality, especially for noisy images. However, if the actual patient anatomy differs significantly from the expected pattern, the convergence of the algorithm may be falsely biased by the assumed constraints. CT scan data can further enhance image reconstruction approaches. With the hybrid SPECT/CT camera systems, the CT can be used during the reconstruction not only for AC, but also as a prior to improve the anatomic constraints.

7.6.1 Performance

The clinical solid-state SPECT systems offer improved sensitivity and spatial resolution compared to conventional Anger cameras. The actual technical performance of solid-state SPECT cameras were compared with conventional dual-head scanners by Imbert et al [3]. Additionally, similar results are available from one other vendor. Comparison of count sensitivity (expressed in %) compared to positron emission tomography (PET) are shown in Fig. 7.2. The solid-state SPECT cameras

Fig. 7.2 Count sensitivity expressed as % of incoming photons for several nuclear imaging systems. Solid-state SPECT cameras (fast-MPI) have almost eight times higher count sensitivity compared to conventional Anger cameras. Therefore, the count sensitivity is more similar to 2D PET than a conventional SPECT camera

offer up to eight times higher count sensitivity and more than double the effective image resolution compared to the conventional Anger cameras. Imaging times with conventional doses of radioactivity are in the range of 2–3 min for systems with dedicated solid-state detectors [48, 49], compared to 15 min on systems with a standard collimator. The count sensitivities for dedicated cardiac CZT systems can approach those of 2D PET systems, which to date have been employed in most of the PET-MPI literature.

7.7 Impact on the Field

7.7.1 Current Clinical Use

It is estimated that over 800 solid-state dedicated cardiac CZT SPECT camera systems are currently in clinical use [50]. The improved technical performance of solid-state SPECT camera systems was initially used to dramatically reduce imaging time, improving patient comfort and minimizing motion artifacts. However, clinical protocols with these systems can also employ very low-dose radiopharmaceutical injections (150–220 MBq of the Tc-99m perfusion agents) [51–53] with standard imaging times. When employing stress-only scans with 10–12 min acquisitions, effective radiation doses under 1 mSv are achieved [54, 55]. By comparison, the average annual background radiation exposure in the US is ~3.1 mSv [56].

7.8 Clinical Protocols

7.8.1 Two-Position Imaging: Upright/Supine or Supine/Prone

The vast majority of solid-state SPECT cameras in clinical use are not in hybrid SPECT/CT configurations, and therefore do not offer CT-based AC. At the same time, very low-dose protocols with reduced image counts challenge the accuracy of visual interpretation, especially in the presence of attenuation artifacts. To address this issue, most clinical protocols employ two sequential scans performed in different patient positions (supine/upright or supine/prone). Since soft tissue shifts in different patient positions, comparing results from two positions can allow differentiation of true perfusion defects from artifacts [57–59]. Two-position protocols add only modestly to the total time of single view protocols with high-sensitivity scanners, with no added radiation exposure.

7.8.2 Low-Dose Protocols

The technical advancements of solid-state SPECT cameras can be used to dramatically reduce radiation exposure during a patient's scan. The list-mode capabilities of SPECT equipment can be used to evaluate retrospectively the efficacy of low-dose

imaging protocols. One such study simulated reduced radiation protocols in 79 patients, who were imaged with a solid-state scanner for 14 min with 802 ± 200 MBq of ^{99m}Tc injected at stress [55]. There was no significant difference in quantitative perfusion or functional measurements even with simulated activity corresponding to an effective radiation dose of <1 mSv, as outlined in Fig. 7.3. The clinical implementation of low-dose protocols was studied in patients who underwent repeat rest scans with split radiation doses. The image quality for very low-dose rest scans (mean effective dose 1.15 mSv) was superior to conventional SPECT imaging (mean effective dose 2.39 mSv) [60]. Einstein et al. reported stress-only imaging in 69 patients with a mean effective radiation dose of 0.99 mSv [61]. In a study of 284 patients undergoing SPECT MPI, Sharir et al. demonstrated similar diagnostic accuracy with low-dose imaging compared to standard dose imaging, but with 50% radiation reduction [62]. This was confirmed by another group who used 160 MBq injected doses for rest and stress acquisitions of 15 min [63]. Palyo et al. showed that regional perfusion defect size and functional parameters were similar in spite of 50% radiation reductions using a hybrid SPECT/CT system with CTAC [64]. With more aggressive radiation reduction (75%), there was a tendency to overestimate perfusion defect size in patients with abnormal results [64]. Importantly, to preserve

Fig. 7.3 Example of a patient with abnormal perfusion in the low-dose simulation study performed by Nakazato et al. [55]. Total perfusion deficit (TPD), which is a quantitative measure of ischemia, was not significantly different except in simulations representing an effective radiation dose <0.5 mSv. (This research was originally published in *JNM*. Nakazato R, Berman DS, Hayes SW, et al. Myocardial Perfusion Imaging with a Solid-State Camera: Simulation of a Very Low Dose Imaging Protocol. *J Nucl Med*. 2013;54:373–379. © SNMMI)

reproducibility between high-count and low-count data the quantification of low-dose protocols requires normal limits specifically calibrated with low-dose images due to higher variability of low-count data [65].

As noted above, the lowest total radiation exposure with current SPECT MPI (~ 1 mSv) can be accomplished clinically by performing stress-only imaging with a solid-state camera system. Stress-only MPI can reduce radiation exposure by up to 60% [66], and also provides a significant reduction in radiation exposure to staff performing the scan [67]. Additionally, stress-only protocols dramatically shorten total study times to as low as 30–45 min, including the stress test, improving the patient experience and laboratory efficiency. Since most SPECT MPI scans are normal [68], an ultralow-dose (1 mSv) stress-only scan, could potentially be performed in the majority of patients undergoing SPECT MPI with a solid-state camera system. Further research is needed to demonstrate the diagnostic accuracy and prognostic value of this ultralow-dose, stress-only approach.

7.9 Simultaneous Dual-Isotope MPI

Solid-state cameras with CZT detectors have superior energy resolution which allows better separation of photons from different isotopes and improved cross-talk correction [69]. In addition, stationary detector systems eliminate projection inconsistencies which confound dual-isotope imaging. One possible clinical application is a combined rest/stress protocol with simultaneous imaging of ^{99m}Tc and ^{201}Tl as proposed for conventional cameras [70], which was not implemented clinically on standard cameras due to technical difficulties and to concerns regarding higher radiation with ^{201}Tl .

To date, a few studies have demonstrated the feasibility of simultaneous imaging of ^{201}Tl (stress) and ^{99m}Tc (rest) SPECT MPI with solid-state cameras. One study proposed a single stress/rest 20-min acquisition for the two isotopes [71]. A separate study demonstrated the feasibility of simultaneous dual-isotope imaging in 24 patients with 80 MBq of ^{201}Tl injected at rest and 250 MBq of ^{99m}Tc sestamibi injected during adenosine infusion [72]. For this application, dedicated scatter correction methods are required because triple energy window corrections overestimate scatter and cross-talk in CZT-based systems [73]. These dedicated corrections have been shown to improve defect contrast and myocardium to blood pool ratios compared to triple energy window corrections [73]. Diagnostic performance and image quality of simultaneous dual-isotope MPI with solid-state systems have been demonstrated to be comparable to conventional SPECT with separate stress/rest acquisitions [69].

While the use of dual-isotope MPI with ^{99m}Tc and ^{201}Tl is now discouraged, simultaneous dual-isotope SPECT may become increasingly utilized for other imaging protocols. As an example, simultaneous dual-isotope for cardiac amyloidosis with ^{99m}Tc -pyrophosphate (PYP) and ^{201}Tl has recently been described, with ^{201}Tl allowing precise definition of myocardial boundaries [74]. This dual-isotope approach has importance for dedicated cardiac systems in which the tight gantry

and imaging focused on the heart makes it is harder to correctly position the ^{99m}Tc -PYP acquisitions.

Simultaneous dual-isotope imaging can also be used in combined SPECT perfusion/metabolism protocols. Many novel metabolism agents, either in clinical or research use, only show abnormal portions of the myocardium which are better understood within the context of perfusion imaging. As an example, ^{123}I -BMIPP has diagnostic and prognostic potential following acute myocardial infarction or in patients with Takotsubo cardiomyopathy [75]. Solid-state cameras have been shown to simultaneously acquire ^{99m}Tc perfusion agent and ^{123}I -BMIPP images with image quality similar to that achieved with separate acquisitions [76]. Simultaneous MIBG and ^{99m}Tc [77] or ^{123}I -MIBG and ^{201}Tl imaging can also be acquired [78]. In phantom studies, ^{123}I and ^{99m}Tc images can be acquired simultaneously with similar image quality as separate acquisitions with two commercially available solid-state cameras [79]. Simultaneous dual-isotope acquisitions, which are facilitated by the high energy resolution of CZT crystals, reduce imaging time, ensure precise image co-registration, and reduce artifacts related to patient or camera motion between acquisitions.

7.10 Normal Perfusion Limits for Solid-State Cameras

Solid-state SPECT scanners have significantly different regional count distributions compared to standard Anger cameras—primarily due to different types of collimation and detector geometry. Early studies of CZT camera systems demonstrated these differences, and dedicated normal limits were subsequently recommended [49], with dedicated normal databases created for the Discovery NM 530c (GE Healthcare) [59, 80] and D-SPECT (Spectrum Dynamics) [49, 57] camera systems. Importantly—for optimal quantification—separate databases may be required for prone and supine acquisitions.

7.10.1 Combined Quantification from Two Positions

Physicians utilize multiple imaging positions to visually differentiate attenuation artifact from perfusion deficits, however, this approach has only more recently been applied to quantitative analysis. Combined quantitative analysis of upright and supine acquisitions on the solid-state D-SPECT (Spectrum Dynamics) scanner has been evaluated [57]. Quantification performed jointly from co-registered images obtained in two positions offered better identification of attenuation artifacts and reduced of false-positive defects (shown in Fig. 7.4). Compared to a reference of invasive coronary angiography, combined quantitative analysis showed higher diagnostic accuracy than separate upright or supine acquisitions. Similar results have been shown with two-position imaging in obese patients using the D-SPECT system [58] and for the Discovery NM530c scanner with supine and prone acquisitions [59]. Two-position imaging may also detect position-related truncation artifacts,

Fig. 7.4 Case example of two-position imaging. In this case, combining supine and prone imaging offers superior visual interpretation but was still interpreted as abnormal. Quantitative perfusion analysis is also improved by integrating supine total perfusion deficit (S-TPD), and prone TPD (P-TPD) into a single, combined measure (C-TPD) which shows no perfusion deficit. The patient had no significant coronary disease on invasive coronary angiography. (Case from REFINE SPECT registry)

which can occur due to the limited field of view on solid-state SPECT cameras [81]. New approaches applying deep learning with combined two-position imaging on solid-state cameras have demonstrated further improvements [82].

7.11 Motion Correction on Solid-State Cameras

Respiratory and patient motion can degrade SPECT image quality, with several recent studies investigating techniques to mitigate these effects. Due to improvements in spatial resolution, heart motion has become the dominant motion-related degrading factor in solid-state SPECT imaging. The feasibility of using list-mode data, with registration of consecutive short-time image frames, to detect and correct for respiratory motion has been demonstrated on these new systems [83]. Respiratory gating can impact functional cardiac parameters, resulting in reduced volume estimates and differences in regional LV wall motion [84]. End-expiratory gating can be used to improve contrast differences between the myocardium and blood pool

[85]. Respiratory phase matched CT attenuation maps may further improve image quality, and has been shown to significantly improve inter-observer agreement compared to uncorrected images [86]. Patient motion can also be corrected using a similar approach to reduce the rate of false-positive perfusion defects [87]. Dual respiratory/cardiac gated MPI has been demonstrated in phantoms and patients showing progressive improvement of the myocardium to blood pool contrast with the application of respiratory and then dual gating [85].

7.12 Potential Pitfalls

Although the novel designs of dedicated cardiac solid-state SPECT camera systems offer important clinical benefits, there are potential imaging pitfalls which need to be considered. The camera geometry is optimized for cardiac acquisitions, so there is non-uniform count sensitivity in the field of view [88]. Therefore, patient positioning is critical and patients with significantly abnormal cardiac anatomy may not be well imaged. Importantly, the typical attenuation defect with supine imaging is more lateral with solid-state camera designs compared to conventional cameras [89]. For example, due to increased space between the chest wall and cardiac border, obese patients may require re-positioning or multiple position imaging to ensure diagnostic quality [81]. In patients with hypertrophic cardiomyopathy, iterative reconstruction algorithms utilizing a cardiac shape model significantly underestimate wall thickness compared to ordered-subsets expectation maximization which does not use a shape constraint [90]. Two-position protocols may allow for detection of position-related artifacts and potentially address some of these concerns [58].

7.13 Emerging Clinical Techniques

7.13.1 SPECT Myocardial Blood Flow

Absolute myocardial blood flow (MBF) and myocardial flow reserve (MFR) provide clinically meaningful data beyond that obtained by assessment of relative perfusion deficit alone. Absolute measurements can identify patients with multivessel CAD and predict the extent of disease more accurately than relative perfusion quantification or visual interpretation [91]. MFR is also a useful prognostic marker, significantly improving risk stratification beyond relative perfusion defects [92, 93]. While myocardial flow measurements were initially developed and validated in PET imaging, SPECT cameras may be capable of obtaining similar measurements. The improved count sensitivity related to collimator and camera geometry advances with solid-state SPECT cameras may make them particularly well suited for flow measurements.

Human dynamic SPECT flow studies have been demonstrated on high-efficiency dedicated SPECT with factor analysis and a 2-compartment model used for

Fig. 7.5 Comparison between SPECT myocardial blood flow (MBF, panel A and B) and myocardial flow reserve (MFR, panel C and D) assessments with (panel B and D) and without (panel A and C) attenuation correction (AC) compared to PET. SPECT MBF measurements at rest or with stress were not significantly different compared to PET values, with or without AC. Similar results were obtained with MFR measurements [96]. (This research was originally published in *JNM*. Wells RG, Marvin B, Poirier M, Renaud J, deKemp RA, Ruddy TD. Optimization of SPECT Measurement of Myocardial Blood Flow with Corrections for Attenuation, Motion, and Blood Binding Compared with PET. *J Nucl Med*. 2017;58:2013–2019. © SNMMI)

quantification. The clinical feasibility was demonstrated in 95 patients, in whom the data was reconstructed to 3-s frames resulting in 60–70 frames for each stress and rest study [94]. The authors demonstrated that MFR derived from such studies was higher in patients with normal scans (as established by standard relative quantification) and that lower MFR (both regional and global) was associated with stress perfusion defect on static imaging, age, and smoking. The MFR also showed step-wise reduction related to the severity of the obstructive disease in a subset of 20 patients, in which invasive coronary angiography was performed. To date, at least seven studies have been performed in humans demonstrating the SPECT MBF measurements with $^{99\text{m}}\text{Tc}$ and solid-state cameras [94–101]. Importantly, Wells et al. has demonstrated close agreement between SPECT MBF and MFR measurements, with or without attenuation correction, compared to PET measurements, [96] (Fig. 7.5). This finding has important implications, since the majority of the solid-state scanners are currently operating without AC capabilities. The clinical protocol for SPECT flow has gained significant attention recently, as the FDA approved dedicated clinical software with both solid-state scanners, with several sites commencing clinical SPECT flow imaging. Example of MPS flow results are shown in Fig. 7.6.

Fig. 7.6 Example of SPECT myocardial blood flow (MBF) information. One-day Tc-99m sestamibi stress-rest protocol (259 MBq for stress and 777 MBq for rest) was used. Stress (Str) and Rest (Rst) flows are computed from early dynamic imaging for each vascular territory, by deriving regional time activity curves for the myocardium and for input blood in the left atrium or left ventricle and applying compartmental models. These values can be used to calculate myocardial flow reserve (MFR) as the ratio between stress and rest MBF. Reduced MFR (<2.0) may be useful to identify the presence of multivessel-disease leading to balanced ischemia. This patient had normal regional myocardial perfusion, but decreased MFR and was ultimately found to have obstructive triple-vessel disease on coronary angiography. (Case provided courtesy of Dr. Alejandro Meretta, Instituto Cardiovascular de Buenos Aires)

Notwithstanding this early enthusiasm about SPECT MPI flow, there are well-known limitations of this use with ^{99m}Tc sestamibi or tetrofosmin. Notably, the myocardial extraction of these radiotracers from the blood is substantially reduced at high flows rates, which requires mathematical compensation. However, even after compensation, this “roll-off” phenomenon increases result variability. Despite these concerns, good agreement between PET and SPECT flows has been shown in head-to-head studies [95, 99]. In a study of 28 consecutive patients undergoing SPECT with attenuation correction and ^{13}N -ammonia PET, MFR was computed without using any extraction fraction correction for ^{99m}Tc -tetrofosmin [99]. The authors found that the hyperemic SPECT MBF values were lower than expected and consequently MFR was lower compared to PET values [99]. Agostini et al. compared ^{99m}Tc -sestamibi SPECT derived MBF and MFR, using a solid-state camera and a correction for ^{99m}Tc extraction fraction, with values obtained with ^{15}O -water PET in 30 patients [95]. SPECT MBF measurements were lower compared to PET values on stress and rest acquisitions. However, SPECT derived MFR was similar to PET values and had high diagnostic accuracy for PET defined ischemia ($>93\%$) or ischemia defined by invasive fractional flow reserve ($>81\%$) [95]. Therefore, while

SPECT flow measurements may not be as robust as PET, it is emerging as an important ancillary measure. Notably, no additional tracer injection is needed, thus minimizing additional costs and adding no radiation. Clinical validation studies for myocardial blood flow measurement with solid-state MPI are summarized in Table 7.1.

7.13.2 Early EF

SPECT measurements of MBF and MFR require an acquisition at the time of radio-tracer injection. This facilitates measurement of stress left ventricular ejection fraction (LVEF) and LVEF reserve (defined as stress LVEF – rest LVEF)—which are important ancillary PET measurements. While post-stress LVEF changes are useful with SPECT, they are obtained at least 15 min following stress and are less sensitive than measurements during stress. High LVEF reserve has been shown to significantly reduce the probability of severe CAD during dipyridamole stress ^{82}Rb PET [102]. The feasibility of LVEF reserve measurements using early post-stress acquisitions with a dedicated cardiac solid-state SPECT scanner has been demonstrated in a study of 50 patients [103]. Significantly lower LVEF reserve was obtained in

the fifth and the ninth minute after regadenoson bolus in patients with significant ischemia compared to patients without ischemia. In the future, it may be feasible to measure LVEF reserve and MBF from the same early SPECT acquisitions, providing critical ancillary diagnostic and prognostic markers.

7.13.3 Large-Scale Clinical Validation

The increasing clinical use of solid-state SPECT camera systems has led to a large body of evidence validating their prognostic and diagnostic utility. Major studies of the diagnostic or prognostic utility of solid-state SPECT cameras are outlined in Table 7.2. One of the largest such efforts is a large, multicenter, international registry—the *REgistry of Fast Myocardial Perfusion Imaging with NExt generation SPECT (REFINE SPECT)* registry [104]. The novel collaborative design of this registry features the contribution of clinical data and image datasets from nine (to date) investigative centers around the world into a comprehensive clinical-imaging database established at the central core laboratory at Cedars-Sinai Medical Center with centralized automatic quantitative analysis [104]. To date (2019), 20,418 solid-state MPI scans with collected prognostic data have been included in the registry. Initial results

The overall effective dose of the test is LD if the dose is between <6 mSv; SD if above 6 mSv Acquisition time: if more than one position is taken, the time specified here is for the default view

Fig. 7.7 Prognostic value of quantitative perfusion analysis from the REFINE SPECT registry with solid-state MPI. Quantitative perfusion assessments, with total perfusion deficit (TPD) provide fine gradation of cardiovascular risk. Each increase in TPD extent, including $<1\%$ ischemia compared to no ischemia, was associated with significant increase in the combined outcome of death, non-fatal myocardial infarction, unstable angina, or late revascularization [105]. (With permission from Otaki Y, Betancur J, Sharir T, et al., 5-year Prognostic Value of Quantitative vs Visual Myocardial Perfusion Imaging in Subtle Perfusion Defects: Results From REFINE SPECT, *JACC Cardiovasc Imaging*, Elsevier, 2020;13(3):774–785)

from the registry have shown that quantitative perfusion analysis, measured as total perfusion deficit (TPD), provides fine gradation of risk [105]. Increasing TPD, even at very low levels, is associated with increasing risk of death, non-fatal myocardial infarction, unstable angina, or late revascularization [105]. Notably, patients with >0 but $<1\%$ TPD had a 40% higher risk of events compared to patients with TPD 0, demonstrating the importance of even small deficits which may be missed without the higher spatial resolution of new solid-state SPECT cameras [105] (Fig. 7.7).

The registry has also allowed researchers to perform various collaborative projects, including the development of novel machine-learning methods tailored for the analysis of solid-state SPECT MPI and subsequent integration of quantitative image data variables with “pre-scan” clinical information. A machine-learning score derived with deep-convolutional neural networks has been shown to have superior diagnostic accuracy for obstructive CAD compared to quantitative ischemia assessments [82, 106]. A separate machine-learning algorithm had superior prognostic accuracy compared to either quantitative ischemia assessment or physician assessments [82]. Other validation studies have been performed for solid-state MPI, these include validation of diagnostic accuracy including two-position imaging and attenuation correction [58], determination of the transient ischemic dilation limits [107], and prognostic performance [105]. Given the rich data collected, further validation studies are expected from this large multicenter cohort in the future.

7.14 Future Hardware Designs

While these recent SPECT hardware improvements have proven to be clinically important, further advancements are still possible. One possible area for improvement is additional gains in photon sensitivity. While more sensitive than

conventional Anger cameras, even dedicated cardiac SPECT scanners detect still only <0.1% of emitted photons. Pre-clinical studies have demonstrated that higher efficiency may be possible. In a simulation, Zeng et al. [108] demonstrated that multi-divergent beam collimators could double the photon sensitivity of current SPECT camera systems without sacrificing spatial resolution. Simulations of multi-pinhole designs with paired curved paraboloid or hemi-ellipsoid detectors could improve photon sensitivity by up to 300% [109, 110]. In phantom studies these designs have improved photon sensitivity and spatial resolution compared to published characteristics or commercially available solid-state camera systems [110]. Nevertheless, these published reports are still pre-clinical, and it remains to be seen if these designs will be cost-effective and adequate for clinical implementation.

7.15 Summary

Solid-state cardiac SPECT offer substantial improvements in photon sensitivity and spatial resolution compared to conventional Anger cameras. These advances are due to novel collimator and geometric designs as well as incorporation of CZT crystals. Solid-state camera systems have facilitated dramatic reductions in both imaging time and radiation dose, while maintaining high diagnostic accuracy. Growing clinical experience has validated the excellent diagnostic and prognostic utility attained with these camera systems. With the CZT systems, simultaneous dual-isotope SPECT is feasible and has been shown to be useful in selected applications. The improved technical performance has also facilitated measurement of ancillary high-risk markers including MBF and LVEF reserve. Additionally, SPECT/CT systems are becoming more commonly used allowing hybrid imaging incorporating either coronary calcium scoring or even CT angiography. While these advances have already provided a substantial improvement over the use of standard NaI crystal-based systems, the full clinical potential of solid-state cardiac SPECT camera systems has not yet been realized.

PET/CT

Myocardial Blood Flow Quantification with PET/CT: Applications

8

Chaitanya S. Rojulpote and Paco E. Bravo

8.1 Introduction

Coronary artery disease (CAD) is the leading cause of death in the USA and worldwide. Nuclear imaging studies, including PET, have traditionally played a key role in the diagnosis, and management of individuals with suspected or known CAD. Experimental data using PET imaging techniques have been fundamental for enhancing the understanding of CAD, and also for the development and implementation of new myocardial perfusion tracers in clinical practice.

Current SPECT methodology is mostly limited to a qualitative assessment of the regional distribution or activity concentration of perfusion tracers in the myocardium. In contrast, PET allows additional *in vivo* quantitative measurement of radio-tracer distribution in the heart; thereby it is possible to evaluate absolute myocardial blood flow (MBF) at baseline and during stressing conditions.

8.2 Coronary Circulation

A review of the coronary circulation physiology is critical for a better understanding of the non-invasive quantification of MBF using PET or any other modality. The heart is highly metabolically active and owns one of the highest oxygen consumptions per tissue mass of all human organs. The average resting coronary blood flow ranges between 0.5 and 1.0 mL blood per minute per gram myocardium (mL/

C. S. Rojulpote · P. E. Bravo (✉)

Divisions of Nuclear Medicine and Cardiology, Departments of Radiology and Medicine, University of Pennsylvania, Philadelphia, PA, USA

e-mail: Paco.Bravo@uphs.upenn.edu

min/g), representing approximately 5% of the total cardiac output. Myocardial oxygen extraction is very high at baseline, averaging 60–80% of all arterially delivered oxygen (compared with 25% for the rest of the body) [1]. Consequently, further increments in oxygen consumption, for example, during exercise, are mostly met by proportional increments in coronary blood flow. Myocardial ischemia results whenever oxygen demand exceeds supply.

Anatomically, the coronary circulation can be divided into two well-defined vascular compartments: (1) the large conduit, low-resistance, epicardial coronary arteries and (2) the small, high-resistance, coronary microvasculature composed of the pre-arteriolar (100–300 μm) and arteriolar (<100 μm) vessels [2]. Blood flow across the myocardium is dependent on the coronary perfusion gradient generated between the diastolic aortic pressure and left ventricular end-diastolic pressure. Under normal hemodynamic conditions, coronary perfusion pressure does not diminish significantly along the large epicardial conduit vessels and much of the pressure drop occurs at the coronary microvascular network, where the driving pressure declines proportionally to the cross-sectional diameter of the small coronary vessels. Flow is also characterized by marked phasic variation during the cardiac cycle with coronary perfusion occurring mostly during diastole and reducing significantly during systole.

The coronary circulation is tightly auto-regulated by several factors influencing the vasomotor and metabolic tone of the coronary microcirculation, remaining constant over a wide range of perfusion pressures at baseline and potentially augmenting three- to fivefold during exercise or vasodilator stress to meet the high metabolic demands of the heart. This change in flow from baseline is known as coronary flow reserve (CFR) and has become an extremely important marker for both diagnosis and prognosis in patients being investigated for ischemic and non-ischemic heart disease. CFR is tightly related to oxygen consumption and the metabolic demand of the myocardium and will be affected by any conditions that adversely rise the resting coronary blood flow and/or impair flow during stress situations.

For example, changes in myocardial work and afterload, such as tachycardia, hypertension, and heart failure, and/or reductions in arterial oxygen supply, including anemia and hypoxia, typically lead to proportional changes in resting flow to meet the higher metabolic demands of the myocardium at baseline, and thus may reduce CFR, which is defined as the maximum hyperemic increase in coronary blood flow during exercise or pharmacologic stress above the resting or baseline coronary flow. On the other hand, the presence of flow-limiting epicardial coronary stenosis will result in downstream reduction of the coronary perfusion pressure. In this setting, autoregulation of the coronary microcirculation can maintain baseline flow even if mean coronary pressures are as low as 40 mmHg [3]. However, at this point, the myocardium subtended by the stenotic vessel will fail to further augment the coronary flow during periods of stress or higher metabolic demand, translating into impaired CFR and eventually symptomatic ischemia. Failure of the coronary flow to augment during vasodilator stress can also occur in the absence of epicardial coronary stenosis and is typically related to microvascular dysfunction. In addition, both tachycardia (by reducing diastolic

filling time), and/or elevated preload (by reducing coronary driving pressure) can also negatively affect CFR.

8.3 Pre-clinical Experience/Validation Studies

In general, radiopharmaceuticals are considered suitable for myocardial perfusion imaging and absolute MBF quantification, if after injection, they exhibit high first-pass extraction fraction (at a wide range of flows), rapid blood pool clearance, stable myocardial retention with minimal washout, and high target-to-background ratios. Dynamic imaging is also a requirement to track the tracer activity in the myocardium and blood pool to generate time activity curves for the myocardium and the arterial input function, respectively.

Nitrogen-13 (^{13}N) ammonia is one of the most studied tracers in the pre-clinical and clinical setting. ^{13}N -ammonia enters the myocardial cells by diffusion across the sarcolemma, followed by metabolic conversion to ^{13}N -glutamine by the glutamine synthetase, becoming trapped within the cell. Schelbert et al. [4], in a landmark experiment, evaluated the kinetics of ^{13}N -ammonia in detail using an open-chest dog model. He compared the myocardial tissue concentration of ^{13}N -ammonia in vivo and ex vivo, against MBF (measured by radioactive polystyrene microspheres, which are considered the gold standard for MBF estimation) over three different flow ranges: (1) at baseline, (2) during mid-left anterior descending coronary artery (LAD) ligation; and (3) inducing hyperemia of the left circumflex coronary artery (LCx) by intracoronary Papaverine HCl administration. He found that regional myocardial $^{13}\text{NH}_3$ concentration was closely related, although in a non-linear fashion, to MBF as it decreased 62% when MBF dropped 100% from baseline, and increased 63% and 103%, when MBF augmented 100% and 200%, respectively, from baseline. Additional MBF increments resulted in disproportionately smaller ^{13}N -ammonia concentration changes. In this experiment, the first-pass extraction fraction of ^{13}N -ammonia was inversely related to MBF, as the mean first-pass extraction fraction at baseline MBF (105.7 ± 35.9 mL/min/100 g) was $72 \pm 0.06\%$, and decreased to $55 \pm 0.05\%$ ($p < 0.001$) during MBF hyperemia (333.0 ± 69.4 mL/min/100 g). In this study myocardial ^{13}N -ammonia retention was stable, and the clearance was minimal (biological half-life of 159 min) [4].

Concomitantly, Gould et al. [5], employing a similar animal model, demonstrated that angiographically-proven coronary artery luminal stenosis of 47% or greater diameter narrowing could be detected using a rest and vasodilator stress protocol (dipyridamole) with ^{13}N -ammonia PET. A few years later, Shah et al. [6] compared the agreement between MBF derived from serial cross-sectional PET images, and MBF determined by the standard microsphere technique in instrumented dogs at baseline, high and low blood flows. In this study, the correlation of the two techniques was excellent, showing a nearly linear relation for flows from 44 to 200 mL/min/100 g, and reaching a plateau at higher flows [6]. These and other experimental studies [7] confirmed the appropriateness of ^{13}N -ammonia as a PET perfusion tracer for: (1) qualitative assessment of the regional distribution of the

tracer in the heart and (2) quantitative measurement of MBF under a variety of physiological and pathological conditions.

Parallel to ^{13}N -ammonia, rubidium-82 (^{82}Rb) has also undergone extensive investigation. ^{82}Rb is a potassium analog with an ultra-short half-life (78 s), actively taken up by myocytes via the Na/K-ATPase. Similar to ^{13}N -ammonia, animal studies have shown that the uptake of ^{82}Rb in the myocardium is non-linearly related to blood flow due to a decrease in the first-pass extraction fraction of ^{82}Rb at high flow rates [8, 9]. Likewise, quantitative PET flow assessment of ^{82}Rb under different hemodynamic states has also been validated against microspheres using canine models of coronary artery stenosis [10, 11].

Oxygen-15 (^{15}O)-water is another important flow agent widely studied in the pre-clinical and clinical setting. ^{15}O -water is regarded as an ideal flow agent based on its high first-pass extraction fraction independent of flow. In an open-chest model of coronary stenosis, the first-pass extraction fraction of ^{15}O -water was in average $96 \pm 5\%$ at the baseline flows and did not change significantly between a wide range of coronary flows (0.12 and 2.3 mL/min/g) [12]. However, this tracer has a fast washout, making delayed acquisition for myocardial perfusion imaging challenging, and thus, somewhat limiting its clinical applicability, in addition to the need for an onsite cyclotron.

Lastly, the investigational radiotracer Fluorine-18 (^{18}F)-Flurpiridaz is a novel fluorinated compound undergoing extensive investigation. ^{18}F -Flurpiridaz binds to the mitochondrial complex I of the electron transport chain with high affinity, and experimental data reports a higher net myocardial uptake in relation to coronary flow compared to ^{13}N -ammonia [13], and likely comparable to ^{15}O -water, with the added advantage of having high retention in the myocardium and a longer half-life (~2 h), therefore, allowing exercise-based imaging protocols in the future.

8.4 Myocardial Blood Flow with PET: Reference Values

PET is a robust technique for MBF quantification, however, there are a number of technical, physiological, and biological considerations that may influence the MBF results, including the selection of the perfusion radiotracer (^{82}Rb vs. ^{13}N -ammonia), scanner (2D vs. 3D), method for time activity curves generation (region of interest vs. factor analysis), type of kinetic analysis performed (e.g. compartment vs. retention model), software package (e.g. 4DM vs. Cedars-Sinai), as well as subject-specific characteristics (e.g. number of risk factors) and baseline hemodynamics (e.g. blood pressure and heart rate).

Consequently, it is not surprising that the definition of PET-derived reference values for MBF remains a matter of debate. Table 8.1 depicts a summary of 30 PET studies that included over 550 healthy volunteers for the purposes of MBF quantification with various methods and radiotracers [14–43]. While the average rest MBF ($0.81 \text{ mL/min/g} \pm 0.16$), stress MBF ($3.06 \text{ mL/min/g} \pm 0.78$), and CFR (4.09 ± 1.13) were relatively similar within studies, there was, however, significant variation in stress flow and CFR ranges (large standard deviation) between studies, consequently

Table 8.1 Summary of PET literature on the mean and proposed reference values for myocardial blood flow (MBF) and coronary flow reserve (CFR) quantification in healthy volunteers

Flow	Studies (n)	Subjects (n)	Age	Tracer	Mean \pm SD	Lower limits ^a	Upper limits

CFR	Study [17]	125	29 \pm 5	⁸² Rb	4.03 \pm 0.84	1.93	6.13

^aLower reference limit and upper reference limit were defined as values 2.5 standard deviations (SD) below and above the mean, respectively

^bSingle largest PET study to date investigating MBF and CFR reference values in healthy volunteers

yielding lower than expected reference values if one were to define the lower limits of normal for stress MBF (<1.11 mL/min/g) and CFR (<1.27) using this large pool of studies. In contrast, the single largest PET study that included 125 patients found comparable rest MBF (0.70 mL/min/g ± 0.15), stress MBF (2.75 mL/min/g ± 0.58), and CFR (4.03 ± 0.84), but significantly less flow heterogeneity between patients (as shown by the narrower SD) so that the lower limits of normal for stress MBF (<1.30 mL/min/g) and CFR (1.93) would be higher based solely on this study [17].

These data (from Table 8.1) also revealed that rest (0.92 mL/min/g ± 0.18) and stress MBF (3.57 mL/min/g ± 1.08) with ^{15}O -water were significantly higher in healthy volunteers than that of ^{13}N -ammonia (0.74 mL/min/g ± 0.13 and 2.72 mL/min/g ± 0.60 , respectively) or ^{82}Rb (0.74 mL/min/g ± 0.18 and 2.75 mL/min/g ± 0.74 , respectively), whereas CFR was highly comparable between tracers (4.18 ± 1.43 vs. 4.00 ± 0.97 vs. 4.08 ± 0.96).

From a methodology perspective, the technique used to determine the arterial input function, and generate tissue time activity curves, and the type of kinetic analysis, and software package employed, can lead to large differences in flow estimates. For example, prior studies have found significant differences in the absolute estimates of rest and stress MBF when comparing different methods and software packages in the same population with ^{82}Rb and $^{13}\text{NH}_3$, whereas CFR tends to be less software dependent [44, 45].

Age and certain hemodynamics also appear to affect MBF. Czernin et al. [19] (using $^{13}\text{NH}_3$) observed that MBF at rest increases with age, heart rate, and systolic blood pressure in normal subjects, in contrast to dipyridamole-induced hyperemic flow, which appears to be unrelated to these baseline characteristics [19].

8.5 MBF and CFR in Ischemic Heart Disease

Similar to experimental data, PET-derived flow data has been associated with the degree of luminal stenosis severity on coronary angiography in humans [46, 47]. In general, stress MBF and CFR are inversely and non-linearly correlated to stenosis severity independent of the radiotracer investigated [46, 47]. Patients with coronary luminal stenosis $<50\%$ diameter narrowing usually have similar CFR values compared to age-matched control individuals; however, there is a stepwise decrement of CFR at increasing degrees of luminal stenosis. Importantly, PET may have the potential to differentiate coronary artery stenosis of intermediate to high-grade severity ($50\text{--}70\%$ vs. $70\text{--}90\%$ vs. $>90\%$) by absolute measurements of MBF [46]. Muzik et al. demonstrated similar findings using ^{13}N -ammonia ($\geq 50\%$ vs. $\geq 70\%$ vs. $\geq 90\%$) to show the correlation between PET-derived CFR and MBF estimates with coronary angiography by means of a dynamic PET acquisition method (Table 8.2) [31]. Furthermore, this method was found to be more sensitive than coronary angiography in earlier stages of CAD, showcasing the utility of PET to evaluate blood flow at a microcirculatory level.

While the limitations of interpreting myocardial perfusion imaging based on relative analysis are known, recent studies have demonstrated that absolute blood

^aHigh risk CAD defined as 2-vessel disease (\geq 70% stenosis), including the proximal left anterior descending artery; 3-vessel disease; or left main CAD (\geq 50% stenosis)

^bRFR = relative flow reserve is the ratio of stress MBF in target myocardial territories to that of a reference vascular territory

flow quantification improved the accuracy of PET for identifying CAD [48]. A clinical trial studied 104 individuals with a high pretest likelihood of CAD using ^{15}O -water and found very high sensitivity (95%), and specificity (91%) in detecting flow-limiting CAD [49]. Of the 104 individuals in the trial, 38 were identified to have significant CAD, based on fractional flow reserve (FFR) ≤ 0.80 or angiographic coronary stenosis $\geq 50\%$, of which 24 were found to have multivessel disease. Absolute quantitative blood flow was able to accurately detect all but one of the 24 individuals with multivessel disease, but five false positives were identified where there was diminished MBF but no presence of CAD as per coronary angiography data. In comparison, relative uptake analysis accurately identified all but two of the 24 individuals with CAD but misidentified 26 other individuals in the study as having multivessel disease.

Others have also established the diagnostic value of global CFR over myocardial perfusion imaging alone to detect angiographically proven CAD [50]. In this study, coronary angiographic data identified 53 of the 73 individuals to have CAD. Initial visual PET assessment of the 73 individuals revealed ^{13}N -ammonia uptake to be abnormal in 46 and normal in 27 patients. However, when an CFR of less than 2.0 was incorporated as the model to best predict CAD, nine patients who were previously considered normal were reclassified as abnormal. These results were confirmed with coronary angiography, with improved sensitivity, specificity, negative predictive value, positive predictive value, and accuracy. This may be explained by the fact that assessing global CFR better reflects CAD beyond just the epicardial circulation and also includes endothelial dysfunction. This method may prove to be superior to regional CFR estimation due to better repeatability and reproducibility of global CFR [42, 51].

While the aforementioned studies have shown ^{13}N -ammonia and ^{15}O -water to be useful tracers for quantifying blood flow, Ziadi et al. sought to assess ^{82}Rb in quantifying CFR as an independent predictor in patients with obstructive multivessel CAD (3-vessels) [52]. Their study found that CFR was globally reduced in 22 of the 25 patients (88%), and moreover that a progressive reduction in the tracer predicted a high likelihood of triple vessel disease. Similarly, Naya and collaborators reported a high sensitivity (86%) and negative predictive value (97%) of CFR (≤ 1.93) ^{82}Rb PET to rule out high risk CAD defined as 2-vessel disease ($\geq 70\%$ stenosis), including the proximal left anterior descending artery; 3-vessel disease; or left main CAD ($\geq 50\%$ stenosis) [53].

Beyond the scope of CAD, quantitative MBF also provides valuable clinical information in post-transplant complications in long-term orthotopic heart transplant survivors. A study investigating the added diagnostic value of quantifying MBF to standard myocardial perfusion imaging for detecting cardiac allograft vasculopathy found that this method not only improves the ability to detect and grade the vasculopathy, but is also predictive in the outcome of major adverse cardiac events [54]. Likewise, an important correlation between stress MBF and angiographic coronary stenosis was shown (Fig. 8.1).

Table 8.2 summarizes the diagnostic performance of stress MBF and CFR for the detection of flow-limiting CAD as defined by angiographic stenosis or FFR [31, 49, 50, 53–56]. Interestingly, in many of these studies stress MBF appears to yield a

Fig. 8.1 Box plot analysis in 198 vessels of the inverse relationship between regional stress myocardial blood flow (MBF) and degree of coronary allograft stenosis ($r^2 = -0.22$, $p < 0.0001$)

higher sensitivity to detect CAD than CFR, which may reflect a cleaner assessment of the epicardial perfusion pressure than CFR which is also influenced or affected by changes in the baseline MBF. For this reason, some authors have proposed the use of coronary flow capacity, which is an integration of CFR and maximal MBF, a measure that may potentially allow for a more extensive assessment of patients with a suspected or known CAD as compared to CFR alone [57–59]. However, this remains an area of research, and further studies investigating the role of coronary flow capacity, as well as other markers such as relative flow reserve are needed [55].

8.6 Relationship of CFR with FFR in Ischemic Heart Disease

While CFR may provide information on a stenotic lesion, direct visualization of coronary microcirculation may not be possible due to the limited resolution of current imaging modalities. Fractional flow rate (FFR) is an invasive method to assess the severity of stenosis in the epicardial coronary system. It is defined as a ratio of pressure measured proximal to the stenosis and pressure distal to the stenosis, with a threshold for ischemia set at ≤ 0.80 . Recent studies such as FAME [60], DEFER [61], and FAME 2 [62] have established evidence-based approaches to guide treatment based on FFR evaluation. Patients with $\text{FFR} \leq 0.80$ may benefit from revascularization therapies while those with an $\text{FFR} > 0.80$ can be managed with medical therapy. In fact, current guidelines state that FFR may prove to be useful and is indicated in patients with moderate stenosis (e.g. 50–90%) when there is a lack of

functional information [63]. An FFR ≤ 0.80 with a CFR > 2.0 is indicative of flow-limiting stenosis with preserved microvascular function (or microvascular dysfunction, CFR < 2) and warrants percutaneous coronary intervention (PCI). Similarly, an FFR > 0.80 and CFR > 2 indicates non-flow-limiting stenosis with preserved microvascular function (or microvascular dysfunction, CFR < 2) and requires medical management without PCI [64]. While CFR and FFR are both used to identify ischemic areas, they are often discordances in approximately 30% of cases with intermediate stenosis [65, 66]. Moreover, the interplay between CFR and FFR, though not fully understood, is thought to be mediated by coronary microcirculation resistance which is largely responsible for the CFR-FFR discordance [67, 68]. An abnormal CFR will not be able to accurately distinguish epicardial stenotic lesions from that of non-obstructive vascular dysfunction [53]. Likewise, FFR cannot consider the presence of diffuse disease that may be present in conjunction with a focal stenosis. Garcia et al. conducted a study to better understand the relationship between the two parameters and found that both FFR and CFR (measured by ultrasound) are in fact complementary tools and moreover that both should be used simultaneously to guide percutaneous coronary intervention (PCI) [69]. This study also sought to establish the prognostic value of a CFR/FFR ratio by assessing pre- and post-PCI CFR and found that CFR in fact increased significantly post-PCI and thus, may have potential to better guide and optimize patient care.

8.7 Prognostic Value of Stress MBF and CFR for Risk Stratification

Coronary artery disease is a combination of multilevel microcirculatory obstructive alterations in the coronary circulation that can be either focal or diffuse [70]. The risk stratification of CAD and its complications requires a comprehensive assessment of the vascular disease activity. CFR's strength lies in its ability to integrate the hemodynamic effects of epicardial coronary atherosclerosis and luminal narrowing with that of microvascular dysfunction thereby being a more accurate marker of the coronary circulation, and this has translated into enhanced risk prediction of adverse cardiovascular events in addition to other indicators such as LVEF, percentage of ischemic myocardium, transient ischemic dilatation, LVEF reserve, and coronary calcium score [71].

Numerous studies have shown that impaired CFR is associated with adverse events independent of the presence of obstructive CAD [72]. A study by Tio et al. showed that after adjustment for age and sex, myocardial perfusion reserve was associated with a hazard ratio for cardiac death of 4.11 (95% CI, 2.98–5.67) per SD decrease, whereas the risk for LVEF was 2.76 (2.00–3.82) per SD which clearly underlines the advantage that coronary flow-based indices have, over left ventricular ejection fraction in predicting negative outcomes [73]. Murthy also showed in a previous study that CFR is a potent predictor of cardiovascular-related mortality independent of myocardial ischemia, scar, LV dysfunction, and traditional risk factors [74]. Table 8.3 was compiled based on several studies investigating the prognostic value of MBF and CFR [72, 73, 75–79]. Overall, all studies consistently show that CFR (typically with a cutoff ≤ 2.0) serves as independent risk marker for

Table 8.3 Summary of prognostic value of stress MBF and coronary flow reserve for risk prediction

all-cause mortality, cardiac death, and MACE. These studies also suggest that CFR may carry higher prognostic value compared to stress MBF. In fact, Gupta reported in over 4000 patients that global CFR is a stronger predictor of cardiovascular-related deaths than stress MBF after adjustment for a large number of clinical variables [78]. As previously mentioned, CFR is tightly related to oxygen consumption and the metabolic demand of the myocardium, and will be, thus, affected by any conditions that adversely rise the resting MBF and/or impair stress MBF, which may explain the stronger predictive value of CFR, by factoring in the results of rest and stress MBF.

A meta-analysis of 11 studies, including 11,867 patients, has further confirmed the power of CFR for predicting MACE (pooled HR 1.93 [95% CI 1.65–2.27]) [80]. Finally, a recent study totaling 12,594 patients who underwent ^{82}Rb for evaluation of suspected or known CAD showed a significant interaction between CFR and early coronary revascularization such that patients with $\text{CFR} < 1.8$ had a survival benefit with early revascularization, regardless of type of revascularization or level of myocardial ischemia, suggesting that in addition to its strong risk prediction, CFR may help identify patients with a survival benefit from early percutaneous or surgical revascularization beyond perfusion defects on MPI [79].

8.8 Summary

In summary myocardial blood flow quantification is a powerful tool that when combined with myocardial perfusion imaging may improve the diagnostic and prognostic value of cardiac PET during the evaluation of individuals with suspected or known CAD.

Hybrid PET-CT Evaluation of Myocardial Viability

9

Wail Nammas and Antti Saraste

9.1 Background

Coronary artery disease is the most prevalent etiology of heart failure. Myocardial ischemia was the underlying cause of heart failure in 62% of patients from a pooled analysis of 24 heart failure trials encompassing more than 400,000 participants [1]. Chronic repetitive myocardial ischemia may result in chronic hibernating myocardium or chronic stunning; both are potentially reversible causes of regional/global left ventricular dysfunction. Myocardial hibernation refers to chronic reversible contractile dysfunction of “viable” cardiac myocytes under conditions of long-standing myocardial ischemia; whereas the term myocardial stunning expresses prolonged suppression of contractile function after brief intense ischemic insult despite restoration of regional myocardial blood flow [2]. Ischemic myocardium presents a continuum from entirely viable, through partially viable myocardial zones, to non-viable scar tissue. The likelihood of recovery of ventricular function after coronary revascularization depends on the presence and extent of myocardial viability, and the amount of scar [3]. Patients with heart failure due to ischemic etiology have the potential to benefit from coronary revascularization in terms of recovery of contractile function, improvement of symptoms, and long-term survival provided that they have adequate myocardial viability in regions of contractile dysfunction. On the other hand, areas of scar tissue represent “non-viable” myocardium with almost no potential for improvement after revascularization. Coronary revascularization in patients with viability was associated with improvement of the annual survival rate, compared with medical treatment; in patients without viability, survival rates did not differ by the line of therapy [4]. Therefore, non-invasive

detection of myocardial viability has a pivotal role in selection of patients with chronic ischemic heart failure who are likely to derive benefit from revascularization.

9.2 Patterns of Viability by PET

Positron emission tomography (PET) can serve to evaluate myocardial perfusion, glucose utilization, fatty acid oxidation, oxygen consumption, and pre- and post-synaptic neuronal activity. Assessment of myocardial viability has been one of the earliest clinical applications of PET; PET is acknowledged as the “gold standard” technique for such indication. Myocardial viability entails intact cell membrane, mitochondrial integrity, preserved glucose and fatty acid metabolism, adequate resting perfusion, and contractile reserve [5–8]. Evaluation of resting myocardial perfusion using a perfusion radiotracer [^{82}Rb (^{82}Rb) or ^{13}N -ammonia] can be employed to assess viability in dysfunctional myocardium analogous to single photon emission computed tomography viability protocols [9, 10]. However, the most common and accurate approach for viability assessment by PET is based on evaluation of myocardial glucose metabolism by ^{18}F -fluorodeoxyglucose (FDG). Viable myocardium shows preserved FDG uptake; whereas markedly reduced or absent uptake indicates the presence of scar [11]. Typically, hibernating myocardium is identified by comparing FDG uptake with resting perfusion. Myocardial segments with reduced perfusion but preserved or increased FDG uptake (perfusion-metabolism mismatch) are classified as viable: contractile function of such segments is most likely to improve with successful revascularization. In contrast, segments with proportional reduction of perfusion and FDG uptake (perfusion-metabolism match) are regarded as scar tissue whose contractility would probably not improve following revascularization (Figs. 9.1 and 9.2) [11]. A third category of segments is characterized by normal or near normal perfusion and preserved FDG uptake: such pattern may represent stunned myocardium after repetitive episodes of ischemia. Some studies reported functional improvement of such segments after revascularization [12, 13].

9.3 Metabolic Considerations

The normal myocardium uses a wide variety of substrates for energy production, including free fatty acids (FFA), glucose, pyruvate, lactate, and ketone bodies [14]. Under normal conditions, metabolism is primarily oxidative, and FFA represent the main source of energy; whereas glycolysis contributes nearly 30% of substrate needed for the citric acid cycle. In the fasting state, the availability of FFA in plasma is high (from lipolysis of triglycerides in peripheral tissues) and thus myocardial FFA oxidation is consistently high; this inhibits glycolysis. After ingestion of carbohydrates, plasma glucose rises with parallel increase in insulin levels. This inhibits peripheral lipolysis, thereby lowering plasma FFA levels, and increasing exogenous

Fig. 9.1 Myocardial viability study using ^{18}F -FDG and resting myocardial perfusion study using ^{15}O -water. The patient had 3-vessel obstructive coronary artery disease, contractile dysfunction in the territory of the LAD coronary artery, reduced left ventricle ejection fraction (35%), and high surgical risk. Resting perfusion is reduced in the LAD territory. Viability study shows absence of ^{18}F -FDG uptake in the apex, but partially preserved uptake elsewhere in the LAD territory indicating partially preserved viability. SA short axis, ^{18}F -FDG ^{18}F -fluorodeoxyglucose, HLA horizontal long axis, LAD left anterior descending, VLA vertical long axis

glucose utilization by the myocardium [15]. On the other hand, mitochondrial β oxidation of FFA is greatly dependent on oxygen supply; therefore, it markedly decreases under conditions of ischemia. Hence, during myocardial ischemia, glucose uptake and metabolism is substantially increased in the ischemic myocardium [16]. Based on this, non-invasive techniques which quantify exogenous glucose utilization can be used for assessment of residual myocardial viability in ischemic

Fig. 9.2 Assessment of myocardial viability by FDG PET: Examples of perfusion–metabolism mismatch patterns. (Reprinted with permission from Bengel FM, Higuchi T, Javadi MS, Lautamäki R. *J Am Coll Cardiol.* 2009 Jun 30;54(1):1–15. <https://doi.org/10.1016/j.jacc.2009.02.065>. Review)

dysfunctional myocardium. Nevertheless, under ischemic states, glycolysis becomes uncoupled from glucose oxidation, leading to excess production of lactate and hydrogen ion. During mild ischemia, such by-products are removed from the myocardium by the residual blood flow. Prolonged severe ischemia leads to tissue accumulation of lactate and hydrogen ion, depletion of high-energy phosphate, disruption of cell membrane, and cell death [14]. Therefore, assessment of resting myocardial perfusion can still provide valued information on the presence of viability in dysfunctional myocardial zones. Following intravenous administration, FDG is taken up by cardiac myocytes, along with glucose, where it undergoes phosphorylation by hexokinase to FDG-6-phosphate. Unlike glucose-6-phosphate, FDG-6-phosphate is a poor substrate for glycolysis and glycogen synthesis, and is quite impermeable to the myocyte membrane; thus it becomes virtually trapped in the myocardium. Therein, it provides robust signal for PET imaging. Regional FDG uptake is normal or increased in viable myocardial segments with ischemic contractile dysfunction, thereby it indicates persistence of metabolic activity, and the potential for recovery of contractile function.

9.4 Protocols for Assessment of Myocardial Viability by FDG

The concentration of FDG in both the myocardium and blood determines the diagnostic quality of myocardial FDG images. Myocardial FDG—along with glucose—uptake depends essentially on plasma concentration of glucose as well as insulin level, which in turn determine the rate of glucose utilization by peripheral tissues. Additionally, myocardial glucose uptake is based on plasma levels of FFA and other substrates, oxygen supply, catecholamine levels, and myocardial work. Therefore, the FDG myocardial viability assessment protocols have sought to optimize the metabolic conditions for myocardial FDG uptake in order to maximize the quality of FDG images, and thereby improve the diagnostic accuracy. The currently implemented protocols for FDG myocardial viability assessment include:

1. **Fasting:** Under fasting conditions, the normally perfused myocardium utilizes predominantly FFA; whereas the uptake of glucose—and correspondingly FDG—is minimal. In contrast, glucose utilization is favored by the ischemic myocardium, and therefore FDG uptake is enhanced. In this way, a remarkable differential of FDG uptake exists between normal and ischemic myocardium, which is seen as a “hot spot.” This is the simplest protocol since it does not require any substrate manipulation. However, in the fasting state FDG becomes heterogeneously distributed throughout the normal myocardium [17]. This along with lack of radiotracer uptake in the normal myocardium might overestimate the extent of residual viability in ischemic dysfunctional myocardium. Moreover, the low uptake of glucose by both cardiac and skeletal muscle results in poor image quality in nearly 50% of the cases [18]. In addition, low FDG uptake by the non-ischemic myocardium hinders the differentiation of scar tissue from normal myocardium.
2. **Glucose loading:** Oral or intravenous glucose load after 6-h fasting stimulates endogenous insulin release. This limits the bioavailability of FFA, and increases peripheral glucose utilization, and myocardial FDG uptake. The more homogeneous distribution of FDG uptake by the myocardium essentially promotes image quality. This is the most commonly adopted protocol for FDG myocardial viability assessment in clinical practice. However, when the plasma concentration of glucose increases, the fraction of FDG sequestered by the myocardium declines, and this might reduce the gain in image quality. Indeed, unsatisfactory images may still be obtained with this protocol in 20–25% of the patients [18, 19]. Impaired glucose tolerance or undiagnosed type 2 diabetes mellitus might underlie the suboptimal image quality in many such patients. Intravenous administration of low doses of regular insulin in diabetic patients may improve image quality, and yield a level of diagnostic accuracy similar to that in non-diabetic patients who receive oral glucose load [20, 21].
3. **Hyperinsulinemic-euglycemic clamp:** This protocol mimics the post-absorptive steady state by means of continuous infusion of insulin with simultaneous infusion of glucose at a variable rate, in order to maintain euglycemia [19]. Insulin clamping stimulates FDG uptake, along with glucose, in the myocardium, and

provides consistently high image quality, even in diabetic patients [19, 22]. Nevertheless, this protocol is technically demanding and time consuming; therefore most centers preserve it for complex studies, for example, in diabetics.

4. Nicotinic acid derivatives: Nicotinic acid inhibits peripheral lipolysis, and consequently, reduces the bioavailability of FFA in plasma, and switches to preferential myocardial glucose utilization. Acipimox is 20 times more potent than nicotinic acid and has more favorable kinetics [23]. It could be given combined with glucose load 60 min before FDG administration. In a small early study, image quality (expressed as the myocardium-to-blood pool FDG ratio) and myocardial FDG uptake patterns after acipimox administration were similar to those obtained during hyperinsulinemic-euglycemic clamp [24]. Another study compared three protocols in a limited sample size, and demonstrated that acipimox administration and hyperinsulinemic-euglycemic clamp achieved comparable FDG image quality and clearance rates that were superior to those obtained after oral glucose load [22]. Apart from flushing, no side effects have been reported. This protocol is simple and practical; however, acipimox is not available in all centers.

9.5 Diagnostic Accuracy of FDG Myocardial Viability Assessment

Myocardial viability assessment by FDG is the most sensitive technique for detection of viability in ischemic dysfunctional myocardial segments, and prediction of contractile recovery of such segments after revascularization. In an early pooled analysis (1980 through January 2000) of 20 studies (598 patients) which employed FDG PET to detect improvement of regional contractile function after revascularization, the weighted mean sensitivity and specificity were 93% and 58%, respectively; weighted mean positive and negative predictive values were 71% and 86%, respectively [25]. In four studies performed after 2000, the sensitivity of FDG PET to predict improvement of regional function after revascularization ranged from 86% to 100%, specificity ranged from 63% to 87%, positive and negative predictive value ranges were 75–89% and 83–100%, respectively [26–29]. In a more recent pooled analysis that included the aforementioned studies (24 studies, 756 patients), myocardial viability assessment by FDG PET predicted improvement of regional function after revascularization with a weighted mean sensitivity and specificity of 92% and 63%, respectively; weighted mean positive and negative predictive values were 74% and 87%, respectively [30]. It is worth mentioning that viability assessment by FDG PET has the highest sensitivity for prediction of functional recovery after revascularization, compared with the other imaging modalities; whereas evaluation of wall motion by dobutamine stress echocardiography and imaging modalities which evaluate myocardial scar tissue, such as contrast-enhanced magnetic resonance imaging have a higher specificity [30]. The reasons for the suboptimal specificity (absence of functional improvement after revascularization of segments classified by FDG PET as viable) seem to be multifactorial, including the presence

of subendocardial scar, advanced degenerative changes of viable myocytes, incomplete revascularization or periprocedural myocardial injury, and delayed improvement of some segments following adequate revascularization [31]. Most of the aforementioned published data were obtained from patients with normal left ventricular function or mild/moderate left ventricular dysfunction: only 3 out of 24 studies included patients with a mean left ventricular ejection fraction $<30\%$; in four studies, there were no available data on left ventricular ejection fraction [30]. It should be noted that the diagnostic accuracy indices of viability assessment by FDG PET for prediction of ventricular function improvement after revascularization differ by severity of global ventricular function impairment before revascularization: the accuracy declines considerably with worsening global left ventricular function [32]. Therefore, data obtained from patients with a mean left ventricular ejection fraction $\geq 30\%$ should not be extrapolated to those with very low ejection fraction. On the other hand, a single study (37 patients; surgical coronary revascularization; median follow-up 8 weeks) reported that the diagnostic accuracy was highest in segments with severe dysfunction and perfusion-metabolism mismatch by FDG PET [12]. Furthermore, improvement of left ventricular function after revascularization appears to be multifactorial. Many other factors might influence such improvement including the presence and extent of myocardial ischemia, the severity of degeneration of viable cardiac myocytes, success and completeness of revascularization, the state of other coronary vessels, as well as the timing of ventricular function assessment after revascularization. Integration of many of these factors along with FDG PET viability assessment in a multivariable prediction model predicted the degree of recovery [33].

9.6 Prognostic Implications of FDG Myocardial Viability Assessment

The detection of viability not only serves to predict contractile recovery of ischemic dysfunctional myocardial segments upon revascularization, but may also predict clinical outcome. In a meta-analysis of 24 viability studies (3088 patients; mean ejection fraction $32 \pm 8\%$; viability detection by PET, single photon emission computed tomography, or dobutamine stress echocardiography) which reported long-term clinical outcome (mean follow-up 25 ± 10 months), coronary revascularization was associated with almost 80% reduction of annual mortality rate, compared with medical treatment, in patients with viability (3.2% versus 16%, respectively, $p < 0.0001$); in those without viability, annual mortality rates were not significantly different by treatment modality (7.7% versus 6.2%, respectively) [4]. In a more recent pooled analysis of ten FDG PET viability studies (1046 patients; clinical outcome assessed at variable durations of follow-up), the annualized mortality rate was 4% in patients with viability who underwent revascularization, compared with 17% in those with viability who were treated medically; in those without viability, the annualized mortality rates were 6% and 8%, respectively [30]. An observational study investigated the effect of viability (^{99m}Tc -sestamibi single photon emission

computed tomography and FDG PET) on long-term (median 6.8 years) cardiac mortality in patients with left ventricular aneurysm. Annual cardiac mortality was significantly higher in patients with viable aneurysm who were treated medically, compared with those who underwent surgical revascularization (11.6% versus 1.5%, respectively, $p < 0.0001$); the rate was also higher than in patients with a non-viable aneurysm treated medically or surgically. Viability in left ventricular aneurysm was an independent predictor of cardiac death; whereas coronary revascularization was associated with better long-term survival, symptoms, and left ventricular function in patients with a viable aneurysm [34]. In another recent observational study, both viability (mismatch score ≥ 2) and left ventricular remodeling (left ventricular volume index ≥ 60 mL/m²) were assessed by gated PET in 126 patients with left ventricular aneurysm who were followed up for a mean of 3.9 ± 1.5 years. In such cohort, patients with viable aneurysm were at increased risk of cardiac death, compared with those who had no aneurysm viability, with or without remodeling [35]. Revascularization in patients with viable aneurysm was associated with improved long-term cardiac survival; no such improvement was observed in patients without aneurysm viability regardless the presence of remodeling [35].

9.7 FDG Myocardial Viability Assessment for Guiding Therapeutic Decision

The value of myocardial viability assessment by FDG PET for guiding therapeutic decision making in patients with severe left ventricular dysfunction and advanced coronary artery disease remains controversial [36, 37]. A relatively small randomized controlled trial (PET and Recovery Following Revascularization-2 trial, 430 patients) assessed the efficacy of FDG PET-assisted management, versus standard care, to reduce major adverse cardiac events (cardiac death, myocardial infarction, or hospitalization for a cardiac cause) in patients with severe left ventricular systolic dysfunction (ejection fraction $< 35\%$) who were considered for revascularization, transplantation, or heart failure work-up, or in whom PET was considered useful. At 1-year follow-up, there was no significant reduction of cardiac events in patients assigned to PET-assisted management, versus standard care [38]. However, at 5-year follow-up, PET-assisted management was associated with significant reduction of the composite endpoint only in the subgroup of patients who adhered to PET recommendations (hazard ratio 0.73, 95% confidence interval 0.54–0.99; $p = 0.042$) [39]. In a post-hoc analysis of the aforementioned trial, there was an interaction between the extent of viability (expressed as mismatch percent of the left ventricle) and treatment modality such that in patients with higher mismatch percent values revascularization was associated with fewer cardiac events, compared with those with lower mismatch percent values ($p = 0.042$) [40]. A cutoff value of 7% mismatch of the whole left ventricle was identified to stratify patients whose clinical outcome improves after revascularization: in patients with mismatch value $\geq 7\%$, revascularization was associated with significant reduction of the primary outcome

compared with medical treatment ($p = 0.015$); whereas patients with mismatch value $<7\%$ had no significant difference in the primary outcome based on treatment modality ($p = 0.923$) [40]. In addition, an observational study investigated the impact of hibernating versus ischemic myocardium on long-term survival after revascularization in 648 patients (age 65 ± 12 years, mean left ventricular ejection fraction $31 \pm 12\%$) with ischemic cardiomyopathy. At a mean follow-up of 2.8 ± 1.2 years, an interaction was present between treatment modality and hibernating myocardium such that early revascularization in the presence of significant hibernating myocardium was associated with survival benefit, versus medical treatment ($p = 0.0009$), specifically when the extent of viability exceeds 10% of the whole myocardium; no such interaction was observed between treatment modality and ischemic myocardium [41]. In another retrospective study which explored the prognostic value of combined viability imaging (PET and single photon emission computed tomography) for prediction of survival in 224 patients with ischemic cardiomyopathy (64.0 ± 10.6 years, mean left ventricular ejection fraction $\leq 45\%$) at a median follow-up of 33 months, patients with mismatch values $\geq 5\%$ who were treated medically had significantly higher mortality than those with similar mismatch values who underwent early revascularization; whereas in those with mismatch values $<5\%$, early revascularization was associated with higher mortality compared with medical treatment [42]. The high procedural risk of revascularization complicates therapeutic decision making in patients with severe left ventricular dysfunction. Nevertheless, it is in this complex patient subset (comorbidities, prior revascularization) where both the possible risk and potential benefit of revascularization are high [36]. According to the current European Society of Cardiology guidelines for treatment of heart failure, PET may be considered for myocardial viability assessment before the decision of revascularization, in patients with heart failure and coronary artery disease whose coronary anatomy is deemed suitable for revascularization (class of recommendation IIb, level of evidence B) [43].

9.8 Hybrid PET-Computed Tomography for Myocardial Viability Assessment

Hybrid scanner systems involving both multidetector computed tomography (CT) and PET have become widespread over the past decade. Hybrid PET-CT scanners enable direct integration of PET imaging data with detailed information acquired from coronary and cardiac CT imaging. Additionally, multidetector CT can be useful for attenuation correction and coronary calcium score assessment. Radiation dose exposure from coronary CT angiography can be reduced by the modern prospective-gated CT acquisition techniques down to 1–3 mSv; this might promote more widespread use of hybrid PET-CT protocols [44]. A hybrid PET-CT scanner allows obtaining myocardial viability scan provided by FDG PET and coronary anatomy images provided by CT angiography in a single imaging session, and provides automatic fusion of the images (Fig. 9.3). Vascular mapping of the left ventricle is based on a standard template that relates each myocardial segment to the

Fig. 9.3 A hybrid PET-CT study of coronary angiography and myocardial viability. The patient presented with new-onset heart failure. Echocardiography demonstrated severe left ventricular dysfunction with akinesia or hypokinesia in the apex, anterior septum, anterior free wall, as well as the posterolateral wall. Due to the presence of a left ventricular apical thrombus, coronary CT angiography was performed initially instead of invasive coronary angiography. Coronary CT angiography showed chronic total occlusion in the proximal LCx, severe stenosis in the proximal LAD (arrow), and chronic total occlusion in the mid-LAD (Panel a). Then, ^{18}F -FDG PET was performed to assess viability. ^{18}F -FDG PET images demonstrated local defects in ^{18}F -FDG uptake in the apex and lateral wall consistent with infarct scars. However, there was preserved ^{18}F -FDG uptake in the septum and most of the anterior wall, as well as in the inferior wall, consistent with large areas of viable myocardium (Panel b). Panel (a) demonstrates 3-D reconstruction of coronary CT angiography and ^{18}F -FDG PET. Co-registration clearly demonstrates viable myocardium (green and red colors) in the septum and anterior wall (supplied by a large diagonal branch) excluding the apical scar (blue color). The patient had successful coronary bypass surgery with venous grafts inserted on the distal LAD, diagonal branch, and LCx. Heart failure symptoms were relieved after surgery. CT computed tomography, ^{18}F -FDG ^{18}F -fluorodeoxyglucose, HLA horizontal long axis, LAD left anterior descending, LCx left circumflex, PET positron emission tomography, SA short axis, VLA vertical long axis

part of coronary tree which supplies blood to that segment. Often the standard template does not mirror the real coronary anatomy; therefore, disparity between imaged myocardial perfusion defects and actual significant coronary lesions may occur [45]. In this context, hybrid PET-CT scanners which integrate FDG PET viability scans with coronary CT angiography images can mitigate such disparity, and enhance the accuracy of viability imaging. Moreover, it has been possible to evaluate myocardial perfusion in contrast-enhanced CT images. In the setting of myocardial infarction (acute, subacute, and chronic) myocardial perfusion defects become apparent during the early phase of contrast bolus (early defect). Subsequently, “delayed enhancement” of infarcts is seen 5–15 min following contrast infusion

[46]. Similar to magnetic resonance imaging, multidetector CT was employed in animal models for the assessment of myocardial viability by studying “delayed enhancement” [47, 48]. In a porcine model of myocardial infarction employing a hybrid PET-CT scanner, contrast enhancement by 64-slice CT could measure infarct size accurately and reproducibly compared with PET perfusion defect size; low-dose prospective-gated acquisition was comparable to high-dose spiral CT [49]. Early small-sized clinical studies demonstrated good agreement between delayed enhancement by multidetector CT and magnetic resonance imaging for infarct size and location [50, 51]. Whether the currently available hybrid PET-CT scanners improve the detection of viability in clinical practice remains unsettled. In a small observational study, the sensitivity, specificity, and diagnostic accuracy of multidetector CT to detect non-viable segments was 70.4%, 85.3%, and 81.4%, respectively, compared with FDG PET [52]. Yet, some segments which deemed viable by FDG PET showed delayed enhancement by multidetector CT. A preclinical study employed a hybrid PET-CT scanner to compare directly FDG PET scans with delayed enhancement by multidetector CT in a porcine model of acute and chronic myocardial infarction. Interestingly, in the acute infarct model, 68% of segments characterized by no-reflow pattern (microvascular obstruction) in multidetector CT images showed increased FDG uptake; this was explained by active inflammation as was detected in histology sections [53]. In the chronic infarct model, there was no microvascular obstruction in multidetector CT images, and areas of delayed enhancement delineated by multidetector CT corresponded well with non-viable segments depicted by FDG PET [53].

9.9 Conclusions

¹⁸F-FDG PET imaging is an accurate method to detect dysfunctional, but viable myocardium that has potential to recover contractile function after revascularization. Although randomized clinical trials have not shown clinical benefit of systematic evaluation of viability in patients with ischemic left ventricle dysfunction, current guidelines indicate that it may be considered in selected heart failure patients to guide decisions on revascularization.

Myocardial Inflammation: Focus on Cardiac Sarcoidosis

10

David J. Murphy and Sharmila Dorbala

10.1 Introduction

The imaging evaluation of myocardial inflammation is challenging, often requiring multimodality input for both diagnosis and monitoring. The most common causes of myocardial inflammation include myocardial infarction, myocarditis from any etiology, or sarcoidosis. While the former two pathological entities have been studied experimentally, they have not yet entered routine clinical practice and hence will not be discussed in this chapter. Cardiac sarcoidosis is the quintessential focal myocardial inflammatory condition in which hybrid imaging plays a key role in both diagnosis and management and will be the focus of this chapter.

10.2 Sarcoidosis Overview

10.2.1 Epidemiology and Demographics

Sarcoidosis is a chronic systemic inflammatory disease characterized by the formation of granulomatous inflammation leading to areas of scarring. The cause is as-of yet unknown, but it is hypothesized that sarcoidosis results from abnormal immune responses from exposure to ubiquitous everyday infectious, organic, and inorganic agents [1]. The fundamental abnormality found in sarcoidosis is the development and accruelement of granulomas, which are organized collections of macrophages and epithelioid cells surrounded by lymphocytes. Granulomas form as a protective mechanism to protect surrounding tissue from pathogens and inflammation, and are initiated and maintained by the presence of CD4+ T cells [1].

10.2.2 Epidemiology and Demographics

Sarcoidosis affects people of all ethnic and racial groups and can occur at all ages, but is most common before the age of 50, with a peak occurring between the ages of 20 and 39 years [2, 3]. There is varying incidence throughout the world, likely due to differing genetic predisposition and environmental agent exposure patterns, with the highest incidence observed in Northern Europeans and African Americans [2]. A recent study from Sweden using national population-based registers demonstrated an incidence of 11.5 per 100,000 persons per year, with a prevalence of 0.16% [4]. In the USA, data taken from a health claims database incorporating 15% of the US population showed an incidence rate varying from 7.6 to 8.8 per 100,000 persons per year for the population as a whole, with an incidence of 17.8 per 100,000 persons per year for African Americans, and 8.1 for Caucasians [5]. There is a slight female preponderance in sarcoidosis, with men tending to have a slightly earlier age of onset compared to women across; for example, in the Swedish registry the mean age at diagnosis was 45 years for men and 54 for women [3, 4].

10.2.3 Cardiac Sarcoidosis

Cardiac sarcoidosis (CS) is associated with increased morbidity and mortality, and affects approximately 25–60% of patients with sarcoidosis based on autopsy examinations [6], but is only clinically apparent in approximately 5–25% of patients [1]. Cardiac involvement in sarcoidosis is associated with elevated mortality and morbidity with disease manifestations include atrioventricular block, severe ventricular dysrhythmias, sudden cardiac death and heart failure due to severe left ventricular (LV) dysfunction in approximately 25% of patients with CS [1, 6]. Early diagnosis

is important, as early immunosuppressive treatment may help stop the progression of heart failure [7, 8], and implanted cardiac defibrillators (ICD) can improve overall survival in at-risk patients [9, 10].

10.3 Cardiac Sarcoidosis Diagnosis

10.3.1 Pathology

The basic pathophysiological abnormality in cardiac sarcoidosis is the accumulation of non-caseating granulomas in the heart. The interaction between antigen presenting cells and CD4+ T cells in response to an unknown antigen initiates the formation and maintenance of granulomas [1]. When these granulomas affect the heart, they can involve the myocardium, pericardium, and endocardial surface of both ventricles and both atria. Macroscopically, cardiomegaly is frequently observed in post-mortem series of patients with cardiac sarcoidosis, and CS can grossly mimic dilated, ischemic or even arrhythmogenic cardiomyopathies [11]. The most commonly affected cardiac site for granulomatous infiltration is the inter-ventricular septum, in particular the basal septum, followed by the left ventricular free wall, right ventricular free wall, atrium, pericardium, and endocardium [12, 13]. CS lesions are mainly distributed in the subepicardial layer, but they can affect anywhere in the myocardium [13].

There are two phases of CS recognized on histopathologic assessment, active and healed CS [14]. Active CS is characterized by the presence of epithelioid granulomas comprised of organized collections of epithelioid cells, macrophages, and lymphocytes, without the presence of central caseation [1]. The presence of these non-caseating granulomas is the key histological feature required to make a firm histological diagnosis of CS [1]. The absence of caseation allows differentiation from Mycobacterial infection, and the absence of eosinophils and adjacent myocyte necrosis allows differentiation from giant cell myocarditis [14]. Replacement of the granulomas with fibrosis characterizes the healed phase, which can coexist with active cardiac sarcoid granulomas-identification of the healed phase alone on histological specimens is not sufficient to make a confident diagnosis of cardiac sarcoidosis. Inflammation of intramyocardial arterioles, epicardial arteries, and the cardiac valves may also be seen infrequently [11, 13].

One of the reasons why confirmation of cardiac involvement in sarcoidosis often proves challenging is due to the unavailability of histopathological confirmation. Endomyocardial biopsies are technically challenging to perform, have an associated morbidity, and are often unsuccessful due to the patchy distribution of CS lesions, with a reported sensitivity of 19–30% [15–17]. Although active inflammation and fibrosis can coexist in the heart, biopsy may not always identify both entities in the same samples. Sarcoidosis is a systemic disease and endomyocardial biopsy cannot identify the presence or absence of systemic sarcoid granulomas. As a result, imaging plays a key role in the diagnosis of myocardial and systemic involvement in sarcoidosis.

Table 10.1 Comparison of Cardiac Imaging modalities used in the assessment of Cardiac Sarcoidosis

	Echocardiography	Cardiac CT	CMR	FDG PET/CT
Temporal resolution	15–60 ms	66–135 ms	20–50 ms	N/A
Spatial resolution	0.6–1 mm	0.4–0.6 mm	1–2 mm	4–8 mm
Acquisition time	30 min	0.5–1 min	45–60 min	20–30 min
Radiation	None	3–10 mSv [18]	None	~7 mSv ^a
Anatomical vs. functional assessment	Functional	Anatomic	Anatomic and functional	Anatomic
Myocardial tissue characterization	+	+	++	+++
Portability	++	–	–	–
Contrast agent	Bubble microspheres	Iodinated contrast	Gadolinium	N/A

^aUsing 10 mCi (370 MBq) of FDG

10.3.2 Imaging

Imaging plays a key role in the diagnosis of CS, in the assessment of disease activity and treatment response. Chest radiographs are useful in the initial detection of mediastinal and pulmonary involvement in sarcoidosis, but are not sensitive for CS detection. Echocardiography, cardiac computed tomography (CT), cardiac magnetic resonance imaging (CMR), and positron emission tomography (PET) can help characterize cardiac involvement in sarcoidosis, with CMR and PET/CT the most useful imaging modalities (see Table 10.1 for comparison between cardiac imaging modalities).

Echocardiography is widely available and is often the first imaging modality used when CS is suspected. Trans-thoracic echocardiography (TTE) is the most frequently employed technique, with trans-esophageal echocardiography (TEE) and stress echocardiography playing a limited role, if any. The majority of patients with CS will have normal LV function on TTE, with approximately 30% demonstrating LV dilatation and reduced systolic function [19]. Due to the patchy nature of myocardial sarcoid infiltration, CS can manifest on TTE as regional wall motion abnormalities and focal myocardial wall thickening in a non-coronary artery distribution [20]. The areas of mild wall thickening results from myocardial edema and infiltration, and these areas may appear mildly hyperechoic relative to normal myocardium. Ventricular aneurysms, particularly affecting the septal and anterior walls are also found in approximately 10% of CS patients [12]. These features, however, are often non-specific, rarely detected on echocardiography, and require further assessment with advanced cardiac imaging modalities.

CT is the most commonly used imaging modality in the diagnosis and assessment of mediastinal and pulmonary involvement in sarcoidosis. The typical pattern of thoracic sarcoidosis on chest CT is of bilateral, symmetric mediastinal and hilar lymphadenopathy, and micronodular, perihilar and bilateral upper lobe pulmonary opacities in a perilymphatic distribution [21]. CT currently plays a limited role in the diagnosis of CS, with the major role of cardiac CT being in the exclusion of

significant coronary artery disease as a potential alternative pathology. Occasionally active CS may manifest on chest CT as a focal area of hypoattenuating myocardial wall thickening [22]. End-stage myocardial changes may manifest on contrast enhanced CT as LV dilatation or ventricular aneurysms. Delayed phase cardiac CT acquisition after 5–8 min can also detect areas of myocardial scarring as areas of delayed iodine enhancement [23], with dual energy cardiac CT techniques with low-kV virtual monochromatic image reconstructions showing promise in the characterization of areas of myocardial scarring [24].

CMR and PET are the key advanced cardiac imaging modalities used in CS diagnosis. They play a complementary role, allowing an assessment of myocardial function, helping to determine the burden of active cardiac sarcoid inflammation and healed myocardial scar. Due to the aforementioned difficulty in diagnosing cardiac sarcoidosis based on endomyocardial biopsies, clinical scoring systems are often used to establish the diagnosis of CS, such as the Japanese Ministry of Health and Welfare (JMHW) criteria [25] and the Heart Rhythm Society (HRS) consensus document [26]. These criteria recognize that incorporating clinical and radiological features are required in order to make a diagnosis of CS, with CMR and PET playing a key role, which will be outlined in the following section.

10.4 Imaging Methods

10.4.1 Cardiac MRI

CMR is a multiparametric imaging test with excellent spatial resolution and soft tissue characterization, and is often the initial advanced cardiac imaging modality obtained in patients with suspected CS. CMR provides an assessment of ventricular function and morphology (wall thinning or aneurysms) using bright blood cine imaging (gradient echo [GRE] or steady state free precession [SSFP] sequences), and myocardial tissue characterization using T2 weighted sequences and T1 weighted late gadolinium enhancement (LGE) imaging following administration of gadolinium contrast agent. Morphological abnormalities can occur in late-stage CS [27], but detecting abnormalities in myocardial tissue characterization is the most common method of diagnosing CS on CMR. There is no pathognomonic pattern of CS abnormalities on CMR, but there are imaging features that are highly suggestive, particularly in a patient with known extra-cardiac sarcoidosis. Mesocardial and subepicardial patterns of LGE (non-infarct patterns) are the most common CMR finding in CS, primarily affecting the basal septum and basal lateral wall [28]. The presence of areas of myocardial LGE does not allow discrimination between active inflammation and fibrosis, as both processes manifest as areas of increased extracellular gadolinium accumulation secondary to expansion of the extracellular space; this slows the wash-out rate of gadolinium, and will manifest as areas of increased signal on T1 weighted LGE imaging [29]. T2 weighted imaging can detect areas of myocardial edema secondary to active inflammation, however, implementing and interpreting this technique in practice is often challenging due to technical difficulties and artefacts [30].

10.4.2 PET

There are several radionuclide imaging tests available to image areas of inflammation, such as ^{99m}Tc (Technetium (^{99m}Tc) or ^{111}In (Indium (^{111}In) labelled white blood cells, ^{99m}Tc bisphosphonates, ^{67}Ga Gallium-citrate, ^{99m}Tc nanocolloids, and ^{99m}Tc or ^{111}In labelled proteins. ^{67}Ga Gallium-citrate SPECT was traditional radionuclide test used for the assessment of sarcoidosis, but is now seldom used as its use is limited by poor spatial resolution and low sensitivity, particularly for extrapulmonary sarcoid when compared to PET with 2-deoxy-2- ^{18}F fluoro-D-glucose (FDG) [12]. The areas of increased cellular FDG uptake in sarcoidosis are related to the presence of active inflammatory cells in granulomas with elevated glycolytic activity. Both FDG and glucose are taken up by cells via cellular membrane glucose transporters and are phosphorylated by the enzyme hexokinase-after this step, the phosphorylated FDG does not undergo further metabolism, and is trapped within the cells and can be imaged [31]. FDG thus accumulates in active sarcoid lesions packed with hypermetabolic inflammatory cells and will appear as focal areas of increased tracer uptake when imaged with PET. FDG PET is the only modality that can currently reliably identify myocardial inflammation. However, FDG PET cannot identify left ventricular function, and it is typically combined with echocardiography or CMR.

10.4.3 Patient Preparation for FDG Myocardial Inflammation PET

The aim of myocardial inflammation FDG PET imaging is to identify areas of active cardiac inflammation, which should manifest as focal areas of increased FDG uptake relative to normal myocardium. Normal myocardium utilizes glucose as one of its main energy sources, therefore in order to distinguish identify inflammatory from physiological myocardial uptake, normal myocyte metabolism needs to be switched from primarily glucose to free fatty acid metabolism [32]. Free fatty acids account for up to 90% of myocyte oxygen consumption in the fasting state compared to primarily glucose in the postprandial state, therefore FDG PET imaging after a prolonged fast is preferable to suppress physiological myocardial glucose uptake [32]. Prolonged fasting alone may still result in variable suppression of physiological myocardial glucose metabolism, and dietary modification with a high-fat, low-carbohydrate diet in the day before scanning has been shown to reduce FDG uptake by normal myocytes [33]. More recently, these approaches to patient preparation prior to a myocardial inflammation FDG PET have been combined, and the 2017 joint European Association of Nuclear Medicine (EANM)/European Association of Cardiovascular imaging (EACVI)/American Society of Nuclear Cardiology (ASNC) CS imaging guidelines recommend a high-fat, very low-carbohydrate diet for 12–24 h prior to the scan followed by a prolonged 12–18 h fast [20]. In addition, a bolus injection of unfractionated low molecular weight heparin approximately 15 min prior to scanning has been proposed as a potential adjunct to

Table 10.2 Sample diet options for suppressing physiological myocardial glucose utilization

Consume	<ul style="list-style-type: none"> • Meat fried in oil or butter without breading or broiled (chicken, turkey, bacon, meat-only sausage, hamburgers, steak, fish) • Eggs (prepared without milk or cheese) • Oil (an option for patients who are vegan or are unable to eat and have enteral access) and butter • Clear liquids (water, tea, coffee, diet sodas, etc.)
Acceptable	<ul style="list-style-type: none"> • Fasting for 18 h or longer if patient cannot eat and has no enteral access or if patient has dietary restrictions preventing consumption of advised diet
Avoid	<ul style="list-style-type: none"> • Vegetables, beans, nuts, fruits, and juices • Bread, grain, rice, pasta, and all baked goods Sweetened, grilled, or cured meats or meat with carbohydrate-containing additives (some sausages, ham, sweetened bacon) • Dairy products (milk, cheese, etc.) aside from butter • Candy, gum, lozenges, sugar, and sucralose (Splenda; Heartland Food Products Group) Alcoholic beverages, soda, and sports drinks • Mayonnaise, ketchup, tartar sauce, mustard, and other condiments Dextrose-containing intravenous medications

Reproduced with permission from Chareonthitawee et al. [66]

myocardial inflammation FDG PET patient preparation, mediated by its effect on transiently increasing serum free fatty acids and causing a reduction in glucose uptake by normal myocytes [32]. Stress testing and exercise should be avoided on the day of scanning, as this may enhance physiological myocardial glucose metabolism [20] (Table 10.2).

10.4.4 Myocardial Inflammation PET Imaging Protocol

The myocardial inflammation FDG PET protocol involves cardiac image acquisition 60–90 min following intravenous injection of 2.5–5 MBq/kg of FDG [20]. The patient should continue to fast and not be physically active between tracer injection and PET image acquisition to minimize physiological myocardial FDG uptake. In addition to cardiac imaging, whole body imaging from the base of skull to mid-thighs is recommended to allow the assessment of extra-cardiac sites of disease, such as lungs, liver, spleen, lymph nodes, and bones. The cardiac and whole body FDG PET images should be reconstructed with and without attenuation correction.

It is recommended that patients undergoing FDG PET for myocardial inflammation should also have rest perfusion imaging assessment performed with either SPECT or PET myocardial perfusion imaging (MPI) using either ^{99m}Tc , ^{13}N -ammonia or ^{82}Rb based radiotracers, depending on local availability and expertise. Whenever possible, attenuation correction should be used with SPECT MPI. Interpretation of perfusion imaging is performed in concert with the FDG imaging, and helps differentiate areas of scar/active inflammation from normal myocardium [34].

10.4.5 PET Image Interpretation

Interpretation of FDG PET images for myocardial inflammation is challenging, and requires an understanding of patient preparation and metabolic state required to reliably distinguish CS related myocardial inflammation from physiological myocardial glucose uptake. The FDG and rest MPI scans are usually displayed side by side with the image intensity normalized to the maximum counts per pixel of each data set. A combination of dedicated cardiac imaging plane (short-axis, horizontal and vertical long axis) and standard orthogonal plane (axial, coronal, and sagittal) nuclear medicine whole body PET images are typically reviewed.

There are four patterns of LV myocardial FDG uptake that should be looked for on the cardiac FDG PET images [20, 35]:

1. “None”—no myocardial FDG uptake
2. “Diffuse”—diffuse myocardial FDG uptake
3. “Focal”—focal area(s) of increased myocardial FDG uptake
4. “Focal-on-diffuse”—focal area(s) of increased FDG uptake on a background of diffuse myocardial FDG uptake.

The “focal” or “focal-on-diffuse” patterns of myocardial FDG uptake are considered abnormal, and are likely to be consistent with CS, with the foci of increased FDG uptake felt to represent areas of myocardium infiltrated with active inflammatory sarcoid granulomas. The normal pattern of myocardial FDG uptake for an adequately prepared patient is to have no myocardial FDG uptake, with the LV blood pool demonstrating higher activity than myocardium. Diffuse, homogenous low-grade FDG uptake throughout the lateral wall is also considered to represent a physiological pattern, particularly in the absence of any superimposed focal areas of increased FDG uptake or resting perfusion defects on MPI [35]. The “diffuse” pattern of myocardial FDG uptake is the most challenging to interpret as it can be non-specific due to poor/lack of suppression of normal myocardial glucose uptake, or it may represent extensive, diffuse sarcoid granulomatous infiltration with heterogeneous FDG uptake. It is also important to evaluate PET images for any evidence of focal right ventricular FDG uptake, which appears to be an adverse prognostic feature in CS [36].

The whole body FDG PET/CT images are reviewed to assess for sites of extra-cardiac sarcoidosis [37]. This can be particularly useful in finding a suitable extra-cardiac site to biopsy to confirm sarcoid diagnosis; common sites of extra-cardiac disease include mediastinal and hilar lymph nodes, pulmonary, liver, splenic, and osseous sites of disease. For patients with implanted cardiac devices in situ, the non-attenuation corrected FDG PET images should be reviewed to avoid reporting of any false-positive lead/device FDG uptake caused by attenuation correction artefact [38].

Combined assessment of FDG and MPI images is recommended to provide additional information about the status of CS (scar versus inflammation) if present, and the extent of myocardial involvement. The rest MPI images are examined for

Fig. 10.1 Images from a patient with newly diagnosed cardiac sarcoidosis. Myocardial perfusion images (N-13 ammonia PET) and FDG images are shown in alternate rows. There is a small perfusion defect of moderate intensity in the basal anterolateral wall (best seen on the short-axis images). There are multiple foci of increased FDG uptake in the left ventricular (septum, and anterolateral and inferolateral segments) and right ventricular (free wall) walls. Partial body FDG images are shown below. Red asterisks indicate focus of fibrosis and inflammation in the left ventricular anterolateral wall and the septum. Green arrows indicated focus of inflammation in the right ventricular free wall. *FDG* ^{18}F -fluorodeoxyglucose

perfusion defects, and are best reviewed at the same time as the cardiac FDG PET (Fig. 10.1). CS perfusion defects on MPI may be present in active inflammatory lesions due to alteration in the coronary microcirculation, and in the chronic phase due to the presence of replacement fibrosis. The rest MPI images are very useful in individuals with a diffuse pattern of cardiac FDG uptake, as patients with diffuse cardiac sarcoid infiltration are unlikely to have a completely normal rest perfusion study. Unlike perfusion defects due to coronary artery disease, the perfusion abnormalities in CS do not match with a typical coronary artery territory.

The following CS FDG and MPI patterns, although not verified pathologically, have been described [36, 39]:

- “early”-mildly FDG positive, normal MPI;
- “progressive inflammatory”-FDG positive with small perfusion defects on MPI;
- “peak active”-high SUV FDG uptake with moderate sized perfusion defects on MPI;

- “progressive myocardial impairment”—high SUV FDG uptake with large perfusion defects on MPI;
- “fibrosis-predominant”—FDG negative with perfusion defects on MPI.

In line with Scadding system for staging pulmonary sarcoid, the following staging system for CS has also been proposed [20, 40]:

- Stage 0 = Normal FDG, normal MPI
- Stage 1 = FDG positive, normal MPI
- Stage 2 = FDG positive with perfusion defects on MPI in the same myocardial segments
- Stage 3 = FDG positive with perfusion defects in different myocardial segments on MPI
- Stage 4 = normal FDG but perfusion defects on MPI.

10.4.6 Pitfalls in FDG Image Interpretation

There are potential pitfalls in image interpretation of myocardial inflammation FDG PET that imagers should be aware of. Firstly, the use of conventional nuclear cardiology schemes to display the cardiac FDG PET images normalize the image intensity range to the most intense pixel within the sampled volume. This may falsely elevate the displayed FDG uptake, particularly when the myocardial uptake is only marginally above that of blood pool. The normalized display systems also may impair judgment of the absolute intensity of myocardial FDG uptake, which may be problematic when assessing for treatment response in follow-up studies. To overcome these difficulties, the cardiac FDG PET images should be reviewed on traditional nuclear medicine PET display systems in addition to the normalized nuclear cardiology display schemes [34].

Unfortunately, despite a better understanding of patient preparation, approximately 10–15% of myocardial inflammation FDG PET scans remain non-diagnostic due to incomplete suppression of physiological myocardial glucose uptake, even with strict adherence to the aforementioned patient preparation protocols (Fig. 10.2) [41]. This appears to especially be the case in the failing heart which can cause glucose upregulation as an adaptive mechanism, hindering conversion to free fatty acid metabolism [42]. It is also important to exclude underlying significant epicardial coronary artery disease, as the pattern of mismatched perfusion defect with increased FDG uptake may be seen hibernating ischemic myocardium as well as in myocardial inflammation. FDG is a non-specific tracer, and there are other conditions that may mimic the focal pattern of increased myocardial FDG uptake seen with CS, including other causes of myocardial inflammation such as giant cell myocarditis, other cardiomyopathies (particularly arrhythmogenic and dilated cardiomyopathies), and benign (myxomas and hemangiomas) and malignant (particularly lymphoma and metastases) cardiac tumors [42, 43]. The risk of solid and hematopoietic malignancies is increased in patients with systemic sarcoidosis [43]; hence,

Fig. 10.2 Limited dietary preparation for FDG PET (a) which improved on repeat imaging (b). An example of perfusion and FDG images showing diffuse FDG uptake in normally perfused segments suggesting incomplete suppression of physiological uptake (a) Repeat images after 3 months (b) using a more stringent carbohydrate restriction and increase intake of high fat diet followed by 12 h fast prior to FDG imaging demonstrated better suppression of physiological myocardial glucose uptake. *FDG* ^{18}F -fluorodeoxyglucose

a careful review of the particle body images for identification of malignancy is particularly important. If there is concern for cardiac malignancy, examination of the partial body PET images for evidence of extra-cardiac malignancy is useful, along with obtaining other cardiac imaging modalities. CMR is particularly useful in the assessment of potential cardiac masses owing to its excellent soft tissue resolution and tissue characterization capabilities [44].

10.4.7 Hybrid Imaging

The benefits of hybrid imaging in myocardial FDG PET, paired with either CT or MRI are manifest. Hybrid FDG PET/CT is currently the standard of care for myocardial inflammation assessment using molecular imaging. Aside from providing attenuation correction for the myocardial FDG PET dataset, the low dose CT component also helps with anatomical localization when viewed alongside the PET images on a hybrid nuclear medicine display system. Accurately localizing cardiac FDG uptake using the PET images alone can be challenging, particularly when there is suppression of physiological cardiac FDG uptake. Interpretation alongside the CT images allows for more accurate localization of myocardial FDG activity, for example, distinguishing papillary muscle from adjacent LV myocardium. The CT component of the PET/CT examination is also crucial in the evaluation, providing more accurate anatomical localization of any abnormal site of FDG uptake, including atrial and right ventricular uptake and in distinguishing myocardial uptake from mediastinal lymph node uptake.

The CT images may also demonstrate changes typical of sarcoidosis, such as mediastinal lymphadenopathy with amorphous central calcification, pulmonary micronodules in a perilymphatic distribution, and upper lobe predominant perihilar fibronodular pulmonary opacification with traction bronchiectasis in more advanced cases [21].

Novel integrated hybrid PET/MRI systems have the potential to marry the superior soft tissue resolution and multiparametric capabilities of MRI with the metabolic information provided by FDG PET in a single examination. Hybrid cardiac FDG PET/MRI combines the comprehensive evaluation of cardiac function, morphology and tissue characterization provided by CMR with the metabolic information provided by FDG PET. Initial series suggest that integrated FDG PET/MRI appears feasible in the evaluation of suspected cardiac sarcoidosis [45–47]. Whole body PET/MRI images should also be acquired akin to the FDG PET/CT protocol, with the caveat that MRI is inferior to CT in evaluation of the pulmonary parenchyma due to its inferior spatial resolution [48]. Recent advances in PET/MRI technology, particularly the development of new, free breathing ultrashort echo time MRI sequences greatly improves the quality of pulmonary imaging by MRI over traditional dual echo gradient echo imaging [49], and would be helpful in the evaluation of suspected pulmonary sarcoid. Integrated PET/MRI is an exciting new imaging modality with the potential to provide a comprehensive “one-stop shop” imaging test for cardiac inflammation evaluation, but its roll out will be limited by the large cost relative lack of availability of this new imaging modality, and unclear benefit when compared to sequential PET and MR imaging.

10.5 Role of Imaging

10.5.1 Cardiac Sarcoid Diagnosis

Early diagnosis of cardiac sarcoid infiltration is important, as studies suggest that steroid immunosuppressive therapy should be initiated before the onset of significant left ventricular dysfunction [8, 50]. As previously described, FDG PET and CMR playing a key role in CS diagnosis. Evaluating their diagnostic performance in CS can be difficult due to the lack of definite gold standard; histopathological assessment is generally the ideal reference standard for any imaging study examining diagnostic performance, but as aforementioned endomyocardial biopsy is poorly sensitive in CS due to its focal nature [15], and is thus seldom used as the gold standard in the literature. As a result, clinical scoring systems that incorporating clinical and radiological features are often used to establish the diagnosis of CS, such as the Japanese Ministry of Health and Welfare (JMHW) criteria [25] and the Heart Rhythm Society (HRS) consensus document [26].

FDG PET/CT has a reported sensitivity and specificity of 0.89 and 0.78 respectively for the diagnosis of CS according to an initial meta-analysis published in 2012 of seven studies with incorporating 164 patients, with an overall disease prevalence of 50% in the cohort [51]. A more recent meta-analysis including 17 studies with 891 patients reports a pooled sensitivity of 0.84 and specificity of 0.83 for CS

diagnosis by FDG PET [52]. One of the problems in these FDG PET meta-analyses is the heterogeneity in the dietary and patient preparation used in the included studies, which is a potential significant confounder. Tang et al. [53] attempted to adjust for patient preparation in their 2016 systematic review and meta-analysis of 16 studies encompassing 559 patients; the authors found that FDG PET had an overall sensitivity and specificity of 0.75 and 0.81 respectively for CS diagnosis amongst the entire cohort, improving to a sensitivity and specificity of 0.88 and 0.84 on a subgroup analysis of studies that employed a prolonged >12 h fast as patient preparation.

CMR usually relies on the presence of a non-infarct pattern of LGE (typically subepicardial/mesocardial), with or without the presence of myocardial edema on T2 weighted imaging to suggest a diagnosis of CS. These changes typically affect the basal septum and lateral wall. A recent meta-analysis incorporating eight studies with 649 participants reported a sensitivity and specificity of 0.93 and 0.85 respectively for CS diagnosis using CMR [54]. The studies included in this meta-analysis have sensitivities ranging from 0.75 to 1 and specificities ranging from 0.68 to 1; this significant heterogeneity is likely due to the variation in reference standards used.

Isolated cardiac sarcoid is a well-described clinical entity, estimated to account for approximately 25% of CS cases [55]. Patients with isolated CS have worse LV systolic function at presentation compared with patients with systemic sarcoidosis [36]. Making a definite diagnosis of isolated CS is particularly challenging due to the poor sensitivity of endomyocardial biopsy, and the requirement for tissue confirmation of extra-cardiac sarcoid in the clinical criteria [41]. This difficulty in “confirming” a diagnosis of CS without recourse to reliable histological sampling is underlined by a recent series examining the hearts of 18 patients who underwent cardiac transplantation and had a pre-transplant FDG PET/CT; using a “probable” cutoff for FDG PET resulted in a sensitivity of 1.0, but a specificity of only 0.33, with 3 out of the 9 probable CS cases by FDG PET found to be cases of arrhythmogenic cardiomyopathy on histological examination of the explant [56].

There is a growing body of evidence that FDG PET and CMR play a complementary role in the diagnosis of CS, increasing diagnostic certainty in this difficult to diagnose condition. CMR and FDG PET will often show different patterns of disease in patients with CS due to differences in their technique. The added benefit of performing an FDG PET after a “positive” CMR for CS is to increase diagnostic certainty and also to provide an assessment of the burden of metabolically active disease that can be helpful to follow response to therapy (Fig. 10.3). A CMR after a “positive” FDG PET can help quantify left ventricular ejection fraction and identify patients who may benefit from an ICD (Class I indications: sustained ventricular tachycardia or cardiac arrest, left ventricular ejection fraction $\leq 35\%$; Class IIa indications: LVEF $> 35\%$ with syncope, or scar by CMR or PET, or inducible ventricular tachyarrhythmia, or any indication for pacing) [10]. Vita et al. [57] categorized the likelihood of active CS in 107 patients based on CMR and FDG PET/CT scans as (a) no ($<10\%$); (b) possible (10–50%); (c) probable (50–90%); and (d) highly probable ($>90\%$). Among the 85% of patients with evidence of non-infarct pattern

Fig. 10.3 Correlation of FDG PET and CMR-LGE. The foci of increased FDG uptake on the cardiac PET images co-localized accurately with regions of late gadolinium enhancement (LGE) on CMR images (from patient from Fig. 10.1). (a) short axis CMR; (b) 4 chamber view on CMR; (c) short axis FDG images; and (d) transaxial FDG images. Red asterisks indicate focus of fibrosis and inflammation in the left ventricular anterolateral wall and the septum. Green arrows indicated focus of inflammation in the right ventricular free wall. *FDG* ^{18}F -fluorodeoxyglucose

LGE on CMR, 66% had increased myocardial FDG uptake on FDG PET, re-enforcing the assertion that the presence of LGE alone cannot be reliably used to diagnose active inflammatory type CS. When the PET findings were added to the CMR results, the authors found that the likelihood of active CS was re-classified in 45% of cases. As expected, the advent of hybrid PET/MRI is of significant interest as a potential single test for CS [45, 46]. Wicks et al. [47] evaluated 51 patients with suspected CS with a simultaneous hybrid FDG PET/MRI protocol, and found it superior for CS diagnosis compared to either PET or CMR alone. These hybrid systems do however remain limited in availability due to cost, and the majority of combined CMR/FDG PET assessments will be performed on stand-alone PET/CT and MRI scanners for the foreseeable future.

The proposed algorithm for the combined CMR and FDG PET/CT assessment of suspected CS is to begin with CMR to determine the likelihood of CS and to evaluate for potential alternative diagnoses [57]. Patients with a CMR that is negative for CS do not need undergo FDG PET/CT scanning unless there is a persistent high clinical suspicion for CS. Individuals with a CMR that is either inconclusive or

positive for CS should proceed to FDG PET/CT to determine the likelihood of CS when uncertainty exists, to evaluate for the presence of active inflammatory disease, and to identify potential extra-cardiac sites for biopsy, if required [41].

10.5.2 Prognosis

Cardiac involvement in sarcoidosis is associated with poorer prognosis, which can be related to worsening heart failure and potentially fatal cardiac arrhythmias [1]. Blankstein et al. [36] assessed outcomes in 118 patients who underwent both MPI and FDG PET/CT for suspected CS, finding that the presence of both a perfusion defect and a pathological pattern of myocardial FDG uptake was associated with an increased risk of death or ventricular tachycardia, after adjusting for ejection fraction (Fig. 10.4). In particular, patients with evidence of right ventricular inflammation had a fivefold increased event rate compared to normal controls. In their hybrid FDG PET/MRI study on 51 patients with suspected CS, Wicks et al. [47] demonstrated that right ventricular uptake on PET was an independent predictor of adverse cardiac events, along with the presence of LGE on CMR. The presence of LGE has

Fig. 10.4 Prognostic value of FDG and myocardial perfusion imaging. In a study of 14 subjects, Blankstein et al. [36] showed that patients with both normal perfusion and no myocardial ^{18}F -FDG uptake (green line) showed the best event free survival (survival free of ventricular arrhythmias), while those with both abnormal perfusion and abnormal ^{18}F -FDG uptake (red line) showed the worst event free survival. *FDG* ^{18}F -fluorodeoxyglucose. (Figure reproduced with permission from Blankstein et al. [36])

been demonstrated as the most prognostic CMR feature of CS—one meta-analysis of ten studies including 760 patients with known or suspected CS undergoing CMR found that individuals with LGE had higher all-cause mortality and major arrhythmogenic events [58]. This confirmed the findings on an earlier meta-analysis of seven studies of 694 patients by Hulten et al. [59].

10.5.3 Response Assessment

FDG PET has unique ability to assess the metabolic response to anti-inflammatory therapy in CS, which can improve outcomes (Figs. 10.5 and 10.6) [60]. CMR is often limited in these circumstances due to the inability to detect changes in LGE and due to the frequent implantation of cardiac pacemakers or defibrillators for heart block, ventricular tachyarrhythmias or for secondary prevention of cardiac arrest. In a small cohort of 23 patients with CS who underwent serial FDG PET/CT imaging post steroid therapy, a reduction in myocardial SUV_{max} on the post treatment PET demonstrated a significant relationship with improvement in LV ejection fraction [61]. Measuring serial myocardial SUV_{max} is straightforward to perform, but comes with the caveat that assigning strict SUV_{max} cutoff values to determine response or progression be problematic due to the myriad of factors that can affect its readings other than lesional metabolic activity, including blood glucose levels, radiotracer uptake time, scanner type, and PET reconstruction algorithm [31]. Other PET metrics such as SUV_{mean} and measurement of the volume of metabolically active myocardium have also shown efficacy in CS treatment response studies [62, 63]. Persistent and increased myocardial FDG PET positivity after steroid treatment is associated with poor clinical outcomes, may help to predict steroid-resistant CS, and indicate which patients require escalation of immunosuppressive therapy [64]. It is not clear whether performing a qualitative visual assessment of FDG uptake suffices for treatment response assessment or whether semi-quantitative measurements, such as myocardial SUV_{max} , should also be used [65], and further studies will be required to determine the optimum approach to treatment response assessment.

Fig. 10.5 Quantitation of volume of inflamed myocardium. Relative FDG imaging is not adequate for evaluation of response to therapy. For this reason, quantitation of FDG uptake using standardized uptake values (SUV) or volume of inflamed myocardium is important. The volume of inflamed myocardium on the cardiac FDG images of the patient from Fig. 10.1, using an SUV_{max} threshold of 2.7 as 138 cm^3 . *FDG* ^{18}F -fluorodeoxyglucose

Fig. 10.6 Evaluation of response to therapy. Repeat imaging of the patient from Fig. 10.1, after 6 months of high dose oral steroid showed near complete resolution of inflammation on FDG images (cardiac and partial body images show blood pool activity without focal myocardial uptake) with a small persistent region of fibrosis in the basal anterolateral wall (perfusion defect on the basal anterolateral wall). Quantitatively, there was no detectable inflamed myocardium (no pixels with $SUV > 2.7$). *FDG* ^{18}F -fluorodeoxyglucose

10.6 Guidelines

Due to the difficulties in obtaining tissue confirmation in cases of suspected cardiac sarcoidosis, clinical scoring systems are often used to establish the diagnosis of CS, such as from the as the Japanese Ministry of Health and Welfare (JMHW) criteria [25] and Heart Rhythm Society (HRS) consensus document [26]. In addition, there is a joint procedural statement on CS imaging issued by the European Association of Nuclear Medicine (EANM), European Association of Cardiovascular imaging (EACVI) and American Society of Nuclear Cardiology (ASNC) [20], and a joint consensus document on the role of FDG PET/CT in CS diagnosis and management issued by the Society of Nuclear Medicine and Molecular Imaging (SNMMI) and ASNC [66].

The JMHW criteria are the longest established, and are commonly used as the reference standard for CS diagnosis in imaging research studies. The most recent iteration of these criteria provides guidance on how a clinical diagnosis of CS can be made in the absence of positive myocardial histology; this requires a positive extra-cardiac biopsy for epithelioid granulomas along with a combination of electrophysiological/ECG (high grade AV block, ventricular tachycardia/fibrillation), functional (LVEF $< 50\%$), morphological (basal septal thinning of ventricular aneurysms), and typical imaging features (increased cardiac uptake on FDG PET/ ^{67}Ga

citrate scintigraphy or non-infarct pattern LGE on CMR) suggestive of CS (see Table 10.3) [25]. The updated guidelines also include a provision for diagnosing isolated cardiac sarcoidosis for patients without evidence of extra-cardiac disease, provided they demonstrate increased myocardial uptake on FDG PET/⁶⁷Ga citrate scintigraphy along with further ECG, functional and morphological features as described above. The HRS criteria are broadly similar, providing a pathway to make a clinical diagnosis of CS once there is a histological diagnosis of extra-cardiac sarcoidosis along with one of a number of clinical, ECG or imaging features, with the latter including patchy cardiac uptake on FDG PET and non-infarct pattern LGE on CMR (see Table 10.3) [26]. The HRS criteria do not allow for a diagnosis of isolated CS, with the HRS recommending endomyocardial biopsy in cases of suspected isolated CS or negative extra-cardiac biopsy.

The joint expert consensus document issued by SNMMI and ASNC provides guidance on the role of FDG PET/CT in CS diagnosis and monitoring [66]. This document identifies the following clinical scenarios in which FDG cardiac PET may be useful for patients with known or suspected CS:

- Patients with histological evidence of extra-cardiac sarcoidosis and abnormal screening for CS (using a combination of ECG, echocardiography, and CMR features)
- Patients under 60 with unexplained new significant conduction system disease
- Patients with idiopathic sustained VT
- Patients with proven CS as a disease response assessment.

This EANM/EACVI/ASNC joint procedural statement covers the role of multi-modality imaging in the diagnosis and monitoring of CS [20]. They propose that CMR should be the first advanced cardiac imaging test for individuals with suspected CS, with FDG PET/CT scanning recommended for patients with abnormal or equivocal CMRs, or as the initial test for patients in whom an MRI is contraindicated (for example patients with a non-MRI conditional implantable cardiac device, severe claustrophobia or severe renal dysfunction precluding gadolinium administration). This multi-society joint statement also recommends that FDG PET with SUV_{max} quantification be used to monitor response to therapy.

10.7 Future Directions for Myocardial Inflammation PET

The future of myocardial inflammation hybrid imaging relies on the development of radioisotopes that are more specific to areas of myocardial inflammation, preferably without physiological cardiovascular avidity. Gallium⁶⁸ linked somatostatin receptor PET radiotracers such as ⁶⁸Ga-DOTA-NaI-octreotide (DOTANOC), ⁶⁸Ga-DOTA-D-Phe-Tyr-octreotide (DOTATOC), and ⁶⁸Ga-DOTA-D-Phe-Tyr-octreotate (DOTATATE) are potentially useful tracers for cardiac sarcoidosis. These radiotracers are primarily used for the diagnosis and staging of neuroendocrine tumors, which abundantly express somatostatin receptors (SSTR) [67]. Activated inflammatory cells found in sarcoid granulomas such as macrophages, epithelioid cells, and multinucleated giant cells have abundant SSTRs on their cell surface, in particular SSTR2A, which is not expressed on normal cardiomyocytes [68]. Exploratory studies have demonstrated that cardiac sarcoid lesions demonstrate increased uptake on PET with ⁶⁸Ga-SSTR targeted radiotracer [69–71]. These radiotracers have a beneficial lack of cardiac uptake under physiological conditions, which is potentially advantageous both in CS lesion detection, and in avoiding the complex dietary preparation required for successful myocardial inflammation FDG PET. An initial pilot study comparing FDG and ⁶⁸Ga-DOTATE PET suggest that FDG may be more sensitive for the detection of cardiac inflammation, while ⁶⁸Ga-SSTR targeted radiotracers may detect more active extra-cardiac disease [72]. These early studies, however, should be interpreted with caution and regarded as preliminary pending larger studies, including treatment response assessment.

3'-Deoxy-3'-¹⁸F-fluorothymidine (FLT) is a promising PET tracer for the evaluation of cell proliferation, accumulating in cells with high-turnover, such as granulomatous inflammatory cells [73]. FLT has an advantageous biodistribution for cardiac imaging with a lack of physiological myocyte uptake, and requires neither

prolonged diet nor a special diet prior to scanning. Experimental data has shown that FLT can detect sites of cardiac and extra-cardiac involvement in sarcoidosis [73]. Further clinical studies will be required, however, to evaluate the novel use of these agents in myocardial inflammation imaging before they can translate to clinical practice and supplant FDG.

10.8 Conclusions

Sarcoidosis is a complex, disease that often requires a multi-disciplinary approach for optimum management. A multimodality imaging approach is optimal in the evaluation of patients with suspected cardiac involvement, and hybrid FDG PET/CT plays an important role in both diagnosis and treatment response assessment.

Novel SPECT and PET Tracers and Myocardial Imaging

11

Inga Melvinsdottir, Ricardo Avendaño,
and Albert J. Sinusas

11.1 Overview

Hybrid multimodality cardiovascular imaging is routinely used to assess cardiac function, structure, and physiological parameters to facilitate the diagnosis and evaluation of myocardial diseases, along with risk stratification, and directing and monitoring therapy. There is now a focus on developing multimodality imaging strategies to assess the underlying cellular and molecular processes that underlie and/or participate in modulating the structural and pathophysiological changes in the heart. While there has been a critical advancement in hybrid imaging technology, there also needed to be a parallel development of imaging probes for improved evaluation of these physiological and molecular changes. The most widely used approaches for molecular imaging include radiotracers that allow for high-sensitivity in vivo detection and quantification of molecular processes with single photon emission computed tomography (SPECT) and positron emission tomography (PET) [1]. While SPECT and PET imaging provide high sensitivity for detection and

quantitative assessment of molecular and physiological processes, they suffer from limited resolution. Therefore, these radiotracer-based imaging approaches have been integrated with high resolution anatomical imaging to provide anatomic colocalization and improved quantification. This chapter will review the development of novel radiolabeled probe for both SPECT and PET imaging of myocardial flow and evaluation of critical molecular processes in the myocardium; including: inflammation, cell death, autonomic regulation, angiogenesis, and myocardial remodeling. This chapter will also introduce the use of reporter probe technology and novel theranostics.

11.2 Physiological Imaging

11.2.1 Myocardial Perfusion Imaging

Myocardial perfusion imaging is an important tool to diagnose, risk stratify, and guide interventions for coronary artery disease. Over the past few decades myocardial perfusion imaging has evolved exponentially and continues to improve with better image quality, lower scan time, and reduced radiation [2]. This has in part been partly facilitated by the introduction of hybrid imaging technology that has allowed for CT based attenuation correction (Fig. 11.1).

11.2.1.1 SPECT Perfusion Imaging

The ideal myocardial perfusion agent should have linear relationship between myocardial uptake and blood flow, low extracardial uptake, minimal myocardial redistribution, and high first pass extraction. Thallium-201 (^{201}Tl) was developed in the 1970s and has been extensively used for evaluation of myocardial perfusion [3]. It is still considered to be the gold standard for evaluation for viability assessment of the myocardium among SPECT agents [4]. However, ^{201}Tl has a long half-life (72 h) so the dose must be kept low (ideally <2 mCi) to minimize radiation, and in addition, ^{201}Tl has a low photon energy which results in more scatter and soft tissue attenuation artifact [5]. Therefore, the use of high-sensitivity imaging systems are critical for ^{201}Tl imaging along with the use of CT imaging for attenuation correction.

Technetium-99m ($^{99\text{m}}\text{Tc}$) based radiotracers have been around since the 1990s and been widely used in the clinical setting, with $^{99\text{m}}\text{Tc}$ -sestamibi and $^{99\text{m}}\text{Tc}$ -tetrofosmin used predominantly. Despite their widespread use they do not demonstrate linear myocardial extraction at high flow rates and have high hepatic uptake, which can interfere with interpretation of defects in the inferior wall [6, 7]. $^{99\text{m}}\text{Tc}$ -teboroxime is another FDA approved SPECT radiotracer for myocardial perfusion imaging. However, this agent never gained popularity in clinical use, mainly because of high initial extracardiac uptake and very rapid washout. This results in a technical challenge in performing the myocardial imaging, since the image acquisition must be performed within 2 min of injection [8].

Several other $^{99\text{m}}\text{Tc}$ based radiotracers are currently under investigation and show promising potential. Research efforts have been focused on to improve

Fig. 11.1 Mechanisms of action of commercially available myocardial perfusion radiotracers in cardiac myocytes. (Reprinted from Sogbein et al. Biomed Res Int 2014)

heart-to-background ratios, specifically heart-to-liver ratio. A few of these agents are mentioned below, although the list is not exhaustive. The ^{99m}Tc-nitrido complex (DBODC5) has high cardiac uptake and shows improved heart/liver ratio compared to ^{99m}Tc-sestamibi in animal studies due to rapid hepatic clearance. In humans, the sensitivity appeared to be similar compared to ^{99m}Tc-sestamibi with possibly improved specificity when evaluating for coronary artery disease. However, this agent needs further verification [9]. ^{99m}TcN-MPO has been tested in rodents and show promising heart-liver ratio due to rapid hepatic excretion but has yet to be tested on humans [10]. ^{99m}Tc-TMEOP showed faster liver washout and similar cardiac uptake in rodents [11].

Mitochondrial complex-1 inhibitors show great promise for cardiac imaging as mitochondria are very abundant in cardiomyocytes. A novel iodine-123 labeled

derivative of rotenone, a MC-1 inhibitor, has been tested in rodents and has shown uniform myocardial distribution and very little extracardiac activity. Cardiac uptake tracked more linearly with increased blood flow with this agent compared to standard SPECT tracers in animal studies [12, 13].

11.2.1.2 PET Perfusion Imaging

PET imaging has gained more popularity for evaluation myocardial perfusion in recent years. This is partly due to increased availability of hybrid PET/CT scanners, development of new radiotracers and post-imaging hardware and software [14]. The most common radiotracers used for myocardial perfusion for PET imaging are Rubidium-82 (^{82}Rb), N-13 Ammonia ($^{13}\text{NH}_3$), and oxygen-15 water ($\text{H}_2\ ^{15}\text{O}$) (Fig. 11.2). Theoretically, the most ideal PET radiotracer for myocardial perfusion is $\text{H}_2\ ^{15}\text{O}$ as it has a complete extraction in the myocardium independent of flow rate and metabolic rate. Therefore, uptake was proportional to flow even at high flows. However, it freely crosses the myocyte membrane and quickly reaches equilibrium between blood and tissues without accumulation in the myocardium [15]. Thus, the images are of poor quality and have limited diagnostic value, requiring dynamic imaging and kinetic modeling for estimation of flow. ^{82}Rb and $^{13}\text{NH}_3$ are well established radiotracers used clinically to assess myocardial perfusion in PET imaging and often have improved sensitivity in diagnosing clinically significant coronary artery disease compared to available SPECT imaging agents [16, 17].

^{82}Rb is actively transferred to the myocardium via the Na/K ATP transporter rapidly and remains in the myocardium. However, the half-life of ^{82}Rb is very short (76 s) allowing only a few minutes for acquisition before the tracer has decayed to background level [18]. This radiotracer requires pharmacological stress test and

Fig. 11.2 Images of digital cardio-torso phantom in simulated short-axis view using different PET radioisotopes. Blurring effect by positron range increases with higher positron kinetic energy. (Image reprinted with permission from Rischpler et al., *Ann Nucl Med* 2012)

cannot be used for exercise testing. Despite this limitation, ^{82}Rb PET scan has shown superiority in diagnostic accuracy and specificity in diagnosing obstructive coronary disease compared to SPECT, specifically in extremely obese population [16, 19]. The principal benefit of this radiotracer is that no access to a cyclotron is needed, since it can be produced next to the scanner using commercially available portable elution generators.

$^{13}\text{NH}_3$ is metabolically trapped in the myocardium within the glutamine pool within the myocardial cells with both active transport and passive diffusion [20]. $^{13}\text{NH}_3$ has a longer half-life than ^{82}Rb (9.96 min) and thus exercise stress test is possible, however, an on-site cyclotron is needed for this tracer which can be costly. $^{13}\text{NH}_3$ is a good radiotracer for quantitative assessment of myocardial perfusion and provides excellent image quality. This is due to high myocardial extraction fraction (above 80%), chemical trapping of the tracer in the myocardium, and relatively long half-life of the isotope [21, 22]. $^{13}\text{NH}_3$ provides high diagnosis accuracy for obstructive coronary artery disease in men, women and obese patients [23].

Fluorine-18 (^{18}F) flurpiridaz is a PET radiotracer that is currently undergoing phase 3 clinical trials to gain FDA approval for assessment of myocardial perfusion (Fig. 11.3) [24]. ^{18}F -flurpiridaz (previously named BMS-747158-02) binds to mitochondrial complex-1 with a rapid uptake in the cardiomyocytes and slow washout [25]. This tracer has a longer half-life than ^{82}Rb and $^{13}\text{NH}_3$ (109 min) and can make use of a regional cyclotron rather than requiring an on-site cyclotron like $^{13}\text{NH}_3$.

Fig. 11.3 $^{99\text{m}}\text{Tc}$ -tetrofosmin SPECT (a, b) and ^{18}F -flurpiridaz PET/CT (c, d) images in 65-year-old male with history of diabetes, hyperlipidemia, hypertension, and family history of coronary artery disease who presents for evaluation of dyspnea on exertion. SPECT images (a) and bullseye maps (b) were considered abnormal with a small to medium sized, mild intensity reversible perfusion defect in the inferolateral wall consistent with ischemia. The hybrid ^{18}F -flurpiridaz PET/CT images (c, d) appear normal. A cardiac catheterization revealed noncritical coronary artery disease and normal resting left ventricular end-diastolic pressure. This patient example illustrates improved specificity with ^{18}F -flurpiridaz PET/CT

Therefore, ^{18}F -flurpiridaz may be more cost effective and could allow for cardiac PET imaging at any location with access to a PET scanner, even for low volume imaging sites. The longer half-life permits exercise stress testing, although may necessitate longer imaging protocols and may be associated with higher radiation exposure. Compared to both $^{13}\text{NH}_3$ and ^{82}Rb , ^{18}F -flurpiridaz provide improved spatial resolution due to a shorter positron range [26]. ^{18}F -flurpiridaz also has a high first pass extraction, and therefore allows for very accurate assessment of quantitative flows with use of dynamic imaging and kinetic modeling.

^{18}F -labeled rhodamines have been developed for myocardial perfusion imaging as rhodamine can accumulate in the mitochondria. Several rhodamine cores have been ^{18}F labeled and assessed for cardiac imaging using hybrid PET/CT imaging. ^{18}F -6G-rhodamine showed very promising results in initial rat studies with favorable myocardial uptake and low hepatic uptake due to the lipophilic characteristic of the compound in rats [27, 28]. Recent porcine studies have demonstrated that ^{18}F -6G-rhodamine has a high first pass extraction with limited flow dependence of the extraction over a wide physiological range of flows [29]. ^{18}F -labeled fluoro-alkyl-phosphonium cations such as ^{18}F -Fluorobenzyl Triphenyl Phosphonium (^{18}F -FBnTP), (4- ^{18}F -Fluorophenyl)triphenylphosphonium (^{18}F -FTTP), (6- ^{18}F -fluorohexyl)triphenylphosphonium (^{18}F -FHTP), (2-(2- ^{18}F -fluoroethoxy) ethyl) tris(4-methoxyphenyl) phosphonium (^{18}F -FETMP), and 1-halomethyl- ^{18}F -fluoromethylbenzenes (^{18}F -FMBTP) have shown encouraging properties in preclinical studies, but no human trials are available [30]. When compared to ^{13}N - NH_3 in rat models of coronary occlusion ^{18}F -labeled fluoro-alkyl-phosphonium cations showed rapid hepatic and pulmonary clearance which lead to excellent image quality [31]. When compared to $^{99\text{m}}\text{Tc}$ -tetrofosmin for assessment of myocardial perfusion in dogs with varying stenosis of coronary arteries ^{18}F -FBnTP showed superior diagnostic performance, specifically in mild or severe stenosis [32].

Copper labeled PET agents have been used in the research setting in the past three decades for assessment of myocardial perfusion but have never been approved for clinical use. ^{62}Cu -PTSM is metabolically trapped in the mitochondria and thus was thought to be attractive agent for myocardial perfusion assessment. However, high liver uptake compromises inferior wall assessment and due to binding to albumin the uptake of this radiotracer in the myocardium was reduced [33].

Among the new ^{18}F -labeled PET imaging agents, ^{18}F -flurpiridaz remains the most promising myocardial perfusion agent, since the initial Phase III clinical trials with ^{18}F -flurpiridaz have shown favorable results (Table 11.1).

11.3 Targeted Molecular Imaging

There are a wide range of new molecular targeted imaging agents for both SPECT and PET imaging. Many of these agents target important molecular processes involved with cardiovascular disease including; inflammation, cell death, autonomic regulation, angiogenesis, and myocardial remodeling. These agents often result in “hot spot” images of the heart that are difficult to reconstruct or interpret without

11.3.1 Inflammation

Myocardial inflammation is a complex process that involves multiple cells, signaling proteins, and receptor–ligand interactions that are directed at repair and removal of damaging or harmful substances. Inflammation also involves a complex cascade of events that include the myocardial cells, the extracellular matrix, cells from the vascular system and inflammatory cells such as lymphocytes, neutrophils, and macrophages. Thus, inflammation plays a crucial role in the etiology and modulation of many cardiac diseases such as myocardial infarction, reperfusion injury, angiogenesis, cardiac allograft rejection, sarcoidosis, and myocarditis [34, 35].

11.3.1.1 SPECT Radiotracers

One of the early techniques used to assess inflammation within the myocardium involved radiolabeling leukocytes with ^{99m}Tc or ^{111}In [36, 37]. This involves removal of blood, *in vitro* labeling and reinjecting the labeled cells intravenously in the patient. This approach provides an opportunity to track active inflammatory cell recruitment within the myocardium, however, this approach evokes non-specific activation of the labeled cells, interfering with the specificity of the image [36]. ^{111}In -Oxine is an FDA approved lipid soluble isotope cell tracker used to label leukocytes and track their *in vivo* distribution by SPECT imaging. This radiotracer has also been used for tracking the molecular and cellular mechanisms of inflammation or for the study the dynamic biodistribution of labeled cells used for therapeutic purposes [38–41]. SPECT imaging with ^{111}In -oxine radiolabeled autologous white blood cells has also been proven to be a useful tool for detection of infective endocarditis [42]. However, potential newer approaches for identification of endocarditis or other bacterial infections involve the actual direct imaging of bacteria with ^{111}In -labeled agents [43].

Tenascin-C is an extracellular matrix protein that is present in wound healing and inflammation and ^{111}In labeled monoclonal antibody anti-tenascin-C has been identified as a potential inflammation imaging agent. Rodents with experimental autoimmune myocarditis showed increased uptake of the tracer compared to control rats [44]. Dual isotope SPECT imaging approach with ^{125}I labeled anti-tenascin-C antibody or ^{111}In -anti-tenascin-C antibody and ^{99m}Tc -sestamibi has been used to monitor ischemia and reperfusion injury in rodents [45, 46]. These studies demonstrate that increased anti-tenascin-C antibody activity was correlated with the ^{99m}Tc -sestamibi perfusion defect indicating the potential for this imaging agent to monitor inflammation associated with myocardial infarction.

Another potential approach for imaging inflammation in the myocardium is to target a chemotactic agent, called leukotriene B4. The receptor is found on neutrophils and when activated it stimulates endothelial adhesion and superoxide production [47]. ^{99m}Tc -RP517 is a leukotriene B4 receptor antagonist and has been shown to have inverse relationship with occlusion flow in open chested dogs, suggesting

increased uptake of the tracer at the site of the ischemic inflammation [48]. However, this agent is very lipophilic which results in high hepatobiliary uptake and has not been tested in humans.

11.3.1.2 PET Radiotracers

Inflammatory cells show increased metabolism when activated and this can be targeted for imaging by using specific metabolic tracers. For example, in activated macrophages glucose utilization is significantly increased [49]. ^{18}F -labeled fluorodeoxyglucose (^{18}F -FDG) has been used to assess inflammatory cell activity in the myocardium and has showed focal uptake following a myocardial infarction [50, 51]. However, suppression of cardiomyocyte uptake of ^{18}F -FDG is required to isolate the leukocyte signal to optimize the target-to-background signal. Current evidence suggests that administering high fat, no carbohydrate diet for at least two meals with a fast of 4–12 h prior to ^{18}F -FDG PET imaging [52] is sufficient for optimization of the signal. Other methods include intravenous heparin administered just prior to imaging following at least one high fat, no carbohydrate meal, and overnight fast [52]. Clinical studies show increased ^{18}F -FDG uptake in infarcted regions compared to remote myocardium 5–7 days post first myocardial infarction [51, 53]. The magnitude of the increase in ^{18}F -FDG uptake in the infarct has been associated with late outcomes [51]. PET imaging with ^{18}F -FDG has also been proved to be valuable in the evaluation of active cardiac sarcoidosis. ^{18}F -FDG has also been applied in evaluation of microvascular disease. However, the use of ^{18}F -FDG imaging is not as well established in evaluation of the role of inflammation in this setting [54].

Another method to assess the metabolism of activated leukocytes within the myocardium is to track amino acid metabolism. The benefit of using amino acid metabolism over glucose metabolism is that amino acids are a minor metabolic substrate for healthy myocardium although are heavily used in activated leukocytes [55]. Transient increase of ^{14}C - or ^{11}C -labeled methionine uptake has been identified both in mice and in humans on Days 3–7 after a myocardial infarction [55–57]. The PET imaging method with ^{11}C -labeled methionine has the potential to provide a valuable localization of inflammation of the myocardium in the acute phase of myocardial infarction.

Mitochondrial translocator protein (TSPO) is another viable molecular target for evaluation of inflammation and is the target of ^{18}F -GE180. This protein is upregulated in activated macrophages, and therefore would be useful for imaging inflammation in mitochondria abundant organ such as the heart. Increased uptake of this radiotracer was seen 1 week post-myocardial infarction and was predictive of LV remodeling 8 weeks post-MI in a mouse model. In the same study, an increase of TSPO signaling was also found in the brain in the setting of a myocardial infarction, both in humans and in mice, suggesting a potential link between inflammation in heart and brain [58].

Targeting leukocyte recruitment rather than targeting leukocyte metabolism can be achieved with chemokine receptor type 4 (CXCR4). The pentapeptide ^{68}Ga -pentixafor is a CXCR4 targeted PET tracer and was originally designed for imaging CXCR4 upregulated tumors [59]. CXCR4 upregulation to the infarct territory has been shown 3 days post-permanent coronary artery occlusion in mice [60].

Furthermore, on Days 4 through 6 following the ischemic insult the signal was more heterogenous. Other investigators demonstrated high levels of ^{68}Ga -pentixafor binding in areas that showed evidence of hypoperfusion, late gadolinium enhancement, and T2-positive edema. Thus, ^{68}Ga -pentixafor PET imaging has the potential to identify patients at increased risk of post-myocardial infarction cardiomyopathy, however, further investigation is required.

CCR2 is an inflammatory monocyte marker that activates monocyte recruitment and ^{64}Cu - or ^{68}Ga -radiolabeled CCR2 binding peptide (^{64}Cu -DOTA-ECL1i or ^{68}Ga -DOTA-ECL1i) have been used for PET imaging to assess myocardial inflammation after ischemia and reperfusion in the heart [61] (Fig. 11.4) as well as to visualize

Fig. 11.4 Hybrid PET/CT images of ^{18}F -fluorodeoxyglucose (^{18}F -FDG) and ^{68}Ga -DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)-ECL1i (extracellular loop 1 inverse) in sham control mice and mice following ischemia reperfusion (I-R) injury. (a) ^{18}F -FDG PET/CT images 5 days after 90 min of I-R injury compared to sham procedure as controls. Maximal-intensity projected views (MIP), transverse and coronal views are shown. White arrows indicate a myocardial infarct (MI) area. (b) Transverse, coronal, and MIP ^{68}Ga -DOTA-ECL1i PET/CT images obtained 4 days after I-R injury showing regional accumulation of ^{68}Ga -DOTA-ECL1i in the MI and border zone. Yellow arrow indicates tracer uptake in hearts that underwent ischemia reperfusion injury compared to sham procedure as controls. White arrows indicate infarct area defined on ^{18}F -FDG imaging. (c) Quantitative analysis of ^{68}Ga -DOTA-ECL1i accumulation in hearts from naïve, sham, I-R injury, and CCR2 (C-C chemokine receptor type 2) KO (knockout) mice with the different timepoints marked after they underwent I-R injury. Each experimental group had $n = 4$ –5 mice. (d) Regional accumulation of ^{68}Ga -DOTA-ECL1i uptake in the MI and remote areas of sham procedure and at different timepoints post I-R injury. (Modified, with permission from Heo et al., *Circulation Research* 2019)

monocyte recruitment in atherosclerosis plaques [62]. Autoradiography demonstrated that ^{68}Ga -DOTA-ECL1i specifically binds to human tissue specimens from patients with heart failure and that the signal intensity was associated with CCR2+ macrophage abundance. This highlights the translational potential of this agent to non-invasively visualize CCR2+ monocyte recruitment and inflammatory macrophage accumulation in patients. However, this tracer has not been tested in vivo in humans.

11.3.2 Cell Death

Two important markers of cell death are necrosis and apoptosis. Apoptosis is a natural process which involves a tightly regulated process where pathways are turned on or off to get rid of unwanted cells such as senescent cells without provoking significant inflammatory response. These pathways are sometimes activated in certain diseases such as cardiomyopathy, myocarditis, heart failure, reperfusion injury, and myocardial infarction. Necrosis is a well-established form of cell death that involves irreversible damage and disruption of the cell membrane. Necrosis is often an acute process that is associated with a significant inflammatory and immune response [63]. This is particularly troublesome in the myocardium as cardiomyocytes have limited regenerative capacities [63]. Thus, visualizing cell death with non-invasive imaging for assessment, and monitoring a therapeutic response is attractive.

11.3.2.1 Apoptosis Imaging

One of the earlier events in apoptosis is disruption of lipid bilayer of the cell membrane which leads to asymmetric distribution of phospholipids which then leads to increased phosphatidyl serine on the outer cell membrane [64]. Annexin-V is an endogenous human protein that has high affinity for phosphatidyl serine and has been used as a target for molecular imaging of apoptosis [64]. Annexin-V has been radiolabeled for both PET (^{18}F , ^{68}Ga , ^{124}I) and SPECT ($^{99\text{m}}\text{Tc}$, ^{123}I) imaging techniques [64, 65]. Most studies have involved $^{99\text{m}}\text{Tc}$ -labeling and several animal studies have shown increased annexin-V uptake in ischemic myocardium [66–69]. However, due to the size of the molecule it clears slowly and this results in significant off target radiation, specifically in the kidneys and liver [70]. Annexin-V imaging has been used in clinical studies for non-invasive detection of cardiac transplant rejection [71], and for identification of apoptosis following myocardial infarction, and more specifically associated with ischemia reperfusion injury [72].

Apoptotic cell membranes show increased concentration of phosphatidylethanolamine similar to phosphatidyl serine described above [73]. $^{99\text{m}}\text{Tc}$ labeled Duramycin binds to externalized phosphatidylethanolamine in a similar fashion as Annexin-V binds to phosphatidyl serine, and therefore is another useful imaging marker for apoptosis (Fig. 11.5) [74]. In preclinical studies in rabbits, $^{99\text{m}}\text{Tc}$ -Duramycin provided a similar efficacy for apoptosis imaging compared to Annexin-V. Duramycin is also significantly smaller compared to Annexin-V and is more rapidly cleared by the kidneys, which leads to lower off target retention and

Fig. 11.5 (left) ^{99m}Tc -duramycin images from ischemic reperfusion injury in a pig model. (a) Whole body anterior planar image was obtained 30 min post-myocardial infarction demonstrating tracer uptake in the ischemic heart region (indicated with blue arrow). Multi-dose vehicle shows low uptake. Single injection of doxorubicin (10 mg/kg) shows high uptake. Two injections of doxorubicin (2.5 mg/kg) shows high uptake. (Modified, with permission from Nakahara et al., JACC: Cardiovascular imaging 2018)

radiation exposure [75]. However, further validation of the safety profile and efficacy of this agent for apoptosis imaging is needed prior to clinical use.

Phosphatidyl serine can also be exposed on the outer surface of the cell membrane in necrosis [76], and accordingly there is a growing interest for developing more specific target for imaging of apoptosis. Activation of either intrinsic or extrinsic pathways ultimately leads to activation of caspase-3 or caspase-7, which are termed the executioner caspases and continue to regulate the cascade that leads to apoptosis [77]. These caspases represent alternative attractive targets, but require probes that are membrane permeable or would only target cells having increased membrane permeability. Isatin sulfonamide analogues are membrane-permeable inhibitors of caspases and have been radiolabeled with ^{18}F and are able to detect apoptotic myocardium in vivo [78–80]. Although caspase inhibitors are considered safe for human use, their true safety has not been established in clinical practice [81].

11.3.2.2 Cell Necrosis Imaging

Myosin is not normally found in the extracellular environment but after cell membrane disruption after necrosis it can be exposed. Therefore, radiolabeled antimyosin antibodies have been used for imaging of necrosis in the myocardium [82, 83]. Antimyosin imaging has been used to detect necrosis in pathologies such as myocardial infarction, myocarditis, cardiomyopathy, and transplant rejection [82, 84, 85]. When compared to endomyocardial biopsy, which is the gold standard of diagnosis of myocarditis, the antimyosin scanning showed similar specificity [82]. Antimyosin antibody conjugated to monocrySTALLINE iron oxide nanoparticles [86] and ^{111}In -antimyosin antibody have been used to detect myocardial infarction [87, 88]. ^{111}In -antimyosin Fab antibody imaging has also been used to detect human cardiac transplant rejection but has shown high false positive rate so a biopsy is still needed for confirmation [85, 89].

Following necrosis there is a sudden influx of calcium ions which accumulate within the mitochondria in the crystalline structure, hydroxyapatite. Using $^{99\text{m}}\text{Tc}$ -pyrophosphate, which labels hydroxyapatite for bone scanning, myocardial infarct can be visualized (Fig. 11.6) [90]. This method has not gained widespread use due to limited sensitivity in detection of early infarction and persistence of the signal late post-myocardial infarction [91]. More recently, quantitative $^{99\text{m}}\text{Tc}$ -pyrophosphate imaging has been used for identification of amyloidosis. This tracer has shown 85% sensitivity and 95% specificity for the diagnosis of transthyretin-related cardiac amyloidosis (ATTR) as a cause of heart failure when computing the ratio of mean myocardial counts to mean ventricular counts [92]. Other investigators have focused on calculating the heart-to-contralateral chest ratio, and when using a cutoff value >1.5 , ATTR subtype amyloidosis can be diagnosed with a 97% sensitivity and 100% specificity [93]. Furthermore, $^{99\text{m}}\text{Tc}$ -pyrophosphate has shown to differentiate between immunoglobulin light chain (AL) from ATTR amyloid, which shows much higher tracer retention [93]. Another trial using the $^{99\text{m}}\text{Tc}$ -pyrophosphate heart-to-contralateral ratio showed that a ratio greater than 1.6 was associated with worse survival among patients diagnosed with ATTR cardiac amyloidosis [94]. Interestingly, serial $^{99\text{m}}\text{Tc}$ -pyrophosphate imaging does not show progressive changes despite obvious clinical progression in ATTR amyloidosis [95].

Another SPECT imaging approach to detect necrosis involves the use of $^{99\text{m}}\text{Tc}$ -glucarate, which binds to exposed histones in the nucleus of the myocytes. Canine models have shown that the compound has high affinity for necrotic myocardial tissue but no uptake was observed in an ischemic but viable tissue [96]. $^{99\text{m}}\text{Tc}$ -glucarate has also been used to assess acute myocardial infarction and reperfusion injury in rabbits, showing an ability to detect myocardial infarcts in both the presence of permanent coronary occlusion and following reperfusion within minutes [97]. In humans, it was able to detect ischemia within 9 h from onset of symptoms, but the sensitivity of this method depends heavily on the onset of symptoms [98].

(c) Fusion of SPECT image with attenuation CT

11.4 Sympathetic and Parasympathetic Imaging

The autonomic nervous system (ANS) is composed of the sympathetic nervous system (SNS) and the parasympathetic nervous system (PNS) both play a key role in regulating blood flow, heart rate, and contractility which translates into cardiac

function. The SNS promotes positive chronotropy, excitability, contractility and increases conduction on heart myocytes; the PNS in turn promotes the opposite. These regulations are possible via the release of neurotransmitters that act directly or indirectly on myocardium and the peripheral vasculature [99–103]. The use of radiotracers to non-invasively image the ANS has become of great interest in the cardiovascular field as it can provide diagnostic and prognostic information in patients with heart failure, arrhythmias, and ischemic heart disease (Fig. 11.7) [100, 104, 105].

Fig. 11.7 Depiction of postganglionic sympathetic nervous system (SNS) and parasympathetic nervous system (PNS) nerve endings (**Left panel**) The synthesis and release of norepinephrine in postganglionic SNS nerve endings and subsequent binding to postsynaptic receptors on cardiomyocytes. The tracers in red depict SNS pre- and post-synaptic radioanalogs. (**Right panel**) The synthesis and release of acetylcholine in the terminal nerve ending and varicosities of postganglionic PNS nerve endings and subsequent binding to postsynaptic receptors on cardiomyocytes. AC adenylyl cyclase, ACh acetylcholine, AChE acetylcholinesterase, ATP adenosine triphosphate, CAT choline-acetyl-transferase, COM catechol-*O*-methyltransferase, cAMP cyclic adenosine monophosphate, MAO monoamine oxidase, mIBG metaiodobenzyl guanidine, MR₂ muscarinic receptor 2, NE norepinephrine, NR nicotinic receptor, VMAT vesicular monoamine ^{18}F - ^{18}F -transporter, 6F-DA 6fluorodopamine, PHEN phenylephrine, EPI epinephrine, HED hydroxyephedrine, $[^{11}\text{C}]$ MQNB (R,S)-*N*- $[^{11}\text{C}]$ -methyl-quinuclidin-3-yl benzilate. (Modified, with permission, from Boutagy NE, Curr Cardiol Rep. 2017)

11.5 Sympathetic Imaging

The basis by which molecular imaging is used to image ANS relies on the normal physiology of how the ANS exerts peripheral effects. These are mediated by the release of norepinephrine (NE) from secretory vesicles in the postganglionic region, NE subsequently binds to G coupled receptor on effector cells (α,β), which in turn will promote a specific function on the cell [106]. After NE has been released by the efferent receptor, about 80% is reabsorbed in an energy dependent manner by reuptake at the presynaptic nerve terminal via the NE reuptake transporter (NET or uptake 1) [106], while the remaining 20% of the NE is reabsorbed by the postsynaptic terminal in an energy-independent fashion [106]. Therefore, the majority of the tracers developed to evaluate the SNS assess cardiac sympathetic nerve density and neuronal integrity.

11.5.1 SPECT Radiotracers

The most common tracer used to assess the integrity of the presynaptic nerve activity is ^{123}I -metaiodobenzylguanidine (^{123}I -mIBG) with planar or SPECT imaging [107, 108]. Most of the literature related to the use of ^{123}I -mIBG has employed planar scintigraphy for risk stratification of patients with heart failure [109, 110]. Quantification of planar ^{123}I -mIBG images involves the calculation of the heart to mediastinal (H/M) ratio as a surrogate for cardiac SNS innervation, whereas the washout ratio from early and late ^{123}I -mIBG images has been used as a surrogate for presynaptic nerve activity [111, 112]. However, 2D planar imaging is not fully quantitative, because of the superposition of background structures with the 2D heart region of interest and lack of corrections for attenuation and scatter. Three-dimensional (3D) SPECT ^{123}I -mIBG imaging has been proposed to overcome this limitation and enable evaluation of regional myocardial tracer uptake [113–115]. Absolute quantification of ^{123}I -mIBG requires hybrid SPECT/CT imaging and kinetic modeling, and the use of CT for both attenuation and partial volume correction [116].

11.5.2 PET Radiotracers

Many agents have been developed for presynaptic SNS PET imaging, but to date the most clinically relevant has been ^{11}C -meta-hydroxyephedrine (^{11}C -HED), which is the most well studied in animal and human models [117–120]. ^{11}C -HED PET imaging offers advantages over ^{123}I -MIBG due to the higher spatial resolution with PET, providing more precise volumetric and regional information (Fig. 11.8). However, the use of ^{11}C -HED is limited by the short half-life and the requirement for a cyclotron. Another presynaptic SNS tracer with a longer half-life and similar kinetics to

Fig. 11.8 Images from PARAPET trial. PET quantification of flow, viable myocardium, and sympathetic innervation from two representative subjects. **(a)** Subject with sudden cardiac arrest (SCA) where there is a mismatch in infarct size (reduced ^{18}F -FDG) and volume of sympathetic denervation (reduced ^{11}C -HED), which was smaller. There was also reduced perfusion (^{13}N -ammonia [$^{13}\text{NH}_3$]) with preserved ^{18}F FDG indicating hibernating myocardium. **(b)** Subject with matched reductions in flow, infarct volume, and sympathetic denervation. Anterior (ANT), Inferior (INF), lateral (LAT), and septum (SEP). (Reproduced with permission from Fallavollita et al., *J Am Coll Cardiol.* 2014 Jan, 63 (2) 141–149)

^{123}I -MIBG is ^{18}F -LMI1195 [121]. Sinusas et al. showed promising properties of this radiotracer in the first-in-human study, demonstrating patient safety, and favorable dosimetry and biodistribution along with excellent kinetics for myocardial imaging [122]. Less clinically used radiotracers that provide vesicular storage and metabolic information, are the neurotransmitter ^{11}C -Epinephrine (EPI) and the synthetic catecholamine ^{11}C -Phenylephrine (^{11}C -PHEN). ^{11}C -EPI provides favorable images due to the rapid blood clearance and slow myocardial clearance [119, 120]. In contrast, ^{11}C -PHEN is susceptible to intraneuronal monoamine oxidase (MAO), and therefore myocardial washout tends to be rapid with lower myocardial retention in comparison to the other presynaptic agents [123]. The targeting of postsynaptic β_1 and β_2 receptors with the ^{11}C -labeled non-selective receptor antagonists such as ^{11}C -CGP-12177 and ^{11}C -CGP-12388 provide acceptable quality images with the possibility of quantitative analyses. However, there has not been any widespread clinical use of these agents due to difficulties in synthesis and the short half-life of ^{11}C [124, 125]. A radiotracer targeting α_1 receptors (^{11}C -GB67) was developed and validated in preclinical studies, although the potential for clinical application has yet to be determined in human studies [126].

11.6 Clinical Applications of SNS Imaging

Most of the clinical evaluations of sympathetic function with radiolabeled probes have been with the use of ^{123}I -MIBG and ^{11}C -HED. These agents have provided mechanistic insights in the setting of cardiac transplantation [127, 128], a guide for placement of implantable cardioverter defibrillators for primary prevention in sudden cardiac death (SCD) [109, 129], and to establish prognosis in patients with cardiomyopathies [130, 131]. The imaging of the ganglionated plexi (GPs) has more recently been of interest in the electrophysiology community, since it has been demonstrated that catheter ablation of the GPs as an add-on to pulmonary vein isolation in patients with atrial fibrillation (AF) may improve clinical outcomes [132, 133]. Furthermore, it has been also reported that the presence of residual GP activity after pulmonary vein isolation (PVI) might predict likelihood of AF recurrence [134]. However, a major limitation for the use of SPECT imaging technology has been the limited resolution of most SPECT cameras, especially because of the small size of these structures (5–10 mm) [135]. More recently, a pilot study showed that the use of CZT SPECT cameras and ^{123}I -MIBG imaging allowed for detection of the GPs in 20 patients with the diagnosis of paroxysmal AF who underwent PVI. These patients had ^{123}I -MIBG imaging performed prior to ablation and SPECT images were registered with pre-PVI cardiac contrast CT imaging. Again, highlighting the importance of hybrid imaging technology or image fusion for clinical application of autonomic imaging. In these studies, uptake of ^{123}I -MIBG correlated with areas of high frequency stimulation demonstrating that SPECT/CT imaging can accurately identify GPs prior to PVI ablation (Fig. 11.9) [136]. However, due to the lack of larger prospective and randomized control trials, the widespread use of this approach in clinical practice is still lacking.

Fig. 11.9 (a, b) Co-registered SPECT ^{123}I -mIBG and cardiac CT images in transverse (a) and coronal (b) planes. The LA region of search is defined (solid lines, arrows) by the CT-derived LA compartment. (c) Color-coded 3D maps of ^{123}I -mIBG uptake and distribution on CT-derived LA compartments, as well as 3D ellipsoidal DUA representations (ellipsoids, arrows). *LSPV* left superior pulmonary vein, *LIPV* left inferior pulmonary vein, *RSPV* right superior pulmonary vein, *RIPV* right inferior pulmonary vein, *DUA* discrete uptake area, *LA* left atrium, *LV* left ventricle. (Modified with permission, from Stirrup, J., Gregg, S., Baavour, R. et al. *J. Nucl. Cardiol.* 2019 [136])

11.7 Parasympathetic Imaging

Nerve conduction in the PNS is mediated by the release of acetylcholine (ACh) from postganglionic terminals. The release of ACh after a depolarization of the cell follows coupling of ACh to the muscarinic and nicotinic receptors to exert effect. The predominant effect following activation of these receptors in the heart is reduction of heart rate and myocardial contraction. The remaining choline after cleavage by acetylcholinesterase (AChE) is taken up by terminal nerve endings which results in a continuous resynthesized of ACh [106]. The particularly dense distribution of the terminal efferent nerves and receptors in the thinner-wall atria compared to the ventricle in conjunction with the rapid degradation of ACh by AChE make the imaging of the PNS in the heart more challenging than SNS imaging. Therefore, there are not many clinically SPECT radiotracer available for this purpose and only PET radiotracers have been developed. Despite these limitations, the use of ^{11}C -Donepezil in preclinical studies has showed promising results as a presynaptic PNS imaging agent, which might provide prognostic information in certain patients [137]. Similar to imaging of the SNS, imaging of the postsynaptic parasympathetic receptors is also of great interest. The use of ^{11}C -MQNB to measure the density of the muscarinic receptors has been validated in preclinical and human studies [138, 139]. More recently, the use of a novel fluorinated agent (^{18}F -85380), which targets $\alpha_4\beta_2$ has showed favorable results in terms of quality of imaging in healthy patients and in those with neurodegenerative disease [140]. In contrast to SNS imaging, the clinical use of PNS radiotracers is far more limited and requires further evaluation to determine potential clinical applications.

11.7.1 Angiogenesis

Angiogenesis is defined as new capillary formation from preexisting microvessels, and is stimulated by tissue hypoxia via activation of hypoxia-inducible factor (HIF) 1- α , which triggers the transcription of numerous angiogenic genes, such as vascular endothelial growth factor (VEGF), VEGF receptors (VEGFR), neuropilin-1, and angiopoietin-2 [141]. Besides the transcription of growth factors and their receptors, hypoxia also triggers inflammatory cells to secrete soluble pro-angiogenic and anti-angiogenic molecules that regulate this process [142]. The secretion of pro-angiogenic molecules induces the migration of endothelial or progenitor cells that proliferate and form new vessels. Activated and proliferating endothelial cells express integrins, which are crucial to the angiogenic process [143]. Targeted imaging of any of these molecular signals allows in vivo evaluation of myocardial angiogenesis in the setting of acute or chronic ischemia with nuclear imaging techniques [141, 144].

11.7.1.1 $\alpha\beta_3$ Integrin Targeted Imaging

The most widely applied strategy for molecular imaging of angiogenesis has been with the use of SPECT and PET tracers that target the $\alpha\beta_3$ integrin, which is a cell

Fig. 11.10 In vivo and ex vivo ^{111}In -RP748 and $^{99\text{m}}\text{Tc}$ -sestamibi ($^{99\text{m}}\text{Tc}$ -MIBI) images from dogs with chronic infarction. (a) In vivo short axis, vertical long axis (VLA) and horizontal long axis (HLA) serial images in a dog 3 weeks after left anterior descending (LAD) coronary artery infarction. Images were at 20 min and 75 min after injection. $^{99\text{m}}\text{Tc}$ -MIBI images (third row) demonstrate the anteroapical perfusion defect (yellow arrows). The 75 min ^{111}In -RP748 SPECT images were colored red and the $^{99\text{m}}\text{Tc}$ -MIBI images were colored green and the images fused together (bottom row). This demonstrates the localization of the ^{111}In -RP748 activity within the heart (white arrows). Right ventricular and left ventricular blood pool activity is seen at 20 min. (b) In vivo $^{99\text{m}}\text{Tc}$ -MIBI and ^{111}In -RP748 SPECT images from a canine model at 8 h, 1 week and 3 weeks after LAD infarction. At all three timepoints increased myocardial ^{111}In -RP748 uptake is seen in the anteroapical wall. When the $^{99\text{m}}\text{Tc}$ -MIBI (green) and ^{111}In -RP748 (red) images are fused the perfusion defect can be appreciated with increased uptake of ^{111}In -RP748. (c) Ex vivo $^{99\text{m}}\text{Tc}$ -MIBI (left) and ^{111}In -RP748 (center) images of myocardial slices from a canine model 3 weeks post-LAD occlusion. Short-axis slices are in standard orientation. Yellow arrows indicate perfusion defect of the $^{99\text{m}}\text{Tc}$ -MIBI images and the white arrows indicate increased uptake of ^{111}In -RP748. Color fused images are seen on the right and demonstrate increased uptake of ^{111}In -RP748 in the nontransmural perfusion defect. (Modified from Meoli DF, J Clin Invest. 2004)

membrane glycoprotein that is highly expressed on endothelial cells during angiogenesis, but not on normal quiescent endothelial cells [145]. Meoli et al. were the first to report that the $\alpha\text{v}\beta 3$ integrin antagonist, ^{111}In -RP748, could bind with high affinity and selectivity to the $\alpha\text{v}\beta 3$ integrin, providing an in vivo index of angiogenesis in the setting of ischemic myocardial injury with SPECT imaging (Fig. 11.10) [146]. Later generation SPECT and PET tracers have employed the arginine-glycine-aspartic acid (RGD) peptide or derivatives for angiogenesis imaging, since this sequence is highly selective for the $\alpha\text{v}\beta 3$ integrin [147–150]. Commonly used

tracers that target $\alpha v\beta 3$ integrin activation in the heart include the SPECT tracer, ^{99m}Tc -NC100692 (^{99m}Tc -maraciclalide) [149], and the PET tracers, ^{18}F -galacto-RGD [151], ^{68}Ga -PRGD2 [152], and ^{18}F -Fluciclatide [153]. Clinical imaging of myocardial angiogenesis has already been performed with ^{99m}Tc -maraciclalide SPECT imaging [154], and PET imaging of ^{18}F -galacto-RGD [155], ^{68}Ga -PRGD2 [152], and ^{18}F -Fluciclatide (Fig. 11.11) [153].

11.7.1.2 Vascular Endothelial Growth Factor (VEGF) and Endothelial Cell Imaging

VEGF is a growth factor that is expressed in response to tissue hypoxia that stimulates angiogenesis via binding and activation of cognate receptors (VEGFR-1, VEGFR-2) [156, 157]. Significant efforts have been made to radiolabel VEGF isoforms or antibodies against specific VEGF receptors for PET and SPECT imaging of angiogenesis [158, 159]. Multiple VEGF isoforms have been radiolabeled for SPECT imaging of angiogenesis. Investigators have also developed radiotracers that target membrane proteins of activated endothelial cells (CD13) or endothelial cells of newly formed vessels (CD105) [160, 161].

11.8 Imaging Fibrosis and Extracellular Matrix (ECM)

Many pathological conditions lead to the deposition of components of the ECM in the heart, this process also known as fibrosis usually occurs as a response to different types of insults such as ischemia, pressure, volume overload, and certain cardiomyopathies [162–164]. Briefly, fibrosis is characterized by a complex process of cytokine release, inflammatory cells migration, angiogenesis through endothelial cell proliferation, and ultimately the presence of myofibroblasts which promote the deposition of collagen to support scar formation [165]. Given the presence of fibrosis in many cardiovascular diseases targeted ECM imaging has been proposed as a tool to assess disease progression, evaluate treatment response, and provide prognosis.

11.8.1 Clinical Applications

Currently, the vast majority of ECM targeted imaging research has been performed in the setting of acute myocardial infarction or for the evaluation of post-infarct remodeling. Here, we will present the most common targets for imaging fibrosis and the ECM.

11.8.1.1 Imaging Somatostatin Receptor

Fibroblasts become activated, proliferate, and differentiate into myofibroblasts during the process of fibrosis. Somatostatin receptors expressed on fibroblasts become upregulated during fibrosis [166]. Therefore, imaging of somatostatin receptors represents a potential target for evaluation of myocardial fibrosis. ^{111}In -Octreotide is

an FDA approved SPECT radiotracer that has been used to image fibrosis in pulmonary sarcoidosis, and may also play a role in imaging cardiac sarcoidosis. ^{68}Ga -DOTA-Nal-octreotide (^{68}Ga -DOTANOC) is a PET radiotracer that also binds to somatostatin receptors on inflammatory cells in sarcoid granulomas. PET imaging with ^{68}Ga -DOTANOC has provided better diagnostic accuracy and inter-observer agreement than FDG-PET, which is used more routinely in the evaluation of cardiac sarcoidosis (Fig. 11.12) [167].

11.8.1.2 Imaging Integrins

Integrins are also expressed on myofibroblasts, and therefore integrin targeted imaging has also been used to image myocardial fibrosis. The binding of the $\alpha\beta3$ integrin to the ECM is dependent on an amino acid complex consisting of arginine-glycine-aspartic acid (RGD). SPECT imaging of a $^{99\text{m}}\text{Tc}$ -labeled Cy5.5-RGD imaging peptide ($^{99\text{m}}\text{Tc}$ -CRIP) has been shown to co-localize with myofibroblasts and track fibrosis following myocardial infarction [168]. A similar $^{99\text{m}}\text{Tc}$ -labeled RGD peptide has been shown to identify scar in patients following myocardial infarction [169]. The $\alpha\beta6$ integrin is another important activator of the profibrotic cytokine TGF- β that is upregulated following tissue injury. SPECT/CT imaging of ^{111}In -labeled A20FMDV2 has enabled detection of increased $\alpha\beta6$ integrin in fibrotic tissues [170]. Other PET probes targeted at the $\alpha\beta6$ integrin are now in clinical trials in patients with pulmonary fibrosis.

11.8.1.3 Imaging Collagen

Molecular imaging of the ECM can involve targeting collagen, which reaches high concentration with fibrosis. There are both indirect and direct approaches for imaging collagen in fibrosis. The MRI extracellular contrast agent, Gd-DOTA is commonly used for the indirect evaluation of fibrosis and viability after MI [171, 172]. DOTA has also been labeled with ^{64}Cu for PET imaging, and has similar properties to the MRI tracers providing good localization and visualization of the MI region

Fig. 11.11 ^{18}F -Fluciclatide uptake in acute myocardial infarction (MI) in three patients with recent subendocardial MI. Patient 1 (a–f), 13 days after anterior MI, displaying a short-axis PET image of the left ventricle with crescentic ^{18}F -fluciclatide uptake (a) that correlates with the interventricular septum and anterior wall on CT angiography (b). The fused PET/CT angiography image (c) shows this uptake to correspond exactly with the region of late gadolinium enhancement (LGE) on cardiac magnetic resonance (CMR) (d). Delineation of myocardial uptake on PET/CT is clearer in the two-chamber view (e) and on a fused CT/three-dimensional-Patlak image, which shows this uptake to follow a watershed-pattern emerging from the coronary stents present in the left anterior descending coronary artery (f). Patient 2 (g, h), 8 days following anterior MI, displaying focal uptake of ^{18}F -fluciclatide in the anterior wall and apex in the 3-chamber view on PET/CT (g) which corresponds to the region of MI on LGE CMR imaging (h). Patient 3 (i, j), showing focal uptake of ^{18}F -fluciclatide in the inferior wall 19 days following MI on PET/CT (i) that again corresponds to the infarction on CMR LGE imaging (j). (Reproduced with permission from Jenkins WSA, et al. Heart 2017;103:607–615)

Fig. 11.12 Patient with cardiac sarcoidosis in which the ^{18}F -FDG PET/CT was inconclusive due to insufficiently suppressed physiological ^{18}F -FDG uptake by the myocardium. (**Left panel**) MIPs showing a patient with dilated cardiomyopathy and multiple ^{18}F -FDG and ^{68}Ga -DOTANOC avid lymph nodes (red arrows) both above and below the diaphragm. Furthermore, there is massive and diffusely increased activity in the lung parenchyma (black arrows) reflecting active pulmonary sarcoidosis. (**Right panel**) The top image raises suspicion for cardiac involvement with a region of focal on diffuse pattern of ^{18}F -FDG uptake in the PET/CT transaxial slices (SUVmax 21 at the septum). This scan was considered non-conclusive by a reviewer panel. In contrast, all reviewers rated the ^{68}Ga -DOTANOC uptake (SUVmax 2.8, target-to-background 3.04) in the septum pathological (**bottom**). The patient was treated with corticosteroids and recovered. *MIP* maximum intensity projections. (Reproduced with permission from Gormsen LC, et al. *EJNMMI Res.* 2016;6:52)

[173, 174]. Although, these agents provide indirect localization of fibrosis, their lack of sensitivity made them unable to detect diffuse fibrosis which can sometimes be observed in cardiomyopathies or secondary to conditions of volume and/or pressure overload. Therefore, collagen specific tracers have been developed to overcome this problem, although these approaches detect an end result of collagen deposition. The first molecule developed was $^{99\text{m}}\text{Tc}$ -collagelin for SPECT imaging. Although $^{99\text{m}}\text{Tc}$ -collagelin demonstrated a high binding capability to Collagen I and

II, the image quality was compromised by a high liver uptake [175]. Analogous PET probes were synthesized to overcome this limitation, including ^{68}Ga - and ^{64}Cu -labeled probes that demonstrated improved target-to-noise and good quality images in vitro, however, the in vivo kinetics did not differ from the non-specific collagen probes during in vivo imaging [174, 176]. For example, ^{68}Ga -CBP8 demonstrated excellent binding to type 1 collagen in human tissue ex vivo, although in vivo binding has not been demonstrated.

11.8.1.4 Imaging of Extracellular Matrix Proteases

Another target of particular interest for imaging the ECM are the matrix metalloproteases (MMPs), which are zinc-dependent proteases that play an important role in the turnover of ECM during normal physiologic conditions [177], and are upregulated during the inflammatory phase of many cardiovascular conditions such as acute MI. The activation of MMPs are kept in balance by tissue inhibitors of MMPs (TIMPs). If this MMP/TIMP balance becomes disrupted, adverse consequences can ensue such as left ventricular remodeling [178]. To date, the most important imaging agent for MMPs in the setting of acute MI is the $^{99\text{m}}\text{Tc}$ -labeled peptidomimetic probe, RP-805, which is a broad spectrum inhibitor of MMPs that binds to the catalytic site of activated MMPs [179, 180]. The effectiveness of $^{99\text{m}}\text{Tc}$ -RP805 for imaging of cardiac remodeling has been demonstrated in both small and large animal models of post-MI remodeling (Fig. 11.13). $^{99\text{m}}\text{Tc}$ -RP805 uptake was found to be the highest at 1 week after MI within the central infarct region, and importantly remained elevated for the following 3–4 weeks after injury [179, 180]. Interestingly, although the majority of the uptake was in the MI region, a modest increase in uptake was also observed in the border and remote regions of the left ventricle as well as the atria of the heart [176]. Therefore, this radiotracer provides an index of global remodeling of the myocardium following MI. Non-invasive dual isotope hybrid SPECT/CT imaging of $^{99\text{m}}\text{Tc}$ -RP805 and ^{201}Tl was also shown to provide a quantitative regional map of MMP activation in the myocardium in relation to regional myocardial blood flow. This hybrid imaging methodology was specifically used to assess the efficacy of the intracoronary delivery of an MMP inhibitor, rTIMP-3, to the MI region, and demonstrated a reduction in MMP activity in association with an increase in myocardial blood flow as assessed with dynamic ^{201}Tl imaging [181]. The myocardial uptake of $^{99\text{m}}\text{Tc}$ -RP805 has also been shown to be increased in models of chemotherapy induced cardiotoxicity and uptake of this compound was found to be directly related to a decline in global left ventricular function [182].

Although, still in a preclinical mouse model, the more selective targeting of MMP-2 with an activatable fluorescent probe (MMP-P12) was developed to non-invasively image the development and treatment response in models of hindlimb ischemia [183]. The value of this probe for cardiac imaging remains uncertain.

11.9 Monitoring Cell and Gene-Based Therapies with Novel Reporter Probe Imaging

Cell and gene-based therapies provide potential new approaches to treat cardiovascular diseases. While many clinical trials have been conducted using cell and gene-based therapy to treat ischemic heart disease the overall benefit has been mixed [184–187]. One limitation of these trials is the inability to non-invasively track the initial delivery and *in vivo* quantitative effects of these therapies. The high sensitivity of nuclear imaging to detect cellular and molecular events offers a unique opportunity to address these limitations. The ability to visualize cellular and gene-based therapies with nuclear relies on two distinct strategies that include, (1) direct labeling and (2) the use of reporter genes.

11.9.1 Direct Labeling

Stem cells have been directly radiolabeled with techniques that allow for cellular incorporation or uptake of radiotracers for SPECT and PET imaging [188]. A gene or components of a gene delivery system have been directly radiolabeled with both gamma (^{111}In) and positron emitting (^{124}I) isotopes for SPECT and PET imaging, respectively [189]. Although useful for monitoring initial cell/gene delivery to a target tissue, major issues exist with these techniques. The direct labeling approach does not facilitate long-term follow-up due to the loss of imaging signal strength because of radioactive isotope decay. More importantly, direct labeling does not allow for the ability to differentiate viable cells from dead cells or even retained isotope by infiltrating inflammatory cells or within cellular debris [188].

Fig. 11.13 *In vivo* $^{99\text{m}}\text{Tc}$ -RP805 SPECT/CT images. **(Top)** Representative *in vivo* hybrid dual isotope SPECT/CT images are shown in vertical long axis (VLA), horizontal long axis (HLA), and short axis (SA) from a pig post-MI. ^{201}Tl SPECT images are shown in green **(a)**, $^{99\text{m}}\text{Tc}$ -RP805 uptake in red **(b)**, and contrast CT in black and white **(c)**. A dense ^{201}Tl perfusion defect (red arrow) is seen in the anteroseptal wall with corresponding hypoperfusion zone on the contrast CT image (yellow arrow). The fusion of the SPECT and CT images **(d)** demonstrates focal $^{99\text{m}}\text{Tc}$ -RP805 uptake within the perfusion defect. Reproduced with permission from Thorn et al., *Circ Cardiovasc Imaging* 2019. **(Bottom)** Dual isotope *in vivo* SPECT/CT imaging reflecting ^{201}Tl myocardial perfusion and $^{99\text{m}}\text{Tc}$ -RP805 uptake reflecting matrix metalloproteinase activity. *In vivo* ^{201}Tl and $^{99\text{m}}\text{Tc}$ -RP805 SPECT/CT images of pigs at 1, 2, and 4 weeks post-myocardial infarction are shown in transaxial, coronal, and sagittal views. Note the perfusion defect in the lateral wall and the time-dependent changes in the intensity of $^{99\text{m}}\text{Tc}$ -RP805 retention in the same regions (green arrows). The yellow double arrows point to $^{99\text{m}}\text{Tc}$ -RP805 activity in the surgical sternal wound. A point source of known activity (orange arrow) can be used to quantify radiotracer uptake. Scale bars: 2 cm. (Modified, with permission, from Sahul ZH, *Circ Cardiovasc Imaging*, 2011 [180])

11.9.2 Reporter Genes

Reporter gene technology overcomes many of the limitations of direct labeling. Reporter genes are genes for specific proteins that elicit an imaging signal by biochemically interacting with an imageable probe. In gene therapy applications, the reporter gene is attached to the regulatory sequence of the protein of interest, and therefore the intensity of signal is related to gene expression of both the report gene and the associated therapeutic gene of interest. Similarly, in stem cell applications, reporter genes are introduced into stem cells prior to delivery. Therefore, probe uptake directly relates to viable stem cell numbers.

Two common reporter genes for nuclear imaging are the herpes simplex virus type 1 thymidine kinase (HSV1-tk) and the human sodium iodide symporter (hNIS). Each of these proteins interact with reporter probes differently. Expression of the HSV1-tk in the target cell leads to the production of thymidine kinase, which in the presence of the radioisotope substrates, 9-(4-¹⁸F-fluoro-3-[hydroxymethyl]butyl)guanine (¹⁸F-FHBG) and 2'-[¹⁸F]fluoro-5-ethyl-1-beta-D-arabinofuranosyluracil (¹⁸F-FEAU), causes phosphorylation and trapping of these probes in the cell. The hNIS is a membrane protein capable of transporting several radioisotopes (e.g., ^{99m}TcO₄⁻, ¹²³I, ¹⁸F-tetrofluoroborate) when expressed in a target cell. Uptake is facilitated by active transport of Na⁺, thus uptake can occur against a concentration gradient and lead to higher radiotracer accumulation and image sensitivity than with the use of enzymes or receptors [190]. Nuclear imaging of reporter genes, especially when combined with anatomical CT imaging, offers adequate image sensitivity for detecting in vivo processes, and are widely used for evaluating these novel therapies.

11.10 Theranostics

Theranostics represents the combination of a molecular diagnostic probe with a targeted therapeutic. The use of theranostics offers many potential advantages, including: (1) improving drug efficacy by directing a therapy to those most likely to benefit, (2) improving the safety profile of a therapeutic by minimizing off target effects, and (3) ultimately improving cost effectiveness and therapeutic drug development or improving selection of clinical trial participants. The initial use of theranostics involved radionuclide therapies with imageable radioisotopes that yield therapeutic radiation. Some prototypical isotopes include ¹⁷⁷Lu or ¹⁸⁶Re for SPECT imaging or ⁹⁰Y for PET imaging. More recent efforts in the development of theranostics involve the use of nanoparticles of multiple configurations that can be engineered to locally delivery therapeutics over a prescribed time frame. This might include the use of micelles, liposomes, dendrimers, or lipoprotein nanoparticles. The application of theranostics for the evaluation and treatment of cardiovascular diseases has been recently reviewed [191, 192].

Part IV

PET/MR

Lukas Kessler and Christoph Rischpler

12.1 Introduction

In the last years PET/MR hybrid imaging entered the market and revealed a variety of possible clinical applications. The first integrated PET/MRI scanner was installed in 2010 and initially the clinical applications focused on oncological examination [1]. It took a few years for this new technology to be implemented in the workup of cardiovascular diseases and until 2013 no original research article was published about PET/MRI applications for cardiovascular diseases. This was because of multiple reasons: One reason was that healthcare professionals (e.g. physicians, physicists, technicians and researchers) needed to get used to this complex technology, which was obviously easier in organs without movement and motion artifacts due to respiration and the heartbeat. Further there are fewer patients who receive PET imaging with cardiovascular diseases than, for example, in Oncology. Nonetheless there are rising applications for PET/MRI in cardiology with promising data and a joint position statement by the ESCR and EANM has been published as a guideline [2]. But PET/MRIs full potential has not been exploited yet. This chapter will focus on PET/MRI in myocardial perfusion, viability imaging, and technical peculiarities of current PET/MRI systems which have to be considered.

12.2 Technical Specialities of PET/MRI Systems

The development and construction of integrated PET/MRI systems was a technically and financially challenging task due to certain technical and physical restraints. On one hand, high magnetic fields, quickly switching gradient fields,

L. Kessler · C. Rischpler (✉)

Department of Nuclear Medicine, University Hospital Essen, University of Duisburg-Essen, Essen, Germany

e-mail: Christoph.rischpler@uk-essen.de

and radiofrequency signals from MRI technology may interfere with the electronics and imaging components (e.g. photomultiplier tubes) of regular PET scanners. On the other hand, MR image quality may suffer from PET components in the scan field of view. Today there are two different kinds of PET/MRI commercially available, the first being a PET connected with a stand-alone MR scanner via table (Philips Ingenuity TF PET/MR) [3]. The second has a PET detector ring installed inside the MR tube and can therefore be referred to as a true integrated PET/MRI (Siemens Biograph mMR, GE SIGNA PET/MR) [1, 4]. For the latter constructional approach new detector technologies had to be engineered. Siemens focused on avalanche photodiodes (ADPs), for example, made of lutetium oxyorthosilicate crystals. These crystals can resist strong magnetic fields without major interference. Compared to that GE-scanners use silicon photomultiplier technology (SiPM)-based PET detectors, which allow time-of-flight PET imaging [5].

A major problem with the integrated scanners has been the attenuation correction (AC) which is most crucial for PET imaging in general. With non-AC PET data only, quantification of absolute activity values is not possible and therefore PET data interpretation would gravely suffer.

Because of the missing CT data and the old time-consuming methods from stand-alone PET were not a real alternative, new methods had to be engineered for AC of PET/MR images. There is a variety of approaches for example tissue classification, maximum likelihood estimation of activity and attenuation (MLAA), homogenization using gradient enhancement (HUGE) or the novel CAIPIRINHA attenuation correction [6–11]. Most approaches for generating AC-maps from MR data are based on templates, segmentation or atlases and of course PET emission data. In concise sentences, segmentation-based algorithms generate AC-maps taking into account different tissue types with varying attenuation coefficients for 511 keV photons [12]. This method, for instance, is applied in the Siemens Biograph mMR. From a Dixon VIBE MR sequence water and fat images are generated and air, lung, fat, and soft tissue are segmented and represented afterwards in the AC-map [6, 13]. A requirement for this method is a breath-hold time of approx. 18 s per bed position, which can be problematic in older, very sick or respiratory impaired patients. An alternative approach is using a T1-weighted (T1w) turbo spin echo sequence to reduce image acquisition time for AC-map generation, however, this method ignores the minor density difference between fat and soft tissue [14]. Lately, a new technique was introduced which also models bone by using an atlas [15]. This approach has already been implemented into the Siemens mMR. In the GE SIGNA PET/MRI a multi-station, whole-body, three-dimensional, dual-echo, RF-spoiled gradient recalled echo (SPGR) sequence (LAVA-Flex) is used and images are also segmented into air, lung, fat, and soft tissue. The Siemens Biograph mMR and the GE Signa approaches are quite similar, the difference lies in slightly different and variable attenuation coefficients of the tissues in the GE scanner [16]. As a result a limited number of tissue types may cause a higher variance in radiotracer uptake estimation for thoracic tumors, which has been reported as 5–23% [6, 14, 17]. Despite that, studies indicate a close agreement between PET/MRI and PET/CT for

cardiac viability imaging with fludeoxyglucose (FDG) [7]. Another approach is the emission-based maximum likelihood estimation of activity and attenuation (MLAA), where non-AC PET data is utilized to calculate the μ -map, but a limitation of this method is photon scatter [8]. Due to the discrepancy of a larger-field of view in PET versus MR imaging, this approach is used to recover parts of the body which cannot be “seen” by MRI but contribute to attenuation (e.g. arms and shoulders) [18]. A constraint of this procedure is variability of tracer uptake in truncated parts of the body depending on the used radiotracer and therefore these parts of the body might be “overlooked” by this method. A novel approach to overcome this constraint has been introduced lately—the so-called B0 homogenization using gradient enhancement (HUGE) technique [10]. Briefly, a reduction of the truncations outside the field of view of the MR scanner can be achieved by optimization of the readout gradient, more specifically by local compensation of B0 inhomogeneities via gradient enhancement. Recent studies suggest that the HUGE method might be more accurate than commonly used MLAA method, especially in radiotracers other than FDG [9].

A novel sequence for AC is the ‘controlled aliasing in parallel imaging results in higher acceleration’, the so-called CAIPIRINHA. It offers higher resolution but identical scan-time [11]. With this sequence other diagnostic sequences with longer acquisition times could potentially be omitted and therefore overall scan time could be drastically reduced (which often poses a downside of PET/MRI compared to PET/CT).

Another peculiarity of PET/MRI is that devices in or around the heart may result in a MRI signal which is larger than the actual size of the device. This may result in an underestimation of the attenuation (in contrast to CT, where metallic objects cause an overestimation of the caused attenuation) and radiotracer uptake. A large number of cardiac devices are implanted every year and numbers are even rising. Not only the compatibility for MRI of the device has to be checked before performing MRI for safety reasons, also it is often not clear if the device is going to cause artifacts which may result in erroneous readings. In a recent study of 20 patients who underwent combined viability and perfusion PET/MR imaging, 20–30% of subjects demonstrated artifacts caused by sternal wires or other metallic implants and maximum relative differences in tracer uptake were observed between 11% and 196% when correcting for artifacts [22]. Figure 12.1 demonstrates a possible artifact on MRI and PET images by a coronary stent.

12.3 Myocardial Perfusion Imaging

In nuclear cardiology myocardial perfusion imaging (MPI) with SPECT and PET is the most common study [19]. It has great impact in the diagnostic workup of coronary artery disease and clinically emerging questions such as hemodynamic significance and extent of ischemia may be answered [20–23]. For quantitative assessment of myocardial blood flow and coronary reserve PET MPI may be seen as the gold standard because of higher image quality and the possibility to quantify the myocardial blood flow (MBF) compared to SPECT MPI [24].

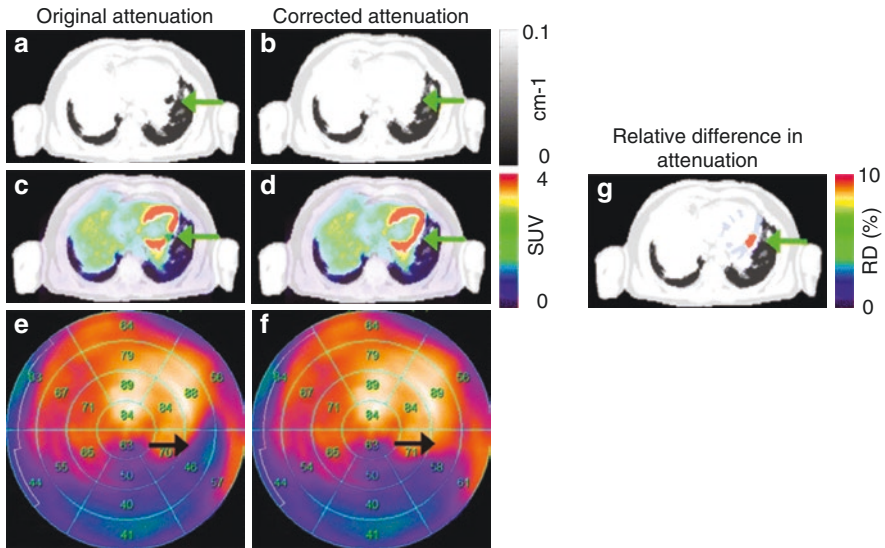

Fig. 12.1 (a–g) Attenuation artifacts in PET/MRI. Cardiac devices may cause artifacts on MR images which translate into PET images. In the depicted case a susceptibility artifact in the left circumflex caused by stent (a, green arrow) resulted in an apparent defect in the lateral wall (c, green arrow; e, black arrow). When correcting for this artifact, the tracer uptake normalized in this region (d, green arrow; f, black arrow). This artifact caused a relative difference of more than 10% in the respective region (g). (Reprinted with permission from Lassen, M.L., Rasul, S., Beitzke, D. et al. *J. Nucl. Cardiol.* (2017). <https://doi.org/10.1007/s12350-017-1118-2>)

There are various radiotracers for PET MPI with different limitations and pitfalls. N-13 ammonia and Rubidium-82 are the only FDA-approved radiotracers for this indication. Other radiotracers are O-15 water and the recently introduced F-18-Flurpiridaz. O-15 water ($T_{1/2} = 122$ s), Rubidium-82 ($T_{1/2} = 76$ s) and N-13 ammonia ($T_{1/2}: 10$ min) are radiotracers with a short half-life and consequently, as a prerequisite an on-site cyclotron is needed or a cost-intensive generator has to be purchased every month. Therefore absolute blood flow quantification is often only available at specialized centers. O-15 water has been extensively studied as perfusion tracer and is thought to be superior due to its free diffusion and thus almost perfect first pass extraction. However, O-15 water is not FDA-approved and there is no reimbursement from healthcare insurance companies.

Because of the accessibility and beneficial properties of F-18 for PET imaging, novel F-18-labeled perfusion radiotracers are being developed. One of the most prominent PET perfusion tracers is F-18-Flurpiridaz, which is still evaluated in clinical phase 3 trials [25–27].

F-18 flurpiridaz has a high first pass extraction of 94% [25] and F-18 has the advantage of a low positron energy ($E_{max} = 634$ keV). Furthermore, neither a cost-intensive and MRI-incompatible Rb-82 generator nor an onsite cyclotron is needed because of its longer half-life ($T_{1/2} = 110$ min). These novel F-18-labeled radiotracers might lead to a wide availability of PET MPI.

Fig. 12.2 Simultaneous myocardial perfusion imaging using PET/MRI. This figure depicts a combined PET/MRI perfusion study of a patient with hypertrophic cardiomyopathy. On N-13 ammonia images a dilation of the left ventricle from rest to stress and a inhomogeneous myocardial perfusion during pharmacological stress can be observed. MR images demonstrate that this apparent dilation of the left ventricle is actually caused by a hypoperfusion of the endocardium during hyperemia. (Reprinted with permission from Kunze KP, Nekolla SG, Rischpler C, et al. Myocardial perfusion quantification using simultaneously acquired $^{13}\text{NH}_3$ -ammonia PET and dynamic contrast-enhanced MRI in patients at rest and stress. *Magn Reson Med*. 2018;00:1–14. <https://doi.org/10.1002/mrm.27213>)

In contrast to that MRI has different advantages and disadvantages in myocardial perfusion imaging and MRI MPI has been widely established. It provides high spatial resolution and is potentially capable to detect small subendocardial areas of ischemia without exposing the patient to ionizing radiation. In the early 1990s the feasibility of MRI with gadolinium-based contrast agents for detecting flow-limiting coronary artery disease (CAD) was first demonstrated [28] and since then many studies reaffirmed its value [29, 30]. Nonetheless one limitation of these studies is that they are mostly based on visual analysis which makes detection of balanced ischemia in advanced CAD difficult (similar to SPECT MPI) [31, 32]. To exceed these limitations many approaches focus on quantifying myocardial blood flow using MRI. One of the simplest methods is the upslope ratio to determine the coronary flow reserve [33]. The central volume principle of quantifying myocardial blood flow is a more complex method that has been used to compare PET and MRI MPI in a group of 41 patients [34, 35]. In that study a good agreement with coronary flow reserve was observed whereas the absolute myocardial blood flow values showed a high variance. Kunze et al. showed recently a good agreement between the two methods in absolute flow values but with underestimated coronary flow reserve by MRI because of an overestimation of resting perfusion in MRI irrespective of the applied MRI deconvolution method [36]. Additionally, in that study it was demonstrated in one patient with hypertrophic cardiomyopathy that MRI is capable of the differentiation between subepicardial and subendocardial blood flow due to higher spatial resolution (see Fig. 12.2). The problems of flow quantification in MRI are mainly but not solely because of the Gd-based contrasted agents. These contrast agents are not taken up by the

cardiomyocytes and suffer from a low “extraction fraction,” which is also not only perfusion dependent. Therefore, this makes quantitative myocardial perfusion assessment using MRI challenging. Another disadvantage is that MRI MPI usually images only a certain number of slices of the left ventricle but does not cover the whole left ventricle like in PET or SPECT MPI. For therapy guidance the extent of whole left ventricular ischemia is a key factor [22], the estimation of this parameter in MRI may be inaccurate when using only three slices of the left ventricle. While approaches have been undertaken to enable 3D first pass perfusion MRI for the estimation of myocardial blood flow in the whole left ventricle, this technique is far from being used in clinical routine.

Hybrid PET/MRI may be a great tool for cross-validation of the two modalities with respect to complicated quantification methods in MRI. It allows the detection of subendocardial ischemia in MRI while PET MPI provides a reliable way to measure absolute myocardial perfusion of the whole left ventricle.

12.4 Myocardial Viability Imaging

Myocardial viability imaging is used to identify chronically hypoperfused myocardium. This myocardium has a changed metabolism from fatty acids to glucose and often shows contractile dysfunction, which is called “hibernation” [37]. Hibernating myocardium has prognostic relevance because its presence is associated with poor cardiovascular outcome and its extent is important in therapeutic guidance, because hibernating myocardium is prone to recover after revascularization [38–42].

Non-invasive methods for the assessment of myocardial viability are, for example, dobutamine stress echocardiography and MRI, Thallium-201 SPECT or F-18 FDG-PET, and late gadolinium enhancement (LGE) MRI, the latter two being two most commonly used methods [43].

For F-18-FDG-PET viability imaging a special metabolic preparation is needed to increase myocardial glucose uptake. A variety of methods are known to increase the glucose transporter expression on cardiomyocytes. A common one is oral glucose loading and the hyperinsulinemic-euglycemic clamp technique. Based on a meta-analysis, FDG-PET has a 92% sensitivity and 63% specificity among viability imaging approaches [44].

As an alternative cardiac MR late gadolinium enhanced (LGE) imaging has emerged lately. LGE utilizes the fact that Gadolinium-chelate-based contrast agents have a slower wash-out in areas with increased extravascular space, e.g. fibrotic/scarred myocardial tissue, compared to a normal wash-out from viable, non-scarred myocardium [45, 46]. Therefore, LGE MR images scarred, non-viable, myocardium compared to F-18-FDG-PET whose objective is to identify viable, hibernating myocardium. But despite these fundamentally different approaches a good agreement between both modalities has been shown [47]. In comparison to FDG-PET LGE MRI has a higher spatial resolution which opens up the opportunity to differentiate between transmural and non-transmural scarring; furthermore, small myocardial scars can be unmasked which proposes prognostic value and clinical relevance [48, 49].

A recent study showed different diagnostic accuracies of PET and cardiac MR depending on the left ventricular function [50]. In that study cardiac MR revealed more scars in patients with ejection fraction (EF) of <30% and 30–50% compared to FDG-PET, but FDG-PET found more scars in patients with EF > 50%. In terms of functional recovery prediction (e.g. after revascularization) PET was found more optimistic than cardiac MR.

Up to date F-18-FDG-PET/MRI in viability imaging is not thoroughly researched and there are only few representative studies. The three currently published studies reported variable agreement between FDG-PET and MRI ranging from moderate to significant (Fig. 12.3) [51–53]. One of those studies recruited a small patient cohort prior to elective revascularization for coronary artery disease and observed a reclassification in 19% of segments in hybrid FDG-PET/MRI compared to SPECT and CMR alone [51]. However, the investigators did not show follow-up data to validate the clinical impact of the reclassification. The other two mentioned studies focused on FDG-PET/MRI after myocardial infarction rather than prior to revascularization and a high intermethod-agreement for transmural LGE and reduced FDG uptake in myocardial segments was found. Furthermore, in one study a better recovery of wall motion of both PET and MRI viable dysfunctional segments could be shown. Additionally, segments with a contradicting pattern of FDG uptake and LGE transmural LGE were demonstrated, namely a decreased FDG uptake with a non-transmural or minor LGE. Only 40% of these contradicting patterns had an improved wall motion after 6 months. [52]. Nensa et al. investigated the alteration of glucose metabolism in the area of infarction in relation to the infarct size measured by LGE MRI and to the myocardium at risk, which was assessed by the endocardial surface area method (ESA) [54]. By definition of this method all myocardial segments which demonstrate any LGE (regardless of degree and transmural LGE) define the area at risk. As anticipated, the area at risk was larger than the actual infarct area

Fig. 12.3 FDG PET/MRI for viability imaging. A 63-year old man was referred to our institution for FDG PET/MRI viability imaging for a known chronic total occlusion of the left anterior descending artery (LAD). Late gadolinium enhancement (LGE) MRI depicts a transmural scar of the anterior wall (left panel). FDG PET shows a well-matched reduction of FDG uptake in the identical region (right and middle panel). Also, a severe wall motion abnormality was observed in this area. Taken together these images demonstrate that myocardium is non-viable in the LAD territory

($31 \pm 11\%$ vs. $10 \pm 10\%$). Interestingly, the area at risk correlated with the extent of reduced glucose metabolism suggesting that myocardium has a decreased FDG uptake early after an ischemic event. But there is no conclusive pathophysiological rationale for this so far and further studies are needed to clarify those findings. To this date no prospective study has been published which evaluated the diagnostic value of myocardial viability FDG-PET/MRI prior to revascularization with follow-up examinations after treatment to estimate the predictive value of hybrid imaging in this setting.

12.5 Conclusion

In cardiac imaging PET/MRI offers unique possibilities not just as a research tool but as well in specific clinical questions. Combined analysis of PET and MR in perfusion and viability imaging successfully provides synergistic functional and morphological information. New radiotracers might further uplift cardiac PET/MRI in the future. Nonetheless the current technologies still have constraints which need to be overcome. Long acquisition times, narrow scanners, and a strong magnetic field need thorough patient screening and preparation and on top of that PET/MRI is very cost-intensive and will therefore not be broadly available.

13.1 Introduction: A Brief History of Hybridization

Positron emission tomography (PET) and magnetic resonance imaging (MRI) are among the most advanced cardiovascular imaging modalities currently available. PET, first introduced in its modern form in 1990 [1], uses scintillation mapping to detect positrons released from administered radiotracer-labeled chemicals [2]. Based on the chemical-radiotracer combination used, various physiologic processes can be assessed including myocardial blood flow, metabolism, and inflammation. However, the lack of precise anatomical localization of functional abnormalities as well as the need for a more rapid and consistent source for attenuation correction have prompted the development of hybrid PET imaging. Following the successful example of SPECT/CT [3], PET/CT was introduced in 2001, and found widespread usage due to its more rapid image acquisition than the traditional germanium-68 rod sources [4] as well as its ability to accurately detect coronary artery calcifications [5] and to identify clinically relevant extra-cardiac findings [6]. These advantages of hybrid PET/CT were sufficient to overcome initial reluctance to its use due to its increased relative cost over germanium-68 rods.

MRI was the natural next target for hybrid PET imaging. Since the first commercial system was made available in 1980 [7], MRI has revolutionized medical imaging with its unsurpassed tissue characterization [8]. By detecting energy emitted from radiofrequency (RF) pulse-aligned protons as they process in a magnetic field, MRI can generate images without the hazards of exposure to ionizing radiation [9]. Furthermore, cardiac magnetic resonance (CMR) excels at delineating anatomy, quantifying left and right ventricular function, and assessing global and regional myocardial contractility. Diffusion MRI offers the ability to measure myocardial blood flow, and late gadolinium enhancement (LGE) on contrast studies can accurately identify regions of myocardial scar [10]. The further development of parametric mapping techniques including T1 and T2 mapping has allowed for quantification of myocardial inflammation and fibrosis [11]. Therefore, cardiac PET and MRI

provide both complementary and potentially corroborative information rendering them potentially ideal partners for hybridization.

13.2 Challenges to PET/MRI

There are several challenges to the successful application of PET/MRI, many of which have not been completely solved. These can broadly be classified into technical issues, patient/workflow issues, and personnel issues.

13.2.1 Technical Issues

13.2.1.1 Hardware Incompatibilities

While Garlick and colleagues pioneered hybrid cardiac PET/MRI imaging using isolated mammalian hearts [12], true clinical hybrid cardiac PET/MRI was not available until 2011 [13]. The major barrier to an integrated PET/MRI scanner at the time had been the incompatibility between the hardware components of the two systems. For instance, the presence of unshielded PET detectors within the MRI magnet coils could disrupt the uniformity of the generated magnetic field, a stringent prerequisite to obtaining MRI images, necessitating the use of PET crystals that have inherently favorable magnetic properties such as lutetium-based crystals [14]. Furthermore, shielding the PET detectors in copper and in essence creating a small Faraday cage around each detector has been demonstrated to inhibit electromagnetic interference emanating from the detector which would otherwise distort the MRI image [13].

Conversely, PET image quality can be negatively impacted by the MRI hardware. For example, the photomultiplier tubes (PMT) used in conventional PET detectors to convert scintillation events into electronic signals fail to function properly in a strong magnetic field due to the Lorentz force [14]. Fortunately, the advent of semiconductor-based avalanche photodiodes, which are not affected by magnetic fields, has alleviated this concern [13].

13.2.1.2 Attenuation Correction

Another pertinent challenge with PET/MRI is the difficulty in performing PET attenuation correction (AC). Attenuation is the phenomenon where positrons are lost from the detector's field of view (FOV) due to dispersion or absorption in dense tissues, leading to weaker signal in denser/deeper regions with the consequent possibility of missing existing areas of abnormal radiotracer uptake. Conventionally, initial transmission scans with germanium-68 radionuclide rods were performed to create an electron density map of the tissues which was subsequently applied to PET data to correct for attenuation artifacts [4]. With the advent of PET/CT, attenuation correction is now increasingly performed using co-registered CT density data. With PET/MRI, MRI measures *proton spin* density, which does not correlate with electron density and consequently cannot be used to perform attenuation correction.

Furthermore, the limited space inside the PET/MR scanner (see Sect. 13.2.2) does not allow for the installation of additional equipment for germanium-68 transmission scans. Several approaches have been considered to address this issue [15–17], with the Dixon 2-point method as one potential solution [18, 19]. This system employs Dixon sequencing to segment tissues into four classes, each with a predetermined attenuation coefficient: lung, fat, soft tissue, and background (Fig. 13.1). While shown to provide results comparable to CT attenuation, this method, however, does not separately classify bone, but rather considers it in the same category with soft tissue, underestimating attenuation values near bony areas such as retrosternally [20]. Potential workarounds include semi-automated addition of atlas-based bone information [21] or using ultrashort echo time (UTE) sequences to separately segment bone [22].

A more recent approach is using MR data to generate “pseudo-CT” images for the patient which can be used for AC. These images are computed based on observed relationships between MR and CT images from population studies and can be either voxel, patch or machine-learning based [23]. This approach has been well-validated in neuroimaging [24], but has yet to be tested for cardiac or whole-body applications.

Patient tissues are not the only concern when performing attenuation correction in PET/MRI. Fixed and flexible phased-array RF coils are routinely used for MRI signal enhancement, with the fixed components being part of the patient table, and the flexible components placed anteriorly on the patient’s chest. Since these components are not entirely PET transparent [25], their attenuation effects need to be accounted for as well. This is performed using pre-acquired CT density maps which

Fig. 13.1 Part of an MR segmented four-class attenuation map generated by the two-point Dixon method (Lean tissue = white, adipose tissue = pink, lung = blue, air = black). (Reproduced with permission from Muzic RF, Jr., DiFilippo FP. Positron emission tomography-magnetic resonance imaging: technical review)

are aligned to the coils using the table position as a reference in the case of stationary coils [26], and MRI-detectable position tags for the flexible components [27].

13.2.1.3 Motion Correction

Although integrated PET/MR scanners boast the benefit of “simultaneous” acquisition, this is not entirely the case; since MRI acquisition is sequential (milliseconds to a few seconds) while PET acquisition is volumetric, typically over a period of 10–30 min. These longer acquisition times render PET motion artifact-prone. While modern PET scanners can reach spatial resolutions up to 4–6 mm in still tissues [28], cardiac PET resolution is typically less due to cardiac and respiratory motion [29], the combination of which can cause myocardial tissue to move by as much as 5–10 mm between respiratory cycles. Motion can also lead to faulty attenuation correction if the patient moves after generation of the tissue density map.

To address this issue, ECG gating is commonly used to generate the image over multiple cardiac cycles. Respiratory gating is also sometimes employed. However, both come at the cost of increased noise (expressed as signal to noise ratio, SNR) which results from the rejection of too many beats in a short interval [30]. In addition, gating techniques are not suitable for imaging of rapidly-changing processes such as myocardial blood flow quantification.

The PET/MRI combination has the potential to solve this dilemma by incorporating real-time MRI generated motion data to correct for cardiac, respiratory, and patient motion, as well as to apply the necessary adjustments to the density map prior to AC [31]. Tissue deformation is measured using MRI “tagging,” where a sequence of RF pulses is used to create a lattice of magnetization “tags” in the tissue which persist long enough to allow their tracking by MRI as they move. MRI motion correction of PET data has the promise of providing images with excellent spatial resolution without the reduction in SNR that occurs with “stop-motion” ECG gating [31].

13.2.1.4 Magnet Bore and FOV

A consequence of placing the 360 degree PET detector array within the MRI scanner is that the magnet bore is smaller than in a conventional MRI machine (60 cm vs. 70 cm respectively), precluding the imaging of larger patients (Fig. 13.2) [14]. Furthermore, the FOV of the magnet is even smaller, typically 50 cm, which means that in large patients who do fit inside the magnet, peripheral parts of the body may fall outside the magnet FOV (especially when acquisition is performed with the patient’s arms at his sides as is frequently the case) and are hence “truncated” (and fail to appear on the Dixon attenuation maps), leading to inaccurate attenuation correction [14]. Proposed solutions to circumvent this issue include utilizing nonspecific PET tracer uptake data from the truncated regions to complete the MRI AC map using a maximum likelihood reconstruction of attenuation and activity (MLAA) algorithm [32] or extending the MRI FOV by applying B_0 homogenization using gradient enhancement (HUGE) [33]. The latter solution is preferable since some tracers are highly specific and do not show significant uptake outside target areas.

13.2.1.5 Software Considerations

While there are no available software packages to date with support for fully integrated PET/MRI data, there are several which can handle fusion and analysis of co-acquired or even separately acquired PET and MRI data, although most are geared toward oncology and are not designed for optimal performance for processing cardiology-specific tasks such as ventricular volume and function calculation, myocardial blood flow estimation, and polar map generation. A technique for integrated analysis of cardiac PET and MRI data using co-registered polar maps and mutual segmentation of myocardial boundaries has recently been developed, which may allow for accurate segmentation and inherent co-registration [34].

In addition, with the amount of information generated by both PET and MRI data as well as the post-generated co-registration and attenuation data among others, the size of the resultant datasets is unusually large, and devising efficient strategies for handling, storing, displaying, and reconstructing these large datasets poses numerous technical challenges.

13.2.2 Patient/Workflow Issues

The long acquisition times required for PET/MRI may be difficult for some patients, especially with breath-hold MRI sequences which require increased patient compliance. Longer scan times also make it more difficult to establish an efficient laboratory workflow, especially in the case of separate MRI and PET machines. Integrated PET/MRI machines offer shorter scanning times, particularly with newer acquisition protocols where redundant/overlapping information is eliminated but is currently limited by availability and technical issues described.

13.2.3 Personnel Issues

The degree of complexity involved in the acquisition, processing, and interpretation of PET/MRI data brings with it the need for highly trained personnel including technologists, physicists, and physicians of multiple disciplines interacting as a team. While there is no formal certification process as of yet for hybrid PET/MRI technologists, the skills involved—aside from operation of the MR scanner—include hotlab work, managing and monitoring the patient after radiotracer administration, as well as any necessary troubleshooting and data post-processing. This entails not only the presence of both a traditional MRI technologist and a nuclear medicine certified technologist, but also that they preferably be dual-trained to optimize seamless integration of the two modalities [35].

13.2.4 Cost

Cost remains a significant barrier to widespread clinical acceptance of PET/MRI. PET/MRI scanners are currently approximately twice as expensive as PET/CT scanners [36], a cost which could be prohibitive in many institutions. Further clinical studies are required to establish the cost-effectiveness of PET/MR before widespread application.

13.3 Advantages of PET/MRI

13.3.1 Compared to Separate PET and MRI

Aside from the potential advantage of improved sensitivity and specificity resulting from combining two already accurate modalities, co-acquisition of PET and MRI data, rather than performing each scan separately, offers several benefits. Simultaneous scanning ensures that patient position is preserved between PET and MRI acquisitions, allowing for more accurate co-registration and minimizing alignment artifacts. In addition, the ability to use real-time MRI data for motion correction of PET images offers the promise of improved spatial resolution without compromising SNR. The simultaneous response on PET and MR imaging to a single stimulus, such as adenosine or regadenoson, in myocardial perfusion imaging is also an advantage. Finally, the ability to combine two examinations into one is more comfortable and efficient for patients, and more conducive to a streamlined workflow, particularly with short acquisition protocols.

13.3.2 Compared to PET/CT

The advantages of PET/MRI over its more established counterpart PET/CT relate to the advantages of MRI over CT, namely, the improved temporal resolution, superior

myocardial tissue characterization, and the lack of iodinated contrast and additional ionizing radiation exposure. It is noteworthy that, with the time spent in MR acquisition, PET acquisition time is also increased, allowing for the use of even lower radiotracer concentrations (as low as one half the usual dose), without compromising image quality [37].

Cardiac MRI can also elicit important information similar to cardiovascular PET, such as myocardial blood flow (MBF) and late gadolinium enhancement (LGE) of the myocardium denoting scar or inflammation.

13.4 Applications of PET/MRI in Inflammatory Heart Disease

Integrated or simultaneous PET/MRI is particularly suited for imaging inflammation in the heart due to the ability to combine tissue characterization, and to visualize, measure, and follow disease activity. The prognostic strength of both modalities has made the hybrid approach an appealing tool in the diagnosis and management of complex disease entities such as cardiac sarcoidosis (CS). Other promising targets in inflammatory heart disease include myocarditis and endocarditis. We will discuss each of these in detail below.

13.4.1 Sarcoidosis

13.4.1.1 Background

Sarcoidosis is a multisystem granulomatous inflammatory disease of uncertain etiology. While involvement of the lungs and lymph nodes is most common, sarcoidosis can also affect the heart, occurring anywhere from 5% in those with clinically manifest disease to 80% in imaging series of sarcoidosis patients [38]. Importantly, CS is the most common cause of death in sarcoidosis patients [38]. Detection of CS is critical but challenging, due to the lack of clinical manifestations during the initial stages in the majority of patients. Furthermore, traditional diagnostic techniques such as right ventricular biopsy and echocardiography have poor sensitivity for the detection of CS [39]. Therefore, the need for advanced diagnostic imaging is critical for this patient population. Both cardiac PET and MRI have emerged as important tools for evaluating patients with known or suspected CS. Both tests provide useful information to help establish the diagnosis, determine prognosis, guide management, and follow response to therapy [40]. Below we first discuss each modality, including unique strengths and limitations. We then examine how the combination of PET and MRI together may provide complementary clinical information and add incremental diagnostic and prognostic value in patients with known or suspected CS than each imaging modality alone.

Cardiac PET may be performed for suspected or known CS in the following scenarios: (1) In the presence of known extra-cardiac sarcoidosis and abnormal screening for CS, including electrocardiographic, Holter, or imaging abnormalities, or unexplained palpitations or syncope; (2) the young patient with advanced

conduction system disease, (3) patients with idiopathic VT; or (4) patients with proven CS to follow response to treatment [41]. PET imaging for CS requires two sets of images, a myocardial perfusion image, preferably with PET, and a dedicated cardiac ^{18}F -Fluorodeoxyglucose (FDG) image, to differentiate the diagnostic and prognostic spectrum of CS. FDG is a glucose analogue widely used to assess inflammation. FDG has the unique ability to detect and quantify disease activity at the cardiac and extra-cardiac levels [41]. With the same injection of FDG, a limited whole-body acquisition that includes at a minimum the chest, liver, and spleen is also recommended, as the presence of extra-cardiac disease (Fig. 13.3) is important not only for the diagnosis of CS, but also for prognosis, potential biopsy sites, and for overall management of patients with known or suspected CS. Focal or multifocal myocardial FDG uptake, particularly in the presence of associated perfusion defect(s) (Fig. 13.4) and in the absence of coronary artery disease, is consistent with CS, especially when extra-cardiac activity is present, and warrants consideration of immunosuppressive therapy in the appropriate clinical context [42]. Areas of

Fig. 13.3 FDG-PET/CT fusion image showing multifocal metabolic activity in the lower neck and chest and lungs, as well as spleen and possibly the right hepatic lobe, compatible with active extra-cardiac sarcoidosis

Fig. 13.4 PET perfusion with N13-ammonia (top row) and FDG (bottom row). Left 3 columns: short-axis view showing moderate to severe perfusion abnormalities in the apical inferior, basal anterior and septal segments with corresponding focal myocardial FDG uptake in the same segments. Right column: Vertical long-axis view showing perfusion defect in basal anterior segment and apex, with corresponding FDG uptake. Results compatible with active cardiac sarcoidosis

Fig. 13.5 PET perfusion with N13-ammonia (top row) and FDG (bottom row). Left 3 columns: short-axis view, right column: vertical long-axis view. Diffuse (physiologic) FDG uptake is observed, secondary to suboptimal patient preparation

fibrosis are more difficult to identify by PET than by MRI but may include a perfusion defect without associated FDG uptake. A limitation of FDG is that glucose also serves as an energy substrate for the myocardium and nonspecific physiological myocardial FDG uptake (Fig. 13.5) can occur despite adequate patient preparation with high-fat, low carbohydrate meals and/or prolonged fasting. Another useful feature of cardiac PET is the ability to quantify FDG uptake which is particularly suitable for serial imaging to follow the effects of treatment. The prognostic value of cardiac PET in CS has also been demonstrated in several observational studies. Blankstein et al. demonstrated that patients with both a perfusion defect and abnormal FDG uptake had a fourfold risk of death or ventricular arrhythmia [43]. Sperry

et al. corroborated these findings by showing that patients with abnormal FDG-PET were more likely to meet the same composite endpoint [44]. Total cardiac metabolic activity (tCMA), LV standardized-uptake-value (SUV) max, pathological right ventricular FDG uptake were specific markers shown in a number of studies [43, 45, 46] to correlate with the rate of adverse cardiac events, and their interval improvement on serial studies was found to be associated with reduction of adverse cardiac event risk [47].

MRI is powerful in its ability to provide detailed tissue characterization and cardiac morphology, in addition to accurate assessments of cardiac function [9]. A typical MRI protocol for cardiac sarcoidosis commences with a localizer scan followed by balanced steady-state free precession imaging to assess cardiac chamber size and function. Short-axis T2-weighted, fat-suppressed imaging is then performed to assess for the presence of edema (representing inflammation). Next intravenous gadolinium is administered, and first pass resting perfusion imaging is assessed. Finally, delayed enhancement imaging is performed to assess for inflammation and/or scar. Late gadolinium enhancement (LGE) permits visualization of myocardial injury or fibrosis due to CS [40] and is often subepicardial, mid-myocardial, and transseptal in location in CS [48]. Fibrosis or scar by MRI LGE is observed more frequently than fibrosis by PET [48]. While myocardial edema signifying inflammation can also be observed as increased T2-weighted signal on MRI, this approach is technically challenging and continues to have difficulties in differentiating between active disease (inflammation) and scar in CS. As shown in Fig. 13.6, an area of transmural LGE in the basal lateral aneurysm was initially thought to represent scar but FDG-PET demonstrated activity consistent with inflammation in a substantial portion of the area of LGE. Another drawback of MRI is its limitations in detecting extra-cardiac disease, which is necessary to diagnose CS via the clinical pathway of most diagnostic algorithms [49, 50]. Complementary to PET, however, MRI has the major advantage of assessing for alternative diagnoses to CS, which also has important diagnostic and prognostic implications [51]. In regard to prognosis, more studies are available with MRI than with PET and are consistent in showing that the presence of delayed enhancement portends a substantial increase in the risk of death or appropriate shock from an internal cardiac defibrillator [52]. In a meta-analysis of 694 patients from seven studies, a sixfold increase in the risk of a composite endpoint of mortality or ventricular arrhythmia was observed in the presence of abnormal delayed enhancement [53]. Another similar meta-analysis of 760 patients from ten studies showed an even higher (tenfold) risk of the composite endpoint [54].

Although studies have attempted to determine the diagnostic accuracy of cardiac PET and MRI for CS, these studies were severely limited by the use of the JMHW criteria as the reference standard [55]. A recent meta-analysis [56] that included 17 studies, representing 891 patients, reported a pooled sensitivity of 84% and a pooled specificity of 83% for PET. A similar meta-analysis for CMR [57] reported a pooled sensitivity of 93% and a pooled specificity of 85%. However, these estimates are biased as the lower specificity of PET in some studies may reflect the fact that this test is more sensitive than the JMHW criteria for identifying CS.

Fig. 13.6 Top: MRI 4-chamber (left) and basal short-axis views (right) showing an aneurysmal basal lateral segment with transmurial delayed enhancement denoting scar. Bottom: N-13 ammonia and FDG-PET showing decreased perfusion but intense FDG uptake in the corresponding segment, indicating active inflammation as opposed to scar

The Hybrid Approach

The 2014 HRS expert consensus statement [49] and the Japanese Society of Sarcoidosis [50] recommend performing either CMR or FDG-PET in patients with biopsy-proven extra-cardiac sarcoidosis and suspected CS. The preference of one over the other has been a source of debate, and in practice both modalities are frequently ordered for the same patient owing to the lack of defining features on either and the complementary nature of the information they afford. By conveniently bundling the two, PET/MRI offers a one-stop solution to the conundrum, with emerging evidence to support the hybrid approach over separate PET and MRI [58, 59].

Studies have shown that using the hybrid approach can correctly classify patients missed by using either modality alone, thereby reducing false negatives. Vita et al. showed that including patients with either LGE on MRI or FDG on PET correctly reclassified 36% of patients to a higher or lower likelihood of CS [60].

Wicks et al. [61] supported this finding by demonstrating the superior sensitivity of the hybrid approach compared to either MRI or PET (sensitivity 94% versus 82% and 85% respectively). They went further to show that having abnormalities on both modalities (Fig. 13.7) was the strongest predictor for major adverse cardiac events (Fig. 13.8), highlighting not only the diagnostic but also the prognostic role of the hybrid approach.

Interestingly, the same study found that correlation between the two modalities in terms of the location of abnormalities was actually quite poor (Cohen's kappa: 0.02) [61], although this may simply represent disease progression/regression between scans.

Dweck et al. examined in closer detail the cases where LGE and FDG did not match [62]. In the one patient who had LGE on MRI but no FDG uptake on PET, the clinical scenario was consistent with inactive cardiac sarcoidosis and residual

Fig. 13.7 Concordant LGE and FDG uptake on PET/MR images in a patient with biopsy-proven cardiac sarcoidosis in short axis (top row—**a–c**) and long axis (bottom row—**d–f**). *Left columns:* MIP images depicting lateral FDG uptake (arrow). *Middle column:* patchy epicardial and mid-myocardial LGE (arrow). *Right column:* fused images demonstrating corresponding LGE and FDG uptake (arrow). *FDG* fluorodeoxyglucose, *LGE* late gadolinium enhancement, *MIP* maximum intensity projection, *PET* positron emission tomography. myocardial scar. Conversely, MRI negative, PET positive patients were compared to a cohort of normal controls, 58% of which also showed the same discrepancy. The authors therefore concluded this was due to failure of physiologic myocardial suppression, including cases with focal or diffuse FDG uptake pattern, which in both groups were localized to the inferolateral wall [62].

13.4.2 Myocarditis

PET/MRI findings in myocarditis are similar to findings in sarcoidosis (Fig. 13.9), namely LGE and increased T2 signal on MRI and increased FDG uptake on PET, with the distinction being mainly based on the clinical context. Several case reports have demonstrated the usefulness of PET/MRI in diagnosing viral myocarditis [63, 64], with a more recent study showing higher detection rates with PET/MRI than either PET or MRI alone, although the study was not sufficiently powered to reach statistical significance [65]. In addition to detection, PET/MRI is useful for

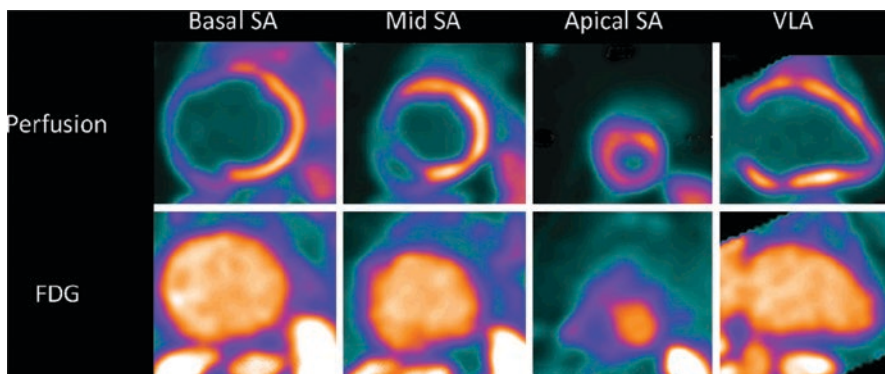

Fig. 13.9 Myocardial FDG-PET of a patient with biopsy-proven giant cell myocarditis “burnt-out” showing a large perfusion defect involving the basal and mid ventricular septal as well as mid ventricular inferior wall with no definitive abnormal FDG uptake

Fig. 13.10 Patient with pericarditis. Left: MRI short-axis views showing significantly increased pericardial thickness (top) with circumferential late gadolinium enhancement (bottom). Right: FDG-PET of the same patient showing intense pericardial FDG uptake. PET views clockwise from top left: apical short axis, mid-short axis, basal short axis, horizontal long axis

monitoring disease activity, response to therapy, and distinguishing between the acute and chronic/persistent variants of myocarditis.

Pericarditis (Fig. 13.10) is often associated with myocarditis (perimyocarditis), and while there is a paucity of literature on the role of PET/MRI in the diagnosis, a recent study has demonstrated feasibility and potential usefulness [66].

13.4.3 Endocarditis

Endocarditis is a dreaded complication affecting prosthetic and native heart valves alike. While transesophageal echocardiography (TEE) shows excellent sensitivity for the detection of the disease in native valves (as high as 92% in some studies) [67], it may not be able to detect the sequelae of the disease in prosthetic heart valves. In these patients, FDG-PET can detect valvular and perivalvular inflammation at an early stage and, when combined with CT, has a higher sensitivity than TEE or multidetector CT angiography (83% vs 75% for both) [68].

MRI can visualize prosthetic valve morphology and identify flow abnormalities as well as annular dehiscence [69], although metal extinction artifacts can significantly interfere with image quality and, in the case of PET/MRI, be incorporated into attenuation correction maps leading to PET tracer uptake underestimation. Data on integrated PET/MR imaging of infective endocarditis patients is lacking, but an ongoing study might hopefully shed some light once completed [70].

13.4.4 Atherosclerotic Plaque Risk Stratification

PET has recently been used to image and risk-stratify inflammation in the aortic valve [71, 72] and arterial atherosclerotic plaques [73], and MRI's tissue characterization makes it an ideal adjunct to PET in that regard since the combination can provide both accurate morphological information on plaque composition as well as visualization of relevant biological processes such as inflammation or neovascularization.

In a more recent study, coronary artery imaging was successfully performed using hybrid PET/MRI with either FDG or the novel radiotracer ^{18}F -NaF, and was able to demonstrate elevated radiotracer uptake localized to individual coronary lesions [74].

This is an attractive prospect since acute complications of atherosclerosis frequently occur in the absence of significant luminal occlusive disease, with no single marker for what constitutes an "unstable" plaque but rather an incompletely understood interplay between a multitude of factors. With MRI's safety profile and the potential for whole-body imaging, atherosclerosis imaging of the entire vascular tree could soon become a reality.

13.4.5 Preclinical Applications

PET/MRI has tremendous potential to help further our understanding of various biological and pathological processes. With the availability of integrated PET/MR scanners for animal models and novel radiotracers being continually developed which can map new molecular and cellular markers and/or even deliver treatment, PET/MRI has become an attractive target for preclinical research. A number of trials are already ongoing which hold exciting prospects (see Sect. 13.7).

Fig. 13.11 Hybrid PET/MRI inflammation imaging protocol. For PET, $^{13}\text{N-NH}_3$ is administered followed by rest perfusion imaging and MBF. FDG is then administered and inflammation imaging is performed, followed by limited whole-body imaging for extra-cardiac disease. For MRI, after the initial scouting images and Dixon attenuation sequencing, Cine MRI images are obtained followed by T1 + T2 mapping. Gadolinium is then administered, followed by perfusion imaging/MBF (this step can potentially be skipped in favor of PET perfusion alone) and LGE mapping, then limited whole-body imaging for extra-cardiac co-localization. T2 weighted sequences and T1 and T2 mapping could potentially be dropped for hybrid acquisition, and similarly gating information can be acquired from MRI only. *MBF* myocardial blood flow, *LGE* late gadolinium enhancement

13.5 Acquisition Protocol and Patient Preparation

13.5.1 Inflammation Protocol

Normal myocardium exhibits some degree of physiological glucose avidity through GLUT4 transporters activated by insulin in response to dietary glucose intake. Inflammation imaging with FDG-PET requires that myocardial metabolism be shifted from glucose utilization to almost exclusive fatty acid consumption, ensuring that any subsequent FDG uptake will be by abnormal, inflamed tissues in which glucose (or FDG) can enter through the constitutively expressed GLUT1 and GLUT3 transporters. FDG is then phosphorylated intracellularly and hence trapped, enabling metabolic imaging by PET [75].

Myocardial glucose suppression can be achieved by prolonged (12–18 h) fasting or high-fat low-carbohydrate (HFLC) diet, with a combination of the two shown to be superior at suppressing physiological myocardial FDG uptake [76]. Based on expert consensus [41] and clinical experience, we recommend at least a 1-day high-fat, low-carbohydrate diet followed by a 12–15 h fast for optimal myocardial suppression, with up to a 91% success rate [41].

A proposed protocol for inflammation imaging by hybrid PET/MRI is outlined in Fig. 13.11 [77].

13.6 Study Interpretation and Reporting

These suggestions are based in part on the ESCR and EANM guidelines with modifications by the authors [77]. The guidelines recommend a unified report for hybrid PET/MR findings, but in practice reimbursement policies require two separate CPT codes for PET and MRI (there is yet to be a CPT code for hybrid

PET/MRI), often each with separate pre-authorizations, which may entail the writing of two separate reports which can reference each other's findings. Patient name, age, weight, and height should be reported, along with a brief medical history. Any relevant patient preparation should be described (see Sect. 13.5). The type and dose of any drug used (e.g. vasodilators) should be specified. For radiotracers, the name, route, and time of administration and amount of activity in MBq should be listed. Time interval between radiotracer administration and acquisition should be noted, and details on the PET/MR equipment should be included along with a short description of the protocol used. The dose of gadolinium administered—if any—should be indicated.

The location, extent, and degree of perfusion defects both on PET and MRI as well as abnormal myocardial FDG uptake on PET and LGE on MRI should be reported in accordance with standardized references [78]. The degree of abnormal FDG uptake should be classified as mild, moderate, or intense, and supported with quantitative measures when applicable (e.g. SUV, perfusion in mL/min/g). The span of LGE should be noted as subendocardial, mid-myocardial, subepicardial, or transmural. For the cardiac MRI examination, the standard components, EDV, ESV, SV, EF, CO, and CI should be reported, along with any abnormal increased wall thickness, focal wall thinning, or wall motion abnormality at rest. If there are other imaging studies or previous PET/MRI exams, then they should be used for comparison and the discrepancies/similarities reported.

Finally, caveats should be noted when present which might adversely affect exam accuracy such as significant patient motion or extra-cardiac radiotracer uptake interference.

The report summary should include overall normality/abnormality of the study, along with a final diagnosis if possible. The referring physician's specific questions should be clearly answered. Approval of the interpreting physicians should be documented together with communication of urgent findings to the referring physician.

13.7 Future Directions

The long scan times in PET/MRI are a source of significant discomfort for some patients. As our understanding of the information provided by PET/MRI evolves, overlapping and redundant information can be identified and shed from acquisition protocols to save time and cost. Achieving this objective will pave the way for yet another future target: PET/MR whole-body imaging, which can revolutionize our conception of “cardiac” diseases once thought to be localized to the heart.

On a different note, the concept of multifunctional molecular imaging agents which can be used to perform PET acquisition, deliver targeted therapy, and at the same time act as an MR probe to detect treatment response is arguably one of the most compelling future directions of PET/MR research [79], and has the potential to transform PET/MR from a mere imaging modality to a therapeutic intervention.

To conclude, PET/MRI is an exciting new modality which has demonstrated a great deal of potential, but the ultimate judge of whether a technology will persist is its ability to influence patient outcomes. Such data is still lacking for PET/MRI, and future studies will be required to determine whether the added benefit of hybrid PET/MRI is worth the associated economic cost.

Innovations in Cardiovascular MR and PET-MR Imaging

14

Camila Munoz, Gastao Cruz, Claudia Prieto,
and René M. Botnar

14.1 Introduction

Cardiac magnetic resonance (MR) and positron emission tomography (PET) imaging have been areas of active research for over three decades. Throughout this time, technical advances in scanner hardware, data acquisition, and image reconstruction techniques have resulted in the clinical adoption of cardiac MR and PET examinations for the assessment of a wide range of cardiovascular diseases.

Conventional cardiac MR and PET imaging have focused on the depiction of the cardiac anatomy and characterization of myocardial function. In clinical practice, both PET and MR images are typically analysed qualitatively, by looking at areas of higher or lower signal intensity in the images as compared to surrounding healthy tissue. However, recently proposed techniques for MR-based tissue characterization and novel target specific PET radiotracers have encouraged a change in the way images are acquired and analysed, moving towards more objective, reproducible, and quantitative cardiovascular imaging. These advanced techniques have great potential to enable early detection of cardiovascular diseases, and accurate quantification of disease progression and therapy response.

Moreover, the introduction of hybrid PET-MR systems in the early 2010s has opened new possibilities for the simultaneous acquisition of complementary information with both imaging modalities, showing promising results for a comprehensive assessment of the cardiovascular system, and potentially improving patient care. This chapter describes state-of-the-art and emerging methods for cardiac MR and PET-MR imaging, highlighting the trends of current research and discussing some their potential for clinical translation.

14.2 Innovations in Cardiac MR: Quantitative Cardiac MRI

Conventionally, image contrast in cardiac MR is determined by optimal sequence parameters, such that disease appears as a hyper-intense or hypo-intense area in the image compared to surrounding healthy tissue. While this approach can be successfully applied when disease is focal and there is enough healthy tissue for comparison purposes, it does not allow to relate the changes in image contrast to the severity of the disease, and it results in a decreased sensitivity to diffuse disease or global changes in tissue characteristics.

More recently, approaches that allow the measurement of intrinsic tissue properties, such as longitudinal relaxation (T_1) or transverse relaxation (T_2), have been proposed for truly quantitative cardiac imaging [1]. These techniques, usually known as tissue parameter mapping or relaxometry techniques, have opened new possibilities for objective tissue characterization, early detection of disease, and improved monitoring of disease progression. This section summarizes established quantitative cardiac MR techniques, including conventional cardiac T_1 and T_2 mapping, and describes some novel techniques for multi-parametric mapping.

14.2.1 Cardiac T_1 and T_2 mapping

T_1 and T_2 relaxation times are key physical properties that play a central role in differentiating healthy from diseased tissue in cardiac MR. As such, these relaxation times are viable biomarkers for disease and have recently emerged as a solution for objective and quantitative tissue characterization. T_1 mapping has been shown to be sensitive to most cardiomyopathies, including myocardial infarction, amyloidosis, and diffuse fibrosis [2], while T_2 mapping has shown value in diagnosing myocarditis, iron overload, and heart transplant rejection, among others. One of the major challenges in cardiac parametric mapping is dealing with physiological (respiratory and cardiac) motion, which must be accounted for in order to avoid errors in the parameter maps.

Conventional myocardial T_1 mapping is generally achieved with 2D breath-held, cardiac triggered sequences. The two most popular approaches are the modified Look-Locker inversion recovery (MOLLI) [3] and the saturation recovery single-shot acquisition (SASHA) [4].

MOLLI encodes T_1 information using a 180° inversion recovery (IR) pulse, acquiring images with different T_1 weightings that are then fitted to an exponential model in order to estimate T_1 values for each pixel in the image. The conventional MOLLI sequence uses a first IR pulse and acquires data over multiple heartbeats. After this, a period of typically three heartbeats without data acquisition follows, allowing the magnetization to return nearly to equilibrium. Another IR pulse is then used, but the data acquisition takes place at a different inversion delay times (TI), effectively sampling new data points along the longitudinal relaxation (Fig. 14.1a). The set of inversion-weighted images are re-sorted by TI and fitted to the equation $M_z(\text{TI}) = A - B \exp(-\text{TI} / T_1^*)$, where T_1^* is an underestimated apparent T_1 , related to the actual T_1 by the expression $T_1 = T_1^* (B / A - 1)$. MOLLI produces precise T_1

Fig. 14.1 (a) MOLLI sequence diagram, red blocks represent inversion recovery (IR) pulses, green blocks represent data acquisition. An IR pulse is used to produce the required T_1 encoding, which is sampled over several heartbeats. A few recovery heartbeats are interleaved to ensure that the second IR pulse produces the same exponential recovery, however, different time-points are sampled. Here the 5(3)3 MOLLI variant is depicted. (b) SASHA sequence diagram, blue blocks represent saturation recovery (SR) pulses. An initial ‘infinity’ image is acquired; following images are acquired at varying time delays after a SR pulse, sampling different points along the T_1 recovery curve

maps, albeit with a negative bias [5, 6]. This is due to several factors: the RF excitation pulses used for imaging disturb T_1 relaxation, there is a T_2 dependency caused by the commonly used b-SSFP readouts [7] and the sequence is intrinsically sensitive to magnetization transfer effects [8]. Furthermore, MOLLI is sensitive to changes in the heart rate, as the length of the cardiac cycle determines which points along longitudinal relaxation are sampled.

SASHA uses a similar acquisition strategy, but relies on saturation recovery (SR) pulses instead of IR pulses to achieve T_1 encoding. An initial image without SR preparation is first acquired; and in the following heartbeats a SR pulse is used with varying saturation time delays (TS), such that different points along the T_1 recovery curve are sampled (Fig. 14.1b). Saturation-weighted images are sorted by TS and fitted to the equation $M_z(TS) = A[1 - B \exp(-TS/T_1)]$. The SR pulse halves the T_1 encoding range, reducing the precision of this technique compared to MOLLI. However, the use of SR pulses reduces heart rate dependency, disturbance due to RF excitation pulses and sensitivity to magnetization transfer, increasing the accuracy of the technique. Both MOLLI and SASHA approaches deliver diagnostic T_1 parametric maps (Fig. 14.2), with MOLLI being currently the preferred choice in clinical practice.

Fig. 14.2 Representative cases for MOLLI and SASHA T_1 mapping at 3 T. MOLLI generally achieves better precision, albeit with a negative bias. SASHA is more accurate, but suffers in precision. (Adapted with permission from Weingärtner S, Meßner NM, Budjan J, et al. *Myocardial T_1 -mapping at 3T using saturation-recovery: reference values, precision and comparison with MOLLI*. J Cardiovasc Magn Reson. 2016;18:1–9)

T_2 mapping encounters similar challenges as T_1 mapping in terms of requiring mechanisms to deal with physiological motion during data acquisition, therefore images are conventionally acquired in 2D, with cardiac triggering and under breath-hold to minimize cardiac and respiratory motion, respectively. Common methods for cardiac T_2 mapping use either T_2 preparation (T_2 prep) pulses together with b-SSFP sequences [9] or gradient and spin echo (GraSE) sequences [10] in order to achieve the necessary T_2 encoding.

The T_2 prep b-SSFP approach achieves T_2 mapping with as few as three images, acquired with T_2 preparation modules of different echo times (TE_{T_2p}), producing images with different T_2 weightings that are then fitted to a model, in a similar fashion to T_1 mapping techniques. A common choice for TE_{T_2p} values is $TE = [0, 24, 55]$ ms, which has been shown to provide good T_2 encoding and signal-to-noise ratio

Fig. 14.3 (a) T2prep bSSFP diagram, yellow blocks represent T_2 preparation pulses (T2prep), green blocks represent data acquisition. T_2 encoding is achieved with T2prep pulses, spaced over several recovery heartbeats to allow (near) complete longitudinal recovery of the magnetization. (b) T2 GraSE diagram, a single heartbeat is highlighted to depict the evolution of the transverse magnetization. In each heartbeat, a GraSE readout is employed. The echo time at which the k -space centre is sampled is changed every heartbeat, such that a different T_2 contrast is sampled

(SNR) for the myocardium [11]. The acquisition of images for each TE_{T2p} is typically interleaved with a number of heartbeats where no imaging is performed, to allow for magnetization recovery and reduce potential bias arising from T_1 effects (Fig. 14.3a). Finally, the T_2 value for each pixel is obtained with the following exponential fit: $M_{xy}(TE_{T2p}) = A \exp(-TE_{T2p}/T_2)$. This approach can suffer from bias arising from several sources: the T_1 recovery occurring in the interval between the application of the T2prep pulse and the acquisition of the centre of k -space readout is typically not modelled in the fitting equation, and the T2prep pulse itself is sensitive to both B_0 and B_1 inhomogeneities, although these errors may be reduced by using adiabatic T2prep pulses [12]. Finally, relying on T2prep pulses for encoding limits the number of data points along the T_2 decay curve that are used for fitting, which can impact accuracy and precision of the resulting T_2 maps.

T2 GraSE is an alternative approach that encodes T_2 information via spin echoes. T_2 -weighted images are acquired in a segmented fashion using EPI readouts in the T2 GraSE approach. In each GraSE block, the central k -space line determines the effective TE (Fig. 14.3b). In this approach, the following fitting model is used: $M_{xy}(TE) = A \exp(-TE/T_2) + B$. Partial volume effect arising from

blood signal can introduce bias in the resulting T_2 maps; so double inversion recovery preparation pulses are commonly employed to enforce a dark-blood contrast. T2 GraSE also has some limitations: long GraSE readouts and the use of spin echoes increase sensitivity to motion. Furthermore, while the EPI component of this approach enables considerable acceleration, it is also known to cause errors due to T_2^* decay, image distortions and artefacts due to fat chemical shift. Both T2prep b-SSFP and T2 GraSE have been shown to produce diagnostic T_2 parameter maps (Fig. 14.4).

Fig. 14.4 Representative cases for T2prep bSSFP and T2 GraSE mapping techniques at 1.5 and 3 T. Lower T_2 values are obtained T2prep bSSFP, particularly at 3 T. (Adapted with permission from Baeßler B, Schaarschmidt F, Stehning C, et al. *A systematic evaluation of three different cardiac T2-mapping sequences at 1.5 and 3T in healthy volunteers*. Eur J Radiol. Elsevier; 2015;84:2161–70)

14.2.2 Cardiac MR Fingerprinting

Conventional parametric mapping approaches, such as MOLLI or T2prep b-SSFP described above, sample T_1 and T_2 relaxation curves at a few discrete points, relying on steady state conditions and simplified fitting models of the MR physics. Magnetic Resonance Fingerprinting (MRF) proposes an alternative approach where the transient state of the magnetization is continuously sampled and then compared to the signal evolution predicted by the Bloch equation [13]. In the MRF framework, some imaging sequence parameters (for instance, flip angle and repetition time) are continuously varied to sensitize the sequence to tissue parameters of interest such as T_1 and T_2 . Prior to the MRF acquisition, Bloch equations are used to simulate the magnetization evolution, so-called fingerprint, for a set of tissues creating a dictionary of expected fingerprints. MRF data acquisition is performed at high acceleration rates leading to considerable noise amplification. However, voxel-by-voxel template matching can be used to identify the correct fingerprint in the pre-computed dictionary, revealing the underlying T_1 and T_2 values.

The MRF framework has been extended to cardiac applications where respiratory and cardiac motion compensation strategies must be considered. Cardiac MRF (cMRF) [14] uses inversion and T2prep pulses in a cardiac triggered acquisition acquired under breath-hold, to simultaneously estimate 2D T_1 and T_2 maps. In each heartbeat a different magnetization preparation pulse (or none) is used; in particular, in the original cMRF implementation, a block of four heartbeats was used with an IR pulse, no preparation pulses, T2prep with a $TE_{T2p} = 40$ ms, and T2prep with $TE_{T2p} = 80$ ms. This block can be repeated with increasing TIs to improve parametric encoding and SNR (Fig. 14.5). While the original MRF idea of varying the flip angles and repetition times throughout data acquisition is still employed by cMRF, most the signal encoding comes from the magnetization preparation pulses. Furthermore, since the cardiac triggering depends on the subject's heart rate, a patient-specific dictionary must be computed every time an acquisition is performed. An initial validation study showed that cMRF produces T_1 and T_2 maps comparable to conventional MOLLI and T2prep bSSFP, but with the advantage of producing co-registered parametric maps in reduced scan times (Fig. 14.6).

In a similar manner to conventional T_1 and T_2 mapping techniques, confounding factors arising from field errors (B0 or B1), magnetization transfer effects or motion will also affect cMRF accuracy and precision. However, the flexibility of the MRF approach provides mechanisms to reduce bias and imprecision in the parametric maps. For instance, while errors coming from B1 and slice profile are present in cMRF, they can be minimized with appropriate corrections or sequences designed to be less sensitive to such errors [15]. Residual cardiac or respiratory motion can also be present in cMRF and affect the accuracy and precision of the maps. Indeed, more recent works expanded on the cMRF framework to include water/fat separation or to resolve cardiac motion using a free-running acquisition [16, 17]. Additional parameters of interest for cardiac imaging, such as T_2^* , $T_{1\rho}$ or MT could also be incorporated into the cMRF framework by using appropriate preparatory pulses and could be investigated in the future studies. Initial studies in patient populations to

Fig. 14.5 cMRF diagram, red blocks represent IR pulses, yellow represent T2prep pulses and green represent acquisition. A combination of both IR and T2prep pulses are used to sensitize the magnetization to both T_1 and T_2 recovery in different heartbeats. Additional heartbeats can be acquired (with different TI) to further improve the precision of the parameter maps

Fig. 14.6 Representative case with conventional cMRF compared to conventional T_1 MOLLI and T_2 prep bSSFP. Comparable parametric maps are obtained; however in cMRF these co-registered maps are obtained in reduced scan time. (Reproduced with permission from Hamilton JI, Jiang Y, Chen Y, et al. *MR fingerprinting for rapid quantification of myocardial T_1 , T_2 , and proton spin density*. Magn Reson Med. 2017;77:1446–58)

thoroughly evaluate the potential of cMRF have recently started, aiming to demonstrate the value of cMRF in clinical setting.

14.2.3 Cardiovascular MRI Multitasking

As mentioned before, most parametric mapping techniques rely on breath-holds and ECG triggering to avoid artefacts arising from respiratory and cardiac motion, respectively. An alternative approach is to attempt to capture and resolve motion as additional dimensions of the imaging object. This is what Multitasking (MTT) [18] proposes, by casting the problem as a low-rank tensor. Within this framework, the imaged object is framed as a tensor with spatial, parametric (T_1 and T_2) and temporal (respiratory and cardiac) dimensions. Whereas in conventional approaches scan time would increase exponentially with the number of dimensions, in MTT the scan time increases approximately linearly with the number of dimensions, as correlated information is naturally shared in the low-rank tensor formulation.

In the MTT approach, data is acquired continuously with a low flip angle FLASH readout, and parametric encoding is obtained by the application of magnetization preparation pulses that periodically interrupt the data acquisition. For native T_1 mapping an inversion pulse is used, whereas for perfusion T_1 mapping a saturation pulse is used instead. For native T_1/T_2 mapping T2prep-IR preparation pulses are employed, generating T_2 weighted inverted magnetization. These preparation pulses are repeated every 2.5 s, with the aim of placing them out of synchronization with physiological motion in order to provide partial parametric encoding along different motion dimensions.

The low-rank tensor framework used in MTT requires prior knowledge about the basis functions that describe each dimension. MTT assumes the parametric and temporal basis functions are known (or can be estimated from the data itself) and recover the spatial basis functions during image reconstruction. MTT acquires data following a golden radial trajectory where every other readout is used as training data for estimation of basis functions. For example, in simultaneous T_1/T_2 mapping, this training data can be used to span the subspace of the respiratory and cardiac dimensions, whereas a training dictionary is used to span the basis of the relaxation (parametric) dimension. Since in this case the reconstructed object is a four-dimensional tensor, it is possible to characterize T_1 and T_2 in every combination of respiratory and cardiac motion states. MTT has been shown to produce parametric maps comparable to conventional methods with the addition of respiratory and cardiac resolved information without the need for patient cooperation (breath-holds) or external sensors (ECG devices) (Fig. 14.7). The first MTT studies focused on the acquisition of multi-parametric 2D images, however, the framework is applicable to volumetric imaging, which could enable whole-heart coverage. In the near future, this technique could be used to obtain fully quantitative information, including, for instance, native and post-contrast parametric maps, perfusion and late gadolinium enhancement (LGE), from a single scan with minimum setup required.

Fig. 14.7 Representative case for Multitasking, compared with standard T_1 MOLLI and T2prep bSSFP. Multitasking T_1 and T_2 maps not only are co-registered, but are also cardiac resolved, generating T_1 and T_2 maps at every cardiac phase. (Adapted by permission from Christodoulou AG, Shaw JL, Nguyen C, et al. *Magnetic resonance multitasking for motion-resolved quantitative cardiovascular imaging*. *Nat Biomed Eng* 2018;2:215–26)

14.3 Innovations in Cardiac MR: Towards Efficient 3D Whole-Heart Imaging

The ability of MR to produce high-resolution images with excellent soft-tissue contrast has encouraged the adoption of cardiac MR in the clinical routine. However, some challenges remain for improving efficiency and patient throughput. MR data acquisition is slower than the physiological motion of the heart; so compensation for respiratory- and cardiac-induced motion of the heart is fundamental to avoid ghosting and/or blurring artefacts in the images, especially for 3D whole-heart MR imaging.

Conventional approaches for motion compensation in cardiac MR rely on acquiring data under breath-holds to minimize respiratory motion, and/or only during

periods of minimal cardiac motion (for instance, during mid-diastole). While these approaches are routinely used in clinical MR examinations, they reduce the time available for data acquisition, so that only a limited spatial coverage can be achieved. Indeed, most clinical cardiac MR protocols consist of the acquisition of several 2D images with different geometries and orientations, including 4-chamber, 3-chamber, 2-chamber and a set of short-axis views of the heart. In order to obtain a sufficient SNR, these images are typically acquired with a large slice thickness (8–10 mm), which can result in partial volume effects that degrade the depiction of small features. Furthermore, as they are acquired under a series of breath-holds, they can be misaligned, which may result in inaccuracies when assessing, for instance, the size of a lesion.

Three-dimensional whole-heart MR imaging offers increased SNR, improved volumetric coverage, and higher spatial resolution, and has progressively been proposed for different cardiac MR applications. However, such approaches require longer acquisition times and therefore advanced motion compensation techniques and/or the use of accelerated MR data acquisition are required in order to acquire whole-heart datasets within a clinically feasible scan time. This section describes some approaches for 3D whole-heart MR imaging, focusing in novel developments for coronary artery imaging, myocardial viability imaging, and quantitative mapping.

14.3.1 Dealing with Physiological Motion

The heart is continuously moving due to the cardiac and respiratory cycles. The cardiac cycle induces periodic motion of the heart due to the contraction and relaxation of the atria and ventricles, with a frequency that ranges from 50 to 80 beats/min in healthy adults but that can vary significantly more in patients with cardiovascular disease. The breathing cycle also induces motion of the heart, due to movement of both the diaphragm and the chest wall, resulting in a complex non-rigid deformation of the heart, with a dominant component that can be represented by superior-inferior (SI) translation. A healthy adult in rest state breathes at a rate of 12–20 times/min, with an inspiration length ranging 1–2 s, and a slightly longer expiration period of 2–3 s. Both the cardiac-induced and the respiratory-induced motion of the heart have significant inter-subject variability, so subject-specific motion compensation schemes are required to minimize blurring and artefacts in the resulting MR images and consequently avoid compromising their diagnostic quality.

The effect of cardiac motion is conventionally minimized by synchronizing data acquisition with the cardiac cycle using an external ECG device. Assuming that cardiac motion is periodic, data is grouped according to their position within the cardiac cycle to produce images with minimal cardiac motion. There are two main approaches for performing this task: ECG-triggered and ‘free-running’ acquisitions, as depicted in Fig. 14.8.

In ECG-triggered approaches, data are acquired only during a short time window within each heartbeat over multiple cardiac cycles, and then combined into a single k -space to produce a ‘motion-free’ image [19]. The R -wave is used as reference for

Fig. 14.8 Conventional approaches for minimizing cardiac motion in cardiac MR imaging. **(a)** ECG-triggered segmented acquisition. In each heartbeat, a segment of k -space is acquired during a period of minimal motion, typically mid-diastole, so that k -space is filled in a series of n subsequent cardiac cycles. **(b)** Free-running acquisition. Data are continuously acquired and retrospectively sorted into m cardiac phases, each of them with minimal cardiac motion

triggering the start of the data acquisition, so that the acquisition window coincides with a period of minimal cardiac motion. There is not an exact correspondence between the motions of different cardiac structures, and therefore, the period of minimal cardiac motion is different for different structures of interest such as the left ventricle or the coronary arteries. For instance, for the coronary arteries the period of minimal motion for adults often corresponds to mid-diastole, with a duration of ~ 100 ms, while in paediatric patients or patients with variable heart rate the end-systolic period may be more stable [20–22], with the disadvantage of being a shorter quiescent period (~ 50 ms). In order to acquire ECG-triggered images, the MR operator is required to set two subject-specific parameters: the trigger delay and the duration of the acquisition window. This approach is routinely used in the clinical practice for both 2D and 3D cardiac MR imaging, when visualization of the heart anatomy at a single cardiac phase is required.

In the so-called free-running approaches, data are continuously acquired during the cardiac cycle. Using the ECG signal as a reference, the data are retrospectively sorted into a number of cardiac phases, assuming that within each of them there is minimal cardiac motion, so that ‘motion-free’ images can be reconstructed at each

Fig. 14.9 (a) Options for respiratory motion tracking in cardiac MR, including diaphragmatic 1D navigator (in blue), self-navigation (in yellow), and image-based navigation (in magenta). (b) In gating approaches, acquired data is accepted (green dots) for image reconstruction only when the respiratory signal is within a predefined acceptance window (in green); otherwise, data is rejected (red dots). (c) In motion-corrected approaches, the acceptance window can be enlarged or entirely removed, so that all acquired data is accepted for image reconstruction. The data is corrected to a reference position (blue line) in a beat-to-beat fashion

phase. The free-running approach is widely used for 2D cine imaging, and more recently it has been demonstrated for whole-heart 3D coronary MR angiography (CMRA) and for 3D cine imaging in combination with undersampled and motion-compensated image reconstruction techniques [23, 24]. Thanks to its ability to produce images at different cardiac phases, the free-running approach is conventionally used to assess cardiac function, through the calculation of clinically relevant parameters such as ventricular volumes and ejection fraction.

Free-running approaches have the advantage of not requiring the operator to prospectively define the length of the acquisition window and trigger delay, reducing operator dependency during data acquisition. Furthermore, the cardiac phase with minimal motion can be found retrospectively, which could be advantageous in patients with irregular heart rate. However, since data are acquired continuously, the longitudinal magnetization does not recover between consecutive excitations, resulting in a loss of contrast and SNR in the images. Moreover, since free-running approaches acquire data in multiple cardiac phases, larger amounts of data and correspondingly longer scan times are needed compared to ECG-triggered scans.

An approach analogous to ECG-triggering can be used for minimizing the effect of respiratory motion, by using a signal related to the breathing cycle to combine data acquired at a similar respiratory position during multiple breathing cycles. External devices such as respiratory bellows can be used for respiratory gating, assuming a high correlation between the motion of the heart and the motion of the abdomen. Alternatively, the respiratory cycle can be directly monitored from the MR images (Fig. 14.9a).

In clinical routine, the most common approach uses interleaved one-dimensional (1D) navigator echoes in the MR acquisition sequence. A navigator echo consists of an image representing a thin column of tissue that can be used to monitor the position of a high-contrast moving structure, such as the liver-lung interface. When this interface is within a predefined window, usually placed at end-expiration with a width of 3–5 mm [25], the acquired data is accepted for image reconstruction. Otherwise, the data is rejected and reacquired in a later breathing cycle (Fig. 14.9b). The information provided by the navigator echoes can also be used to further reduce motion artefacts by correcting for motion within the acceptance window. This approach, known as gating and tracking, corrects for the SI translation of the heart assuming that it is directly proportional to the displacement of the diaphragm [26].

Although 1D navigator approaches are widely used in the clinical setting for 3D whole-heart imaging due to its robustness, they have several limitations. Firstly, the motion of the heart is not measured directly, but it is inferred from the motion of the diaphragm. A population-based tracking factor of 0.6 to relate the motion of the diaphragm to the motion of the heart is commonly used for this purpose. However, this factor is not appropriate for all subjects [27]. Furthermore, even if subject-specific tracking factors were used [28, 29], the 1D navigator approach only accounts for translational motion in the SI direction, does not consider hysteretic effects, and is incapable of including corrections for the complex non-rigid deformations of the heart during the breathing cycle. Finally, the efficiency of the acquisition (i.e. the percentage of acquired data that is accepted for image reconstruction) varies significantly between subjects, typically ranging from 20% to 60%, leading to prolonged and unpredictable scan times.

Self-navigation methods that estimate the respiratory motion of the heart from the acquired data itself have been proposed in the literature to address some of the limitations of diaphragmatic navigators. These methods derive a respiratory signal from a repeated acquisition of either the centre of k -space [30] or a central line in k -space [31], usually acquired in the SI direction. Compared to diaphragmatic navigation, self-navigation methods have the advantage of directly measuring the motion of the heart and thus not relying on a motion model. However, they also perform motion correction in the SI direction only and motion estimation is only relative as the motion signal is unit less. Furthermore, their ability to estimate a respiratory signal is impaired by the presence of static tissue, as both the centre of k -space and the central line of k -space are projections of the whole field of view.

In order to address these limitations, respiratory motion compensation techniques that use image-based navigators (iNAV's) have been proposed more recently. By acquiring low-resolution 2D [32–34] or 3D images [35–40] before or after the high-resolution 3D data acquisition, respiratory motion can be directly measured in the heart by tracking a region of interest.

Both self-navigation and iNAV-based methods can be used for gating the acquisition and correcting for respiratory motion within a small gating window in a similar manner to 1D navigator echoes. However, since these methods directly measure the motion of the heart and correct for it, a much larger gating window can be used (Fig. 14.9c). These approaches usually incorporate most of the acquired data for

image reconstruction (i.e. achieving near 100% scan efficiency), leading to predictable and significantly reduced acquisition times. Several self-navigated and iNAV-based techniques correct for respiratory motion in a beat-to-beat fashion, by applying a linear phase shift in k -space corresponding to the estimated 1D, 2D, or 3D translation of the heart [32, 33, 36, 41, 42]. While enabling 100% scan efficiency, these techniques do not account for the complex non-linear motion of the heart, thus remaining motion artefacts can affect the quality of the images.

Respiratory binning techniques have been more recently introduced to handle higher-order motion models (Fig. 14.10a). In this approach, the SI displacement obtained from the iNAVs or from self-navigation signals is used to sort the acquired data into a number of respiratory bins representing different respiratory positions

Fig. 14.10 Advanced respiratory motion compensation approach using binning. (a) The respiratory signal is used to group the acquired MR data into several states of the breathing cycle or ‘bins’ with high spatial resolution. The bin images are registered to a reference position, in order to estimate motion fields. This motion information can be then incorporated directly in the image reconstruction process. (b) Examples showing the impact of respiratory motion correction in whole-heart water/fat imaging and in simultaneous bright- and black-blood imaging

throughout the breathing cycle. Then, images reconstructed at each respiratory position can be used to estimate, for instance, 3D affine motion parameters. The acquired k -space can be then corrected in a bin-to-bin fashion, as shown in [43–46] for various cardiac MR applications.

Although the 3D affine motion model is a better approximation of the respiratory-induced motion of the heart, it assumes that the whole field of view is affected by a unique transformation. In practice, some tissues remain mostly static during the acquisition, such as the spine and subcutaneous fat; and different organs in the thorax are affected differently by the expansion and contraction of the lungs. Thus, applying a global k -space correction using motion parameters estimated by tracking the heart will induce ghosting and artefacts arising from an erroneous correction of the surrounding organs and tissues. Instead, a more general non-rigid motion model can be used.

Approaches that include the non-rigid deformation fields as part of an iterative image reconstruction algorithm have been proposed for coronary MR imaging [47] and more recently for multi-contrast cardiac MR imaging [48, 49], and techniques that use local auto-focus to model the non-rigid motion of the heart have also been proposed [40, 50]. Example images before and after non-rigid motion correction for different clinical applications can be seen in Fig. 14.10b. It is worth noting that these approaches seek to produce one respiratory motion-corrected image that includes all the acquired data. Alternatively, the respiratory-binned data can be simultaneously reconstructed by exploiting sparsity along the respiratory dimension, so that high-quality respiratory-resolved images can be obtained [51, 52]. Indeed, this technique can be extended to obtain cardiac and respiratory-resolved images, as demonstrated in [53].

14.3.2 Accelerating Data Acquisition

As discussed in the previous section, the use of motion compensation techniques can reduce average cardiac MR scan time by providing higher scan efficiency. However, even when motion correction techniques are used, the acquisition of 3D cardiac MR images with sufficient spatial resolution and coverage takes several minutes. Indeed, a 100% efficient fully sampled whole-heart 3D CMRA scan with a spatial resolution of 0.9 mm^3 isotropic resolution may take as long as 30 min at an average heart rate of 70 beats/min.

Beyond motion compensation, more advanced methods that combine faster acquisition trajectories and undersampled reconstruction techniques can be used to increase acquisition speed and thereby achieve clinically feasible scan times. Although several of these techniques have focused on accelerating CMRA imaging, due to the high resolution and volumetric coverage required to accurately depict the coronary arteries, they have also been used for other cardiac applications.

Fast non-Cartesian acquisition trajectories, such as radial and spiral trajectories, enable to fill the k -space in a more efficient manner, and produce incoherent motion artefacts and noise-like undersampling aliasing, making them suitable for advanced

undersampled reconstruction techniques, such as compressed sensing [54]. One of the most prevalent of these is the spiral phyllotaxis 3D radial trajectory. Originally proposed for CMRA imaging [42, 55], this trajectory has now been applied to late gadolinium enhancement (LGE) imaging [56], T_2 mapping [57], and ‘free-running’ CMRA imaging for the simultaneous assessment of cardiac anatomy and function [23]. A closely related trajectory is the ‘spiral on the sphere’ radial trajectory, which has been extensively used for conventional and free-running CMRA [41, 44, 45, 58]. Other trajectories include 3D cones [59], stack of stars [46], and stack of spirals [60]. The main disadvantages of these non-Cartesian trajectories are a reduced SNR, higher sensitivity to off-resonance effects and gradient delays, and the complexity they pose for image reconstruction. On the other hand, novel Cartesian trajectories that follow spiral-like sampling patterns on the Cartesian grid [43, 61] or variable density Poisson discs [62] can alleviate these issues while maintaining many of the benefits of non-Cartesian trajectories.

A clinically established method for accelerating data acquisition is the use of parallel imaging undersampled MR reconstruction. Techniques such as SMASH [63], SENSE [64], and GRAPPA [65] pioneered this field, by using spatial information obtained from the sensitivity of multiple receiver coils to partially recover samples not acquired in k -space. These approaches are widely used in cardiac MR protocols, to reduce acquisition time by a factor of 2–3 without affect the diagnostic quality of the resulting images.

In order to achieve higher acceleration, compressed sensing and other sparsity-based image reconstruction techniques have been applied to cardiac MR imaging. These techniques use assumptions about the compressibility of the image in some domain to reduce the amount of data required to produce a good quality image. For instance, the compressibility of the wavelet coefficients was used in [62] to accelerate CMRA imaging up to 6 times, while a similar technique was used in [66] to enable single breath-hold whole-heart cine imaging. The difference between respiratory states has also been used as a sparsifying transformation to reconstruct respiratory-resolved CMRA images from undersampled data [51, 52] (Fig. 14.11a). Instead of reducing scan time, these methods can be used to increase spatial resolution, as recently demonstrated in [67], where a patch-based undersampled reconstruction technique was used to achieve sub-millimetre resolution in CMRA with a scan time of approximately 5 min (Fig. 14.11b).

14.3.3 Coronary MR Imaging

An accurate visualization of the coronary artery anatomy is fundamental for the detection of coronary artery disease. Although invasive X-ray angiography remains the reference modality for imaging of the coronary lumen and detection of coronary stenosis, non-invasive imaging, including computed tomography (CT) and MRI, are increasingly being used as alternative diagnostic tools. Indeed, CT coronary angiography (CTCA) has been recently incorporated into healthcare guidelines as a cost-effective first test for patients with suspected coronary disease [68] due to its high

Fig. 14.11 Advanced image reconstruction methods for accelerated CMRA. **(a)** The XD-GRASP method enables respiratory-resolved image reconstruction, by exploiting sparsity in the respiratory dimension, resulting in improved image quality compared to conventional Gridding reconstructions (reproduced with permission from Piccini D, Feng L, Bonanno G, et al. *Four-dimensional respiratory motion-resolved whole heart coronary MR angiography*. Magn Reson Med. 2017;77:1473–84). **(b)** The 3D-PROST method exploits the similarity between 3D patches in the CMRA image, achieving improved image quality compared to conventional iterative SENSE (itSENSE) and conventional compressed sensing (CS) reconstructions for acquisitions with up to ninefold acceleration. (Reproduced with permission from Bustin A, Ginami G, Cruz G, et al. *Five-minute whole-heart coronary MRA with sub-millimeter isotropic resolution, 100% respiratory scan efficiency, and 3D-PROST reconstruction*. Magn Reson Med. 2019;81:102–15)

spatial resolution and short acquisition time. Although CTCA has the advantage of being a non-invasive procedure, it results in an average radiation dose of 16 mSv to the patient [69]. On the contrary, MR is a radiation-free imaging modality, which enables the visualization of the coronary artery lumen while also providing a depiction of vessel wall and characterization of atherosclerotic plaque, including imaging of intraplaque haemorrhage and thrombi.

The depiction of the coronary artery lumen via CMRA requires the use of contrast mechanisms to suppress the signal arising from surrounding tissues such as epicardial fat and myocardium. Some of the current CMRA imaging protocols rely on the use of exogenous gadolinium-based contrast agents to increase the contrast between blood and myocardium, resulting in bright-blood images [70]. Alternatively, the difference in the T_2 relaxation time between the arterial blood pool and the surrounding tissues can be used as an endogenous contrast mechanism by including a T_2 preparatory pulse (T2prep) before the acquisition of imaging data [71]. Adipose tissue has a short T_1 and long T_2 relaxation times, leading to a strong signal arising from the epicardial fat in most CMRA acquisition sequences. Such signal can obscure the visualization of the coronary arteries if not adequately suppressed. While conventional fat suppression techniques based on SPIR [72] have been shown

Fig. 14.12 Innovations in coronary MR imaging. (a) Water/fat coronary MR angiography improves fat suppression and contrast-to-noise ratio at 3 T compared to conventional fat suppression (SPIR) (adapted from Nezafat, M., Henningsson, M., Ripley, D.P. et al. *Coronary MR angiography at 3T: fat suppression versus water-fat separation*. Magn Reson Mater Phy (2016) 29: 733). (b) Interleaved T_2 -preparation can be used for simultaneous imaging of the coronary vessel wall and coronary lumen. (Adapted from Cruz G, Atkinson D, Henningsson M, et al. *Highly efficient non-rigid motion-corrected 3D whole-heart coronary vessel wall imaging*. Magn Reson Med. 2017;77:1894–908)

to be robust at 1.5 T, they can result in incomplete fat suppression at higher magnetic fields due to their sensitivity to field inhomogeneities. Alternatively, the difference in resonance frequency (i.e. the chemical shift) between water and fat can be used to separate the two species into images that reflect the water and fat content of each voxel in the image, using the so-called water/fat or Dixon separation methods. The water/fat separation approach has been applied to 1D navigator gated CMRA imaging, where it has been shown to improve image quality both at 1.5 T [73] and 3 T [74] compared to conventional fat saturation, increasing SNR of the arterial blood and improving blood-to-fat contrast-to-noise (CNR) ratio in the water images (Fig. 14.12a). A motion-corrected water/fat CMRA approach with $\sim 100\%$ scan efficiency has been recently demonstrated at 3 T [75]. An alternative approach for improving fat suppression is the use of efficient water-selective excitation pulses in order to obtain ‘fat-free’ images, as recently proposed in [76], however, their impact in cardiac imaging remains to be studied. Finally, advances that combine T_2

preparation and water-selective RF excitation pulses have been proposed in the literature [77].

While high-resolution bright-blood CMRA can be used to detect proximal luminal stenosis, it is known that early stages of the disease involve changes in the arterial wall without luminal narrowing. In order to visualize the coronary artery wall with sufficient contrast, several black-blood imaging techniques have been proposed in the literature. The first approaches for black-blood coronary imaging used double inversion recovery (DIR) preparation pulses to null the signal arising from the blood [78, 79]. The DIR technique enables the selective depiction of static tissue within the field of view, relying on the blood flow perpendicular to the imaging plane to achieve blood nulling, and thereby limiting this approach to the acquisition of 2D slices or carefully planned targeted 3D acquisitions. Therefore, flow-insensitive techniques have been more recently introduced to enable 3D whole-heart volumetric coverage. Techniques based on a T2prep-IR preparation pulse have been shown to produce good quality images of the aortic and peripheral vessel wall [80, 81], while an interleaved acquisition of data with and without T2prep has shown promising results for the simultaneous visualization of the coronary lumen and vessel wall [47, 82] (Fig. 14.12b). The interleaved T2prep approach acquires two bright-blood volumes, and uses a patient-specific weighted subtraction to produce an additional black-blood image where the vessel wall can be visualized. A novel interleaved T2prep-IR acquisition has been recently proposed [49], which produces the black-blood image by direct subtraction of the two bright-blood images, removing the need for a weighting factor and increasing the robustness of the technique.

14.3.4 Myocardial Viability MR Imaging

Late Gadolinium enhancement (LGE) is an established technique for the assessment of myocardial scar and fibrosis. Most LGE imaging sequences are based on the use of an IR preparation pulse, which enables the exploitation of the differences in the T_1 relaxation time between healthy and diseased myocardium. This difference in T_1 arises from the different wash-in and wash-out rates of the contrast agent in different tissues, resulting in an optimal time window for image acquisition, typically between 10 and 30 min after injection of contrast. Conventional LGE imaging protocols null the signal arising from the normal myocardium by selecting an appropriate inversion time (TI) from visual inspection of a so-called TI-scout acquisition. Although routinely used in the clinical practice, this approach is highly sensitive to the selection of TI. Phase-sensitive IR (PSIR) [83] is a more robust technique that interleaves the acquisition of the IR-prepared data with a low flip angle reference scan, so that this additional information can be used to preserve the polarity of the magnetization, enabling a better separation between signal arising from scar and myocardium.

As in most conventional cardiac MR sequences, LGE images are conventionally acquired under breath-hold as a series of 2D slices, with reasonably good in-plane

spatial resolution but large slice thickness and limited volumetric coverage. Motion correction techniques have been introduced to enable free-breathing 2D LGE imaging [84, 85], achieving similar resolution and contrast-to-noise ratio compared to conventional breath holding. In order to achieve higher spatial resolution and whole-heart coverage, several approaches have been proposed for 3D LGE imaging, either using diaphragmatic navigators to enable free-breathing acquisitions [86, 87] or using fast trajectories and undersampled acquisitions to enable single breath-hold imaging [60, 88]. The single breath-hold techniques acquire images in ~ 20 s, compared to the several minutes required by free-breathing techniques. While efficient, these long breath-holds might be difficult to achieve for the patients. Furthermore, the single-breath-hold approach can only achieve a limited spatial resolution, with a typical slice thickness of 5–7 mm, and normally acquires data at each heartbeat, preventing the use of the PSIR technique. On the other hand, free-breathing techniques have enabled the acquisition of high-resolution LGE PSIR images with whole-heart coverage and isotropic image resolution of 1.4–2 mm³ [86, 87].

While both conventional IR and PSIR LGE imaging achieve an excellent contrast between non-viable and normal myocardium, the contrast between the blood pool and the non-viable myocardium is significantly reduced, as the blood pool also appears bright. Therefore, the delineation of the scar may be impaired, particularly in cases of sub-endocardial infarct. Combined IR-T2prep [89, 90] and T2prep-IR [91] pulses have been recently introduced for dark-blood PSIR LGE imaging, showing promising results for enhanced depiction of gadolinium enhancement. A different approach for dark-blood IR-prepared PSIR LGE imaging is proposed in [92], where the TI is selected to null the blood signal instead of nulling the viable myocardium. In this approach, the PSIR reconstruction produces images with grey blood, while the nulled viable myocardium and bright scar signal are preserved.

Most conventional LGE imaging sequences do not include any mechanism for fat suppression. Both myocardial fibrosis and intramyocardial fat can appear bright in LGE images since they both have a low T_1 , hindering the distinction between both types of tissue. Multi-echo Dixon approaches have been incorporated to breath-held 2D PSIR LGE imaging for the assessment of fibro-fatty infiltration in the myocardium [93], and more recently extended to single breath-hold 3D LGE imaging [94] (Fig. 14.13).

14.3.5 Multi-Contrast Whole-Heart MR Imaging

Cardiac MR offers a multitude of possible image contrasts that reflect different tissue characteristics and provide complementary information about different disease mechanisms. The conventional methodology for cardiac MR in the clinical routine consists of acquiring each of these image contrasts in a sequential fashion. However, an alternative and more efficient approach is the acquisition of two or more of such contrasts interleaved in a single scan, so that the resulting images are better aligned and can be more easily fused and interpreted together.

Fig. 14.13 A visual comparison shows good correspondence between short-axis LGE images acquired with (a–c) conventional 2D multi breath-hold PSIR and (d–f) single breath-hold 3D mDIXON acquisition, with a clear depiction of anterolateral scar in both sets of images. However, the 3D image acquisition (~15 s) required approximately 5% of the time required for acquiring the 2D images (~320 s). (Reproduced from Foley JRJ, Fent GJ, Garg P, et al. *Feasibility study of a single breath-hold, 3D mDIXON pulse sequence for late gadolinium enhancement imaging of ischemic scar*. *J Magn Reson Imaging* 2019;49:1437–45)

An interleaved scheme was proposed by Xie et al. in [95], where an IR pulse is applied every other heartbeat in order to obtain a T_1 -weighted black-blood volume and a bright-blood image reference. This sequence, known as CATCH, enables the depiction of high-risk atherosclerotic plaque by the T_1 -weighted black-blood image, where intraplaque haemorrhage and coronary thrombus appear as hyper-intense features, while simultaneously providing a bright-blood image that can be used as anatomical reference (Fig. 14.14a). The CATCH sequence integrates respiratory self-navigation and affine bin-to-bin motion correction, resulting in a highly efficient examination. However, it has some limitations. First, due to the lack of signal in the T_1 -weighted black-blood images, the CATCH sequence relies only on the bright-blood data for motion tracking and correction, assuming that the respiratory motion between consecutive heartbeats is negligible. Furthermore, the lack of preparatory pulses in the bright-blood image results in contrast degradation, limiting the diagnostic use of this image. An extension of this approach has been recently proposed [96], where an acquisition scheme that interleaves a T2prep-IR pulse in even heartbeats with a T2prep pulse in odd heartbeats is used. This sequence, called BOOST, results in two bright-blood volumes with different T_1 weighting, which can be combined in a PSIR reconstruction to produce a complementary black-blood volume where signal from thrombus is enhanced. Compared to the CATCH

a CATCH sequence**b** MTC-BOOST sequence

Fig. 14.14 Examples of novel multi-contrast whole-heart imaging sequences. **(a)** CATCH sequence for visualization of vulnerable plaque and coronary anatomy (adapted from Xie Y, Kim YJ, Pang J, et al. *Coronary Atherosclerosis T1-Weighted Characterization With Integrated Anatomical Reference: Comparison With High-Risk Plaque Features Detected by Invasive Coronary Imaging*. *JACC Cardiovasc Imaging*. 2017;10:637–48). **(b)** MTC-BOOST sequence for simultaneous visualization of the pulmonary veins and assessment of atrial wall thickness. (Adapted from Ginami G, Lopez K, Mukherjee RK, et al. *Non-contrast enhanced simultaneous 3D whole-heart bright-blood pulmonary veins visualization and black-blood quantification of atrial wall thickness*. *Magn Reson Med*. 2019;81:1066–79)

sequence, BOOST has the advantage of producing two bright-blood volumes, enabling respiratory motion estimation at each heartbeat. Indeed, the BOOST sequence integrates an iNAV-based motion compensation scheme. Furthermore, the anatomical reference (given by the T2prep-IR image) has a higher blood-to-myocardium contrast, making it suitable for assessment of the coronary lumen.

The BOOST sequence provides a flexible framework for the acquisition of bright-blood images that provide complementary information. The framework has also been used after injection of a Gadolinium-based contrast agent for

simultaneous bright-blood CMRA and black-blood LGE [91], improving the contrast between blood pool and scar. Furthermore, BOOST approach has been extended to the pulmonary circulation, for the visualization of bright-blood pulmonary veins and black-blood quantification of atrial wall thickness, using an interleaved Magnetization Transfer Contrast (MTC)-IR and MTC preparation [97] (Fig. 14.14b).

14.3.6 Whole-Heart Quantitative T_1 and T_2 Mapping

As described in Sect. 14.2, quantitative mapping techniques for cardiac MR have commonly relied on breath-holds to avoid respiratory motion artefacts. However this strategy typically limits the available scan time, resulting in limited volumetric coverage, spatial resolution, and SNR. Furthermore, repeated breath holding is challenging to achieve for some patient populations, which may result in suboptimal image quality. In this section, some of the advances made to move from breath-held 2D toward free-breathing 3D cardiac quantitative mapping are discussed.

Free-breathing solutions for both inversion-based and saturation-based 3D T_1 mapping have been proposed in the literature, using respiratory triggering [98] and diaphragmatic navigators [99]. These methods monitor respiratory motion and accept data only in end-expiration, effectively reducing respiratory-induced motion artefacts. However, as the remainder of the respiratory cycle is excluded from data acquisition, this approach significantly lengthens the scan time. Instead of using this inefficient (cardiac or respiratory) triggering approach, it is possible to estimate and correct for motion, minimizing residual artefacts. Approaches for 3D T_2 mapping using diaphragmatic navigator [100] and self-navigation techniques [57] have been demonstrated in the literature, and the combination of free-breathing motion-corrected 3D T_2 mapping has also been developed using navigators to guide the motion model [46]. These techniques have the potential of providing a high-resolution T_2 parametric map for improved quantification (Fig. 14.15).

14.4 Innovations in Cardiac PET-MR Imaging

Since the development of simultaneous PET-MR scanners, cardiovascular imaging has been proposed as one of the clinical applications that could benefit the most from this new technology. The complementary anatomical and functional information offered by both imaging modalities, and the ability to simultaneously produce MR images with high spatial and temporal resolution and superior tissue contrast and quantitative PET images that can target a variety of molecular processes has a great potential for improving the diagnosis and monitoring of different cardiac conditions from a single scan session.

In the early days of cardiac PET-MR, most research studies focused on either cross-validating both imaging modalities, particularly for the assessment of myocardial viability and perfusion [101–105], or on studying the potential added value

More recently, technical developments in motion compensation for cardiac PET-MR have focused on improving PET image quality by acquiring MR images with enough resolution and soft-tissue contrast simultaneously with PET, so that motion information obtained from such MR images can be used to correct the PET data. Some of these approaches have been also used to correct the MR data, enabling the acquisition of truly simultaneous diagnostic co-registered MR and PET images. Furthermore, the flexibility of PET to target specific molecular processes has stimulated the development of novel radiotracers for targeting different mechanisms of cardiovascular disease, for both conventional PET imaging and simultaneous PET-MR imaging. This section describes technical innovations for cardiac PET-MR, focusing on novel motion compensation techniques, and describes recently introduced PET radiotracers that could be of particular interest for cardiac PET-MR imaging.

14.4.1 Motion-Compensated Cardiac PET-MR Imaging

Simultaneous PET-MR systems have made possible the use of MR-measured motion information to correct the motion-degraded PET data. While the first approaches for MR-based PET respiratory motion compensation focused mainly on enhancing image quality for ^{18}F -FDG PET-MR in thoracic and abdominal oncology imaging, the growing interest in cardiovascular PET-MR applications has encouraged the extension of such techniques to cardiac imaging. Most of the current approaches for motion compensation in cardiac PET-MR estimate the motion-induced deformation of the heart by using one of the following techniques: (1) pre-calibrated motion modelling, where MR images are acquired before or during the first few minutes of the PET acquisition to create a motion model that is then used to correct for motion during the whole PET acquisition or (2) simultaneous motion modelling techniques, where motion information is obtained by applying image-based registration algorithms to MR images acquired throughout the whole PET data acquisition (Fig. 14.16).

In order to measure cardiac or respiratory motion from MR images, two components are required: first, a signal related to the cardiac and/or breathing cycle is

Fig. 14.16 Conventional approaches for MR-based motion correction of PET data in cardiac PET-MR imaging. (a) Pre-calibrated motion models estimate a motion model before or during the first part of the PET-MR examination. (b) Simultaneous motion models estimate motion information by using MR images acquired throughout the whole PET data acquisition

needed for assigning the acquired data to one of a number of bins or gates, so that each of these bins contains data acquired at similar position over multiple cardiac and breathing cycles. Second, a suitable MR data acquisition protocol that allows the creation of a patient-specific motion model is required. In general, the surrogate signal is acquired simultaneously with the imaging data or derived from the data itself, so that the created model approximates the relationship between the surrogate and the motion.

Once the motion information is available, two different approaches can be used to compensate for motion in the PET images: reconstruct transform average (RTA) or motion-compensated image reconstruction (MCIR). In RTA approaches [116], the acquired data is first binned into a number of near motion-free datasets which are reconstructed independently. Once all datasets have been reconstructed, motion information is used to transform the frames back to a reference position, and subsequently transformed frames are aggregated so that one motion-compensated image is obtained using all measured data. Alternatively, in MCIR approaches [117] the motion information is incorporated as an additional term in the update equation of an iterative PET image reconstruction algorithm, so that a motion-corrected image is directly obtained by modelling the motion during the image reconstruction process. Since the introduction of simultaneous PET-MR scanners, a variety of MR imaging sequences have been proposed to estimate respiratory-, cardiac-, or respiratory and cardiac-induced motion of the heart. Such sequences have been used in combination with either method of motion compensation of the cardiac PET data, as described hereafter.

14.4.1.1 Respiratory Motion Compensation

Although variety approaches have been proposed to measure and correct for respiratory motion in oncologic PET-MR imaging [118–120], just a couple of studies have been performed to assess the impact of respiratory motion correction of cardiac PET data in the context of cardiac PET-MR imaging. In the study by Fieseler et al. [121], a pre-calibrated motion model is created by acquiring 35 near real-time 3D T_1 -weighted MR images. Using an image-based navigator as MR surrogate respiratory signal, each acquired volume is classified according to their position within the respiratory cycle, and six of them covering the whole respiratory cycle are chosen to form the motion model. In parallel, a PET data-driven respiratory surrogate is obtained, which allows the binned PET data to be related to the MR-based motion model. This approach was used in an RTA framework to correct PET data acquired throughout 20 min from a cardiac phantom that modelled both respiratory and cardiac motion, and an improved correspondence to the anatomy depicted in the MR images was observed after motion correction.

A pre-calibrated motion model approach was also proposed by Kolbitsch et al. [122] where a short 75 s MR acquisition was used to simultaneously provide respiratory motion information and respiratory-resolved attenuation maps for accurate attenuation correction of the PET data. In this study, the proposed MR sequence consisted of a triple-echo Dixon scan acquired following a 3D golden radial phase encoding (GRPE) trajectory [123], which can be used to extract a respiratory signal from the

data itself (i.e. a self-navigator signal), sampled every 750 ms. Interestingly, the proposed MR sequence not only provided a motion model but also motion-resolved attenuation maps, that were incorporated in a MCIR framework for improved accuracy of attenuation correction of the PET data. This framework was tested in a cohort of six patients without known cardiac disease, and findings show improvements in PET image quantification compared to uncorrected reconstructions. While this approach was also used to correct the triple-echo Dixon images for respiratory motion, these MR images showed reduced contrast between blood and myocardium due to the absence of preparation pulses, and limited spatial resolution for visualization of the relevant cardiac structures, impairing the diagnostic use of such MR images.

A different approach for simultaneous respiratory motion-corrected cardiac MR angiography and cardiac PET imaging was proposed by Munoz et al. [124]. In this work, 3D CMRA data is acquired using a T_1 -weighted gradient echo sequence, following a golden-step Cartesian spiral (CASPR) sampling trajectory [43]. The acquisition scheme also includes the acquisition of 2D iNAV's at each heartbeat enabling the estimation of foot-head and right-left motion of the heart during the respiratory cycle in a heartbeat-to-heartbeat fashion. Using the foot-head motion as a respiratory signal surrogate, both the PET and CMRA data are binned into a number of respiratory windows. Then, MR images reconstructed at each respiratory position are used to estimate 3D non-rigid motion fields, which are used for correcting both the CMRA and PET data to the same respiratory position, using an RTA approach to correct the PET data (Fig. 14.17). While this is a simultaneous motion model approach, which measures motion throughout the whole PET-CMRA acquisition, it produces co-registered diagnostic images in both imaging modalities, potentially improving the interpretability of both PET and MR images together. This approach

Fig. 14.17 Motion-corrected PET-CMRA reconstruction scheme proposed in [124]. Foot-head (FH) respiratory motion, estimated from image navigators integrated in the CMRA acquisition sequence, is used to bin the acquired 3D CMRA and PET data into respiratory windows or ‘bins’. MR images reconstructed at each of these respiratory positions are used to estimate 3D non-rigid motion fields (in green). These motion fields are then used to correct both PET (emission and attenuation) and CMRA data to the same respiratory position, resulting in co-registered diagnostic images, facilitating the fusion and joint interpretation of findings from both imaging modalities. (Modified from Munoz C, Neji R, Cruz G, et al. *Motion-corrected simultaneous cardiac positron emission tomography and coronary MR angiography with high acquisition efficiency*. Magn Reson Med. 2017;79:339–50)

was first tested in oncology patients [124], and then in a small cohort of patients with cardiovascular disease [125], showing promising results for a comprehensive assessment of coronary disease.

14.4.1.2 Cardiac Motion Compensation

Cine MR imaging is one of the most widely used approaches for tracking cardiac-induced motion of the heart. For instance, a stack of 2D cine MR images is proposed in [121] to estimate cardiac motion in a phantom PET-MR study, using non-rigid registration of 25 cardiac phases with respect to an arbitrary reference phase and an RTA approach to correct the PET images for cardiac motion. A drawback of this approach is that as the motion is estimated from 2D images, no information about 3D motion is available. Furthermore, if such an approach were applied to patient studies, the acquisition of the stack of 2D cine images would be performed in a series of breath-holds, leading to potential inaccuracies in the motion estimation due to misalignment between slices.

An alternative sequence commonly used for measuring cardiac motion is tagged MRI. In this approach, a sinusoidal pattern of alternating bright and dark stripes is superimposed over the MR image being acquired, and the deformation of the pattern over time enables the visualization and estimation of cardiac motion. In the context of cardiac PET-MR, tagged MR images have been successfully used in cardiac beating phantom studies [126], proof-of-concept clinical studies [127] and more recently in myocardial perfusion pre-clinical studies [128], using MCIR for cardiac motion correction of the PET data in all cases.

One of the main advantages of the tagged MR approach is that thanks to the superimposed pattern, accurate motion measurements can be performed even in regions with uniform contrast such as the left ventricle myocardium. Furthermore, by acquiring a set of tagged MR images in multiple orthogonal planes (i.e. coronal, sagittal, transverse) a complete description of 3D cardiac motion can be obtained, though at the expense of prolonged acquisition times. As reported in [127], the acquisition time of fully sampled tagged MR images for nine cardiac phases was longer than 8 min, so that this technique would likely be used as a simultaneous motion model. In order to move towards a pre-calibrated motion model approach, half k -space acquisition [126] and compressed sensing and parallel imaging techniques [127] have been proposed to accelerate the acquisition of tagged MR images. Indeed, Huang et al. [127] demonstrated that measuring cardiac motion from tagged MR images acquired with up to 3 \times -accelerated GRAPPA parallel imaging [65] or up to 8 \times -accelerated kt-FOCUSS compressed sensing [129] yields cardiac motion-corrected PET images with similar image quality as those corrected with cardiac motion measured from fully sampled tagged MR images. This significant reduction of time dedicated to cardiac motion estimation could enable the acquisition of clinically relevant MR sequences during the simultaneous PET-MR examination.

14.4.1.3 Respiratory and Cardiac Motion Compensation

Although cardiac-only and respiratory-only motion correction studies have showed promising results in terms of PET image quality and quantification, a more general

approach to motion compensation in cardiac PET-MR requires addressing both cardiac and respiratory motion simultaneously. Several approaches have been recently proposed in the literature, focusing on the impact of accurate motion correction in simulations, oncologic patients, and preliminary studies in cardiovascular patients.

A popular choice for MR-based cardiac and respiratory motion estimation is the 3D golden radial stack-of-stars T_1 -weighted MR sequences. This sequence has the advantage of enabling the estimation of cardiac and respiratory surrogates from the MR data itself, removing the need of using additional motion surrogates. For instance, in [130] a 3D golden radial stack-of-stars sequence is continuously acquired during 5 min. Using cardiac and respiratory motion surrogates estimated from the k -space centre, the acquired MR data was sorted into 20 respiratory and 12 cardiac overlapping phases. In order to produce images with sufficient quality for motion estimation, a two-step approach was used in this study. In the first step, MR data was binned into 20 respiratory phases neglecting any cardiac motion, and images were used to estimate respiratory motion only. In the second step, respiratory motion was used to correct the MR raw data to a reference respiratory position, and then the corrected MR data is binned into 12 cardiac phases to produce cardiac motion estimates. The respiratory and cardiac motion fields can then be combined to warp the data at any cardiac and respiratory phase to the reference mid-diastolic, end-expiratory position.

The same stack-of-stars trajectory was used in [131] to correct PET data for cardiac and respiratory motion. However, in this study authors stated that cardiac-induced motion of the heart is more complex than the respiratory-induced motion, so images of higher resolution are required to estimate it accurately. Therefore, they propose the use of two separate acquisitions to create the cardiac and respiratory motion model: a first low-resolution acquisition covering the whole thorax for respiratory motion estimation only, and a second high-resolution whole-heart acquisition for cardiac motion estimation only (Fig. 14.18). In this study, PET data was binned into four respiratory and three cardiac phases, and each bin was independently reconstructed following an RTA approach for motion correction. The PET images were first transformed to end-expiration using the corresponding respiratory motion transformation, and then transformed to late-diastole using the cardiac motion fields.

Due to the length of the MR data acquisition, both of these studies used a simultaneous motion model approach. However, similar acquisition approaches have been used to create pre-calibrated motion models. For instance, the GRPE trajectory described before was used in [132] to produce cardiac and respiratory motion estimates in less than 5 min. Using a self-navigator for respiratory gating and an external ECG device for cardiac gating, the acquired MR data was sorted in to eight respiratory and 8–12 cardiac phases. Following an approach similar to [130], in a first step the cardiac binning is ignored to produce good quality images for respiratory motion estimation, while in the second step respiratory motion-corrected data is used for cardiac binning, and subsequently for cardiac motion estimation. Finally, motion fields are combined and used in a MCIR framework (Fig. 14.19).

An even shorter MR acquisition is proposed in [133], where a 90 s 3D Cartesian acquisition was used to create a cardiac and respiratory motion model. In this study,

the MR data was acquired following a variable density Cartesian pattern called ESPReSSo [134], which provides a self-navigator signal for respiratory binning in a similar fashion to previously described approaches. Using a sensor-fusion

Fig. 14.18 MR-based cardiac and respiratory motion-corrected PET reconstruction proposed in [131]. List-mode PET data is dual-gated into N respiratory and M cardiac bins. PET images for each bin are then reconstructed independently. Using two dedicated MR acquisition sequences performed at the beginning of the simultaneous PET-MR acquisition, respiratory and cardiac motion fields are estimated using image registration. For respiratory motion, a 3D affine motion model is used, while for cardiac motion 3D non-rigid registration is applied. Finally, the $N \times M$ dual-gated PET images are transformed by applying the corresponding respiratory and cardiac motion fields into a reference frame and aggregated to produce the final motion-compensated PET image. (Reproduced from Robson PM, Trivieri M, Karakatsanis NA, et al. *Correction of respiratory and cardiac motion in cardiac PET/MR using MR-based motion modeling*. Phys Med Biol; 2018;63:225011)

Fig. 14.19 (a–d) Cardiac and respiratory motion correction for cardiac PET/MR proposed in [132]. 3D MR data are continuously acquired during free-breathing without ECG-triggering gating over several respiratory and cardiac cycles. First, MR data are grouped in N different respiratory bins, and images are reconstructed for each respiratory state. Affine registration is used to estimate respiratory motion fields ($RM_1 \dots RM_N$), which is used to correct the acquired MR data to the same respiratory position. Then, the MR data is sorted into M cardiac phases, and non-rigid registration is used to estimate cardiac motion fields ($CM_1 \dots CM_M$). Finally, respiratory and cardiac motion information is used to correct both MR and PET datasets, by including the motion fields in the image reconstruction process, resulting in co-registered motion-compensated PET and MR images. (Reproduced from Kolbitsch C, Ahlman MA, Davies-Venn C, et al. *Cardiac and respiratory motion correction for simultaneous cardiac PET-MR*. J Nucl Med. 2017;58:846–52)

approach, data were binned into eight respiratory and eight cardiac phases, and a joint MR reconstruction and motion estimation scheme was used to produce the motion estimates, which were incorporated into a MCIR framework to produce motion-corrected PET images.

While the approaches described above rely on non-rigid registration of T_1 -weighted images to produce motion estimates, the contrast of such images might not be optimal to track the motion of smaller cardiac structures. In [135], fat-only MR images were used to track respiratory and cardiac motion of the coronary arteries. This proof-of-concept study used simulated fat-only images for eight cardiac and six respiratory phases, showing improvements in the detectability of coronary plaques in ^{18}F -NaF PET motion-corrected images.

Other research groups have focused on the use of both MR and PET datasets to improve the reliability of cardiac and respiratory motion estimation. For instance, in the myocardial perfusion simulation study presented by Wang et al. [136], respiratory motion was estimated from cardiac-uncorrected PET images, while cardiac motion was estimated from 3D T_1 -weighted MR images simulated at end-expiration.

Interestingly, in this study a combination of MCIR and RTA motion correction was used, so that respiratory motion was included in a MCIR approach at each cardiac phase and RTA was used to warp all the cardiac phases into one final motion-corrected image.

A joint image registration functional that enables the estimation of motion from PET and MR images was used in [137] to exploit the complementary information from both imaging modalities. In this study, whereas MR images provided excellent respiratory motion information, the lack of contrast between blood and myocardium impaired the MR-based cardiac motion estimation. On the contrary, ^{18}F -FDG PET images provided excellent myocardial depiction, enabling an accurate cardiac motion tracking. Results from a cohort of oncologic patients showed improved image quality when using motion fields estimated from both PET and MR compared to using either only MR or only PET to estimate motion.

14.4.2 Novel PET Radiotracers for Clinical Cardiac PET-MR Applications

A recently published joint statement by the European Society of Cardiovascular Radiology (ESCR) and the European Association of Nuclear Medicine (EANM) suggests that including hybrid PET-MR examinations in the routine clinical practice could enhance the diagnosis and aid decisions in the management of a variety of cardiac conditions, including stable coronary artery disease, acute coronary syndrome, ischaemic cardiomyopathies, and cardiac inflammation [138]. While some of these clinical applications are based on exploiting the complementary information offered by MR and conventional PET radiotracers (i.e. ^{13}N - NH_3 , ^{15}O - H_2O and ^{18}F -FDG), an increasing number of them could benefit from novel PET radiotracers that target specific disease mechanisms. Table 14.1 summarizes some of these recently introduced radiotracers, indicating their mechanism and potential clinical uses.

While some of these tracers have been used for cardiac PET/CT or cardiac PET-MR in small proof-of-concept human studies, many of them have only been used in pre-clinical studies or for studying other tissues/organs. In particular, most of the radiotracers proposed for atherosclerotic plaque imaging have been demonstrated in the carotid arteries as opposed to the coronary arteries. A notable exception is ^{18}F -NaF, which has been recently demonstrated in the context of cardiac PET-MR in a cohort of 12 patients with either documented coronary artery disease or documented risk factors for developing this disease [115]. Thanks to its ability to target micro-calcification, ^{18}F -NaF has shown promise for identifying high-risk and ruptured atherosclerotic plaque. In combination with simultaneously acquired MR anatomical images that provide information about the plaque location and integrity of the artery lumen (Fig. 14.20), and in addition to novel MR sequences that allow for characterization of intraplaque haemorrhage [95, 96], the ^{18}F -NaF PET-CMR approach could potentially allow for a comprehensive non-invasive assessment of vulnerable plaque. Furthermore, simultaneous PET-MR imaging could aid the

translation of the intraplaque inflammation radiotracers to coronary artery imaging, as the focal nature of the tracer uptake would require accurate cardiac and respiratory motion compensation techniques.

Another particularly promising radiotracer for cardiac PET-MR imaging is ¹⁸F-flurpiridaz. PET has been long established as the reference modality for myocardial perfusion imaging, allowing for an accurate diagnosis of obstructive coronary artery disease through the assessment of stress-induced myocardial perfusion defects. However, most of the conventionally used perfusion radiotracers (i.e. ¹³N-NH₃, ¹⁵O-H₂O) require an on-site cyclotron because of their short half-life, which has prevented the wide clinical adoption of perfusion PET imaging. The introduction of ¹⁸F-labelled perfusion radiotracers, such as ¹⁸F-flurpiridaz (in clinical phase 3 trials at the time of writing) could advance the adoption of this technique in the clinical practice. Furthermore, in the context of cardiac PET-MR, encouraging results have been shown in a pre-clinical study for MR-based cardiac motion correction of simultaneously acquired ¹⁸F-flurpiridaz data, with significant improvements in depiction of the left ventricular myocardium after motion correction [128].

Fig. 14.20 Example images from a cardiac ^{18}F -NaF PET-MR examination. Patient exhibited an increased uptake of the radiotracer in a culprit atherosclerotic plaque in the left anterior descending coronary artery. (a) Luminal stenosis is observed on the MRA image, which corresponds to an area of focal ^{18}F -NaF uptake (b). (c) LGE images from the same patient show a near-transmural myocardial infarction in the corresponding territory of this lesion. (d) The increased ^{18}F -NaF uptake in the culprit lesion can also be observed on a 2-chamber view of the left ventricle. Please note that all images were acquired during a single PET-MR scan session. (Reproduced from Robson PM, Dweck MR, Trivieri MG, et al. *Coronary Artery PET/MR Imaging: Feasibility, Limitations, and Solutions*. *JACC Cardiovasc Imaging* 2017;10:1103–12)

Finally, by using an appropriate suppression of normal physiological glucose metabolism, the widely available ^{18}F -FDG can be used for imaging inflammatory response in the myocardium, reflecting only the increased glucose uptake by macrophages and other inflammatory cells. This suppression can be achieved in numerous ways [164], namely by prolonged fasting (more than 12 h), by prescribing a high-fat low-carbohydrate and protein-permitted diet for approximately 24 h before examination, by intravenous administration of unfractionated heparin or a combination of the latter two. In combination with LGE MRI, the glucose-suppressed ^{18}F -FDG PET approach has been used in several cardiac PET-MR studies, showing promise for improving the differential diagnosis in myocardial inflammation. Recent clinical experience has been reported in [109], including cases of myocarditis, congestive heart failure, and cardiac sarcoidosis. In particular, the latter has received considerable attention in the cardiac PET-MR community, as early reports suggest that the complementary information obtained by PET and MR improves the diagnostic accuracy of cardiac sarcoidosis compared to each modality alone [110–112]. Therefore, cardiac PET-MR could potentially become in the future the reference modality for a non-invasive tool for the detection and monitoring of cardiac involvement in patients with known or suspected sarcoidosis.

14.5 Concluding Remarks

MR and PET imaging are established non-invasive techniques for the diagnosis, therapy planning, and monitoring of cardiovascular disease. While conventional MR protocols have focused on the depiction of the heart anatomy and ventricular function, the introduction of advanced quantitative MR T_1 , T_2 and joint T_1/T_2 mapping sequences has enabled tissue characterization, and demonstrated the potential use of these tissue properties as biomarkers for specific disease mechanisms. Moreover, novel technical developments in efficient motion compensation and accelerated data acquisition techniques have shown a variety of possible solutions for cardiac MR to achieve higher spatial resolution and whole-heart volumetric coverage within clinically feasible acquisition times.

On the other hand, cardiac PET has traditionally concentrated on imaging myocardial integrity, including perfusion and viability for the assessment of coronary disease. Emerging radiotracers could expand the range of conditions for which PET imaging can make a difference in patient care. In particular, tracers that target vascular inflammation, micro-calcification, and hypoxia in atherosclerosis have shown promising results for the identification of vulnerable plaque, and novel tracers and imaging protocols for myocardial inflammation could improve diagnosis of diseases such as myocarditis and cardiac sarcoidosis.

Despite the introduction of several technical advances that have improved image quality over the last decades, some challenges remain in both PET and MR imaging. Particularly, most of clinically available solutions to prevent image degradation due to physiological motion are based on rejecting data acquired outside quiescent periods in the cardiac and breathing cycles. These techniques require long acquisition times in order to acquire enough data, i.e. with enough signal-to-noise ratio for PET and enough samples for a desired spatial resolution and coverage for MR, increasing overall scan time and negatively impacting patient comfort and throughput.

The introduction of hybrid PET-MR scanners has enabled the development of novel techniques to alleviate the problem of motion simultaneously for both modalities. Recently proposed approaches for motion-corrected cardiac PET-MR could enable increased efficiency and improved resolution and quality in both imaging modalities, with promising results that remain to be translated to the clinical practice. This, in addition to the complementary information about different disease processes that each modality offers, could open the door for PET-MR to become the preferred modality for the assessment of the cardiovascular system from a single, efficient and comprehensive examination.
