1.1 Indications

Ultrasonography of the lung has now become an established imaging procedure for chest diseases. Owing to comprehensive scientific investigations and studies (Beckh et al. 2002; Beaulieu and Marik 2005; Mathis et al. 2005; Niemann et al. 2009; Reuß 2010; Reissig et al. 2012; Volpicelli et al. 2012; Bartheld 2013; Squizzato et al. 2013) the “Point of Care Ultrasound” (POCUS) has been widely accepted as a basic tool with rapid diagnostic information in medical examination.

In emergency cases and in intensive care medicine the findings of ultrasound allow a conclusive and strategic course of action (Diacon et al. 2005; Soldati et al. 2006; Arbelot et al. 2008; Copetti and Cattarossi 2008; Copetti et al. 2008; Noble et al. 2009; Moore and Copel 2011; Blank and Heinzmann 2012; Volpicelli et al. 2012; Böer et al. 2014; Squizzato et al. 2015; Blank et al. 2019; Mayo et al. 2019; Kluge et al. 2020; Soldati et al. 2020). The acceptance of the method is reflected in a number of well-known international guidelines (Havelock et al. 2010; Hooper et al. 2010; Piscaglia et al. 2012; Bamber et al. 2013; Cosgrove et al. 2013; Detterbeck et al. 2013; AWMF Leitlinie 2015, 2018; Ewig et al. 2016; Dalhoff et al. 2018; Rose et al. 2017; Stoelben et al. 2018).

New developed handheld devices in the size of a mobile phone create an “ultrasound-stethoscope”. In

this dimension ultrasound may provide an imaging diagnosis even in most difficult situations (Bachmann Nielsen et al. 2019; Soldati et al. 2020). Thus bedside imaging information in isolated patients will be much easier (Kluge et al. 2020; Soldati et al. 2020).

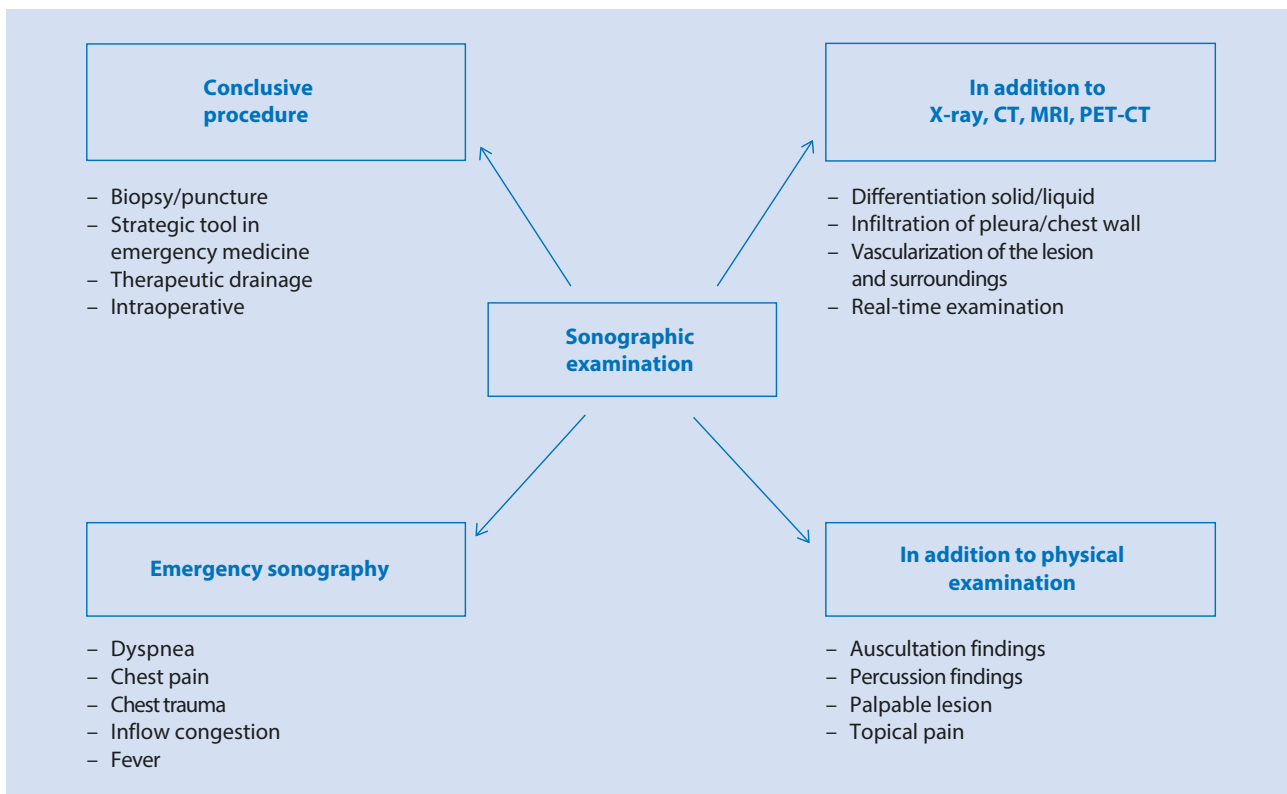

The usefulness of chest sonography is proven in permanent enlargement of applications (Lesser 2017; Davidsen et al. 2020).

The ultrasound image does not provide a complete overview of the chest. However, it does show a certain portion of the chest and thus provides diagnostic information about a variety of problems (■ Fig. 1.1).

About 99% of the ultrasonic wave is reflected by the healthy lung. Intrapulmonary processes can be registered by ultrasound only when they extend to the visceral pleura or can be visualized through a sound-conducting medium such as fluid or consolidated lung tissue (■ Fig. 1.2).

Acoustic shadowing occurs due to nearly complete absorption of the ultrasonic wave on bone, especially behind the sternum, the scapula, and the spine. Impairment due to the rib shadow can be balanced, at least in part, by appropriate breathing techniques.

The immediate retrosternal and posterior portions of the mediastinum cannot be viewed from the percutaneous aspect. Transesophageal and transbronchial ultrasound may be used additionally, but it should be noted that these examination procedures are invasive in

■ Fig. 1.1 Spectrum of applications of ultrasonography for pleural and pulmonary diseases

Fig. 1.2 Entities and pathological changes that can be accessed by ultrasound

terms of effort and handling (Lam and Becker 1996; Aabakken et al. 1999; Herth et al. 2004; Annema et al. 2010; Haas et al. 2010; Walker et al. 2012; Silvestri et al. 2013; ► Sect. 6.2, ► Chap. 7).

Ultrasonography provides diagnostic information during the investigation of individual entities in the chest (Overview).

Diagnostic Information During the Investigation of Individual Entities in the Chest

- Chest wall
 - Benign lesions:
 - Benign neoplasms (such as lipoma)
 - Hematoma
 - Abscess
 - Reactivated lymph nodes
 - Perichondritis, Tietze syndrome
 - Rib fracture
 - Malignant lesions:
 - Lymph node metastases (primary diagnosis and the course of disease under treatment)
 - Growing invasive carcinomas
 - Osteolyses
- Pleura
 - Solid structures:
 - Thickening of the pleura, callosity, calcification, asbestos-induced plaques
 - Space-occupying lesion:
 - *Benign*: fibrous tumor, lipoma
 - *Malignant*: clearly identifiable metastases, diffuse carcinosis, pleural mesothelioma
 - Fluid:
 - Effusion, hemothorax, pyothorax, chylothorax
 - Dynamic investigation:
 - Pneumothorax
 - Differentiating between an effusion and a callosity

- Adherence of a space-occupying lesion
- Invasion by a space-occupying lesion
- Mobility of the diaphragm
- Lung
 - Interstitial syndrome
 - *Benign peripheral lesions*:
 - Inflammation, abscess, embolism, atelectasis
 - *Malignant peripheral lesions*:
 - Peripheral metastasis, peripheral carcinoma, tumor/atelectasis
 - Mediastinum, percutaneous:
 - Space-occupying lesions in the upper anterior mediastinum
 - Lymph nodes in the aortopulmonary window
 - Suspected thrombosis in the vena cava and its afferent vessels
 - Visualization of collateral circulation
 - Pericardial effusion

Additional pathologies of the heart that can be visualized by ultrasonography will not be addressed in this book; for further information the reader may consult appropriate echocardiography textbooks.

1.2 Required Technical Equipment

Devices used for ultrasound investigation of the abdomen and the thyroid may also be used for investigation of the chest. A high-resolution linear transducer of 5–10 MHz is suitable for imaging the **chest wall** and the **parietal pleura** (Mathis 2004). Additionally, the recently introduced probes of 7.5–18 MHz are very useful for evaluating **lymph nodes** (Prosch et al. 2014), nerves (Winter et al. 2019) the **pleura**, and the **surface of the lung**.

A convex or sector probe of 3–4 MHz ensures sufficient depth of penetration for investigation of the **lung** (Mathis 2004).

Vector, sector or narrow convex probes are recommended for the **mediastinum**. The smaller the footprint, the better the probe can be placed on the jugulum or the supraclavicular fossa. The frequency range should be 3.5–5 MHz. It should be noted that the device settings commonly used for examining the heart are not suitable for the rest of the mediastinum. Contrast, image rates and the grayscale balance must be aligned to the visualization of mediastinal structures.

A special probe with an appropriate connecting channel to the ultrasound device is needed to perform a transesophageal ultrasound investigation.

Endobronchial ultrasonography is performed with special thin high-frequency probes (12–20 MHz) which are introduced through the working channel of the flexible bronchoscope.

1.3 Investigation Procedure

1.3.1 Chest Wall, Pleura, Diaphragm, Lung

The investigation should be performed, as far as possible, with the patient seated, during inspiration and expiration, and if necessary in combination with respiratory maneuvers such as coughing or “sniffing”. Raising the arms and crossing them behind the head expands the intercostal spaces and facilitates the access. The transducer is moved from ventral to dorsal along the longitudinal lines in the chest (■ Fig. 1.3):

- the anterior median line
- the sternal line
- the parasternal line,
- the middle and lateral clavicular line,
- the anterior, middle and posterior axillary line,
- the lateral and medial scapular line, and
- the paravertebral line.
- the posterior median line

The respective anatomic location of the findings should be mentioned in the report.

Subsequent transverse transducer movement parallel to the ribs in the intercostal spaces (■ Fig. 1.4) provides

the additional information needed for accurate localization of the respective finding.

The investigation of lesions behind the scapula should be performed under maximum adduction of the arm with encirclement of the contralateral shoulder (■ Fig. 1.5).

The supraclavicular access enables the investigator to view the apex of the lung (▶ Sect. 1.3.2).

From the suprasternal aspect one is able to inspect the upper anterior mediastinum (▶ Chap. 6). From the abdominal aspect one can investigate the diaphragm from the subcostal approach through the transhepatic route on the right side (■ Fig. 1.6), and to a limited extent from the trans-splenic route on the left side.

Additionally, the longitudinal acoustic plane from the flank shows both costodiaphragmatic recesses (■ Fig. 1.7b).

The supine patient is examined in the same manner. The abdominal access is better in this setting, but the intercostal view might be more difficult because the mobility of the pectoral girdle is limited.

In emergency situations the chest should be divided in four quadrants on each side. The transducer will be positioned in turn on each quadrant (■ Fig. 1.7a)

■ Fig. 1.3 a, b Investigation of the seated patient. a Linear probe placed longitudinally on the right parasternal line. b Corresponding longitudinal panoramic ultrasound image (SieScape). (K Cartilaginous insertion of a rib, ICR Intercostal space, M Muscle, P Pleural line)

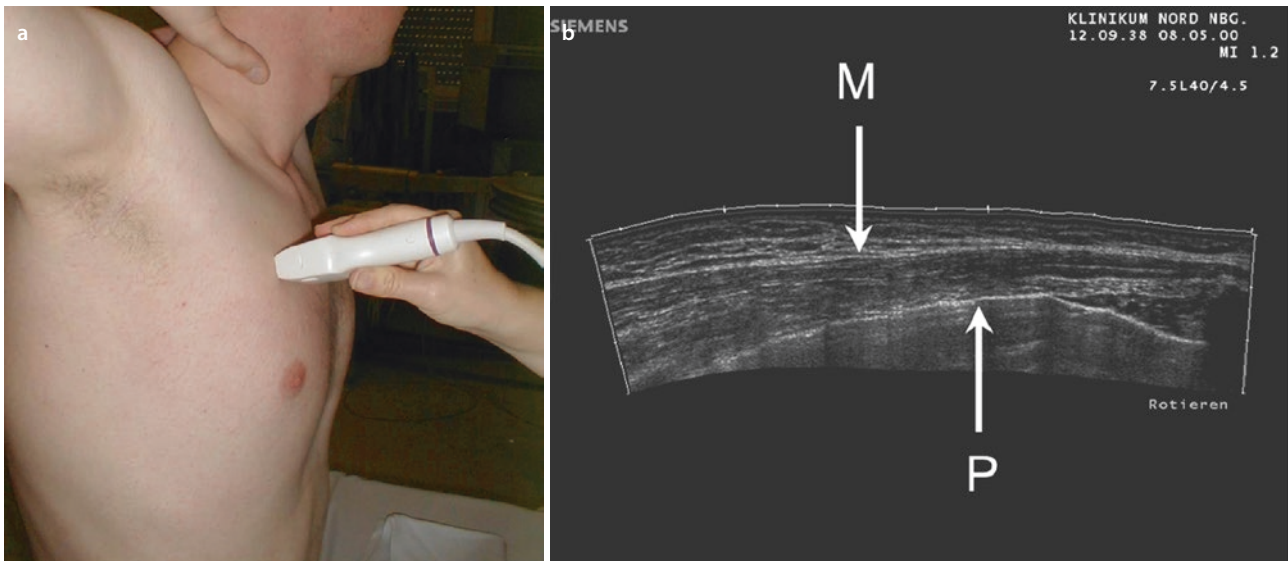

Fig. 1.4 a, b Investigation of the seated patient. a Linear probe placed parallel to the ribs in the 3rd intercostal space. b Corresponding transverse panoramic ultrasound image (SieScape). (M Muscle, P Pleural line)

Fig. 1.5 Position of the patient for investigating retroscapular entities

1.3.2 Investigation of the Upper Thoracic Aperture

Special approaches are needed to investigate the upper thoracic aperture. The patient is required to lie flat for the investigation of cervical and supraclavicular lymph nodes, ideally with a hyperextended cervical spine (Prosch et al. 2014). The axillary region is investigated with the patient's arm in elevated position. High-resolution transducers of 5–18 MHz are used to view the structure of lymph nodes and the brachial plexus, including its branches. The thoracic aperture and the supraclavicular region should be investigated by ultrasound in cases of the following questions:

- Invasion of a Pancoast tumor
- Lymph node staging
- Trauma (parturition, accident)
- Puncture of the upper thoracic aperture
- Brachial plexus block (anesthesia)

The investigation is started at the base of the lateral cervical region (Fig. 1.8a, b).

The nerve branches pass through the gap between the anterior and middle scalene muscle, in lateral and downward direction. The branches reach the axilla by passing between the first rib and the clavicle. The course of the nerve branches along the axillary artery is registered by the infraclavicular approach (Fig. 1.9a–d).

Fig. 1.6 a, b Transhepatic investigation. a Convex probe placed subcostally from the right side, tilted slightly in cranial direction. b Corresponding ultrasound image (L Liver, LV Hepatic vein, S Reflection of the liver above the diaphragm, ZF Diaphragm)

Fig. 1.7 a Investigation of the lying patient. a Division of chest in four quadrants in case of emergency examination. b Lateral aspect (ZF Diaphragm). A lung with normal mobility is shifted during inspiration into the costodiaphragmatic recess and obscures the upper margin of the liver

Fig. 1.8 a, b Investigation of the upper thoracic aperture. a Semisagittal longitudinal section at the base of the lateral cervical region. b Corresponding ultrasound image (AS Subclavian artery, VS Subclavian vein, PL Pleura, N Branches of the brachial plexus, V Innominate vein)

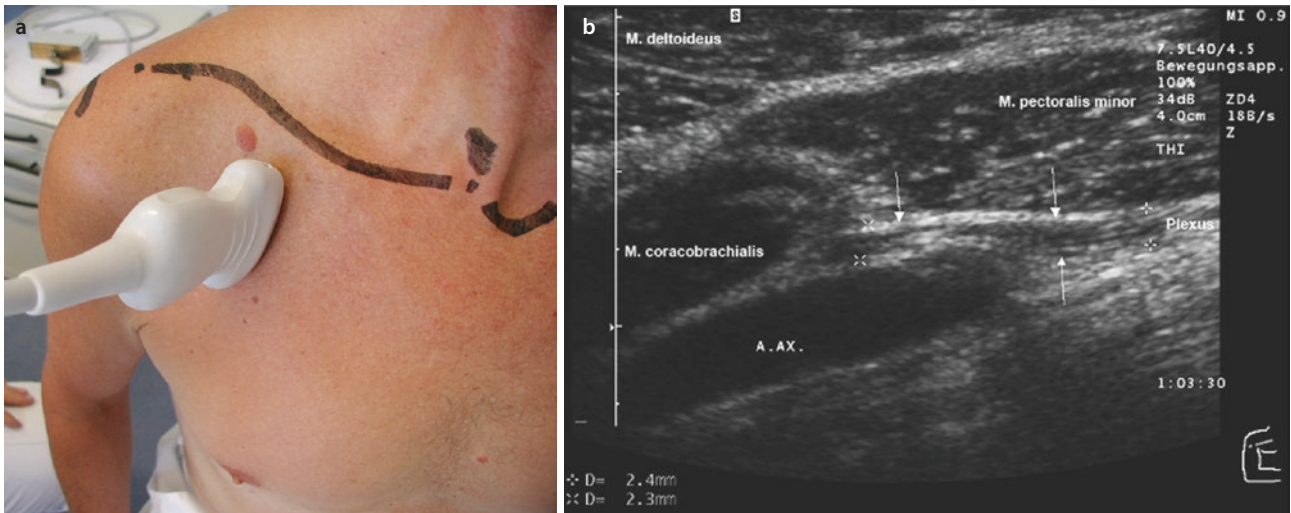

Fig. 1.9 a–d. a Oblique infraclavicular longitudinal section in the medioclavicular line. b Corresponding ultrasound image (A. Ax. Axillary artery). Arrows and crosses mark the course of the plexus nerve. c Infraclavicular cross-section parallel to the clavicle in the mid-clavicular line. d Corresponding ultrasound image. Arrow on the pleural line

Fig. 1.9 (continued)

Fig. 1.10 a Transaxillary longitudinal section in the mid-axillary line. b Corresponding ultrasound image—dorsally tilted view. 1 Anterior serratus muscle, 2 Intercostal muscle, 3 Pleural line (arrows). c Corresponding ultrasound image—ventrally tilted view

The investigation is concluded by using the transaxillary approach (Fig. 1.10a–c).

With regard to transesophageal and transbronchial ultrasonography, please refer to the corresponding chapters.

Conclusion (See Abstract)

Thanks to excellent resolution and the possibility of dynamic investigation, ultrasonography provides crucial information in patients with chest disease. Entities of the chest wall and changes in pleura can

be visualized directly with ultrasound; pulmonary processes can be registered by ultrasound when they extend to the visceral pleura or when the ultrasonic wave is able to pass through a sound-conducting medium. The anterior portions of the mediastinum can be viewed percutaneously by the use of special sonic windows. To investigate the chest, one should use a combination of a linear transducer (5–7.5 MHz) for the near field and a convex or sector probe (3.5–5 MHz) for the deeper regions. High-resolution transducers of 5–18 MHz are needed to investigate the upper thoracic aperture and the supraclavicular region, in order to visualize the nerve branches of the brachial plexus and the structure of lymph nodes.

2.1 Introduction

Due to its rather superficial location, the chest wall is almost ideally suited for ultrasound investigation. The primary indications for performing an ultrasonography of the chest wall include the clarification of swelling or suspicious findings in the chest wall on palpation, and targeted investigation of painful sites in the chest wall (Abstract). Furthermore, ultrasonography of the chest wall plays an important role in performing biopsies and planning surgery for tumors of the chest wall or space-occupying lesions of the lung invading the chest wall. Last but not least, ultrasound plays an important role in the investigation of lymph nodes

Indications for an Ultrasound Investigation of the Chest Wall

- Swelling of the chest wall
- Pain
- Ambiguous findings on palpation
- Ambiguous findings on X-rays
- Chest trauma
- Tumor staging
- Intervention
- Follow-up, monitoring progress

2.2 Accumulation of Fluid

2.2.1 Hematomas

Depending on their red blood cell content and degree of organization, hematomas may cause a variety of echo patterns. Usually they are anechoic or hypoechoic (■ Fig. 2.1). Occasionally one finds subtle veil-like internal echoes. Intermediate forms may be seen in rare cases, which include more dense echoes in the internal spaces. Organized hematomas may be very inhomogeneous in terms of their echo pattern.

■ Fig. 2.1 Hematoma. Extensive hematoma of the dorsal portion of the chest wall after a fracture of the scapula and a serial rib fracture. Ultrasound investigation reveals an anechoic septated hematoma measuring 15 cm in length

2.2.2 Abscesses of the Chest Wall

Depending on their cell and protein content, a variety of internal structures may be found in an abscess cavity. Thus, the content of abscesses may be similar to that of hematomas. Quite often they cannot be delineated by ultrasound investigation alone, especially because there may be many intermediate stages such as infected hematomas. A major difference between abscesses and sterile hematomas is that abscesses tend to be accompanied by a capsule of differing shape, with floating internal structures (■ Fig. 2.2). In the majority of cases, clinical features such as reddening of the overlying skin clearly indicate the presence of an abscess.

2.2.3 Postoperative Seromas

Postoperative seromas are frequently observed after a muscle-sparing lateral thoracotomy. Postoperative seromas are largely anechoic, round or bizarre in shape, and do not have a capsule. Lymphatic cysts have a similar structure and are mainly round or -oval. Occasionally the occluded lymphatic vessel can be visualized.

■ Fig. 2.2 A painful swelling in the right armpit raises suspicion of a sweat gland abscess. Ultrasonography reveals a largely anechoic space-occupying lesion measuring 3 x 1.5 cm in size. The moderately echogenic margin is indicative of an incipient capsule. The ultrasound-guided puncture reveals pus

2.3 Space-Occupying Lesions of the Chest Wall

Tumors of the chest wall are rather rare and usually benign. In most cases, the clinical symptoms alone permit conclusions about the benign or malignant nature of the lesion. Benign tumors are usually asymptomatic, grow slowly, and retain their tissue margins. In some tumors such as lipomas or fibromas, the combination of clinical symptoms and ultrasound features is so typical that a biopsy is not required. In contrast, malignant tumors grow rather rapidly, invasively, and are painful.

2.3.1 Lipoma and Fibroma

Lipomas are the most common tumors of the chest wall and are usually diagnosed by clinical investigation. The echogenicity of lipomas and fibromas depends on their cellular fat content, the quantity of connective tissue, and interstitial impedance differences. The texture may range from hypoechoic to relatively echodense (Fig. 2.3). Their demarcation from the environs may be blurred, and a capsule may develop.

2.3.2 Neurogenic Tumors

Neurogenic tumors such as schwannomas or neuromas are seen on ultrasound as oval hypoechoic lesions with sharp demarcations, and therefore do not differ significantly from space-occupying lesions of a different etiology. Evidence of the corresponding nerve is a diagnostic sign of a neurogenic tumor (Fig. 2.4).

2.3.3 Sarcoma and Soft Tissue Metastases

A major criterion of a malignant space-occupying lesion is the presence of invasive growth (Fig. 2.5). In terms of echotexture it is frequently hypoechoic, with inhomogeneous hyperechoic portions. The use of color-Doppler ultrasonography may be helpful in assessing hypoechoic structures suspected of being malignant. The suspicion of a malignant lesion may be confirmed by the type of vascularization and the course of vessels.

Knowledge of the pattern of vascularization is also very helpful in performing ultrasound-guided punctures. In this convenient location, which is usually very close to the transducer, an ultrasound-guided puncture is very useful because it provides material for histological investigation and subsequent confirmation of the diagnosis.

Fig. 2.4 Neurofibroma of the chest wall (*) in a patient with known neurofibromatosis. Evidence of the corresponding nerve is a diagnostic sign of a neurogenic tumor (arrow). Courtesy of Gerd Brodner, Medical University of Vienna

Fig. 2.3 a, b Lipomas of the chest wall: a Lipoma with a hyperechoic texture, b Lipoma with a hypoechoic texture

Fig. 2.5 a, b Chondrosarcoma of the chest wall **a** CT reveals an extensive space-occupying lesion with dense soft tissue and chondroid calcifications (*Arrow*). **b** Ultrasonography shows an inhomogeneous hypoechoic space-occupying lesion (*) with coarse cloddy calcifications (*Arrow*). An ultrasound-guided biopsy was able to confirm the suspected chondrosarcoma

The treatment of choice for a sarcoma is usually radical surgery. The resection margins and microscopic nodules can be determined better by performing a preoperative ultrasound investigation than by CT or MRT (Briccoli et al. 2007a, b). However, a preoperative CT and MRI are necessary to determine the intraosseous spread of the tumors, their depth, and exclude pulmonary metastases.

2.4 Lymph Nodes

Subcutaneous palpable swellings are usually caused by enlarged lymph nodes. The ultrasound morphology of lymph nodes is indicative of their etiology and permits a tentative assessment of the malignant or benign nature of the lesions in accordance with the patient's clinical

condition (Table 2.1). High-frequency probes provide a highly differentiated B-mode image. The pattern of vascularization on color Doppler provide information about the type of lymph nodes. The possibility of assessing the malignant or benign nature of a lesion has certainly been improved by the better resolution of the B-mode image as well as the use of various Doppler procedures for the assessment of vascularization patterns (Ying et al. 2004).

However, the benign or malignant nature of a lesion can only be established tentatively by its ultrasound morphology. Confirmation of the diagnosis requires a histological investigation of tissue obtained by performing a puncture. Alternatively, the course of the disease will confirm the diagnosis. In clinical practice, changes in ultrasound morphology are especially significant. Thus, ultrasound follow-up investigations are useful to confirm the diagnosis of inflammatory disease and document the success of treatment in cases of malignant lymph nodes.

2.4.1 Inflammatory Lymph Nodes

Inflammatory lymph nodes are rarely larger than 20 mm in size. They usually have smooth margins, are oval, triangular, or longitudinal (Fig. 2.6). A typical feature of lymphadenitis is the presence of lymph nodes arranged like a pearl necklace along lymph node stations. In accordance with the anatomical structure, one frequently finds a more or less echogenic internal zone which is referred to as the hilar fat sign and corresponds to the fatty and connective tissue in the center of the lymph nodes. This sign is especially seen in healing inflammatory processes. The zone, with sharp edges as opposed to the surroundings, is hypoechoic. One commonly finds regular courses of vessels in this region on Doppler ultrasound. The lymph node hilum with the afferent and efferent vessels are also seen.

2.4.2 Tuberculosis

After the lung, lymph nodes are the second most common site of manifestation of tuberculosis (TB). Lymph node tuberculosis occurs in about 90% of patients without accompanying pulmonary tuberculosis.

On the B-mode ultrasonography image, lymph nodes are seen in various forms in the presence of tuberculosis. Some patients have rather sharply demarcated and sequentially arranged lymph nodes, whereas others have lymph nodes spreading into the environs diffusely or centrally fused hypoechoic lymph nodes with blurred margins, similar to metastases of solid tumors (Figs. 2.7 and 2.8). The pattern of vascularization of

Table 2.1 Ultrasound morphology of lymph nodes

	Inflammatory	Malignant lymphoma	Lymph node metastasis
Shape	Oval, longitudinal	Round, oval	Round
Edge	Smooth	Smooth	Irregular
Demarcation	Sharp	Sharp	Blurred
Growth	Pearl-necklace-like	Expansive, displacing	Invasive
Movability	Good	Good to moderate	Poor
Echogenicity	Hypochoic margin, “hilar fat sign”	Hypochoic, pseudocystic	Inhomogeneous, hypochoic
Vascularization	Regular, central	Irregular	Corkscrew-like

Fig. 2.6 Ultrasound image of a normal lymph node with a bean-shaped appearance, a hyperechoic hilum, and a hypochoic cortex

Fig. 2.8 Pseudocystic necrosis of a lymph node in the presence of lymph node tuberculosis

Fig. 2.7 Bean-shaped hypochoic lymph nodes with sharp margins and a significant surrounding soft tissue edema

tuberculous lymph nodes cannot be distinguished from that of lymph node metastases.

2.4.3 Malignant Lymphoma

On the B-mode ultrasound image, lymph nodes in the presence of lymphoma are usually round, hypochoic, with sharp margins, without a hilum, and thus cannot be distinguished from lymph node metastases of solid tumors (Fig. 2.9). Markedly poor echogenicity of

Fig. 2.9 Lymph nodes arranged sequentially in a cobblestone-like pattern, in a patient with a small-cell lymphocytic lymphoma. The lymph nodes are round, with sharp margins, hypoechoic, and without a hilum

Fig. 2.10 Micronodular pattern of a lymph node in a patient with a small-cell lymphocytic lymphoma

the lymph node could be interpreted as sign of lymphoma. On older ultrasound devices the lymph nodes look almost like cysts. On modern ultrasound devices, high-resolution transducers usually show a micronodular reticular internal echo (Fig. 2.10) (Ahuja et al. 2001). Lymph nodes arranged bilaterally around a vessel (“sandwich-like”) may be interpreted as a sign of a malignant lymphoma. The vascularization of malignant lymphomas may be regularly enhanced or even irregular at the edges.

2.4.4 Lymph Node Metastases

On the B-mode ultrasonography image, round lymph nodes and the loss of the hyperechoic hilum are signs of lymph node metastases (Fig. 2.11). The demarcation is frequently blurred. Aggressive growth in terms of the invasion of muscles and vessels may be observed. Lymph node metastases are usually irregularly hypoechoic. Lymph node metastases of papillary thyroid carcinomas may be hyperechoic due to thyroglobulin deposits (Esen 2006). Size is an unreliable criterion of malignancy. In supraclavicular lymph nodes, a transverse diameter of 5 mm or more is considered pathological. Occasionally one also finds reactive lymph nodes in the vicinity of metastatic lymph nodes. The pattern of vascularization of lymph node metastases is very characteristic: vessels tend to be located at the edges, are distributed unevenly, follow a chaotic route, flow in various directions, and show changes in color (Tschammler et al. 2002).

Non-palpable lymph node metastases can be seen on ultrasound. Therefore, in the presence of breast cancer an ultrasound investigation of the axilla is recommended in preoperative staging and when monitoring the progress of disease (Ciatto et al. 2007; Krishnamurthy et al. 2002; Johnson et al. 2011).

An ultrasound investigation of the supraclavicular region is especially important in staging bronchial carcinoma because enlarged and usually non-palpable supraclavicular lymph nodes are found in as many as 51% of patients with mediastinal N3 lymph nodes (Prosch et al. 2007a, b; van Overhagen et al. 2004). An inoperable tumor stage (III B) can be demonstrated with minimal

Fig. 2.11 Lymph node metastasis of a supraclavicular lymph node (arrow) immediately adjacent to the jugular vein (*). On ultrasound the lymph node has rounded contours and no fatty hilum

risk, at a low cost, by performing an ultrasound-guided biopsy of the lymph nodes (■ Figs. 2.12, 2.13, and 2.14).

The change in the size of lymph node metastases is a useful parameter of its progress. Despite the fact that the patient responds to chemotherapy or radiotherapy, reactive lymph nodes may persist.

■ Fig. 2.12 Supraclavicular lymph node metastasis of a squamous cell carcinoma of the lung with disruption of the capsule and invasion into the adjacent jugular vein

■ Fig. 2.13 Supraclavicular lymph node metastasis of an ovarian carcinoma. The lymph node is seen on ultrasound as a nearly anechoic (cystic) rounded lesion with sharp margins and calcified edges (arrow)

■ Fig. 2.14 Supraclavicular lymph node metastasis of an adenocarcinoma of the lung. On high-resolution ultrasound it is seen as a largely homogenous hyperechoic oval lymph node with sharp margins and without a hyperechoic hilum (*)

2.5 Bony Thorax

2.5.1 Fractures of the Ribs and the Sternum

Non-displaced rib fractures may be difficult to diagnose in clinical routine because rib fractures frequently escape detection even on targeted X-rays of the ribs. However, timely detection of a rib fracture is important for early initiation of appropriate pain treatment on the one hand, and for differential diagnosis on the other. A number of studies performed in the last few decades have shown that rib fractures are demonstrated with much greater sensitivity by a targeted ultrasound investigation than by an X-ray of the ribs (Bitschnau et al. 1997; Griffith et al. 1999a, b; Turk et al. 2010; Battle et al. 2019). In 19 of 20 patients with no rib fractures on conventional X-rays, Turk et al. found rib fractures in the ultrasound investigation (Turk et al. 2010).

By performing a targeted investigation at the site of pain, a rib fracture can be detected quite rapidly even by an inexperienced investigator. In contrast, the diagnostic reliability of ultrasonography in demonstrating fractures of the sternum is poor.

Criteria of a fracture on ultrasound investigation include direct evidence of a fracture gap or a cortical step (■ Fig. 2.15). In cases of a very narrow fracture gap (more marrow than the lateral resolution capacity of ultrasound), the fracture may be demonstrated indirectly by the evidence of reverberation echoes or the so-called chimney phenomenon. These reverberation artefacts arise at the boundaries of fracture fragments and extend vertically into the deeper aspect. In non-displaced fractures, the chimney phenomenon can be triggered by gentle pressure on the point of pain. Some patients have a circumscribed hematoma, which is an indirect sign of a fracture.

Demonstration or exclusion of concomitant injuries like a pneumothorax, a hemothorax, a lung contusion, or injuries to the organs of the upper abdomen are clinically more important than the detection of rib fractures. In clinically stable patients, the rib fracture itself *and* the concomitant injuries can be clarified by performing an ultrasound investigation (Wüstner et al. 2005).

The narrow gap between the osseous cartilaginous portion of the rib and the primary bony rib, a regular phenomenon in elderly patients, may lead to the false-positive diagnosis of a rib fracture (Fig. 2.16).

Anatomical conditions and normal variants should be considered when assessing the sternum as well, in order to rule out the risk of false-positive diagnoses. The normal discrete cortical interruption in the synchondrosis between the corpus and the manubrium should not be mistaken for a fracture. Various forms of missing fusion or bone appositions that may occur in rare cases should also be taken into account (Chan 2009; Hyacinthe et al. 2012).

Fig. 2.15 Rib fracture with a cortical step directly at the site of pain

Fig. 2.16 Potential reasons for a false-positive diagnosis of a rib fracture on ultrasound investigation. **a** Cortical interruption in the region of the synchondrosis between the corpus and the manubrium. **b** Gap between the osseous cartilaginous portion of the rib and the primary osseous rib

In clinical monitoring one first finds a local hematoma as a hypoechoic/anechoic edge in the region of the fracture gap. The subsequent formation of callus is marked by incipient organization and consolidation. The beginning calcification causes fine acoustic shadows or even complete ossification. Once this has been concluded, all that remains is a forward hump of the continuous and strong cortical reflex (Fig. 2.17). Disrupted healing can be easily established by the absence of continuous ossification. Consolidation starts from the 3rd to 4th week after an injury; in normal cases complete restitution is achieved after a few months (Friedrich and Volkenstein 1994).

2.5.2 Osteolytic Metastases

An osteolysis is usually a tumor metastasis. A notable aspect of an osteolysis is an interrupted and destroyed cortical reflex with pathological echo transmission. Osteolytic metastases are usually well demarcated, round or oval space-occupying lesions, partly hypoechoic, and of gross echostructure. Color-coded duplex ultrasonography demonstrates corkscrew-like newly formed vessels. In tumor staging, ultrasound is a reliable procedure to differentiate rib fractures from bone metastases (Paik et al. 2005). In cases of doubt, an ultrasound-guided biopsy can be used at minimal risk for histological investigation and confirmation.

During ongoing treatment, osteolysis in the bony portion of the chest serves as a progress parameter in the presence of multiple myeloma, small-cell bronchial carcinoma, prostate or breast carcinoma. An increase or decrease in size on the one hand, and a change in internal structures in terms of ultrasound morphology on the other, can be compared and documented. Recalcification under treatment is seen earlier on ultrasonography than on X-rays.

Fig. 2.17 a, b Fracture a A recent fracture (arrow) of a rib in the ventral portion of the costal arch, close to the cartilaginous part (*). b Complete healing and a minimal hump: a residual finding after 3 months (arrow)

Fig. 2.18 Panoramic view of a lung carcinoma invading the chest wall (arrow) between two ribs (*)

! Cave

The staging of bone metastases cannot be performed by ultrasonography. It would be meaningful to examine the sites of positive scintigraphy findings, palpable swellings, and painful sites.

2.5.3 Invasion of the Chest Wall by Bronchial Carcinoma

Percutaneous ultrasonography is especially informative for the assessment of an invasion of the chest wall by a lung carcinoma. According to the TNM staging system, an invasion of the chest wall is defined as a T3 tumor and is found in 6% of patients at the time of diagnosis (Mountain 1997; Facciolo et al. 2001). Invasion of the chest wall as such is no exclusion criterion for curative resection of the tumor but is of crucial importance for the surgical procedure because parts of the chest wall also must be resected in these cases (Fig. 2.18).

Owing to its high spatial resolution, ultrasonography is markedly superior to CT for evaluating an invasion of the chest wall (sensitivity 89–100 % versus 42–68 %) (Bandi et al. 2007; Suzuki et al. 1993). Reliable signs of invasion include direct evidence of tumor spread into the chest wall or rib destruction (cf. Overview, Fig. 2.19) (Bandi et al. 2007). Widening of the pleura and/or limited respiratory motion of the tumor are interpreted as indirect signs because an inflammatory reaction of tissue surrounding a tumor may also cause both of these changes.

Signs of Invasion of the Chest Wall

Reliable signs

- Direct evidence of chest wall invasion
- Rib destruction

Additional signs

- Pleural thickening
- Limited respiratory motion

Preoperative clarification of an invasion of the chest wall is especially significant in tumors that invade the chest wall at the apex of the lung; these are referred to as Pancoast tumors. ‘According to the TNM staging system, Pancoast tumors are T3 tumors as long as they do not invade the mediastinum, a vertebral body, the subclavian artery or vein, the C8 nerve root or higher (Detterbeck et al. 2013a, b). The imaging procedure of choice for the investigation of a Pancoast tumor is an MRI scan. In patients who cannot be investigated by MRI due to contraindications, invasion of the nerve roots or the plexus can be determined by a targeted ultrasound investigation (Fig. 2.20).

Fig. 2.19 a, b Pancoast tumor on the right side **a** MRI (coronal T2 STIR) shows an extensive tumor growing around the C8 nerve root and touching the C7 root. **b** High-resolution ultrasound. The C8 nerve root (*arrow*) in the efferent portion is entirely ensheathed by the tumor (*) and swollen

Fig. 2.20 Soft tissue metastasis of a squamous cell carcinoma. On ultrasound the metastasis is seen as a hypoechoic space-occupying lesion with partly sharp and partly blurred margins

Conclusion

Fractures of the ribs as well as the sternum are seen well on ultrasound. Fracture diagnosis based on ultrasound is not only more sensitive than conventional X-rays, but also provides reliable and rapid views of soft tissue lesions, hematomas and pleural effusions.

The visualization of lymph nodes and a tentative assessment of the malignant or benign nature of a lesion are important indications to perform an ultrasound investigation of the chest wall. In case a puncture needs to be performed for the purpose of treatment, all ambiguous lesions of the chest wall can be easily accessed for an ultrasound-guided puncture and subsequent histological confirmation of the diagnosis. The risk associated with puncture are very low because of the convenient location of the lesions. When the malignant nature of a chest wall lesion has been proven, its progress under treatment can be monitored by ultrasonography.

In the normal thorax the transthoracic sonographic view reaches to the pleura at the most. The healthy air containing lung is not depictable due to the total sound reflection at its surface. In the early years of ultrasound up to the nineteen eighties the presentation of pleural effusions was considered the only reasonable application for chest sonography apart from echocardiography.

The bony chest cage impedes the presentation of the pleura because of the shadows behind the ribs and the sternum. An appropriate examination technique allows an insight to the pleura through the intercostal spaces, when angulating the transducer also to the parietal pleura behind the ribs. By respiratory maneuvers the lungs move up and down. The visceral pleura slides through the intercostal field of view and thereby becomes sonographically visible. The diaphragmatic pleura is seen best in deep inspiration through the abdomen using liver and spleen as an acoustic window. The pleura of the apex of the lung is directly detectable through the supraclavicular fossa. The scapula as an osseous obstacle can be shifted or rotated by arm movements in medial or lateral direction. The mediastinal pleura and its continuation along the spine is largely invisible by transthoracic examination (see ► Chap. 1).

3.1 Technical Visualization of the Pleura

The pleural surface of the lung can be approximately estimated by means of CT sectional images. Supposing the invisibility of the mediastinal pleura about 70% of the pleural surface can be visualized by a transthoracic approach (Reuss 2010). Fortunately most of the pathologic changes of the pleura are in this region. Pathologic changes exclusively located at the mediastinal pleura are rare.

The normal pleura is approximately 0.2 mm thick. This is within the range of the axial resolution of 0.2 mm of a 10 MHz-transducer. Nevertheless the visualization of the pleura also succeeds with a transducer with lower frequency due to the differences in the impedance between the pleura and the neighbouring layers of fat and fluid (► Fig. 3.1). The visceral pleura covers the aerated lung. At this interface arises a total reflection of the ultrasound, visible on the screen as a very bright line including the visceral pleura (Reuss et al. 2002). Actually the visceral pleura is not really visible when the healthy lung is filled with air. In case of an usually hypoechogenic subpleural consolidation of the lung the visceral pleura is demarcated with the same echogenicity and thickness as the parietal pleura (► Fig. 3.2).

► Fig. 3.1 Clearly identifiable double contour in the region of the parietal pleura (arrow) corresponding to the actual parietal pleura and the endothoracic fascia. Disproportionately thick visceral pleura (arrow heads), due to an artifact

► Fig. 3.2 Subpleural consolidation in a patient with lung embolism and pleural effusion. Thus the pleura is delineated separately from the total reflection at the air in the lung. Visceral and parietal pleura are displayed equally thick and equally echogenic

3.2 Indications for Pleural Sonography

The clinical questions that indicate an ultrasound examination of the pleura are manifold (Reuss 2010) (► Table 3.1). However wide overlap with indications for ultrasound of the chest wall, lung, diaphragm and abdomen is present. Only the symptom dyspnea may be triggered by sonographically visible changes such as pleural effusion, pleurisy, pleural tumor, pleural fibrosis or pneumothorax, but also by interstitial syndrome in cardiac failure, ARDS, pneumonia, lung atelectasis due to a central lung tumor and lung embolism, a diaphragmatic paresis or diaphragmatic eventration due to ascites. The broad use of thoracic ultrasound is worthwhile (Mathis 1997). Almost always, the two main clinical

Trauma	Pleural effusion Hemothorax Pneumothorax	
Artificial ventilation	conventionally-radiologically occult pneumothorax conventionally-radiologically occult effusion	Sulcus anterior syndrome

symptoms of the thorax, namely dyspnea and pain, are of great importance. After patients history and clinical examination, thoracic sonography should be carried out quickly as the diagnostic tool of first choice. Thoracic sonography performed promptly in the clinic, practice, and emergency medicine is rewarding (Mathis, 1997) and sets an early diagnostic course.

3.3 Normal Pleura

In transthoracic intercostal examinations the intercostal space is smoothly limited by the very thin, moderately echogenic parietal pleura. Provided good examination conditions there is occasionally a double line visible representing the parietal pleura and the endothoracic fascia (Reuss et al. 2002) (■ Fig. 3.1). Between parietal pleura and intercostal muscles is an individually very different hypoechoic layer, the extrapleural fat layer. The visceral pleura is separated from the parietal layer by the thin anechoic pleural space. Inwards the pleural space follows the normally hyperechoic line of the visceral pleura sliding up and down with respiration. Pleural sliding is diagnostically important to prove normal conditions. Missing pleural sliding may have different causes (■ Table 3.2). Absence of pleural sliding can be found among different conditions, in pneumothorax, emphysema, pleural rind, but also physiologically in the area of the lung apex. Here, one must not misinterpret the sometimes barely perceptible sliding movements as pneumothorax.

Normally both pleural sheets are completely smooth. Occasionally comet-tail-artifacts with a ring-down-effect are originating from the visceral pleura, mostly in elder persons due to small scars in the pleura or subpleural lung. Particularly common are comet-tail-artifacts starting from the diaphragmatic pleura, depicted in a transhepatic or translienal view. Similar artifacts also originating from the visceral pleura must be differentiated. These artifacts are laser-like traversing to the bot-

tom of the screen without ring-down-effect and move breath dependent with the visceral pleura. These artifacts are called B-lines and represent interstitial subpleural changes in the lung, mostly in cardiac lung edema, less often in lung fibrosis or in the border area of focal malignant or benign subpleural lung lesions (see ► Chap. 4). Hence B-lines are not of real pleural origin.

3.4 Pleural Effusion

In erect position free floating effusion is located in the lowest parts of the costo-diaphragmatic pleural recessus. The effusion is surrounded by the chest wall, the diaphragm and the inferior parts of the lung (■ Figs. 3.3 and 3.4). most pleural effusions are echofree, especially in cardiac failure, severe hypalbuminemia, overhydration in renal insufficiency and in decompensated liver cirrhosis. Even in small effusions an air-free sonolucent cuspidate compression atelectasis waving breath-dependently is visible (see ► Sect. 5.4). In the sitting position also minute effusions of 20 ml are detectable (Grymiski et al. 1976; Kocijancic et al. 2004) (■ Fig. 3.5). In conventional X-ray of the chest the minimal detectable volume is about 100 ml (Colins et al. 1972).

Color Doppler demonstrates the breath-dependent and pulse-dependent internal movement in the effusion (■ Fig. 3.6). Color Doppler can be used to visualize respiratory- and pulse-dependent internal fluid movement in the effusion and thus delineate echo-poor to echo-free solid structures from fluid (■ Fig. 3.6). However, lung motion also triggers a color signal over the lung. This color Doppler signal is not always reliable, especially in very small effusions. This respiratory dependent color signal is not very reliable to distinguish

■ **Table 3.2** Missing pleural sliding, differential diagnosis

Pneumothorax	Pleural space not visible Missing lung puls No B-lines Occasionally “lung point” (see below)
Emphysema	Minimal or missing pleural sliding, minimal respiratory excursions
Pleural fibrosis	Hypoechoic or mostly hyperechoic pleural thickening
Apex of lung	Also normally minimal sliding

■ **Fig. 3.3** Large nearly echofree pleural effusion. The echoes in the deep parts of the effusion are artifacts (arrow). Lung compressed with minimal residual air in central bronchi

■ Fig. 3.4 Small posterior pleural effusion between spine and diaphragm in a transhepatic examination

■ Fig. 3.6 Small pleural effusion. The flow signals in the effusion are produced by the pulse and breath synchronous inner shift and characterize the anechoic region as fluid

■ Fig. 3.5 Very small strip-like postoperative pleural effusion in the angle between ribs and diaphragm. The deformation during respiration in the dynamic examination excludes a circumscribed pleural thickening

■ Fig. 3.7 No presentation of fluid between lung and liver, thus ruling out free floating pleural effusion. To rule out a captured effusion, the whole pleura must be examined

echopoor thickenings of the pleura from minute strip like effusions. However, a color signal is triggered also by the lung movement.

Large pleural effusions can fill the whole hemithorax forming a serothorax. Then the lung is completely collapsed and can only be seen as a small airfree lobed structure in the hilus, possibly a residual bronchoaerogram of the large bronchi in the hilus. In a serothorax after pneumonectomy the collapsed lung is lacking.

In the supine patient the pleural effusion is extending along the lateral chest wall. In a conventional chest-X-ray such an effusion is noticed only as a slight uniform unilateral opacification. Owing to a missing difference in lung transparency bilateral effusions are not detectable even under study conditions. The ultrasound examination of the supine patient must be performed from

the posterior axillary line possibly after slight rotation of the patient.

In the erect patient a freefloating effusion can be ruled out by examining the whole inferior pleura (■ Fig. 3.7). Only aerated lung with its typical reflection is visible. For this purpose a supine patient has to be rotated completely on the left or right side.

3.4.1 Volume Assessment

Measuring of the volume of a pleural effusion by means of ultrasound is not possible. Several proposals have been made to estimate the volume reaching correlation coefficients up to 0.75. The difference to the actual volume may be substantially. But for clinical purposes the

Fig. 3.8 Schematic presentation of volume estimation of pleural effusions. Valuable parameters are maximal extension of the effusion (1), inferior distance between lung and diaphragm (4), and the subpulmonary extension of the effusion (5). The thickness of the layer between lung and chest wall (2), the distance between an inferior atelectasis and the chest wall (3) and the extension of the atelectasis (6) are not suitable for the volume estimation (according to Goecke and Schwerk 1990)

estimation is mostly sufficient. Volume estimation may be important in the follow up of effusions under conservative treatment or to forecast a positive effect of a thoracocentesis in dyspnoeic patients. Thoracocentesis of an effusion volume less than 500 ml is successful only in exceptional cases concerning the respiratory function. For less experienced examiners it may be helpful to estimate the volume by a formula (Fig. 3.8).

Numerous formulas exist for calculating effusion volume (Kelbel et al. 1991; Roch et al. 2005; Balik et al. 2006; Eibenberger et al. 1994; Vignon et al. 2005; Goecke and Schwerk 1990; Hassan et al. 2017)

The following methods for estimating pleural effusion volume have been found to be practical:

1. With the patient seated, the maximum effusion height is measured along the laterodorsal thoracic wall (H). The height in centimeters multiplied by the empirical factor of 90 gives the effusion volume in milliliters (correlation coefficients 0.73) (Goecke and Schwerk 1990).

$$V = H(\text{in cm}) \times 90$$

2. With the patient lying on his back, possibly also ventilated (whose upper body is raised approximately 15° for sonographic examination), the measurement of the maximum distance (D) in millimeters between the parietal and visceral pleura is performed in end expi-

Table 3.3 Estimation of the effusion volume in supine patients

Author	Result	Comment
Roch et al. (2005)	PLDbasal > 5 cm corresponding > 500 ml effusion volume PLDbasal = distance between basal lung and posterior chest wall end expiratorically	Sens. 83%, spec. 90% Low interobserver variance
Balik et al. (2006)	$V(\text{ml}) = 20 \times \text{Sep}(\text{mm})$ V = effusion volume Sep = separation distance between basal lung and chest wall in posterior axillary line	Correlation coefficient $r = 0.72$
Eibenberger et al. (1994)	Effusion thickness dorsobasal 20 mm corresponding 380 ± 130 ml 40 mm corresponding 1000 ± 330 ml Measurement expiratorically	Correlation coefficient $r = 0.80$
Vignon et al. (2005)	Effusion thickness dorso-basal > 45 mm right/ > 50 mm left corresponding > 800 ml effusion volume	Sens. 94% right, 100% left Spec. 76% right, 67% left

ration. The volume in milliliters is calculated multiplied by the empirical factor of 20 (correlation coefficient 0.72).

$$V = D(\text{in mm}) \times 20$$

3. When calculating the effusion volume with the current highest correlation coefficient of 0.83, add the lateral effusion height (H) in centimeters with the distance of the diaphragm to the lung in centimeters (D) in a sitting patient and multiply by the empirical factor of 70 (Hassan et al. 2017) (Table 3.3).

$$V = H(\text{in cm}) + D(\text{in cm}) \times 70$$

3.4.1.1 Etiology of Pleural Effusion

Depending on the etiology of the effusion, the content may present differently. Transudates in cardiac failure, hypoproteinemia or liver cirrhosis are usually echofree (Yang et al. 1992). Due to considerable differences in the impedances in the effusion and in the aerated lung or the chest wall arise scatter artifacts in the effusion. These artifacts shift typically with the transducer movements (Fig. 3.3).

Blood, pus or chylus reflect the ultrasound differently, therefore these effusions are echogenic (Figs. 3.9 and 3.10). The internal echoes shift breath and pulse dependant in the effusion, sometimes nearly circular. Protein agglomerates in inflammatory and malignant effusions

Fig. 3.9 Exclusively subpulmonary pleural effusion in severe right heart failure, latero-posterior longitudinal section. The infra-pulmonary and lateral diameters of the effusion add up to an estimated volume 720 ml, according to the formula of Goecke and Schwerk. In exclusively subpulmonary effusions this formula underestimates the actual volume. Actually aspirated volume 850 ml

Fig. 3.10 Echogenic protein containing pleural effusion in a patient suffering from an IgA-myeloma. In contrast to artificial echoes these echoes move swinging or rotating synchronous with breath or pulse. Inflammatory, hemorrhagic or chylous effusions present in a similar manner. Transudates are usually echofree

also cause an echogenic appearance of the effusion (Chian et al. 2004). A reliable distinction between transudates and exudates by ultrasound is impossible. Also one third of exudates appear echofree (Yang et al. 1992). Modern ultrasound devices are highly sensitive and show occasionally internal echoes also in transudates (Fig. 3.11). If diagnostically necessary a thoracocentesis is acquired. The indication should be provided generous (Hooper et al. 2010). With the patient's consent this is possible immediately after sonographically establishing a puncture site. The aspirate is then further analyzed in the laboratory depending on the specific issue (Table 3.4).

Fig. 3.11 Homogenous echogenic pleural effusion with atelectasis of the lower lobe of the lung. Lack of fever or clinical signs of inflammation and no trauma in the history is unlikely for an empyema or hemothorax. Aspiration reveals a chylous effusion due to metastases of a lung carcinoma in the mediastinum with destruction of the thoracic duct

Table 3.4 Analysis of aspirate from pleural effusions

Macroscopy	Appearance	Clear, turbid, purulent, bloody
	Consistency	Runny, viscous, ropy, frothy
Leucocytes	Transudate < 1000/μl Exudate > 1000/μl	
Hemoglobin	Hematocrit	Almost equal to blood => hemothorax
Clinical chemistry	pH	<7.2 => parapneumonic, empyema
	Total protein	Limit transudate/exudate 3 g/dl
	Glucose	< 60 mg/dl or quotient effusion/serum < 0.5 => parapneumonic, rheumatic, tbc
	LDH	Quotient effusion/serum >0.6 => parapneumonic
Bacteriology	Culture aerobic and anaerobic and	Gram staining
In case of clinical suspicion	Tbc-PCR and -culture, cytology, virology, tumor-marker, cholesterol, triglycerides, chylomicrones, lipase	

3.4.2 Complicated Parapneumonic Effusion

Infected, septated and captured pleural effusions are referred to as complicated (Light 2006). Rounded margins due to the adhesion of the pleural layers are characteristic for captured pleural effusions, a finding similar to that in CT and MRI. Captured and loculated effusions show less deformation as free floating effusions when holding the transducer fixed to the chest wall. Compared to CT and MRI ultrasound is the best method to detect septations. Septations often develop spontaneously in a parapneumonic effusion or in an empyema (■ Figs. 3.12 and 3.13). Inadequately treated

■ Fig. 3.12 Malignant pleural effusion in metastasized ovarian carcinoma. Even on the stationary image one suspects the dynamic circular movement of the echoes in the effusion (arrowheads). Deep in the effusion strip-like artifacts. Small pleural metastasis on the diaphragm (arrow)

■ Fig. 3.13 Partly clear echogenic effusion, the subphrenic ascites and the humpy cirrhotic liver clearly depictable. The aspirate of the effusion clear, with a protein content of 29 g/L formally a transudate.

parapneumonic effusions have a high risk of prolonged hospitalization, prolonged systemic toxicity, increased mortality after late or inadequate tube drainage, a residual decline of respiratory function, a local spreading of the inflammation and an increased mortality (Light 2006). The prognostic risk of parapneumonic effusions is rising correlated to an increasing volume. Captured or septated effusions and a thickened pleura are typical signs of an increased risk. Ultrasound is best suitable to detect effusion volume, loculation and pleural thickening. A negative bacterial culture or Gram staining and a pH > 7.20 in the aspirate mark a low risk. Aspirates with positive culture or Gram staining, purulent aspirates or a pH < 7.20 are typical for an empyema (Colice et al. 2000; Heffner 2010) (■ Table 3.5).

Hemorrhagic as well as malignant effusion can also appear septated or loculated. Also as a result of multiple thoracenteses fibrinous strings and bands appear. Fibrinous strands, pleural thickenings and accompanying consolidations of the lung are nearly always indicating an exudate, except the typical compression atelectasis of the lower lobe of the lung.

To exclude septations prior to each diagnostic pleurocentesis and especially prior to a therapeutic thoracentesis an ultrasound scan should be done. Puncturing of single chambers, if necessary, may be carried out under ultrasound guidance. Different echogenic content of chambers may indicate a partial empyema or hemorrhage.

3.4.3 Pleural Empyema

Pleural empyemas usually present as capsulated, low to moderately echogenic and relatively homogenic effusions. Owing to the adhesions they are not free floating when changing the patients position. Usually the pleura is thickened. With the panoramic function of modern ultrasound scanners also large empyemas can be mapped in their whole extension.

In CT empyemas appear with moderately and uniformly thickened pleura with relatively smooth margins to the cavity (Light 2006). The separation of the pleural sheets, known as “split pleura sign”, may also be depicted by ultrasound. Usually the inflammatory infiltration into the surrounding lung is limited. Passive atelectases close to the empyema may occur. Complex septations and passive atelectases support with a sensitivity of only 40% the diagnosis of an empyema. A pleural puncture is needed to confirm the diagnosis.

A careful and differentiated transthoracic ultrasound examination can already clarify the therapeutic pathway with establishing the diagnosis (■ Figs. 3.14 and 3.15). Loculated empyema are not suitable for percutaneous

Table 3.5 Parapneumonic pleural effusion and empyema

	Uncomplicated PPE	Complicated PPE	Empyema
Pleural morphology	Thin	Fibrinous exudates, septations	Thickened, granulation tissue, septae and loculations
Pleural aspirate	Clear	Turbid	Purulent
pH	>7.30	7.1–7.2 (7.3)	<7.1
Lactatdehydrogenase	<500 U/L	>1000 U/L	>1000 U/L
Glucose	>60 mg/dl	<40 mg/dl	<40 mg/dl
Cytology	PMN +	PMN ++	PMN +++
Microbiology	Sterile aspirate	Occasionally positive (microscopically and in culture)	Often positive (microscopically and in culture)

Examination of pleural fluid; PMN polymorphonuclear cells; PPE parapneumonic effusion
According to Tasci et al. (2005)

Fig. 3.14 Honeycomb-like loculated post-inflammatory pleural effusion. Ultrasound avoids frustraneous puncture attempts with a possible risk of injury

tube drainage. Such empyema need a surgically or video assisted thoroscopically guided drainage with destruction of the septae (Fig. 3.16). Unilocular empyema nowadays are drained transthoracically with tubes of 10–30 Char. under ultrasound guidance. Highly viscous contents of an empyema need a greater diameter of the tube (Figs. 3.17, 3.18, and 3.19) (see Chap. 10).

A lung abscess may be difficult to differentiate from a pleural empyema. Lung abscesses often have an extended inflammatory infiltration and atelectatic parts of the surrounding lung, mimicking a very thick wall. Repositioning the patient air containing lung abscesses present with a change of the air-fluid level. Air content

Fig. 3.15 Captured effusion after pancreatitis. Radiologically the effusion the formation impresses as a pleural based tumor. A reliable differentiation of a unilocular empyema is impossible, therefore a diagnostic puncture is needed

is a reliable sign for a connection of a lung abscess to a bronchus. After multiple previous punctures also pleural empyema may contain a few air. Gas-forming bacteria are rare in pleural empyema. The prove of vessels in the pericavitary consolidation occurs more frequently around an abscess and is not typical for an empyema. But using CEUS vessels may be found also around an empyema.

For the transthoracic therapy of a lung abscess it is crucial not to drain through aerated lung. The drainage should strictly be performed in an area where the pleural

Fig. 3.16 30 year old patient suffering from pneumonia, only few residual air in the lung parenchyma. Around the consolidated lung a septated effusion with irregular thickened and not well demarcated pleural sheets. Sonographically the image of a complicated effusion. The aspirate showed 8500/μl leucocytes and pH 7.05 according to an empyema. Drainage by video-assisted thoracoscopy

Fig. 3.17 Pleural empyema spreading over multiple intercostal spaces. The ribs with their shadows clearly visible. Volumetry and overall view is possible with the panoramic function

Fig. 3.19 Clearly visible thickening of the pleural sheets in an already drained empyema. Small air bubbles in the otherwise empty cavity

sheets are glued together, otherwise there is a high risk for the development of an additional pleural empyema.

3.4.4 Hematothorax, Chylothorax

A hematothorax develops posttraumatic, occasionally after interventions, e.g. after faulty puncture with injury of the lung or a vessel in the chest wall. Rarely a hematothorax occurs induced by a disease-related or anticoagulant-related coagulopathy. Not so rare is a hematothorax or hemorrhagic effusion in primary or secondary tumor diseases of the pleura, especially pleural mesothelioma.

Blood in the pleural cavity may present very differently. Fresh blood is mostly echofree similar to the flow-

ing blood in the vessels. Newly coagulated blood may be considerably echogenic, clots are usually moderately echogenic and may appear like solid tissue, frequently with cystic inclusions. After secondary liquefaction of the clots the pleural content is again echofree. Frequently septae develop in hematothoraces. Septae are obstacles for a sufficient drainage, therefore hematothoraces should be drained very early, e.g. immediately after admission to a hospital in the emergency room. Thick drainage tubes should be preferred. Determining the puncture site by ultrasound reduces the risk of secondary intervention related injuries of diaphragm, liver or

spleen, especially in case of an unknown elevation of the diaphragm. Without a sufficient drainage of a hemothorax frequently develops a pleural peel with restriction of ventilation.

Injuries or tumor related destructions of the thoracic duct lead to a chylothorax. The effusion mostly appears moderately echogenic, sometimes highly echogenic. The aspirate looks milky, with a high concentration of triglycerides and chylomicrons. The cause for the leakage may be very small tumors or metastases e. g. due to breast cancer or lung cancer. These small tumors may be very difficult to localize.

3.4.5 Pleurodesis

In malignant pleural diseases with recurrent large effusions and consecutive dyspnea, mainly due to pleural carcinosis, pleurodesis is a beneficent palliative therapy. Spraying talc solution thoroscopically over the pleura achieves the best results. But this procedure cannot be performed in every patient and everywhere. For catheter pleurodesis the pleura is emptied via a ultrasound guided drainage tube. Through this tube the talc solution is instilled into the pleural cavity. In successful pleurodesis pleural gliding is no more visible by ultrasound (■ Figs. 3.20, 3.21, and 3.23). In inadequate pleurodesis ultrasound differentiates much better between residual effusion, septation, lung consolidation or partial lung atelectasis than conventional chest-X-ray does. This suc-

■ Fig. 3.20 After successful pleurodesis. The drainage tube used for application of the talc suspension still in situ. The surrounding pleura hypoechoic and thickened. In the dynamic examination no gliding sign

cess can be secured by ultrasound after thoracoscopic pleurodesis too. For clarification of this problem a computed tomography is nearly never necessary. Ultrasound nowadays has the advantage to be available nearly everywhere in hospitals and private practice.

■ Fig. 3.21 Extended fibrinous clot after attempted pleurodesis. Inferior lung fixed to the diaphragm but not to the chest wall. Beneath the clot a significant effusion, included in the clot also liquid parts

■ Fig. 3.22 Incomplete pleurodesis. In the left part of the image the visceral pleura fits tight to the parietal pleura, there no gliding sign. In the right part of the image the pleural sheets apart with effusion in between. The inferior lung fixed with multiple fibrinous strings (arrow). Panoramic view with eight ribs in cross section and their shadows

■ **Fig. 3.23** Successful pleurodesis with formation of a broad hypoechoic pleural peel. Owing to the scarred distortions the lung surface irregular

3.5 Solid Pleural Changes

Pleural thickenings may occur diffuse, circumscribed, ribbon-shaped, nodular, regular, irregular, hypoechoic or complex structured. The changes may be limited to a single pleural sheet or affect both sheets. In an effusion or in case of a preserved gliding sign the thickening can be clearly assigned to the parietal or visceral pleura, depending on the movement with the lung. In case of interconnected pleural sheets the original pleural cavity can only be guessed by an echogenic partly interrupted line. Pleural thickenings can be observed in inflammatory diseases as well as in primary or secondary tumorous diseases. From the sonographic shape or structure of a pleural thickening cannot be deduced the etiology even though hypoechoic nodules are typical for metastases.

3.5.1 Pleuritis

Breath dependent chest pain and pleural rales are typical for pleuritis. To confirm the diagnosis multiple diseases like cardiac chest pain and myocardial infarction have to be ruled out. Conventional chest X-ray may present an opacification corresponding to a small effusion, but is often completely inconspicuous and therefore does not rule in nor rule out pleuritis. In most of these patients abnormalities of the pleura can be detected by ultrasound (overview).

Sonographical findings in pleuritis (acc. to Gehmacher et al. 1997)

- rough appearance and interruption of the normally smooth pleura (89.4%)
- small subpleural consolidations with a diameter between 0.2 and 2.0 cm (63.8%), which picks up increased contrast on CEUS

■ **Fig. 3.24** Acute pleuritis with moderately thickened pleura, the line of the parietal pleura irregular edged. Examination in the painful area of the chest

■ **Fig. 3.25** 35y old female patient in the 24. week of gestation with localized breath dependent pain. Small subpleural consolidation in pleuritis. This small consolidation could also be assigned to a lung embolism, but there was no other evidence for that

- localized parietal or basal pleural effusions (63.8%)
- CEUS: early marked contrast enhancement of the pleura

In most cases the parietal pleura is hypoechoic to moderately echogenic thickened. The lung gliding is restricted due to the pain (■ Fig. 3.24) (Gehmacher et al. 1997; Volpicelli et al. 2012). Small wedge-shaped echopoor subpleural consolidations occur as a sign of inflammatory co-reaction of the lung (■ Fig. 3.25). This is interpreted as a focal interstitial syndrome, especially when B-lines appear at the edges or comet tails behind the

Fig. 3.26 Tuberculous pleuritis without thickening of the parietal pleura, irregular visceral pleura and tiny nodular subpleural consolidations. Thin fibrinous strands in the effusion. Diagnosis confirmed by detection of mycobacterium tuberculosis in the aspirate

small conciliations (see ► Chap. 4; Lichtenstein et al. 1997). More extended hypoechoic consolidations suggest the suspicion of subpleural infiltrations in a viral pneumonia. Typical consolidations of a bacterial pneumonia can be accompanied by a pleuritis (■ Fig. 3.26, see ► Sect 5.1). Apart from the real pleural thickening ribbon-shaped moderately echogenic fibrinous deposits are detectable continuing as strings and bands through the accompanying effusion. In the late phase they are responsible for the loculation (■ Fig. 3.14).

Perfusion in the thickened pleura is only detectable by color Doppler in 23.4% of patients (Gehmacher et al. 1997). In contrast enhanced ultrasound (CEUS) the hyperemia is visible. The inflammatory thickened pleura and particularly the accompanying pneumonic consolidations display after application of contrast medium (e.g. Sonovue®) a very short time to enhancement in contrary to peels, tumors or the muscles in the chest wall (Görg et al. 2005). Though contrast enhancing agents are rarely necessary to confirm the diagnosis.

3.5.2 Pleural Peels

A pleural peel is a fibrosis of the pleura and develops as a result of different diseases like pleuritis or empyema, but also postoperatively (■ Table 3.6). Initially the pleural sheets glue together. The subsequent fibrosis spreads from one sheet to the other and produces a thickening of the pleura of sometimes several centimeters. Lung sliding is no more possible. Calcified peels are easily detectable by X-ray. Non-calcified peels manifest radiologically as parietal opacification at the chest wall or in the angle between chest wall and diaphragm. Sonographically peels are moderately echogenic, in the individual case

Table 3.6 Causes of pleural fibrosis

Spontaneously arising inflammatory diseases	Pleuritis Pleural empyema
Induced inflammation	Pleurodesis
Trauma	Chest wall trauma with pleural injury Hemothorax Recurrent pneumothorax Postoperatively, especially after pleurectomy

Table 3.7 Differential diagnosis of pleural fibrosis

Subpleural lipomatosis

sometimes nearly echofree, mimicking a small shell-like effusion. The missing of lung gliding and deformation during breathing rules an effusion out (■ Table 3.7). The demarcation of the fibrosis against the chest wall or the lung may be smooth, but often bizarre irregular (■ Fig. 3.27). In the latter case the differentiation from an infiltration by a pleural carcinosis or mesothelioma is difficult (■ Fig. 3.28). Hyperechoic calcifications with shadows are typical for old fibroses. Residual air in adjacent lung consolidations must be excluded. Extended shell-like calcifications prevent any deeper sonographical insight into the chest. Cyst-like inclusions in peels as probable residuals of former effusions are not so rare. Atypical vessels can be ruled out by color Doppler.

3.5.3 Pleural tumors

Primary benign and malignant pleural tumors are rare in contrast to metastases. Sometimes pleural tumors are accidentally discovered during a chest ultrasound. In most cases parietal tumors are previously detected by other imaging procedures like conventional chest-X-ray, computed tomography or magnetic resonance imaging. For further clarification a “point-of-care”- ultrasound examination is performed.

Fig. 3.27 Unusual pleural peel. The parietal pleura is thickened up to 6mm, but smooth demarcated. The visceral pleura is not involved. Large pleural effusion due to cardiac failure

3

Fig. 3.28 a–c Extended moderately echogenic masses with irregular demarcation in the pleural area are ambiguous without otherwise reliable clinical data and therefore need to be proven histologically. A differentiation between fibrosis, pleural carcinosis and pleural mesothelioma solely by ultrasound is difficult or impossible. **a** Extended pleural fibrosis in a young woman after several operations in the chest. The cause for the first operation was a already existing peel of unknown origin suspected to be a tumor. **b**

Slowly growing radiologically detectable non-calcified “pleural peel”. Because of the clinical suspicion of a occult carcinoma repeated transthoracic biopsies which revealed at last the “peel” as pleural carcinosis in CUP-syndrome. Between the arrows one believes to recognize the former pleural cavity. **c** Nearly identical ultrasound image as in a and b, but histologically a pleural mesothelioma in a former asbestos worker

Fig. 3.29 a, b a Small round clearly demarcated tumor of the parietal pleura. The lung is gliding breath-dependently unimpeded over the tumor. The tumor is isoechogenic compared to the chest wall muscles. In chest-X-ray a small pleural based lesion was noticed.

b Also in computed tomography a well demarcated tumor with fat density corresponding to a lipoma. No histological confirmation, but stable over many years in follow-up

3.5.3.1 Benign Pleural Tumors

Benign tumors like lipomas, neurinomas, chondromas, fibromas or benign mesotheliomas account for less than 5% of all pleural tumors. In chest-X-ray they are noticed as pleural based opacifications with smooth margins. Frequently they give rise to extended diagnostic examinations to rule out a pleural metastasis or a peripheral lung cancer. Sonographically most of the benign pleural tumors are moderately echogenic and clearly demarcated by a thin capsule. Depending on the size they displace neighboring structures, but are not growing invasively (Fig. 3.29). However, displacement and invasion are not always clearly to distinguish. Transpleural growth with missing lung gliding is compatible with malignant infiltration. Small accompanying pleural effusion can also occur with benign pleural tumors. A distinction of the different benign pleural tumors by means of ultrasound is impossible. The classification of the benign tumors by small needle biopsy specimens or only by cytology is often very difficult or impossible for the pathologist. Calcifications are more common in benign tumors. Density measurements as in CT, e.g. in lipomas, are not available in ultrasound.

Solitary fibrous tumors of the pleura, formerly known as hemangiopericytoma, are often asymptomatic and are discovered by chance in an advanced stage. Two third of all cases are originating from the visceral pleura. Occasionally this can be depicted by CEUS. However, the often existing peduncle often comes up during the operation. The tumor shows beside well perfused areas also necroses and cystic parts. Most of these tumors turn out as benign, also histologically, but may metastasize after decades. Even after malignant transformation the tumors have a good prognosis, also after operation of recurrent masses. The secretion of

insulin-like- growth-factor in large tumors can cause recurrent and difficult to treat hypoglycemias (Abu Arab 2012; Cardillo et al. 2012).

3.5.3.2 Pleural Metastasis

Pleural metastases are frequently occurring in advanced breast and lung cancers, but in many other tumors as well. The development of pleural metastases is often combined with pleural effusions. This acoustic window facilitates the displaying of the metastases. If suspicious lesions are already located by other imaging procedures, also the rare metastases without effusion are easily to depict by ultrasound. Ultrasound is in these cases usually used for the assignment of the lesion either to the lung, pleura or chest wall, to distinguish whether they are solid or liquid and to guide the transthoracic biopsy.

In a newly discovered pleural effusion of unknown origin the pleura should be scanned for suspicious metastatic lesions. A regular search for a pleural effusion in oncologic patients can reveal the occurrence of pleural metastases the first time. But since ultrasound is only a conditionally appropriate procedure for intrapulmonary metastases, an additional CT is mandatory.

Most of the metastases are located on the pleura along the chest wall, the diaphragm and in the pleural recessus, that is in regions that are well accessible for ultrasound (Figs. 3.30, 3.31, 3.32, and 3.33). Pleural metastases are mainly hypoechoic to moderately echogenic. In rare cases they seem to be echofree, mimicking liquid formations. Metastases are nodular, round, hemispherical or broad-based polyp-like protruding into the effusion. Metastases are, of course, of varying size and are detectable from a size of 1–2 mm. Large metastases can invade deeply the underlying lung or chest wall. An interrupted or missing demarcation of the vicinity or

Fig. 3.30 Metastasis located on an otherwise normal parietal pleura. Metastasized breast carcinoma. Large pleural effusion

Fig. 3.32 Patient with breast carcinoma supposed to have a singular liver metastasis. Sonographically a pleural effusion with small metastasis in the pleural recesses

Fig. 3.31 Pleural metastases in a patient with breast carcinoma and ovarian carcinoma in her history. The origin of the metastasis can only be proven by biopsy and histology. The parietal metastases are invading the chest wall and the visceral pleura, discernable by the rough lung surface and the missing gliding sign. Parasternal longitudinal section on the right side in the region of the cartilaginous ribs (arrows)

Fig. 3.33 Extended pleural carcinosis due to an endometrial cancer, known since 2 years. The diaphragm walled in, deformed and partially destroyed by the carcinosis (arrow), furthermore invasion of the liver

pseudopodia-like branches indicate malignancy. Due to the lower echogenicity they are distinguishable from the chest wall or the diaphragm. Single, well demarcated metastases cannot be differentiated from benign pleural tumors by means of ultrasound alone. Multiple occurrence of identical possibly different sized formations is nearly proving metastases especially in a known underlying malignant disease. Therefore a biopsy is not required in every case. In first detected and suspected, but not proved primary tumor an ultrasound guided needle biopsy may clarify the tumor diagnosis (Adams & Gleeson 2001). Single metastases located in the visceral pleura may occur like a peripheral lung cancer. Both lesions can spread to the other parietal pleural in the same way leading to an adhesion of the pleural sheets.

Fibrinous clots adjacent to the pleura after trauma or interventions may appear like metastases. In the real time examination metastases are rigid whereas fibrin clots slosh forth and back. In CEUS fibrin clot do not enhance contrast medium.

An expanded plate-like carcinosis of the pleura with or without effusion is rare. The sonomorphological distinction from peels or a mesothelioma is difficult. Even the needle biopsy may fail, when malignant, inflammatory-reactive and fibrinous areas and small blood clots are close together.

In CEUS most metastases enhance only moderately, dependent also from the grade of vascularization of the primary tumor. In the early arterial phase the supply through parietal pleural vessels or peripheral bronchial vessels may be observed. Visceral pleural metastases are not supplied by pulmonary arterial vessels, therefore the

Table 3.8 Differential diagnosis of pleural metastasis

Pancoast tumor with chest wall infiltration

beginning of the early arterial phase in the metastases is markedly later (>10 s) than in a surrounding atelectasis or pneumonia (3–10 s). See [Table 3.8](#).

3.5.3.3 Malignant Pleural Mesothelioma

The malignant pleural mesothelioma with an incidence of about 20/1 Mio inhabitants is one of the less frequent tumors in Germany. Most affected patients had contact to asbestos in their history (Neumann et al. 2013). Asbestos as well-known trigger of this disease is banned in the whole European Union since 2005. In western Germany sprayed asbestos is prohibited already since 1979, a general prohibition followed in 1993 (no general asbestos ban up to now in the United States of America). Today a delay between exposition and disease outbreak up to 50 years is accepted, explaining the still rising incidence. In Germany a plateau is expected for the year 2030 (Lehnert et al. 2009).

Asbestos plaques in the pleura characterize people with previous exposure to asbestos. These patients bear a risk to develop a mesothelioma. Asbestos plaques occur as calcified or noncalcified pleural thickenings typically in the posterior-inferior parts of the parietal pleura. Their appearance in chest-X-ray and computed tomography is well known. Members of risk groups are surveyed radiologically. Plaques are not only shaped like a mesa-like, but also flat tapering plaques are common. Preferably with high resolution transducers the moderately echogenic plaques with their smooth boundaries are detected in the parietal pleura with breath dependent gliding of the lung. The internal structure of the plaques is according to previous observations homogenous.

Fig. 3.34 Hypoechoic asbestos plaque with typical table-mountain-like appearance in the posterior-inferior pleura on the right side

Fig. 3.35 Newly diagnosed mesothelioma spreading tapestry-like nearly over the whole pleura of the right hemithorax, single nodules (between the markers). The patient was admitted to the hospital because of dyspnea within 2 days. In the chest-X-ray a “white hemithorax”. Decade-long asbestos exposition

About 10% of the plaques calcify and then present high echogenic and with shadows. Tiny effusions may occur.

Compared to the plaques mesotheliomas have an irregular edged and often unclear boundary. Beside tumorous mesotheliomas exist also tapestry-like spreaded mesotheliomas with embedded nodules in the pleura ([Figs. 3.34 and 3.35](#)).

The infiltration of the chest wall and the diaphragm is best depicted with high frequency transducers as hypoechoic streaky branches ([Figs. 3.36 and 3.37](#)). The tumor spreads early to the other pleural sheet. In an ultrasound study 28% of the patients both sheets of the pleura were affected at first diagnosis. Accompanying pleural effusions may be echogenic due to hemorrhage.

Fig. 3.36 Pleural mesothelioma. Already extended chest wall infiltration with inclusion of the ribs (arrow heads), and lung infiltration (arrow)

Fig. 3.37 Former asbestos workers with pleural mesothelioma. In the pleural recesses markedly thickened hypoechoic inhomogeneous pleura corresponding to the tumor. Deep infiltration into diaphragm and chest wall. The diaphragm at the dome destroyed. Small tumor dependent effusion

Making the diagnosis by cytology of the effusion or blind pleural biopsy (Abrams needle) is only in about 30% of patients successful. Thoracoscopically gathered biopsies achieve a positive diagnosis in over 90%. Percutaneous imaging guided biopsies have a comparable good success rate.

After biopsies by operation or thoracoscopy about 40% of patients develop metastases in the biopsy channel in the chest wall, but also 0-15% of patients after percutaneous biopsies, especially along the channels of the drainage tubes (Geiger et al. 2003). Therefore a short time radiation of the concerned area of the chest wall is

recommended e.g. with 3×7 Gray. Curative operations in pleural mesothelioma are possible only in few patients.

Computed tomography is the standard procedure for the lymph node situation in mesotheliomas. For lack of detailed ultrasonographic studies the magnetic resonance imaging is the gold standard for treatment planning concerning infiltration of chest wall and diaphragm. In an older study ultrasonography was also very sensitive in detecting this infiltration. The presentation of the pericardial invasion by ultrasound is highly specific (Layer et al. 1999). Data from large studies are lacking.

3.6 Pneumothorax

A pneumothorax can occur spontaneously, but also after trauma or pleurodesis. Symptoms may be mild dyspnea to severe rapidly increasing shortness of breath in tension pneumothorax (Fig. 3.38). A spontaneous pneumothorax represents often predominantly with chest pain.

Sonomorphologic signs of pneumothorax are (Alrajab et al. 2013, Soldati et al. 2008, Wilkerson & Stone 2010, Yarmus & Feller-Kopman 2012) (Table 3.9):

- Absence of lung sliding (horizontal breathsynchronous movement of the lung in relation to the lococostant reflex of the parietal pleura).
- Absence of vertical artifacts (vertical, breathsynchronous reflexes that begin at the visceral pleura and do not attenuate distally).
- Evidence of lung point (transition from breathsynchronously moving lung to standing air column of pneumothorax) (Lichtenstein et al. 2000).
- Absence of lung pulse on color or power Doppler (pulse-synchronous vertical movement of the pleura by transmission of the heartbeat through healthy lung tissue to the pleura).
- For documentation of an existing pneumothorax or normal findings, short video loops of the present or just absent pleural sliding are useful. It is also possible to obtain a side-differentiated image of pulmonary sliding or lung pulses with the aid of color or power Doppler (Figs. 3.39 and 3.40).
- To diagnose an incomplete pneumothorax, the examination should be extended dorsolaterally.

In patients with emphysema the extend of lung gliding is reduced and may be difficult to detect. B-lines in a healthy lung are often completely lacking.

Fig. 3.38 a–c Pneumothorax. **a** Ventilated side with pleural reflex and few B-lines. The ventilated lung is gliding synchronous with breathing. **b** Inforced pleural reflex at the entering of the air-

filled pleural cavity with multiple horizontal reverberation artifacts. **c** Lung point (arrow), normally aerated lung on the left, air in the pleural space on the right (partial pneumothorax)

Fig. 3.39 Color sign to rule out a pneumothorax. The color signal can represent either the lung gliding (breathsynchronous) or the lung pulse (pulsesynchronous)

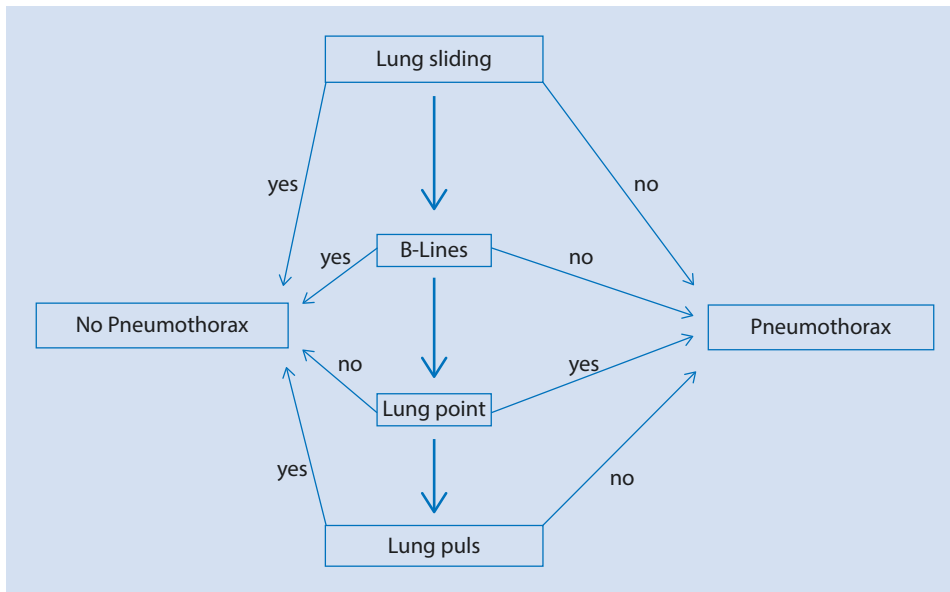

Fig. 3.40 Algorithm in suspected pneumothorax (acc. to Volpicelli et al. (2012))

Table 3.9 Diagnostic signs to detect or exclude a pneumothorax

Pneumothorax	No	Gliding sign	Yes	No pneumothorax
		No	B-lines	
	No	Lung puls	Yes	
	yes	Lung point	No	

3.7 Traumatic Changes in the Pleural Cavity

Small pleural effusions without compromising respiratory effects are common after mild to moderate chest trauma. E-fast (extended focused abdominal sonography in trauma) detects these usually non-hemorrhagic effusions. Merely only a sonographic follow up is needed.

The result of a primary or secondary bleeding into an effusion is a hemorrhagic effusion. Depending on the content of blood the effusion appears more or less echogenic. The internal echoes are moving breath dependent, often circular. The hemoglobin concentration is usually significantly lower than in a venous blood sample.

A hemothorax contains pure blood in the pleura, the hemoglobin concentration in a punctured and venous sample are almost equal. A hemothorax results usually due to a trauma, occasionally spontaneously in patients with not well-adjusted anticoagulation. Liquid

Fig. 3.41 Emergency examination in the surgical emergency room in a roofer, fallen from the roof. Dyspnea and severe chest pain on the right side. Echofree but still bloody effusion with lung atelectasis and partial rupture of the chest wall. Fluid mass included in the chest wall at the same location as a visible hematoma at the skin

blood is often completely anechoic (Fig. 3.41). Coagulation develops different grades of echogenicity. Then the echogenic pleural content is deformable, e.g. by respiration, but is obviously not liquid. Later the hemorrhage gets organized and a fibrosis develops. To prevent this process a hemothorax should be drained early with large-caliber tubes. Patients with a severe chest trauma should be examined soon by ultrasound already in the emergency room, if possible earlier at the scene or in the ambulance. If fluid is detected in the

pleura and a bloody effusion is confirmed by aspiration, immediately a tube drainage is administered after previous sonographical localization of a suitable puncture site. The following computed tomography then shows possible further injuries, especially at the spine and the big vessels.

As a result of stab injuries, rib fractures with pike-like broken ribs penetrating into the lung or due to an explosion trauma with lung rupture a pneumothorax can occur. Patients with a tension pneumothorax develop rapidly increasing dyspnea and a shock. By ultrasound the diagnosis of a pneumothorax is established within a few seconds (see ► Sect. 3.6) and the mandatory chest tube immediately can be administered. Supine chest-X-ray displays in only 50% a traumatic pneumothorax. Many emergency physicians nowadays know about the high potentials of ultrasound to prove a pleural effusion or a pneumothorax with high sensitivity and specificity.

A chest wall emphysema may prohibit the sonographic examination of the pleura (see ► Chap. 2). A posttraumatic chest wall emphysema is often combined with a pneumothorax.

3.8 Diaphragm

The diaphragm is routinely displayed by ultrasound during a transabdominal examination of spleen and liver, but attracts little attention. Many studies in the last few years dealt with the diaphragm.

3.8.1 Normal Diaphragm

The muscular part of the diaphragm inserts in the region of the lower aperture of the thorax at the ribs, the sternum and the spine. The diaphragmatic muscle presents in the ultrasound image as a narrow three-layered structure, the real muscle in the middle hypoechoic. During respiration, especially during forced respiration, the thickening in the contraction is visible (► Fig. 3.42). In particular in patients suffering from chronic obstructive lung disease the contraction-dependent thickening can be well recognized. The dome of the diaphragm consists of only a thin aponeurosis, sonographically often not to separate from the line of total reflection at the bottom of the lung. The diaphragmatic crura can be discovered on both sides of the upper abdominal aorta cranial of the origin of the celiac axis. In posterior longitudinal sections through liver or spleen the diaphragmatic crura can be found as strictly muscular organ along the spine. Normally the trigonum sternocostalis on both sides cannot be seen as well as the posterior hiatus pleuroperitonealis Bochdalek on both sides.

Normally the diaphragm bulges like a dome into the lower thorax. The flattening of the diaphragm in obstructive lung diseases can be detected in the individual case by ultrasound, not only radiologically. In severe emphysema the diaphragm may be bulged inversely.

In obese or COLD- patients often exist furrows of the diaphragm, impressing consecutively the liver. The diaphragmatic duplication is well detectable in the furrow at the liver surface. An “unsuccessful” flat transverse section through such a furrow can fake a focal liver

► Fig. 3.42 a, b Diaphragm with pleural effusion, the transition of the thicker muscular part into the aponeurosis in the dome is well to differentiate. In inspiration the muscle shortens and becomes thicker (a, arrow) and slackens during expiration (b, arrow)

lesion. Furrows at the spleen are usually only detectable in splenomegaly.

3.8.2 Visualization

Because of the pleural recesses and the normal air-filled lung the diaphragm is only depictable through the abdomen, through the liver on the right side and through the spleen on the left side. A pleural effusion enables to demonstrate the complete diaphragm through the pleural cavity. Then the aponeurosis in the dome is also clearly to visualize. Under real time conditions the diaphragmatic motion can be observed and, if necessary, recorded in a short video clip.

3.8.3 Diaphragmatic Hernia

Congenital hernias are only exceptionally discovered in the adult. The most important findings are abdominal organs, located in the thorax, e.g. mostly gut, less common liver, spleen or kidneys. In newborns with severe respiratory insufficiency a congenital diaphragmatic hernia has to be considered. According to a S1-guideline (Leutner et al. 2016) the standard diagnostic procedure in infants is a chest-X-ray. But gut in the chest can also be proven by means of ultrasound. Skilled ultrasound specialists are able to find a diaphragmatic hernia also in fetuses beyond the 18. week of gestation (■ Fig. 3.43).

The esophagogastric transition zone can be nearly regularly demonstrated as round multilayered formation. Axial sliding hernias are occasionally visible by ultrasound, but its evidence is of limited value. In reflux

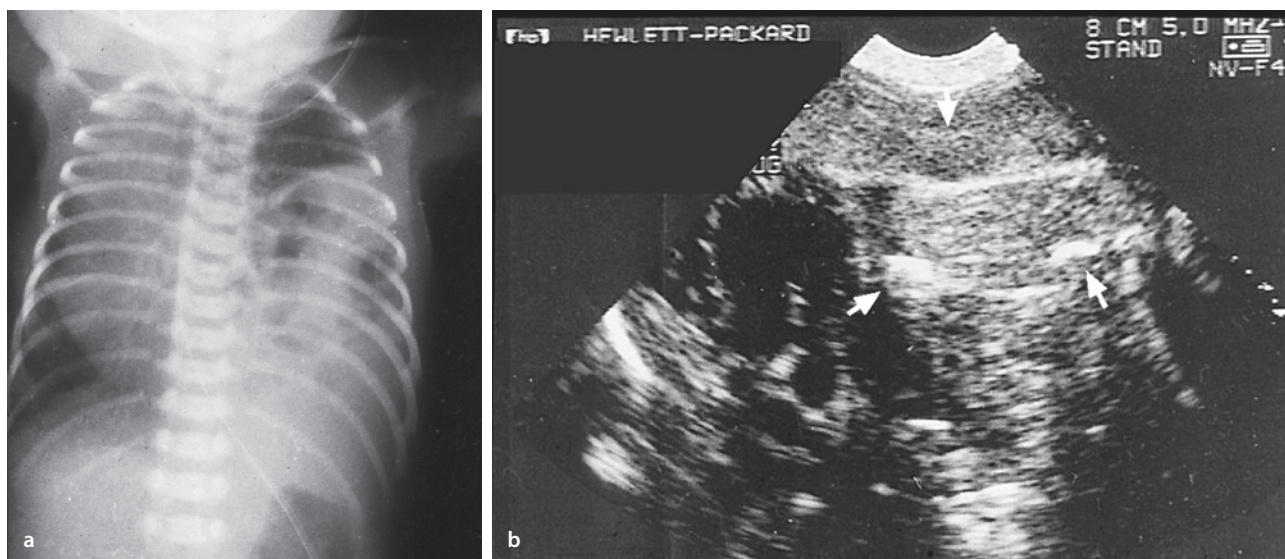

complaints endoscopy is mandatory to find a possible Barrett's esophagus.

3.8.4 Diaphragmatic Rupture

Ruptures of the diaphragm after severe abdominal or chest traumas occur in 1–3%. Only in one quarter of the patients these ruptures are detected preoperatively (Rubikas 2001; Ozpolat et al. 2009). The displacement of abdominal organs into the chest is the main sonographical symptom. The patients often have a hemorrhagic effusion. This ultrasound window improves the visualization of the diaphragm.

The margins of the rupture and the gap in the diaphragm are only depictable in individual cases (■ Fig. 3.44). A seeming gap in the diaphragm caused by an edge shadow artifact should not be misleading. The changing localization of the gap with changing the position of the transducer excludes an actual gap. These severe ill patients need a computed tomography to visualize preoperatively additional findings in the chest, abdomen, retroperitoneum and skeleton which are not demonstrable by ultrasound. In many of these cases the sonographic proof of liquid in the abdomen by FAST leads to an emergency operation. Then intraoperatively the diaphragmatic rupture turns out (Hansen and Muhl 1997).

Occasionally diaphragmatic ruptures are diagnosed years after the trauma, e.g. due to small rupture without severe symptoms. With time, the traumatic hernia canal widens and larger parts of the abdominal organs are displaced into the chest and cause respiratory insufficiency or perfusion disturbances at the herniated organs.

■ Fig. 3.43 a, b a Chest-X-ray of an infant with gas-containing intestinal organs in the left hemithorax indicating a large congenital diaphragmatic hernia. b Typical ultrasound image of a congenital diaphragmatic left-sided hernia with the stomach beneath the clearly

identifiable heart. Subxiphoidal cross section. (Courtesy Prof. Manfred Teufel, Children's hospital, Klinikverbund Südwest, Bunsenstr.120, D 71032 Böblingen)

Fig. 3.44 a–d Male patient after fall from a balcony in the fourth floor. Despite tube drainage due to hemothorax worsening oxygen saturation in mechanical ventilation. **a** In the chest-X-ray opacification infero-lateral on the left, therefore immediate ultrasound examination because of suspected not drained part of the hemothorax. **b** Sonographically in the chest a round indeterminate structure filled with echogenic fluid. **c** Below the diaphragm parts of the stomach with tube. In the dynamic examination the stomach can be tracked through the diaphragm into the chest (composite image). **d** Confirmation of the diagnosis by filling the stomach with contrast via the tube. In CT the diaphragmatic rupture shown but misinterpreted

3.8.5 Diaphragmatic Tumors

Primary tumors of the diaphragm are rare and the diagnosis is usually not made in early stages, at most as an incidental finding (Belaabidia et al. 2006) (■ Figs. 3.45 and 3.46). Also metastases in the diaphragm are rare, but may cause pain by infiltrating adjacent nerve plexuses (■ Figs. 3.47 and 3.48). Diaphragmatic metastases are typically enclosed in the diaphragm in contrary to pleural or—less common—peritoneal metastases placed on the diaphragm. Large pleural metastases may infiltrate into or break through the diaphragm (■ Figs. 3.47, 3.48, and 3.49). Pleural mesotheliomas may present an infiltration of the diaphragm as well as into the liver or spleen. By ultrasound not only the tumor infiltration is visible but also the tumor related fixation and paresis of the diaphragm.

■ Fig. 3.45 Rare finding of a lipoma in the diaphragm. Smoothly demarcated tumor (arrow) presenting in similar fashion in CT showing fat density

■ Fig. 3.46 a–c a Smoothly demarcated opacification at the diaphragm in chest-X-ray, incidental finding. In retrospect this lesion was already guessed on a previous chest-X-ray 7 years earlier. b By ultrasound a cyst-like lesion with solid parts and septae seeming to originate from the diaphragmatic pleura. No calcifications, with color-Doppler no vessels detectable. c By CEUS in the bronchial-

arterial phase the solid parts and the septae contrast enhancing, the vessels originating from the diaphragm. Thus a hydatid disease ruled out, the echinococcus titer negative. The tumor was removed by operation, histologically a solitary fibrous tumor of the diaphragm with low malignant tendency (Prof. Katenkamp, Jena, Germany), formerly known as hemangiopericytoma

■ **Fig. 3.47** In ultrasound a similar finding like in ■ Fig. 3.45 in a patient with known lung cancer, so far no metastases. The lesion was found during a routine follow up examination. Computed tomography could not comprehend the lesion. By ultrasound guided puncture a metastasis of the known lung cancer confirmed

■ **Fig 3.49** Pleural metastasis with deep infiltration, deformation and destruction of the diaphragm. Pleural carcinosis with effusion. 19 years ago diagnosis of a breast cancer, two years ago diagnosis of a ovarian cancer

■ **Fig. 3.48** Metastasis of a breast cancer in the diaphragm. Artificial echoes in a large pleural effusion

3.8.6 Diaphragmatic Eventration

Behind the radiological description of a diaphragmatic eventration can hide different situations. The diaphragm can in fact be dislocated due to paresis or due to displacement by giant organs or liquid collections. Unusual inferior lung consolidations or tumors or a subpulmonary effusion

can pretend a diaphragmatic eventration. By ultrasound the situation can soon be clarified (■ Table 3.10).

3.8.7 Functional Examination

The real time ultrasound examination offers the best conditions for the functional examination of the diaphragm. A normal bilateral up-and-down-movement of the diaphragm with respiration, identical on both sides, is clearly visible. Pleural peels close to the chest wall cause a immobility of the parietal part of the diaphragm. A residual motion can be detected, ruling out a complete phrenical paresis. Old pleural lesions may be very discreet in the image, so that the dynamic examination with demonstration of the “sticking” is important. Short video clips are optimal for the documentation of the diaphragmatic motion. Using the time-motion-mode not only the movement of the diaphragm can be detained, but also the extent of the motion can approximately be measured. For this measurement the transducer, preferably a phased-array-transducer, is positioned on the abdomen in the medioclavicular or anterior axillary line, directed to the posterior part of the diaphragm, thus ensuring that the diaphragm in the B-mode is well detectable and during respiration is moving towards the transducer. From the time-motion-curve

Table 3.10 Sonographically discernable causes of a diaphragmatic eventration

Unilateral	Abdominal cause	Large liver or spleen Large liver tumors Subphrenical capsulated liquid formations (seroma, bilioma, abscess) Unilateral paresis of the diaphragm
	Cause in the chest = seemingly eventration	Atypical inferior lung consolidation (pneumonia, atelectasis) Subpulmonary effusion, capsulated or loculated Inferior pulmonary, pleural or diaphragmatic tumor, possibly in combination with lung atelectasis
Bilateral	Abdominal cause	Abdominal obesity Ascites
	Cause in the chest = seemingly eventration	Bilateral subpulmonary effusion Bilateral inferior atelectasis

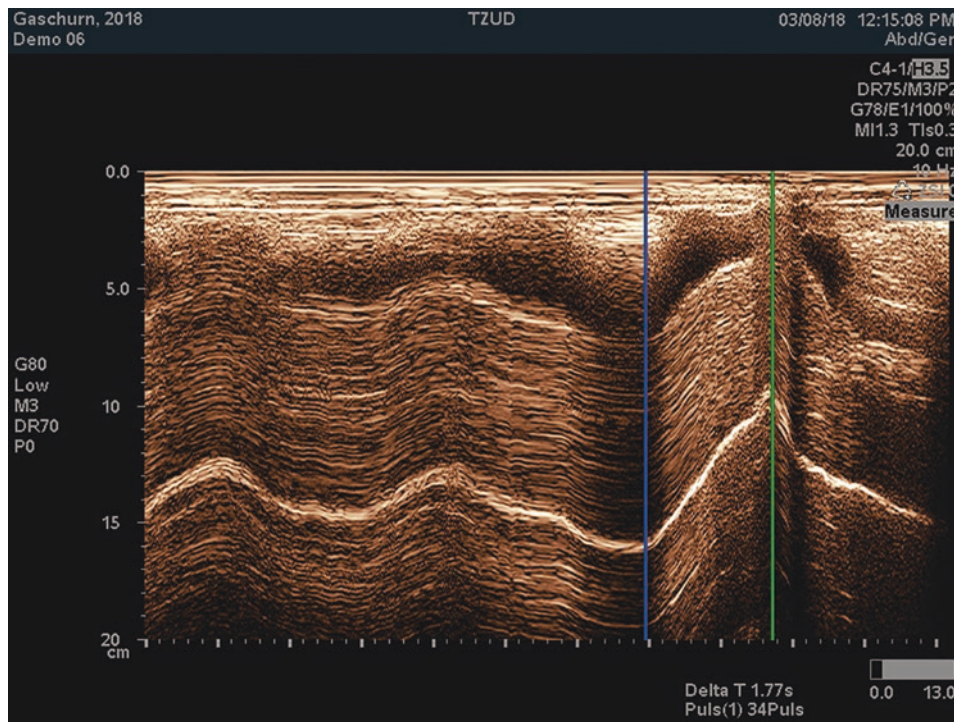

Fig. 3.50 Diaphragm mobility in M-mode. Left for calm breathing, right for deep inspiration

different parameters can be picked out. The most frequently used parameter is the shift of the diaphragm in centimeter during normal and forced breathing (Figs. 3.50, 3.51 and 3.52). Other values are the contraction velocity of the diaphragm as well as the inspiration and breath cyclus time (Lloyd et al. 2006; Matamis et al. 2013; Soilemezi et al. 2013). See Table 3.11

A phrenical paresis is immediately noticed by missing or paradoxical diaphragmatic movement (Lloyd et al. 2006). Tumors at the neck or in the mediastinum causing the paresis are detectable by ultrasound. Diaphragmatic pareses acquired during birth can be recorded sonographically by the pediatrician (Urvoas

et al. 1994). Normal chest_X-rays do not allow a reliable conclusion concerning the diaphragmatic function, but ultrasound (Epelman et al. 2005). Patients after stroke and residual dysphagia show a markedly reduced diaphragmatic motility, in normal breathing as well as under forced breathing and when coughing. The reduced motility correlates with lung function. In studies these data are already included in the rehabilitation planning (Jung et al. 2014). A sonographical assessment after long-term mechanical ventilation in adults provides information about the function and the respiratory mechanical function can be estimated—sufficient experience and expertise provided (Dorffner et al. 1998,

■ Fig. 3.51 Diaphragm thickness at expiration 23 mm

■ Fig. 3.52 Diaphragm thickness at deep inspiration 44 mm

■ **Table 3.11** Benchmarks for diaphragmatic motion measured by ultrasound (according to Matamis et al. 2013)

		Normal values	
		m	f
Motion (cm)	Normal breathing	1.8	1.6
	Forced breathing	7.0	5.7
	Sniffing	2.9	2.6
	Mechanical ventilation	1.8	
Contraction velocity (cm/s)	Slope	1.3	

Goligher et al. 2015). This protects the patients against premature extubation and serves as basis for an additional forced training in the weaning phase (Gibis et al. 2019, Turton et al. 2019).

4.1 General Considerations

It is standard textbook knowledge that «because ultrasound energy is rapidly dissipated by air, ultrasound imaging is not useful for the evaluation of the pulmonary parenchyma» (Manaker and Weinberger 2008). The concept that ultrasound cannot be employed for evaluating the lung is linked to the presence of air, which determines a very high acoustic mismatch with the surrounding tissues, causing a complete reflection of the ultrasound beam, which prevents the creation of real imaging of the pulmonary parenchyma. In a normally aerated lung, the only detectable structure is the pleura, visualized as a hyperechoic horizontal line. Even this image is an artefact due to a reverberation phenomenon at the interface between alveolar air and the soft tissues of the thoracic wall. Below the pleural line, the artefact image of the lung moves synchronously with respiration against the chest wall. In addition, some hyperechoic, horizontal lines arising at regular intervals from the pleural line can be seen: the A-lines (Fig. 4.1). However, even if the corresponding lung area is imaged only as artifacts at ultrasound, these give many important clinical information (Volpicelli 2013).

When combined with a respiratory movement, the reverberation artefacts represent a sign of normal or excessive content of air in the alveolar spaces. When the air content decreases and lung density increases due to the presence in the lung of exudate, transudate, collagen, blood, hyper cellularity, the acoustic mismatch between

Fig. 4.1 The white arrows indicate the linear echoic images corresponding to the pleural line (large arrow) and the A-lines (small arrows)

the lung and the surrounding tissues is lowered, and the ultrasound beam will be partly reflected at deeper zones and repeatedly. This phenomenon creates on the screen some vertical reverberation hyperechoic artefacts, known as B-lines, formed by multiple short horizontal lines that are repeated in a vertical tight sequence (Fig. 4.2). B-lines belong to the family of the comet-tail artefacts, very well known in abdominal ultrasound (Ziskin et al. 1982). In some studies, published before an experts agreement on nomenclature that was obtained in the recent consensus conference on lung ultrasound (LUS), B-lines have also been addressed as comet-tail artifacts or ultrasound lung comets (Volpicelli et al. 2012). B-lines are defined as discrete laser-like vertical hyperechoic reverberation artifacts that arise from the pleural line, extend to the bottom of the screen without fading, and move synchronously with lung sliding. Multiple B-lines are considered the sonographic sign of lung interstitial syndrome, and their number increases along with decreasing air content and increase in lung density (Volpicelli et al. 2012).

Therefore, although air limits the reconstruction of a real image of the normal lung, the alteration in the balance between air and fluids of the diseased lung significantly modifies the normal ultrasound pattern. This can happen both in case of deflation of the lung with maintenance of a constant weight, but also when the weight of the lung rises for the increase in fluids, cells, connective tissue or blood content. In other words, whether the cause is a simple deflation or an increase in fluids and cellularity of the lung parenchyma, ultrasound is highly sensible to variations of the organ density as deduced by studies on phantoms, animal models and humans (Volpicelli 2013).

Fig. 4.2 An ultrasound lung scan showing multiple B-lines, in a case of acute pulmonary edema

Thus, the acoustic limitations of ultrasound in the assessment of an air-rich organ such as the lung can paradoxically become a diagnostic advantage. The artifacts created by the mismatch between air and tissues in the lung are easy to detect and correspond to their quantitative balance.

However, the diagnostic approach based on LUS can vary according to different settings and clinical situations, following the main principle of what is today known as “point-of-care ultrasound” (Moore and Copel 2011). On occasion, the best efficacy of the method is obtained by a clinically driven, focused assessment. If properly driven and correctly interpreted, even signs that have low significance in the general population become highly accurate for diagnosing specific pulmonary conditions (Gargani and Volpicelli 2014). The correlation with the specific setting and patient’s symptoms of presentation, the clinical history, but also the evolution of the clinical situation and the corresponding change in the ultrasound pattern during the time course of our observation and treatment, may be crucial for a correct interpretation.

4.2 Interstitial Syndrome

The interstitial syndrome is a condition where alveolar air is impaired due to increase of fluids in the interstitium, but some lung aeration is still preserved as opposed to a condition of complete consolidation of the lung. The potential of LUS for the diagnosis of the interstitial syndrome has been mainly shown in studies on critically ill patients and in patients attending the emergency department (Lichtenstein and Meziere 2008; Pivetta et al. 2015). Also, some other studies showed the usefulness in chronic fibrosis and in chronic renal failure patients submitted to dialysis (Reissig and Kroegel 2003; Mallamaci et al. 2010).

The main principle of the ultrasound diagnosis of interstitial syndrome is based on the recognition of B-lines, a rough and very basic count in the single scan and the count and distribution of positive scans. At least three B-lines visualized in a longitudinal view, define a positive scan. The bilateral distribution of multiple positive scans in at least two different chest areas per side, generally define the condition of diffuse interstitial syndrome. Isolated positive scans, or more than one but not bilateral, are diagnostic of a focal interstitial syndrome (Volpicelli et al. 2012).

Even if detection of the B-line pattern cannot differentiate between cardiogenic edema, ARDS and pulmonary fibrosis, this simple bedside technique has immediate effect in the in real-time diagnostic process of

the critically ill and dyspneic patients. The use of a simplified LUS protocol was more accurate than the conventional tools in the first 2 h initial diagnoses in acute respiratory failure, showing a better immediate effect and yielding correct prompt diagnoses in 90.5% of patients (Lichtenstein and Meziere 2008).

In the evaluation of patients with acute respiratory failure, the B-line pattern allows for a differentiation between a cardiogenic and a respiratory origin of the disorder, because exacerbation of COPD, pulmonary embolism, pneumonia, pneumothorax yield a non-interstitial ultrasound pattern (Gargani et al. 2008; Zanobetti et al. 2011). In selected patients with acute decompensated heart failure or end stage renal failure, B-lines represent a sign of extravascular lung water, which allows monitoring of pulmonary congestion by simply observing its clearance at repeated LUS examinations (Volpicelli et al. 2008). In ARDS patients submitted to invasive ventilation with positive pressure, sonographic evaluation for B-lines allows monitoring of re-aeration and can be used to guide therapeutic maneuvers (Bouhemad et al. 2011).

4.3 Technique

In a patient with acute dyspnea, if cardiogenic pulmonary edema is in the differential diagnosis, LUS will be used to examine the anterior and lateral chest to detect the diffuse signs of interstitial and alveolar edema, which usually respect three highly specific features: they are correlated with the severity of the respiratory failure, follow a regular and symmetric spatial distribution, and usually progress from the lateral inferior (dependent zones) to the anterior upper chest areas. The scanning technique that should be employed in the emergency setting is the eight-zone examination, consisting of scanning four chest areas per side: areas 1 and 2 denote the upper anterior and lower anterior chest, while areas 3 and 4 denote the upper lateral and basal lateral chest, respectively (■ Fig. 4.3) (Volpicelli et al. 2006). In the critically ill patient with acute respiratory failure, a more rapid anterior two-region scan may be even sufficient to rule out the interstitial syndrome due to cardiogenic acute pulmonary edema (Lichtenstein and Meziere 2008). However, this focused anterior scanning, while still highly accurate in acute situations in the critically ill, may not be sufficient in patients who are not so severely dyspneic, since presence of B-lines on the anterior chest usually denotes a more severe degree of pulmonary congestion in case of heart failure. This interpretation is an example of adaptation of the LUS technique and signs to the specific setting and clinical condition.

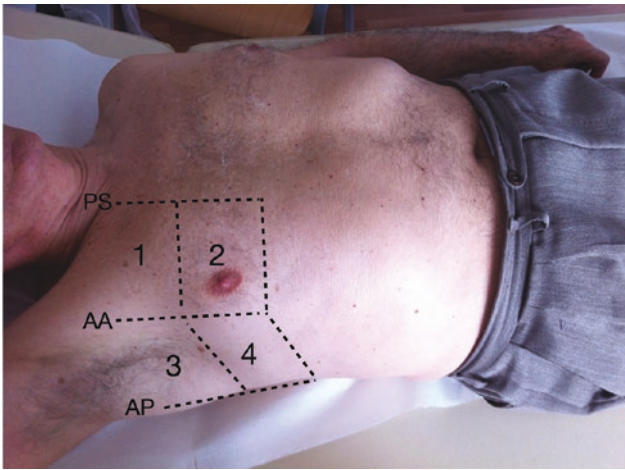

Fig. 4.3 The eight zones examination consisting of scanning four chest areas per side: the upper (1) and lower (2) anterior, the upper (3) and basal (4) lateral. PS parasternal line, AA anterior axillary line, AP posterior axillary line

In the setting of chronic patients, with less time pressure and more borderline cases, the scanning technique should always be more comprehensive. It can include the anterior, lateral, but also the dorsal chest. Different approaches have been proposed: a detailed scanning scheme has been used in many studies on patients with heart failure, on dialysis, and with pulmonary fibrosis, focused on the assessment of the consistency and distribution of B-lines. This comprehensive approach is particularly useful for quantifying the extent of the LUS abnormalities, and for assessing intra-patient variations after therapeutic interventions, including dialysis. Ultrasound scanning of the anterior and lateral chest is obtained on the right and left hemithorax, from the second to the fourth (on the right side to the fifth) intercostal spaces, and from the parasternal line to the axillary line. The posterior chest is scanned along the paravertebral line, scapularis line and posterior axillary line. The sum of the B-lines found on each scanning site yields a score denoting the extent of the pulmonary interstitial syndrome (see below for the techniques of quantifications).

In the case of limited time, even in a chronic setting the examination can be more focused and should be clinically driven. In patients with heart failure, it is important to scan also the dependent zones, i.e., lung posterior basis if we are evaluating an out-patient, or along the posterior and mid-axillary lines if we are scanning an in-patient who has been lying down for many hours. In patients with interstitial lung disease such as pulmonary fibrosis, it is mandatory to scan the posterior chest, because the disease generally starts in this region of the lung (Gargani and Volpicelli 2014).

The patient can be scanned in any decubitus, since lung abnormality distribution does not change so rap-

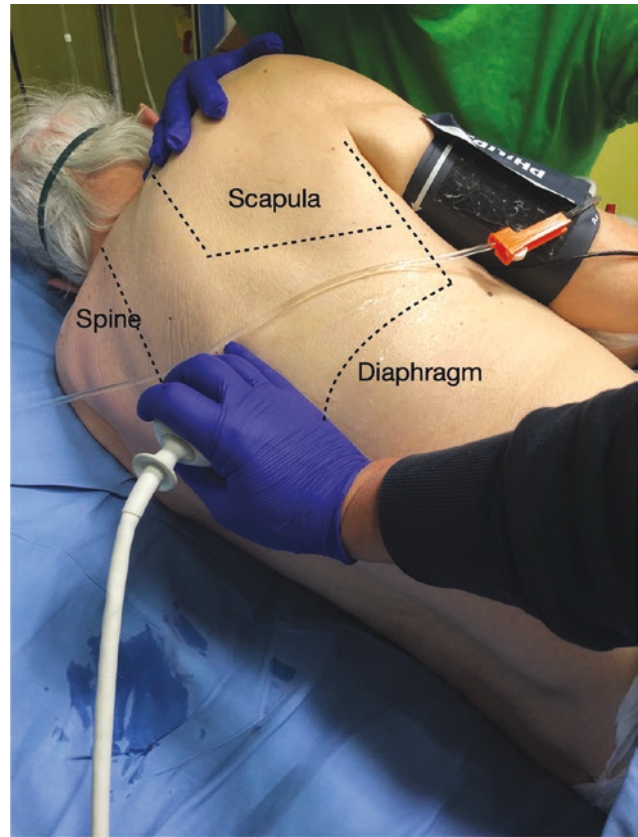

Fig. 4.4 The use of small probes may be helpful in examining the dorsal scans in bedridden patients

idly that significant information would be missed (apart from pleural effusion) just by changing the patient's position. Moreover, in the case of pulmonary congestion, even if the position of B-lines changes, the overall distribution tends to remain the same, without clinically relevant differences. The supine position is ideal for scanning the anterior chest, whereas the lateral chest may be examined in the semi-supine position (on the left decubitus to scan the right axillary lines, and on the right decubitus to scan the left axillary lines). The optimum position for scanning the posterior chest is with the patient sitting on the bed, his/her back turned to the operator. Indeed, it is possible also to scan patients while they are standing, sitting or lying flat, without significant differences in results. The only real limitation is when LUS needs to be extended to the dorsal chest of a patient lying down who is intubated in the intensive care unit, or a patient who is unconscious and cannot be moved. In these situations, using small probes that may be better placed between the bed and the patient may allow the best result (Fig. 4.4).

Although the number of B-lines may be slightly different when using different probes in a specific chest site,

the overall clinical picture does not change by changing the transducer. The possibility of easily assessing B-lines with any kind of transducer is one of the advantages of this technique, so no one should give up on scanning a patient just because the “ideal” probe is not available. Portable machines and pocket-sized devices have also been proposed for assessing B-lines. There is no need for a second harmonic or Doppler imaging mode, so even very old ultrasound machines can be employed. Normally the focus should be positioned at the pleural line level.

4.4 Interpretation of the Sonographic Interstitial Syndrome

Interpretation of LUS images is usually not very challenging. We must keep in mind that LUS is more affected by lack of specificity than lack of sensitivity. A LUS pattern showing multiple B-lines may be not enough to establish a specific diagnosis, since it can be linked to different pathologic conditions. Indeed, this limitation in specificity is a common feature of several diagnostic tools that we routinely interpret in daily clinical practice, from physical examination to EKG, from chest X-ray to more sophisticated instrumental findings. The power of these tools resides in the interpretation of signs when combined with each other at bedside, together with a consideration of the overall clinical picture. When all patient characteristics are taken into account, including history, symptoms, physical examination, setting, comorbidities, medications, etc., specificity can increase significantly. For example, in a patient with systemic sclerosis and without any known left heart conditions, presence of multiple B-lines is more probably related to pulmonary fibrosis than to extravascular lung water. On the other hand, presence of multiple diffuse bilateral B-lines in a patient with reduced cardiac function is more likely to be related to extravascular lung water than to fibrosis.

Distribution of B-lines and pleural line characteristics are also crucial to increasing the specificity of LUS. B-lines due to cardiogenic pulmonary edema are usually bilateral, start appearing in the dependent zones and usually diffusing or recovering symmetrically. B-lines due to pulmonary fibrosis generally start at the posterior lung basis, and are often associated with irregularity of the pleural line and subpleural small consolidations. In contrast to pulmonary edema due to congestion or overhydration, acute lung injury/ARDS shows an inhomogeneous and irregular pattern, featuring many subpleural consolidations, highly fragmented pleural line and intense hyperlucent multiple B-lines alternating with spared areas (■ Fig. 4.5). This irregular distribution of B-lines contrasts with that observed

■ Fig. 4.5 This lung scan shows highly fragmented pleural line and intense hyperlucent multiple B-lines (alternating with spared areas when looking at the other zones). This pattern is typical of ARDS

in cardiogenic pulmonary edema, where B-lines are usually detected in more homogenous distribution, which is gravity-related, while it is quite rare when visualizing subpleural consolidations.

Dynamic response to therapy can also be useful for increasing the accuracy of LUS. In the case of multiple bilateral B-lines that are dissolved in days during ordinary treatment, or even in a few hours by an acute diuretic load, the cardiogenic or volume overload origin of B-lines is strongly suggested (Volpicelli et al. 2008). Similarly, in end-stage renal disease patients, B-lines decreasing or even disappearing after either a hemodialysis or peritoneal dialysis session, indicate pulmonary congestion due to overload (Mallamaci et al. 2010).

Additional information deriving from a bedside focused ultrasound evaluation of other organs may also be helpful. This approach has been described in patients with undifferentiated hypotension, where the integrated point-of-care multiorgan ultrasonography of the heart, inferior vena cava, lungs and abdomen significantly agreed with a final clinical diagnosis obtained by retrospective chart review (Volpicelli et al. 2013).

A controversial issue is quantification of B-lines. In critically ill patients the assessment can be qualitative, since the ultrasound finding of acute conditions is usually well defined and clear. For instance, in a critically ill patient with acute respiratory failure, if the underlying condition is cardiogenic pulmonary edema, the sonographic appearance of the lungs will be striking, with multiple diffuse bilateral B-lines that may even become very intense and numerous to convey a picture of “white sonographic lung”. In these patients, B-lines can also be found in the least dependent zones, i.e. the anterior chest.

On the contrary, finding a limited number of B-lines (even if bilateral) in a very symptomatic respiratory failure patient should lead to excluding the diagnosis of a cardiogenic origin of the actual condition, and orientate the diagnosis towards infection or other conditions.

In non-critical patients, a more careful assessment and quantification of B-lines may be useful, especially for the follow-up of a chronic condition. A semi-quantification of B-lines has been proposed and subsequently used in many papers from different research groups. This quantification is made possible by counting all B-lines in a specific scanning site. Zero is defined as a complete absence of B-lines in the investigated area, whereas when using a cardiac probe the full white screen in a single scanning site is considered as corresponding to ten B-lines (Gargani and Volpicelli 2014). However, B-lines cannot always be easily enumerated, especially if they are many, since they often tend to be confluent. A helpful rule is to consider the percentage of the scanning site occupied by B-lines (i.e. the percentage of white screen compared to black screen below the pleural line) and then divide it by ten. For clinical purposes, the final number of B-lines can then be categorized ranging from mild to severe degrees, similar to what is done for most echocardiographic parameters (Gargani and Volpicelli 2014). This counting approach can be imprecise when considering single scanning sites, but nevertheless provides a reliable overall LUS picture, allowing more accurate monitoring of patients, both in acute conditions—i.e., rapid changes after diuretic therapy or dialysis—but also in stable outpatients. Moreover, this approach has shown good intraobserver and interobserver variability, around 4–5% in many studies and never superior to 7%.

In the past two decades lung ultrasound has been proposed to assess interstitial lung diseases by detecting and quantifying sonographic B-lines. They have a good diagnostic accuracy, especially high sensitivity, and correlate well with HRCT findings (Wang et al. 2017). The number of B-lines evident on LUS imaging may be a valuable marker of disease severity in patients with interstitial pneumonia (Asano et al. 2018; Xie et al. 2019).

In ARDS, it has been shown that B-lines correlate with interstitial involvement of the lungs, and B-pattern-predominant lungs are suggestive of alveolar processes such as ARDS. Ultrasonography has a role in both the diagnosis and management of ARDS (Papazian et al. 2016).

In times of COVID-19, bedside real-time lung ultrasound could support and integrate lung imaging with several advantages for the detection of pulmonary

■ Fig. 4.6 This lung scan shows a focal interstitial syndrome around the pulmonary consolidation (alveolar syndrome), in a case of pneumonia

involvement. Lung ultrasound is showing a growing value in everyday clinical practice, especially in the emergency and intensive care units (Gargani et al. 2020).

A focal interstitial syndrome can sometimes be the “peripheral alarm” of a more medial pathological condition, for example in the case of peri-lesional interstitial edema, due to either inflammation or other causes of localized consolidations (■ Fig. 4.6).

4.5 Limitations

It must be emphasized that LUS does not rule out pulmonary abnormalities that do not reach the pleura. The pulmonary interstitial syndrome from some specific etiologies sometimes may save the subpleural space, which will prevent visualization by sonography. However, these are only rare conditions particularly in emergency situations. Indeed, most of the lung conditions observed in the critically ill and emergency situations are characterized by lesions that reach the lung surface. The analysis of the lung anatomy may help to understand the reason. The secondary pulmonary lobule is the fundamental unit of the lung structure. In different pulmonary regions the lobule is variably surrounded by the interlobular septa, which are connective structures that envelope the lung like a network and contain pulmonary veins and lymphatics. Secondary pulmonary lobules in the periphery are relatively large and are marginated by interlobular septa that are thicker than in deeper parts of the lung. Thus, the periphery of the lung is highly representative of systemic diseases and conditions, and

alterations of the most peripheral septa can be studied by LUS (Volpicelli 2013).

Conditions that alter the regular interaction between the emitting surface of the probe and the chest wall, may limit the ultrasound evaluation of the interstitial syndrome. Very obese patients are occasionally difficult to be studied. Combination with other pulmonary conditions, like pneumothorax or large pleural effusion, may make difficult or impossible the evaluation of the interstitial syndrome. Bandages, wounds and other hindrances may sometimes prevent the ultrasound study.

Summary

In the last 15 years, from its traditional assessment of pleural effusions and masses, LUS has moved towards the revolutionary approach of imaging the pulmonary parenchyma, mainly as a point-of-care technique. Although limited by the presence of air, LUS has proved to be useful in the evaluation of interstitial syndromes, from cardiogenic pulmonary edema to acute lung injury and ARDS, from interstitial lung disease to interstitial pneumonia. In the next few years, the assessment of interstitial syndrome by point-of-care LUS is likely to become increasingly important in many different clinical settings, from the emergency department to the intensive care unit, from cardiology to pulmonology and nephrology wards.

5.1 Inflammatory Consolidations in the Lung

Gebhard Mathis
gebhard.mathis@cable.vol.at

5.1.1 Pneumonia

According to the World Health Organization, pneumonia is the leading cause of death among infectious diseases worldwide, accounting for 15% of deaths in children under five years of age (WHO 2019).

5.1.1.1 Pathophysiological Prerequisites

In cases of lobular and segmental pneumonia, large amounts of air are displaced from the lung as a result of extensive fibrinous exudation. Affected lobes or segments are depleted of air and sink in water. The phase of engorgement offers good conditions for pathological echo transmission. In this phase, pneumonia is imaged well on the sonogram. In the phase of lysis, the inflamed portion of the lung is ventilated to an increasing extent.

Focal pneumonias and interstitial pneumonias barely extend up to the pleura and are therefore poorly accessible to sonographic imaging. However, bronchial pneumonias are often accompanied by involvement of the pleura and are therefore partly visualized by sonography.

5.1.1.2 Sonomorphology of Pneumonia

A number of sonomorphological criteria are characteristic for pneumonic infiltrations. They are of varying intensity in the course of disease.

- Sonomorphology of pneumonia:
- Liver or tissue like in the early stage
 - Lentil-shaped air trappings
 - Bronchoaerogram
 - Fluid bronchogram (poststenotic)
 - Blurred or serrated margins
 - Reverberation echoes at the margin
 - Hypoechoic to anechoic in the presence of abscess

5.1.1.3 Phase of Engorgement

In the initial phase of disease, i.e., in the phase of engorgement, the pneumonic lesion is hypoechoic, relatively homogeneous, and hepatoid in form. Its configuration is bizarre. It is rarely explicitly segmental like the pulmonary infarction or rounded like carcinomas and metastases. Its margins are irregular, serrated, and somewhat blurred (■ Figs. 5.1 and 5.2).

■ Fig. 5.1 A 68-year-old severely ill man with clinical signs of acute pneumonia. In the upper lobe of the lung on the left side, there is a liver-like consolidation with a bronchoaerogram. A subpleural fluid alveologram

■ Fig. 5.2 Oblique section of lobar pneumonia in the right lower lobe. The pneumonic infiltrate (P) is similar to the liver in terms of echotexture (L). D diaphragm

5.1.1.4 Air Bronchogram

A marked bronchogram (bronchopneumogram, air bronchogram) with treelike ramifications is seen in up to 90% of cases. The intensive reflexes of the bronchial tree run between consolidated portions of the parenchyma. In all stages of the disease the bronchoaerogram is more pronounced than in cases of pulmonary embolism. Quite often one finds a small number of, and in most cases numerous, lenticular internal echoes just a few millimeters in size (■ Fig. 5.1). These echoes indicate the presence of air in the small bronchi. In other words, this is a partial image of a bronchoaerogram. These internal echoes can be partly explained by congested secretion of highly diverse impedance (Weinberg et al. 1986; Mathis et al. 1992; Gehmacher et al. 1995; Reissig and Kroegel 2007; Reissig et al. 2012; ■ Figs. 5.2 and 5.3). The air bronchogram moves dynamically in a breath-dependent manner. This is an important difference between an air bronchogram and obstructive atelectasis: the latter is accompanied by a less prominent air bronchogram and is static (Lichtenstein et al. 2009).

The bronchogram visualized by sonography cannot be equated with that seen on a radiograph. Viral

pneumonias are often less ventilated and/or reveal less pronounced bronchoaerograms. These are smaller and more compact than bacterial pneumonia and may resemble large pulmonary infarctions. In contrast to pulmonary infarctions, they are strongly perfused with blood (■ Fig. 5.4).

■ Fig. 5.3 Pneumonia after H1N1-Influenza (Fig as in German edition)

■ Fig. 5.4 A 52-year-old woman with pain on inspiration, fever, and hemoptysis. **a** Sonography reveals a consolidation measuring 5×3.5 cm in size, with a small bronchoaerogram. **b** Color-Doppler shows regular perfusion—viral pneumonia

Fig. 5.5 A 32-year-old woman who had experienced segmental pneumonia for the third time in 1 year. **a** Sharply demarcated segmental shadow on the X-ray. **b** Largely homogeneous consolidation on computed tomography. **c** The morphology of the lesion on sonography is very similar to that on computed tomography. The echotexture

contains significantly few air trappings. In the center, there is a small anechoic fluid area. **d** On the longitudinal section one finds tubular structures; parallel to the vessel a typical fluid bronchogram. **e** The adenocarcinoma is verified on bronchoscopy; on surgery, it is staged T1 N0

5.1.1.5 Fluid Bronchogram

The fluid bronchogram is marked by anechoic tubular structures along the bronchial tree. The bronchial wall is echogenic and the fluid in the segmental bronchi is hypoechoic. The reflexes around the bronchi are wider than those along vessel walls. Given good resolution, the bronchial walls are ribbed and the vessel walls are smooth; therefore, tubular structures can be easily classified on B-mode image. In the case of doubt, color-coded duplex sonography helps to distinguish between vessels and bronchi. The fluid bronchogram is seen in approximately 8% of patients with pneumonia and develops in the early phase of the disease as a result of bronchial secretion or owing to bronchial obstruction. A persistent fluid bronchogram always raises suspicion of poststenotic pneumonia and is an indication for bronchoscopic investigation (Fig. 5.5). A tumor may be found or ruled out; the obstructive secretory embolus is aspirated and material obtained for bacteriological investigation (Mathis 1997; Reissig et al. 2012).

5.1.1.6 Poststenotic Pneumonia

Poststenotic pneumonias that develop in the periphery or the margin of carcinomas are better delineated from the tumor by means of sonography than by X-ray investigation. Poststenotic pneumonia is typically characterized by a fluid bronchogram (Fig. 5.5d). Monitoring the effectiveness of ther-

apy is important in this setting—is the pneumonia subsiding or is the tumor increasing in size (Yang et al. 1990a, b)?

5.1.1.7 Circulation

On color-coded duplex sonography pneumonia has a typical appearance: Circulation is uniformly increased, ramified, and the vessels run a normal course. In fact, circulation is increased in the entire infiltrate up to beneath the pleura (Fig. 5.6). This is interesting when pneumonia needs to be differentiated from pulmonary infarctions that have poor or no blood flow, or even from tumors with an irregular circulation pattern. Carcinomas are strongly vascularized in their margins. Owing to neovascularization, vessels in the margins of carcinomas are characterized by a typical corkscrew pattern (Gehmacher et al. 1995; Mathis 1997).

On contrast-enhanced sonography pneumonias are rapidly enriched with contrast medium and achieve intensive saturation after just 8–10 s (Görg 2007; Bertolini et al. 2008; Fig. 5.7; Chap. 9).

5.1.1.8 Parapneumonic Effusion

Parapneumonic fluid accumulations can be imaged better on ultrasound than on conventional X-rays (55% versus 25%). These must be discovered and their course monitored in order to initiate invasive therapy in terms

■ Fig. 5.5 (continued)

■ Fig. 5.6 On color-coded duplex sonography pneumonia is seen as an accentuated, regular pattern of circulation

of puncture or video-assisted thoracoscopy on a timely basis (Reissig et al. 2012; ■ Fig. 5.8).

5.1.1.9 Abscess Formation

Bacterial pneumonias tend to develop colliquations and form abscesses. This is the case in approximately 6% of patients with lobar pneumonia (this figure refers to radiographic investigations). Sonography more commonly reveals *microabscess* (Yang et al. 1991, 1992a, b; Mathis 1997).

The *sonomorphology of pulmonary abscess* is highly characteristic: round or oval and largely anechoic lesions. Depending on whether a capsule is formed, the margin is smooth, echodense, and white (■ Fig. 5.9). Blurred

Fig. 5.7 Signal-enhanced sonography in pneumonia. The saturation starts very early and achieves its maximum after 5–16 s

Fig. 5.8 Parapneumonic effusion. Remission observed by ultrasound

Fig. 5.9 Colligated abscesses with persistent fever. Sonography-guided aspiration showed a surprisingly large number of tubercle bacilli

internal echoes are indicative of high cell content or viscous pus rich in protein. In cases of abscesses due to gas-forming pathogens, highly echogenic small air trapplings move actively within the fluid in concordance with the respiratory rhythm. Microabscesses cannot be easily distinguished from vessels on color-Doppler imaging.

Considering the scarce quantity of material for bacteriological investigation obtained from the sputum or from bronchial lavage, it is useful to taken a specimen for the detection of pathogens by means of sonography-guided aspiration. When the puncture is performed with an ordinary injection needle, a thorough sonographic preinvestigation should be performed, if necessary under sonographic visual guidance, to ensure that air-filled lungs and vessels are avoided. The cause of pulmonary infections can be determined by this method in 80% of cases (Yang et al. 1992a, b; Chen et al. 1993; Liaw et al. 1994a, b; Mathis 1997).

Lung abscess drainage may be performed under sonographic or computed tomography visual monitoring. The risk of a pneumothorax is minimized when one passes through the chest wall obliquely, in a regular fashion, and enters the lung at the site where the abscess is closest to the pleura. The risk of a dreaded broncho-pleural fistula is minimized when the correct approach is used, i.e., when one only traverses the homogeneous infiltrate and avoids ventilated areas (Yang et al. 1991; Talayanagi et al. 2010).

5.1.1.10 Healing Phase

When pneumonia is in the phase of healing, the infiltrated lung tissue is ventilated to an increasing extent. Such air gives rise to reflection and reverberation artifacts. The pneumonia recedes on the sonography image and usually appears smaller than on the chest radiograph. The resolution of these lesions on ultrasound correlates well with the patient's clinical progress (Fig. 5.10).

Fig. 5.10 A 72-year-old man with clinically severe pneumonia. **a** Typical appearance on X-ray. **b** On sonography the echotexture is similar to that of the liver, with a pronounced bronchoaerogram. *Z* diaphragm, *L* liver, *VC* vena cava. After 1 week of antibiotic therapy

the patient is afebrile and has recovered to the extent that he can be discharged. **c** On the X-ray there still is a marked residual infiltrate. **d** Sonography only shows a receding infiltration

5.1.1.11 Diagnostic Value

Primary diagnosis of pneumonia is usually performed on the basis of clinical signs and chest X-rays. The extent of infiltration may be underestimated on ultrasound. Central pneumonias are not seen on sonography. The severity of interstitial pneumonia can be assessed (Asano et al. 2018).

Can ultrasonography of the lung replace conventional X-rays as a diagnostic imaging procedure? The authors of older studies have compared ultrasound

with chest X-rays and achieved favorable results (89% sensitivity) (Mathis et al. 1992; Gehmacher et al. 1995). With CT as the reference method, ultrasound was able to show 12–25% more pneumonias than the chest X-ray (Targhetta et al. 1992; Copetti and Cattarossi 2008; Parlamento et al. 2009; Sperandeo et al. 2011).

Four meta-analyses of up to 1515 patients have shown a pooled sensitivity of 88–97% and a specificity of 86–96% (Hu et al. 2014; Mathis 2019).

The most relevant manifestation of COVID-19 disease is pneumonia. The most frequent lung ultrasound features are: bilateral B-lines-pattern, subpleural consolidations, and several typical pneumonic infiltrations with aerobronchogram. These findings correlated well with MRCT (Dacrema et al. 2021). For an optimal detection and monitoring of COVID-19 we depend on a fast and reliable diagnosis and severity assessment. Current Antigen und PCR-Tests have a sensitivity of 60–90%. In addition to pulseoxymetry, the usual methods stethoscope and Chest-X-ray are unreliable (Osterwalder 2020).

In Covid-19 pneumonia, pulmonary ultrasound has been shown to be very useful in initial diagnosis and follow-up in intensive care units and emergency rooms using portable devices (Liu et al. 2020; Lyu et al. 2020; Osterwalder 2020).

Especially in children, pulmonary ultrasound has been shown to be very useful in the diagnosis of pneumonia and radiation exposure is avoided (Orso and Ban 2018). In ventilated patients, the distinction between pneumonia and atelectasis is often only possible in the context of laboratory findings. However, pulmonary sonography can make an uncomplicated contribution to imaging diagnostics and follow-up during daily rounds (Mongodi et al. 2016; Wang et al. 2016).

A large multicenter study comprising 362 patients confirmed ultrasound morphology criteria on the one hand, and yielded a sensitivity of 93.4% and a specificity of 97.7% on the other. In combination with auscultation the accuracy was even higher (Reissig et al. 2012).

In cases of clinical suspicion of pneumonia, further radiological investigations may be necessary. However, after the clinical investigation and after obtaining the required laboratory data concerning inflammatory parameters, immediate antibiotic treatment can be initiated almost everywhere: at the medical office, the emergency department, the intensive care unit, and in stroke patients among others (Busti et al. 2014).

5.1.2 Tuberculosis

In pulmonary tuberculosis, ultrasonography is helpful in detecting pleural effusions, subpleural consolidations and pneumonic infiltrates. Ultrasound-guided diag-

nostic punctures are meaningful in this setting. Chest X-rays and computed tomography are indispensable to obtain an overview of the condition (Yuan et al. 1993; Kopf et al. 1994; Mathis 1997; ■ Figs. 5.11–5.13).

Tuberculous lung lesions may be seen on sonography as rounded or irregular structures of relatively homogeneous texture. Depending on the size of the lesion, these infiltrates may also be accompanied by air trappings

■ Fig. 5.11 Small lymphocytic pleural effusion. US-guided biopsy of the nodule showed tuberculosis

■ Fig. 5.12 Peripheral lung lesion on a routine X-ray of a young woman. On sonography one finds a hypoechoic, poorly vascularized lesion. Biopsy indicated tuberculosis

Fig. 5.13 Miliary tuberculosis. **a** Fragmented pleura (arrowheads) with numerous subpleural nodes measuring 2–3 mm in size. **b** Chest X-ray showing miliary tuberculosis

as in pneumonia. Nodular dissemination, as in miliary tuberculosis, is visualized as multiple subpleural nodes measuring a few millimeters in size (■ Fig. 5.13).

Colliquations can be imaged well, but air in cavities might be a disturbing factor and might limit visualization. Even very small quantities of the specific pleural effusion are seen. Pleural thickening may also be revealed. A patient's response to tuberculostatic therapy can be monitored well with sonography, especially in cases of pleural and subpleural tuberculosis lesions.

In cases of rarer infectious lung consolidations such as aspergillosis or echinococcus, typical lesions can be visualized and significant additional information (in addition to the information available from radiographs) obtained (■ Fig. 5.14).

5.1.3 Interstitial Lung Disease

Technically sonography is entirely unsuitable to diagnose diseases of the lung framework. However, it was shown that such diseases are frequently accompanied by *involvement of the pleura* and the latter is significantly better visualized by sonography than by other imaging procedures:

- Minimal pleural effusions
- Fragmented pleura with several comet-tail artifacts (B-lines)
- Subpleural consolidations (■ Figs. 5.15–5.18)

The value of the method lies in the detection of a grave condition and in steering the diagnostician's attention towards a specific target – point of care ultrasound.

Fig. 5.14 Echinococcus cysticus. A 28-year-old man with pulmonary echinococcosis in his medical history. The patient was admitted to the hospital because of fever, cough, and marked dyspnea. **a, b** The X-ray shows multiple round lesions in the lung and pneumonic infiltrates. **c, d** Sonography revealed the round lesions extending to the surface of the lung. Thick-walled cysts (*crosses*) with internal secondary cysts showing no vascularization on color-Doppler

sonography. Additionally one finds several areas indicative of pneumonia. An echinococcal lesion is present in the liver as well. Further diagnostic procedures confirmed bilateral pneumonia in terms of superinfection and preexisting pulmonary echinococcosis. The patient subsequently developed severe pulmonary hypertension despite antibiotic therapy plus albendazole

Therapy controls are highly efficient in cases of minimal pleural effusions and subpleural infiltrations; no method is superior to sonography in this regard (Wohlgenannt et al. 2001; Reissig and Kroegel 2003).

5.1.4 Interstitial Syndrome

The 1st International consensus conference on pleura and lung ultrasound has defined the interstitial syndrome presenting B-lines as discrete laser-like vertical hyperechoic reverberation artifacts that arise from the pleural line (previously described as “comet tails”), extend to the bottom of the screen without fading, and move synchronously with lung sliding. In the evaluation of *diffuse* interstitial

syndrome, the sonographic technique ideally consists of scanning eight regions, but a more rapid anterior two region scan may be sufficient in some cases. A positive region is defined by the presence of three or more B-lines in a longitudinal plane between two ribs. However, focal multiple B-lines may be present in normal lung.

Causes of the interstitial syndrome include the following conditions: pulmonary edema of various causes, interstitial pneumonia or pneumonitis, diffuse parenchymal lung disease (pulmonary fibrosis).

Focal sonographic pattern of interstitial syndrome may be seen in the presence of many lung diseases, e.g., pneumonia and pneumonitis, atelectasis, pulmonary contusion, pulmonary infarction, pleural disease, and neoplasia.

Fig. 5.15 Sarcoidosis. **a** Minimal basal pleural effusion. Z diaphragm. **b** Uneven, fragmented visceral pleura with several reverberation echoes (comet-tail artifacts). **c** Subpleural nodes measuring about 5 mm in size

5.2 Neoplastic Consolidations in the Lung: Primary Lung Tumors and Metastases

Sonja Beckh
sonja.beckh@gmx.de

Thanks to ongoing scientific work, the recent international guidelines and recommendations have incorporated ultrasound as a part of the diagnostic procedure for the investigation of lung carcinoma (Pan et al. 1993; Suzuki et al. 1993; Yuan et al. 1994; Yang 1996; Hsu et al. 1996, 1998; Mathis 1997; Mathis et al. 1999a, b, c; Beckh et al. 2002; Thomas et al. 2002; Detterbeck et al. 2003; Görg and Bert 2004; Bandi et al. 2008; Volpicelli et al. 2012a, b; AWMF 2018). Due to its excellent resolution, ultrasound has proved equivalent to nuclear resonance tomography in the investigation of the chest wall affected by tumor invasion (Goekenjan et al. 2011). Percutaneous diagnostic and therapeutic ultrasound-guided puncture is recommended, and has been accepted as a reliable procedure (Goekenjan et al. 2011; Detterbeck et al. 2003). Endobronchial and endoesophageal ultrasound is the state of the art for staging mediastinal disease (Goekenjan et al. 2011; Detterbeck et al. 2003). The visualization of vessels with color-Doppler or ultrasound contrast medium provides valuable additional information for the differential diagnosis of space-occupying lesions (▶ Chap. 8).

Lung consolidations are seen on sonography only when no aerated tissue hinders the echo transmission. For staging of the disease and planning treatment in cases of malignant lung disease, procedures that provide sectional images such as computed tomography or

magnetic resonance tomography are absolutely essential in order to obtain an overview of the entire chest (van Kaick and Bahner 1998; Tuengerthal 2003; Knopp et al. 1998; Schönberg 2003). As a rule, the sonographic investigation is performed when the findings of various radiographic procedures are known. Given specific symptoms, however, a targeted symptom-oriented investigation is also meaningful (▶ Chap. 11) (■ Fig. 5.19).

Pulmonary malignancies may have a highly variable *echotexture*. They are usually hypoechoic, moderately echodense, or very inhomogeneously structured; more rarely they are nearly anechoic (Mathis 1997; Mathis et al. 1999a, b, c; ■ Table 5.1). However, the echotexture alone does not allow the investigator to draw conclusions about the malignant or benign nature of the disease (■ Figs. 5.20 and 5.21).

In contrast to acute inflammatory infiltrations, the sonomorphology of malignant lesions does not change during a short course of disease. Chronic organizing pneumonia and peripheral callused cicatricial lesions are problematic in terms of differential diagnosis; it may be difficult to differentiate these entities from malignant disease (Mathis 1997).

Decisive criteria to grade the malignant or benign nature of a pulmonary lesion are the following (■ Table 5.2):

5.2.1 Contours of the Lung Surface

The *contours* of the lung surface are very well delineated from the surrounding pleural fluid. ■ Figure 5.22 shows the convex swelling surface of the lung by a lung carcinoma. A benign inflammatory infiltration would never lead to such irregular deformation of the lung surface.

■ Fig. 5.19 Sonography in diagnosis of lung cancer

Table 5.1 Sonomorphology of lung carcinomas

Morphology	Echotexture	Vessels	Complex structures
Sharp margins	Inhomogeneous	Displacement of vessels	Residual ventilated areas
Rounded	Hypoechoic	Destruction of vessels	Accompanying pneumonia at the margin
Polypoid	Rarely echogenic	Interruption of vessels	Solid space-occupying lesion/pneumonia
Ramifications	Rarely anechoic	Neovascularization	Bacterial/fungal colonization
Serrated margin	Necrotic areas	–	Bizarre pattern in large necroses

Fig. 5.20 A small hypoechoic lesion in a 78-year-old man: an incidental finding in the upper lobe of the left lung, in infraclavicular location. Sonography-guided biopsy indicated squamous cell carcinoma

Fig. 5.21 A 40-year-old man with recurrent eosinophilic pleural effusion. X-rays showed a peripheral lesion in the upper lobe of the left lung. On sonography in the anterior axillary line in the second intercostal region, there is a hypoechoic peripheral pulmonary lesion with central vessels and rather sharp margins. Removal of the lesion by thoracoscopy led to the diagnosis of hyalinosis and callus. The source of the pleural effusions is still not clear

Table 5.2 Sonomorphology of pulmonary metastases

• <i>Contours</i> of the lung surface
• <i>Margins</i> to ventilated lung tissue
• <i>Invasion</i> of adjacent structures (chest wall, diaphragm, pericardium)
• <i>Destruction</i> of normal tissue architecture
• <i>Displacement</i> of regular vessels
• <i>Neovascularization</i>
• <i>Differentiation</i> between a central space-occupying lesion and a poststenotic invasion/atelectasis

Fig. 5.22 Small-cell lung carcinoma invading the lower lobe of the left lung (diagnosed by bronchoscopic biopsy), irregular lung surface, narrow pleural effusion

A benign inflammatory infiltration would never lead to such irregular deformation of the lung surface.

5.2.2 Delineation of Margins from Ventilated Lung Tissue

Malignant lesions are often very *sharply demarcated* from lung tissue (■ Fig. 5.23). Occasionally, however, one finds *fringed or finger-shaped ramifications* into the normally ventilated parenchyma—a sign of invasive growth (■ Fig. 5.24).

In contrast to inflammatory lesions, such solid malignant formations in marginal zones are not venti-

lated and therefore are more sharply demarcated from the surrounding tissue.

5.2.3 Invasion of Adjacent Structures: Chest Wall, Diaphragm, and Pericardium

Practically at first glance, a malignancy *invading* adjacent structures is indicative of the aggressive nature of the tumor (Suzuki et al. 1993; Bandi et al. 2008). In the case of a Pancoast's tumor, a space-occupying lesion penetrating the dome of the pleura is clearly visualized (■ Fig. 5.25).

Malignant invasion of the chest wall frequently causes local pain. Targeted investigation of the region with the transducer will help to diagnose the condition early (■ Fig. 5.26).

Invasion into adjacent structures of the chest wall is a very reliable sign of malignant growth. Therefore, the current S-3 guidelines demand a sonography for staging in lung cancer (Goekenjan et al. 2011). In terms of differential diagnosis only one disease is likely to be present here, namely, actinomycosis or nocardiosis (Corrin 1999; ■ Fig. 5.27a–c).

The inflammation frequently spreads into the chest wall. The regular cardinal anatomic structures of the lung, however, are well preserved within the pneumonic infiltration of tissue. In conjunction with clinical symptoms and bacteriological investigation, they permit the investigator to make the correct diagnosis.

The diaphragm on the right side of the chest is usually fully visible, with the liver serving as the sonic window. On the left side, tumors lying medial to the spleen are only seen if there is an effusion or when the tumor itself serves as the sonic window. In the latter case the insertion at the diaphragm may be seen as in ■ Fig. 5.27d.

For staging of the disease and planning therapy, among other factors the relation between the tumor and the pericardium is important. Owing to the excellent resolution and the possibility of dynamic investigation, tumor invasion of the parietal pericardium can be clearly visualized (■ Fig. 5.27e).

5.2.4 Destruction of the Normal Tissue Architecture and Displacement of Regular Vessels

Malignant invasion *destroys* the normal texture of tissue. Bronchial branches may be displaced or fully destroyed (■ Fig. 5.28).

5

■ Fig. 5.23 Large hypoechoic space-occupying lesion in the upper lobe of the right lung, sharply demarcated from ventilated lung tissue. In medial location (arrow) one finds an unremarkable echogenic pleural line. Sonography-guided biopsy indicated poorly differentiated neuroendocrine carcinoma G4

■ Fig. 5.24 Hypoechoic space-occupying lesion in the upper lobe of the right lung with fringed branches into the ventilated lung tissue (arrows). Histological investigation of the resected upper lobe yielded a mixed-cell lung carcinoma (squamous cell or large-cell carcinoma)

Fig. 5.25 **a** A 72-year-old man with pain in the left chest for several months; initially interpreted as angina pectoris. On the overview X-ray a shadow was noted on the left side in apical location. **b** On the coronary computed tomography section there was a space-occupying lesion on the left side in apical location, surrounding the first rib and penetrating the soft tissue. **c** Corresponding sonographic image: large hypoechoic tumor formation penetrating the dome of the pleura and invading the supraclavicular soft tissue. The subclavian artery is slightly compressed and displaced medially by the tumor. Sonography-guided biopsy indicated moderately differentiated adenocarcinoma developing within scar and connective tissue

Fig. 5.26 This woman slipped on a staircase 6 months ago and has been experiencing renewed pain in the left chest for 4 weeks. Computed tomography shows a suspected hematoma. On sonography there is a space-occupying lesion invading the muscles of the chest wall and causing obvious destruction of the third and fourth rib laterally. Sonography-guided biopsy indicated poorly differentiated adenocarcinoma

The original normal vessels are either displaced (■ Figs. 5.25 and 5.29a) or disappear altogether (■ Fig. 5.28).

In some cases, vessels of the tumor itself are found particularly in the margin (■ Fig. 5.29b). Such vessels are convoluted and marked by changes in diameter (Yuan et al. 1994; Mathis 1997; Hsu et al. 1996, 1998).

5.2.5 Additional Investigations to Assess the Possibility of Resection

For further planning of treatment in terms of *whether the entity can be operated on and resected*, a detailed dynamic investigation has to be performed (Beckh and Bölskei 2003). In order to decide between video-assisted thoracoscopy (VATS) and thoracotomy, it is important to know whether the pathological entity is widely fixed to the parietal pleura or is freely movable in conjunction with the lung (Landreneau et al. 1998). However, adherence alone does not permit the investigator to decide whether the lesion is malignant or benign.

Fig. 5.27 **a** This 37-year-old man was severely ill: high fever and dyspnea. On sonography the lesion was clearly found to be crossing margins. Regular branches of the bronchial tree and vessels were well preserved; therefore, a malignancy was considered very unlikely despite the large size of the lesion. **b** Corresponding computed tomography image with the invasion which is continuing from the right lower lobe into the chest wall. **c** The biopsy specimen obtained from surgery shows evidence of actinomycetes. Under high-dose penicillin therapy

the invasion resolved within 10 weeks and a narrow basal callus formation remained. (Histological specimen provided by Peter Wunsch, Institute of Pathology, Klinikum Nürnberg, Nuremberg.) **d** Large tumor below the left lower lobe, inserting into the diaphragm (*arrow*). Histology of the sonographic biopsy and the operation specimen indicated benign fibrous tumor of the pleura. **e** Tumor in the lingula, invading about 3.5 cm of the parietal pericardium (*arrow*). Sonographic biopsy indicated poorly differentiated adenocarcinoma

Fig. 5.28 A 50-year-old man with retrosternal pain that initially raised suspicion of coronary heart disease. Sonography showed a large tumor in the upper lobe in left parasternal location, penetrating the mediastinum and fully destroying the bronchial branches. In the tumor there is a calcification accompanied by obliteration of echoes in the dorsal aspect (*arrow*). Sonographic biopsy indicated poorly differentiated adenocarcinoma with tumor cell complexes in lymphatic recesses

In the course of tumor staging, sonography is more suitable than computed tomography to demonstrate metastases in supraclavicular lymph node regions (Fultz et al. 2002; Prosch et al. 2007; **Fig. 5.30a**).

The basic diagnostic procedures must include sonography of the abdomen in order to identify metastases (**Fig. 5.30b**).

5.2.5.1 Tumor-Related Complications in Mediastinal Vessels

In case of mediastinal tumor spread, the vena cava and its supplying vessels must be examined in order to identify compression syndromes or thrombosis (Ko et al. 1994; Fig. 4.30c).

5.2.5.2 Differentiation of a Central Space-Occupying Lesion from an Atelectasis

Atelectatic lung tissue is a suitable sonic window to the tumor that occludes the branch of the bronchus. Quite often sonography (**Fig. 5.31a**) allows better differen-

Fig. 5.29 a Large tumor in the upper lobe of the right lung, displacing the artery and vein of the upper lobe in medial direction. Sonographic biopsy indicated poorly differentiated neuroendocrine

carcinoma. **b** Tumor in the lateral middle lobe with central necrosis; in the marginal areas there are strong, convoluted vessels of changing diameter

Fig. 5.30 a Supraclavicular lymph node metastases in a woman with a bronchial adenocarcinoma. **b** Diffuse metastatic invasion of the entire right lobe of the liver in a man with a non-small-cell lung carcinoma. **c** This 69-year-old man with a known right-sided adeno-

carcinoma and mediastinal lymphomas developed a swelling in the right arm. Sonographic investigation from the right supraclavicular aspect shows a recent thrombosis subclavian vein

tiation of the tumor from nonventilated lung tissue than computed tomography (■ Fig. 5.31b).

In the presence of additional pleural effusion the contours of the tumor-bearing atelectatic portion of the lung are rendered (■ Fig. 5.31c).

5.2.6 Heterogeneous Structural Pattern

The assessment of malignant lesions might be rendered difficult by their highly *heterogeneous structural pattern* (Pan et al. 1993; ■ Table 5.2).

Tumor consolidations may still contain residually ventilated bronchial branches (■ Fig. 5.27e) or *colliquations* and/or *necrotic zones* (■ Figs. 5.29b and 5.32).

Lung tissue adjacent to a tumor might be affected by inflammation (■ Fig. 5.32) or contain calcifications (■ Fig. 5.28).

In a diseased portion of the lung, solid portions of the tumor might exist along with complex inflammatory infiltrations (■ Fig. 5.33).

Sonographic assessment of bronchoalveolar carcinoma is highly problematic. On the one hand, multiple peripheral consolidations with variable air content might mimic multifocal pneumonia (Görg et al. 2004; ■ Fig. 5.34). On the other hand, one may only find an uncharacteristic uneven lung surface (■ Fig. 5.35).

In all cases of ambiguous pulmonary lesions, sonography may serve as an important aid in decision-making. It helps the investigator to decide about the subsequent diagnostic procedure—either immediately in terms of a sonography-assisted biopsy (Mathis et al. 1999a, b, c; Beckh et al. 2002), or as a complementary imaging method to select the appropriate surgical procedure.

■ Fig. 5.31 a Central tumor in the left upper lobe (*broken line*); behind it there is atelectatic lung tissue with a regular vascular architecture. b Computed tomography image of the tumor and the atelectasis in the

upper lobe. c Large tumor (*arrow*) in the right lower lobe; in the marginal area there is atelectatic lung tissue surrounded by a pleural effusion. Sonographic biopsy of the tumor indicated small-cell carcinoma

■ Fig. 5.32 Space-occupying lesion in the upper and middle lobe with several necrotic zones (*arrowheads*). Initially there were marked signs of inflammation on clinical examination. Under antibiotic therapy the invasive pneumonic portion resolved (*arrow*). Sonographic biopsy from solid portions of the space-occupying lesion indicated squamous cell carcinoma

■ Fig. 5.33 Inhomogeneous and medially rather echodense (*arrow*) space-occupying lesion in the middle lobe. Sonographic biopsy from the more echodense portions showed, on histological examination, inflammatory lung parenchyma. Bacteriological investigation revealed *Aspergillus niger*. The sonographic biopsy from the more hypoechoic marginal areas (*arrowheads*) additionally showed a poorly differentiated, nonkeratinizing squamous cell carcinoma

■ **Fig. 5.34** In the right lower lobe, in the dorsal aspect, there is a nearly triangular invasive lesion with blurred margins. A bronchoalveolar carcinoma was confirmed by thoracoscopic biopsy. *INF* invasion, *PULMO* lung

■ **Fig. 5.36** This 77-year-old man complained of pain in the right chest. Sonography revealed a large tumor formation extending from the lung to the chest wall and leading to osteolytic destruction of a rib (*arrow*). Sonography-guided biopsy indicated metastasis of a urothelial carcinoma operated on 2 years ago

■ **Fig. 5.35** This woman had a bronchoalveolar carcinoma confirmed on radiographic investigation and by bronchoscopic biopsy. The carcinoma fills the entire right lower lobe. Sonography only shows an irregular and finely grained surface of the lung (*arrow*)

5.2.7 Pulmonary Metastases

Pulmonary metastases are documented on sonography when they reach the margin of the lung. Owing to poor visibility in this region, sonography is not a suitable screening method. Metastases have no small air trappings and are usually homogeneously hypoechoic; occasionally, they have branches extending into tissue (Mathis et al. 1999a, b, c). Pathological vessels are predominantly found at the margin (■ Fig. 5.36, ■ Table 5.3).

■ **Table 5.3** Sonomorphology of pulmonary metastases

Morphology	Echotexture	Vessels
Round	Hypoechoic	Bizarre new vessel formation at the margin
Oval	No ventilated portions	–
Serrated	Necrosis possible	–
Sharp margins	–	–

Summary

Sonography does not permit the investigator to make a distinction between metastases and peripheral carcinoma. The interpretation must take the patient's medical history and survey radiographs into account. In terms of differential diagnosis, the formation of lesions in the parietal pleura must be excluded by dynamic investigation. Even benign pulmonary lesions, e.g., hamartoma or hemangiofibroma, might extend to the periphery of the lung as hypoechoic formations. Cyst walls may be of varying thickness. They usually have an anechoic content. Occasionally they contain fluid with internal echoes. In order to differentiate between a cyst and a pulmonary abscess or an encapsulated

empyema, the diagnostic procedure must take clinical parameters and computed tomography investigations into account. In the final analysis, bacteriological, cytological, and histological investigations are of decisive importance.

5.3 Vascular Lung Consolidations: Pulmonary Embolism and Pulmonary Infarction

Gebhard Mathis
gebhard.mathis@cable.vol.at

Pulmonary embolism is the most common clinically undiagnosed cause of death. Autopsy observations indicate a frequency of 10–15%, and up to 30% in chronic heart failure, of which pulmonary embolism is again the cause of death in 40% of cases. In 10% of hospital deaths, pulmonary embolism is the cause of death, and in another 10%, it is a contributing cause. Clinical symptoms are nonspecific, and chest radiography is not very sensitive. Even in times of MSCT, it must be assumed that 40% of fatal pulmonary embolisms are not diagnosed. The most important diagnostic step is still to even think about it. The clinician is challenged to use any method that improves the diagnosis of pulmonary embolism and reduces mortality, which is still 15% (Goldhaber et al. 1999; Burge et al. 2008; Özsu et al. 2017).

5.3.1 Pathophysiological Requirements

A few minutes after pulmonary subarterial occlusion, surfactant collapse occurs. Interstitial fluid and erythrocytes flow into the alveolar space. Hemorrhagic choking provides ideal conditions for ultrasound imaging. These consolidations are directed toward the pleura, opening as it were with their base to the periphery, providing good conditions for lung sonography.

Pulmonary embolism is a dynamic event. Small hemorrhages are rapidly resorbed by local fibrinolysis. Both common reperfusible fresh transient hemorrhages (early

■ Fig. 5.37 Pathophysiological prerequisites for sonographic imaging in cases of pulmonary embolism. Peripheral engorgement of the alveolar lumen is a good prerequisite for pathological echotransmission

infarcts) and the rare true pulmonary infarcts with tissue necrosis (late infarcts) can be visualized sonographically. Small, premonitory emboli (signal emboli) may occur before a massive or fulminant pulmonary embolism, which, if recognized in time, give rise to appropriate therapeutic measures (Mathis and Dirschmid 1993; ■ Fig. 5.37).

5.3.2 Sonomorphology of Pulmonary Embolism

5.3.2.1 Shape and Echotexture

Fresh peripheral pulmonary emboli are sonographically echo-poor and largely homogeneous. Older and larger infarcts may also be granular in texture. The shape of embolism-related lung consolidation is predominantly triangular with a pleural base. The pleura may be slightly bulging. Sometimes the foci are rounded toward the hilus, sometimes polygonal. The margin may be somewhat blurred initially, but is usually sharp. Behind it, pseudosmall enhancement may be evident (■ Fig. 5.38; Reißig et al. 2003; Mathis et al. 2005).

5.3.2.2 Size

The average size of pulmonary infarcts is 12 × 16 mm (5–70 mm). Lesions smaller than 5 mm should not be scored, at most in the course, because they may also be scars. Pleurisy may give a similar picture once. However, this is localized at the point of pain and has extensive fragmentation of the pleural reflex. When in doubt, pleuritic consolidations can be differentiated from embolic consolidations by signal-enhanced ultrasound (■ Figs. 5.38–5.45).

■ **Fig. 5.38** a Two adjacent pulmonary infarctions in the same region of terminal flow in the presence flow of an obstructed pulmonary secondary artery. b Two further infarctions in the same woman. c Accompanying pleura effusion

5.3.2.3 Number

An average of 2.4 infarcts present with pulmonary embolism. If 2 or more foci are present, the accuracy with clinical probability is very high. In slender patients, it is recommended that a high-frequency transducer also be used to examine the visceral pleural reflex (■ Fig. 5.40).

5.3.2.4 Vascular Signs

In some cases, a small echoless vascular band directed from the tip of the lesion to the hilus can be visualized on the B-scan. It corresponds to the thromboembolically engorged pulmonary artery branch, as also described in computed tomographic studies ("vessel sign, vascular sign") (■ Fig. 5.46f).

5.3.2.5 Pleural Effusion

In about half of the cases, mostly small pleural effusions can be visualized, focally (16%) over the lesion or in the pleural sinus (33%). The effusion is largely echoless and

small in relation to the infarct lesion, which is an important distinguishing criterion to differentiate it from compression atelectasis. Internal echoes in the effusion and fibrin threads indicate infarct pneumonia (Mathis et al. 1993; ■ Fig. 5.47).

5.3.2.6 Localization

Two thirds of pulmonary infarcts are localized dorsally in the lower lobes of the lung, more so on the right than on the left. This is anatomic and hemodynamic because the basal pulmonary arteries are more straight, whereas the upper lobe arteries branch at steeper angles. The dorsobasal region is particularly accessible to transcutaneous sonography (■ Fig. 5.48).

5.3.2.7 Signal Emboli

Massive pulmonary embolism is often preceded by smaller embolic events, which then present as signal emboli. These present as single triangular or rounded small lesions. If several such small defects are adjacent,

Fig. 5.39 A 42-year-old male patient 2 weeks after dyspnea following appendectomy. **a** MSCT demonstrates the pulmonary embolism in central and peripheral location. **b** The pulmonary embolism

measuring 2 cm on ultrasound corresponds to the peripheral consolidation on MSCT. **c, d** Two pulmonary infarctions measuring 1 cm in size were not seen on the 32-slice CT

Fig. 5.40 Two lung infarcts: the left triangular, the other rounded

Fig. 5.41 a Five hours after the embolic event there is a rounded, homogeneous early infarction. b After 5 days the lesion is triangular in shape. c After 12 days the lesion has developed into a classic pul-

monary infarction that is somewhat smaller than the original lesion, triangular in shape and marked by serrated margins

the appearance of a frayed boundary between pleural nonventilated and normally ventilated lungs is seen. Such small lesions may signal an impending pulmonary embolism as a precursor, but they may also coexist with a massive central pulmonary embolism and thus support the diagnosis without the central embolus itself being detectable by thoracic sonography, which cannot succeed because of the intervening air (Mathis 1997). Currently, there is a high incidence of thrombotic complications in critically ill ICU patients with covid-19 (Klok et al. 2020).

5.3.2.8 Color-Coded Duplex Sonography in Pulmonary Embolism

Visualization of embolic-related circulatory arrest by color-coded duplex sonography (FKDS) is successful in only a few cases (Fig. 5.49). There are two reasons for this limitation:

- Short-breathing patients cannot hold their breath sufficiently long, resulting in many artifacts in FKDS.
- It is difficult to hit the feeding vessel in the correct plane.

5

Fig. 5.43 **a** Early triangular pulmonary infarctions. The D-dimer test was still negative at this time. **b** The infarction is vascularized only at the margin and not in the center. **c** Four days later the patient had an infarction pneumonia that was seen clinically as well. This is larger than the original lesion, partly ventilated, and revascularized

Fig. 5.44 A 25-year-old woman with sudden dyspnea and mild respiratory chest pain. **a** Sonography revealed two small pulmonary infarctions. **b** On spiral computed tomography the central pulmonary embolism was confirmed and only one lesion was seen in the periphery

Fig. 5.45 Large, classic pulmonary infarction with highly serrated margins and a central bronchial reflex

Fig. 5.46 Most pulmonary infarctions are found in the dorso-basal location owing to anatomical and hemodynamic factors

Fig. 5.47 Circulatory stop at the tip of the wedge-shaped pulmonary infarction

Nevertheless, color Doppler sonography is an important piece of the puzzle in the differentiation of subpleural lung lesions (Yuan et al. 1993; Gehmacher and Mathis 1994).

5.3.2.9 Contrast Enhanced Ultrasound (CEUS)

Pulmonary infarcts and embolic-related hemorrhages largely show a lack of contrast on contrast-enhanced sonography. Delayed and low contrast enhancement may occur at the margin of the lesion due to bronchial arterial supply. Pleurisy and pneumonia, on the other hand, are early and strongly contrasted. However, old pulmonary emboli or infarct pneumonias may be well perfused again and have good contrast saturations (Görg et al. 2004; Bertolini et al. 2008; Trenker et al. 2019; Findeisen et al. 2019; Fig. 5.50).

Tips for the Procedure

About 50% of patients complain of pleuritic pain in pulmonary embolism, and others describe discomfort in a specific region. Then first look where it hurts and quickly find it. If no localization is given, one begins the examination dorsobasally, where most pulmonary emboli can be detected. If clinical suspicion persists, the entire lung should be scanned, which can take as little as a few minutes. The dorsobasal region must be examined in any case.

5.3.2.10 Healing Phase: Infarct Pneumonia

In the healing phase, the sonomorphology of the pulmonary infarction is less typical. With increasing re-aeration, the sonographic picture is similar to that of pneumonia, so that sonomorphologic differentiation is now difficult (Fig. 5.43). In cases presenting for initial ultrasonography at the stage of infarct pneumonia 1–2 weeks after the event, it is probably possible to visualize the focus sonographically but offer few differential diagnostic criteria sonomorphologically (Table 5.4).

! Cave
 Infarct pneumonia cannot be sonographically differentiated from primary bacterial pneumonia.

Fig. 5.48 In contrast enhanced ultrasound pulmonary embolism shows a very late and less intensive enhancement—very well for differentiation of inflammatory consolidations

Fig. 5.49 Searching for the source of embolism: leg vein thrombosis in the femoral vein. The vein is larger than the artery, congested with echogenic material, and cannot be compressed. A small amount of flow is seen at the margin

5.3.3 Accuracy of Thoracic Sonography in the Diagnosis of Pulmonary Embolism

A large multicenter study of 352 patients in a normal round-the-clock service setting, even with less experienced examiners, has shown that peripherally typical foci are detectable sonographically in three quarters of patients with pulmonary embolism. An astonishingly high specificity of 95% was achieved (Mathis et al. 2005).

Worse results are shown by studies in which the dorso-basal region was not or too little examined (Nazerian et al. 2014).

In two meta-analyses of 5 and 10 studies in 652 and 887 patients, respectively, the pooled sensitivity is 80–87% and specificity is 82–93%. The authors conclude

Fig. 5.50 **a** Acute load of the right side of the heart with massive dilatation of the right ventricle. **b** At the level of valve there is a floating thrombus in the right side of the heart

that given the increasing number of CT examinations and the increasing collective radiation dose for specific clinical situations, thoracic sonography exists as a diagnostic alternative to CT (Niemann et al. 2009; Squizzato et al. 2013).

Table 5.4 Sonomorphology of pulmonary embolism

– echo-poor
– sharply demarcated
– pleural based
– triangular > round > polygonal
– 1–2 cm in size (0.5–7)
– vascular sign
– small pleural effusion focal/basal
– 2/3 dorsobasal localized
– central not perfused

A recent consensus conference and the current AWMF guidelines recommend pulmonary ultrasonography as an alternative to angio-CT when it is contraindicated (pregnancy, renal insufficiency, contrast agent allergy) or unavailable (Volpicelli et al. 2012a, b; AWMF 2016).

! Cave

Normal chest sonography does not exclude pulmonary embolism, nor does negative CT or negative D-dimers.

5.3.4 Multi-organ Ultrasound in Thromboembolism

In the diagnosis of leg vein thrombosis, 2-point compression ultrasonography of the leg veins has become the method of first choice. The experienced examiner can inspect several clinically actual or possibly involved body regions with one imaging system in one examination procedure, in which he can investigate the source, route, and destination of the embolic event. Recently, it has been shown that, according to the history and clinical picture, a targeted use of different organ ultrasound examinations with the D-dimer test significantly improves the accuracy. This has also been shown in the combination of lung ultrasound with compression sonography of the leg veins (Abootalebi et al. 2016; Nazerian et al. 2017; Zhu and Ma 2017; Mathis 2019).

Compression sonography of the leg veins

Well over half of pulmonary emboli originate in the leg veins. Compression ultrasonography of the leg veins is a safe approach to confirm the source of embolism from deep vein thrombosis. When deep vein thrombosis is suspected, the median sensitivity is 95% and the median specificity is 97%. Even in isolated thrombosis of the lower leg, which should not be underestimated, sonog-

Fig. 5.51 Echo through the chest of a fetus in the 32nd gestational week. Both lungs are homogeneously hypoechoic, as in complete atelectasis (AT)

raphy shows a median sensitivity of 89% and median specificity of 92% (Jäger et al. 1993; Eichlisberger et al. 1995; Abootalebi et al. 2016; Fig. 5.51).

5.3.5 Echocardiography

Approximately 40% of patients with acute LE have right heart strain. This particularly captures the hemodynamic risk patients who need immediate lysis as a life-saving measure. The first hours after symptom onset are crucial for the prognosis of hemodynamically relevant LE. Right heart strain is most commonly seen at first glance. Other typical signs include: abnormal septal motion, tricuspid insufficiency, McConnell's sign, thrombi in the right heart, hypokinesia of the right ventricle, and tricuspid annular plane systolic excursion (TASPE). Most of these signs are rapidly visible and easily learned during focused echocardiography (Fields et al. 2017).

Considering the accuracy of echocardiography, for unselected patients with suspected LE, the sensitivity is only 25–55% with a specificity of 90% (Jackson et al. 2000; Dresden et al. 2014). On the other hand, the accuracy in hemodynamically unstable patients is very high (Fig. 5.52).

A major advantage of sonographic embolic diagnosis is its availability independent of location and bedside, whether in the emergency department or even prehospital. The combination of chest sonography, echocardiography, and leg vein compression sonography yields

Fig. 5.52 **a** Chest x-ray: a 60-year-old man with global decompensated heart failure and bilateral pleural effusions. **b** B-mode ultrasound: In right-lateral intercostal scan one sees a pleural effusion with a wedge-shaped hypoechoic transformation of parts of the lower lobe of the lung as in the presence of atelectasis (AT). The demarcation to the ventilated lung (LU) is blurred. An extensive “air bronchogram” is seen. L liver

a sensitivity of more than 90% for pulmonary embolism (Mathis 2006; Nazerian et al. 2014).

The introduction of MSCT as the gold standard in the diagnosis of pulmonary embolism has increased the incidence but not significantly decreased mortality (Burge et al. 2008). Thus, the question arises to what extent the effect and side effect (radiation exposure in pregnancy, renal insufficiency, allergic reactions and overtreatment) of MSCT are balanced in the diagnosis of PE (Newman and Schriger 2011; Osman et al. 2018). A recent consensus conference and current guidelines recommend pulmonary sonography for the diagnosis of PE as an alternative to MSCT in certain clinical situations (Volpicelli et al. 2012a, b; Mathis 2014). If we want

to make a timely diagnosis in those patients at risk of fatal pulmonary embolism, we need to think about it more often, improve the use of clinical scores, and perform imaging immediately, for example, with ultrasound (Nazerian et al. 2017).

Sonography in pulmonary embolism: "Kill three birds with one stone - three birds with one stone".

Summary

In pulmonary embolism, lung ultrasound can show an average of 2.4 subpleural, low-echo lesions in at least three quarters of cases. On the one hand, these correspond to embolism-related reperfusion alveolar edema and hemorrhages (pulmonary premature infarcts). On the other hand, they are distinct pulmonary infarctions that present a typical sonomorphologic picture with small pleural-based triangular or slightly rounded foci. In combination with echocardiography and leg vein compression sonography, the accuracy is above 90%, making lung ultrasound an adjunct and, in certain clinical situations, an alternative to angiocomputed tomography.

5.4 Subpleural Lung Consolidation

Christian Görg
christian.goerg@uk-gm.de

C. Görg

5.4.1 Definition

Atelectasis is defined as the absence of ventilation in portions of the lung or the entire lung. Such lack of ventilation may be permanent or transient, complete or partial (dysatelectasis), congenital or acquired (Fig. 5.51).

5.4.2 Pathomorphology

Depending on the origin, a distinction is made between compression atelectasis and resorption atelectasis (obstructive atelectasis). Compression atelectasis may be anticipated when an accumulation of fluid causes intrapleural pressure to increase to a level higher than that of external air. This may be expected when the effusion is more than 2 l (Grundmann 1986).

Resorption atelectasis occurs when a bronchus is displaced in terms of its region of vascular supply, as a result of external compression or endobronchial obliteration.

In cases of resorption or obstructive atelectasis, a distinction is made between the central and the periph-

eral form. Central obstruction is usually caused by endobronchial processes (e.g., bronchial carcinoma or foreign body) or extrabronchial alterations (e.g., enlarged lymph nodes), whereas peripheral bronchial obstructions are marked by inflammatory mucus plugs and displacement of small bronchial branches. Displacement of the lumen of the middle lobe by mucus or pus, scarred kinking of the bronchus, external lymph node compression or tumor leads to the middle lobe syndrome.

Atelectasis impairs circulation in parenchyma, causing undersaturation of arteries owing to reduced gas exchange in perfused but not ventilated atelectatic lung parenchyma. In terms of pathological anatomy, the early phase of obstructive atelectasis is marked by high-protein fluid in intraalveolar spaces. The next stage is characterized by the migration of macrophages and lymphocytic infiltration. In cases of compression or even obstructive atelectasis of longer duration, the parenchyma shrinks and fibrous induration of lung tissue occurs.

Additional attendant phenomena or complications in cases of bronchial obstruction include secretion retention; bronchiectasis is seen in approximately 40% of cases (Burke and Fraser 1988; Yang et al. 1990a, b; Liaw et al. 1994a, b). In rare cases the patient develops bacterial superinfection and microscopic or gross abscesses; necrotic or hemorrhagic lesions in atelectatic tissue may also be found.

5.4.3 Sonomorphology

Lung atelectases are characterized by partial or complete absence of ventilation; therefore, in principle, they can be imaged by sonography. Furthermore, the echotransparency of the lung allows the investigator to assess the parenchyma. Especially in the presence of obstructive atelectasis, atelectatic lung tissue serves as “an acoustic window” for the investigation of central structures that possibly underlie the atelectasis.

5.4.4 Compression atelektaseis

The most common form of atelectasis is accompanied by the formation of pleural effusion. Depending on the amount of intrapleural fluid, the patient may develop homogeneous hypoechoic transformations shaped like a wedge or a pointed cap, especially in the area of the lower lobe (■ Fig. 5.52a, b). The margin towards the adjacent aerated lung tissue is blurred. Usually the atelectatic lung is surrounded by fluid, but also may be partly adherent to the pleura. The following features help to confirm the diagnosis by sonography:

- Partial reventilation during inspiration (■ Fig. 5.53),
- Partial reventilation after thoracentesis of effusion (■ Fig. 5.54a, b).

■ Fig. 5.53 a In left-lateral intercostal scan one sees a pointed cap-like, smoothly margined hypoechoic transformation in the tip of the lower lobe of the left lung (arrow) in the presence of a pleural effusion. Lu lung, PE pleural effusion. b Reventilation of lung tissue is achieved after deep inspiration, as in the presence of compression atelectasis

Fig. 5.54 A 66-year-old man with an alveolar carcinoma. **a** Chest x-ray: homogenous shadow of the caudal right-sided hemothorax. **b** B-mode ultrasound: right-lateral intercostal echo transmis-

sion shows a marked pleural effusion (PE) with atelectasis in the lower lobe (UL). After thoracentesis of the effusion (1 l, middle, and 2 l, right) there is increasing reventilation

In cases of compression atelectasis, lung tissue is partially reventilated after drainage of the effusion. This is also dependent on the elasticity of the lung. Of course, ventilation of the parenchyma after puncture of the effusion does not rule out the possibility of an additional central space-occupying lesion.

During inspiration sonography reveals an increasing quantity of air in atelectatic regions and the formation of a so-called »air bronchogram«. However, in the presence of exudative effusion, fibrin strands, septa and echogenic pleural effusion, one frequently observes poor reventilation during inspiration as a result of reduced elasticity of the lung. This condition has been described as a “trapped” lung (Lan et al. 1997). Concomitant inflammatory invasion of parenchyma in atelectatic tis-

sue is a further limitation. It leads to congestive pneumonia and restricts inspiratory ventilation. On the basis of sonomorphology alone this condition cannot be distinguished from pneumonia (Fig. 5.55). In the case of multiple fibrin threads, the use of local fibrinolysis or video-assisted thoracoscopic surgery should be considered.

An exudative effusion can also be fixed to the lung by a fibrin mantle or pleural carcinosis (Salamonsen et al. 2014) (Figs. 5.56 and 5.57). This may result in the fixed lung being unable to re-expand with a relieving puncture due to the loss of elasticity, and the resulting negative pressure even at low puncture volumes may lead to a “spontaneous pneumothorax” caused by shear forces after the relieving effusion puncture.

Fig. 5.55 Patient with exudative effusion with atelectasis and increased inflammatory markers. **a** Chest x-ray: shadowing in the area of the right caudal lung. **b** B-mode ultrasound: lung consolidation with focal air bronchogram and septated effusion. The lung is trapped

Possible Sonography Findings in Compression Atelectasis:

— B-mode ultrasound

- Moderate to marked pleural effusion
- Triangular pointed cap-like hypoechoic transformation of lung parenchyma
- Blurred margins towards the ventilated lung parenchyma

- Partial reventilation during inspiration (“air bronchogram”)
- Partial reventilation after thoracentesis of the effusion
- Color-Doppler sonography (CDS)
 - on intraindividual comparison with the liver/spleen one finds enhanced flow phenomena (▶ Chap. 8)

Fig. 5.57 **a** Patient with benign pleural effusion caused by congestive heart failure, visualized by chest x-ray and lung ultrasound; in M-mode ultrasound, the atelectatic lung shows significant pulse-synchronous mobility. **b** Patient with malignant pleural effusion

caused by metastatic pancreatic carcinoma, visualized by chest x-ray and lung ultrasound; in M-mode ultrasound, the atelectatic lung shows a lack of mobility. After thoracentesis, the patient developed a pneumothorax that needed to be drained

5.4.5 Obstruktive Atelektase

The sonographic image of obstructive atelectasis is marked by a largely homogeneous, hypoechoic presentation of lung tissue as in hepatization (■ Fig. 5.58). Effusion is absent or is very mild and is not in any way related to the consolidated lung tissue. In cases of lobar atelectasis, the margin towards ventilated lung tissue is rather distinct (■ Fig. 5.59). Depending on the duration of atelectasis, intraparenchymatous structures also may be seen:

- Hypoechoic vascular lines and echogenic reflexes
- Anechoic, hypoechoic or echogenic focal lesions

Atelectasis of long duration is accompanied by sonographic tree-like reflexebands in the lung parenchyma. The reflexeband are caused by dilated bronchi, as a

result of secretory congestion (so-called fluid bronchogram (■ Figs. 5.60 and 5.61). Vessels along the bronchi are seen as branches of the pulmonary artery and the pulmonary vein on CDS (■ Fig. 5.61; ► Chap. 8). In the case of prolonged tumor-related atelectasis, the occlusion of the pulmonary arteries can shift to a sole bronchial arterial perfusion (► Chap. 8).

Quite often the investigator finds **focal lesions** in the lung parenchyma (■ Figs. 5.62a–c, 5.63a–c, 5.64a–c, and 5.65a–c). As a result of dilated bronchi (due to congestion of secretion), one occasionally finds small anechoic, hypoechoic or even echogenic lesions within the parenchyma. Given corresponding clinical features, the lesions are due to microabscesses. Occasionally the abscesses contain air echoes (Yang et al. 1992a, b; ■ Fig. 5.65). Atelectasis caused by tumor often leads to intraparen-

Fig. 5.58 A 74-year-old woman with dyspnea. **a** Chest x-ray: signs of right-sided upper-lobe atelectasis. **b** B-mode ultrasound: right-ventral intercostal echo transmission shows a smoothly margined, wedge shaped hypoechoic transformation of the lung as in atelectasis. The central vessels are seen; a shadow of the tumor core cannot be demarcated. AO aorta, PV pulmonary vein, PA pulmonary artery. CDS shows pronounced arterial and venous flow profiles. The characteristic flow profiles of the pulmonary artery and the pulmonary vein are seen

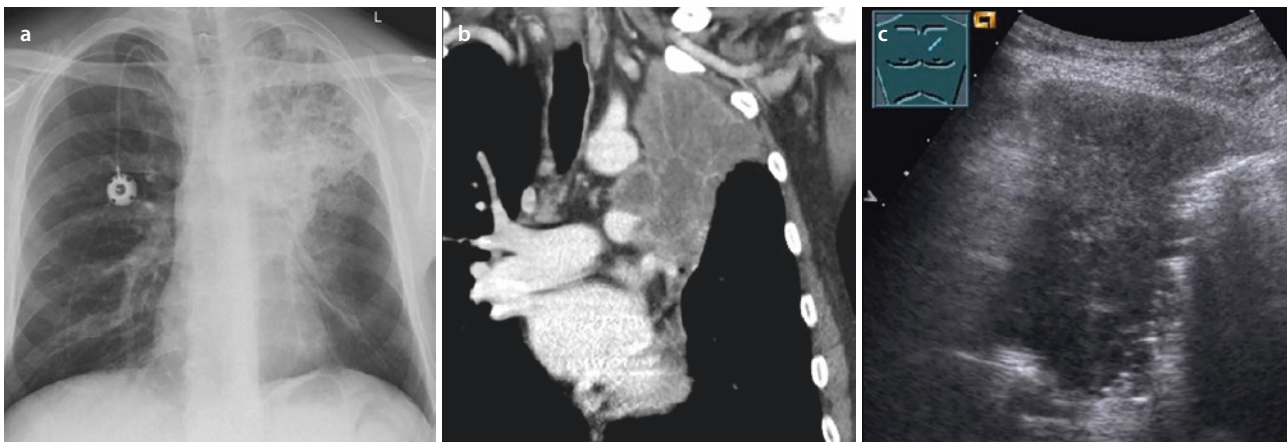

Fig. 5.59 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: shadows in the region of the left apical lung. **b** CT: visualization of the central tumor with subsequent atelectasis. **c**

B-mode ultrasound: lung consolidation with centrally located, slightly hypoechoic tissue and subsequent atelectasis, which is not sharply demarcated

Fig. 5.60 A 68-year-old man with a bronchial carcinoma. **a** Chest x-ray: signs of middle-lobe atelectasis. **b** B-mode ultrasound: right-ventral intercostal echo transmission shows atelectasis in the middle lobe (AT) with accentuated dilated bronchi, indicative of a fluid bronchogram (“sticks”). The central tumor formation cannot be clearly demarcated

Fig. 5.61 Patient with histologically confirmed bronchial carcinoma. **a** B-mode ultrasound: right apical upper lobe atelectasis with anechoic duct structures. **b** The following structures are differentiated using CDS: 1, pulmonary artery; 2, bronchial artery; 3, pulmonary vein; 4, extended bronchial branch

Fig. 5.62 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: nearly complete shadowing of the left hemithorax. **b** CT: visualization of the central tumor formation, with subsequent inhomogeneous atelectasis with multiple hypodense areas. **c** B-mode ultrasound: lung consolidation without central tumor visualization; the atelectasis shows honeycomb-like tissue liquidation similar to pronounced secretion retention

Fig. 5.63 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: shadowing in the area of the right caudal lung. **b** CT: visualization of an effusion with round hypodense lesions in the atelectasis, with a small amount of air in the lesions. **c** B-mode ultrasound: lung consolidation with central anechoic lesion. The finding is indicative of abscess formation

Fig. 5.64 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: shadowing in the area of the right caudal lung. **b** CT: visualization of a hypodense lesion in the atelectasis. **c** B-mode ultrasound: lung consolidation with central homogeneous hypoechoic lesions. The finding is indicative of abscess formation

Fig. 5.65 **a-c** A 68-year-old man with a bronchial carcinoma. **a** Chest x-ray: space-occupying lesion in the left hilum and a suspected central cavity. **b** B-mode ultrasound: left-ventral intercostal echo transmission shows atelectasis in the upper lobe (AT) and, demarcated from the atelectasis, a hilar tumor formation (Tu). Centrally in the atelectatic lung tissue there is an air-filled cavity (arrows), most likely an inflammatory retention. Lu lung, PA pulmonary artery. **c** CT: atelectasis in the upper lobe with air-filled retention

Fig. 5.66 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: shadowing in the area of the right caudal lung. **b** CT: visualization of an atelectatic lung consolidation with a

hypodense lesion. **c** B-mode ultrasound: imaging of the needle reflex in the lesion with confirmation of an abscess formation

chymatous liquefaction, which is seen on sonography as large hypoechoic circular lesions with characteristic motion echoes on “realtime” investigation. This is primarily due to necrosis or tumor-related retention of secretion (■ Figs. 5.63 and 5.64). Abscesses cannot be entirely excluded on the basis of sonomorphology alone. Here the clinical findings will be one of the main determinants of the diagnosis. However, sonography-guided aspiration will allow the investigator to confirm the diagnosis and obtain material for bacteriological investigation (■ Fig. 5.66a, b) (Görg 2003; Liaw et al. 1994a, b; ► Chap. 8).

The evaluation of focal lesions is performed clinically. In addition to infectious lesions (■ Figs 5.62–5.65), metastases or other benign lesions may also be detected in a lung atelectasis (■ Fig. 5.67a, b). Contrast-enhanced ultrasound (CEUS) has differential diagnostic value in the evaluation of focal lesions in atelectasis (► Chap. 8).

- Possible findings on sonography in cases of obstructive atelectasis:
- B-mode ultrasound
- Mild to no pleural effusion
- Homogenous hypoechoic transformation of lung parenchyma

- Hyperechoic reflexebands may be seen (fluid bronchogram)
- Focal intraparenchymatous lesions may be seen
 - Liquefaction of parenchyma
 - Microabscesses, macroabscesses
 - Parenchymal metastases
- A central space-occupying lesion may be seen
- No reventilation during inspiration
- Color-Doppler sonography (CDS)
- On intraindividual comparison with the liver/spleen, enhanced flow phenomena are visualized
- Triphasic spectrum of the arterial flow curve of pulmonary arteries (type, arteries of the extremities) (► Chap. 8)

Essentially, in the presence of lobar or pulmonary atelectasis, central portions can be imaged through atelectatic lung tissue by sonography. The main purpose here is to demonstrate the central tumor. On the basis of sonographic structural features, a definite distinction between atelectatic lung tissue and tumor tissue can be made in less than 50% of cases (Görg et al. 1996; ■ Fig. 5.68a–d). Here, CEUS enables a better demarcation of the central tumor from the atelectatic tissue (► Chap. 8).

Fig. 5.67 **a** Patient with pleural effusion after thoracic trauma, visualized by chest x-ray. On B-mode ultrasound, in addition to the pleural effusion, a hypoechoic round lesion in the atelectasis is detectable. The US-guided biopsy of the lesion after drainage of the hemorrhagic effusion reveals a diagnosis of focal lung hematoma. **b**

Patient with left-sided pleural effusion caused by metastasized pancreatic carcinoma; US reveals a hyperechoic focal round lesion in the atelectatic lung; a few years earlier, computed tomography showed that the round lesion was already detectable as a lung lipoma.

The significance of being able to visualize the central tumor lies in the fact that the tumor can be biopsied through atelectatic lung tissue under sonographic guidance with practically no risk of complications (Yang et al. 1990a, b; Fig. 5.69a–d).

5.4.6 Lung Contusion

In cases of chest trauma, particularly serial rib fractures, pulmonary contusions are visualized better

on sonography than on radiographs. Alveolar edema and alveolar hemorrhage caused by trauma are seen as moderately hypoechoic, blurred, pale lesions with indistinct margins (Wüstner et al. 2005; Figs. 5.70 and 5.71). These are more pronounced in the presence of concomitant minimal pleural effusions, but are also imaged on sonography in the absence of pleural effusion. In the event of any clinically relevant chest trauma, radiographs as well as sonograms should be obtained (▶ Chap. 2).

Fig. 5.68 Patient with histologically confirmed bronchial carcinoma. **a** Chest x-ray: shadowing of the left hemithorax. **b** The left apical central lung tumor is difficult to differentiate from the atelectasis by B-mode ultrasound. **c** In a CT, the tumor is more clearly

demarcated. **d** In the positron emission tomography-computed tomography image, the tumor shows increased glucose metabolism only in the marginal area.

Fig. 5.69 new figure. Patient with suspected bronchial carcinoma; the tumor could not be confirmed via bronchoscopy. **a** Chest x-ray: shadowing in the area of the left apical lung. **b** CT: visualiza-

tion of a central tumor formation with narrow atelectasis. **c** B-mode ultrasound: visualization of the needle reflex in the atelectasis and central tumor, with confirmation of a bronchial carcinoma.

Fig. 5.70 Patient with history of trauma. **a** Chest x-ray: shadowing of both lower lung lobes, right more than left. **b** Ultrasound evidence of rib fracture and **c** atelectatic lung consolidation in a case of

hemorrhagic effusion. **d** Corresponding evidence of effusion and atelectasis by CT

Fig. 5.71 new figure. Patient with history of trauma. **a** Condition after thoracic drainage of the hemothorax. **b** Chest x-ray: correct drainage of the effusion. **c** CT: extensive lung lesions with suspicion of lung hemorrhage. **d** B-mode ultrasound evidence of sternal frac-

ture and **e** complex atelectatic lung consolidation compatible with lung hemorrhage. **f** Abdominal computed tomography shows an additional splenic injury

Summary

Depending on the extent of intrapleural fluid in case of compression atelectasis, one finds a pointed cap-like, wedge-shaped, homogenous, hypoechoic transformation with blurred margins towards the aerated adjacent lung tissue. The sonographic image of obstructive atelectasis is marked by largely homogenous hypoechoic lung tissue, similar to hepatization. An effusion may be absent or is very mild. In cases of lobar atelectasis, the margin towards the ventilated lung tissue is rather blurred. Intraparenchymatous structures are seen as hypoechoic vascular lines, echogenic bronchial reflex-bands or focal lesions.

6.1 Transthoracic

Mediastinal structures can be visualized comprehensively by computed tomography as well as magnetic resonance tomography. Sonography in contrast identifies only parts of the mediastinum.

As early as in 1971 Goldberg (1971) pointed out the suprasternal sonographic access to the mediastinum. This access was used by cardiologists for the representation of the thoracic aorta and aortic valve (Herth 2009). In the mid-1980s sonography of the mediastinum was researched in pediatrics (Lengerke and Schmid 1988; Liu et al. 1988) as well as in adult medicine and its efficiency was proved (Braun 1983; Blank et al. 1986; Wernecke et al. 1986; Brüggemann et al. 1991). In the following years the diagnostic potential of sonography was systematically researched (Heizel 1985; Wernecke et al. 1986; Wernecke 1991; Blank et al. 1996b; Bosch et al. 2007; Subacul 2013). Further possibilities were disclosed by the application of color-Doppler sonography and, recently, through contrast-enhanced sonography (Betsch et al. 1992, 1994; Dietrich et al. 1997, 1999; Kunz et al. 2004; Caremani et al. 2009; Chen et al. 2014).

6.1.1 Sonographic Investigation Technique and Reporting

Profound knowledge of anatomy is absolutely essential (■ Figs. 6.1 and 6.2). Because of the small sonic window and the penetration depth only 3.5- and 5-MHz sector, convex and vector transducers with small apertures are suitable for sonographic diagnosis. In sonography the mediastinum is accessed from the suprasternal and the parasternal approach, occasionally also from the infrasternal approach (Blank et al. 1996a). The large vessels and their spatial relationship to the heart in the various planes serve as cardinal structures. The investigation from suprasternal is performed with the patient in the supine position. Viewing the upper mediastinum is facilitated by having the patient recline his/her head, ideally by cushioning the thoracic spine. Turning the head to the right and left is additionally helpful. In the right- and left-sided position described by Wernecke et al. (1988) and by Brüggemann et al. (1991) the mediastinum is shifted and the pulmonary cavity is displaced, which permits better viewing of the mediastinum. It is easier to assess the mediastinum in expiration (Beckh et al. 2002; Koh et al. 2002; Braun and Blank 2005; Herth 2009).

Transsternal sonographic access to the mediastinum is possible in children in the cartilage stage (Supakul and Karmazyn 2013).

6.1.2 Sonoanatomy

In principle, from suprasternal the supraaortic and paratracheal region and the aorticopulmonary window can be imaged (■ Figs. 6.3, 6.4, 6.5, and 6.6):

Suprasternal access (supine position): superior/anterior mediastinum

- Right side—tracheal region
- Truncus brachiocephalicus, a. carotis, a. subclavia
- Arcus aortae
- V. cava superior, veins brachiocephalicus
- Truncus pulmonalis, arteries pulmonales
- Left atrium, veins pulmonales
- Thymus
- Retrosternal space

For this purpose half-sagittal (from the right and left sides), coronary and transverse images are needed. Cervical portions of the esophagus (posterior mediastinum) can also be visualized (5–8 cm) (Blank et al. 1998; Zhu et al. 2005; Palabiyik et al. 2012; ■ Fig. 6.4d). From parasternal the combined use of right-sided and left-sided lateral decubitus position permits evaluation of the anterior and mid-mediastinum (■ Figs. 6.7 and 6.8). For this purpose the transducer is placed adjacent to the sternum, cranially, and then moved caudad. Anatomical structures visualized through transverse and sagittal sections in angulated planes are summarized as follows (■ Figs. 6.4, 6.5, and 6.6):

1. Parasternal access (lateral decubitus, right side): anterior/middle mediastinum
 - V. cava superior
 - Ascending aorta
 - pulmonalis dextra
 - Left atrium, vv. pulmonales
 - Left ventricle, right ventricle
2. Parasternal access (lateral decubitus, left side): anterior/middle mediastinum
 - Descending aorta
 - Truncus pulmonalis
 - Left atrium, vv. pulmonales
 - Left ventricle, right ventricle, right atrium

The infrasternal access only provides a limited view of caudal portions of the posterior mediastinum. The esophagus, aorta and vena cava are seen at the point where they pass through the diaphragm. Transverse and sagittal images in angulated planes are obtained through the left lobe of the liver (Blank et al. 1996a; Janssen et al. 1997; ■ Fig. 6.9).

Fig. 6.1 (continued)

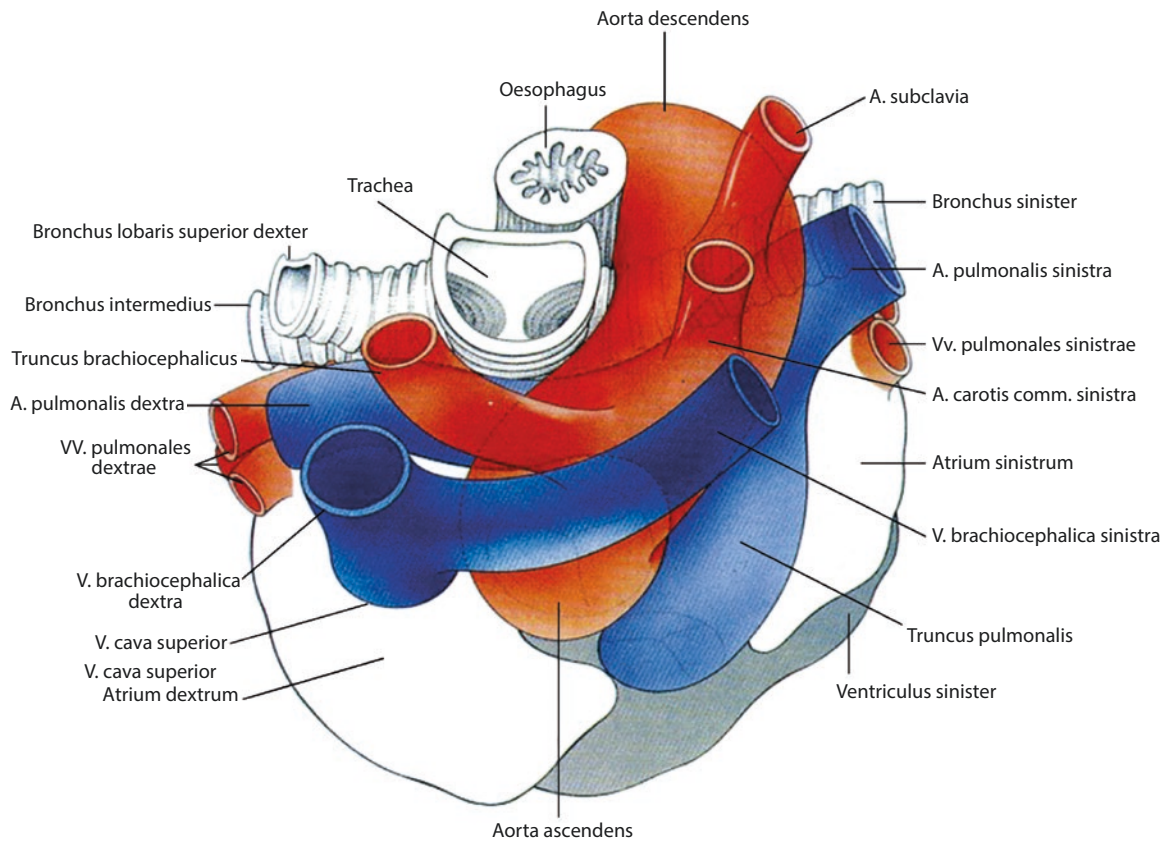

6.1.3 Imaging Compartments of the Mediastinum

The upper and mid-mediastinum can be imaged well on sonography. The suprasternal access permits adequate evaluation in 90–95% of cases. The posterior mediastinum, paravertebral region, the hilum of the lung and the immediate retrosternal space, however, can only be partly assessed from a transthoracic approach. Transthoracic sonography may be severely hampered by

obesity, pulmonary emphysema, mediastinal distortion as well as spinal deformities.

Factors that limit visualization of mediastinal structures:

- Low-lying structures
- Adiposity, large breasts
- Pulmonary emphysema
- Distortion of the mediastinum (surgery, inflammation, radiotherapy)
- Deformity of the vertebral column

■ Fig. 6.2 Topographic anatomy of the mediastinal vessels—suprasternal view. (From Wernecke 1991)

■ Fig. 6.3 Suprasternal examination. The ultrasound head is located in the jugular fossa; there is a cushion under the shoulders and the head is reclined at the maximum angle

6.1.4 Imaging Tumors in the Mediastinum

Approximately 75% of clinically relevant space-occupying masses in the adult mediastinum are located in the anterior and mid-mediastinum and are therefore readily accessible for sonographic assessment (Rosenberg 1993). The topographic position of a mediastinal space-occupying mass, its size and mobility can be determined by sonography. High-resolution sonography permits good differentiation of tissue on the basis of echogenicity (cystic, solid to calcified). Surrounding vessels can usually also be imaged well in the B mode. More detailed information (differentiation of vessels, indicators of vessel infiltration, tumor vascularization) may be gathered by color-Doppler sonography (Betsch 1994; Blank and Braun 1995; Chen et al. 2014). Tumor vascularity can be demonstrated with much more sensitivity and without motion artifacts through contrast-enhanced sonography, if good-quality equipment is provided (Blank and Braun 1995; Görg et al. 2003). Various space-occupying masses in the mediastinum have a characteristic sonomorphology (■ Table 6.1). A definite diagnosis, however, is usually made after removal of tissue and its histological investigation (► Chap. 9).

Fig. 6.4 Suprasternal examination. Supraaortic vessels. **a** The suprasternal transverse section demonstrates the cross section of the supraaortic vessels, right, distal to the branching of the brachiocephalic trunk. *ACC* common carotid artery, *AS* subclavian artery, *VS* subclavian vein, *TR* trachea, *PL* pleura/pulmonary reflex. **b** Half-sagittal right-hand section. The brachiocephalic trunk (*TR*) is shown by color-Doppler sonography, branching into the subclavian artery (*AS*) and the common carotid artery (*ACC*). The paratracheal region with its lymph nodes can be seen dorsal to the trunk in this section. Lateral to the reflex of the pleura/lung (*PL*), there is a mirror artifact of the artery. **c** A slight ventral tilting of the probe demonstrates the

right subclavian vein. A venous valve can be distinguished. *PL* pleura/pulmonary reflex, *R* rib. **d** The cervical portions of the esophagus (*arrows*) show the left thyroid gland dorsomedial if the sonography probe is tilted slightly laterally. High-resolution sonography probes allow a five-layer separation to be made of the esophagus wall (*arrows*). When the patient swallows, the course of the peristaltic wave and the passage of a high reflexogenic air-liquid portion can be observed. Average wall thickness is 2.5 mm. *OES* esophagus, *SD* thyroid, *WK* cervical vertebra

6.1.5 Diagnostic Value of Sonography, Chest Radiographs and Computed Tomography

Sonography is superior to survey radiographs of the chest in the assessment of nearly all portions of the mediastinum (with the exception of the paravertebral region). In the evaluation of supraaortic, pericardial, prevascular and paratracheal regions, sonography has a sensitivity 90–100% and is nearly as reliable as computed tomography. However, in the aorticopulmonary window and the subcarinal region, sonography achieves a sensitivity of only 82–70% (Wernecke et al. 1988;

Wernecke 1991; Brüggemann et al. 1991; Betsch 1994; Dietrich et al. 1995). Thus, sonography occupies an intermediary position between chest radiographs and computed tomography (Castellino et al. 1986; Bollen et al. 1994).

6.1.6 General Indications

Sonographic investigation of the mediastinum is performed after chest radiographs have been obtained, when the findings of the latter are not distinct or if a mediastinal space-occupying mass is suspected.

Fig. 6.5 Suprasternal examination. Suprasternal, sagittal section. The aorticopulmonary window (*arrow*) between the aortic arch and the pulmonary artery (*P*) shown in the cross section. If conditions for examination are difficult, the vessels can often be better differentiated from the surrounding soft-tissue structures by color-Doppler sonography and may be identified with more certainty (pulsed-Doppler sonography with characteristic frequency spectrum)

For an initial examination, mediastinal sonography can be rapidly implemented in preclinical and emergency diagnosis as a point-of-care sonography for adults with acute thoracic symptoms (pain, upper inflow congestion; important diagnoses such as thoracic aortic aneurism, a Vena cava superior thrombosis (■ Fig. 6.10) or a malignant lymphoma (Blank et al. 2014) can be made without delay. The procedure is also appropriate for primary imaging of children, and helps to reduce exposure to radiation. Reliable identification of mediastinal tubercular lymph nodes in children is thus made possible (Bosch et al. 2007; Supakul and Karmazyn 2013; Mosem and Andronikou 2014).

Sonography is the first investigation procedure in cases of acute chest symptoms (■ Fig. 6.10). The general indications for transthoracic sonography of the mediastinum are:

- Acute thoracic symptoms (Schmerz, obere Einflusstauung) (pain, upper inflow congestion)
- Suspected pulmonary tuberculosis, especially in children)
- Chest radiograph: space-occupying mass in the mediastinum
- Chest radiograph: undefined space-occupying mass
- Tumor staging (vascular complications)

Fig. 6.6 Suprasternal examination. Suprasternal coronal section. **a** Lateral to the aortic arch (AOB), which is shown in an oblique section, the vena cava (VC) can be distinguished with certainty by color-Doppler sonography because of its reverse direction of flow

(coded blue). **b** The branching of the pulmonary artery (P) and the aorticopulmonary window can be demonstrated better on B-mode after switching off the color Doppler

Table 6.1 Sonomorphology of space-occupying masses in the mediastinum

Appearance	Type of space occupation
Anechoic	Cystic formations, vessels
Hypoechoic	Lymphomas, “active” lymph nodes, more rarely “silent” lymph nodes
Hypoechoic–inhomogeneous echoes	Carcinoma, filiae, inflammation, aneurysm
Echodense	Physiological structures, thymus, scar (exception, rare liposarcoma and teratocarcinoma)

Modified according to Wernecke (1991)

- Monitoring the course of disease/therapy (tumor therapy)
- Puncture and drainage

6.1.7 Specific Sonographic Findings in Selected Space-Occupying Masses in the Mediastinum

6.1.7.1 Lymph Node Disease

Lymphomas account for approximately one quarter of all primary mediastinal tumors, whereas lymph node metastases of bronchial carcinomas, for instance, are more common.

On the basis of their hypoechoic transformation, inflamed and enlarged lymph nodes (e.g., Boeck’s disease tuberculosis) or lymph nodes invaded by tumor (Hodgkin’s or non-Hodgkin’s lymphoma, lymph node metastases) can be well differentiated from the surrounding hyperechoic tissue (Wernecke 1991; Bosch et al. 2007; Alvarez et al. 2013; Mosem and Andronikou 2014) (■ Figs. 6.11 and 6.12).

In contrast to the mostly “avascular” carcinoma metastases, lymphomas show strong blood flow in Color-Doppler Sonography (Chen et al. 2014); however, reliable differentiation of the above mentioned lymph node disease cannot be achieved through sonographic investigation without a tissue sample being taken (Gulati et al. 2000).

Differentiation of the above-mentioned diseases of lymph nodes by sonography alone is not possible without biopsy (Gulati et al. 2000).

Under treatment lymph nodes again become increasingly echogenic (Wernecke 1991). Color-Doppler Sonography and, as an even more sensitive method that has been recently employed, contrast-enhanced sonography will reveal reduced blood circulation (Betsch 1994; Braun and Blank 2005). With the use of high-resolution devices, normal mediastinal lymph nodes (hypoechoic) are also visualized very often (paratracheal, aorticopulmonary window). A reliable differentiation of pathological processes (► Chap. 10), however, is not possible without obtaining bioptic material (Dietrich et al. 1995, 1999; Bosch et al. 2007).

6.1.7.2 Tumors of the Thymus

The thymus is located in the anterior mediastinum, behind the sternum. In adults it cannot be distinguished from its hyperechoic surroundings. Approximately one quarter to one third of all primary mediastinal tumors originate from the thymus. There are various malignant tumors; thymomas and lymphomas are the most common ones (more rarely, germ cell carcinoma, carcinoids and carcinomas). These entities have characteristic sonographic features (■ Fig. 6.13, ■ Table 6.2). The diagnosis is verified by performing a sonography-guided or computed tomography-guided biopsy (Schuler et al. 1995; ► Chap. 10).

6.1.7.3 Germinal Cell Tumors

Teratomas and seminomas are mostly situated in the ventral and middle part of the mediastinum, accounting for approximately 10% of primary mediastinal tumors. Teratomas usually occur in the second and third decades, grow slowly and only produce symptoms if they have grown to a large size (encroaching upon surrounding structures). These tumors are clearly delineated, and contain cystic as well as epithelial structures (skin and

Fig. 6.10 Known non-Hodgkin's lymphoma. **a** Acute upper inflow congestion. Condition after port implantation. **B**-image sonography of still parasternal tumor masses. The port catheter can be differentiated as an echogenic double structure (*arrow*) in the

hypoechoic vena cava. *AOA* ascending aorta, *AP* right pulmonary artery, *ST* sternum, *PL* pleura. **b** Thrombosis of the vena cava superior (*VC*) can be substantiated

Fig. 6.11 Lymph node tuberculosis. Suprasternal semisagittal section, *right*. Dorsally to the color-Doppler sonography image of the brachiocephalic trunk (*TRBC*), one can see a hypoechoic, indistinctly delineated lymph node (*crosses*) in the paratracheal region, which normally has a homogeneous, hyperechoic structure. The diagnosis of lymph node tuberculosis was made possible by color-Doppler sonography of the fine-needle puncture. *LU* lung

appendages) and also tissue of mesenchymal origin (cartilage, bone, smooth muscle). Twenty-five to thirty percent of tumors show malignant transformation (**Fig. 6.14**).

6.1.7.4 Neurogenic Tumors

Neurogenic tumors originate from the sympathetic trunk, intercostal nerves or the vagus nerve, and therefore commonly grow in the posterior mediastinum. They can therefore only be demonstrated by transthoracic sonography if they have displaced pulmonary structures paravertebrally or extend cranially (retrosternal approach) or caudally (infrasternal approach). Transesophageal imaging and puncture, if necessary, are usually easy to perform.

6.1.7.5 Retrosternal Portions of the Thyroid and Parathyroid

These can be reliably assigned to the thyroid or the parathyroid on the basis of their topography and typical sonographic pattern. In problematic cases color-Doppler sonography may be used to prove the source organ of the lesion.

Parathyroid adenomas extending retrosternally usually appear as markedly hypoechoic well-vascularized

Fig. 6.12 Primary sonographic examination of an upper inflow congestion. **a** Multiple lymph nodes (*LK*) suspected of malignancy in the neck region. The panorama presentation (SieScape, from Siemens) enables an impressive documentation of a relatively large region of the body. **b** Low-echo tumor infiltration into the thyroid gland. Tumor masses (*crosses*) reaching into the retrosternal region. **c** Left parasternal section, in the vicinity of the infiltrating low-echo mass (*crosses*). The wall of the aorta (*AO*) can no longer be sharply delineated. *ST* sternum, *R* rib. **d** Pericardial deposits and pericardial

effusion (*crosses*). Suspected diagnosis of bronchial carcinoma (man, smoker) with substantiation of a mass suspected of being a metastasis in the region of the right adrenal gland (*crosses*). The diagnosis was confirmed by a sonographically controlled parasternal punch biopsy (Sonocan needle, 1.2-mm diameter). Histology indicated small cell bronchial carcinoma. **e** Chest X-ray overview. Mediastinal dissemination. **f** Computed tomogram. Tumor on the *right* lower lobar bronchus with extensive mediastinal metastases

Fig. 6.13 Thymoma. **a** Parasternal, transversal section. Even with the patient in the supine position, it was possible to see a low-echo mass in a ventral position to the aorta and well delineated. Cen-

tral liquid area. Sonographically controlled incision biopsy (diameter 1.2 mm). *AO* aorta, *ST* sternum. **b** Slide of pathology specimen. The tumor is clearly delineated

Table 6.2 Sonomorphology of thymomas

Benign	Malignant
Hypoechoic	Hypoechoic, inhomogeneous
Sharp margins	Blurred margins
Rounded, partly lobed	Tumor cones
No infiltration	Infiltration (pericardium, vessels)

space-occupying masses (typical laboratory constellation is increased parathyroid hormone and calcium). Puncture may be helpful to differentiate lymph node enlargement (Braun 1992).

6.1.7.6 Mediastinal Cysts

Pericardial and bronchial cysts usually can be clearly identified. If they contain highly viscous fluid, however, differentiation may not always be possible even by dynamic B-mode imaging (change of patient position-

ing, etc.). Absence of vascularization (in color-Doppler or contrast-enhanced sonography) verifies the diagnosis (Fig. 6.15).

6.1.7.7 Pericardial Alterations

Pericardial alterations like pericardial effusion, hemopericardium and tumor infiltration are easily demonstrable.

6.1.7.8 Esophageal Disease

Proximal and distal portions of the esophagus can be clearly visualized by the suprasternal and infrasternal access (Zhu et al. 2005). Esophageal tumors crossing the wall are seen as hypoechoic tumor formations with blurred margins (Figs. 6.16 and 6.17). In cases of surgical replacement of the esophagus, the upper anastomosis can be viewed. Recurrent tumors can also be detected (Blank et al. 1998; Palabiyik et al. 2012).

Sonography is a valuable aid in the detection of “dysphagia close to the cardia” (Blank et al. 1996a; Janssen et al. 1997).

Fig. 6.14 Cystic teratoma. A 32-year-old patient, slight dyspnea when jogging. **a** Plain chest radiograph with tumor and mediastinal distortion to the right. **b** Left parasternal section in supine position. Clearly delineated mass with echogenic septum- like structures. In the *center*, high amplitude reflexes with dorsal shadowing. The space-occupying lesion displaces the pleura to the side toward the thoracic wall, which moves with breathing. The feeding vessels suggest a mediastinal origin of the lesion. **c** Contrast-enhanced sonography clearly demonstrates cystic parts of the tumor which otherwise

only shows moderate vascularization and has a smooth border. A teratoma is suspected (central calcifications), and further preoperative diagnostics include computed tomography and transesophageal echocardiography. **d** Computed tomography reconstruction of the coronary section. **e** The gross pathological specimen demonstrates the smoothly demarcated tumor with septae, cystic areas, fatty tissue and cartilage/bone. Histology reveals a benign teratoma

The proximal esophagus is recognizable dorsal to the thyroid gland on the *left*. **b** No blood circulation is detectable in the cross section even with highly sensitive technology. Movement of liq-

uid is made recognizable in the B-image and in the color-Doppler sonography by a shaking movement. Diagnostic fine-needle puncture. Therapeutically operative resection due to compression syndrome

Fig. 6.16 **a** Proximal esophageal carcinoma spreading over the wall (*TU*) with infiltration into the epiglottis, upper esophageal sphincter (*OBERER ÖS-MUND*, *arrow*). The overgrown metal stent (*arrow*) is well delineated. An image with plenty of contrast and low

in artifacts as a result of tissue-harmonic imaging. *THI* thyroid. **b** Tumor masses (*crosses*) with infiltration and stenosis of the esophagus (*OES*)

Summary

Mediastinal space-occupying masses are most frequently found in the anterior upper mediastinum. They can be evaluated with transthoracic sonography nearly as reliably as with computed tomography, and histological material can usually be easily obtained by sonography-guided puncture (Nasi 2013; Chen et al. 2014; Dogan et al. 2019) (► Chap. 10).

In case of acute thoracic symptoms, this procedure can be implemented as a point-of-care sonography in emergency diagnosis (Blank et al. 2014).

The disadvantages of sonography, however, are significant. The procedure is strongly investigator dependent and only reveals portions of the mediastinum

compared with computed tomography. Moreover, the image quality is highly variable (Dietrich et al. 2015). Some of these disadvantages (► Table 6.3) can be balanced by the application of endoluminal transesophageal and endobronchial sonography (► Sect. 6.2) (Jenssen et al. 2015).

Acknowledgments

I would like to express my thanks to Martin Lenz (former chief consultant surgeon in the Radiology Department of the Steinberg Clinic, Reutlingen) for preparing and providing the radiological findings, and my son Valentin for the technical photographic work.

6.2 Transesophageal Sonography for Lung Cancer and Mediastinal Lesions

Jouke T. Annema Maud Veselić, and Klaus F. Rabe

Assessing a tissue diagnosis of mediastinal lesions, for example in patients with lung cancer and enlarged mediastinal lymph nodes, is often of major clinical importance. To date, surgical staging—such as mediastinoscopy and mediastinotomy—is still regarded as the standard of care for mediastinal assessment. However, these procedures are not only invasive and require clinical admission with associated high costs, they also have limitations in their diagnostic reach. The development of transesophageal sonography-guided fine-needle aspiration (FNA) provides a minimally invasive alternative for mediastinal analysis. Transesophageal sonography-guided FNA is currently used for the staging for various gastrointestinal malignancies. Since the first report in 1996 on transesophageal sonography-guided FNA for mediastinal staging (Pedersen et al. 1996), this method has evolved to an important diagnostic tool in chest medicine. In this part of the chapter, technical aspects as well as the use of transesophageal sonography-guided FNA in pulmonology will be discussed with an emphasis on the diagnosis and staging of lung cancer.

6.2.1 Technical Aspects

Transesophageal sonography is performed with technology which is also used by gastroenterologists.

Both radial and linear sonography probes are available, which both enable visualization of paraesophageal lesions. Real-time sonography-controlled FNAs (■ Fig. 6.18a, b), however, are only possible with linear or longitudinal probes. The fine needle aspirates obtained can be used for cytological (■ Fig. 6.18c) as well as molecular analysis—for instance, PCR analysis in patients with suspected tuberculosis.

In chest medicine, only linear sonography probes are used as tissue sampling is indicated in the vast majority of cases. Patients are investigated in a left lateral position in an ambulatory setting under conscious sedation using a low dose of midazolam. After the pharynx has been anesthetized with a lidocaine spray, the echoendoscope is introduced into the distal esophagus until the left liver lobe is visualized. From this point the echo-

endoscope is slowly retracted—meanwhile making circular movements, which enables complete visualization of all paraesophageal lesions that are located in the mediastinum. Once lymph nodes have been identified, size, shape, echo texture and borders of lesions can be described. Mediastinal nodes with a short axis exceeding 1 cm, a hypoechoic texture, a round shape and sharp borders are suspected to be malignant. When indicated, images and short movies of mediastinal abnormalities can be recorded. In order to prove malignant nodal involvement it is necessary to obtain tissue (Toloza et al. 2003b). Suspected paraesophageal lesions can be aspirated under real-time sonographic guidance (■ Fig. 6.19). Nodes from which tissue is obtained should be classified according to the Naruke classification (Mountain and Dresler 1997; ■ Fig. 6.20). In the case of suspected adrenal metastases, left-sided adrenal masses can be aspirated from the stomach (Eloubeidi et al. 2004). On-site cytological evaluation of aspirates has been proven to be useful in order to ensure that representative samples are obtained. In experienced hands, a complete transesophageal sonographic examination for the diagnosis and staging of lung cancer takes about 25 min. A prerequisite for performing pneumological EUS-FNA investigations independently is a minimum record of 50 supervised endoscopies (Annema et al. 2010).

Although few absolute contraindications exist for transesophageal sonography procedures of the upper gastrointestinal tract, esophageal strictures and diverticula exhibit an increased perforation risk. Complications related to mediastinal lymph sampling have as yet not been reported. (Annema et al. 2005c, d; Eloubeidi et al. 2005b; Fritscher-Ravens et al. 2000a; Kramer et al. 2004; Larsen et al. 2002; Wallace et al. 2001; Williams et al. 1999). A cyst, however, poses an increased risk of infection and therefore should not be aspirated owing to an increased risk of mediastinitis (Annema et al. 2003a; Wildi et al. 2003).

The advantages of this novel diagnostic tool—as compared with radiological and surgical alternatives—are numerous (■ Table 6.4). Regarding mediastinal nodal staging, transesophageal sonography has a superior sensitivity compared with computed tomography (Hawes et al. 1994; Toloza et al. 2003a, b) and additionally provides the opportunity for tissue sampling. Compared with surgical alternatives, transesophageal sonography is less invasive, is performed in an outpa-

Fig. 6.18 a Computed tomography of the thorax. Right upper-lobe tumor (*T*) and enlarged subcarinal lymph node (*LK*). b Endosonography. node station 7). c Cytology. Fine-needle aspirate demonstrating adenocarcinoma with vacuoles and enlarged central nuclei. Squamous cells from the esophagus can be recognized on the *left*

Fig. 6.19 Endosonography. Sonography-guided fine-needle aspiration (*N* needle) of a round hypoechoic lymph node with sharp borders, situated between the esophagus (*Ös*), aorta (*Ao*) and pulmonary artery (*PA*) (lymph node station 4 L)

tient setting and is therefore more cost-effective (Kramer et al. 2004).

The lower mediastinum is the area which can be visualized completely by transesophageal sonography, especially regarding the subcarinal (station 7) and the lower paraesophageal (station 8) nodes as well as those nodes located in the pulmonary ligament (station 9) (Fig. 6.20). Although nodes located in the aortopulmonary window (station 5) and adjacent to the aorta (station 6) can be detected by transesophageal sonography, tissue sampling is not always possible owing to intervening vascular structures. Limitations of EUS are its inability to reach the upper (station 2) and lower (station 4) paratracheal nodes as air in the trachea and main bronchi regularly inhibits visualization of these areas of the mediastinum. EUS is complementary to both mediastinoscopy and endobronchial sonography regarding its diagnostic reach (Annema et al. 2005d; Eloubeidi et al. 2005a). Mediastinoscopy provides good access to both the upper and the lower paratracheal lymph nodes.

Superior mediastinal nodes

- 1 Highest mediastinal
- 2 Upper paratracheal
- 3 Pre-vascular and retrotracheal
- 4 Lower paratracheal (including Azygos nodes)

N₂ = single digit, ipsilateral
 N₃ = single digit, contralateral or supraclavicular

Aortic nodes

- 5 Subaortic (A-P window)
- 6 Para-aortic (ascending aorta ar phrenic)

Inferior mediastinal nodes

- 7 Subcarinal
- 8 Paraesophageal (below carina)
- 9 Pulmonary ligament

N₁ nodes

- 10 Hilar
- 11 Interlobar
- 12 Lobar
- 13 Segmental
- 14 Subsegmental

6.2.2 Transesophageal Sonography-Guided Fine-Needle Aspiration and Lung Cancer

6.2.2.1 Diagnosing Lung Cancer

Patients with suspected lung cancer and enlarged or PET-positive mediastinal nodes—for whom no diagnosis is obtained after bronchoscopy—are often good can-

didates for a transesophageal sonography-guided FNA investigation. If mediastinal metastases are assessed by transesophageal sonography-guided FNA, both a tissue diagnosis and locoregional staging are obtained with a single diagnostic test. In a prospective study of 142 patients with suspected lung cancer and enlarged mediastinal nodes, transesophageal sonography—after a nondiagnostic bronchoscopy—assessed a tissue diagnosis in 73% of patients (Annema et al. 2005d).

Transesophageal sonography-guided FNA is also indicated for diagnosing intrapulmonary tumors directly, provided they are located adjacent to the esophagus (Annema et al. 2005b; Varadarajulu et al. 2004a; ■ Fig. 6.21). In a study of 32 patients with a centrally located lung tumor—in which bronchoscopy failed to achieve a tissue diagnosis—lung cancer was proven by transesophageal sonography-guided FNA in 97% of cases (Annema et al. 2005b).

6.2.2.2 Staging of Lung Cancer

Mediastinal staging of lung cancer is the most common indication for a transesophageal sonography-guided FNA investigation, and the accuracy is between 76% and 98% (Annema et al. 2005c, d; Eloubeidi et al. 2005b; Fritscher-Ravens et al. 2000a; Kramer et al. 2004; Larsen et al. 2002, 2005; Leblanc et al. 2005; Savides and Perricone 2004; Wallace et al. 2001, 2004; Williams et al. 1999; ■ Table 6.5). So far, most studies have included

■ **Table 6.4** Transesophageal sonography-guided fine-needle aspiration—advantages and limitations

Advantages	Limitations

Minimally invasive	
Cost-effective	

selected patient with enlarged (short axis greater than 1 cm) or PET-positive (Annema et al. 2004; Eloubeidi et al. 2005b; Kramer et al. 2004) mediastinal nodes. For mediastinal restaging—an emerging indication for transesophageal sonography-guided FNA—an accuracy of 83–92% has been reported (Annema et al. 2003b, Stigt et al. 2009).

Centrally located lung tumors can often be detected by transesophageal sonography, and in these cases it is often possible to assess whether mediastinal tumor invasion (T4) is present (Schroder et al. 2005; Varadarajulu et al. 2004b; ■ Fig. 6.22). In a study with 97 patients with a lung tumor located immediately adjacent to the esophagus, transesophageal sonography had an accuracy of 92% regarding invasion in the aorta (Schroder et al. 2005).

The left adrenal gland, a common site for distant metastases in patients with lung cancer, can be visualized from the stomach by transesophageal sonography (■ Fig. 6.23). In a study of 31 patients with enlarged left adrenal glands on computed tomography, transesophageal sonography provided tissue proof of metastatic involvement in 42% of cases (Eloubeidi et al. 2004). Whether the left adrenal gland should be investigated routinely during a transesophageal sonographic investigation for lung cancer staging is the subject of debate (Ringbaek et al. 2005).

6.2.2.3 Clinical Implications

A randomized study showed that the need for surgical staging is significantly reduced by EUS investigations (Tournoy et al. 2008).

Transesophageal sonographic investigations in patients with (suspected) lung cancer can prevent up to

■ **Fig. 6.21** a Computed tomography of the thorax. Relatively smooth shaped intrapulmonary lesion (*T*) located in the right upper lobe (3 cm × 3 cm × 6 cm) located adjacent to the esophagus (*Os*).

70% of scheduled mediastinoscopies by providing tissue proof of mediastinal metastases (Annema et al. 2005c; Larsen et al. 2002). Patients prefer an ambulatory transesophageal sonographic investigation to surgical staging, which involves clinical admission and general anesthesia (Annema et al. 2005d). In the case of replace-

ment of surgical staging by transesophageal sonography-guided FNA, cost reductions up to 40% can be achieved (Kramer et al. 2004).

6.2.2.4 Transesophageal Sonography in Lung Cancer Staging Algorithms

What are the indications for transesophageal sonography-guided FNA in the diagnosis and staging of lung cancer? On the basis of current evidence, transesophageal sonography-guided FNA is indicated early—after a nondiagnostic bronchoscopic evaluation that includes transbronchial needle aspiration—in the diagnostic workup or mediastinal staging of lung cancer.

When transesophageal sonography-guided FNA is added to mediastinoscopy, locoregional staging is improved owing to the complementary reach of both diagnostic methods in reaching different lymph nodes and the identification of mediastinal tumor invasion (T4) (Annema et al. 2005d; Eloubeidi et al. 2005a). Therefore, performing EUS as an additional staging test to routine mediastinoscopy leads to a significant reduction of futile thoracotomies (Larsen et al. 2005). Analyzing mediastinal lesions that are suspected for mediastinal metastases based on fluorodeoxyglucose PET by transesophageal sonography-guided FNA is regarded as an accurate, minimally invasive staging strategy for lung cancer (Annema et al. 2004; Eloubeidi et al. 2005b; Kramer et al. 2004; Iwashita et al. 2008). By combined use of EUS-FNA and EBUS-TBNA, nearly the entire mediastinum can be examined (Wallace et al. 2008). According to current guidelines, EUS or EBUS may be performed as an alternative to mediastinoscopy for the identification of mediastinal

Fig. 6.24 **a** Endosonography. Multiple nodes (*LK*) with sharp borders and an isoechoic ultrasound pattern suggestive of sarcoidosis. *PA* pulmonary artery. **b** Cytology of this lymph node indicates a typical granuloma without central necrosis

lymph node metastases (De Leyn et al. 2007; Detterbeck et al. 2007).

Transesophageal sonography-guided FNA indications in chest medicine:

- Suspected lung cancer, enlarged mediastinal nodes
- Suspected lung cancer, tumor located adjacent to the esophagus
- Mediastinal (re-)staging
- Analyzing PET-positive mediastinal lesions
- Staging of centrally located lung tumors suspected for tumor invasion (T4)
- Suspected left adrenal metastases (left-sided)
- Suspected sarcoidosis
- Suspected tuberculosis
- Suspected mediastinal cysts

6.2.3 Transesophageal Sonography-Guided Fine-Needle Aspiration and Sarcoidosis

Sarcoidosis is the most common interstitial lung disease in which mediastinal nodes are often involved. Frequently, a tissue diagnosis supporting the presumed diagnosis of sarcoidosis is needed, either before treatment with steroids or to rule out other diseases such as tuberculosis, lymphomas or malignant epithelial diseases. For the diagnosis of sarcoidosis, a state-of-the-art bronchoscopic evaluation—including several peripheral lung biopsies—has a diagnostic yield of 66% (Costabel

and Hunninghake 1999). However, peripheral biopsies include the risk of a pneumothorax or hemoptysis. Transesophageal sonography has both a high yield (82%; Annema et al. 2005a) and a high sensitivity of 89–94% (Fritscher-Ravens et al. 2000b; Wildi et al. 2004) in assessing noncaseating granulomas and so far no adverse events have been reported. Sonographic images of mediastinal nodes in patients with sarcoidosis often demonstrate a specific ultrasound pattern consisting of multiple, well-defined mediastinal nodes with an isoechoic or hypoechoic texture and the absence of a centrally located hypoechoic area. Often vessels within these nodes can be detected by color-Doppler sonography (Fritscher-Ravens et al. 2000b). On cytological evaluation, mediastinal nodes in patients with sarcoidosis present as noncaseating granulomas without necrosis (Fig. 6.24).

6.2.4 Transesophageal Sonography and Cysts

Paraesophageal and parabronchial cysts account for a considerable portion of mediastinal lesions. Cysts located adjacent to the esophagus (Fig. 6.25a) can be visualized by transesophageal sonography and often present with a round shape, well-defined borders and an echo-free or echo-poor content (Fig. 6.25b). Aspiration of cysts is not indicated owing to the risk of mediastinitis (Annema et al. 2003a; Wildi et al. 2003).

Fig. 6.25 **a** Computed tomography of the thorax. Sharp well-defined lesion (*R*) ($2\text{ cm} \times 1\text{ cm} \times 1\text{ cm}$) located in the lower mediastinum. The heart and descending aorta are easily identified. **b** Endosonography. Remarkably echo-poor, well-demarcated, easily

compressible lesion (cyst located immediately adjacent to the esophagus (*Ös*)) without a signal on color-Doppler sonography—sonographically compatible with a cyst. *Ao* aorta

6

Summary

Ten years after the first reports of mediastinal evaluation by transesophageal sonography-guided FNA, there is strong evidence that transesophageal sonography-guided FNA qualifies as an accurate and safe method for diagnosing and staging of lung cancer. Additionally this test is helpful for the analysis of various other mediastinal lesions. When used in clinical practice, transesophageal sonography-guided FNA not only prevents surgical diagnostic procedures to a large extent, it also reduces the number of futile thoracotomies and is cost-effective. Recently, linear echo-bronchoscopes—derived from transesophageal sonography scopes—have become clinically available. Comparison studies between transesophageal sonography-guided FNA and endobronchial sonography-guided transbronchial needle aspiration are needed for definitive position of these echo-endoscopic methods in diagnostic and staging algorithms (Herth et al. 2005; Vilmann et al. 2005; Wallace et al. 2008). The end point for such studies should include accuracy, safety, feasibility and patient preference. Randomized studies are being performed at the present time to compare complete endosonographic staging (EUS + EBUS) with surgical staging.

According to the authors, supported by the available peer-reviewed literature, transesophageal sonography-guided FNA can be regarded as an important diagnostic tool for the analysis of mediastinal lesions and the diagnosis and staging of lung cancer.

7.1 Instruments and Technique

7.1.1 Endobronchial Sonography Miniprobes

The different impedance of soft tissues has made sonography an indispensable diagnostic tool in medicine. Instruments that are used for gastrointestinal application could not be applied inside the airways because of their diameter. For application inside the central airways, therefore, flexible catheters for the probes with a balloon at the tip were developed, which allows circular contact for the ultrasound, providing a complete 360° image of the parabranchial and paratracheal structures

(■ Fig. 7.1a). Thus, under favorable conditions structures at a distance of up to 4 cm can be visualized (Herth and Becker 2000). The probes have been on the market since 1999 and can be applied with regular flexible endoscopes that have a biopsy channel of at least 2.6 mm.

7.1.2 Endobronchial Sonography Transbronchial Needle Aspiration

The latest developments are special bronchoscopes with an integrated curvilinear electronic transducer at the tip (Olympus BF-UC160F; ■ Fig. 7.2). So a realtime needle puncture under endoscopic control is possible. The

■ Fig. 7.1 a–c Excision of the wall infiltration. *TU* tumor, *LN* lymph node, *AOA* ascending aorta, *TR* trachea, *ES* endoscopic probe, *In* small lymph node, *VC* vena cava

■ Fig. 7.2 Head of the sonography bronchoscope

outer diameter of the insertion tube is 6.2 mm. The angulation range of the distal end of the endoscope is 160° upward and 90° downward. The instrument has a small curved linear-array electronic transducer, of length 10 mm, located at the distal end of the endoscope in front of a 30° oblique forward-viewing fiber-optic lens (angle of view 80). The endoscope has a biopsy channel of 2 mm. The ultrasonic frequency is 7.5 MHz with a penetration depth of 5 cm. The scanning direction is parallel to the longitudinal axis of the endoscope with a scanning angle of 50°, which enables full sonographic monitoring of a needle when it is inserted via the biopsy channel during scanning (Krasnik et al. 2003).

7.2 Sonographic Anatomy

The wall of the central airways show a seven-layer structure which can be demonstrated by high magnification only. The layers represent the mucosa and submucosa, the three layers of the cartilage and the adjacent external structures of loose and dense connective tissue, respectively (Kurimoto et al. 1999). Under low-power magnification and in the periphery only a three-layer structure is visible. Orientation by sonography within the mediastinum is difficult. Besides the complex mediastinal anatomy this is due to motion artifacts by pulsation and respiration as well as the unusual planes of the sonography images as with the probes we have to follow the course of the airways. For orientation, therefore, the analysis of characteristic anatomical structures is more reliable than observation of the position of the sonography probe inside the airway. Vessels can be diagnosed by their pulsation. But even after application of echo contrast media discrimination of venous and arterial vessels can be difficult owing to the great number of variations. However, as during the procedure pulse oxymetry is applied, arterial pulsations can be diagnosed according to their synchronism with the acoustic signal. Lymph nodes and solid structures can be differentiated down to a size of a few millimeters from the blood vessels by their higher echodensity.

7.3 Indications and Results for the Endobronchial Sonography Miniprobe

Since 1999 the probe has been on the market and endobronchial sonography is applied in several centers worldwide. For some indications the superiority of sonography over conventional imaging has been proven in prospec-

tive studies and in some centers endobronchial sonography is already established as a routine procedure. According to the structures that can be analyzed, current indications comprise endoluminal, intramural and parabranchial structures; with respect to medical indications, early detection and tumor staging, inflammatory destruction of the airways, mediastinal lesions and malformations of mediastinal structures.

7.3.1 Early Cancer

In small radiologically invisible tumors the decision for local endoscopic therapeutic intervention is dependent on their intraluminal and intramural extent within the different layers of the wall. In contrast to radiological imaging by endobronchial sonography even very small tumors of a few millimeters can be analyzed and differentiated from benign lesions. As different authors demonstrated, endobronchial sonography is a very reliable tool in analyzing the extent of these small lesions. We could demonstrate that by endobronchial sonography in small autofluorescence-positive lesions that were negative in white light bronchoscopy we could improve specificity (predicting malignancy) from 50 to 90. Combination of endobronchial sonography with autofluorescence has been proven to be efficient in prospective studies and today has become the basis for curative endobronchial treatment of malignancies in some institutions (Herth et al. 2002; Miyazu et al. 2002; Fig. 7.3). The most important paper in this respect was that of Miyazu et al. They used the finding of endobronchial sonography for the therapy decision in patients with early cancer lesions. In 18 patients they found nine with a tumor limitation to the bronchial wall; these patients were treated with photodynamic therapy. All other patients had extracartilaginous tumor growing and were treated nonendoscopically (surgery, radiation and chemotherapy). Using the finding as a decision maker they achieved a 100% complete remission rate in the endoluminal treated group. In a mean follow-up time of 32 months none of the patients developed a recurrence. Compared with earlier published trials using endoluminal techniques in early cancer lesions, they could show that with the help of endobronchial sonography, endoluminal-treatable patients could be identified.

7.3.2 Advanced Cancer

In preoperative staging, endobronchial sonography allows detailed analysis of intraluminal, submucosal and intramural tumor spread, which can be essential for

Fig. 7.3 a–g Local staging of an early carcinoma. The arrow in **f** shows the destruction of the bronchial wall by the tumor

decisions regarding resection margins. Endobronchial sonography proved especially useful in diagnosis of mediastinal tumor involvement in the great vessels such as the aorta, the vena cava, the main pulmonary arteries and the esophageal wall which by conventional radiology frequently is impossible. In a trial it was shown that differentiation of external tumor invasion from impression of the tracheobronchial wall by endobronchial sonography is highly reliable (94%) in contrast to computed tomography imaging (51%). One hundred and four patients with a central tumor were examined with endobronchial sonography and computed tomography and the tumors were classified into invasion or impression types. All patients underwent surgery, and the findings were compared with the initial classification. The sensitivity (from 89% to 25%) and also the specificity (from 100% to 89%) shows the superiority of the sonography technique in the differentiation between airway infiltration and compression by tumor. Thus, many

patients considered to be nonresectable by the radiologist owing to supposed T4 tumors could be operated on in a curative approach after use of endobronchial sonography (Herth et al. 2003) (■ Fig. 7.4).

7.3.3 Peripheral Lesions

For histological diagnosis of peripheral intrapulmonary lesions by bronchoscopy an instrumental approach under fluoroscopic or computed tomography guidance is the standard procedure ■ Fig. 7.5a–c. This demands expensive X-ray equipment in the bronchoscopy suite or coordination with the radiology department and causes exposure to radiation for the patient and the staff. In a prospective study we were able to show that those lesions could be approached by endobronchial sonography guidance with the same success rate of approximately 75%. Recently these data were confirmed by a group of

Fig. 7.4 a–f Local staging of an advanced tumor. *DAO* descending aorta, *PA* pulmonary artery, *TU* tumor, *LMB* left main bronchus

Japanese bronchologists. Shirakawa et al. also achieved a diagnostic yield of 75% using the miniprobe as a guidance tool for the forceps (Omori et al. 2002; Herth et al. 2002, 2006a; Eberhardt et al. 2007, 2009).

7.3.4 Lymph Node Staging

Under favorable conditions lymph nodes can be detected by endobronchial sonography down to a size of 2–3 mm and the internal structure (sinuses and folliculi) as well as small lymph vessels can be analyzed. By endosonographic localization of lymph nodes the results of TBNA can be significantly improved up to 85%. This is especially true for those positions in which reliable landmarks on the computed tomogram are

missing, e.g., high and low paratracheal localization. Herth et al. (2004) investigated the results of an endobronchial sonography-guided TBNA compared with those of conventional TBNA. In this randomized study, they confirmed that the yield of an endobronchial sonography-guided TBNA is higher than that of the conventional TBNA (85% vs. 66%). In an additional analysis of the lymph node station they showed that especially in locations without endoscopic landmarks (lymph node stations 2, 3, 4, Mountain scheme) the detection technique is helpful to increase the yield. On the other hand, they showed that in the case of enlarged subcarinal nodes a conventional TBNA has the same yield as the TBNA after endobronchial sonography detection (Takemoto et al. 2000; Yasufuku et al. 2004).

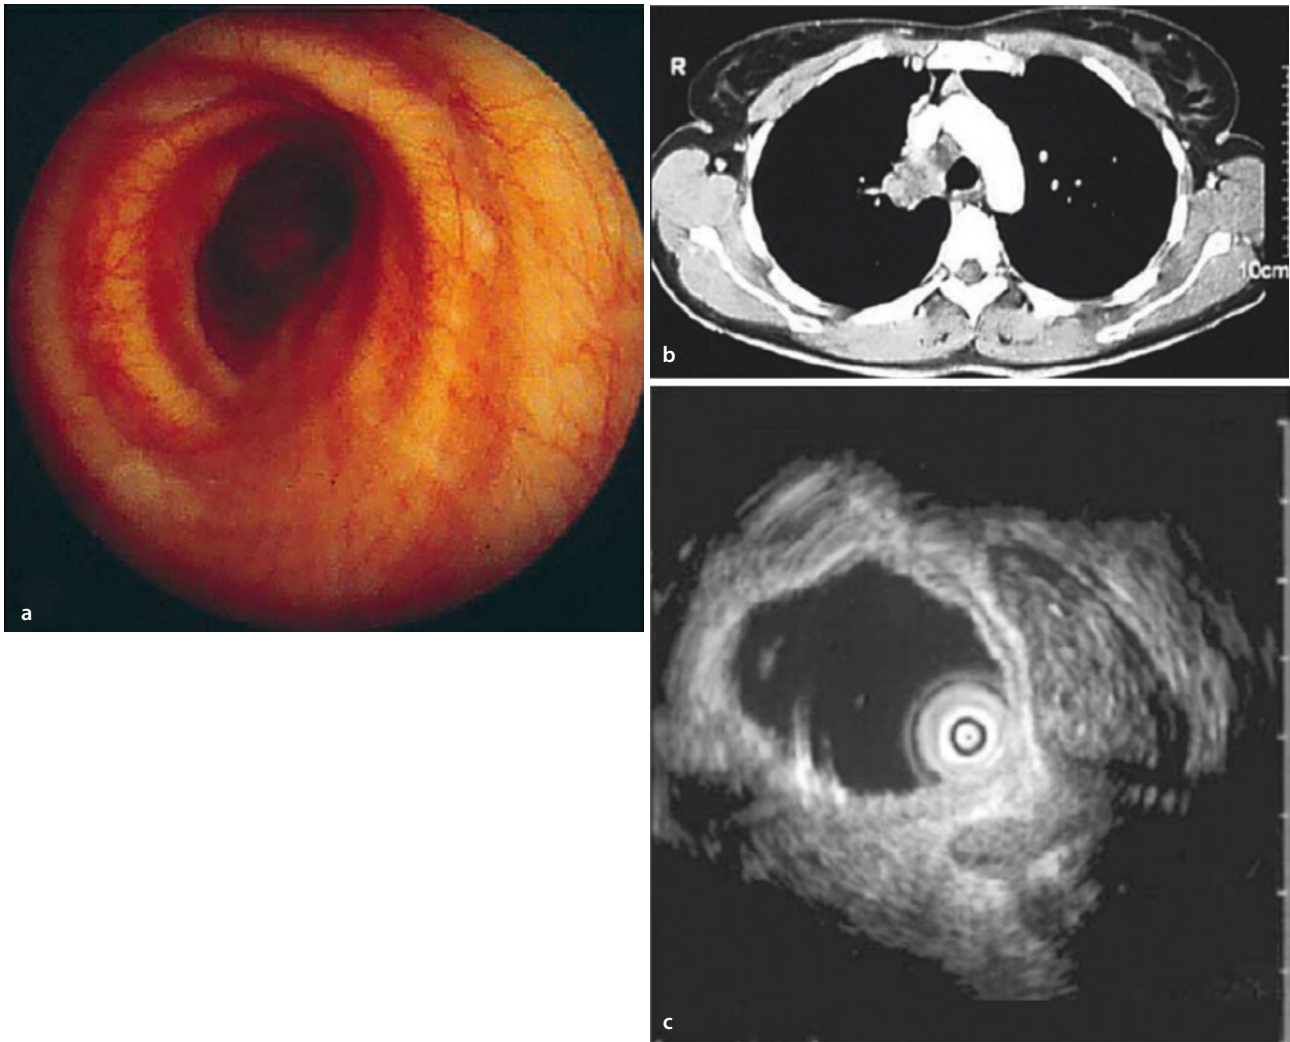

Fig. 7.5 a–c Compression of the trachea by a tumor. **a** Bronchoscopy reveals an impression of the trachea. **b** The corresponding CT image shows a mass in the upper lobe. **c** Ultrasound reveals a well-defined tumor; an infiltration is unlikely

7.3.5 Endobronchial Sonography in Therapeutic Interventions

Especially for making decisions in potentially curative endobronchial therapy of malignancies such as photodynamic therapy or endoluminal high-dose radiation by brachytherapy, diagnosis of limitation of the lesion to the bronchial wall or to the close vicinity is essential. Here endobronchial sonography is superior to all other imaging procedures owing to the detailed analysis of the layers of the bronchial wall.

In decision-making for endobronchial therapy of advanced lung cancer, endobronchial sonography provides important data (Herth et al. 2003). In complete bronchial obstruction, the base and the surface of the

tumor can be assessed as can whether the different layers of the bronchial wall are involved, how far the tumor is penetrating into the mediastinal structures and whether the airways beyond the stenosis are patent. Also patency of the adjacent pulmonary artery can be diagnosed, which is important to predict postinterventional perfusion of the dependent lung and prevent increase of dead-space ventilation (Fig. 7.6). Endobronchial sonography is also useful for exploration of benign central airway stenosis to assess the extent and the cause of the disease, the relationship to vessels and other surrounding structures and to make the correct decision for therapy, such as mechanical dilatation, laser ablation or stent implantation and endoscopic control of the results

Fig. 7.7 **a–c** Tumor in the trachea, after partial laser resection an infiltration in the esophageal wall is detected by EBUS and a stent was placed before the additional treatment

7.4 Indications and Results for the Endobronchial Ultrasound Guided Transbronchial Needle Aspiration (EBUS-TBNA)

The lymph node staging is also the main indication for the new endobronchial sonography TBNA scope.

The sonography bronchoscope is introduced via an endotracheal tube under visual control or under local

anesthesia to the area of interest. Endobronchial ultrasound TBNA is performed by direct transducer contact with the wall of the trachea or bronchus. When a lesion is outlined, a 19, 21, or 2522-gauge full-length steel needle is introduced via the biopsy channel of the endoscope. Power-Doppler examination is used immediately before the biopsy in order to avoid unintended puncture of vessels between the wall of the bronchi and the lesion. Under real-time sonographic guidance the needle is placed in the lesion **Fig. 7.8**. Suction was applied with

Fig. 7.8 Ultrasound-controlled lymph node puncture. The needle is clearly delineated in the lymph node

a syringe and the needle was moved back and forth inside the lesion.

To date, several papers have been published on this procedure (Bonta et al. 2016).

The largest trial (Herth et al. 2006b) reports the results of the technique in 502 patients. A total of 572 lymph nodes were punctured, and 535 (94%) resulted in a diagnosis. Biopsies were taken from all reachable lymph node stations (2l, 2r, 3, 4r, 4l, 7, 10r, 10l, 11r and 11l). The mean diameter of the nodes was 1.6 cm (0.36 cm) and the range was 0.8–3.2 cm. The sensitivity was 92%, the specificity was 100% and the positive predictive value was 93%. Like in all other trials no complications occurred.

Herth et al. (2006c) also examined the accuracy of endobronchial sonography TBNA in sampling nodes less than 1 cm in diameter. Among 100 patients, 119 lymph nodes with a size between 4 and 10 mm were detected and sampled. Malignancy was detected in 19 patients but missed in two others; all diagnoses were confirmed by surgical findings. The mean diameter of the punctured lymph nodes was 8.1 mm. The sensitivity of endobronchial sonography TBNA for detecting malignancy was 92.3%, the specificity was 100% and the negative predictive value was 96.3%. Again no complications occurred. They summarized that endobronchial sonography TBNA can sample even small mediastinal nodes, therefore avoiding unnecessary surgical exploration in one fifth of patients who have no computed tomography evidence of mediastinal disease. Potentially operable patients with clinically non-metastatic non-small-cell lung cancer may benefit from presurgical endobronchial sonography TBNA biopsies and staging (Herth et al. 2008, 2010; Ernst et al. 2010).

7.5 Endoesophageal Ultrasound with the EBUS Scope (EUS-B)

The endoscopic techniques introduced to pulmonary diagnostics are: endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) and endoscopic ultrasound-guided fine needle aspiration (EUS-FNA). Nowadays more and more often in use is the ultrasound bronchoscope (EUS-B in the esophagus). The use of endoscopic ultrasound with bronchoscope-guided fine-needle aspiration (EUS-B-FNA) has been described in the evaluation of mediastinal lymphadenopathy.

The optimal approach (transbronchial or transesophageal) and the selection of mediastinal lymph node stations considered for biopsy still need evaluation. In a recent published metaanalysis 10 studies (1080 subjects with mediastinal lymphadenopathy) were summarized. The sensitivity of the combined procedure was significantly higher than EBUS-TBNA alone (91% vs 80%, $P = .004$), in staging of lung cancer (4 studies, 465 subjects). The additional diagnostic gain of EUS-B-FNA over EBUS-TBNA was 7.6% in the diagnosis of mediastinal adenopathy (Dhooira et al. 2015). No serious complication of EUS-B-FNA procedure was reported. Therefore, combining EBUS-TBNA and EUS-B-FNA is an effective and safe method, superior to EBUS-TBNA alone, in the diagnosis of mediastinal lymphadenopathy.

Summary

Endobronchial sonography has been widely available for more than 8 years. A growing body of good-quality literature supports its significant role in airway assessment and procedure guidance. Its usefulness is especially well documented in lymph node staging via guided TBNA and in lending support for therapeutic decision-making with regard to endoluminal or alternative treatment strategies for malignant airway abnormalities.

Endobronchial sonography is a routine adjunct to endoscopy in many centers, and we expect its role to grow in the near future.

In addition to the sonographic characteristics of the B-mode ultrasound (B-mode US), the type of vascularization is of major importance for assessment of a lesion in terms of differential diagnosis. In sonographic examinations, the established procedures of color-Doppler sonography (CDS) and contrast enhanced ultrasound (CEUS) are used for this purpose. Guidelines for the use of CEUS are discussed on a regular basis and published in special consensus meetings (2004, 2008, 2011, 2018). However, the authors recommend the use of CEUS on the thorax depending on indications, generally with a low level of evidence (Sidhu et al. 2018; Jacobsen et al. 2020).

In recent years, CDS characteristics of bacterial pneumonia, obstructive atelectasis, lung infiltrates and bronchial carcinoma have been described (overview: Görg and Bert 2004a, b). An increasing number of studies have indicated that CEUS can be performed on the thorax and that various lung diseases are characterized by distinctive CEUS findings (overview: Görg et al. 2006a; Görg 2007; Siduh et al. 2018).

The aim of this review is to describe CDS and CEUS findings for peripheral lung consolidation.

8.1 Pathophysiological Basics

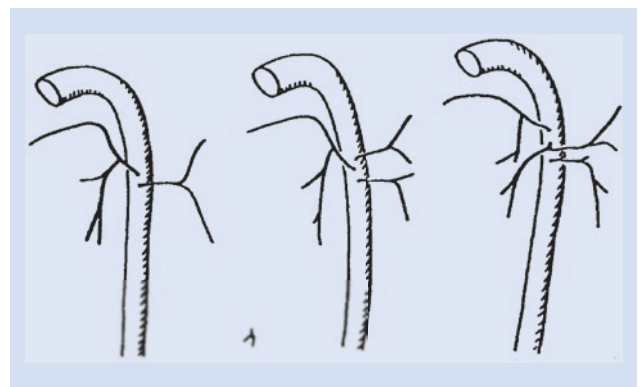

The lung is characterized by dual vascularization. Vascularization is achieved on the one hand by lung circulation, which is responsible for pulmonary gas exchange. Lung circulation is accomplished by the pulmonary arteries and their ramifications as well as venules and lung veins. The lung itself is nourished by the bronchial arteries.

In contrast to systemic circulation, circulation by the pulmonary arteries is marked by specific characteristics. Pulmonary arteries and their initial branches are elastic. The subsequent arteries have muscular walls. From the level of the arterioles onward, these arteries turn into partly muscular and nonmuscular precapillaries. In contrast to systemic circulation in which arterioles are the main vessels of resistance, in lung circulation the resistance is more or less equally distributed between arteries, capillaries and veins. Thus, flow in the pulmonary arteries and capillaries is pulsatile and not continuous. In contrast to hypoxic vasodilatation in systemic circulation, hypoxic vasoconstriction occurs in lung circulation. The purpose of such vasoconstriction is to reduce the intrapulmonary shunt volume (Euler–Liljestrand mechanism) (Quaranto et al. 2020). When lung tissue is

affected by a malignant tumor, the carcinoma has been reported to invade the pulmonary arteries of the affected lung segment in 56–87% of cases (Kolin and Koutllakis 1988; Fissler-Eickhoff and Müller 1994). Particularly in the center of the tumor the regular vascular pattern is completely altered. Vascularization is reduced by stenosis and occlusion of the pulmonary arteries.

As a rule, the bronchial arteries originate on the left side from the aortic arch and on the right side from the intercostal artery. They form a vascular ring at the hilum of the lung. From this vascular ring the arterial branches run parallel to the respiratory bronchial branches and the pulmonary vessels (■ Fig. 8.1). The arterial bronchial branches (rami bronchiales) supply the bronchi, pulmonary vessels, alveoles and supporting tissue. Interstitial arterial branches run into the interlobar and interlobular septa and supply the visceral pleura. Anastomoses (blocked arteries) between the two systems are normally closed. In cases of occluded pulmonary vessels, the anastomoses become open owing to hypoxia and blood supply is provided by bronchial arteries. Angiographic studies have shown that particularly peripheral lung processes at the pleural wall, such as benign cavitary lesions, lung cysts, lung abscesses and liquefying pneumonia, are nourished by bronchial arteries (Görg and Bert 2004a). However, malignant primary lung tumors and lung metastases are vascularized by bronchial arteries to a differing extent (Müller and Meyer-Schwickerath 1978; ■ Fig. 8.2).

The intercostal arteries originate from the thoracic aorta and run a strictly intercostal course in the chest wall along the ribs. They are the only vessels that can be visualized on sonography, even in healthy volunteers.

■ Fig. 8.1 Schematic illustration of the anatomy of the bronchial arteries. (Uflacker L et al. 1985, *Radiologie* 157: 637–644)

Fig. 8.2 Schematic illustration of the pathophysiology of the supply of the bronchial arteries. **1** bronchobronchial anastomoses, **2** bronchopulmonary anastomoses, **3** intercostopulmonary anastomoses, **4** intercostobronchial anastomoses (Babo et al. 1979)

Particularly in cases of lesions in the chest wall these vessels play an important role in tumor vascularization.

Tumor neoangiogenesis of primary bronchial carcinomas mainly originates in the bronchial arteries. The neoangiogenesis potential of pulmonary vessels appears to be low (Müller and Meyer-Schwickerath 1978; Hsu et al. 1996).

8.2 Principles of Color-Doppler Sonography (CDS)

The hemodynamic parameters used in transcutaneous CDS at the chest to evaluate vessels can be divided into qualitative and semiquantitative parameters (Overview).

Sonographic Analysis of Thoracic Perfusion

1. Qualitative findings of parenchymal perfusion
 - Absence of flow signals
 - Sporadic flow signals
 - Pronounced flow signals
 - Arterial turbulence phenomena

2. Spectral curve analysis: with patterns of different arterial flow signals
 - Pulmonary artery (PA)
 - Bronchial artery (BA)
 - Intercostal artery (ICA)
 - Tumor neoangiogenesis (TN)
3. Contrast-enhanced ultrasound with different criteria of assessment
 - a. Time to enhancement (TE)
 - b. Extent of enhancement (EE)
 - c. Homogeneity of enhancement (HE)
 - d. Decrease of enhancement (DE)

Qualitative findings include assessment of the presence, the direction and the characteristics of blood flow. In this regard a distinction is made between the absence of flow signals (FS; Fig. 8.3), evidence of individual flow signals (Fig. 8.4), evidence of markedly disorganized vascularization (Fig. 8.5) or pronounced regular tree-shaped vascularization (Fig. 8.6) and evidence of arterial turbulence phenomena in consolidated areas (Fig. 8.7). Semiquantitative parameters such as the resistance index and the pulsatility index are used for spectral curve analysis of arterial blood flow. Spectral curves of pulmonary arteries, bronchial arteries, intercostal arteries and arteries of tumor angiogenesis can be differentiated within pathological processes, and can be used to differentiate ambiguous peripheral lung lesions. In principle, evidence and documentation of flow signals at the chest is device-dependent and is additionally influenced and limited by the location and the size of the lesion, its cause, and breath-dependent or pulsation-dependent movements. For instance, 20% of peripheral lung lesions emit no flow signals (Yuan et al. 1994). Local fluid, lung cysts and lung infarctions show no flow signals on CDS. The color-Doppler sonography pattern of poorly visualized vessels is primarily seen in malignant pleural lesions. Markedly ramified vessels are characteristic for pneumonia and atelectasis (Yuan et al. 1994; Civardi et al. 1993). Turbulence phenomena within a lesion have been reported in pleural arteriovenous fistulae and vascular abnormalities in connection with Osler's disease (Fig. 8.7).

Quantitative parameters such as the resistance index and the pulsatility index are used to analyze arterial spectral curves. Civardi et al. (1993) were the first to perform quantitative and qualitative spectral curve

Fig. 8.7 a, b A 14-year-old male patient with Osler–Weber–Rendu syndrome. **a** The B-mode ultrasound shows an anechoic space occupying lesion close to the pleura. **b** CDS reveals a large vessel that supplies the ectatic vessels close to the pleura. On spectral curve analysis this vessel was identified as a pulmonary artery

analyses for peripheral lung lesions. They found a triphasic flow signal more commonly in benign lesions and a monophasic flow signal in malignant lesions. Yuan et al. (1994) registered a sensitivity and specificity of more than 95% for differentiation of benign lesions from malignant ones by the use of arterial spectral curve analysis. The authors interpreted the monophasic low-impedance flow primarily seen in tumors as flow signals of tumor neoangiogenesis, while they correlated the high-impedance flow of pneumonias and atelectases with vessels of the pulmonary arteries (Yuan et al. 1994). In a subsequent study the authors

registered different resistance indices for atelectasis and pneumonia, indicative of differing vasoconstriction due to hypoxia (Yuan et al. 2000). In a controlled histological study, Hsu et al. (1996) were the first to show that the vessels from which low-impedance monophasic flow signals originated were not tumor vessels but were bronchial arteries. “True” tumor vessels are characterized by nearly constant flow without variations between the systolic and the diastolic phase (Hsu et al. 1996). Owing to the technical limitations of commercially available ultrasound devices for slow blood flow (less than 2 cm/s), tumor vessels are usually not seen

Fig. 8.8 a–d A 65-year-old man with a centrally located bronchial carcinoid tumor and obstructive atelectasis. **a** The B-mode ultrasound shows a triangular hypoechoic consolidation with a fluid bronchogram (arrows). AT atelectasis. **b** CDS reveals different vessels in the central region of the atelectasis (1 bronchial artery, 2 pulmonary artery, 3 pulmonary vein). **c** Spectral curve analysis shows a high-impedance triphasic flow signal as a sign of a pulmonary artery (designated 2 in b). **d** Spectral curve analysis reveals a low-impedance arterial flow signal oriented towards the periphery, indicative of a bronchial artery (designated 1 in b)

on sonography (Harvey and Albrecht 2001). In a subsequent study, Hsu et al. (1998) registered a much lower sensitivity and specificity of 53 and 72% for differentiation of benign lesions from malignant ones by the use of arterial spectral curve analysis. A common feature of all of these studies is that the authors only used one arterial spectral curve pattern to analyze a lesion. By sonographic “mapping,” the authors of a more recent study were able to demonstrate several different flow signals within a lesion in nearly half of the patients with pleural lesions examined (Görg et al. 2003; Fig. 8.8). This may be interpreted as an indication of the fact that arterial blood supply to peripheral lung lesions is a complex phenomenon. In a subsequent study, chest wall lesions were examined with the aid of arterial spectral curve analysis and were found to be vascularized by intercostal arteries among other sources (Görg et al. 2005a). However, intercostal arteries have a monophasic high-impedance flow signal.

Thus, the following flow signals may be distinguished with the aid of arterial spectral curve analysis (Fig. 8.9):

- **Pulmonary arteries** may be present in various locations, run a centrifugal course from the hilum to the surface of the lung and have a high-impedance, usually triphasic flow signal.
- **Bronchial arteries** are present in various locations, vary in terms of their direction of flow and have a low-impedance monophasic flow signal.
- **Intercostal arteries** are characterized by their strictly intercostal location, run a nearly horizontal course and have a high-impedance, usually monophasic flow signal.
- Arterial vessels of **tumor neoangiogenesis** are present in various locations, vary in terms of their direction of flow and are marked by a nearly constant flow with no variation between the systolic and the diastolic phase (Fig. 8.10).

Fig. 8.9 a–d A 31-year-old man with a malignant lymphoma affecting the lung. **a** CDS shows a biphasic high-impedance flow pattern in the central region of the consolidated lung—a sign of a pulmonary artery (arrow). **b** In the periphery of the tumor there is a monophasic high-impedance arterial flow pattern, typical of an intercostal artery (arrow). **c** In the central region of the consolidated lung there is a monophasic low-impedance arterial flow signal—a sign of a bronchial artery (arrow). **d** Within the tumor one finds a nearly uniform flow signal without fluctuations in the diastolic and the systolic phase. Here one is inclined to suspect a vessel of tumor neoangiogenesis (arrow)

8.3 Contrast Enhanced Ultrasound (CEUS)

In the last few years contrast-enhanced ultrasound (CEUS) has become a widely used procedure to investigate the liver, particularly to describe focal liver lesions. The second generation of contrast media now available for clinical use cause microscopic bubbles in the vessel lumen which lead to enhanced reflection of the ultrasound wave, thus increasing the signal amplitude and eventually yielding better contrast of vessels than that achieved with CDS. The use of CEUS allows infinitesimally small vessels whose width is just a little larger than that of capillaries to be visualized. In the experimental setting, vessels with a diameter of 74–134 μm were demonstrated by contrast-enhanced ultrasound. Vessels smaller than 38 μm in diameter have not been visualized thus far even with the use of contrast medium. The echogenicity of the contrast medium is caused by interface reflection off the gas bubbles and by backscattering, whereby the signal strength is amplified by 10^3 (Delorme et al. 2006).

In principle, CEUS should be applied according to the guidelines of the EFSUMB (Albrecht et al. 2004).

With regard to the application of CEUS in the lung it should be noted that, as with all transcutaneous sonographic modalities, investigation of the healthy lung is not possible. However, like the liver, the lung is marked by dual arterial supply and is therefore predestined for the use of CEUS. Consolidated lung tissue can be examined with CEUS. Pathological lung lesions are first characterized by arrival of contrast enhancement (time to enhancement = EE). In cases of perfusion by the pulmonary arteries

alone, this time point is marked by early arterial contrast enhancement about 1–6 s after application of contrast medium. The contrast medium can be demonstrated by sonography in the right side of the heart just a few seconds later. The time until contrast-medium flooding depends on the type of access (peripheral-, central vein) and on hemodynamic parameters (heart failure, COPD). The arrival of a contrast agent to a lesion before the thoracic wall or a parenchymatous organ indicates pulmonary arterial perfusion. In cases of perfusion of a lesion by the bronchial arteries alone, contrast enhancement may be expected only after the contrast medium has passed through the lung. Thus, contrast enhancement of the left ventricle is seen at the earliest 7–10 s after application of contrast medium in the peripheral vein (Fig. 8.11). This is always performed simultaneously with the enhancement of the thoracic wall or parenchymatous organs as an indication of systemic arterial perfusion. The extent of contrast enhancement (EE) is basically dependent on the presence or absence of perfusion, the type of perfusion—whether through the pulmonary arteries or through the bronchial arteries—and also by the presence of collaterals or extent of vessels of tumor neoangiogenesis. Depending on the phase, a distinction may be made between the arterial phase (1–30 s) and the parenchymatous phase (1–5 min). The extent of contrast enhancement has been quantified so far only in comparison with an intra-individual reference; a distinction is made between reduced and increased contrast enhancement. A parenchymatous organ such as the spleen is a suitable *in vivo* reference. The healthy spleen is known to be characterized by organ-specific contrast tropism and homogenous contrast enhancement. As a third evaluation criterion, a differentiation can be made between homogeneous and inhomogeneous contrast enhancement (HE). Focal parenchymal lesions in consolidated lung tissue are characterized in terms of number, shape (round, wedge-shaped) and location (central, peripheral). A last criterion is the decrease of enhancement (DE) in the parenchymal phase (wash out), which can be classified into a rapid wash out (<120 s) and a late wash out (>120 s) (Caremani et al. 2008). Benign consolidations like pneumonia and atelectasis prefer a late wash out, whereas malignant lesions predominantly have a rapid wash out. Thus, with the use of CEUS the following perfusion patterns can be distinguished:

- **Time to contrast enhancement** which allows the differentiation of early pulmonary arterial vascularization (Fig. 8.12) from delayed bronchial arterial vascularization (Fig. 8.13)
- **Extent of contrast enhancement** compared with spleen enhancement (Fig. 8.14)
- **Homogeneity of contrast enhancement** with detection of focal lesions in consolidated lung tissue (Fig. 8.15).
- **Decrease of enhancement in the parenchymal phase (wash out)** (Figs. 8.31d and 8.41f).

Fig. 8.11 a-f Visualization of the time until contrast enhancement: four-chamber view in a healthy proband. After injection of contrast medium one sees contrast enhancement in the right ventricle as early as 1 s later **a-d**. After 8 s there is contrast enhancement in the left ventricle **e, f**

ment, most likely corresponding to lung metastases (arrow). **d** Echogenic space requirement after aspiration, with a central inhomogeneous area of absence of contrast enhancement, as in necrosis (arrow). **e** Peripheral lung tumor with only marginal contrast enhancement and larger necrosis (arrow). **f** Inhomogeneous contrast enhancement with histologically confirmed peripheral pulmonary embolism.

8.4 Predominantly Anechoic Peripheral Lung Consolidation

8.4.1 Color-Doppler Sonography (CDS)

These lesions are rare and constitute an important differential diagnosis for localized effusion. Primary lung cysts at the pleural wall are seen on B-mode ultrasound as anechoic, usually polycystic tumors. CDS shows qualitative flow signals in the septa and the region of the visceral pleura. On semiquantitative spectral analysis they show a monophasic pattern and thus correspond to bronchial and intercostal arteries (Fig. 8.16). Vascular tumors at the pleural wall, such as those asso-

ciated with Osler's disease, have a characteristic appearance on CDS. The supplying pulmonary artery can be visualized (Fig. 8.7). The malignant cystic lung tumor shows centrally liquefied areas usually on a floor of liquefactions and is seen on the sonographic B-mode ultrasound as a semiliquid structure with septa in some cases. The tumor receives its blood supply from bronchial arteries, and more rarely from pulmonary arteries. Therefore, the spectral curve reveals a monophasic high-impedance arterial flow in keeping with bronchial arteries and occasionally a biphasic high-impedance arterial flow that corresponds to pulmonary arteries (Fig. 8.17). The aortic aneurysm at the dorsal wall of the pleura is a notable pitfall (Fig. 8.18); the same

Fig. 8.16 a–c A 70-year-old man with a primary lung cyst. a On the B-mode ultrasound one finds an anechoic lesion close to the pleura. C ribs, LC lung cyst. b CDS in the power mode shows a

strong vessel surrounding the lesion (arrows). c Spectral curve analysis demonstrates a monophasic high-impedance flow signal indicative of an intercostal artery

Fig. 8.17 a–c A 44-year-old man with sarcoma of the lung. a CDS shows a tumor with solid and cystic portions and vessels in the seventh course. b Spectral curve analysis reveals an arterial high-

resistance flow signal. This is indicative of a pulmonary artery. c Visualization of a low-impedance flow signal in the margin of the lesion, indicative of a bronchial carcinoma

is true for the right lateral part of the heart at the chest wall in cases of cardiomegaly (Fig. 8.19).

8.4.2 Contrast Enhanced Ultrasound (CEUS)

Specific studies focusing on CEUS for the assessment of anechoic lung consolidations have not yet been pub-

lished. Lung abscesses, pleural effusions, pleural empyema and liquefied lung tissue, however, are marked by the absence of contrast enhancement. Primary or secondary lung cysts are rare (Fig. 8.20).

Fig. 8.20 **a** Patient with pleural effusion and sharply demarcated cystic mass at the visceral pleura as a random finding. On CEUS, the lesion shows no enhancement, as in a primary pulmonary cyst. **b** Patient from Iraq with confirmed pulmonary echinococcosis and multiple lung consolidations in a computed tomography image, pre-

dominantly located at the pleura. The dorsal lesion on B-mode ultrasound is predominantly anechoic, with an indicated cyst within the cyst. On CEUS, the polycystic lesion shows no enhancement, as in a secondary pulmonary cyst in terms of echinococcosis

8.5 Predominantly Echogenic Lung Consolidation

8.5.1 Lung Infarction

8.5.1.1 Color-Doppler Sonography (CDS)

The lung infarction could be a correlate of pulmonary embolism. In the case of peripheral obstruction of branches of the pulmonary arteries and insufficient nourishment from the bronchial arteries the patient

may develop intra-alveolar hemorrhage which is visualized morphologically on the B-mode ultrasound as displaced air (Mathis and Dirschmid 1993). On qualitative CDS the lesion characteristically shows the absence of flow signals (Fig. 8.3). On semiquantitative spectral analysis one occasionally finds a monophasic pattern close to the pleura; this pattern can be attributed to bronchial arteries. In some cases, the disconnected supplying branch of the pulmonary artery is visualized (Fig. 8.21)

■ **Fig. 8.21** Patient with computed-tomography-confirmed pulmonary embolism. **a** B-mode ultrasound shows a wedge-shaped lesion. **b** On CDS, the feeding pulmonary arterial vessel breaks off

■ **Fig. 8.22** **a** Patient with pulmonary embolism confirmed by computed tomography. **b** On B-mode ultrasound, a smooth, wedge-shaped, homogeneously hypoechoic lung consolidation is recogniz-

able. **c** On contrast-enhanced ultrasound, an absence of contrast enhancement in the lesion can be observed

8.5.1.2 Contrast Enhanced Ultrasound (CEUS)

In keeping with findings on CDS, lung infarctions/lung hemorrhages are marked by the absence of contrast enhancement on CEUS (■ Fig. 8.22). Occasionally one finds delayed and reduced contrast enhancement in the border area, which is indicative of vascular nourishment being provided by bronchial arteries (■ Fig. 8.23). In a

recently published study in patients with CT-confirmed pulmonary artery embolism and sonographically detected pleural defects, in 80% of the cases an absence or inhomogeneous contrast enhancement with areas of non-enhancement could be detected, which is consistent of pulmonary infarction and indicative for pulmonary arterial embolism. However, in 20% of the cases

Fig. 8.23 **a** Patient with computed-tomography-confirmed central pulmonary embolism and peripheral consolidation. **b** On B-mode ultrasound, a peripheral hypoechoic consolidation is visual-

ized. **c** On contrast-enhanced ultrasound, an inhomogeneous enhancement with areas of non-enhancement is revealed after 25 s

8

a homogeneous pulmonary arterial vascularization was found (Bartelt et al. 2016), which may be an indication for repair processes by fibrinolysis. There are no follow up CEUS studies to describe different healing phases in peripheral pulmonary embolism. On CEUS examination of the infarct area, a detailed analysis of the early arterial phase must be performed, because a primary absence of pulmonary arterial vascularization can be overlaid by a secondary bronchial arterial vascularization, and therefore, after a few seconds, a homogeneous enhancement through systemic flooding could be present (Fig. 8.24). In addition, CEUS patterns typical of peripheral infarctions could be detected in individual cases of clinical suspicion of pulmonary artery embolism (high well score) and negative CT findings regarding pulmonary artery embolism (Trenker et al. 2017). In a follow-up study, the peripheral consolidations were histologically confirmed as infarcts (Fig. 8.25) (Trenker et al. 2019). The clinical relevance of these "CT negative" peripheral subsegmental pulmonary artery embolisms is unclear (Raslan et al. 2018; Goy et al. 2015). It is important to note that CEUS can reliably differentiate between vascularized and non-vascular-

ized peripheral lung tissue and therefore has a differential diagnostic potential for distinguishing infectious pleuritis, infarction-caused pneumonia or infarction-caused pleural effusion with atelectasis (Fig. 8.15b) (Görg et al. 2006a). Initial studies have indicated that COVID-19 infections with evidence of pleural defects and lung consolidation are characterized by an inhomogeneous contrast enhancement with non-perfused areas as an indication of peripheral perfusion disturbances in terms of infarcts (Fig. 8.26)

8.5.2 Pleurisy

8.5.2.1 Color-Doppler Sonography (CDS)

The appearance of pleurisy on the B-mode ultrasound is similar to that of a lung infarction (Gehmacher et al. 1997). Depending on the size of the lesion an upgrading, into pleural pneumonia is possible. The qualitative CDS characteristically shows pronounced vessels with predominant evidence of an arterial high-impedance flow profile on spectral analysis such as that seen in branches of the pulmonary artery (Fig. 8.27).

Fig. 8.24 **a** Patient with computed-tomography-confirmed central pulmonary embolism and peripheral consolidation. **b** On B-mode ultrasound, a moderate pleural effusion with partial lower lobe atelectasis is recognizable. **c** On CEUS, an inhomogeneous pul-

monary arterial enhancement is observed in the early arterial phase after 2 s. **d** On CEUS, a bronchial arterial reperfusion of the area with primarily an absence of contrast enhancement is observed after 12 s

8.5.2.2 Contrast Enhanced Ultrasound (CEUS)

In keeping with the CDS findings, it takes very little time for contrast enhancement to start in pleurisy, and it is marked by strong contrast enhancement on CEUS (Fig. 8.28a), while chronic scarred pleural thickening is characterized by reduced systemic contrast-medium enhancement (Fig. 8.28b). In tuberculous pleuritis, an inhomogeneous enhancement of contrast medium

with non-perfused areas can be seen in the region of the pleural thickening (Fig. 8.29). The value of CEUS lies in the differential diagnostic discrimination of non-vascularized or in homogeneously vascularized peripheral lung lesions, such as pulmonary infarction, malignant lesions or scar tissue, in patient with the leading clinical symptom of breath-dependent pain (Görg et al. 2005b).

Fig. 8.25 a Patient with clinical suspicion of pulmonary embolism, with no evidence of central pulmonary embolism on computed tomography and evidence of peripheral consolidation on B-mode ultrasound (US). b On B-mode ultrasound, a wedge-shaped pleural

defect is detected. c On contrast-enhanced ultrasound, the lesion shows no enhancement. d US-guided biopsy confirms the diagnosis of a peripheral pulmonary infarction

8.5.3 The Peripheral Round Lesion/Lung tumor

8.5.3.1 Color-Doppler Sonography (CDS)

A peripheral round pleural based consolidation of the lung may be a benign or malignant lesion. Of decisive importance is the fact that, independent of the cause, the evidence of flow signals is dependent on the size of the lesion. On careful investigation one frequently

finds both arterial high impedance flow signals from pulmonary arteries and low-impedance flow signals from bronchial arteries in benign as well as malignant peripheral lung lesions (■ Figs. 8.30 and 8.31). In the published literature, less visualization of vessels on qualitative CDS and evidence of arterial monophasic flow signals with low resistance indices are reported to be characteristic features of malignant peripheral lung tumors or metastases (Yuan et al. 1994; Hsu et al. 1996,

Fig. 8.26 a Patient with COVID-19 infection and computed tomography (CT) evidence of lung consolidation in the lower segments. On B-mode ultrasound, a lung consolidation on the left side is visualized. On CEUS, an inhomogeneous contrast enhancement in the consolidated tis-

sue indicates small infarction areas. b Patient with COVID-19 infection and CT evidence of lung consolidation in the lower segments. On B-mode US, a right-sided lung consolidation can be seen. On CEUS, the lesion shows an absence of enhancement, as in pulmonary infarctions

Fig. 8.27 a–c 55-year-old woman with respiration-related pain; suspected pleurisy. **a** B-mode ultrasound shows a small wedge-shaped pleural defect. **b** CDS shows vessels within the defect.

c CEUS shows contrast enhancement of the lesion such as that seen in the presence of pleurisy

8

Fig. 8.28 a Patient with breath-dependent pain suspected of having pleurisy. B-mode ultrasound (US) shows a long, irregular entry echo in the area of the right lower lobe of the lung. On CEUS, a clear pulmonary arterial contrast enhancement of the lesion is revealed after 4 s. In the late parenchymal phase, the lesion shows a homogeneous contrast enhancement. **b** Patient with pleural thickening

visualized by computed tomography (CT). The B-mode US shows a long pleural thickening in the area of the right dorsal lung. On CEUS, there is a near-absence of contrast enhancement of the lesion after 34 s, as in chronic fibrosing pleurisy (histologically confirmed)

1998; Civardi et al. 1993). In some cases, the vessels seen on sonography may be identified as those resulting from tumor neoangiogenesis (originating from bronchial arteries) on pathological investigation (Hsu et al. 1998; **Fig. 8.9d**). However, studies that have used a single impedance measurement to assess the benign or malignant nature of a lesion must be viewed with caution. In principle CDS is not suitable for distinguishing between benign and malignant peripheral round lesions.

Contrast Enhanced Ultrasound (CEUS)

In keeping with the variable findings on CDS, CEUS also shows a heterogeneous pattern of perfusion. Malignant lesions—whether lung metastases or peripheral bronchial carcinomas—are marked by delayed arrival of contrast enhancement and reduced extent of contrast enhancement in both phases. This is indicative of predominant vascularization through bronchial arteries (**Table 8.1; Fig. 8.32**). In a study that investigated the perfusion

Fig. 8.29 a Patient with a medical history of tuberculosis and radiographic shadowing of the right diaphragmatic rib angle. b A pleural thickening can be detected by computed tomography. c On B-mode ultrasound, a long pleural thickening can be seen. d The CEUS discriminates against the pleural thickening: after 14 s, the

visceral pleura shows a homogeneous strong pulmonary arterial enhancement, while the parietal pleural thickening does not yet show an enhancement. e After 20 s, the bronchially supplied parietal pleura shows an inhomogeneous enhancement with small non-enhanced nodules. The biopsy confirmed active tuberculosis

Fig. 8.30 a–c A 56-year-old man with a plasmocytoma and histologically confirmed amyloidosis in the lung. **a** On CDS one finds several vessels. **1** pulmonary artery, **2** pulmonary vein, **3** bronchial artery. **b** Spectral curve analysis shows a high-impedance flow signal

indicating a pulmonary artery (marked **1** in **a**). **c** Spectral curve analysis shows a low-impedance monophasic flow pattern oriented towards the hilum of the lung, as a sign of a bronchial artery close to the pleura (marked **3** in **a**)

8

Fig. 8.31 a–d A 30-year-old woman with sudden onset of dyspnea and fever. **a** B-mode ultrasound shows a peripheral hypoechoic round lesion of the lung. **b** On CDS one finds evident flow signals in the lesion. **c** Spectral curve analysis of a central vessel shows a low-impedance flow signal such as that seen in a bronchial artery. **d** Spectral curve analysis of a vessel from the margin shows a high-impedance flow signal such as that seen in pulmonary arteries. Under antibiotic therapy the lesion resolved completely

pattern of histologically confirmed peripheral bronchial carcinomas, 72% of the lesions showed a bronchial arterial enhancement (Fig. 8.13a–d) and 28% showed a pulmonary arterial enhancement. Tumor necrosis was proved in 47% of the lesions (Fig. 8.15e) (Findeisen et al. 2018). For this reason, a CEUS-guided tumor biopsy from perfused areas should be preferred to avoid a missed biopsy (Dong et al. 2005; Sartori et al. 2004; Wang et al. 2015). Depending on the underlying histol-

ogy, however, lung metastases of renal cell carcinomas and frequently also metastases of malignant lymphoma show pronounced contrast enhancement in the arterial phase (Fig. 8.33). The extent and homogeneity of tumor neoangiogenesis depends, inter alia, on the tumor size and underlying disease (Fig. 8.34). In a few cases, the CEUS is useful in the evaluation of the nature of the lesions. For example, hematomas (Fig. 8.35a) and lipomas (Fig. 8.35b) are characterized by an absent

Table 8.1 Time to enhancement (short vs. delayed) and extent of enhancement (reduced vs. marked) in 137 patients with pleural based pulmonary lesions subdivided into patients with pneumonia, compression atelectasis, pulmonary embolism, benign pleural based lesions, central lung cancer and peripheral malignant lesions (Görg et al. 2006b)

Fig. 8.32 Patient with pancreatic carcinoma and histologically confirmed lung metastases. **a** On computed tomography, a round lesion is visualized with central melting. **b** On B-mode ultrasound, an inhomogeneous, hypoechoic pleural-edge lung lesion with central

air reflex is presented. **c** On contrast-enhanced ultrasound, a reduced bronchial arterial contrast enhancement in the lesion can be seen after 10 s. **d** in the parenchymal phase after 1 min, a late decrease of enhancement (wash out) can be detected in the lesion

Fig. 8.33 Patient with diagnosed sarcoma and histologically confirmed multiple pulmonary metastases. **a** On computed tomography, there is a pleural round nodule. **b** On B-mode ultrasound, an oval, pleural-edge, homogeneously anechoic lesion is recognizable. **c** On contrast-enhanced ultrasound, after 15 s, a marked contrast

enhancement from the periphery can be seen as an indication of peripheral bronchial arterial perfusion. **d** After 25 s, a highly homogeneous contrast enhancement is observed in the lesion. This is an indication of a strong tumor neoangiogenesis

Fig. 8.34 Graphic representation, CDS findings and CEUS patterns of different degrees of bronchial arterial tumor perfusion dependent on tumor size (after Müller and Meyer-Schwickerath 1978)

and a reduced contrast-medium enhancement, respectively. In addition, intrathoracic splenomas can also be diagnosed by CEUS (Fig. 8.36). Contrast enhanced ultrasound, like CDS, is of limited suitability for distinguishing between benign and malignant peripheral round lesions.

8.5.4 Large Lung Consolidation: Pneumonia

8.5.4.1 Color-Doppler Sonography (CDS)

Pneumonia is seen on X-rays and sonography as a peripheral lung consolidation in conjunction to the pleural wall. On B-mode ultrasound, pneumonia is seen as a consolidation with more or less pronounced air bronchogram (Gehmacher et al. 1995), while a complete consolidation is seen as so-called lung hepatization. On CDS, pneumonia is marked by significantly ramified vessels that correspond to segmental branches of the pulmonary artery (Fig. 8.37). In principle it should be noted that certain subtypes of adenocarcinoma may

appear similar to pneumonia on the B-mode ultrasound and on CDS as well (Görg et al. 2002). Depending on the extent of hypoxic vasoconstriction in the pulmonary artery, the peripheral vascular tree of pulmonary arteries may not be visualized on qualitative CDS in the presence of advanced pneumonia. Bronchial arteries react to hypoxia by developing vasodilatation, as do all other arteries in the body. This explains the different resistance indices of pneumonia and atelectasis (Yuan et al. 2000). Thus, in the presence of lobar pneumonia parallel to the pulmonary arteries one occasionally finds an arterial monophasic flow pattern with low resistance indices, indicative of central bronchial arteries. The tuberculous infiltrate is a special phenomenon. It is characterized by marked vessels on CDS in terms of qualitative findings. On spectral analysis, however, it is seen as a monophasic curve, corresponding to bronchial arteries (Babo et al. 1979). Cavitary lesions such as tuberculosis, liquefactions, necrosis, abscesses and pseudocysts are characterized by the presence of predominant perfusion through the bronchial artery in the marginal areas around the lesion. (Hsu et al. 1998).

Fig. 8.35 **a** Patient with a mass in the right supraclavicular fossa, which is visualized by X-ray and computed tomography. The patient's medical history shows a condition after a central access on the right side was performed. On B-mode ultrasound, the tumor is hypoechoic. On CEUS, the tumor shows no contrast enhancement, so a hematoma

can be assumed, which was confirmed by a regression in the sonographic course. **b** Patient with pleural lesion as an incidental finding, with visualization by a chest X-ray and CT. On B-mode US, the lesion is hypoechoic; on CEUS, the lesion shows a reduced enhancement in all phases. Histologically, a lipoma was found

8

Fig. 8.36 **a** Patient with computed tomography of a left dorso-caudal mass. The patient's medical history included a condition after traumatic splenectomy. On B-mode ultrasound, the tumor is oval and homogeneously hypoechoic. On CEUS, the tumor shows a homogenous marked enhancement after 6 min, as in thoracic spleno-

sis. This was histologically confirmed. **b** Patient with peripheral lung lesion as an incidental finding, without evidence of an underlying malignant disease. The tumor is echogenic on B-mode US and shows a marked enhancement. Histologically, a solitary fibrous tumor (SFT) was confirmed

Fig. 8.36 (continued)

8.5.4.2 Contrast Enhanced Ultrasound (CEUS)

In keeping with the findings on CDS, classic pneumonia is characterized by a short period until the arrival of contrast enhancement and strong contrast enhancement on CEUS (Linde et al. 2012). This is indicative of predominant vascularization through pulmonary arteries (Fig. 8.37). Reduced contrast enhancement

is observed in cases of lobar pneumonia and can be explained by hypoxic vasoconstriction of the pulmonary artery (Table 8.1). Delayed contrast enhancement indicates perfusion by bronchial arteries and is observed in cases of liquefaction and chronic pneumonia (Figs. 8.38 and 8.39). An inhomogeneous contrast enhancement is useful for the identification of atypical

Fig. 8.37 **a** Patient with clinically and radiographically diagnosed pneumonia. **b** On B-mode ultrasound, a typical flat consolidation with a positive air bronchogram can be seen. **c** On CDS, an ordered vessel tree can be observed. **d** In the spectral curve analysis,

the arterial centrifugal vessels show a high-impedance flow signal similar to that of pulmonary arteries. **e-f** On CEUS a pulmonary arterial vascular tree can be recognized with a marked and homogeneous contrast enhancement

Fig. 8.38 **a** Patient with chronic therapy-resistant pneumonia and radiographic infiltrate in the upper region with suspected tuberculosis. **b** Computed tomography confirms the infiltrate with a gentle melting. **c** On B-mode ultrasound, a hypoechoic consolidation with standing air reflexes is revealed. **d** On CDS, a vessel is seen running from the lung surface to the center. **e** Using spectral curve analysis,

these vessels can be identified as bronchial arteries based on their low impedance flow signal. **f** and **g** On CEUS, the lesion shows a delayed bronchial arterial enhancement, with reduced and inhomogeneous contrast enhancement. The biopsy confirmed the diagnosis of chronic scarified pneumonia with pronounced fibrosis without evidence of tuberculosis

Fig. 8.39 **a** Patient with pneumonia resistant to antibiotics and cortisone therapy. On computed tomography, a homogeneous consolidation is observed. **b** On B-mode ultrasound, a hypoechoic consolidation is observed. **c** On CEUS, after 11 s the lesion shows a delayed marginal bronchial arterial enhancement without pulmo-

nary arterial perfusion. **d** In the parenchymal phase, a reduced and inhomogeneous contrast enhancement is present. The biopsy revealed the diagnosis of chronic cryptogenic pneumonia (COP), without evidence of malignancy

courses with evidence of melting, necrosis, infarction areas, bleeding and abscesses (■ Fig. 8.40). In particular, in parapneumonic polyseptated echogenic effusions with suspicion of pleural empyema, this area can be clearly demarcated from the infiltrated lung. Furthermore, a parainfectious pleural thickening with contrast-medium enhancement can be detected (■ Fig. 8.40a). The value of CEUS in pneumonia is in the detection of atypical and complicated courses.

A common pitfall is identifying bronchioloalveolar carcinoma, which reveals a perfusion pattern like that of acute “pneumonia” on CDS and CEUS (■ Fig. 8.41) (Findeisen et al. 2018).

8.5.5 Large Lung Consolidation: Compressive Atelectasis

8.5.5.1 Color-Doppler Sonography

Compressive atelectasis is seen on radiographs and sonography in conjunction with pleural effusion and the cardinal finding of a peripheral basal lung consolidation. The main finding is a pleural effusion, followed by the visualization of the consecutive compressed lung tissue. On qualitative CDS atelectasis is seen as strongly tree-like vessels. On arterial spectral analysis one usually finds a high-impedance flow signal indicative of pulmonary arteries (■ Fig. 8.42).

Fig. 8.40 Visualization by computed tomography, B-mode ultrasound and CEUS of a patient with atypical pneumonia. **a** Patient with pneumonia and parapneumonic empyema: CEUS sharply demarcates the empyema from the infiltration and shows a non-enhancement lesion with narrow contact with the empyema, as in the case of a pulmonary abscess perforated into the pleural space. **b** Patient with acute myeloid leukemia and condition after *Aspergillus* pneumonia: CEUS

clearly shows a non-enhanced central area in terms of necrosis. A resection of the infiltrate was performed before planned bone-marrow transplantation (BMT). **c** Fire-eater who aspirated paraffinized hydrocarbon: CEUS clearly shows central necrosis in the infiltrated lung. **d** Patient with acute lymphoblastic leukemia and residual pneumonic infiltrate before planned BMT: CEUS provides a diagnosis of infarct pneumonia. A BMT was performed

Fig. 8.41 Patient with dyspnea without fever and a mass in the right midfield, which is shown by X-ray **a** and by computed tomography **b** as typical pneumonia. **c** B-mode ultrasound shows a hypochoic consolidation with air bronchogram, as in pneumonia. **d**

On CEUS, the tumor shows an increased, homogeneous and early arterial contrast enhancement, as in pneumonia. The US-guided biopsy revealed the diagnosis of bronchioloalveolar carcinoma

Fig. 8.42 **a** Patient with left-sided pleural effusion on chest X-ray. **b** On B-mode ultrasound, a homogeneous consolidation as in atelectasis is present. **c** On CDS, the targeted, pronounced vascular visualization is impressive. **d** On spectral curve analysis, the arterial

centrifugal vessels show a high-impedance flow signal as in pulmonary arteries. **e, f** On CEUS, the enhanced pulmonary arterial vascular tree with a homogeneous parenchymal contrast enhancement is characteristic of compression atelectasis

8.5.5.2 Contrast Enhanced Ultrasound (CEUS)

The performance of a CEUS can be indicated in cases of unexplained effusion formation and complicated clinical courses. The lung parenchyma, pleura and effusion should be assessed using CEUS. According to the findings of CDS, "normal" compression atelectasis shows a short time to the arrival of contrast-medium and an increased extent of contrast-medium enhancement in

CEUS (Fig. 8.42). This suggests a completely pulmonary arterial perfusion. The CEUS pattern of compression atelectasis is very specific (Table 8.1). Round intraparenchymatous lesions may indicate pulmonary metastases (Fig. 8.43a), wedge-shaped peripheral defects may indicate infarcts (Fig. 8.43b), and inhomogeneous areas in lung may indicate hemorrhage in patients with chest trauma (Fig. 8.43c). These lesions

Fig. 8.43 Visualization of computed tomography, B-mode ultrasound and CEUS findings in a patient with focal lesion in an atelectatic lung. **a** Patient with known breast carcinoma and large pleural effusion: on CEUS, multiple round lesions (arrow) can be detected in atelectasis, as in metastases. **b** Patient with pancreatic carcinoma in their medical history and a large polyseptate pleural effusion and atel-

ectasis: on CEUS, an absence of contrast enhancement of the atelectasis is detected, as in pulmonary infarction. **c** Patient with chest trauma and basal shadows in the chest X-ray due to confirmed hemothorax: B-mode US shows a pleural effusion with pulmonary atelectasis; on CEUS, an inhomogeneous enhancement in the atelectatic tissue occurs in terms of a pulmonary hemorrhage (arrow).

can be visualized in atelectatic lung tissue by a reduced, absent or inhomogeneous contrast enhancement, respectively. Chronic compression atelectasis can lead to a shift from pulmonary arterial supply to completely nutritive bronchial arterial perfusion (Fig. 8.44). The CEUS can provide useful information regarding the etiological clarification of pleural effusions. A benign echogenic polyseptated effusion (Fig. 8.45) can be clearly differentiated from echogenic polyseptated tumor tissue (Fig. 8.46), and pleural tumor (Fig. 8.47) from a benign pleural thickening (Fig. 8.48). The differentiation of hematoma or fibrin bodies from vital tissue

is also possible with CEUS (Fig. 8.49). However, the definitive diagnosis is principally made histologically.

8.5.6 Large Lung Consolidation: Obstructive Atelectasis

8.5.6.1 Color-Doppler Sonography (CDS)

The obstructive lung atelectasis is seen as a largely homogeneous hypoechoic transformation on the B-mode ultrasound. Depending on the duration of the obstruction, evidence of a “fluid bronchogram” is a characteris-

Fig. 8.44 **a** Patient with non-small-cell lung carcinoma, in their medical history with condition after radio chemotherapy and now right-sided pleural effusion in the chest X-ray. **b** B-mode ultrasound shows a homogeneous consolidation of the lung, as in atelectasis. **c** On CEUS, after 20 s, a systemic vascularization in the atelectasis

(arrow) simultaneously with the enhancement of the thoracic wall (arrow) is recognizable as an indication of a central bronchial arterial nutritive perfusion of the atelectasis. **d** After 1 min, the atelectasis shows a homogeneous enhancement, possibly as an indication of tumor neoangiogenesis

tic feature in this setting. On qualitative CDS one finds pronounced vessels with evidence of an arterial high-impedance flow signal due to the branches of the pulmonary artery. A frequent finding is the central tumor responsible for the atelectasis. The consolidated atelectatic lung tissue serves more or less as an “acoustic window” to explore central lung structures (■ Fig. 8.50). According to Fissler-Eickhoff and Müller (1994), invasion and infiltration of the pulmonary arteries located in the region of the tumor occurs in 96% of the cases of bronchial carcinoma investigated. This disturbed vascular architecture of the pulmonary artery is seen on sonography as reduced or no visualization of vessels in the downstream atelectatic lung tissue.

8.5.6.2 Contrast Enhanced Ultrasound (CEUS)

In keeping with the CDS findings, a recent obstructive atelectasis is marked by the same features as compressive atelectasis with a short arrival time to contrast enhancement and strong contrast enhancement on CEUS. This is indicative of atelectatic lung tissue being entirely vascularized by the pulmonary arteries. In this phase, in patients with a central tumor formation, the tumor may be demarcated from atelectatic lung tissue more clearly by CEUS than by B-mode sonography (■ Fig. 8.51). In cases of obstruction of longer duration, within the atelectasis one may find liquefactions and abscesses formations (■ Fig. 8.52). Prolonged obstruction can lead to liquidations, pulmonary artery

Fig. 8.45 **a** Patient with parapneumonic pleural effusion. In the chest X-ray, a shadowing of the left diaphragmatic rib angle is visualized. Computed tomography (CT) shows a left-sided effusion. B-mode ultrasounds shows a lower lobe consolidation with polyseptated effusion. On CEUS, the septa do not show an enhancement. **b** Patient with parapneumonic pleural effusion. In the chest X-ray, a shadowing of the left diaphragmatic rib angle is visible. On CT, a

left-sided effusion with partial consolidation of the lung and pleural thickening is visualized. B-mode US shows a partial consolidation of the lower lobe with polyseptated effusion and thickened pleura parietalis. On CEUS, the septa show no enhancement, but the pleura shows a marked enhancement. Video-assisted thorascopic surgery revealed the diagnosis of a pleural emphysema, with evidence of calcifying granulomas due to *Mycobacterium carnetii* infection

8

Fig. 8.46 Patient with known malignant melanoma. **a** In the chest X-ray, a complete right-sided shadowing of the hemithorax is recognizable. **b** On CT, solid parts of the effusion cannot be reliably delimited. **c** B-mode ultrasound shows a polyseptated hemithorax. **d** On CEUS, a contrast

enhancement in the central atelectasis (AT) can be seen after 7 s. **e** After 26 s, a marked contrast enhancement from the periphery can be seen as an indication of peripheral bronchial arterial vascularization. Only a small part of the thoracic cavity shows polyseptated pleural effusion

Fig. 8.47 Patient with bronchial carcinoma. **a** A right-sided pleural effusion is visualized by chest-X-ray. **b** On B-mode ultrasound, a flat pleural thickening is visible. **c** On CEUS, the pleural formation shows a contrast enhancement. The US-guided biopsy revealed the diagnosis of pleural carcinosis

Fig. 8.48 Patient with pleural effusion due to congestive heart failure for clarification. **a** In the chest X-ray, a left-sided shadowing of the caudal hemithorax is recognizable. **b** On CT, a clear effusion with a dorsal flat pleural thickening is present. **c** B-mode ultrasound shows the hypoechoic pleural thickening. **d** On contrast-enhanced ultrasound, the pleural formation shows no contrast enhancement. The US-guided biopsy revealed the diagnosis of chronic fibrinoid pleuritis

Fig. 8.49 Patient with pleural effusion in non-small-cell lung cancer. **a** In the chest X-ray, a right-sided shadowing of the caudal hemithorax is visualized. **b** On CT, a clear effusion with atelectasis is seen. **c** B-mode ultrasound shows a large echogenic tumor forma-

tion. The diagnostic thoracocentesis revealed a hemorrhagic effusion. **d** On contrast-enhanced ultrasound, the tumor shows no contrast enhancement in terms of a localized blood clot

aneurysms (■ Fig. 8.53a) and abscesses within the atelectase/tumor (■ Fig. 8.53b). These potential lesions as well as metastases can be reliably diagnosed in atelectatic lung tissue by CEUS (■ Figs. 8.43a and ■ 8.49h). In the course of a tumor-related obstructive atelectasis, depending on the structure of the tumor there may be infiltration and occlusion of pulmonary arteries of different extent. In this situation CEUS shows delayed arrival of contrast enhancement and reduced contrast enhancement (■ Fig. 8.54). This is indicative of a switch to vascularization of atelectatic lung tissue from pulmonary to bronchial arteries (Görg et al. 2006a). In the case of a missing bronchoscopic diagnostic confirmation of the central tumor, the suspected consolidation can

be biopsied through atelectasis under CEUS guidance. (■ Fig. 8.55). In general, the CEUS pattern in cases of obstructive atelectasis is variable.

8.5.7 Space-Occupying Lesion of the Chest Wall

8.5.7.1 Color-Doppler Sonography (CDS)

Sonography is the method of choice to explore the chest wall. The intercostal arteries supplying the chest wall are usually seen even in healthy individuals by the use of CDS (■ Fig. 8.56). Tumors in the chest wall or parietal

Fig. 8.50 Patient with bronchial carcinoma. **a** In the chest X-ray, a complete right-sided shadowing of the hemithorax is recognizable. **b** On computed tomography, a narrow effusion and a mass in the right upper lobe are revealed. **c** On B-mode ultrasound, an atelectasis (AT) and an underlying central tumor formation (TU) are visible. **d** On CDS, a large centrifugal vessel is visualized. **e** On spectral curve analysis, the vessel shows a high-impedance arterial flow signal, as in

the pulmonary artery. **f** On CEUS, the pulmonary arterial vascular tree is visible after 5 s. **g** After 13 s, a contrast enhancement in the AT is present. **h** In the parenchymal phase, a washout in the area of the central TU is visible; furthermore, a focal parenchymal lesion is demarcated (differential diagnosis: melting, abscess, metastasis)

Fig. 8.51 Patient with bronchial carcinoma. **a** In the chest X-ray, a right-sided shadowing is observed in the area of the upper lobe. **b** On CT, an atelectasis (AT) is visualized without demarcation of a central tumor formation. **c** On B-mode ultrasound, the atelectasis

(AT) is recognizable without the demarcation of a central tumor formation. **d** On CEUS, the atelectasis (AT) is recognizable, with the demarcation of a central tumor formation (TU)

Fig. 8.52 Patient with renal cell carcinoma and mediastinal mass. **a** CT shows an atelectasis (AT), with demarcation of a central tumor formation. **b** B-mode ultrasound shows the atelectasis (AT), with demarcation

of a hypoechoic central tumor formation (M). **c** The CEUS shows an atelectasis (AT), with the demarcation of a mass with marked enhancement, indicating the presence of a central mediastinal lymph node metastasis

Fig. 8.53 **a** Patients with mediastinal malignant lymphoma and detection of a subsequent atelectasis in B-mode ultrasound. On CDS, arterial turbulence phenomena in the tumor can be detected. In the early arterial phase, the aneurysm fills rapidly and retains the contrast medium up to the parenchymal phase. **b** Patient with bronchial carcinoma. In the

chest X-ray, a right-sided shadowing in the area of the lower lobe can be seen. CT shows a central tumor formation (TU) with subsequent atelectasis (AT). B-mode ultrasound shows a clearly inhomogeneous mass without a central tumor formation. On CEUS, atelectasis shows a rounded mass with no contrast enhancement, as in necrosis (N), abscess or melting

■ Fig. 8.53 (continued)

pleural metastases are characterized by predominantly intercostal perfusion with a monophasic flow profile in spectral curve analysis (■ Fig. 8.57). When the tumor has invaded the lung, CDS may show different flow signals as a sign of complex arterial tumor vascularization (Görg et al. 2005a; ■ Fig. 8.58).

8.5.7.2 Contrast Enhanced Ultrasound (CEUS)

Specific studies to assess the value of contrast-assisted sonography in cases of space-occupying lesions of the chest wall are not available. Intercostal arteries are

strong vessels, and these can be visualized by CEUS (■ Fig. 8.56e). They show a marked by a delayed systemic arrival of contrast enhancement. The extent of contrast enhancement of the arterial phase may vary. Tumors with pronounced neovascularization show marked contrast enhancement (■ Fig. 8.59). Contrast-enhanced ultrasound can also play a role in the differentiation of non-vascularized lesions, such as hematoma (■ Fig. 8.60) and abscess (■ Fig. 8.61) and can be helpful for tumor biopsy under CEUS guidance to avoid necrotic areas.

Fig. 8.54 Patient with bronchial carcinoma and condition after radio chemotherapy. **a** In a chest X-ray, a left-sided shadowing in the area of the upper field is recognizable. **b** On B-mode ultrasound, a central mass (TU) with atelectasis (AT) is observed. **c** On CEUS,

after 20 s, a disorganized slow contrast enhancement, as in bronchial arterial vasculature, can be seen. **d** After 1 min, the lesion is characterized by an increased and homogeneous contrast enhancement

8

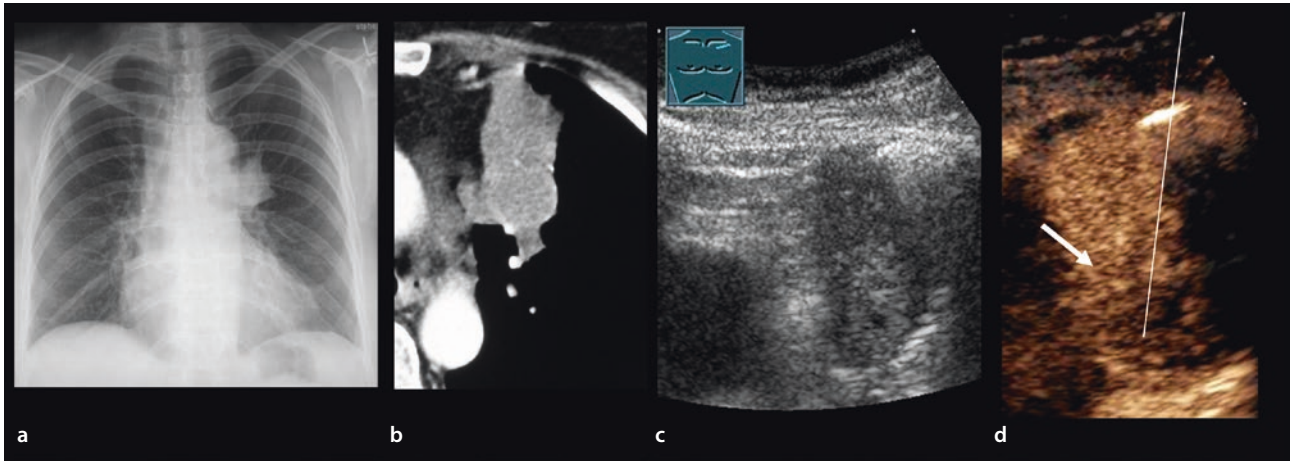

Fig. 8.55 Patient with bronchial carcinoma. **a** In a chest X-ray, a left-hilar mass is recognizable. **b** CT shows a central tumor formation in contact with the thoracic wall. Bronchoscopically, no tumor was detected. **c** B-mode ultrasound shows an inhomogeneous mass over a narrow "window" with no demarcation of a central tumor forma-

tion. **d** On CEUS, a central mass with reduced contrast enhancement is visualized, as in a central tumor (TU); this lesion was biopsied through the AT, with confirmation of a bronchial carcinoma

Fig. 8.56 Visualization of a normal intercostal artery in a healthy proband. **a** On B-mode ultrasound, the intercostal artery can be recognized with intercostal scan. **b** On CDS, the craniocaudal scan shows vascular reflexes beneath the ribs (PE, pleural effusion).

c CDS shows the intercostal artery in a longitudinal scan. **d** Spectral curve analysis shows a monophasic high-impedance flow signal. This flow signal is characteristic of an intercostal artery. **e** On CEUS, the intercostal artery can be regular visualized

Fig. 8.57 Five-year-old patient with thoracic wall metastasis with known hypernephroma. **a** On B-mode ultrasound, a plain hypoechoic transformation of the left thoracic wall can be recognized (TU). **b** On CDS, an increased perfusion of the tumor forma-

tion can be visualized. **c** The spectral curve analysis shows a monophasic high-impedance flow signal similar to that of an intercostal artery

8

Fig. 8.58 a-c 34-year-old man with testicular carcinoma and metastatic disease in the chest wall. **a** CDS reveals a tumor formation growing into the lung. Vessels are seen within the tumor tissue. **b** Spectral curve analysis shows a monophasic low-impedance flow sig-

nal such as that seen in bronchial arteries. **c** Spectral curve analysis shows a monophasic high-impedance flow signal such as that seen in intercostal arteries. This finding is indicative of complex tumor perfusion

Fig. 8.59 a Patient with a mass located to the thoracic wall (arrow). **b** On chest X-ray the mass can be seen in the left apical region. **c** On B-mode ultrasound, a large hypoechoic lesion of the

thoracic wall is visualized. **d** On CEUS, the lesion has a homogeneous marked contrast enhancement. The biopsy confirmed the diagnosis of a plasmocytoma

Fig. 8.60 **a** Patient with initial resected bronchial carcinoma who now shows a mass in the area of the scar (arrow). **b** CT shows the mass located in the thoracic wall. **c** B-mode ultrasound shows a

large, hypoechoic lesion of the thoracic wall. **d** On CEUS, the lesion shows no contrast enhancement, as in hematoma, confirmed by a biopsy

Fig. 8.61 Patient with thoracic back pain that has existed for months. **a** The chest X-ray was reported without pathological findings. **b** On CT, a liquid mass can be seen in the left cervical triangle extending into the upper thoracic aperture. **c** On B-mode ultrasound, a large liquid structure is visualized in the neck, descending into the

thorax. **d** On CEUS, the peripheral wall surrounding the non-enhanced abscess area shows a marked contrast enhancement. **e** The US-guided diagnostic biopsy resulted in pus. The diagnosis of tuberculosis was confirmed

Summary

Qualitative CDS shows varied and partly characteristic findings in the presence of various types of lung consolidations and is therefore a valuable adjunct to B-mode ultrasound with regard to the etiological classification of peripheral lung lesions. In keeping with the physiological dual vascularization of the lung by the pulmonary arteries and the bronchial arteries, on CDS one can distinguish between arterial high-impedance spectral curves and arterial low-impedance spectral curves in consolidated lung tissue. The former are assigned to pulmonary arteries and the latter to bronchial arteries. Within peripheral lung consolidations, different entities show characteristic distribution patterns of pulmonary-artery and bronchial artery flow signals in respect of frequency and location. Arterial spectral curve analysis is time-consuming. Reliable demarcation of vessels of tumor neoangiogenesis is currently not possible with CDS. The orienting CDS is used only in the daily clinical routine, but the spectral curve analysis is often too time-consuming and susceptible to faults.

Experience concerning CEUS in cases of peripheral lung lesions is limited. Lung lesions can be described by the time to the start of contrast enhancement and by the extent and homogeneity of contrast enhancement. Contrast enhanced ultrasound at the chest can be performed easily and rapidly, and is therefore basically suitable for routine clinical use. The possible indications are (1) in the area of the thoracic wall, differentiation of vital and avital tissue and tumor characterization; (2) for the leading symptom of thoracic pain, CEUS is helpful in the differential diagnosis of pleurisy and peripheral pulmonary embolism; (3) in the leading symptom of radiographic shadowing, CEUS is helpful in the diagnosis of malignant pleural effusion (PE) and infarction-related PE, as well as in the discrimination of tumor from central atelectasis, in the detection of atypical pneumonic processes and in the evaluation of the malignancy of pulmonary nodules or peripheral bronchial carcinomas. In the field of interventional sonography, CEUS enables a safe differentiation between tumor, necrosis and atelectasis.

Diffraction	Attenuation

9.1 Artifacts

Artifacts are a system-immanent aspect of ultrasonography. They arise due to physical phenomena when ultrasound waves pass through the human body (Table 9.1). Artifacts are disruptive artificial products that make it very difficult to image and evaluate the thorax, especially due to the anatomical features of this region. Artifacts can distort existing structures in terms of their size, position, form, and echogenicity; cause incorrect or incomplete imaging of their topography; or suggest the presence of structures that, in fact, do not exist. On the other hand, artifacts are indispensable and very important determinants of the diagnosis of specific diseases. The absence of certain typical artifacts (air: reverberation; bone: acoustic shadow) at the surface of the lung or in the bony thorax enables the investigator to diagnose certain diseases (lung lesion, rib lesion), as it is then possible to evaluate parenchyma, bone, and/or soft tissue. Artifacts also serve as a diagnostic criterion when they are seen at an unusual site, e.g., air with reverberation echoes in the pleural space in cases of pneumothorax.

9.2 Pitfalls

These are sources of error in ultrasonographic diagnosis, caused by anatomical, topographic, pathophysiological, or physical ultrasound-based misinterpretation on the part of the investigator, leading to incorrect diagnosis. Incomplete history taking, missing clinical information or examination, or insufficient knowledge of sonographic (and clinical) differential diagnosis may also be the reason for such “pitfalls.” Last, but not least, every conscientious ultrasonographer must be aware of the limitations of the method so that additional diagnostic procedures can be applied efficiently, economically, and in a manner that is conducive to the patient’s well-being. By so doing, several pitfalls can be avoided or resolved.

9.3 Ultrasound Physics in the Chest

Ultrasound images are created by the transmission and passage of ultrasound waves in the human body and the registration and processing of the backscattered/received echo of the emitted ultrasound beam. In an entirely homogeneous medium, a sound wave is carried forward in a uniform fashion. It is altered at the margin between two media. The phenomena/changes that are liable to occur in this process are summarized in Table 9.1. They include the geometry of the ultrasound wave, the angle at which it strikes the reflector, the physical properties of the reflector, and its surface consistency. The magnitude of the impedance difference between two different media is represented by various factors, one of them being the intensity of the backscattered echo. Thus, on the B-mode image, it is represented by the brightness of a pixel. Human tissue contains a number of marginal surfaces whose anatomical origin can be determined by characteristic ultrasound phenomena. In contrast to the abdomen, ultrasonography of the chest is more frequently confronted with disturbing artifacts because of the surrounding “echo-opposing” structures (aerated lung, bony chest). Therefore, the specific ultrasound phenomena in air and bony structures will be briefly discussed in the following.

Air This is a strong ultrasound beam reflector. Depending on the structure of the surface, the impedance difference and the gas volume at the marginal surface, ultrasound waves differ in terms of their reflex behavior:

- Large extent of absorption
- Total reflection with acoustic shadow
- Partial reflections with change of transmission and a narrow acoustic shadow

The most common phenomenon is that up to 99% of the ultrasound wave is reflected at the first marginal surface between tissue and air, i.e., the “initial lung echo.” Therefore, it is not possible to visualize the deeper lung parenchyma by ultrasonography. Only when the structure of the surface is altered and in the presence of specific physical features (e.g., the absence of air in inflammatory or tumor-related processes, atelectasis, etc.) is it possible to image lung parenchyma. However, in such cases, the lung itself has several marginal sur-

Fig. 9.1 Reflective shadowing at the clavicle (CL). Dorsal acoustic shadow (S) due to absorption of ultrasound waves at the surface of the clavicle. Additional reverberations (repetitive echoes, arrows) at the surface of the clavicle when the ultrasound waves hit perpendicularly. *PL* pleural reflex

faces (air in the bronchoalveolar space, bronchial wall, interstitial space, vascular wall, blood). The abovementioned alterations in the ultrasound wave also occur at these marginal surfaces.

Bone in bone, there is nearly complete absorption of ultrasound energy. As a result, the “dorsal” ultrasound wave is obliterated (no further echoes in axial direction of the beam). When ultrasound waves hit bone at right angles, they may cause strong reflection and repetitive echoes of the bone surface in deeper portions (**Fig. 9.1**).

9.4 Imaging of Marginal Surfaces of the Pleura and the Diaphragm

The image varies, depending on the angle of incidence of ultrasound waves and the consistency (roughness) of the surfaces. Furthermore, the improved resolution of ultrasound probes and continuous advancement of technology permit differentiated imaging. At an angle of incidence of 0 to about 25°, total reflection may be expected to occur at the marginal surface between the pleura and the lung. Only when the surface of the pleura/lung is thickened due to inflammation or scars and the surface is irregular and “roughened,” is it imaged even in the presence of a steeper angle of incidence.

Most of the diaphragm can be imaged by the trans-abdominal approach (as a rule through the liver from

Fig. 9.2 “Diaphragmatic gap.” A female patient with a primary peritoneal mesothelioma, ascites (A) and basal pleural pneumonia. The central portion of the diaphragm (D) is found to be markedly thickened. In areas close to the transducer, there seems to be a gap (x-x). Furthermore, a lateral marginal shadow phenomenon is seen in the diaphragm and also a comet-tail artifact in air in the cranially located lung (arrows). *RLL* right lobe of liver, *R* rib with dorsal acoustic shadow

the right side and through the spleen from the right side). Due to the high impedance difference as well as scatter phenomena, the diaphragm is visualized as much thicker than it actually is (**Fig. 9.2**). Central portions of the diaphragm are not imaged well by the intercostal approach because of the unfavorable angle of incidence of the ultrasound wave. Apparent gaps might irritate the investigator. Moreover, lateral marginal shadow phenomena limit the assessment. Indistinct processes must be imaged in the complementary second plane.

9.5 B-Mode Artifacts

Based on their mechanism of origin and physical ultrasound features, artifacts may be divided into four categories (**Table 9.2**; Kremkau and Taylor 1986; Schuler 1998).

9.5.1 Ultrasound Beam Artifacts in Chest Sonography Reverberations (Repetitive Echoes): Margin Between Tissue and Air, Bone Fracture Fissures

They arise due to nearly complete reflection of the emitted ultrasound wave at the marginal surface between tissue and air (initial lung echo). This marginal surface acts as a strong reflector. It reflects the striking ultra-

Table 9.2 Classification of artifacts

Ultrasound beam artifacts

Other artifacts

Fig. 9.3 Reverberations and comet-tail, parasternal longitudinal section from the right side. One finds reverberation artifacts (horizontal arrows) dorsally in the aerated lung, and a short comet-tail artifact (arrowheads). Furthermore, a muscle fascia of the thorax musculature is mirrored dorsally (vertical arrows) at the pleural reflex (PL). Rib (R) with an incomplete acoustic shadow (S); the pleural reflex acts as a strong reflector and is imaged here through partly cartilaginous rib with partial echo transmission

sound wave back to the transducer membrane, where the wave is re-reflected and reemitted, hits the marginal surface again, etc.

Depending on the duration, the marginal surface reflex is imaged dorsally, in axial direction of the ultrasound wave. Deeper reflectors are weaker and are imaged darker (Figs. 9.2 and 9.3). The artifact caused by insufficient probe-to specimen contact (Fig. 9.10), e.g., when a linear ultrasound probe is used on the surface of the thorax, actually is a reverberation artifact (at the transducer membrane).

9.5.1.1 Image Artifacts and Pitfalls

A narrow fissure in a rib fracture might become noticeable because of a reverberation artifact (so-called chimney phenomenon) (Dubs-Kunz 1992). The fracture end of the rib serves as a strong reflector in this setting (Fig. 2.17).

9.5.1.2 Mirror Artifacts: Liver Parenchyma in the Diaphragm, Vessels at the “Pleura”

These are caused by incidence-angle-dependent reflection of the ultrasound wave at a strong reflector (e.g., the diaphragm), oblique deflection in issue, repeated reflection on a reflector, back-scatter to the first reflector, and back-reflection to the ultrasound probe. This is imaged as a structure tot primarily in the axial direction of the ultrasound beam, within a region axial distal to the actual reflector.

This causes the classical mirror artifact phenomena of the liver at the diaphragm (Fig. 9.4), but also of

Fig. 9.4 Mirror artifact. Subcostal oblique section from the right side. “Classical” mirror artifact of the liver at the diaphragm. Portions lying at a distance from the transducer and the diaphragm, i.e., cranially by the subcostal approach, are not “lung parenchyma” but liver parenchyma reflected at the strong reflector, namely the diaphragm. A hemangioma (x-x) lying immediately subdiaphragmal in the original image is more clearly seen in the mirror image (x-x) and is displaced centrally to the mid portion of the image (a). Lung struc-

ture could be seen, if artifacts are reduced or disappeared due to alteration of the physical environment. If there is pneumonia, air (and artifacts due to air: i.e. reverberation), lungs structure could be seen (b). In some cases, the mirror image might reveal structures outside the main beam that cannot be imaged (multiple beam artifacts) and cause considerable confusion. Additional comet-tail artifacts (arrows) in air

Fig. 9.5 Mirror artifact on color Doppler. The subclavian artery (A. SUBCLAVIA) is reflected at the pleura (PL). A vessel (arrow) lying dorsal to the pleura is seen on the mirror image; the vessel, however, does not really exist

Fig. 9.7 Scatter lens artifact. The pleura (PL) dorsal to the rib cartilage (R) is shifted ventrally towards the transducer (arrows) as a result of various ultrasound beam rates in cartilage and soft tissue of the chest wall

Fig. 9.6 Arcuate artifact in the pleural effusion. A female patient with pulmonary and pleural metastatic breast carcinoma. A strong reflector (bony thorax) lying outside the main beam is visualized as a circular arch (AA arcuate artifact), discretely opening upward. Distally, it may mimic septation of the pleural effusion (E). The internal echoes (R) are not corpuscular portions of the effusion but noise artifacts ("speckles"). D diaphragm, LU lung atelectasis in the presence of pleural effusion

the subclavian artery at the initial lung reflex. This artifact phenomenon exists not only in B-mode sonography, but also in color Doppler and the Doppler frequency spectrum (Reading et al. 1990; **Fig. 9.5**). As a rule, the multiple backscattered echoes of mirror images are more hypoechoic and somewhat more blurred or distorted as a result of previous weakening of the ultrasound beam when it passes through tissue.

9.5.1.3 Arcuate Artifacts: Rib Reflex in Pleural Effusion

Arcuate artifacts may arise due to displacement of a reflex at a strong reflector in the lateral ultrasound beam or side lobe into the center of the main beam. Characteristically, in sector transducers and upwardly oriented curved arrays, one finds upwardly open circ-

lar arches. In linear probes, one finds a hyperbola. Thus, a reflection in a bony portion of the thorax could mimic a septation in a pleural effusion (**Fig. 9.6**). This problem can be resolved by altering the echo angle or the echo plane.

Scatter Lens Artifact/Shortening Phenomenon: Distortion of the Lung Surface Dorsal to Rib Cartilage This artifact phenomenon is a result of the different transmission rates of ultrasound waves in rib cartilage (faster) than in the adjacent soft tissue of the chest wall. This may mimic a pseudolesion at the marginal surface of air/lung, because there is an apparent protrusion of contours in the direction of the ultrasound probe (**Fig. 9.7**). This artifact is simple to detect and plays a rather important role in abdominal diagnosis of the liver (apparent space-occupying mass on the surface of the liver) dorsal to rib cartilage (Böhnhof and Linhart 1985).

Marginal Shadows: Diffraction/Refraction at Strong Reflectors ("Diaphragmatic Gap") This artifact occurs when the ultrasound beam hits a surface obliquely. It is the result of diffraction and refraction phenomena at strong reflectors (e.g., the diaphragm; **Fig. 9.2**). The artifact is detected by the fact that it disappears when the echo plane or the echo angle is changed.

9.5.2 Artifacts Caused by Alterations in Echo Enhancement Acoustic Shadow/Echo Obliteration

Formation of Plaque on All Bony Structures of the Chest This certainly is one of the most common artifact phenomena in the thorax and greatly hinders the assessment of structures lying dorsal to such strong reflectors. Due to strong absorption, dorsal bone structures (ribs, scapula, clavicle, sternum, vertebral column) are nearly completely obliterated and practically all information is

■ **Fig. 9.8** Echo enhancement. Dorsal to a small, not entirely anechoic pleural effusion (E) there is marked “echo enhancement” (EE). This actually is reduced weakening of the echo, as the spread of the ultrasound beam in the pleural effusion is altered in comparison with adjacent tissue. Also note the nonanechoic effusion dose to the chest wall. The reflexes are noise artifacts. Furthermore, an echodense small bright linear reflex (N) is seen, the tip of the puncture needle introduced under sonographic guidance

■ **Fig. 9.9** Comet-tail and probe-to-specimen artifact. Dorsal to a septate pleural effusion in the presence of breast carcinoma one finds numerous comet-tail artifacts (arrowheads) arising in the air at the margin between the visceral pleura and the lung. Furthermore, given insufficient contact between the ultrasound probe and the chest wall, a shadow with an artifact reflex (arrow), although not like a classical ring-down artifact. Dorsal to the pleural effusion, there is marked echo enhancement. PLE pleural effusion

lost (■ Fig. 9.1). However, interruptions of the otherwise regular acoustic shadow in the bony thorax (bone contour, bone surface, joints) may be very helpful for diagnosis, as pathological changes will be present in such cases (fracture, bone tumor, joint effusion, joint empyema). Acoustic shadows in the pleura are also signs of pathological alterations, e.g., of plaque in the presence of asbestosis or calcification during the healing of pleural lung lesions or lung lesions dose to the pleura (pneumonia, tuberculosis) or in lymph nodes.

Echo Enhancement: Distal to Hypoechoic Structures (Pleural Effusion, Cyst, Vessel, Hypoechoic Space-Occupying Mass) This phenomenon of “brighter,” more hyperechoic areas distal to the above-mentioned structures is not due to echo enhancement but due to lesser

weakening of ultrasound waves in the more hypoechoic portions closer to the probe. This causes distal parts to appear brighter (more hyperechoic and stronger echoes) than the surrounding areas, which have uniformly weakened echoes. In the thorax, this is found in the presence of large quantities of fluid in the pleural space or hypoechoic peripheral pulmonary processes (■ Figs. 9.8 and 9.9).

9.5.2.1 Echo Resolution Artifacts

z Noise: In Fluid-Filled Structures At the surface of anechoic areas, one finds diffuse “noise” caused by interference from returning echoes at different marginal surfaces, such as those caused by “background noise,” depending on general enhancement (this is also true for Doppler sonography). Here caution is advised, as apparently internal structures that in fact do not exist might be mimicked (e.g., in the pleural effusion; ■ Figs. 9.6 and 9.8). Marginal surfaces are frequently blurred.

9.5.2.2 Image Artifacts and Pitfalls

z Slice Thickness Artifact: at Reflectors with a Strong Impedance Difference (Pleura, Diaphragm)

This common and irritating artifact also belongs to the category of resolution artifacts. When the ultrasound beam hits strong reflectors obliquely and in the presence of a high impedance difference, the marginal layer is much thicker (partly) blurred, and distorted. This phenomenon might mimic pleural and diaphragmatic lesions or thickening (■ Fig. 9.2), but also thrombosis or sediments in vessels.

9.5.3 Other Artifacts Comet-Tail (Resonance Artifact), B-Lines: In Aerated Structures

At the margin, of the lung surface and air one frequently finds small comet-tail artifacts (■ Figs. 9.2, 9.3, 9.4 and 9.9). They are seen as bright, narrow strips of strong dorsal reflectors and their origin is controversially discussed. One explanation is reverberations (repetitive echoes) between two very closely located reflectors and resonance phenomena (vibrations) in a thin structure of soft tissue (e.g. thickened interstitial alveolar septa surrounded by air with a strong echo response). In addition to air or other gas bubbles, a common site of origin is metal foreign bodies. Many authors refer to these artifacts as B-lines, the “sound of lung water” (Lichtenstein et al. 1997; Lichtenstein 2005; Gargani et al. 2008; Noble et al. 2009; Soldati et al. 2009). When occurring in large numbers in the region distal to the ultrasound reflection on the aerated lung, these artifacts indicate interstitial lung lesions such as interstitial edema or lesions in the

■ **Fig. 9.10** B-Lines (comet tail artifacts: arrows) due to pulmonary edema with a size of 3 to 7mm (crosses)

■ **Fig. 9.11** Interstitial syndrome with comet-tail artifacts (arrows, calipers: 3–8 mm wide), bacterial pneumonia in the phase of healing, infiltrate not seen on the image

■ **Fig. 9.12** Congestive pneumonia

presence of contusion, pneumonia, etc. (Soldati et al. 2006; Volpicelli et al. 2008). In more rare cases, fibrotic lesions in the lung may also be present (Wohlgenannt et al. 2001; Reissig and Kroegel 2003). However, these

artifacts are not sufficiently selective as regards their differentiation from the above-mentioned diseases. To put it simply, the evidence of these artifacts means that “the lung is not healthy” (■ Figs. 9.10, 9.11, and 9.12). The 1st International consensus conference on pleura and lung ultrasound has defined B-lines as discrete laser-like vertical hyperechoic reverberation artifacts that arise from the pleural line (previously described as “comet tails”), extend to the bottom of the screen without fading, and move synchronously with lung sliding. Multiple B-lines are the sonographic sign of lung interstitial syndrome. In the evaluation of diffuse interstitial syndrome, the sonographic technique ideally consists of scanning eight regions, but a more rapid anterior two region scan may be sufficient in some cases. A positive region is defined by the presence of three or more B-lines in a longitudinal plane between two ribs. However, focal multiple B-lines may be present in normal lung.

The consensus conference statement omits discussion of additional information yielded by high resolution ultrasound interrogation of the lung surface including excluding changes of the pleura and distinct analysis of the shape of the artefact. In addition, the consensus paper not only focused on edema but also on other pathophysiological disorders of the lung parenchyma including pulmonary fibrosis and interstitial pneumonia, which the authors referred to as “interstitial syndrome”.

Since the publication of the consensus statement, some authors extended the term “focal interstitial syndrome” to include other disorders such as lung contusion, pneumonia or pulmonary embolism. In this context, all vertical reverberation artefacts radiating from the pleura into the lung parenchyma were designated BLA. An accurate analysis of the various published descriptions of BLA shows undifferentiated, mixed, and often contradictory conclusions. The imprecise use of the terms BLA and CTA in lung US have led to confusion, which is seen in routine daily practice as well as published literature. A more precise definition of the spectrum of reverberation artefacts may be helpful to better differentiate cardiogenic pulmonary edema from parenchymal lung diseases. Therefore, parenchymal lung diseases have to be excluded before a BLA analysis for cardiogenic pulmonary edema is undertaken (Dietrich et al. 2016; Mathis et al. 2021).

Artifacts Caused by Foreign Bodies: Needle Tip, Drainage Iatrogenic or accidental foreign bodies introduced into the body cause artifact phenomena. As a result, projectiles, fragments of glass or wood, other substances might be imaged in the chest wall and in soft tissue. This is significant when such artifacts are visualized during sonography-guided diagnostic or therapeutic measures. Small pulmonary consolidations close to the pleura, pleural effusions a few millimeters in size, or pleural empyema can be punctured or drained under

■ **Fig. 9.13** Ring-down (probe-to-specimen artifact). Patient with a peripheral bronchial carcinoma in a ventral location on the right side. A probe-to-specimen artifact (arrow) is caused by insufficient contact between the transducer and the chest wall. A simultaneous fine-needle puncture performed for histological verification of the diagnosis shows the needle artifact (N) in the tumor (LU-TU)

■ **Fig. 9.14** Directional artifact (color Doppler). The axillary artery (infraclavicular) (A.AX.) with a branch for the musculature/chest wall. Blood flowing towards the ultrasound probe is coded red; blood flowing away from the probe is coded blue (see color scale). The branching artery (arrow) is blue, the change of color from red to blue occurs via black. Thus, here (at a 90° Doppler angle to the ultrasound probe), there is no blood flow relative to the ultrasound probe

9
 realtime sonographic guidance. Space-occupying masses in the soft tissue of the thorax or rib cage should also be punctured under sonographic guidance. Detection of the needle reflex in aerated structures might be difficult. Here, real-time control through subtle movement of the needle tip under simultaneous sonographic imaging is useful (Blank 1994; ■ Fig. 9.8). Ring-Down Artifact: Insufficient Probe-To-Specimen Contact If the geometric configuration of the probe is unfavorable in relation to the investigated region (for instance a linear probe in a curved chest wall), this artifact can easily be detected by characteristic repetitive echoes (arising between the ultrasound crystal and the transducer membrane) (■ Fig. 9.13).

9.6 Color Doppler Artifacts and Pitfalls in the Chest

The basic principles and settings of the various Doppler modalities will not be presented in this chapter. They have been discussed in detail elsewhere (Wild 1996).

9.6.1 Pulse Repetition Frequency

Overall Enhancement, Filter, Background Noise Insufficient or incorrect setting of the overall enhancement of color Doppler either leads to incorrect imaging of actual blood flow (excessively low gain) or “over-radiation” due to numerous color pixels that do not represent blood flow but only background noise (poor signal-to-noise ratio). A low pulse repetition frequency (PRF) should be selected for small vessels with low flow rates so that flow signals are not “overlooked.” When

large arteries are visualized (mediastinum, suprasternal, parasternal), it may be necessary to increase the PRF or reduce overall enhancement. The same is true for spectral Doppler. Selection of the wall filter should also be controlled, so that slow flow signals or signals of low intensity are not “filtered away.”

9.6.2 Directional Artifact

The directional artifact is not actually an artifact phenomenon but evidence of directionally encoded visualization of blood flow on color Doppler (■ Fig. 9.14). Thus, in a vessel with blood flow in the opposite direction of the ultrasound probe (for instance, when the vessel has a curved flow), the colors red and blue will be present in one and the same vessel. The actual change in the direction of blood flow is seen at the margin of the two colors; this area will be black (corresponding to null flow; see color scale).

9.6.3 Aliasing

In contrast to directional artifacts, aliasing is marked by a change of color through the bright color zones. This phenomenon is expressed as a colorful mosaic in the transition zone between two colors and will be seen at higher flow rates than the selected PRF (■ Fig. 9.15a). In spectral Doppler, portions of higher frequency appear as being “cut off” at the lower or upper margin of the Doppler frequency spectrum. Aliasing shows, for instance, higher-grade stenosis and disturbance of flow within vessels (■ Fig. 9.16). Increasing the PRF

Fig. 9.15 **a** Aliasing on color Doppler in a pulmonary vessel in the presence of pneumonia. Given a low pulse repetition frequency in color Doppler (color scale, here 15 cm/s), color alone does not permit the investigator to conclusively establish the direction of flow. The change of color in the vessel is achieved via brighter colors. Thus, the mean flow rate in this vessel is more than 15 cm/s. **b** Pulmonary artery. Only when pulse repetition frequency is increased to 30 cm/s is it possible to clearly distinguish pulmonary vessels. On red color coding, color Doppler shows an afferent artery. On spectral Doppler, the corresponding Doppler frequency spectrum, suggesting four-phase flow. **c** Pulmonary vein. Blue color coding shows centrally aligned blood flow. Spectral Doppler shows the venous flow signal

Fig. 9.16 Stenosis of the subclavian artery. In spite of high pulse repetition frequency (maximum 69 cm/s), there is markedly faster flow within the vessel, which is imaged by the bright color pixels in the vessel. Furthermore, the vessel itself is poorly delineated; color pixels are also seen outside of it. This is also known as a vibration artifact and is caused by tissue vibration secondary to stenosis and due to concomitant pulsations that cannot be reliably distinguished from the vessel in terms of space. Spectral Doppler shows flow maxima of about 1.5 m/s and retrograde flow (below the null line), as well as pathological, non-triphasic flow in this extremity artery Image

of color and spectral Doppler (up to the Nyquist limit) will help at least to reduce aliasing. It might also be possible to clearly determine the direction of flow (Fig. 9.15b, c).

9.6.4 Motion Artifacts

Mechanical movement of tissue against the ultrasound probe (breathing, musculature, cardiac and vascular pulsation, etc.) causes an apparent “frequency shift,” which creates a signal in color Doppler as well. This disturbs, in particular, the assessment of structures close to the heart and vessels due to persistent superimposition, and is a limitation of the method, e.g., in the detection of low blood flow in such areas. Various “artifact suppression” modalities proposed by manufacturers of ultrasound devices have achieved some improvement in this regard. Even in the presence of stenosis, movement of tissue due to concomitant motion (vibrations) on color Doppler might represent apparent flow signals outside the vessel (Fig. 9.16). The gliding pleural reflex is very useful in terms of diagnosis. Due to motion, it also causes a strong power Doppler artifactual signal. The absence of this gliding sign, viewed in conjunction with the absence of comet tail artifacts distal to the US reflection on the

aerated lung, indicates a pneumothorax with a specificity of nearly 100% (Kirkpatrick et al. 2004).

9.6.5 Unfavorable Angles

An angle of more than 60–90° may lead to incorrect Doppler measurements or incorrect imaging of blood flow (color Doppler and spectral Doppler). In such cases, the modality of power Doppler would at least help to image vessels in the thorax/lung (Yang 1996). In this setting, a largely angle independent, directionally non-encoded, more sensitive documentation of blood flow is achieved by the visualization of amplitude (not frequency shift) of the backscattering echo.

10.1 Introduction

The cause of many diseases in chest organs can be determined by a combined evaluation of the patient's history, clinical findings and diagnostic imaging procedures. An elaborate diagnostic "cascade" which strings together any available methods is neither justifiable economically nor sensible from a medical viewpoint.

A definitive evaluation often requires additional biochemical, microbiological, cytological or histological expert assessment. The material needed for such investigations can be obtained by targeted puncture. Given the appropriate indication, the puncture may be followed by interventional therapeutic measures.

One should always employ the interventional method which provides a definite diagnosis in the fastest and least stressful manner for the patient.

Interventional measures in the thorax—various procedures:

1. Percutaneous access
 - (a) Sonography
 - (b) Radiographs (fluoroscopy, computed tomography, CT)
2. Endoluminal access
 - (a) Bronchoscopy
 - (b) Endoluminal sonography
3. Surgical (mediastinoscopy, thoracoscopy, surgical exposure)

10.2 General Indications

In addition to the frequent use of puncture for pleural effusion, space-occupying masses accessible to sonographic investigation, located in the chest wall, pleura, lung or anterior mediastinum, are important indications (Braun 1983; Börner 1986; Weiss and Weiss 1994; Pedersen et al. 1986; Koenig et al. 2011; Laursen et al. 2016).

Depending on their topographical position and the diagnostic availability and expertise, pathological changes not detectable by a transthoracic approach may be identified diagnostically by one of the interventional procedures displayed in the list in the previous section (Di Bardino et al. 2015).

Interventions in the Thorax—Indications:

1. Space-occupying mass in the thoracic wall (tumors, abscesses, hematomas, changes in the skeletal parts)
2. Space-occupying masses in the pleura
3. Pleural effusion and pleural empyema (very small quantities, loculated effusions)
4. Peripheral lung consolidations (lung tumor, pneumonia, lung abscess)
5. Mediastinal processes (anterior mediastinum)

Because of the potential risk of complications, the indication for the procedure should be established with care.

Even if any sonographically demonstrable space-occupying lesion can be punctured in principle, one should only perform punctures if therapeutic consequences (e.g., radiation, chemotherapy) or important prognostic information is to be expected. In a patient who is operable, a suspected malignant tumor located in the periphery will normally not be punctured but will be resected as a first-line measure. It is not reasonable to merely seek confirmation of already established or plausible diagnoses. If the same information may be gathered in a less invasive way, puncture should not be performed (Blank 2006; Beckh and Bölskei 1997; Müller and Blank 2011; Jeon et al. 2014).

10.3 Contraindications

The limits of acceptable coagulation parameters depend on the positioning of the mass and the invasiveness of the intervention. Urgent interventions require Individual assessment of risk (see ■ Table 10.1) (Blank 2019). Special caution is necessary under Clopidogrel. Lung biopsies should not be undertaken; recommendations

■ **Table 10.1** Recommendations on coagulation diagnostics and coagulation management before thorax punctures (adapted from Patel et al. 2012, 2013)

Procedure	Laboratory examination	Technique
Thoracocentesis Superficial biopsy	INR in case of pathologies involving anticoagulation and liver diseases PTT: Pat. with intravenous heparin Platelet count: not routinely recommended Hematocrit: not routinely recommended	INR > 2.0: threshold for treatment (i.e., FFP, vitamin K) PTT: no consensus Thrombozyten <50.000/ μ l: Transfusion ASS/NSAR: do not withhold Thienopyridine (Clopidogrel) 0–5 Tage Pause LMWH (therapeutic dose): withhold one dose before procedure
Biopsy or drainage of abscesses Mediastinal and lung biopsy and thick catheters	INR recommended PTT: Pat. with intravenous heparin Platelet count: not routinely recommended Hematocrit: not routinely recommended	INR >1.5: threshold for treatment (i.e., FFP, vitamin K) PTT: no consensus Thrombozyten <50.000/ μ l: Transfusion ASS/NSAR: do not withhold Thienopyridine (Clopidogrel) withhold for 5 d before procedure LMWH (therapeutic dose): withhold one dose before procedure

aPTT activated partial thromboplastin time, *INR* international normalized ratio, *LMWH* low molecular weight heparin

on superficial intervention are not univocal (see [Table 10.1](#)). Reference is made to the literature (Patel et al. 2013).

Bullous pulmonary emphysema and pulmonary hypertension are relative contraindications. When respiratory function is severely restricted or blood gas values are poor, a puncture should only be performed when the patient's condition is expected to be improved by the therapeutic intervention. High-risk puncture sites should be avoided (Yang et al. 1992; Mathis et al. 1999; Dietrich and Nürnberg 2011).

10.4 Sonography-Guided or CT-Guided Puncture

In several diseases of the lung and mediastinum, CT provides the best overview. It should, however, only be used as an interventional measure when the target and pathway of puncture cannot be reliably assessed with sonography (Blank 2006; Mathis 1997a; Müller and Blank 2011). The success rate of the US-guided puncture (89–97%) is comparable to CT (92–96%) (Di Bardino et al. 2015; Sconfienza et al. 2013).

The *advantages* of sonography-guided puncture are manifold: fast availability and bedside application (intensive care unit, emergency room), low rate of complications, absence of radiation exposure and low cost. In contrast to CT-guided puncture, the sonographic puncture can be carefully observed during the process. The investigator is free to use the pathway he/she desires in terms of direction; the ventilated lung is protected (low rate of pneumothorax) (Lee et al. 2018). The nerve cords of the plexus in the region of the upper thoracic aperture may be demonstrated with high-resolution ultrasound probes, thus avoiding injury through puncture ([Fig. 10.1](#)).

Fig. 10.1 Brachial plexus (arrows). Tumor masses (TU) in the region of the upper thoracic aperture

Vessels are detected with color-Doppler sonography (upper thoracic aperture, parasternal). Active (vascularized) sections of a tumor may be identified by color-Doppler sonography and, recently, by the even more sensitive method of contrast-enhanced sonography. Diagnostic puncture may be performed with a high success rate or the tumor may be ablated therapeutically, if advisable. Atelectatic or pneumonia-affected parts of peripheral lung consolidations may be differentiated from tumors by color-Doppler sonography or contrast-enhanced sonography (fewer motion artifacts) (Wang et al. 1995; Yang 1996; Zimmermann et al. 2003; Görg et al. 2006; Cao et al. 2011; [Fig. 10.2](#)).

Sonography-guided percutaneous puncture also has its limitations, however. If the space-occupying mass is hardly or not at all visible percutaneously on sonography (Lesions < 1 cm), or if the puncture channel is not safe, other endoluminal procedures (bronchoscopy, endoluminal sonography) may be used or a computer-assisted puncture may be performed (Klose and Günther 1996; Mikloweit et al. 1991; Anzidei et al. 2017; [Fig. 10.3](#)).

In principle, the interventional procedure constituting the fastest means of arriving at the diagnosis and placing the least stress on the patient should be used.

The advantages of sonography-guided punctures are as follows:

1. The method can be carried out quickly and at the bedside (portable US-devices).
2. There is no exposure of radiation to patients, assisting personnel or physicians.
3. The direction of puncture may be chosen freely, and the needle monitored continuously.
4. Nerves (plexus in the upper thoracic aperture), vessels (color-Doppler sonography), and the ventilated lung are spared (lower rate of pneumothorax).
5. Active tumor parts (color-Doppler sonography, contrast-enhanced sonography) may be punctured with a higher success rate.
6. Lung tumors may be differentiated from areas of pneumonia or atelectasis by color-Doppler sonography and contrast-enhanced sonography (fewer motion artifacts).
7. It is a low-cost procedure, and it may often be performed on an outpatient basis.

!

» In US you see what you do, in CT you see what you have done—(Heilo 1996).

Fig. 10.2 Tumor inside an atelectasis. Computed tomography: obstruction atelectasis, cause not discernable. Bronchoscopy: no tumor found. **a** On B-mode sonography extensive atelectasis with a slightly

conspicuous focal structural change (*arrow*). **b** In the area of structural irregularity there is no recognizable “normal” vessel architecture. **c** Space-occupying mass with little contrast on signal-enhanced sonography

Fig. 10.3 Transesophageal puncture. **a** Longitudinal probe with puncture unit (Hitachi). **b** Paraesophageal hypoechoic tumor mass in the dorsal mediastinum. The puncture needle is easily recognizable (*arrows*). Cytology indicated small-cell bronchial carcinoma

10.5 Apparatus, Instruments and Puncture Technique

For lesions of the chest wall, the investigator should use high-frequency linear probes. Lesions in the pleural space and lung should be investigated with sector-like probes equipped with a narrow covering. For endosonography-

guided puncture, special intraluminal probes with biopsy canals are available (Kelbel et al. 1996; Jennsen et al. 2014)

The puncture needle can be guided in many ways (■ Fig. 10.4). A simple and economical method is so-called free puncture. Ninety percent of interventions are performed by the free-hand technique under sonographic visual control.

■ **Fig. 10.4** Various puncture methods. **a, b** Free puncture. **a** Free-hand puncture after sonographic location. Inexpensive two-step method (no visual surveillance of the target area during the puncture). Very suitable for small processes located on the surface. **b** Puncture under sonographic observation. Low cost, puncture route variable, so punctures are possible from various areas, needle well visible, difficult with small processes located on the surface. Sterile gloves should be used for therapeutic procedures. **c, d** Guided puncture.

c Ultrasound puncture probe. Expensive, puncture route not very variable, limited imaging through the perforation region, needle not easily visible, good view at close range. Seldom necessary for punctures of the thorax. **d** Sector/curved array scanner with attachment. Relatively cheap, needle is easily visible, but poor view at close range, puncture route prescribed but can be superimposed electronically, disinfection of the attachment necessary. Not sensible on the thorax

10.5.1 Puncture Needles

A distinction is made between fine (diameter less than 1 mm) and gross (diameter more than 1 mm) needles (■ Fig. 10.5). The rate of complications increases with the thickness of the needle and the duration of the procedure. The ideal puncture needle should fulfill the following criteria: it should be as thin as possible, sufficiently stiff to maintain the direction of puncture, cut sharply, be such that it can be advanced forward fast and be able to obtain sufficient material for investigation (Weiss and Düntsch 1996; Westcott 1980). ■ Table 10.2 compares different classifications of needle diameters.

10.5.1.1 Fine Needles

For aspiration cytology, fine needles with a diameter of 0.7–0.9 mm are sufficient. They are available with and without a mandrin and have no cutting tip (economical injection needles, spinal puncture needles and Chiba needles).

Mandrins are usually not necessary, but their use is advisable if the pathway for puncture is long (through

pulmonary tissue, for instance), because the needle bends less and there is no danger of abrading tissue outside the region to be punctured. A needle diameter of 0.7–0.9 mm is sufficient for cytological or bacteriological examination. If the liquid which needs to be aspirated is highly viscous (pus, blood), needles of a larger diameter must be chosen (1–2 mm maximum).

The puncture technique is as follows. Once the target of puncture has been reached, the puncture is performed, if possible, in a fan-like fashion under suction, in order to collect tissue from different areas (■ Fig. 10.6). With smaller tumors (less than 2 cm), it is often only possible to aim in one direction. In this case, turning the needle shaft may be helpful in collecting a tissue sample.

During forward and backward movement, cells are peeled off and aspirated into the tube. No suction should be applied during backward movement, so that material is not sucked into the syringe and dissemination of tumor tissue into the puncture canal is avoided.

A cytological slide is prepared by injecting the material collected onto the middle of the slide with high

■ Fig. 10.5 Puncture needles. **a** Coarse needles. *A* Tru-Cut needle, diameter 1.4–2 mm. *B* Menghini needle, diameter 1.6 mm. *C* Bone punch needle (Angiomed). *D* Aspiration needle for viscous liquids, diameter 2.0 mm. **b** Fine needles. *E* Vaku-Cut needle based on Köhler (Angiomed). When the puncture destination has been reached, the stylet is withdrawn three quarters of its length to create a partial vacuum. Diameter 0.8–1.2 mm. *F* Sonocan biopsy needle (Braun, Melsungen, Germany), diameter 0.8–1.4 mm, length 100–160 mm. Puncture technique as for the Otto needle, but without any rotating movement. *G* Cutting biopsy needle based on the Otto needle with a mandrin (Angiomed), diameter 0.8–1.2 mm, length 100–200 mm. *H* Chiba needle with a mandrin, diameter 0.6–0.9 mm. *I* Lumbar puncture cannula with a mandrin, diameter 0.9 mm. *J* Puncture cannula with no mandrin, diameter 0.7 mm

pressure. With use of a second slide, the material is spread with slight pressure and then, according to the agreement with the “house pathologist,” fixated with alcohol (fixating spray, Merckofix, for instance) or air-dried. It is necessary to immediately scan the material under a microscope in order to make sure that there are enough cells for evaluation, so that a repeat puncture may be performed in the same session, which is necessary in one third of patients with suspected tumors. Bacteriological slides are made with Gram stain and bacteriological cultures started. If tuberculosis is suspected, special examinations are instigated (cultures, PCR, etc.)

The material obtained by this procedure usually only allows a cytological investigation which distinguishes between malignant and benign disease; it does not permit the investigator to determine the type of malignant lesion (e.g., lymphomas). If a quick diagnosis is needed and the proof of malignancy is sufficient, cytology is preferable at least as a first step. Zum Nachweis eines Lungenkarzinoms ist sie der Schneidbiopsie sogar überlegen und sicherer (Diacon et al. 2007). Recent immunocytological techniques with specially coated slides have improved results, but determining the type of many malignant changes (lymphomas, for instance) is usually not possible, so examinations of histological material become necessary. Immunohistological techniques have also distinctly improved the results of cut biopsies (Müller and Blank 2011).

Possible mistakes in puncture cytology are:

1. Insufficient puncture technique
2. Little or useless material (possibly repuncture)
3. Aspiration of blood
4. False technique of slide preparation or fixation procedure
5. Little experience in cytology

10.5.1.2 Cutting Biopsy Needles

Tissue cylinders for histological assessment can be obtained with these needles. One-hand needles are useful, as *one* investigator performs the sonographic investigation and the puncture. Automatic one-hand needles (so-called puncture guns) are especially suitable in the thorax, as the procedure of puncture is fast, does not require the investigator to avoid the lung, and very representative puncture cylinders can be punched out from soft tissue (Fig. 10.7). The results of puncture are better and the complication rate is lower—especially the rate of pneumothorax. In the case of hard tumors or tumors of the bony skeleton, the spring pressure of the automatic needle is often not sufficient to penetrate the tumor.

Disadvantages are the cumbersome procedure and the absence of the sensation of performing a puncture (Mathis 1997b).

In the meantime, there are a variety of equivalent needles available on the market. It is sensible to familiarize oneself with *one or two* needle types. Three needle techniques can be differentiated:

1. *Tru-Cut principle*: The True-Cut needle contains a biopsy chamber, securing the cylinder which has been cut. A disadvantage is that the volume of the tissue particle is thinner in comparison with the needle diameter and also is only half-cylindrical.
2. *Surecut principle*: The cutting process happens through a quick forward movement of the needle. On retraction, the tissue cylinder is held within the cylinder by suction. If the negative pressure fails, the tissue cylinder may be lost (Fig. 10.8).

Fig. 10.7 **a** Automatic single-hand needle. The required depth of injection (measured sonographically) can be preset. *Top*: Auto-Vac puncture, disposable set (Bard). *Middle*: Reusable pistol from Barth with insertable Tru-Cut needles. The Tru-Cut needle contains a biopsy chamber. An advantage is that the cut cylinder of tissue can-

not be lost when the needle is withdrawn. A disadvantage is the short tissue cylinder. *Bottom*: BioPince—biopsy pistol (Pflugbeil-Amedic). The full tissue cylinder is secured inside the needle by a special holding wire. **b** Surecut needle (*top*), Tru-Cut needle (*middle*) and BioPince needle (*bottom*)

10

Fig. 10.8 **a** Pleural drainage set (trocar technique). *A* Thin (12-Fr) pneumo-catheter (Intra). *B* Trocar catheter (Argyle). **b** Navarre universal draining catheter (Bard—Angiomed 8–12 Fr). This catheter has

many advantages: direct puncture only requires a small incision, introduction is possible without preceding dilatation, it does not kink, the lumen rarely occludes and the pig-tail prevents dislocation

3. *BioPince principle*: Similar to the Surecut principle, complete cylinders are cut, thus yielding large tissue volumes (needle diameter 1.2 mm), producing better histological results. The needle combines the advantages of both principles mentioned above. A special “fixation wire” which gets propelled within the needle after the puncture procedure secures the tissue cylinder. Tumor seeding is very unlikely with this method (■ Fig. 10.7).

10.5.1.3 Gross Needles

Gross needles (1.2–2 mm) are usually only needed for aspiration of highly viscous fluid. For histological differentiation of benign lesions of the thoracic wall, pleu-

ral affections or interstitial pulmonary disease, True-Cut needles of a large size might be necessary (Gleeson et al. 1990; Ikezoe et al. 1990; ■ Fig. 10.7).

10.5.2 Drainage Catheter

The diameter of the selected catheter depends on the viscosity of the liquid formation. In principle, drainage may be performed using the trocar or Seldinger’s technique. *The trocar technique* is commonly used in the thorax (■ Fig. 10.8). Both drainage techniques are preceded by diagnostic puncture (■ Fig. 10.9).

Fig. 10.9 Empyema of the pleura. **a–c** Pleural drainage. Outline of the technique. **d** On diagnostic puncture, the puncture needle (*large arrows*) is inserted in an upward direction at the upper edge of the rib. After instillation of liquid, an echogenic cloud shows up at the tip of the needle. *X* empyema. **e** On insertion, the trocar is visible

as a straight echogenic reflex, partly producing acoustic shadowing (*arrows*). *X* empyema, *PL* parietal pleura. **f** After removal of the trocar, the soft draining tube (double reflex) is more difficult to recognize because of its winding course

10.5.3 Checking the Position of the Needle and the Catheter

Correct placement of the needle is not demonstrated by sonography alone. Moreover, the “sensation of puncture” usually changes when the target of puncture is reached. Depending on the situation, resistance is noticeable. The feeling of hitting something hard suggests a malignant tumor. The absence of any palpable sensation when cutting a cylinder is one of the few disadvantages of using a “puncture pistol.” Optical visualization of the needle depends on the angle of the needle and the ultrasound beam. Ideally, when a needle is intro-

duced at the level of the transducer, the needle shaft is seen as an echogenic double reflex. However, in deeper lesions, only the tip of the needle is seen as a bright double reflex (■ Fig. 10.10b). A compromise must be found between demonstrability of the needle (better with a larger angle) and targeting precision (better with a smaller angle). The choice of the points of approach is often limited in the thorax by the anatomy.

In tissue with high echodensity it may be difficult to localize the needle. Here, it is useful to move the needle or the mandrin backward and forward and even to employ brief suction. Color-Doppler sonography will show the needle as a colored line (■ Fig. 10.11). When

■ Fig. 10.10 a The needle shaft can be depicted at a great angle (45–90°) as an echogenous, straight-line reflex (arrows). The needle tip appears as an echogenic double reflex (arrow far from the sound head), but only if the needle is being guided correctly at the sound level. Crosses encapsulated pleural empyema. b Echogenic double reflex of

the needle tip: double reflex is indicated by the arrow far from the sound head. As is so often the case, the puncture was not possible exactly at the insonation level. The needle shaft could only be indicated by wobbling movements (arrow close to the sound head). Hypoechoic tumor on the thoracic wall. Peripheral bronchial carcinoma (squamous cell)

■ Fig. 10.11 a Color-Doppler sonography allows liquid movements in the needle to be detected. The exit of the liquid at the tip of the needle can be seen as a cloud of color. b Tissue shifts in the

region of the needle tip (slight movement of the needle, or caused by suction) can also be detected by color-Doppler sonography (power Doppler). Crosses peripheral bronchial carcinoma

a gun is used, the incision canal (air) is visible even several seconds after the puncture.

A drainage catheter is typically visualized as a bright double contour, which might not show up the whole way, however. On color-Doppler sonography, the course of the catheter during instillation of fluid is clearly depicted by color-coding (Wang et al. 1995). If both techniques failed the correct positioning of the catheter can be checked by the injection of NaCl 0.9%, mixed with a drop of SonoVue® (ultrasound contrast agent)

The coordination between the ultrasound probe and the needle tip works best if carried out as “one person— one hand puncture.” Visualization of the spatial relations is better and necessary corrections in the position of the needle tip can be performed more quickly.

» The inexperienced investigator should practice on models, e.g., on a steak interlarded with olives, or in a water bath or on puncture models commercially available (Mathis et al. 1999). Cheap puncture models for ultrasound-controlled drainage can be manufactured in homemade—(Mohr et al. 2014)

10.5.4 Hygiene, Preparation and Execution of Puncture

Most diagnostic puncture and draining procedures (of pleural effusions, for instance) may be performed on an outpatient basis. In principle, interventional procedures may be carried out in any room (emergency rooms, normal wards, intensive care wards), provided daily disinfection measures are guaranteed. Transportable ultrasound machines may be advantageous (Blank et al. 2014; Müller et al. 2018).

According to the recommendations of the Commission for Hospital Hygiene and Infection Prevention of the Robert Koch Institute (RKI 2011), the risk of a puncture-associated infection depends on the type and anatomical region of the intervention, the patient's defensive position and the experience of the person performing the puncture

Special puncturing equipment should be available: syringes, cannulas, puncture needles, drainage sets, gloves, disinfection spray, local anesthetics, sterile draping material and containers for further diagnostic processing (microbiological, chemical, cytological and histological examination) of the material obtained (Müller et al. 2018).

Coagulation status should be known (except in the case of lesions of the thoracic wall. (Tbl.1)

In an emergency case, the risk must be calculated individually.

As with any invasive procedure, the patient must be informed of the course and risk of the procedure. The sonographical status of the thorax is evaluated. Utilizing other imaging methods (plain chest radiograph, CT), the puncture goal, the site of puncture needle placement, puncture direction and puncture pathway are determined (the four P's).

The nonsterile ultrasound gel is removed. In cases of diagnostic puncture the investigator should use sterile gloves, local disinfectant spray and sterile catheter gel if necessary. The patient is positioned such that the focus is optimally accessible in a sitting, dorsal, lateral or ventral decubitus position. Local anesthesia is only required in cases of multiple puncture or needles with a thick lumen though many patients opt for it.

During the puncture the patient must be asked to briefly hold his/her breath.

In the case of simple therapeutic interventions (thoracocentesis), no special hygiene measures are necessary. Sterile covers for the probe and keyboard are mandatory (Müller et al. 2018).

Interventional Procedures of the Thorax— Preparation and Performance

1. Preparation

- (a) Acknowledging preexisting findings (bronchoscopy, chest radiograph, CT).
- (b) Sonographic thorax status.
- (c) Verifying the indication for puncture.
- (d) Is a sonography-guided intervention technically feasible?
- (e) Are there contraindications for an intervention?
- (f) Has the patient received prophylactic antibiotic treatment (especially in the case of an abscess)?
- (g) Have information about the procedure and written consent by the patient obtained?
- (h) Cytology or histology?
- (i) Selection of puncture equipment (needle, drainage).

2. Performance of intervention

- (a) Positioning the patient (sitting, dorsal, lateral or ventral decubitus position).
- (b) Visualization of the goal of puncture, the pathway and direction.
- (c) Disinfection and local anesthesia, if wanted.

3. Follow-up

- (a) For outpatients
 - Three hours of surveillance after intervention.
 - Sonographical check before discharge of patient (pneumothorax? bleeding?).
 - Preliminary report for referring doctor.
 - Final evaluation of the procedure.

- Immediate return to the hospital in case of symptoms.
 - Decision on who informs about the result and when.
- (b) For inpatients
- Preliminary report for doctor in charge.
 - Instructions for nursing personnel (checkup examinations, suction for drainage, etc.).
 - Sonographic reevaluation after 3 h (pneumothorax?, bleeding?).
 - Checkup examinations after therapeutic punctures and drainage.
 - Possibly repuncture in cases of inconclusive result.

Sonographically Guided Interventions— Conditions for Achieving Good Results

1. Careful formulation of indication (clinical experience).
2. Experience in sonography and puncturing.
3. Knowledge of possible complications and limitations of the method.
4. Quality of and preparation of material obtained.
5. Experience of the pathologist (immunohistology) and microbiologist.
6. Interdisciplinary cooperation.

10.6 Indications

10.6.1 Processes of the Chest Wall

Soft-tissue tumors should be punctured parallel to the surface of the lung as far as possible. The needle can then be (at a suitable angle) nearly completely imaged in its length and the risk of pneumothorax is minimized (■ Fig. 10.12).

Needles with a large caliber may be used for this technique (1.4–2 mm). By doing so, even benign lesions are better differentiated (Gleeson et al. 1990; Bradley and Metreweli 1991; Siström 1997).

Postoperative accumulation of fluid is treated by multiple puncture or, if necessary, with drainage.

Pathological processes of the bony skeleton are a domain of computer-assisted puncture, if the cortical bone is still intact. Frequently, diseases lead to defects in the cortical bone and may consequently be visualized well by sonography and also punctured (■ Fig. 10.13). Fine-needle aspiration puncture is usually sufficient for differentiation of inflammation/malignoma and carries a success rate of 88–100%. If plasmocytoma is suspected, puncture is always preferable to cut biopsy, because diagnosis is easier from a slide preparation. For typification of a malignoma, a cut biopsy might be preferred in some cases.

Before puncturing tumors of the upper thoracic aperture, the nerve cords (brachial plexus) and vessels (color-Doppler sonography) should be identified in order to avoid injury to these structures (Vogel 1993; Civardi et al. 1994; Blank 1995, 2007) (■ Fig. 10.14).

10.6.2 Pleural Cavity

10.6.2.1 Thoracentesis

In cases of large quantities of effusion, sonography helps to establish the extent of the effusion and mark the site of puncture in the optimal intercostal space. The puncture is then performed on the ward (Reuß 1996). In cases of complex effusions (small, loculated, encapsulated, inconvenient location), the puncture is safer when performed under continuous sonographic visual control (■ Figs. 10.12 and 10.15). By doing so, the rate of pneumothorax is markedly reduced (less than 1%). The success rate is 97% (O'Moore et al. 1987; Wang and Doelken

■ Fig. 10.12 a Classic puncture technique, upper thoracic aperture. b Classic puncture technique. Metastasis of the thoracic wall. The needle shaft (arrows) can be delineated very well at this favorable angle

Fig. 10.13 a Destroyed rib (R). Echo-free “soft tissue tumor” (TU). Color-Doppler sonography allows vessels to be depicted in the destroyed rib and in the surrounding soft tissue tumor. PL pleura. b

c Fine-needle puncture of the soft-tissue tumor. The tip of the needle can be seen as an echogenic double reflex (arrow). Cytology indicated plasmocytoma. c Classic puncture technique

Fig. 10.14 Septated pleural effusion. Primary diagnostic puncture disclosing an encapsulated empyema (arrow). The secondary step involved pleura drainage. D diaphragm

2009). Unsuccessful punctures can be avoided when “the fluid color sign” is demonstrated (Wu et al. 1995; **Fig. 10.15**). Synthetic indwelling catheters should be given preference over metal ones because of the risk of injury to the lung from metal.

After application of local anesthesia, the synthetic tube is pushed forward at the upper margin of the rib (in order to avoid injury of the nerve-vessel bundles running along the lower edge of the ribs) upward to the pleura with a mandrin (Abbocath; Abbott, Abbott Park III). Entry into the pleura is marked by a mild increase in resistance. The mandrin is then removed. In a closed system, special pleural drainage sets can be used to perform manual aspiration.

Uncomplicated pleural effusions in the presence of cardiac failure, pneumonia and even small pneumothorax after puncture can be treated with thoracocentesis.

Malignant pleural effusions, accumulation of pus or blood should be treated with a drain because of the risk of septation (Müller and Blank 2011)

The success rate of cytology in malignant effusions is no more than 50–75% (Gartmann 1988). In tuberculous effusions, pathogens are demonstrated in only 20–40% of cases (Vladutiu 1986).

Fig. 10.15 **a** B-mode sonography for a differential diagnosis of an encapsulated effusion or fresh rind. *PL* visceral pleura. **b** Power Doppler demonstrates advanced vascularization with high-caliber vessels. Fresh pleural rind

10.6.2.2 Pleura Biopsy

Since even the classic pleural blind biopsy according to Abrams or Ramell has an accuracy of no more than 50% in malignant effusions, video-assisted thoracoscopy is being used more and more. Sonography-guided pleural biopsy is one alternative. The procedure has only been used in a very small number of cases so far, however (Mueller et al. 1988). As an alternative, automatic single-hand needles (BioPince needle, for instance) may be used successfully (sensitivity 70–80%, specificity 100%) (Chu et al. 1994; Heilo 1996). Fine-needle aspiration biopsy of tissue taken from a pleural thickening is of no value and is even hazardous (danger of bleeding). It may only be employed in the presence of focal lesions (Mathis et al. 1999).

10.6.2.3 Percutaneous Pleural Drainage

Given the appropriate indication, malignant, hemorrhagic and inflammatory pleural effusions may normally be treated with a sonography-guided pleural drain quickly, safely and successfully. Only rarely CT-guided puncture is necessary if the approach is difficult. Thin catheters (8–14 Fr, Pleurocat, for instance) are sufficient (Fysh et al. 2010; Davies et al. 2011). These thin catheters are tolerated better by most patients than thick catheters traditionally used in many hospitals. Their success rate is equivalent, and they carry a much lower complication rate. Puncture is usually performed with the trocar technique. The catheter should be placed in the lowest possible part of the pleural cavity.

Parapneumonic fluid collections should be drained soon in cases of septum formation and a pH level below 7.2. A drain should be left in place for 5–10 days, depending on the extent of inflammation (Kolditz and Höffken 2008).

In cases of malignant effusions, catheters with a narrow lumen (7–12 Fr, e.g., Pleurocat, Plastimed), will suffice. The puncture is usually performed using the trocar

Fig. 10.16 An 80-year-old patient, whose temperature rose rapidly a few days after a fall which injured the left side of the thorax. X-ray image reveals a shadow located on the thoracic wall, suggestive of a fractured rib. Sonographic mass with infiltration into the thoracic wall. Minor liquid movements were perceptible during the dynamic examination. The diagnostic puncture was not successful until a coarse needle (with a diameter of 2 mm) was used. It proved possible to extract highly viscous pus. A pleural drainage was then inserted. *Arrows* needle shaft

technique. The catheter is placed in the lowest part of the pleural cavity.

Early diagnostic verification of a pleural empyema is important, as percutaneous therapy is only successful (success rate, 72–88%) in the acute phase (weeks 1–4) (Klose and Günther 1996; Müller and Blank 2011; **Fig. 10.9, 10.16, and 10.19**). The success of drainage in the presence of septation can be markedly improved by the instillation of urokinase (50–100,000 IU/treatment) (Sistrom 1997).

The correct positioning of the catheter can be checked by the injection of NaCl 0.9%, mixed with a drop of SonoVue® (ultrasound contrast agent). This “off label” use has its advantages: it is possible to identify incorrect drainage and dislocations; septic developments and, as a result, insufficient drainage show up through the missing diffusion of the contrast medium in the pleural space (Heinzmann et al. 2012) (■ Fig. 10.17). In the case of therapy resistant effusions the drainage with a tunneled catheter could be appropriate.

■ Pleurodesis

Malignant effusions are prone to build septa under recurrent thoracocentesis. It is therefore wise to proceed a early drainage treatment. Possibly. After the complete and possibly fractional emptying of the effusion (portions not to exceed 1.5 L) and the administering of a

■ Fig. 10.17 The contrast medium spreads through the entire pleural space

■ Fig. 10.18 **a** Several small peripheral lung tumors (maximum diameter 18 mm) located on the thoracic wall. Delicate pleural effusion. Fine-needle aspiration cytology indicated small-cell bronchial carcinoma. **b** Large mass, left dorsobasal location (crosses), alongside

topical anesthetic follows the instillation of sclerosing substances, 4–5 g Talc mixed with 50 ml NaCl seems to be the most efficient; Bleomycin is an alternative (Roberts et al. 2011). Pleurodesis obtained by thoracoscopy is all the more effective (Tan et al. 2006).

10.6.3 Lung Consolidations

Peripheral pulmonary lesions may be visualized sonographically if they are situated in a favorable topographical position. They may be punctured if they reach the visceral pleura or if a poststenotic atelectasis or pneumonia provides an acoustic window.

At the time of diagnosis, two thirds of lung carcinomas are no longer curable by surgery. The histological type must be determined before palliative therapeutic measures are employed. In the diagnosis of the peripheral lung tumor, sonography-guided puncture is markedly superior to bronchoscopy, much easier and faster to perform than radiography or even computer-assisted percutaneous biopsy, and devoid of radiation (Chandresakar et al. 1976; Börner 1986; O’Moore et al. 1987; Hsu et al. 1996; Diacon et al. 2004a, b; ■ Fig. 10.18).

Peripheral tumors larger than 3 cm in size should be diagnosed by fine-needle cut-biopsy (histology) (Mathis and Gehmacher 1999; Schubert et al. 2005). Peripheral tumors smaller than 3 cm in size can be better diagnosed by fine-needle aspiration cytology (Sistrom 1997). Biopsy is not always sufficient (accuracy 70%) to distinguish benign tumors. Wedge resections obtained by thoracoscopy are given preference in many cases (Beckh and Böleskei 1997).

the diaphragm and also the descending aorta (AO). A dissecting aortic aneurysm had been identified in this patient 4 years earlier. Arrow dissection membrane. Fine-needle incision biopsy (Sonocan needle, 0.9 mm in diameter). Histology indicated squamous cell carcinoma

■ Special Puncture Technique

A safe pathway for puncture circumventing the ventilated lung is an important prerequisite of avoiding pneumothorax. Larger tumors may be punctured in the classical way. The needle is inserted at the level of the ultrasound probe. The needle tip is pushed toward the parietal pleura under continuous sonographic observation. While the patient holds his/her breath, the lesion is punctured in such a way that the needle does not reach the ventilated lung. To achieve this, the puncture depth is measured beforehand and marked on the needle in the case of using an automatic one-hand needle.

Small (less than 1-cm) tumors located in the periphery may also be punctured if expertise is sufficient. Puncture technique must be adjusted to the individual type of lesion. Similar to puncture of the thyroid, atypical puncture is often necessary (Blank 2007). The tip of the needle must be inserted through the skin almost vertically, near the middle of and parallel to the probe, which has as little contact with the skin as possible. By tilting the probe in a plane vertical to the plane of the probe, one can identify the needle tip inside the thoracic wall, push it toward the pleura and insert it into the lesion under observation. Visualization of the needle tip is facilitated by moving it back and forth abruptly.

Alternatively, small lesions may be punctured “from memory” after marking the intended site of puncture with a ballpoint pen, for instance (small ring pressed into the skin). The results are no worse in the hands of experienced examiners.

If a small perforated ultrasound probe is available, this may also be used for a successful puncture.

■ Pneumonia and Pulmonary Abscesses

The cause of consolidation of sections of the lung may be difficult to classify in immunosuppressed patients, especially. Aspiration puncture or cut biopsies of the areas with consecutive microbiological, cytological and histological examination of the material obtained allow a diagnosis in up to 93% of cases (Yang et al. 1985).

Even small pulmonary abscess that escape detection on the radiograph can be imaged by sonography (6–7 mm) (Kolditz and Höffken 2008). If antibiotic therapy does not yield the desired result (75–90% success rate), fluid may be aspirated from the region of the abscess under sonographic guidance. By this means, the pathogen can be isolated in about 65–93% of cases (Gehmacher

et al. 1986; Yang et al. 1992). If therapy continues to fail, a lung abscess drainage may be performed under sonographic guidance but this is rarely necessary (Sonnenberg et al. 1991; Klein et al. 1995; ■ Fig. 10.19). The risk of bronchopleural fistula formation is minimized when the investigator uses the shortest access and traverses solid, homogeneous, infiltrated or atelectatic tissue (Mathis and Gehmacher 1999; Wali et al. 2002).

10.6.4 Mediastinum

Few space-occupying masses in the mediastinum (retrosternal goiter, cyst, aneurysm, thrombosis) can be reliably classified on the basis of characteristic sonographic features. An investigation of fine tissue is needed in order to determine the cause of the lesion. Gentle removal of tissue without causing a large defect is very important in the diagnosis of space-occupying masses that can be removed by surgery. Therefore, puncture under image guidance should be the first procedure. When this is done, space-occupying masses in the mediastinum can be easily punctured from a suprasternal or parasternal approach under sonographic guidance (Nordenstrom 1967; Rubens et al. 1997; Koegelenbug et al. 2009). The accuracy is 54–100%, and the rate of complications is 0–4% (Dogan et al. 2019). Vessels should be avoided (Color-Doppler Sonography) (Blank et al. 1996; ■ Figs. 10.20, 10.21, and 10.22). In cases of superficial lesions (thymomas, lymphomas), gross needles are given preference. With use of a needle with a thick lumen, correct histological classification is achieved in up to 93% of cases and the rate of complications is only slightly higher, at less than 1% (■ Fig. 10.23). In our experience, a needle diameter of 1.2 mm (BioPince needle) is normally sufficient.

In contrast to radiographic or CT-guided puncture (10–44%), pneumothorax is rarely encountered (Yang et al. 1992; Heilo 1993, 1996; Schuler et al. 1995; Gupta et al. 1998; Koegelenberg et al. 2011; Marchevsky et al. 2011).

In recent years, endosonographic transesophageal-guided puncture has also been used successfully. It is a good complement to percutaneous puncture, as lesions in the anterior mediastinum are not easily accessed, in contrast to those in the posterior and lower mediastinum (Schlotterbeck et al. 1997; Pedersen et al. 1996; Hünner et al. 1998; Janssen et al. 1998, 2014).

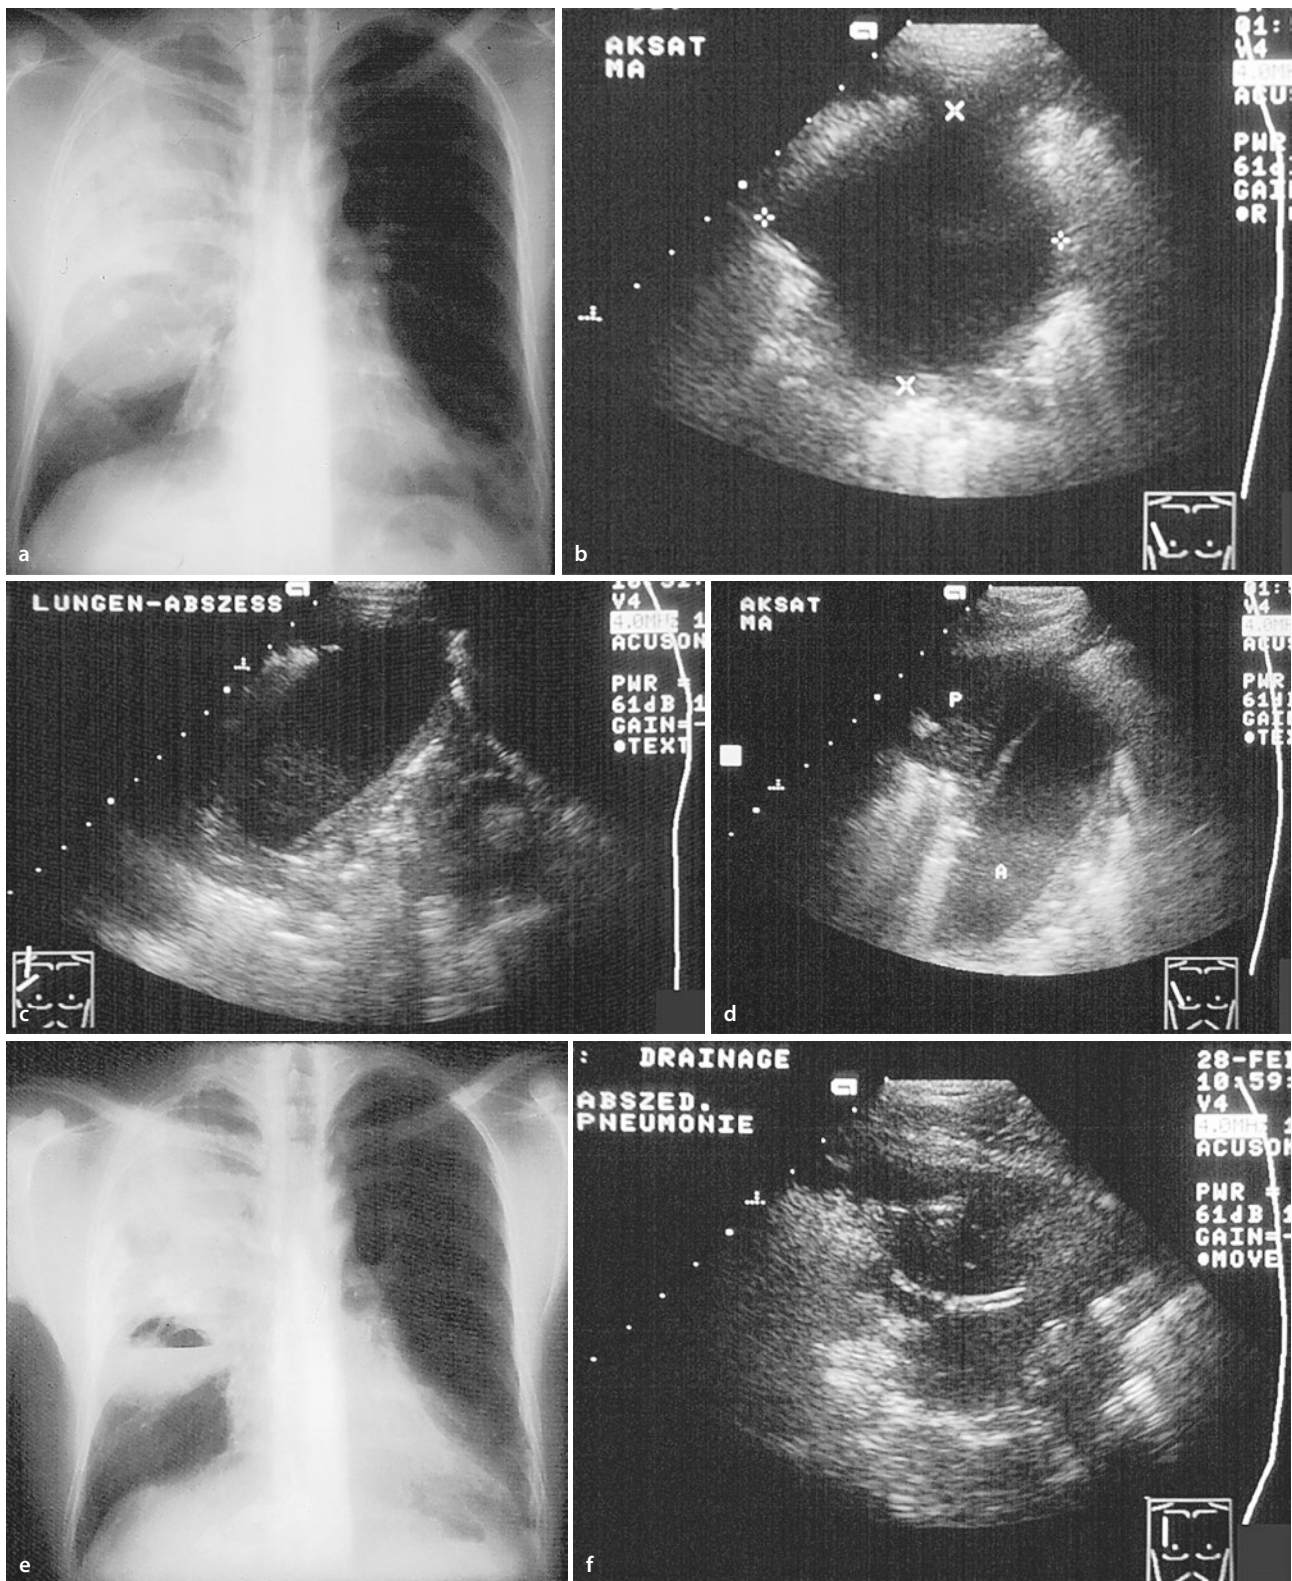

Fig. 10.19 Lung abscess with drainage. Young man with community-acquired pneumonia not responding to standard antibiotic therapy. Continuing high temperatures and respiratory deterioration. **a** On chest X-ray, extensive infiltration of the right upper lobe of the lung. **b** Sonography clearly demonstrates abscess formation. **c** Next to the abscess (*A*), pneumonic consolidation (*P*) is visible. If

this does not contain air, puncture passing through this section would be feasible. The abscess is encapsulated by a membrane. **d** The shortest pathway for transthoracic puncture is chosen, and pus can be aspirated through the needle. **e** Abscess formation on chest X-ray. **f** The abscess is drained by a suction-rinse-drainage (echogenic double lumen) over 4 days. Quick recovery ensues

Fig. 10.20 a Mediastinal tumor. Parasternal plumb line in the right lateral position. Hypoechoic, indistinctly delineated mass (located in the color window). Color-Doppler sonography in

“power” mode shows the mammary vessels located parasternally, b which have to be avoided during a punch biopsy

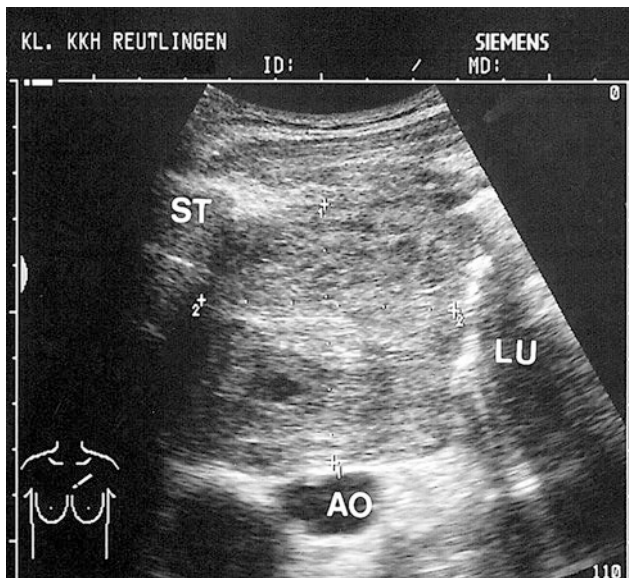

Fig. 10.21 A large mediastinal mass was discovered primarily by sonography, located parasternally on the left, in a 19-year-old patient during emergency treatment connected with a superior vena cava syndrome. A punch biopsy was performed immediately (Sonocan needle, 1.2-mm diameter). Histologically, a highly malignant non-Hodgkin lymphoma was diagnosed. *ST* sternum, *LU* lung, *AO* descending aorta

Fig. 10.22 Paravertebral abscess in a case of spondylodiscitis. At first, open surgical drainage of the spondylodiscitis was performed, followed by endosonographically guided nasal/transesophageal

drainage used for rinsing with isotonic saline. **a** Space-occupying mass located next to the spine and the aorta. **b** Insertion of drain

Fig. 10.23 **a** A blood clot (*arrow*) as a complication following a diagnostic puncture of a pleural effusion. *PL* parietal pleura, *L* compressed lung, *D* diaphragm. **b** Pneumothorax was excluded by showing the sliding sign of the pleura. **c** Color-Doppler sonography in “power” mode allowed the respiration-dependent sliding sign to be docu-

mented in an impressive way even in the static image. The repeat echoes that could be demonstrated with B-mode sonography (artifact) dorsal to the pulmonary surface show up accordingly as a color artifact. This cannot be demonstrated in cases of pneumothorax

10.7 Risks

Sonography-guided puncture has a low rate of complications. The rate of pneumothorax is 2–4.4%, only 1% require drainage. Hemorrhage or hemoptysis is observed in up to 2.8%. Data concerning air embolism or even death are not available so far (Mathis et al. 1999; Weiss and Düntsch 1996; Tombesi et al. 2009; Di Bardino et al. 2015). Tumor dissemination through the procedure of puncture (vaccine metastases) is of little clinical significance and very rare, in less than 0.003% of cases. In cases of malignant pleural mesothelioma, it is slightly more common. When surgery is performed, the site of puncture is also resected (Bydder et al. 2004).

10.7.1 Pneumothorax After Puncture

If the focus is no longer visible after the puncture, the likelihood of a pneumothorax is high. This can be reliably detected by sonography, through the absence of respiration-dependent gliding movement of the pleura sensitiver als in der Thoraxübersichtsaufnahme erkennbar (Sensitivität 90–100%; Abb. 10.24b, c; Blank 1994; Herth et al. 2004; Reissig and Kroegel 2005; Volpicelli et al. 2012;  Fig. 10.23).

The quantity of free air can only be measured by obtaining a chest radiograph. A pneumothorax usually reaches its maximum dimensions after 3 h, so the decision regarding a therapeutic procedure is made thereafter, when the pneumothorax is small. If the patient is symptomatic or if a larger volume is present, the patient is initially given protracted thoracocentesis. The success rate within the first 10 h is 90% (Klose and Günther 1996). In the event of renewed collapse, the clinician should use a percutaneous drain and a catheter with a small lumen.

A routine chest radiograph is not required after sonography-guided puncture.

Summary

Provided the indication is established with care, interventional measures in the thorax are very successful. The rate of complications is low when the procedure is performed by trained therapists.

» **The basic principle to be applied is: “try ultrasound first” (Sistrom 1997).**

10.8 List of Materials

Sterican. Disposable injection cannula, size 1 (G 20/0.9 × 40/80 mm). B. Braun Melsungen AG, 34209 Melsungen, Germany

BioPince. Disposable full-cylinder biopsy pistol (G 18/1.2 × 100/150 mm). Inter. V, Gainesville, FL 32608 USA. Distributor Peter Pflugbeil GmbH, Georg-Wimmer-Ring 21, 85604 Zorneding, Germany, Fax: +44-8106-241333, email: info@pflugbeil.com, Internet: <http://www.pflugbeil.com>

Sonocan. Disposable set for sonography-guided full-cylinder biopsy by B. Braun Melsungen AG (G 20/0.9 × 100 mm/150 mm). Distributor Nicolai GmbH & Co. KG, Ostpassage 7, 30853 Langenhagen, Germany, Fax: +44-511-733235

Max Core Disposable biopsy pistol (G 20–16/0.9–1.2 × 100/160 mm). Bard

Magnum Core. Reusable biopsy pistol. Bard GmbH, Wachhausstrasse 6, 76227 Karlsruhe, Germany

Magnum disposable needles. (G 20–16/0.9–1.2 × 100/160 mm). Bard

Navarre universal drainage catheter with Nitinol (6–12 F × 30 cm). Bard

Universal adapter with Luer-Lock. Bard

Argyl trocar catheter (Charr 12–17/4–6 mm). Sherwood-Medical Company, Tullamore, Ireland

Argyl Sentinel Seal Thoracic drainage unit. Tyco Healthcare Company, Tullamore, Ireland

Acknowledgments I would like to express my thanks to Martin Lenz (former chief consultant surgeon in the Radiology Department of the Steinenberg Clinic, Reutlingen) for preparing and providing the radiological findings, and my son Valentin for the technical photographic work.

Technical advancements in sonography devices, which have led to the production of mobile and even portable units, have allowed rapid use of sonography at the bedside for a large number of indications (Sartori et al. 2007; Volpicelli and Fracisco 2008; Copetti and Cattarossi 2008; Lichtenstein and Mezière 2008; Reißig et al. 2009; Moore and Copel 2011; Arntfield and Millington 2012; Gardelli et al. 2012; Hyacinthe et al. 2012; Kreuter et al. 2012; Reißig and Görg 2012; Volpicelli 2013, Al Deeb et al. 2014). The transducer virtually serves as a technical extension of the palpating hand or the stethoscope. In the presence of chest diseases the cardinal symptoms are chest pain, fever and dyspnea. These symptoms may occur either separately or in combination, and thus allow the diagnostician to orient himself/herself to the situation (■ Fig. 11.1). The extent and the intensity of the individual symptoms are mainly determined by the severity of the respective disease. The great diversity of symptoms in pulmonary embolism (Goldhaber 1998) may render the diagnosis of this condition extremely difficult (► Sect. 5.3).

11.1 Chest Pain

Chest pain is a common symptom in the emergency setting as well as the outpatient setting. It is always necessary to identify the cause, and particularly the five life-threatening diseases, namely, myocardial infarction, acute dissection of the aorta, pulmonary embolism, tension pneumothorax and rupture of the esophagus (Kurz et al. 2005; Kontos et al. 2010; Arntfield and Millington 2012).

The character of pain and the findings of clinical and sonographic investigation provide information about differential diagnosis in the presence of various diseases (■ Table 11.1).

The fibers responsible for the perception of pain are located in the parietal pleura, in the aorta with its branches (■ Fig. 11.2), in the soft tissues, and the bony structures of the chest wall. The lung and the visceral pleura, on the other hand, are insensitive to stimuli that trigger pain. Pain that accompanies an inflammation in the medial portion of the diaphragm is projected into

■ Fig. 11.1 Symptoms in diseases of the chest

Table 11.1 Findings in the presence of diseases accompanied by chest pain

Diagnosis	Characteristic of pain	Findings obtained from investigation	Sonographic findings
Tension pneumothorax	Sudden onset, sharp	Vesiculotympanic resonance, no respiratory sounds, dyspnea, possibly symptoms of shock	Absent: sliding sign vertical artifacts lung pulse Present: repetitive echos Possibly lung point
Pulmonary embolism	Increased during inspiration	Pleural rales, dyspnea or fever may be present	Usually hypoechoic lesions in subpleural location; a small pleural effusion may be present
Acute dissection of the aorta	Strong pain, either in substernal location or between the shoulder blades, may radiate into the neck	Breath sounds are normal, diastolic murmur above the aortic valve may be present, symptoms of shock	Dissection of the aortic wall, dilated aorta
Myocardial infarction	Retrosternal, persistent, independent of breathing	Symptoms of shock may be present	Chest sonography is normal, diagnosis by ECG, laboratory findings, possibly echocardiography
Rupture of the esophagus	Retrosternal	Mediastinal emphysema	Not informative, diagnosis by X-ray
Chest wall processes	Local	Pain is increased on palpation or movement, fever in case of inflammation	Fracture: step formation and hematoma Abscess: hypoechoic, internal echoes Malignancy: destruction and infiltration
Pleuritis	Increased during inspiration	Pleural rales, fever; dyspnea may be present	Fragmentation of the pleural line, subpleural infiltrates, possibly pleural effusion
Pleuropneumonia	Increased during inspiration	Pleural rales, bronchial respiration, rales, fever, cough, dyspnea	“Hepatization” of lung tissue, aerobronchogram, hypervascularization, pleural effusion may be present
Pericarditis	Increased during inspiration and in relation to position	Pericardial rales, fever	A small pericardial effusion may be present; diagnosed by ECG

Fig. 11.2 A 56-year-old woman with retrosternal pain caused by a thymoma (TU) broad adjacent to the aortic wall. Diagnosis was established with sonographic biopsy and confirmed by operation

the ipsilateral shoulder and neck region (Murray and Gebhart 2005).

The ultrasound transducer is specifically targeted to the site of maximum pain, the site indicated by palpation or the physical investigation. In a physician's office, in the emergency setting (Volpicelli and Frascisco 2008; Moore and Copel 2011; Gardelli et al. 2012; Hyacinthe et al. 2012; Kreuter et al. 2012; Volpicelli 2013) or at the bedside, sonography contributes to the establishment of the diagnosis, may even provide an unequivocal diagnosis or may lead to further meaningful imaging procedures. Sonography is particularly useful to diagnose diseases of the chest in children (Kim et al. 2000).

■ **Fig. 11.3** Patient with a spontaneous pneumothorax. On high-resolution computed tomography one finds an extensive emphysematous bulla in the right upper lobe

11.1.1 Chest Pain as a Symptom of Life-Threatening Diseases

11.1.1.1 Tension Pneumothorax

Sudden onset of pain is the main characteristic of a tension pneumothorax. Depending on the magnitude of the pneumothorax, it may be accompanied by mild or excessive dyspnea. Within a very short period of time, the patient develops symptoms of shock owing to the pressure of mediastinal organs and vessels.

Sonography reveals repetitive echoes on the affected side and the absence of a gliding echogenic pleural reflex (► Chap. 3). An overview radiograph is (■ Fig. 11.19) needed to determine the depth of the pneumothorax space. High-resolution computed tomography reveals the extent and size of the emphysematous bulla (■ Fig. 11.3).

11.1.1.2 Pulmonary Embolism

A pulmonary embolism (► Sect. 5.3) is accompanied by pain on breathing when the parietal pleura is also inflamed. When the Doppler sonography investigation is extended to the leg veins in order to look for the site of thrombosis and when echocardiography is additionally performed in the case of circulatory symptoms to evaluate the right heart load, the diagnosis can be made efficiently within a short period of time (Squizzato et al. 2013; Mathis 2014).

11.1.2 Acute Dissection of the Aorta

This condition is typically accompanied by severe pain, frequently in dorsal location; maximum pain occurs between the shoulder blades. The pain may resolve for a short period of time but may also extend in the direction

■ **Fig. 11.4** Callus formation (the arrow is pointing to the fracture site) 2 weeks after a traumatic rib fracture

of dissection of vessels, for instance, in the neck when the carotid arteries are involved. Insonation from suprasternal or parasternal (► Chap. 6) permits immediate viewing of the ascending aorta, the aortic arch with the vessels connected to it, and the upper part of the descending aorta, even in the emergency setting (Arntfield and Millington 2012).

11.1.3 Pain Due to Diseases of the Chest Wall

The cardinal symptom is local pain, which is usually stronger during palpation or movement. In the case of irritated intercostal nerves or nerve roots the pain radiates into the area supplied by these nerves. The various structures of the chest wall are very well accessible to sonographic investigation (► Chap. 2).

11.1.3.1 Rib Fracture

Rib fractures are usually triggered by trauma of appropriate magnitude. In patients with osteoporosis, however, fractures may even be caused by severe coughing. Sonography reveals the formation of a step at the site of maximum pain (Wüstner et al. 2005), frequently a smaller hematoma and occasionally the so-called chimney phenomenon (► Figs. 2.13 and 2.14). Even in the presence of older fractures, the patient experiences pain, which is seen on sonography as a starting callus formation (■ Fig. 11.4).

11.1.3.2 Tumor Invasion of the Chest Wall

A peripheral lung tumor that reaches the visceral pleura causes no pain. Only when it has invaded the parietal

Fig. 11.8 A 51-year-old man with a painful swelling in the left sternoclavicular joint. Sonography reveals fragmentation of the cortical bone, which is surrounded by hypoechoic and strongly vascularized tissue. The surgical biopsy specimen yielded the diagnosis of a plasmocytoma. Clinically the patient had a solitary manifestation of a plasmocytoma which, however, was not secretory on laboratory investigation

11.2 Fever

The occurrence of fever is always an expression of inflammatory disease activity. The reasons may be numerous. On the one hand it may be a reaction of the organism to pathogens; on the other hand it may be a manifestation of pathological processes in the body, triggered without external influences. Depending on the structures of the chest affected by inflammation, the condition may be accompanied by pain. Respiratory pain is indicative of pleural involvement. The intensity of fever—for instance, it may be low in the presence of pulmonary embolism or very high in the presence of pneumonia—as well as laboratory findings and bacteriological investigations serve as additional aids to establish the diagnosis.

11.2.1 Fever with Chest Pain

11.2.1.1 Abscesses in the Chest Wall

Inflammation in the soft tissues of the chest wall, for instance, in the presence of an abscess (► Fig. 2.3), causes local pain occasionally accompanied by swelling. Abscesses in the chest wall may be quite extensive (■ Fig. 11.9).

11.2.1.2 Pleuritis

Inflammatory diseases of the pleura (► Chap. 3) cause pain which is enhanced during inspiration. Auscultation frequently discloses marked pleural rales. High-resolution transducers reveal changes that cannot be detected on conventional overview radiographs. Most of all, sonography is a useful imaging procedure when one has to avoid irradiation:

Fig. 11.9 A 35-year-old man with diabetes, renal insufficiency and a history of drug addiction. Extended abscess in the soft tissue of the right ventral chest wall (markers) caused by an infected central venous line in the jugular vein. Microbiological analysis of sonography-guided aspiration revealed *Staphylococcus*

Fig. 11.10 A 25-year-old woman with a narrow pericardial effusion (arrow) in the presence of Churg-Strauss disease. RA right atrium, RV right ventricle

11.2.1.3 Pulmonary Embolism

In some cases of recurrent pulmonary embolism (► Sect. 5.3) the only symptoms may be intermittent chest pain and fever for a long period of time; however, fever rarely exceeds 38.3 °C (Fedullo and Morriss 2005). In one investigation of geriatric patients, fever was frequently observed in connection with pulmonary embolism (Ceccarelli et al. 2003).

11.2.1.4 Pericarditis

Pericarditis is associated with moderately high fever, breath-related and position-related precordial pain. The main diagnostic tool is ECG, assisted by laboratory investigations. On sonography, at the onset of the disease one usually finds a fluid margin of lesser or greater magnitude in the pericardial space (■ Fig. 11.10). In

every case sonography is the method of choice for further assessment of the progress of the disease.

11.2.2 Fever with Dyspnea

When a patient with fever develops dyspnea it is always a clinical sign of impairment of respiratory or ventilatory function.

11.2.2.1 Pneumonia

Pneumonia is usually associated with very high fever. In cases of pneumococcal pneumonia, the patient typically experiences sudden fever without prolonged onset of the disease. Inflammatory exudation of fluid in the alveoles eliminates air from the parenchyma and permits sonographic imaging even if the invasion extends up to the visceral pleura (► Sect. 5.1) (Blaivas 2012; Reißig and Görg 2012; Chavez et al. 2014). Secretory retention due to obstruction secondary to a tumor leads to atelectasis and frequently also poststenotic pneumonia. The sonographic image shows the distribution of vessels as well as necrosis in the parenchyma. A bronchoscopy must be performed to assess the central bronchial system (■ Fig. 11.11).

11.2.2.2 Pleural Empyema

Pleural empyema, or collection of pus in the pleural space, is associated with fever, dyspnea and a severely impaired general condition. The disease is usually a threatening toxic condition which, if not identified on time or if treated too late, exposes the patient to the risk of sepsis and high lethality (Kolditz et al. 2004; Davies et al. 2010). Pleural empyema may occur as an inflammation of the pleura, for instance, in the presence of a tuberculous infection, or may be a complication of a parapneumonic effusion in case of bacterial pneumonia

(■ Fig. 11.12a, b). The emergence of a pleural empyema always heralds a more severe course of disease, whether due to the impaired resistance of the individual or a particularly virulent pathogen. Pain usually occurs in the initial stage of the disease and disappears as the exudation in the pleural space increases. On sonography the fluid is frequently seen in conjunction with dense internal echoes which correlate with the high cell content of the fluid. The longer an empyema exists, the more pronounced are the septations and chambers (■ Fig. 11.13a, b). Sonography also permits localization of the optimum site of aspiration, even at the bedside (Levin and Klein 1999; Davies et al. 2010; Heffner et al. 2010), to obtain material for investigation and place a drain. On the basis of the sonography report, the extent of empyema can be assessed in children (Carey et al. 1998; Ramnath et al. 1998) and the investigator will be able to decide whether conservative or surgical treatment should be used. In adults—as far as possible—computed tomography should be performed to plan the treatment and determine the exact extent and size of the chambers (■ Fig. 11.13c).

When a suppurative effusion fills more than half a hemithorax, the patient has a pH below 7.2 and positive evidence of bacteria, a drain needs to be placed immediately (Colice et al. 2000; Davies et al. 2010; Heffner et al. 2010). In cases of chambered empyema, immediate intrapleural fibrinolysis therapy may be successful (Hamm 2005; Davies et al. 2010). The largest study conducted thus far on local fibrinolysis of empyema (Maskell et al. 2005) revealed no advantages in terms of the duration of disease or mortality in patients treated with streptokinase. However, the significant difference between chambered and nonchambered empyema was not taken into account. Video-assisted thoracoscopy and thoracotomy are surgical treatment procedures

■ Fig. 11.11 a, b A 91-year-old woman with middle-lobe pneumonia, a large peripheral colliquation (arrow) and regular central vessels a. Bronchoscopy b reveals obstruction of the middle lobe

secondary to the tumor, which proved to be an adenocarcinoma on histological investigation. Partial resolution of the middle-lobe invasion under antibiotic therapy

Fig. 11.12 a A 52-year-old man with fever and dyspnea. In the right lower lobe infiltration with air trappings, pleural thickening and several fibrinous bands. PH-value in the pleural fluid 6, 8. **b**

Color Doppler shows hypervascularization in the infiltrated part of the lung. Successful treatment with drainage and antibiotics

Fig. 11.13 a A 58-year-old man with high fever and critical sickness. On the left side dorsobasal pleural empyema with a thick wall and several loculations. **b** Above the empyema consolidated lung infiltration with air trappings. **c** Corresponding CT-image with section of the empyema and the infiltration. Therapy by means of

VATS. **d** A 70-year-old woman with dyspnea and chest pain. The bedside sonographic examination from the right lateral aspect illustrates a compact consolidation in the right lower lobe and a small basal effusion (PE, markers)

which, however, must be viewed under consideration of other factors present in the individual patient (Hamm 2005; Davies et al. 2010; Heffner et al. 2010).

11.2.3 Fever with Dyspnea and Chest Pain

The more extensively the pleura is affected in case of pleuritis, or the more extensively the lung parenchyma and pleura are affected in the case of pleuropneumonia, the more likely one will find a combination of all three symptoms. Fluid in the pleural space as well as invasion of peripheral portions of the lung (■ Fig 11.13d) can be viewed rapidly by sonography, independent of the patient's condition or mobility. Further investigations such as diagnostic aspiration of the pleura or additional radiological investigations serve to conclude the diagnostic procedures and make the diagnosis.

11.2.4 Fever as the Sole Symptom in Chest Diseases

In the case of ambiguous fever the investigator is confronted with a large number of possibilities in terms of differential diagnosis (Roth and Basello 2003). As a rule the first diagnostic step is laboratory investigations, which serve as the basis for further diagnostic procedures. The sonography investigation is not the first step for diseases of the chest because it does not provide a general overview of the chest organs. Sonography of the chest is usually requested in connection with a specific question in the case of an appropriate suspected diagnosis.

11.2.4.1 Polyserositis

Sonography, the most sensitive procedure to provide evidence of fluid, is used to investigate small pleural effusions (► Chap. 3) that frequently occur on both sides and usually cause no symptoms for the patient. Even small pericardial effusions (■ Fig. 11.10) in the course of autoimmune diseases or vasculitis can be very well demonstrated by sonography.

11.2.4.2 Mycobacteriosis

The disease starts slowly and insidiously, and is associated with a gradual reduction of physical performance, nocturnal sweating and intermittent fever. Months may pass before an overview radiograph showing the pulmonary manifestation is performed. Pulmonary symptoms might be entirely absent. Some patients have a persistent dry cough which initially misleads the clinician in terms of diagnostic procedures and treatment. Depending on the individual's immune defense and additional organs

that may be affected, the symptoms of disease may be very diverse (Hopewell 2005).

In the case of active disease the conventional chest X-ray shows soft, pale infiltrates, occasionally in conjunction with colliquations. Peripheral inflammatory lesions are accessible to sonography (■ Figs. 11.14 and 11.15). Sonomorphological or radiological criteria that permit a reliable distinction between atypical mycobacteriosis and infection with *Mycobacterium tuberculosis* do not exist (Müller et al. 2003). Newly introduced Interferon-gamma-Release-Assays (IGRAs) measure the TB-antigen-specific immunologic activation. This method allows a differentiation between tuberculous and not-tuberculous (MOTT) mycobacteria (Diel et al. 2011; Schönfeld et al. 2013)

■ Fig. 11.14 A 68-year-old man with loss of strength and bouts of fever for several months. In the right upper lobe, in lateral location, there is a relatively homogeneous area with blurred margins and vessels at the margin. The sonographic biopsy (in NaCl!) showed bacteria on microscopic investigation; the bacteria were subsequently differentiated as atypical *Mycobacteria* using PCR

■ Fig. 11.15 A 73-year-old man with a chronic cough, who was known to suffer from chronic obstructive pulmonary disease. Sonography showed an area with blurred margins in dorsal and basal location, with residual air. A small pleural effusion (arrow). *Mycobacterium tuberculosis* was cultured in the bronchial and pleural secretion

In cases of mycobacteriosis, sonography may be used in addition to radiological investigations, in order to evaluate the progress of peripheral lesions under treatment or when a sonography-guided biopsy is indicated for diagnostic purposes. However, conventional overview radiographs, possibly complemented by computed tomography, are always needed to assess the entire lung.

11.2.4.3 Endocarditis

Fever, physical weakness and loss of physical performance may be the only signs of endocarditis. In the presence of good transthoracic insonation, vegetation in the heart valves is visualized. Blood cultures should be performed to obtain evidence of bacteria. In the case of Löffler's endocarditis, transient thrombi may be observed at the endocardium. A sonography investigation of the heart for the purpose of orientation can be performed even by the less experienced investigator. For a more detailed examination the investigator must possess the knowledge and skills required to perform echocardiography.

11.3 Dyspnea

The symptom of dyspnea is strongly dependent on the patient's subjective experience. Specific receptors that may be responsible for triggering dyspnea have not been identified thus far (Fitzgerald and Murray 2005). A multifactorial mechanism via medullary and peripheral chemoreceptors, pulmonary vagal afferences, and mechanoreceptors in the locomotor apparatus are presumed to exist (ATS 1999; Pfeifer 2005; Stulbarg and Adams 2005). In the meantime, clinically a distinction is made between acute, chronic, resting and stress dyspnea. Even the investigator finds it difficult to quantify dyspnea; therefore, particularly acute dyspnea should be rapidly investigated on the basis of clinical parameters (breath and pulse rate, auscultation, blood pressure), by laboratory investigation (blood gas analysis, determination of the acid–base balance of the body, blood count, typical enzymes associated with infarction) and imaging procedures. A strong respiratory drive is triggered by hypoxia and hypercapnia through afferent stimuli acting on the respiratory center. Reduction of the gas-exchange surface, mechanical hindrance of dilatation of the lung, muscular and neurogenic deficits lead to greater respiratory effort. Cerebral disorders cause varying degrees of respiratory impairment. The possibilities of sonographic imaging in the presence of dyspnea, for the various compartments involved in respiration, are presented in the following.

Fig. 11.16 A 55-year-old woman with advancing stress dyspnea for several weeks; inspiratory stridor. Sonography shows a space-occupying lesion arising from the right lobe of the thyroid, entering the trachea (arrow) and destroying the right lateral tracheal wall. A narrow air reflex (arrowheads) remains in the constricted trachea.

11.3.1 Respiratory Tract

The upper and deeper respiratory tracts are the domain of endoscopy in terms of diagnosis. In the case of dyspnea with inspiratory stridor, sonography of the thyroid should always be considered as part of the routine investigation (■ Fig. 11.16).

11.3.2 Pleura

Fluid in the pleural space, depending on its quantity, leads to compression of lung tissue and reduces the respiratory surface. In patients with concomitant cardiopulmonary disease, even a few hundred milliliters of effusion can lead to dyspnea. Patients with a healthy contralateral lung may tolerate several liters of effusion and experience only mild dyspnea. Sonography allows rapid estimation of the quantity of effusion (■ Fig. 11.17) and the possibility of septation (■ Fig. 11.18).

As in a pleural effusion, the extent of a pneumothorax and the presence of concomitant diseases are of decisive importance for the emergence of dyspnea. A conventional X-ray is always needed to determine the size of the pneumothorax (■ Fig. 11.19).

11.3.3 Lung

Diseases of the lung parenchyma reduce the gas-exchange surfaces. Acute dyspnea may be caused by inflammatory, vascular or tumor diseases of the lung (▶ Chap. 5). Lung diseases accompanied by interstitial

■ **Fig 11.17** A pleural effusion with a tumorous lesion based on the diaphragm (*cross markers*) turns out to be the cause of dyspnea in a 84-year-old woman. Malignant effusion is probable because of an operated breast cancer 2 years before (patient refused puncture and biopsy)

■ **Fig 11.18** After VATS due to complicated pleural empyema residuary small septate effusion and adherence of the lung to the diaphragm (*ZF, LE liver*)

and chronic progressive loss of substance are more often accompanied by chronic and stress dyspnea. Pneumonia (▶ Sect. 5.1), tumors (▶ Sect. 5.2) and embolic consolidations (▶ Sect. 5.3) are accessible to sonographic diagnosis when ventilated tissue does not superimpose the path of insonation. Sonography serves as a valuable diagnostic adjunct when the investigator is confronted with the radiological report of a so-called white lung (▶ Sect. 5.4).

In the case of a severe dyspneic patient the findings of bilateral coalescent B-Lines (▶ Chap. 4) help to dif-

■ **Fig. 11.19** A 63-year-old man with a tumor in the left upper lobe. Four hours after a biopsy had been obtained by transaxillary sonography, the patient developed dyspnea accompanied by elimination of gliding of the lung surface on sonography. The tumor previously seen on sonography was no longer visible. X-ray investigation showed a pneumothorax that needed drainage

ferentiate between pulmonary edema or exacerbation of a chronic obstructive pulmonary disease.

11.3.4 Heart

In cases of acute dyspnea the investigator must include cardiac diseases in the differential diagnosis. A physician trained in general internal medicine, as well as sonography, should be familiar with typical sonographic findings. In case of failure of the left side of the heart (Ware and Matthay 2005) owing to left-ventricular cardiomyopathy, one finds a massively dilated and ballooned left ventricle (■ Fig. 11.20).

In the case of cor pulmonale, diseases of the right side of the heart are manifested in terms of dilatation of the right side of the heart and hypertrophy of the right ventricle (■ Fig. 11.21).

Determination of the size of the right side of the heart helps to assess the severity of disease in cases of a suspected pulmonary embolism (Goldhaber 1998; ▶ Sect. 5.3).

An indirect criterion of cardiac decompensation, easy to identify by sonography, is investigation of the vena cava in longitudinal section in the upper abdomen, through the left lobe of the liver. The diameter of the vena cava is more than 20 mm, and its diameter is inadequately reduced during inspiration.

■ **Fig. 11.20** A 55-year-old man with a pulmonary edema as a result of left-ventricular cardiomyopathy due to alcohol toxicity. The apical four-chamber view shows a dilated and ballooned left ventricle (LV)

■ **Fig. 11.21** A 64-year-old man with decompensated cor pulmonale as a result of pulmonary hypertension in the presence of the CREST syndrome. The apical four-chamber view reveals an enlarged right atrium (RA) and a massively dilated and hypertrophic right ventricle (RV). A pericardial effusion (arrows) lateral to the right atrium, the right ventricle and the left ventricle

■ **Fig. 11.22** A 91-year-old woman with global cardiac decompensation and a large circular pericardial effusion. Under diuretic therapy that reduced the cardiac load, the effusion resolved partially and dyspnea improved; therefore, in consideration of the patient's age a diagnostic aspiration was not performed

A hemodynamically significant pericardial effusion leads to impairment of the systolic and diastolic function of the left ventricle, as well as congestion of venous blood flow. Large pericardial effusions can also be seen well in subcostal insonation from the epigastrium (■ Fig. 11.22).

11.3.5 Respiratory Muscles

The most important respiratory muscle is the diaphragm (► Chap. 3). In the rare event of bilateral paresis of the diaphragm the patient may be unable to lie supine because of dyspnea, which starts immediately (Fitzgerald and Murray 2005). Reduced mobility of the diaphragm due to fixation of the lung at the diaphragmatic pleura and unilateral partial or complete paresis of the diaphragm are seen well in the dynamic sonography investigation, particularly on comparison of the right and the left side (McCool and Tzelepis 2012). The cause of a local compression of the cranial part of the phrenic nerve may be visible in the supraclavicular view (■ Fig. 11.23a, b).

Fig. 11.23 **a** A 52-year-old man presenting with dyspnea, an elevated left diaphragm, local pain and increase of dyspnea on palpation left supraclavicular. Unremarkable radiologic findings except for the elevated diaphragm. In the left thyroid lobe (anamnestic “harmless node”) inhomogeneous node with larger calcifications

and irregular marginal vessels. **b** Next to the left thyroid lobe supraclavicular echo poor lymph node causing the elevated diaphragm by compression of the phrenic nerve. Diagnosis after curative surgery: papillary thyroid carcinoma with local lymph node metastasis

Summary

Chest pain, fever and dyspnea are frequent symptoms in cases of chest disease. The combination and varying intensity of symptoms allows conclusions to be drawn about the structures involved and the severity of the disease. Sonography, a readily available method that is very suitable for investigation at the bedside, makes a significant contribution to the diagnosis when investigating regions that can be viewed by the procedure. Sonography provides very significant information about the cause of sudden chest pain in the presence of a tension pneumothorax, in cases of pulmonary embolism, and in acute aortic dissection. Pathological changes in the chest wall can be visualized in an excellent manner because of the high quality of near-field resolution on the sonography image. Fever is a symptom in cases of inflammation of the chest wall, the pleura, and the lung. Sonography not only shows which structures are affected, but is also a reliable method for targeted diagnostic isolation of fluid and tissue. Sonography control investigations are particularly valuable in the course of pleural and pericardial effusions. In the case of dyspnea, sonography permits a distinction between a cardiac and a pulmonary cause of the condition. The dynamic investigation allows assessment of functional disorders of the diaphragm.

Diagnostic ultrasound is the next stethoscope: used by many, understood by few (1).

12.1 Basic Principles

After an extensive presentation of the sonomorphology of various injuries and diseases of the chest wall and lungs in the main part of this book and a symptomatic approach in chapter 11, the focus here is on emergency situations. All that remains is to put together the single diagnostic elements and to show how sonography of the chest can be integrated into emergency daily routine.

First, however, two questions arise: What is an emergency? Is it a life-threatening condition, severe trauma, dyspnea, coughing or fever and what does the term emergency sonography mean? The answers to these questions are simple: By an emergency we understand a subjective assessment of symptoms or signs of illness or injuries for which the person affected is seeking urgent professional medical help either himself or herself or a person present on behalf of the patient. What is emergency sonography? The term emergency sonography is used to describe a well-performed, problem-oriented, bedside sonography of the emergency patient integrated into the course of care as a continuation of the clinical examination. Today, the new pocket devices can largely replace the stethoscope and be part of the exam. Emergency sonography is independent of location and medical specialties, used across all organs and regions and divided into four clinical applications (■ Table 12.1).

The term point-of-care ultrasound (PoCUS), which was discussed in the introduction, includes emergency sonography too. The emergency thoracic ultrasound (TUS) or also known as thoracic emergency PoCUS is a multimodal ultrasound and comprises the focused sonography of the chest wall and lungs, the focused car-

diac ultrasound FoCUS) and, depending on the individual patient, also the focused vascular sonography (Picano et al. 2018; Kameda and Kimura 2020). It is now undisputed that these combined applications in the clinical context achieve better results than lung ultrasound alone (LUS). Furthermore, aerosol or droplet infections can be avoided. They can occur during auscultation and are reduced during sonography. Scanning can be done without forced breathing, which is often accompanied by coughing attacks. Therefore it is a great advantage in the current SARS-Cov2 pandemic, and should not be underestimated.

For more than a hundred years, chest x-ray (CXR) was the compulsory standard examination for patients with cardiovascular and pulmonary problems. This situation has changed fundamentally. Many studies show that pulmonary ultrasound is diagnostically superior to CRX (see ■ Tables 12.2 and 12.3). In selected cases it even achieves the diagnostic performance of computed tomography (CT). This is very important because LUS usually replaces CRX and often chest CT, thus saving waiting times for radiological examinations and unnecessary demands on personnel and space in crowded emergency departments (Zanobetti et al. 2017). The PoCUS application with pocket devices can also reduce the risk of transmitting infectious diseases due to less requirement on personal, technique and room compared to CXR and CT, as well as easier hygienic handling. Furthermore, costs can be reduced and harmful side effects of CT such as radiation exposure and anaphylactic reactions or contraindications for the use of iodine-containing contrast media in renal failure and latent or manifest hyperthyroidism are eliminated. For some of these topics and a couple of other “clinical outcome variables”, good scientific studies exist in the emergency context (■ Table 12.4). However, there is still a lack of research investigating the benefits in terms of mortality and morbidity of LUS compared to CXR and CT.

In summary, PoCUS has become an established and helpful tool for the diagnosis of diseases and injuries of the chest. Except for the thoracic E-FAST (Extended Focused Assessment with Sonography for Trauma), which is part of the standard ATLS-procedure in the shock room, the thoracic PoCUS has also become increasingly important in other emergency situations. It allows relevant clinical decisions to be made quickly and increases efficiency and safety in patient monitoring as well as difficult punctures. Below, indications and procedures of PoCUS in patients with trauma and diseases of the chest are discussed.

■ Table 12.1 Clinical applications of emergency sonography

Applica-tions	Content
Diagnosis	Medical history, symptoms, findings of the exam, laboratory and ECG lead to simple sonographic yes-no questions
Algorithm	Protocol
Monitor-ing	Monitoring and evaluation of treatment
Invasive procedures	Ultrasound-assisted puncture and placement of catheters in vessels and on nerves

Table 12.2 Pooled sensitivities and specificities of chest-x-ray (CXR) and lung ultrasound (LUS) compared to computed tomography for selected pathological findings in critically ill patients

Diagnosis	CXR sensitivity	LUS sensitivity	CXR specificity	LUS specificity
Consolidations	69%	97%	90%	94%
Pleural effusion	55%	97%	90%	94%
Pneumothorax	21%	100%		
Interstitial syndrom	53%	95%	91%	91%
Lung contusion	38%	98%	90%	90%
Summarising sensitivity and specificity	49%	95%	92%	94%

Table 12.3 Summary of multiple systematic reviews/meta-analyses on the validity of chest-X-ray (CXR) and thoracic ultrasound (TUS) (Blank et al. 2019)

Diagnosis	CXR sensitivity	TUS sensitivity	CXR specificity	TUS specificity
Pneumothorax	29–55%	68–98%	98–100%	97–99%
Pneumonia (adult)	44–77%	80–97%	90–91%	70–96%
Pneumonia (children)		93%		96%
Lung embolism without CEUS	–	80–87%	–	81–93%
Pleural effusion	51%	94%	91%	98%
Pulmonary edema	66–67%	82–94%	76–83%	83–92%
Lung contusion	44%	89%	98%	89%
Rib fractures	12–24%	80–90%	–	–
Sternal fractures	71%	100%	–	100%

Table 12.4 Outcome-studies

Type of study	Question	Results
Prospective randomized trial in the emergency room (Laursen et al. 2014) N = 320 participants-	Difference in the correct diagnosis of patients with dyspnea after 4 h using TUS versus standard procedure?	Group with LUS and focused echocardiography: 88% correct diagnosis Group with standard procedure: 63% correct diagnosis $p < 0.001$
Prospective cohort study in ICU (Silva et al. 2013) N = 78 participants	Impact of LUS and FoCUS on clinical decisions in patients with respiratory symptoms?	Significant improvement of initial treatment for patients with pneumonia, pulmonary edema, decompensated COPD and pulmonary embolism after TUS
Prospective cohort study in the emergency room (Zanobetti et al. 2017) N = 2683 participants	Time difference for diagnosis of dyspnea with and without PoCUS?	PoCUS was 186 min faster than the standard procedure with identical diagnostic accuracy for ACS, pneumonia, pleural/ pericardial effusion, pneumothorax and dyspnea of other causes; better for pulmonary edema and worse for COPD/asthma and pulmonary embolism
Prospective randomized controlled trial in a ward of internal medicine (Golan et al. 2020) N = 60 participants	Time difference until correct diagnosis and appropriate treatment of patients with chest pain and dyspnea for PoCUS and standard procedures ?	Time to correct diagnosis: control group in median 48 h and early PoCUS group in median 24 h; $p = 0.12$ Time to appropriate treatment: control group median 24 h and early PoCUS group median 5 h; $p = 0.014$
Systematic review (Platz et al. 2017) • N = 6 studies/438 participants • N = 7 studies/953 participants	Dynamic change of B-lines in acute heart failure patients to emergency treatment? Prognostic benefit of B-lines in outpatients with heart failure?	Number of B-lines decreases already 3 h after first treatment and it helps to monitor therapy. Patients with ≥ 3 B-lines in 5 or 8 zones have a fourfold risk of hospitalization or death within 6 months. The presence of B-lines helps in the decision to intensify or hospitalize the therapy

12.2 Emergency PoCUS for Chest Trauma

The main symptom of chest trauma is pain. Dyspnea and/or shock are frequent additional companions. Despite detailed inspection and even after a thorough clinical examination of trauma patients, it is often not clear: what, where and how is wrong. Thanks to TUS, however, precise image information can be obtained easily and quickly. It helps to find the causes of chest pain, obstructed airways, impaired breathing and intrathoracic bleeding. As said above the TUS has been a standard part of E-FAST for more than 15 years and is routinely used in any seriously injured patient regardless

of clinical findings. It involves the detection of pneumothorax, hemothorax and hemopericardium. However, diagnostics in trauma using sonography has developed further. We are able to detect additional problems and injuries in chest trauma and are not only focused on the severely injured patient. It is therefore advisable to expand E-FAST, which focuses on the primary survey, and to use also the full spectrum of TUS in the secondary survey. ■ Tables 12.5 and 12.6 summarize the most important indications and ■ Fig. 12.1 the procedure for the primary and secondary survey.

In this context, we would like to briefly discuss the pulmonary contusion. It is one of the most common

■ Table 12.5 TUS indications in the primary ATLS-survey

Organ	Clinical questions	Sonographic findings
Pleura	<ul style="list-style-type: none"> • Pneumothorax? • Unilateral/false intubation • Hemothorax? 	<ul style="list-style-type: none"> • No lung sliding, no vertical artifacts and no lung pulse Lung point (incomplete pneumothorax) • No lung sliding (on one or both sides), but lung pulse • Spine-sign
Heart	<ul style="list-style-type: none"> • Pericardial effusion? • Cardiac tamponade? 	<ul style="list-style-type: none"> • Hypo- to hyperechoic (coagulum) band between the pericardial leaves • Inversion to collapse of right atrium in late diastole, inversion to collapse of right ventricle in early diastole, shift of septum during inspiration to the left and expiration to the right, swinging heart and extended VCI

■ Table 12.6 TUS indications in the secondary ATLS-survey

Organ	Clinical questions	Sonographic findings
• Chest wall	• Hematoma?	• Echofree to hyperechoic inhomogeneous, clearly definable area (for detection of active bleeding color Doppler and/or CEUS)
• Ribs • Sternum	<ul style="list-style-type: none"> • Rib fracture? • Sternal fracture? 	<ul style="list-style-type: none"> • Sonopalpation (painful, fragments move) • Interruption or step of corticalis line • «Kaminphänomen» (fireplace phenomenon) • Circumscribed hematoma
• Diaphragm	• Diaphragm rupture?	<ul style="list-style-type: none"> • Fluid in the pleural cavity (blood) • Stomach and/or intestine in the pleural space • Gap in the diaphragm (cave artifact)
• Lung	• Lung contusion?	<ul style="list-style-type: none"> • Thin smooth or irregular pleural line • Normal lung sliding • Multifocally distributed vertical artifacts with spared areas • Small and large subpleural consolidations
• Heart	• Injury of the heart?	<ul style="list-style-type: none"> • Atrial, ventricular, septal rupture • Heart valve or chorda tear • Regional wall movement abnormalities
• Vessels	<ul style="list-style-type: none"> • Hypovolemia? • Rupture of thoracic vessels (aorta, subclavia, internal thoracic and intercostal arteries?) • Safe puncture? 	<ul style="list-style-type: none"> • Dimension and respiratory variability of the inferior vena cava • Hematoma around vessels, color Doppler signals also outside the vessel/CEUS • Puncture and catheter localization under sight

Sonographic approach for chest trauma in emergency situations (primary and secondary survey)

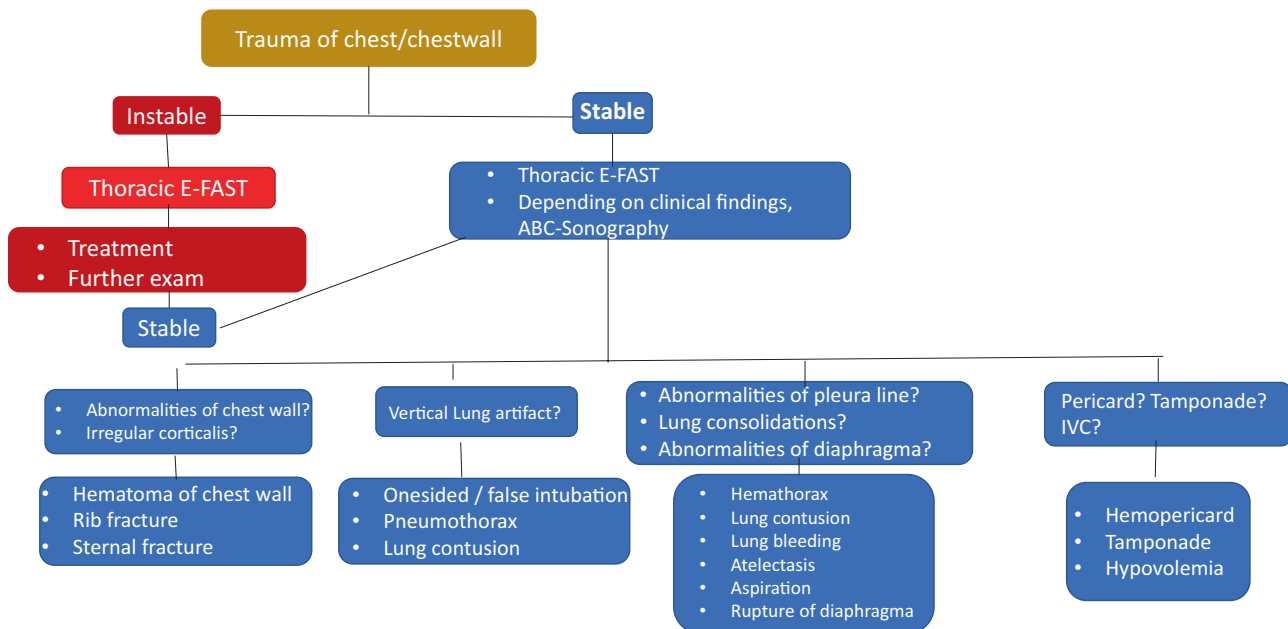

Fig. 12.1 Sonographic approach for chest trauma in emergency situations

injuries in blunt chest trauma. Its early detection is of great prognostic importance. The lung parenchyma is torn from subpleural to central by blunt force with the pleura usually remaining intact. This leads to bleeding and cytokine-induced permeability disturbances with subsequent increase of interstitial fluid. Sonographically, bleeding and edema in the interstitium appear as irregular pleura line and thickening, vertical lung artifacts and small subpleural consolidation. The abnormalities of the pleura line and the vertical artifacts are caused by changes in the lung contents, whereby air decreases and tissue/fluid increases. Lung bleeding and changes in the equilibrium between air and tissue/liquid are subpleural and therefore easily accessible by sonography. They allow both the extent and severity of lung contusion to be assessed. There is also no doubt that CRX is inferior to LUS in the detection of lung contusion (Tables 12.2 and 12.3). Furthermore, various studies indicate that LUS can detect patients

at an early stage who later develop ARDS (Leblanc et al. 2014). It is therefore recommended that all patients with blunt chest trauma, regardless of their severity and CXR findings, be screened for signs of pulmonary contusions using sonography and, if the findings are positive, the indication for hospitalization should be generous in order to prevent the threat of ARDS.

Examples of Images for Injuries of the Chest

- Hematoma in the chest wall (Fig. 2.1)
- Fracture of the rib and sternum (Figs. 2.15, 2.16, and 2.17)
- Pneumothorax (Figs. 3.38, 3.39, and 3.40).
- Hemothorax (Fig. 12.2)
- Contusion of the lung (Fig. 12.3)
- Rupture of the diaphragm (Fig. 12.4)
- Prandial status (Fig. 12.5)
- Pericardial tamponade (Fig. 12.6)

■ Fig. 12.2 Hemothorax due to a stab injury. a Four days after drainage, there is still a residual effusion, partly with internal echoes. b Compression atelectasis

■ Fig. 12.3 Lung contusion due to a rib fracture after a fall from a ladder

■ Fig. 12.4 Diaphragm rupture showing pleural effusion, perisplenic fluid collection and a gap in the ventral part of diaphragm

■ Fig. 12.5 Full stomach with fluid and leftovers from food

■ Fig. 12.6 Pericardial tamponade. a Stab injury. b Pericardial tamponade. c Blood clot in the hemopericardium

12.3 Emergency PoCUS for Diseases in the Chest (Examples of Images Are Summarized in Table 12.7)

For a long time, emergency sonography of the chest (excl. echocardiography) has focused on the detection of pleural effusion and pneumothorax even in non-traumatological patients. In the last fifteen years, the main focus in the literature has been largely limited to the interpretation of specific vertical reverberation artefacts (previously called B-lines) and to the increase or decrease of horizontal reverberation artifacts (A-lines). This has various personal and cultural backgrounds. They are not discussed here. Nevertheless, great progress has been made in the same time frame. The diagnostic value of sonography could be proved for several diseases. It concerns typically those with dyspnea and/or inspiratory pleural pain, but also those without pain. Both groups are often accompanied by fever and cough.

The most common pleural abnormalities (pleuritis) and/or subpleural lung consolidations (pneumonia, pulmonary embolism and atelectasis) can be well differentiated in their sonomorphology. If CT is used as a reference method, significantly more pneumonia can be visualized by ultrasound than by CRX. And in pulmonary embolism imaging, we currently have two silver standards that complement each other, namely multi-slice CT and sonography (see Sect. 5.3). If there are any remaining doubts with normal ultrasound, CEUS, i.e. signal-enhanced sonography, can help. It is important to know that LUS can accurately visualize pleural effusions, pneumothorax, pleuritis, pulmonary atelectasis, pneumonia, pulmonary embolism, DD carcinomas/metastases, is helpful in the diagnosis of aspiration and diffuse parenchymal lung diseases and TUS as a combination of LUS and FoCUS can differentiate pulmonary edema from ARDS. It should also be noted that LUS cannot diagnose bronchial asthma or exacerbated COPD, but it

Table 12.7 Sonographic approach for thoracic diseases in emergency situations

Phase of exam	Anatomy				
	Chest wall	Pleura und lung artifacts	Lung consolidations	Heart	Vessels (aorta and branches, pulmonary arteries, IVC and central veins)
Sonographic questions	<ul style="list-style-type: none"> • Mass? • Interruption of corticalis? • Destruction of corticalis? 	<ul style="list-style-type: none"> • Fluid? Simple/complex? • Abnormalities of pleura/ pleural line? • Lung sliding? • Lung pulse? • Lung point? • Vertical artifacts? 	<ul style="list-style-type: none"> • Boundary? • Echogenicity? • Air inclusions? • Bronchoaerogram? • Fluidobronchogram? • Doppler and color Doppler pattern? • CEUS pattern? 	<ul style="list-style-type: none"> • Abnormalities of pericard • Dimensions of heart chambers? • Heart wall? • Heart function? • Valve morphology • Doppler and color Doppler patterns? 	<ul style="list-style-type: none"> • Dimension? • Respiratory variability? • Wall changes? • Pathology in the lumen? • Doppler and color Doppler pattern? • Needle and catheter
Interpretation in the clinical context	<ul style="list-style-type: none"> • Hematoma • Seroma • Abscess • Rib-/sternal-fracture • Tumor/metastasis 	<ul style="list-style-type: none"> • Effusion • Pleurisy/rind • Adhesions/ Bulla • Unilateral/false intubation • Focal SIS^a (pulmonary contusion, viral pneumonia, ARDS) • Diffuse SIS^b (Pulmonary Edema, DPLD^b) 	<ul style="list-style-type: none"> • Pneumonia • Tumor • Pulmonary infarction, embolism • Compression atelectasis • Obstruction atelectasis 	<ul style="list-style-type: none"> • Pericarditis, pericardial effusion/ tamponade, pericardial tumor • ACS • Cardiomyopathy • Left ventricular dysfunction (e.g. cardiac pulmonary edema) • Right ventricular dysfunction • Rupture • Endocarditis • Valve disease, leaflet, chorda and papillary dysfunction 	<ul style="list-style-type: none"> • Aneurysm • Dissection • Thrombus • Volume status, -reactivity • Real-time puncture assistance and catheter localization

^a Sonographic interstitial syndrome

^b Diffuse parenchymal lung disease

helps to rule out pneumothorax in these situations or to distinguish COPD from cardiac pulmonary edema.

Examples of Images for Thoracic Diseases

- Pleural effusion (► Sect. 3.4)
- Pneumothorax (► Sect. 3.6)
- Pleurisy (► Sect. 3.5.1)
- Lung atelectasis (► Sect. 5.4)
- Pneumonia (► Sect. 5.1)
- Pulmonary embolism (► Sect. 5.3)
- DD: Carcinoma/metastases (► Sect. 5.2)

History and bedside clinical findings are essential for guiding the diagnostic process in clinical medicine. Unfortunately, they are often unspecific. Here too, PoCUS can usually provide crucial assistance, as shown in the case of thoracic injuries. Pathophysiologically, we distinguish two types of morphological and functional abnormalities in diseases of the chest: (1) the oxygen source with the lung as receiving organ and the chest and the diaphragm as the receiving motor; (2) the oxygen transport system with pump (heart) and tube system (vessels). The sonographic approach is primarily based on the patient's medical history, clinical presentation and examination, and adjuncts (ECG and initial point-of-care laboratory results). When these groundbreaking basic informations do not lead to a diagnosis, they are summarized into clinical questions and further translated into simple yes-no sonographic questions. Depending on the situation, the examiner starts with the lung, heart, vascular or thoracic wall sonography and then

determines the further course of the examination and the further procedure.

 Fluid bronchogram 61–63, 92, 94, 96, 146, 172
 FNA. *See* Fine needle aspiration (FNA)
 Focused assessment with sonography for trauma (FAST) 236
 Fractures 12, 17–20, 25, 43, 97, 99, 100, 189–192, 210, 223, 224, 237–242
 Functional examination 47–49

G

Gas-forming bacteria 31
 Germinal cell tumor 113–114
 Gliding sign 33, 34, 38, 42, 195
 Gross needles 204

H

Healing phase 65–66, 85, 156
 Heart 3, 25, 29, 44, 53–55, 77, 80, 86–88, 92, 106, 126, 148, 153, 175, 195, 224, 230–232, 238, 239, 242, 243
 Heart failure 25, 29, 53, 54, 80, 88, 92, 148, 175, 237
 Hematoma 3, 12, 17, 18, 25, 42, 75, 97, 150, 162, 165, 172, 179, 183, 198, 223, 224, 238, 240, 242
 Hematothorax 25, 29, 32–33, 35, 45, 100, 172
 Hemopericard 239
 Hemorrhages 30, 39, 42, 80, 85, 88, 97, 100, 154, 155, 171, 172, 216
 Hemothorax 238, 240
 Heterogeneous structural pattern 78–79
 Hodgkin's disease 144
 Homogenous echogenic pleural effusion 29
 Hyalinosis 73
 Hyperechoic calcifications 35
 Hypoechoic asbestos 39
 Hypoechoic space-occupying mass 192

I

Indication 2–9, 24–26, 62, 110–113, 123–125, 133, 137, 142, 146, 148, 156, 163, 173, 174, 184, 198, 207–211, 222, 236, 238–240
 Infarction pneumonia 84
 Inflammatory consolidations 61–100
 Inflammatory lymph node 14
 Infraclavicular approach, upper thoracic aperture 5
 Interlobular septa 56, 142
 Interstitial lung disease 54, 56, 57, 68–69, 125
 Interstitial syndrome 3, 24, 34, 51–57, 69, 70, 193, 242

Intervention
 Investigation
 – procedure 2–9, 111
 – technique 106

L

Lateral cervical region 5, 7
 Leg vein thrombosis 86, 87
 Lipoma 3, 13, 35, 37, 46, 97, 162, 165
 Lung abscess 31, 65, 142, 153, 198, 212, 213
 Lung abscess drainage 65, 212
 Lung carcinoma 19, 29, 72–74, 77, 173, 211, 225
 Lung consolidation 25, 33, 35, 47, 48, 68, 72, 80–100, 142, 152–184, 198, 199, 211–212, 239, 242
 Lung contusion 18, 35, 39, 97–100, 193, 237–241
 Lung cyst 142, 143, 152, 153
 Lung gliding 34, 35, 37, 40, 41
 Lung infarction 143, 144, 154–156
 Lung point 26, 40–42, 223, 238, 242
 Lung pulse 40, 41, 223, 238, 239, 242
 Lung surface 34, 38, 56, 72–74, 78, 168, 191–193, 231
 Lung ultrasound (LUS) 52, 56, 67, 69, 87, 88, 92, 193, 236, 237
 Lymphatic cyst 12
 Lymph node(s) 3, 5, 9, 12, 14–17, 20, 40, 72, 77, 89, 110, 111, 113–116, 120–122, 124, 125, 132, 133, 135–138, 192, 233
 Lymph node metastases 3, 11, 15–17, 77, 113, 125
 Lymphocytic pleural effusion 67

M

Magnetic resonance imaging (MRI) 35, 40
 Malignant lesions 3, 13, 72, 74, 78, 145, 148, 157, 160, 163, 203
 Malignant lymphoma 15, 16, 111, 147, 162, 178
 Malignant pleural mesothelioma 39–40, 216
 Marginal surface reflex 190
 Mediastinal cyst 116, 125
 Mediastinal tumor 77, 113, 123, 124, 134, 214
 Mediastinoscopy 120, 121, 124, 198
 Mediastinum 2–4, 9, 19, 29, 48, 72, 77, 105–126, 133, 144, 194, 198–200, 212–215
 Melanoma 174
 Mesothelioma 3, 32, 35, 37–40, 47, 189, 216, 225
 Metastasis 3, 15–18, 20, 25, 30, 37–39, 47, 79, 115, 177, 178, 182, 208, 233, 242
 Metastatic lung 71
 Microabscess 64, 65, 92, 96
 Micronodular pattern 16
 Miliary tuberculosis 68
 Mirror artifact 110, 190–191
 Modern ultrasound devices 16, 29
 Motion artifacts 109, 133, 195–196, 199
 MRI. *See* Magnetic resonance imaging (MRI)
 MSCT 80, 82, 88
 Multiple myeloma 18
 Mycobacteriosis 229, 230

N

Needle tip 193, 194, 206, 207, 212
 Neoangiogenesis 143, 145–148, 160, 162, 163, 173, 184
 Neurogenic tumor 13, 114
 Nocardiosis 74
 Non-displaced rib fractures 17
 Non-Hodgkin's lymphoma 113

Non-palpable lymph node metastases 16
 Normal pleura 24, 26

O

Obstructive atelectasis 39, 61, 88, 89, 92, 96, 100, 142, 146,
 172–173, 176
 Osler's disease 143, 152
 Osteolytic metastases 18–19, 225

P

Pancoast's tumor 74, 225
 Pancreatitis 25, 31
 Parapneumonic effusion 25, 30, 31, 62, 65, 227
 Parasternal examination 112
 Parenchyma 32, 52, 61, 69, 74, 89–92, 96, 137, 143, 148, 160, 163,
 169, 171, 177, 178, 188, 190, 193, 227, 229, 230, 240, 242
 Parietal pleura 3, 24, 26, 33–40, 75, 79, 161, 175, 212, 215, 222, 224
 Perfusion 35, 46, 63, 92, 135, 136, 145, 148, 156, 160, 163, 164, 167,
 169, 171, 172, 179, 182
 Pericardial tamponade 240, 241
 Pericarditis 197, 200
 Pericardium 72–76, 116
 Peripheral round lesion 158–160, 164
 Photodynamic therapy 133, 136
 Phrenic paresis 47, 48
 Pleura 2–5, 8, 9, 23–49, 52, 56, 61, 62, 65, 68, 69, 72, 74, 76, 79–81,
 89, 110, 142, 145, 152–154, 161, 162, 171, 189–193, 198, 209–212,
 215, 216, 222, 227, 229, 230, 238–240, 242
 Pleura biopsy 185
 Pleural cavity 32–34, 36, 41, 42, 44, 208–210, 238
 Pleural drainage 204, 205, 209, 210
 Pleural effusion 24–31, 34–39, 42–44, 49, 54, 67–70, 73, 78, 81, 96,
 97, 135, 145, 153, 154, 156, 157, 169, 171–176, 181, 191–193, 198,
 209–211, 215, 222, 223, 229, 231, 237, 239, 241–243, 8892
 Pleural empyema 30–32, 35, 39, 153, 169, 174, 193, 198, 206, 210,
 222, 227, 228, 231
 Pleural fibrosis 24, 26, 35, 36
 Pleural mesothelioma 3, 32, 35, 36, 39, 40, 47, 216, 225
 Pleural metastases 37, 38, 47, 179
 Pleural peel 33–36, 39, 47
 Pleural sonography 24–26
 Pleural tumors 35–38
 Pleuritis 34, 35, 156, 157, 175, 222, 223, 226, 229, 242
 Pleurodesis 25, 33–35, 40, 211
 Pneumonia 24, 25, 32, 35, 48, 53, 56, 61–67, 69, 71–73, 81, 84, 85,
 90, 109, 142, 143, 148, 156, 163, 164, 167, 169–171, 192, 193,
 198, 209, 211–213, 222, 226, 227, 229, 237, 242, 243
 Pneumothorax 3, 18, 24–26, 35, 40–43, 53, 57, 65, 90, 92, 125, 188,
 196, 199, 203, 207–209, 212, 222–224, 230, 231, 233, 237–239,
 242, 243
 Point-of-care ultrasound 35, 53, 235–243
 Polyserositis 25, 222, 229
 Postoperative seromas 12
 Poststenotic pneumonia 27, 62
 Primary lung tumors 72–80
 Pseudocystic necrosis 15
 Pulmonary abscess 64, 79, 170, 212
 Pulmonary edema 52, 53, 55, 57, 69, 193, 231, 232, 237, 239, 242,
 243
 Pulmonary embolism 80–88, 151, 154–158, 163, 193, 222–224, 226,
 231, 233, 242, 243
 Pulmonary infarction 61, 62, 69, 80–85, 88, 151, 155, 157–159, 172, 242
 Pulmonary interstitial syndrome. *See* Interstitial

Pulmonary metastases 14, 37, 79, 163, 171
 Puncture 2, 5, 12–14, 20, 31, 32, 42, 43, 47, 64, 65, 67, 72, 90, 113,
 114, 116, 118, 119, 132, 137, 138, 192–194, 198–216, 238, 239, 242
 Puncture needles 18, 176–178, 181, 182

R

Resonance artifact 192–194
 Respiratory chest pain 84
 Respiratory muscles 232
 Respiratory tract 222, 230
 Reverberation 17, 41, 52, 61, 65, 69, 70, 188–190, 192, 193, 239, 242
 Rheumatic nodule 39, 71
 Rib 2–5, 12, 16–20, 24, 27, 32–34, 40, 43, 53, 75, 97, 99, 110,
 177–180, 191, 194, 205, 209, 210, 224, 225, 237, 238, 240–242
 Rib fractures 3, 12, 17–18, 20, 25, 43, 97, 190, 224, 237–239, 241
 Ring-down artifact 192, 194

S

Sarcoidosis 70, 125
 Sarcoma 13, 14, 152, 163
 Scanning technique 53, 54
 Scapula 2, 4, 5, 12, 24, 54, 191
 Scatter lens artifact 191
 Secondary pulmonary lobule 56
 Seroma 12, 25, 48, 239, 242
 Shortening phenomenon 191
 Signal embolism 80
 Signal-enhanced sonography 65, 200, 242
 Small-cell lung carcinoma 73, 77, 173
 Soft tissue metastases 13–14
 Solitary fibrous tumors 37
 Sonoanatomy 72–74
 Sonography-guided biopsy 71, 73–75, 79, 230
 Sonography-guided/CT-guided
 Space-occupying lesion 3, 12–14, 18, 20, 72–75, 77, 78, 90, 95, 96,
 117, 176, 179, 198, 230
 Split pleura sign 30
 Spondylodiscitis 215
 Squamous cell carcinoma 17, 20, 78, 211, 225
 Staging 5, 12, 16, 18, 19, 25, 72, 74, 77, 120, 122–126, 133–135, 137,
 138
 Sternum 2, 17–18, 20, 24, 43, 106, 112–116, 214, 238, 240
 Supraclavicular lymph node metastases 77
 Supraclavicular region 5, 9, 16
 Suprasternal examination 109–111
 Surfactant 80
 Synchronosis 18
 Syndrome 3, 24, 25, 34, 36, 51–57, 69, 70, 77, 89, 118, 145, 193,
 214, 239, 242, 243

T

Tension pneumothorax 40, 43, 222–224, 233
 Teratoma 113, 117
 Thoracic duct 29, 33
 Thoracocentesis 11, 25, 28–30, 176, 198, 208, 209, 216
 Thromboembolism 87, 198
 Thymus 106, 113
 Transbronchial needle aspiration 124, 132–133, 137–138
 Transesophageal echocardiography 117
 Transesophageal puncture 200
 Transesophageal sonography 120–126
 Transthoracic therapy 31

Transudate 28–30, 52
Trauma 5, 12, 25, 29, 32, 35, 38, 40, 42–44, 46, 97, 99, 100, 166, 171, 172, 224, 236, 238–240
Triangular lung infarction 143
Tricuspid annulus plane systolic excursion (TAPSE) 87
Triple-organ-ultrasound 87
Tuberculosis (TB) 14, 15, 35, 111, 114, 125, 126, 164, 168, 183, 192, 203, 229
Tuberculous pleuritis 35, 157
Tumor invasion 72, 74, 123–125, 224–225
Tumor-related complications 77

U

Ultrasound 2–9, 12–18, 20, 24, 27–35, 37–40, 42–49, 52–57, 62, 65–69, 72, 80, 82, 85–88, 90–99, 132, 136–138, 141–184, 188–195, 207, 212, 219, 235–237, 239, 241–243

Upper inflow congestion 111, 114, 115
Upper thoracic aperture 5, 7, 183, 199, 208

V

Vascularization 2, 13–16, 38, 62, 69, 73, 109, 116, 141–184, 210, 223, 228
Vascular signs 81, 87, 239
Vessel signs 81

X

X-ray 2, 12, 17, 20, 27, 33–35, 37, 39, 43–46, 48, 55, 62, 63, 66–69, 73, 75, 88, 90–99, 115, 134, 153, 164, 165, 171, 174–178, 180, 229–231, 237
