## Foreword

Artificial Intelligence, aka AI, is a term that became very familiar to us in recent years. Indeed AI is part of our daily life, with a number of applications almost impossible to count, and now incorporated in most technological innovations. The relevance and impact of AI is hard to estimate, due to its incredibly rapid growth and diffusion, and this is true also for AI in medicine.

Proposal of using AI in medicine started in the 1950s, mainly as futuristic prediction, while a real boom occurred with the new millennium, and now counting thousands of papers and proposals every year, making difficult to stay updated, especially in areas where AI has been intensively studied, such as medical imaging.

For those reasons, it is very important to have reference reviews that make possible to understand the state of the art, and this is the scope of this book from J.Andreou, P. Kosmidis and A.Gouliamos, covering the applications of Artificial Intelligence in Oncological PET/CT.

The book is focused on the use of AI in the most advanced functional imaging method, and it covers all oncological clinical indications for PET/CT, being at the same time exhaustive and synthetic, while updated. Different perspectives are presented, as AI in PET/CT is clearly a very multidisciplinary field, bringing together the expertise of medical doctors, informatics, physics and many other professionals. The book is useful and recommended for all those specialists who will surely benefit from such a comprehensive text.

## Preface

The content of this book is mainly updated chapters from the second edition of *Imaging in Clinical Oncology* (2017) with addition of an introductory chapter about AI systems for Oncology.

Originally positioned as a means for noninvasive molecular phenotyping and quantification in the 1970s, PET's technological improvements in the 2000s and PET/CT fusion imaging generated renewed interest in quantification, which has grown over the last 5 years for cancer treatment planning. With fusion imaging radiologists and oncologists can combine anatomical and metabolic information and estimate the response to therapy. This progress is parallel with the development of artificial intelligence (AI) systems for Oncology which is an AI system with the aim of providing the best possible treatment to patients suffering from lung, breast, brain, prostate, liver and other types of cancer.

Applications of AI systems in imaging modalities have the following trends:

1. Artificial intelligence applications may help in detection of disease, tissue characterisation (benign vs malignant), staging and correlation with molecular biomarkers.
2. Radiomic signatures may help in prediction of response to therapy, risk scores for recurrence and classification of patients based on prognosis.
3. Correlation of data sets with imaging findings and pathology findings.
4. AI is under intensive research for massive screening for early diagnosis of cancer. More specifically, radiological screening for lung and breast cancer is more advanced. Additionally, colorectal polyps screening is another attractive examination through colonoscopy for early diagnosis of cancer.

Considering how different things were 10 or 20 years ago can we imagine or foresee the advancements in medical technology in the next 10 years? We should be thankful to the many pioneers who have made PET/CT during the past 20 years what is today: a useful tool for depiction of anatomy and pathology for the benefit of millions of patients around the world.

Although technical difficulties were encountered at the beginning, limited applications of AI in PET/CT are already here and appear promising in the near future as have been in other imaging modalities. There is no doubt that

AI can help radiologists lessen their workload and oncologists develop novel tools.

# Introduction: Artificial Intelligence (AI) Systems for Oncology

1

João Santinha, Ana Castro Verde,  
and Nikolaos Papanikolaou

## 1.1 Introduction

Artificial intelligence (AI) is a topic of growing interest in various fields, including finance, entertainment, transports, agriculture, and healthcare. The application of **machine learning (ML)** and **deep learning (DL)** algorithms in medicine was enabled by three essential aspects: the increase in data availability, the development of innovative software technologies, and the capacity improvement of the computing systems [1]. The former was most evident in radiology and nuclear medicine due to the accessibility of digitised images, but it also impacted dermatology, ophthalmology, histopathology, and clinical and genetic data. Although plenty of research was conducted several decades before, in the 2012 ImageNet

Challenge—a natural image classification competition with more than 14 million images of more than 20,000 categories—a convolutional neural network (CNN) model named AlexNet was able to substantially reduce the classification error showing the potential of DL-based models in comparison with traditional computer vision approaches [2]. By this time, the limitation in transposing this work to medicine was the insufficient labelled data. Two facilitators for this were, in 2015/2016, the emergence of transfer learning algorithms [3]—where DL networks pre-trained on non-medical images are used and/or finetuned for medical imaging applications—and, in 2017/2018, the development of synthetic data augmentation—mainly, using Generative Adversarial Networks (GANs) to generate synthetic images that are visually mistaken with real medical images and, when fed into CNN, can increase the performance of these models in

medical tasks. Besides those, additional contributions to the field were the UNet architecture for image segmentation in 2015 [4] and, in 2015/2016, the advent of multiple medical imaging DL challenges.

In parallel to the emergence of DL solutions for medical problems and as an extension of computer-aided diagnosis and detection (CAD) systems, **radiomics** (Fig. 1.1) was first coined in 2012 [5]. It is based on the principle that images contain unexplored information on the tumour phenotype and microenvironment that can only be identified through quantitative analysis [6]. Radiomics refers to the extraction of high-dimensional features reflecting intensity, shape, size or volume, and texture—from computer tomography (CT), magnetic resonance (MR), and positron emission tomography (PET) images. These features are to be combined with addi-

tional information from multiple data sources and used for hypothesis generation and testing. The number of radiomics publications (Fig. 1.2) has seen a drastic increase over the past 10 years, with more developments in oncology due to support from the National Cancer Institute (NCI) Quantitative Imaging Network (QIN). Although we verify this trend, further work is still necessary for tackling multiple challenges in the field (see Sect. 1.3 for a more detailed description) to achieve reproducible results with the end goal of clinical translation [7].

Overall, the establishment of validated imaging biomarkers is an opening opportunity to drive **precision medicine** forward by characterising a patient’s tumoral heterogeneity across space and time [8].

## 1.2 Applications

Artificial intelligence (AI) has been applied to different fields with considerable success, and oncology is no exception. The utilisation of AI applications in oncology allows the optimisation of multiple tasks contributing to cancer detection, diagnosis, staging, treatment planning, and prognosis. Cancer imaging, encompassing digital pathology, radiographic imaging, and clinical photographs, is the area within AI in oncology where the most promising work has been done [1]. While in digital pathology and clinical pictures, the main focus has been to automate and improve image analysis and diagnostic performance, in radiology, the application of AI is also being widely applied to image reconstruction and enhancement, segmentation, and registration, and computer-aided detection (CADe) and computer-aided diagnosis (CADx) tasks with promising results. Improvements in image reconstruction and enhancement, segmentation, and registration may also improve results obtained in CADe and CADx tasks. Furthermore, these applications are expected to facilitate the radiologists' work by decreasing the variability inherent to interpretation and reducing human errors due to the short time to evaluate medical images and increased workload [9].

Regarding the use of AI in PET-CT images, several studies have already demonstrated that the use of AI in image reconstruction and enhancement allows faster acquisitions (low-count acquisitions) while providing better diagnostic images [10–14]. In the study performed by Arabiand Zaidi, a deep learning-based metal artefact reduction algorithm reduced the adverse effects of metal artefacts on PET images by improving the generation of accurate attenuation maps in the presence of CT images corrupted due to the presence of metallic implants [14]. Chaudhari and colleagues demonstrated that deep learning could reconstruct images from low-count whole-body PET acquisition (fourfold count reduction), restoring diagnostic image quality and maintaining SUV accuracy [11]. Furthermore, the authors showed that the method generalised on an external dataset comprised patients from multiple institutions and scanner types [11]. Gong et al. proposed an iterative reconstruction neural network that can improve PET image quality, outperforming denoising neural networks used as postprocessing tools and conventional penalised maximum likelihood methods [10]. More recently, Sanaat et al. and Feng et al. also investigated the use of deep learning methods to reconstruct PET images with 1/ eighth of standard injected activity or acquisition

time and within the limits of the current hardware, respectively [12, 13]. Some AI commercial applications like SubtlePET™ [15] and OncoFreeze AI [16] are already available for image reconstruction and enhancement.

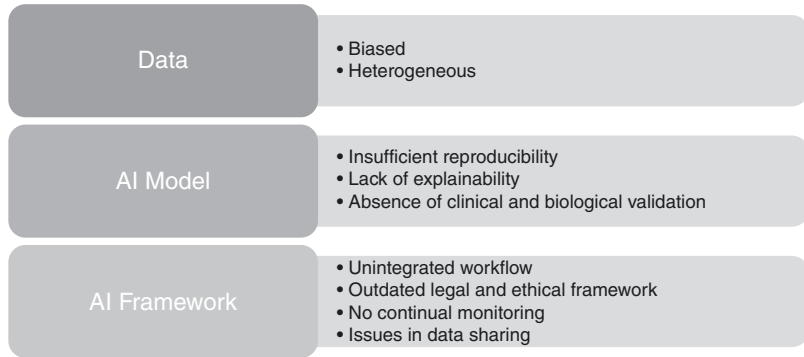

In terms of AI-based segmentation, Edenbrandt and colleagues demonstrated the benefits of using convolutional neural networks to segment lesions in PSMA PET/CT images which reduced variability between readers [17]. In the studies by Zhao et al. and Moe et al., a multi-modality convolutional neural network with both PET and CT images as input showed significant improvements over methods that use only PET or CT [18, 19].

Several studies also investigated the use of AI for CADe and CADx in PET/CT images. Kawauchi and colleagues investigated the use of CNNs to classify patients into benign, malignant, or equivocal using FDG PET/CT examinations [20]. Peng et al. evaluated the prognostic value of DL PET/CT-based radiomics for individual induction chemotherapy in advanced nasopharyngeal carcinoma [21]. In another study by Polymeri et al., the authors assessed the association between DL-based quantification of PET/CT prostate gland uptake and overall survival [22], which was followed by a study by Borrelli and colleagues in which an AI method was developed to automatically detect lymph node metastasis that was shown to be associated with prostate cancer-specific survival [23]. Sibille and colleagues used DL to localise and classify uptake patterns into foci suspicious and non-suspicious in lymphoma and lung cancer [24]. An automatic method to detect abnormal lung lesions and calculate the total lesion glycolysis (TLG) on FDG PET-CT was developed by Borrelli and colleagues [25]. As for the use of texture-based analysis, the studies by Fan, Satoh, and Zheng assessed its performance for the differential diagnosis in spinal metastases, for comparing diagnosis of primary breast cancer using whole-body PET/CT and high-resolution dedicated breast PET, and to predict mediastinal node metastasis in non-small cell lung cancer patients, respectively [26–28].

### 1.3 Challenges

In combination with the growing number of applications of AI in oncology, some challenges need to be addressed for achieving the end goal of implementation into clinical practice. One can broadly divide these challenges into three topics: Data, AI Model, and AI Framework, as shown in Fig. 1.3. Firstly, challenges with Data come from the fact that the training data used to feed the algorithms can be **biased**, under-representing specific age, gender, and racial populations or perpetuating social biases, possibly leading to undertreatment of specific races and/or socio-economic groups, known as under-served populations, by perpetuating systematic mistakes in inpatient care [29]. Potential solutions to this problem are, on the one hand, the utilisation of large *real-world* datasets that are representative across patient groups, time (historically vs. recently treated patients), and data sources (data obtained at different institutes, using different scanner models and manufacturers), and on the other hand, the development of methods to estimate and eliminate preexisting biases in the training data. However, the advent of larger datasets coming from multiple institutions is still hindered by the need to protect patient information, which may be overcome with federated learning. Furthermore, multiple institution datasets, acquired using different equipment, parameters, and/or reconstruction algorithms and settings, pose the challenge of data **heterogeneity**, leading to variability in algorithms' performance. Individual variations in the images can be observed in multi-centre studies, as shown in Fig. 1.4, resulting in a shift in data distribution across various settings. For the case of radiomics—mentioned previously in Sect. 1.1, different harmonisation methods can be applied to ensure repeatability and/or reproducibility of the radiomics features across diverse settings [30]. One possible scenario is to harmonise the image/intensities domain, whether by using guidelines for the acquisition and reconstruction parameters' standardisation or by utilising meth-

**Fig. 1.3** Schematic on the current challenges of AI in oncology

**Fig. 1.4** Multi-center centre variability of PET and CT slices of four different patients, taken from [30]

ods on the raw or reconstructed image data. For PET imaging standardisation, the European Association of Nuclear Medicine (EANM) launched the EARL (EANM Research Ltd.) [31]. For more than one modality, the RSNA’s Quantitative Imaging Biomarkers Alliance (QIBA) [32] and the Image Biomarker Standardisation Initiative (IBSI) [33] provide common nomenclature and definitions for image biomarkers, benchmarks for image processing and feature extraction, and reporting guidelines. Since guidelines may be insufficient to accommodate the number of scanner and protocol combinations, postprocessing of raw sensor-level data, data augmentation techniques using generative adversarial networks (GANs), or the style transfer methods can be employed to overcome

such variability. In the first case, studies have shown similar performance when using raw data and the reconstructed images [34], so one possible methodology is to use the raw data’s latent information to reduce the variability introduced by image reconstruction. As for GANs, which are formed by two adversarial networks, a generator that learns to synthesise “realistic” data capable of “fooling” the discriminator, which in turn learns how to discriminate real and synthesised data better, has been used to generate new data [35]. In the case of style transfer, images are translated from one domain to another (e.g., from Philips to Siemens data, from low to high resolution, to normalise slice thickness and dosage in CT, from one CT reconstruction kernel to another [36]), a particular type of GANs, called

CycleGANs [37], has been widely studied as it does not need paired data, allowing the harmonisation multiple institutional data and subsequent improvement of AI models generalizability. These have traditional normalisation alternative methods like statistical normalisation (min-max, Z-score) and intensity normalisation (histogram matching to align the image intensity histograms to a reference intensity histogram) [38]. In the case of radiomics, several techniques can be applied in the feature domain, where non-robust features across institutions may be disregarded. Alternatively, normalisation techniques like the min-max, Z-score, or ComBat may be applied to minimise differences in features values from different institutions. Several studies using phantoms and patients have proposed workflows for identifying reproducible features in MRI [39] and PET-CT [40], allowing the selection of repeatable and reproducible features for AI model development. Although ComBat harmonisation—a methodology developed for genomic analysis that eliminates batch effects by scaling and shifting the values of each feature—has been extensively used and frameworks to obtain “ComBatable” radiomics features were established [41], it fails to generalise to new unseen cases. On the other hand, using a simple neural network to learn a non-linear normalisation transformation allows generalisation to unseen textures and scanners, representing a future direction in harmonisation when validated on real patients.

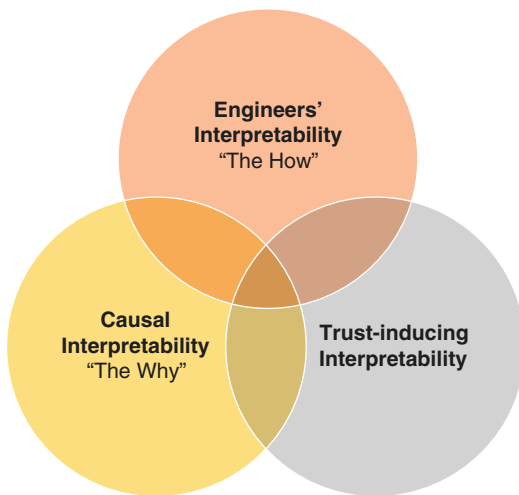

When developing AI models, large-scale annotated datasets comprising data acquired from multiple institutions with different scanner models and manufacturers and different patient demographics will likely result in more generalisable models. Nonetheless, models shall be **evaluated** using internal (via temporal partitioning of the dataset to provide insights into temporal variability of the model performance) and external datasets. Furthermore, reporting best practices shall be followed to ensure that research and development of these AI models are appropriately conducted.

Several reporting guidelines are being developed to define these best practices for AI algorithms. The Transparent Reporting of a

multivariable prediction model of Individual Prognosis Or Diagnosis (TRIPODAI), the Prediction model Risk Of Bias ASsessment Tool (PROBAST-AI) [42], the Reporting Guidelines for Clinical Trial Protocols for Interventions (SPIRITAI) [43], the Reporting Guidelines for Clinical Trial Reports for Interventions (CONSORT-AI) [44], the Standards for Reporting of Diagnostic Accuracy Study (STARD-AI) [45], and the Developmental and Exploratory Clinical Investigation of DEcision-support systems (DECIDE-AI) [46] are some of these guidelines recently designed to improve reporting when using AI models.

Concerning the latter, to ensure model **reproducibility**, it is crucial to establish AI reporting standards on the model’s source code, datasheets describing the utilised datasets [47], and training conditions [1]. Furthermore, a significant challenge that has been a thriving topic of discussion is model **explainability**. Global initiatives and regulations, like the Explainable AI (XAI) from the United States (US) Defense Advanced Research Projects Agency (DARPA) or the European Union (EU) regulation on General Data Protection Regulation (GDPR), have been established to restrain the clinical utilisation of noninterpretable highly complex models. The solutions for delivering explainable models can range from developing transparent models with low complexity to black-box models that can be explained a posteriori using textual or visual maps of explanations. The latter includes saliency maps that highlight relevant image components explaining the model’s predictions but need further validation due to its questionable trustworthiness [48]. However, some argue that current explainability techniques are seen as insufficient for decision support at the individual patient level [49] and that if the model is useful and shows accurate predictions, a detailed explanation of its functioning may not be necessary [50]. The latter is especially true in medicine, where the principle behind effective drugs routinely prescribed by clinicians is not entirely understood.

Moreover, humans are biased to trust a wrong model’s decision because it is interpretable. So, the need for interpretability depends on the con-

**Fig. 1.5** Types of AI interpretability

text, and different individuals may look at different types of interpretability (Fig. 1.5). Whereas engineers are interested in revealing factors to boost models' predictive power, clinicians are keener on causality and trust. Presenting an explanation outside of the area of interest can result in a loss of trust in a potential accurate and useful model. From the point of view of the model's **clinical validation** and cost-effectiveness, randomised controlled trials (RCTs) are the gold standard of care to evaluate whether a new prediction tool using traditional statistics (TS), ML, or DL provides an improvement compared to the clinical standard of care. By evaluating 65 RCTs, a review [9] has shown that good performance in model development is not a sign of a clinical benefit to patients since two-fifths of trials did not present a clinical benefit compared to standard care. Although DL and ML solutions have demonstrated a higher percentage of positive results, this difference decreased or disappeared after stratifying by the risk of bias when considering only trials with low risk-of-bias. To our knowledge, only six RCTs of DL in medicine have been conducted so far. There is a paramount need to increase the number of high-quality RCTs to estimate the benefits of new AI medical technologies in realistic settings [51]. Besides, **biological validation** of the findings is vital to promote a clinical translation of

the models. Indeed, current models may have high predictive power but lack a clear causal relationship between the extracted features and the clinical outcome. To trust model decisions, there are different strategies to select features that are biologically meaningful, including selecting only semantic features that are accepted by radiologists and describe morphologic and location characteristics, combining the extracted features with mutation information coming from genetic analysis and with histopathologic findings and immunohistochemistry (IHC), and identifying functional sub-regions within the tumour, known as habitat imaging [52].

Thirdly, most current AI applications are **not integrated** into the clinical workflow from the AI framework's perspective. Although some of these applications are not created to be directly used by clinicians, for instance, clinical decision support systems (CDSS) for oncologists require interactive and explanatory environments [1]. As mentioned before, regarding explainability, the level of understanding that needs to be provided will depend on the use case and AI methodology. Moreover, existing **legal and ethical frameworks are outdated** and fail to accompany AI solutions' progress and self-learning characteristics. The system should minimise automation complacency so that the end user does not blindly accept the clinical recommendations or overlook alternatives when the algorithm confirms its initial assumptions. Most consider it insufficient to regulate AI in oncology with existing legislative frameworks, so a new regulatory framework needs to be developed. Source data has a **dynamic distribution**, with constant updates on the data standards and ontologies and on the scanner's technology and protocol, which is likely to cause drifts in the algorithm's performance. Continual learning solves this problem, with deployed models in the production environment being automatically retrained when new data input is entered to maintain high-performing models [53]. Finally, there is the challenge of **data sharing** across multiple sites that can be overcome by creating large centralised repositories—with limited permissions or personal information removed from data—or by implementing federated approaches,

with each institution maintaining individual data and only sending out the models, or with a single honest broker assessing data for all the involved institutions [6].

For all the mentioned challenges for AI in oncology, efforts should be made by multi-disciplinary professionals (clinicians, epidemiologists, computer scientists, biomedical engineers, informaticians, ethicists, and legislators) to address them to deliver robust, explainable, and reproducible AI models that can be implemented into clinical practice.

# Positron Emission Tomography in Bone and Soft Tissue Tumors

# 2

Nikoletta K. Pianou

## 2.1 Introduction

Positron emission tomography/computed tomography (PET/CT) with the use of  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG) is an imaging modality that combines both functional and anatomical information. The combination of PET with CT has been established as an imaging modality and is currently widely used in oncology. Bone and soft tissue tumors, as of course the majority of tumors, are characterized by multiple metabolic and molecular alterations, which allow us imaging with positron emitters. These alterations include increased glycolysis, increased amino acid and increased nucleic acid metabolic activity.

There are several radiotracers available for PET imaging, but the most widely used tracer in oncology is  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG) which is a glucose analogue. Contemporary PET scanners are equipped also with CT (PET/CT scanners) and very recently with MRI (PET/MRI scanners), thus allowing a comprehensive functional and an anatomical assessment of tumors.

$^{18}\text{F}$ -FDG follows the pathways of glucose into the cells, meaning that it enters into the cells through membrane glucose transporters (GLUT 1–GLUT 7). After its entrance into the cell, it is phosphorylated by an enzyme called hexokinase

and converted to FDG-6-phosphate. The difference from glucose is that  $^{18}\text{F}$ -FDG is not further metabolized, and it is metabolically trapped into the cell. Taking advantage of the fact that tumors are characterized by increased glycolysis, we can depict images of the tumor. During tumor proliferation, the glucose transporters, especially GLUT 1, are over-expressed, but other changes as well, like increased hexokinase activity and reduced glucose-6-phosphatase activity, make tumors “visible” to PET.

$^{18}\text{F}$ -FDG is injected intravenously to the patient and then the patient remains at rest for about 1 h. Hydration and fasting for at least 6 h prior to the examination are mandatory. Blood glucose levels should also be measured as it is preferred that the glucose level remains  $<160$  mg/dL. Then the patient initially undergoes CT imaging and then PET imaging, usually from the base of the skull to the thighs. In selected patients, the extremities may be in the field of interest. PET images are attenuation corrected with the CT and both images are fused.

## 2.2 Positron Emission Tomography in Sarcomas

Sarcomas are relatively rare and account for about 1% of all malignancies. They arise from tissue of mesenchymal origin and are very heterogeneous group of malignancies comprising

N. K. Pianou (✉)  
Division of Nuclear Medicine, Department of PET/CT, “EVANGELISMOS” General Hospital of Athens, Athens, Greece

bone sarcomas (BS) and soft tissue sarcomas (STS). However, sarcomas can develop from many types of tissue such as bone, cartilage, muscle, connective tissue, fat, peripheral nerves or vessels, occurring almost anywhere in the body. They usually grow locally, infiltrating surrounding tissues. They occur in both children and elderly. Ewing's sarcoma, which is a malignant primary bone tumor, and rhabdomyosarcoma usually occur in children and adolescents, but osteosarcoma may occur in the elderly also. Lungs are the most frequent site for metastases, as sarcomas tend to spread hematogenously, although lymphatic spread is also possible. Extremities, especially lower limbs, are usual sites where sarcomas grow up, but some of them may occur intra-abdominally, like gastrointestinal stromal tumors (GIST), which are the most common sarcomas (mesenchymal tumors) of the gastrointestinal tract.

When the disease is initially diagnosed, there are some parameters which are very important

for the management of these tumors, such as the exact location of the tumor, the size and grade of the tumor and the accurate staging. The conventional imaging modalities (CIM) which are used to determine the location and the size of the primary tumor are the magnetic resonance imaging (MRI) and the CT. However, benign soft tissue masses and STS may be difficult to separate with the use of CIM, while sarcomas show very heterogeneous character. Biopsy remains the method of choice for the diagnosis and grading of sarcomas. The biopsy site determines the result which is dependent and directed by anatomical imaging. A problem which often arises when biopsy is performed is that the site of the biopsy taken may not represent the "behavior" of the whole mass; therefore, clinically significant high-grade areas of the tumor may be missed.  $^{18}\text{F}$ -FDG PET/CT can help improve the localization of the biopsy site, helping for a more accurate staging (Fig. 2.1). However, there are substantial differences in  $^{18}\text{F}$ -FDG uptake values between low-

**Fig. 2.1** (a–c) Young patient with fever of unknown origin. There is focally increased  $^{18}\text{F}$ -FDG uptake at left humeral soft tissues. Biopsy revealed sarcoma. ((a)  $^{18}\text{F}$ -

**Fig. 2.2** (a–c) Male patient with history of resected low-grade synovial sarcoma of the right lower extremity. Lung metastases on CT images showing mildly increased  $^{18}\text{F}$ -

FDG uptake on PET images ((a)  $^{18}\text{F}$ -FDG PET, black arrow; (b) CT, white arrow; (c) fusion PET/CT, white arrow)

and high-grade BS and STS, while  $^{18}\text{F}$ -FDG uptake correlates with histological grade in heterogeneous sarcomas.

High-grade sarcomas show more intense  $^{18}\text{F}$ -FDG uptake, while low-grade sarcomas the opposite, leading sometimes to false negative result (Fig. 2.2). Nevertheless, in clinical practice, the noninvasive assessment of the sites with the highest grade of malignancy is very important for the guidance of biopsy.

$^{18}\text{F}$ -FDG uptake is not pathognomonic for malignancy. Some benign lesions, such as giant cell tumors of the bones, inflammatory changes, as well as bone fractures may present a high level of tracer accumulation. Among these, inflammatory disease is the most common cause of a false positive  $^{18}\text{F}$ -FDG PET/CT scan and malignant lesions should always be confirmed either with histopathology examination or with a follow-up. False negative  $^{18}\text{F}$ -FDG PET/CT results may also occur. Malignant diseases may show nonspecific or asymmetric  $^{18}\text{F}$ -FDG uptake, while the limited spatial resolution of  $^{18}\text{F}$ -FDG PET/CT scan may be a reason for some occult or sub-centimeter lesions to be missed [1].

A semiquantitative method which is used to determine the  $^{18}\text{F}$ -FDG uptake by the primary tumor is the maximum standardized uptake value (SUVmax). SUVmax of the primary tumor seems to be a prognostic factor of survival and high SUVmax values indicate a poor prognosis. In a recent study of 74 patients with STS, Schwarzbach et al. divided the patients into three groups based on SUVmax, those with values  $<1.59$ , values  $>1.59$  but  $<3.6$  and  $>3.6$ , with 5-year survival rate 84, 45, and 38%, respectively [2].

Recently, Chen et al. evaluated the usefulness of  $^{18}\text{F}$ -FDG PET/CT-derived parameters to differentiate STS and BS from benign lesions, in a total

of 70 patients. SUVmax index is a marker of glucose metabolism of a single integrin in the tumor. On the other hand, Metabolic Tumor Volume (MTV) and Total Lesion Glycolysis (TLG) reflect the global metabolic activity of the tumor. Another parameter is the intratumoral heterogeneity of glucose metabolism, which is expressed by the heterogeneous factor (HF). As it was expected, the tumor size, SUVmax, MTV, TLG, and HF in the STS and BS group were all significantly higher than in the benign lesions group. Additionally, only SUVmax and HF were identified as independent risk factors for malignant tumors. Despite the usual false positive causes, six false negative malignant lesions were also determined. For example, myxofibrosarcomas, as well as other malignancies which were rich in mucous matrix, usually exhibited insufficient glucose transporter expression and showed low FDG uptake [3].

RHR Marles et al. conducted a retrospective study on patients diagnosed with STS, which included 83 patients. The most common tumor types were adipocytic tumors (31%), smooth muscle tumors (16%), fibroblastic/myofibroblastic tumors (13%), and undifferentiated or unclassified sarcomas (13%). Several metabolic parameters were also calculated, like SUV, MTV, and TLG. The SUVmax remains the most accurate parameter to distinguish between high-grade and low-grade STS, which is also correlated with the histological grade measured in the baseline PET/CT. However, when considering the relationship between MTV and TLG parameters with the tumor grade, the authors concluded that these parameters do not allow defining a significant cut off point to discriminate high- from low-grade STS.

In the same study, the authors concluded that patients with high SUV<sub>max</sub>, SUV<sub>peak</sub>, MTV, and TLG values of baseline <sup>18</sup>F-FDG PET/CT have significantly lower Overall Survival (OS) [4].

During staging procedure a total body assessment of the metastatic spread of the disease is also important, concerning either the lymph nodes metastases or the distant metastases (Figs. 2.3, and 2.4). <sup>18</sup>F-FDG PET/CT has high accuracy for staging lymph node metastases and shows high sensitivity and specificity, although

lymph node metastases are not very frequent. In a recent study by Fuglo et al. [5] which included 89 sarcoma patients, the <sup>18</sup>F-FDG PET/CT revealed a sensitivity of 100%, a specificity of 90%, and an accuracy of 91% for the detection of lymph node metastases. Nevertheless, false negative results may occur if the cancer has low glucose metabolism, if the metastatic lymph nodes are small in size, or a focus may be missed if it is located adjacent to an area of high physiological or pathological.

**Fig. 2.3** (a–c) Female patient with history of resected uterine leiomyosarcoma. Right pulmonary nodule shows increased <sup>18</sup>F-FDG uptake on PET/CT consistent with

metastasis. ((a) <sup>18</sup>F-FDG PET, black arrow; (b) CT, white arrow; (c) fusion PET/CT, white arrow)

**Fig. 2.4** a–e Female patient with uterine leiomyosarcoma. <sup>18</sup>F-FDG PET/CT performed at initial staging shows increased <sup>18</sup>F-FDG uptake at the primary mass (red arrows), at left iliac lymph node compatible with metastasis

(black arrows) and at T8 vertebra compatible with metastasis (white arrows). (Transverse views: (a) <sup>18</sup>F-FDG PET, (b) CT, (c) fusion PET/CT; Sagittal views: (d) <sup>18</sup>F-FDG PET, (e) fusion PET/CT)

**Fig. 2.5** (a–c) Male patient at initial staging of angiosarcoma of the left lung (black and white arrows). There is increased  $^{18}\text{F}$ -FDG uptake at a right pulmonary nodule con-

sistent with metastasis (long red arrow) and at the shaft of the right humerus consistent with bone metastasis (short red arrow) ((a)  $^{18}\text{F}$ -FDG PET; (b) CT; (c) fusion PET/CT)

$^{18}\text{F}$ -FDG uptake. On the other hand, false positive results may occur due to reactive/inflammatory lymph nodes, as increased glucose metabolism is not specific only to cancer cells but in activated leukocytes and macrophages as well. In situations such as following biopsy, tumor resection, or during infection we may have a false positive  $^{18}\text{F}$ -FDG uptake in lymph nodes. The tumor itself may also lead to reactive  $^{18}\text{F}$ -FDG uptake in the regional lymph nodes due to inflammation.  $^{18}\text{F}$ -FDG PET/CT may be used to guide sampling of sites of unexpected nodal metastases.

As for the distant metastases,  $^{18}\text{F}$ -FDG PET/CT seems to be a very accurate method of staging (Fig. 2.5). In the study by Fuglo et al. [5], the  $^{18}\text{F}$ -FDG PET/CT detected distant metastases with a sensitivity of 95%, a specificity of 96%, and an accuracy of 95%. In this study, the positive predictive value was 87%, which shows moderate to high ability of  $^{18}\text{F}$ -FDG PET/CT to diagnose distant metastases, with not too many false positive results. However, the negative predictive value was high (98%), which means that  $^{18}\text{F}$ -FDG PET/CT may exclude with confidence the presence of distant metastatic disease. In another study by Tateishi et al. [6], which included 117 patients with BS and STS combined PET/CT and CIM helped to avoid surgical resection in 13% of patients and to alter management in additional 14% of patients. In the same study the sensitivity, specificity, and accuracy of  $^{18}\text{F}$ -FDG PET/CT were found to be 92, 91, and 91%, respectively. Another advantage of  $^{18}\text{F}$ -FDG PET/CT is that the whole-body imaging may also reveal incidental findings, such as other malignancies.

In a study of Franzius et al. [7]  $^{18}\text{F}$ -FDG PET was compared to bone scintigraphy in the detection of osseous metastases in 38 patients with Ewing Sarcoma (ES). The sensitivity, specificity, and accuracy of  $^{18}\text{F}$ -FDG PET was 100, 96, and 97%, respectively, on a patient-based analysis. The comparable values for bone scintigraphy were 68, 87, and 82%. On a lesion-based analysis, the sensitivity of  $^{18}\text{F}$ -FDG PET was 88% and for bone scintigraphy was 69%. The superiority of  $^{18}\text{F}$ -FDG PET over bone scintigraphy for the detection of osseous metastases from ES may be explained by the fact that  $^{18}\text{F}$ -FDG PET depicts the increased glucose metabolism of the metastases before bone scintigraphy shows increased osteoblastic activity. Also,  $^{18}\text{F}$ -FDG PET has a better spatial resolution than bone scintigraphy. Small metastases adjacent to the growth plates in children, which are areas of normal radiotracer accumulation in a bone scintigraphy, might be missed giving a false negative result. The only exception where bone scintigraphy is superior to  $^{18}\text{F}$ -FDG PET is the depiction of metastases to the skull because  $^{18}\text{F}$ -FDG normally accumulates in the adjacent cerebral cortex which uses glucose. Bone scintigraphy is more sensitive in that case than  $^{18}\text{F}$ -FDG PET. In addition,  $^{18}\text{F}$ -FDG PET may detect soft tissue metastases, while bone scintigraphy may not. As for pediatric sarcoma patients, Volker et al. [8] evaluated the impact of  $^{18}\text{F}$ -FDG PET in 46 pediatric patients with ES, osteosarcoma, and rhabdomyosarcoma at initial staging, compared to other CIM. Authors concluded that  $^{18}\text{F}$ -FDG PET and CIM were equally effective in the detection of primary tumors, while  $^{18}\text{F}$ -FDG PET was superior to CIM concerning the correct detection of lymph node

involvement (sensitivity 95% vs. 25%, respectively) and bone manifestations (sensitivity 90% vs. 57%, respectively). However, CT was more reliable than  $^{18}\text{F}$ -FDG PET in depicting lung metastases (sensitivity 100% vs. 25%, respectively).

Local recurrence occurs in approximately 10–15% of patients with STS, while distant recurrence develops in 35–45% of patients, even when treated suitably. Surgical resection usually disturbs the normal anatomy of the area and as a result, local recurrence is difficult to be detected (Figs. 2.6, and 2.7). In addition, radiotherapy may disturb the anatomy of the area, leading to difficulties in detecting local recurrence and  $^{18}\text{F}$ -FDG PET/CT may be false positive due to post radiation inflammatory changes. On the other hand, CIM are most prone to errors and CT and MRI, although they are more suitable techniques for visualization of anatomy, usually cannot differentiate a scar from local recurrence.  $^{18}\text{F}$ -FDG PET/CT depicts the increased metabolism associated with abnormal tissues enabling visualization of recurrences. Nevertheless, the study

should be performed at least 4–6 months after radiation therapy and the results should be interpreted with caution.

Distant recurrence usually occurs in the lungs. In a study by Franzius et al. [9],  $^{18}\text{F}$ -FDG PET was compared to spiral thoracic CT for the detection of pulmonary metastases in 39 patients with ES. There was no patient with a true positive  $^{18}\text{F}$ -FDG PET and a false negative CT, and no pulmonary metastasis was detected earlier with  $^{18}\text{F}$ -FDG PET than with spiral CT, giving a clear superiority to CT for detecting pulmonary metastases in ES patients. On an examination-based analysis,  $^{18}\text{F}$ -FDG PET had a sensitivity of 56%, a specificity of 91%, and an accuracy of 82%, while the same values for CT were 88, 100, and 97%, respectively. In conclusion, an  $^{18}\text{F}$ -FDG PET should not be recommended to exclude lung metastases when the lung CT is negative. However, a positive  $^{18}\text{F}$ -FDG PET result can be used to confirm lesions seen on CT as metastatic disease because of its high specificity.

$^{18}\text{F}$ -FDG PET may also be used in evaluation of treatment response after neoadjuvant chemo-

**Fig. 2.6** (a–c) Female patient with history of resected uterine leiomyosarcoma.  $^{18}\text{F}$ -FDG PET/CT during restaging shows increased  $^{18}\text{F}$ -FDG uptake in anatomical

position of the uterus, consistent with local recurrence ((a)  $^{18}\text{F}$ -FDG PET, black arrow; (b) CT, white arrow; (c) fusion PET/CT, white arrow)

**Fig. 2.7** (a–c) Female patient with history of resected uterine leiomyosarcoma.  $^{18}\text{F}$ -FDG PET/CT during restaging shows increased  $^{18}\text{F}$ -FDG uptake in a left iliac lymph

nodes compatible with recurrence ((a)  $^{18}\text{F}$ -FDG PET, black arrow; (b) CT, white arrow; (c) fusion PET/CT, white arrow)

therapy in patients with STS. Herrmann et al. evaluated prospectively whether  $^{18}\text{F}$ -FDG PET imaging after one cycle of neoadjuvant therapy could predict overall survival in patients with primary high-grade STS. They pointed out that  $^{18}\text{F}$ -FDG PET can potentially serve as an intermediate end point biomarker in clinical research and patient care [10]. Fendler et al. also evaluated 73 patients with STS after chemotherapy with regional hyperthermia (RHT). All patients underwent a baseline  $^{18}\text{F}$ -FDG PET and after two to four cycles of neoadjuvant chemotherapy with RHT. PET Response Criteria in Solid Tumors (PERCIST 1.0) and Response Evaluation Criteria in Solid Tumors (RECIST 1.1) were applied. Metabolic response by PERCIST ( $n = 44/73$ ) was an independent predictor of Progression-Free Survival (PFS) ( $P = 0.002$ ) and time to local or distant progression [11]. More recently Koshkin et al. analyzed assessments made during a clinical trial of a novel IGF1R antibody in patients with Ewing sarcoma.  $^{18}\text{F}$ -FDG PET studies were conducted at baseline and on day 9 of treatment. Functional imaging assessment of progressive disease could be identified as early as day 9 versus at 6 weeks by using any of the anatomic imaging criteria, giving PET a superiority to anatomic imaging in identification of responders [12].

---

### 2.3 Positron Emission Tomography in Gastrointestinal Stromal Tumors

As for the monitoring of treatment,  $^{18}\text{F}$ -FDG PET/CT seems to have the most important role in GIST therapy [13]. GIST have a common molecular pathogenesis with activating mutations in the gene encoding Kit (a tyrosine kinase and stem cell factor receptor). For that reason, treatment of GIST is currently regarded as the paradigm of molecular-targeted therapy in solid tumors, and targeted therapies by means of the tyrosine kinase inhibitor imatinib mesylate and other similar drugs have been introduced in clinical practice. Conventional cytotoxic chemotherapy and radiotherapy are not effective in this kind of tumors [13].

Most GIST show increased metabolic activity in  $^{18}\text{F}$ -FDG PET/CT at initial diagnosis and decreased  $^{18}\text{F}$ -FDG uptake during treatment, which is related to a positive treatment result. Treatment with c-Kit inhibitors causes some changes in the tumor structure, such as decreased vascularity, hemorrhage, necrosis, cystic or myxoid degeneration, which may not alter the tumor volume. For that reason the morphologic criteria only, meaning the tumor size, as it is depicted by CT imaging, is not the optimal way to assess treatment response of GIST to drugs, usually underestimating the treatment result. The metabolism of the tumor cell is reflected by the decrease of  $^{18}\text{F}$ -FDG uptake, which usually precedes changes in tumor size. There are many studies showing that  $^{18}\text{F}$ -FDG PET/CT may identify GIST patient responders to imatinib or other drugs, earlier than CT, while in others  $^{18}\text{F}$ -FDG PET/CT is considered as the gold standard technique for the assessment of treatment response in patients with GIST.

Holdsworth et al. [14], studied 63 patients with advanced GIST disease and compared CT bidimensional measurements and  $^{18}\text{F}$ -FDG PET/CT SUVmax values to determine response to imatinib treatment. The authors concluded that after 1 month of treatment, the SUVmax cut off value of 3.4, the reduction of the SUVmax value of 40% compared to the baseline PET, and the absence of growth of the tumor are optimal criteria for treatment response.

Unfortunately, 14% of GIST patients may show primary imatinib resistance, while 50% of those who responded initially might develop secondary resistance. In these patients, the alteration of therapy with newer tyrosine kinase inhibitors is mandatory [13].  $^{18}\text{F}$ -FDG PET seems to be the most significant independent predictor of PFS predicting patient outcome. Demetri et al. [15] studied 97 patients with imatinib-resistant GIST and bulky metastatic disease who were treated with sunitinib. A baseline  $^{18}\text{F}$ -FDG PET was performed initially and follow-up  $^{18}\text{F}$ -FDG PET scans were performed at several points during treatment. In the majority of patients, a partial metabolic response was evident on  $^{18}\text{F}$ -FDG PET within 1 week of starting sunitinib. On the con-

trary, objective responses on CT took much longer to detect. In another study by Fuster et al. [16], 21 patients with locally advanced and/or metastatic GIST refractory to imatinib, treated with doxorubicin (four cycles), followed by imatinib maintenance, were evaluated with CT and  $^{18}\text{F}$ -FDG PET at baseline and after completion of therapy. A correlation was found between PET response and PFS. A residual SUV<sub>max</sub> <5 after treatment correlated with improved PFS while survival curves showed a significant association between PET response and PFS.

Recently, Fendler et al. investigated the SUV-based parameters with the tumor grade of STS. SUV<sub>peak</sub> and SUV<sub>peak</sub>/SUV<sub>liver</sub> showed diagnostic accuracy separating between low- and high-grade GIST tumors [17]. Miyake et al. retrospectively evaluated 46 patients with primary GIST who received preoperatively  $^{18}\text{F}$ -FDG PET followed by complete resection without any neoadjuvant therapy. They concluded that ring-shaped  $^{18}\text{F}$ -FDG uptake preoperatively may be a potential predictor of postoperative tumor recurrence of localized primary GISTs [18].

---

## 2.4 Artificial Intelligence

Artificial intelligence (AI) is a growing field of research that is emerging as a promising adjunct to assist physicians in detection and management of patients with cancer. AI applications are mathematical techniques and programs that use a variety of approaches (e.g., convolutional analysis, various types of neural networks and deep learning) in order to analyze datasets of base or raw data after scientists or radiologists set up parameters about the data. This process allows the AI application to learn on its own by recognizing patterns in the data sets by using many layers of processing to yield the same results as an expert radiologist or nuclear medicine specialist. AI is a complex field, mostly applicable in patients with lung cancer and lymphoma [19].

A recent study by Peng et al. included  $^{18}\text{F}$ -FDG PET/CT images of 48 patients with pathology-proven STS from a publicly available dataset (24 with distant metastases and 24 with-

out metastatic disease). The aim of the study was to develop a deep multi-modality collaborative learning (DMCL) model to predict distant metastases. The model provided higher accuracy, sensitivity, and area under the ROC curve (AUC) in comparison with other state-of-the-art models including single-modality PET convolutional neural network (CNN) and multi-modality CNN [20]. Further studies are needed to establish the utility of AI in patients with STS and BS.

---

## 2.5 Conclusion

Conclusively,  $^{18}\text{F}$ -FDG PET/CT is a useful imaging modality in the management of bone and soft tissue tumors. At the initial staging, its role is primarily to indicate the site of biopsy, to characterize a lesion, and to detect metastatic disease. During restaging, the differentiation between viable tumor and necrosis is the most important advantage of  $^{18}\text{F}$ -FDG PET/CT for the detection of local recurrence, but distant recurrence may be depicted as well. As for the monitoring of therapy,  $^{18}\text{F}$ -FDG PET/CT seems to be an important tool to evaluate treatment efficacy primarily in GIST. The role of artificial intelligence is also under evaluation.

# PET/CT in Brain Tumors: Current Artificial Intelligence Applications

# 3

Julia V. Malamitsi

## 3.1 Introduction

The best anatomic study of brain tumors is acquired by conventional magnetic resonance imaging (MRI). **However**, by offering metabolic information, Positron Emission Tomography (PET) has been extensively used in the study of brain tumors. Co-registration of PET with MRI data is nowadays possible, either by software fusion of PET/CT images with MR images or on integrated PET/MR tomographs. The role of radiomics in acquiring valuable quantitative information on almost any aspect of glioma and brain metastases management is presented. The focus is set on gliomas, because they represent the majority of primary brain tumors, and on brain metastases because they are more common than primary brain tumors.

## 3.2 Radiopharmaceuticals

Radiopharmaceuticals used for brain tumor imaging are mainly markers of glucose metabolism, amino acid transport, proliferation rate, membrane synthesis, hypoxia, and angiogenesis. Molecular imaging tracers are being developed to select patients for targeted therapies.

**Glucose Metabolism** 2-[18F] fluoro-2-deoxy-D-glucose (FDG), the most frequently used radiopharmaceutical for PET, is taken up by 3–6% of low-grade and 21–47% of high-grade gliomas [1]. FDG is taken up by normal brain tissue, a fact that compromises the detection and delineation of an adjacent brain tumor, and by inflammatory cells. FDG uptake correlates with tumor cell density, grading, and malignancy of the tumor.

**Amino Acid Transport** Radiolabeled amino acids, being a marker of amino acid transport which is increased in malignant transformation, are taken up by both high- and low-grade gliomas and to a minor degree by normal brain tissue. [11C]methionine ([11C]MET), [18F]fluoroethyl-tyrosine ([18F] FET) [2], and [18F]fluorodopa ([18F]DOPA) [3] are the most widely used amino acids. Radiolabeled tryptophan [11C]AMT which can be metabolized not only via the serotonin but also via the kynurenine pathway shows increased uptake in gliomas [4]. [18F]fluciclovine, a cyclic amino acid, is taken up by brain tumors and not by normal brain [5], by targeting the overexpression of L-type amino acid transporter (LAT) system subtypes LAT1 and LAT2.

**Proliferation Rate** Proliferation markers are taken up by both high- and low-grade gliomas. [18F]fluorothymidine (FLT), a marker of DNA replication, is an index of malignant transformation and therefore of tumor progression and ther-

J. V. Malamitsi (✉)  
Medical Physics, Medical School, National and Kapodistrian University of Athens, Athens, Greece

apy response [6]. FLT is practically not taken up by normal brain tissue, due to low neuronal cell division and intact blood-brain barrier (BBB).

**Membrane Synthesis** [18F]fluorocholine, an index of cell membrane biosynthesis and hence of cell proliferation, has been used in distinguishing malignant from benign brain lesions [7].

**Hypoxia** [18F]fluoromisonidazole ([18F]FMISO) is a marker of hypoxia and therefore of aggressiveness of the brain tumor. Its metabolites are trapped exclusively in hypoxic cells [8]. Various radioisotopes of copper have been used to label ATSM, another hypoxia marker. [64Cu] seems to be the most appropriate copper radionuclide. Radiolabeled ATSM diffuses freely in tumor cells, and under hypoxic conditions, its metabolite is trapped by intracellular proteins [9].

**Angiogenesis** Peptides are eligible ligands for imaging gliomas. Arginine-glycine-aspartic acid (RGD) peptides, markers for  $\alpha v \beta 3$  integrin expression, monitor response to antiangiogenic treatment and detect early recurrence. They are labeled with 18F ([18F]Galacto-RGD) and more recently with 68Ga ([68Ga]-PRGD2), a generator-produced radionuclide [10, 11].

**Other Tracers** Radiolabeled with PET tracers antisense oligonucleotides, small chains of nucleic acids, have been used to trace specific mRNA in vivo and hence any endogenous gene for imaging and treatment purposes [12]. A novel small molecule tracer for apoptosis [18F]-ML-10 has been used to monitor response to radiation therapy of brain metastases [13]. A [68Ga] bombesin analog [68Ga]-BZH3, associated with gastrin-releasing peptide receptor expression, is used in gliomas in the framework of quantitative dynamic PET [14].

---

### 3.3 Radiomics in the Study of Brain Malignancies

Radiomics in Neurooncology, an application of Artificial Intelligence, is the way of extracting a significant amount of quantitative information concerning brain tumors (primary or metastatic),

which is also associated with biological features, and is taken either from MRI images, conventional or advanced, or from PET images or both. In addition radiomics' purpose is to set up models for predicting clinical results with the aid of selected features and this is accomplished through machine learning [15].

The information acquired through radiomics, concerning inner heterogeneity and microenvironment of the tumor lesion, can lead to a more efficient and personalized handling of brain malignancies [16]. Radiomics is implicated in predicting molecular subtypes of primary tumors, in differential diagnosis, grading, tumor proliferation and mutation status, treatment response, as well as in issues of recurrence vs. pseudoprogression or necrosis concerning both gliomas and brain metastases.

Furthermore, radiogenomics combines gene expression with features extracted from radiomics. This may explain how genetic changes by inducing changes to the phenotype can lead to radiomics' features alterations [17].

---

## 3.4 Identification of Brain Tumors, Molecular Markers, Grading and Prognosis

The 2021 WHO Classification of Tumors of the Central Nervous System, an update of the 2016 WHO version, has put great emphasis on the role of molecular diagnosis in classifying brain tumors, while remaining committed to histology and immunohistochemistry [18]. The most significant molecular biomarkers in classifying gliomas are Isocitrate Dehydrogenase (IDH) genotype and the loss of heterozygosity of the 1p/19q chromosome arms. O6-methylguanine-DNA-methyltransferase (MGMT) promoter methylation status is an independent prognostic factor in treated by temozolamide and radiation high risk-low grade gliomas [19].

### 3.4.1 FDG PET

FDG is taken up mainly by high-grade tumors and anaplastic areas of low-grade tumors [20, 21]. In low-grade tumors on repeat FDG scans,

newly appearing areas of increased FDG uptake must be interpreted as areas of anaplastic transformation and therefore of higher grading and worse prognosis.

FDG PET radiomics has been used for predicting glioma proliferation. In a retrospective study 123 patients with primary glioma were assigned randomly into the primary cohort ( $n = 82$ ) and validation cohort ( $n = 41$ ). Tumor proliferative activity was known from the Ki-67 index on immunohistochemical examination. The derived radiomics signature based on 9 features stratified the patients into two prognostic groups, the results being similar to those obtained with Ki-67 on immunochemistry; however a less satisfactory accuracy was found in the validation cohort [22].

In addition FDG PET radiomics has been used in detecting Isocitrate Dehydrogenase (IDH) genotype and overall survival (OS) in gliomas preoperatively. In a retrospective study with 127 patients, by using a combined model applied for IDH genotyping, where age and type of metabolism (cystic vs. solid) were included, the obtained radiomic signature was associated with IDH genotype (wild type vs. mutant) to a statistically significant degree ( $p < 0.05$ ), the derived areas under the ROC curve being 0.911 and 0.900 on the training and validation cohorts, respectively. Moreover, the results predicted from this combined model could reliably differentiate high- from low-risk groups. OS differed to a statistically significant degree between these two groups ( $p < 0.001$ ) and was similar to the actual survival of the patients with the respective genotypes. This combined model acted as an independent risk factor for prognosis and could become a promising biomarker [23].

High-grade glioma patients with methylated MGMT promoter show a higher uptake of FDG than those with unmethylated MGMT promoter. Although high uptake is a sign of worse prognosis, the former patients have a better response to temozolomide compared to the latter who develop resistance [24].

FDG PET radiomics has been applied in studying MGMT promoter methylation status. In a retrospective study 107 glioma patients were assigned

randomly to the primary ( $n = 71$ ) and the validation cohort ( $n = 36$ ). The MGMT promoter methylation status was assessed by pyrosequencing. A radiomics signature constructed by five radiomics features stratified the patients in two significantly different prognostic groups, which however did not differ significantly from the MGMT methylation status predicted groups in terms of prognosis. Area under the curve for the primary cohort was 0.94 and for the validation cohort 0.86, which were higher than in the case of the fused (clinical and radiomics) signature and definitely higher than the clinical signature [25].

### 3.4.2 MET PET

The uptake of FDG by inflammatory cells makes differentiation between neoplastic and non-neoplastic lesions difficult. In contrast to FDG, all amino acid tracers are taken up by both low- and high-grade gliomas. A comparison between FDG and MET has shown that, by reflecting the biology of gliomas, MET PET is more accurate than FDG PET in identifying active tumors [26].

The potential for MET-PET/MRI in classifying gliomas according to the revised WHO classification using a machine learning model was studied on a patient cohort preoperatively. Postoperatively patients were divided into the following subtypes: IDH wild-type glioblastoma (GBM), IDH wild-type grade II/III glioma (GII/III-IDHwt), IDH mutant grade II/III glioma with co-deletion of 1p/19q (GII/III-IDHmut1p/19qcod) or without 1p/19q-co-deletion (GII/III-IDHmut1p/19qnc). Maximum tumor-to-brain ratio (TBR max) proved highest in GBM patients ( $TBR_{max} = 3.83 + 1.30$ ) and significantly higher from GII/III-IDHmut 1p/19q non-co-deleted group which had a  $TBR_{max}$  of  $2.05 \pm 0.94$  ( $P = 0.004$ ). In the GII/III-IDHmut 1p/19q co-deleted group, TBR values were mildly elevated compared with the IDHmut1p/19q non-co-deleted group. Area under the ROC curve for predicting IDH status proved higher (0.79), than for predicting glioma subtyping, which was 0.62 respectively [27].

### 3.4.3 FDOPA PET

Tumor uptake of FDOPA is similar to that of MET [28]. In order to predict MGMT promoter methylation status in high-grade gliomas, a radiomics model was constructed based on FDOPA PET images. With extraction of three features an accuracy for the prediction of MGMT status of  $80\% \pm 10\%$  (for 95% confidence level) was achieved. Median overall survival was found to be 18 months for the patients with predicted unmethylated MGMT status and 39 months for the patients with predicted methylated status respectively. This model proved to be of high predictive accuracy [29].

### 3.4.4 FET PET

FET uptake does not depend on the blood-brain barrier integrity; therefore FET PET is also eligible for non-contrast enhancing lesions. FET PET detects anaplastic foci and can differentiate histologically grade II from grade III within the same lesion, when dynamic analysis is applied [30]. On a meta-analysis on 462 patients with a newly diagnosed brain lesion, FET PET, used for initial assessment prior to treatment, demonstrated a pooled sensitivity of 82% and specificity of 76% respectively [31]. Besides, increased amino acid uptake in remnant glioma tissue goes along with worse survival [32].

IDH genotype plays a significant role in the response to therapy and the assessment of prognosis, IDH wild-type gliomas being of worse prognosis than the IDH mutated variant [33]. FET PET radiomics has been applied to noninvasively predict IDH genotype in gliomas (i.e., IDH wild-type vs. IDH mutant), complementing in this way radiomics-derived information from MRI.

FET PET textural features have been used in combination with static and dynamic FET PET parameters preoperatively for differentiating IDH mutant from IDH wild-type gliomas. Standard PET parameters combined with textural features increased the diagnostic accuracy significantly. The highest diagnostic accuracy (93%) for prediction of IDH genotype was achieved with the

Hybrid PET/MR scanner, compared to stand-alone PET, acquired after combination of TBRmean with a specific textural feature (SZHGE) [34].

Multiparametric FET PET-MRI and MR fingerprinting have been used on patients with suspected brain tumor preoperatively, to produce radiomics signatures for predicting mutational status of IDH1, 1p/19q, ATRX (alpha-thalassemia mental retardation syndrome X-linked), and MGMT and for differentiation of low-grade vs. high-grade gliomas. Areas under the curve in predicting mutations of ATRX, MGMT, IDH1, and 1p/19q were 85.1%, 75.7%, 88.7%, and 97.8% respectively. The area under the curve for the differentiation between low-grade and high-grade glioma was 85.2% [35].

### 3.4.5 FLT PET and Other Tracers

Although FDG uptake in brain tumors has prognostic significance (Fig. 3.1), the most reliable prognostic information is given by FLT PET, in cases however with disrupted BBB [6] (Fig. 3.2). Kaplan-Meier curves show that a negative FLT PET scan shows an excellent survival, whereas a positive scan goes along with a fast-declining curve. Tumor/cortex SUV values and kinetic analysis of radiolabeled tryptophan (AMT) can differentiate glioblastoma from brain metastases with an accuracy of over 90% for ring-enhancing lesions [4]. On a Phase IIa clinical study in preoperative patients, 18F-fluciclovine demarcated areas of malignant extent greater than those seen on CE-T1WMRI and even disclosed areas not seen on CE-T1WMRI, as proven by histopathological specimen taken during surgery [5].

RGD peptides markers for tumor angiogenetic integrin imaging are taken up by brain tumors but not by normal brain, except choroid plexus. SUVmax of [68Ga]RGD correlates well with tumor grade [36]. [68Ga]-BNOTA-PRGD2, a marker for alphavbeta3 ( $\alpha v \beta 3$ ) integrin, showed on a prospective study better differentiation between high-grade and low-grade gliomas than FDG [11].

**Fig. 3.1** Glioblastoma multiforme in the left parietal lobe postsurgery and chemoradiotherapy. The treated area appears on MRI as contrast enhanced (left) and on FDG

PET co-registered with MRI as hypermetabolic (right), suggestive of recurrence. The patient died 4 months after the PET/CT study. (Courtesy of Dr. V. Prassopoulos)

**Fig. 3.2** FLT uptake in the left frontal lobe, suggestive of recurrent tumor in the treated area of a glioblastoma. FLT PET (left) and FLT PET/CT (right). (Courtesy of Dr. V. Prassopoulos)

( $[^{18}\text{F}]\text{FMISO}$ ) shows a high uptake in high-grade and not low-grade gliomas, since hypoxia characterizes the more malignant tissues, is capable of predicting pathological necrosis, and correlates with HIF-1 $\alpha$  and VEGF expression in newly diagnosed and recurrent malig-

nant gliomas [8, 37].  $[^{62}\text{Cu}]\text{ATSM}$  uptake in gliomas can help differentiate tumor grade, since it correlates with the presence of necrosis, uptake within contrast-enhanced regions on MRI, and HIF-1 $\alpha$  expression on immunohistochemistry [38].

### 3.5 Biopsy Guiding

MRI/CT biopsy guidance may be misleading in cases of high-grade gliomas and anaplastic astrocytomas when contrast enhancement on gadolinium T1, necessary for stereotactic biopsy, is absent [39], as well as in cases of low-grade gliomas with peritumoral edema and contrast enhancement [40]. As brain tumors can be heterogeneous, PET is able to define the most malignant area for a biopsy specimen and help select anaplastic specimens on previously characterized as low-grade gliomas. For stereotactic biopsy, microsurgery, and radiotherapy purposes, neuro-navigation relies on fusion of MRI/CT with PET, diffusion tensor imaging (DTI), and functional MRI (fMRI) data. FDG is better in selecting site for stereotactic biopsy compared with CT or MRI alone, but worse than amino acids especially in low-grade gliomas [41]. Although amino acids are useful in biopsy planning and patient selection, they are not adequate to replace histology in order to assess recurrence or progression.

However, tissue sampling taken on biopsy represents only a minor part of the tumor in contrast to diagnostic imaging which assesses the tumor in its entirety. Quantitative mapping accomplished by radiomics techniques possesses a higher predictive potential, considering its ability to detect mutations of significant biomarkers present, which determine prognosis [42].

### 3.6 Radiation Therapy Planning

PET data are valuable in all forms of radiotherapy planning, i.e., stereotactic radiotherapy, radiosurgery, intensity-modulated radiotherapy, and brachytherapy, because they reveal tumor biology. Biological tumor volume (BTV) based on PET imaging has been proposed for radiotherapy planning, since morphological gross tumor volume (GTV) does not cover adequately the area of the tumor [43]. BTV is promising in sparing normal tissue, reducing toxicity, and better defining the target volume; therefore, it has been

suggested to identify areas for conformal boost [44]. Treatment planning based on amino acid PET combined with CT/MRI was associated with improved survival than when CT/MRI were used alone [45]. Hypoxia may drive the peripheral growth of glioblastoma. Combined with MRI, images of hypoxia may reveal areas of tumor neoangiogenesis [46], which are radioresistant and thus help individualize treatment.

Applications of radiomics in the field of glioma radiotherapy planning are preliminary and concern tumor segmentation [47], differentiation of recurrence from chemoradiation effects (pseudoprogression or radiation necrosis) [48], as well as predicting the site of glioma first recurrence, so to contribute to a more personalized approach in dose escalation [49]. The above-mentioned applications are accomplished by applying radiomics on the combined use of FET PET and contrast-enhanced MRI scans.

### 3.7 Treatment Monitoring

With multimodality therapy strategies available, i.e., surgery, radiotherapy, chemotherapy, and novel treatments, early assessment of response is necessary. **However**, with MRI and CT it takes weeks or months to show tumor response to treatment. Contrast-enhancing lesions on post-treatment MRI cannot be attributed to tumor necrosis or tumor recurrence [50]. Magnetic resonance spectroscopy and PET are eligible for this discrimination [51]. Differentiation of recurrence from radiation necrosis with FDG has given a variable sensitivity (40–90%) and specificity (40–80%), respectively [1]. However FDG can help in clinical decision-making of brain tumors post-radiosurgery because FDG uptake depends on lesion metabolism and not on histological findings suggestive of recurrence [52].

Since radiolabeled amino acid tracers are not taken up by inflammatory cells, they are more eligible to discriminate recurrence or progression from post-treatment changes. FET PET with dynamic data analysis has a sensitivity of 100%

and a specificity of 93% in discriminating the two entities [53]. In patients scheduled for radiotherapy and temozolomide treatment, FET PET-based biological tumor volume (BTV) was a strong independent prognostic factor for overall survival [54, 55]. Increasing BTV, poor performance status, MGMT promoter methylation status, and high age in glioblastoma patients are independent prognostic factors for overall survival [54]. FET PET with dynamic analysis has been used to monitor antiangiogenic treatment (bevacizumab/irinotecan) in cases with recurrent high-grade glioma and has given more reliable results concerning antiangiogenic treatment failure than MRI [56]. Rising time activity curves (TAC) of FET in glioblastomas before radiochemotherapy are consistent with a longer overall survival [55].

Changes in FLT kinetic parameters early during treatment are a criterion of the efficacy of the applied therapy [57]. Since FLT uptake is BBB breakdown dependent, FLT should only be used to evaluate high-proliferating tumors and not for treated low-grade gliomas with disrupted BBB.

Effectiveness of therapeutic agents in gliomas such as antivascular endothelial-like growth factor receptor-1 antibody bevacizumab and topoisomerase I inhibitor irinotecan has been evaluated by FLT PET; the metabolic response as assessed by FLT PET was a better predictor of survival than gadolinium contrast MRI response [58]. Radiolabeled RGD peptides are useful in assessing tumor response to antiangiogenic treatment. In addition after radiolabeling with therapeutic radionuclides like [177Lu] and [90Y], RGD peptides can become therapeutic agents, another application of theragnosis [36].

Concerning radiomics and treatment monitoring, MET PET differentiated recurrent tumor from radiation necrosis in treated gliomas and brain metastases, on the basis of 42 PET extracted features, with a sensitivity of 90.1%, and a specificity of 93.9%, the area under the ROC curve being 0.98. T/N (tumor-to-normal cortex) ratio with a cut-off value 2.83 gave definitely lower scores [59].

An FET PET radiomics model could reliably differentiate progression from pseudoprogression in a cohort of 34 IDH wild-type glioblastomas with a sensitivity 100% and a negative predictive value also 100%, while static parameter TBRmax had lower scores (sensitivity 81% and a negative predictive value also 80%) [48].

---

### 3.8 Role of PET/CT in Brain Metastases

PET has been used post chemo-/radiotherapy of the whole brain or stereotactic radiosurgery, to discriminate between tumor recurrence and radiation injury (radiation necrosis, pseudoprogression), since this is not possible on the basis of CT and MRI. FDG PET has been used extensively to differentiate tumor recurrence from radiation necrosis of brain metastases (Fig. 3.3). Dual phase FDG PET differentiates the two entities in a more reliable manner [60]. Cerebral metastases are mostly associated with high amino acid uptake; therefore, differentiation between recurrence and necrosis is preferable with them. [11C] AMT kinetic analysis can differentiate brain metastases from glioblastomas [4]. Due to its low uptake by normal brain, FLT has been used to assess the presence of brain metastases [61] (Fig. 3.4). Lastly [18F]-ML-10 is used to monitor response to radiation therapy of brain metastases [13].

As far as radiomics in brain metastases is concerned, MET PET has been used in a mixed population of gliomas and brain metastases to discriminate between recurrence and radiation necrosis. Radiomics and T/N ratio evaluation had a sensitivity of 90.1% and a specificity of 93.9%, and an area under the curve of 0.98; T/N ratio gave much lower values [59]. In another study with brain metastases treated mainly with radiosurgery FET PET radiomics and MRI radiomics were applied separately and combined, in order to discriminate between recurrence and radiation injury; the combination of the two gave the highest diagnostic accuracy (89%) [62].

**Fig. 3.3** Contrast enhancement on MRI scan (left) after gamma knife radiosurgery of a Ca breast cerebral metastasis in the R parietal area. FDG PET/CT scan co-registered with MRI (right) shows hypermetabolism in the treated area, suggestive of recurrence. Physiological uptake by normal brain tissue has been suppressed for better distinction of the hypermetabolic lesion. (Courtesy of Dr. V. Prassopoulos)

**Fig. 3.4** MRI (left) shows contrast enhancement of a brain metastasis in the right cerebellum, treated with gamma knife radiosurgery. FLT PET/CT co-registered with MRI shows hypermetabolism in the contrast-enhanced area, suggestive of tumor recurrence. (Courtesy of Dr. V. Prassopoulos)

# Artificial Intelligence in Head and Neck Cancer Patients

# 4

T. Pipikos, M. Vogiatzis, and V. Prasopoulos

## 4.1 Introduction

Positron emission tomography (PET) has a major role in patients with head and neck cancer (HNC), and this group of malignancies was identified as one of the first clinical indications for the performance of PET [1].  $^{18}\text{F}$ -fluoro-deoxy-glucose ( $^{18}\text{F}$ -FDG) PET-computed tomography (CT) can be used in the diagnostic investigation of patients with a malignant neck lymph node, without any other evidence of cancer in the upper aerodigestive tract mucosa. Moreover,  $^{18}\text{F}$ -FDG-PET can contribute to the staging of HNC patients, the detection of residual or recurrent disease, as well as the follow-up of HNC survivors. Apart from  $^{18}\text{F}$ -FDG, there are additional PET tracers that have been investigated using PET-CT techniques, under certain clinical questions [2]. Hypoxia-specific PET radiotracers, such as  $^{18}\text{F}$ -fluoromisonidazole,  $^{18}\text{F}$ -fluoro-azomycin arabinoside,

and  $^{18}\text{F}$ -flortanidazole, may add useful information regarding the biological characteristics of these malignancies, like foci of tumour hypoxia. Furthermore, a more accurate differentiation between post-radiotherapy inflammation and residual or recurrent disease may be feasible with the administration of radiolabelled amino acid PET tracers, showing increased uptake by tumour cells but limited accumulation in inflammatory tissues. On the other hand,  $^{18}\text{F}$ -fluoro-thymidine activity evaluation, following therapy, may serve as an early indicator of treatment response. Finally, according to recent research evidence, PET-magnetic resonance (MR) techniques could offer multi-parametric imaging data that may be useful in terms of head and neck malignancies characterization and patient prognostication [3]. Figures 4.1 and 4.2 show fused PET-MRI images in two patients with HNC referred to our department.

Department of Nuclear Medicine, Hygeia Hospital,  
Athens, Greece

**Fig. 4.1** Fused PET–MRI images in a 50-year-old heavy smoker with newly diagnosed (positive biopsy) laryngeal cancer referred for primary staging with  $^{18}\text{F}$ -FDG-PET/CT. Images show a small lesion with high FDG uptake

located in the left part of the larynx. No regional lymph nodes or distant metastases were depicted. *CT* computed tomography, *FDG* fluoro-deoxy-glucose, *MRI* magnetic resonance imaging, *PET* positron emission tomography

**Fig. 4.2** Fused PET–MRI images in a 65-year-old male patient with known nasal carcinoma referred for restaging—evaluation with  $^{18}\text{F}$ -FDG-PET/CT 6 months after surgery, due to equivocal findings on MRI. Images show intense FDG uptake in the area, compatible with local recurrence. No regional lymph nodes or distant metastases were depicted.

PET–MRI method has high diagnostic accuracy in Head and Neck cancers combining metabolic activity data and high resolution anatomic imaging information. *CT* computed tomography, *FDG* fluoro-deoxy-glucose, *MRI* magnetic resonance imaging, *PET* positron emission tomography

## 4.2 Artificial Intelligence: Performing Tasks Requiring Human Intelligence

Artificial intelligence (AI) can be defined as the theoretical basis and the development of computer systems which are able to perform tasks normally requiring human intelligence, such as visual recognition and decision-making [4].

Nowadays, AI includes applications in various fields of science, which mimic human intelligence using logic, decision tress, and machine learning (ML). In oncology, AI represents a promising tool that may contribute to the clinical decision-making, particularly in complex cases. Nevertheless, over the last seven decades, there have been periods of great promise, as well as serious disappointment, in the field of AI.

The first step towards AI implementation was the article entitled “A logical calculus of the ideas immanent in nervous activity” [4]. In their model, McCulloch and Pitts provided a demonstration of the computational power that can be obtained using simple elements connected in a neural network. Later, based on the “McCulloch-Pitts neuron,” Hebbian proposed a model for neural networks learning and, in 1950, Minsky and Edmonds built the first analogue neural net machine. In parallel, the initial development of AI was significantly influenced by the studies of Turing. His computing machine could perform any mathematical computation, provided that it could be represented as an algorithm.

The term AI was coined by McCarthy, during a two-month workshop at Dartmouth College in 1956 [4]. The results of the Dartmouth Conference were strongly related to the work of Newell and Simon, demonstrating a mathematics-based system for proving symbolic logic theories. During the same period, Samuel’s work is regarded as the first reinforcement learning-based AI programme, a type of AI algorithm in which an AI agent learns to fulfil its scope through a reward system. In 1957, Rosenblatt presented an analogue neural network with the ability to learn via trial and error. One year later, McCarthy introduced the first AI-specific programming language (LISP), while Freidberg conducted the first experimental work involving evolutionary algorithms in AI. Furthermore, in 1962, Widrow and Rosenblatt enhanced the Hebbian learning method in their networks (Adaline and Perceptrons, respectively). Interestingly, in 1966, Weizenbaum presented ELIZA which was developed to serve as a virtual therapist. ELIZA was able to ask questions and provide follow-ups in response to the patients. Several other research projects were also developed and presented to the media, causing high expectations to the public [4].

Mainstream AI research efforts had a general purpose approach, aiming to provide general solutions [4]. A main drawback of this approach (weak AI) was the lack of scalability to larger or more complex domains. In the early 1980s, another research strategy was developed using domain-specific information for stronger reason-

ing, albeit in narrower areas of expertise (expert systems) [4]. DENDRAL was the first effective knowledge-intensive system, successfully inferring molecular structure from mass spectrometry data. Another system, MYCIN, could identify bacteria causing sepsis and recommend antibiotic dosage according to patient weight. Moreover, in 1980, Fukushima proposed the first convolutional neural network architecture (neocognitron) and his work is currently regarded as the origin of the present-day convolutional neural networks.

In the late 1980s and the 1990s, a conservative shift was observed in the field of AI research, towards more established theories, such as statistics-based methods (e.g. Markov models) [4]. Another important parameter was the development of public benchmark datasets during the 1990s, such as breast or lung cancer datasets and liver or thyroid disorders datasets. The availability of these public datasets permitted a thorough evaluation of AI research advancements [4]. Apart from statistics, additional tools, like control theory and operational analysis, were included in AI research in the 1990s. Moreover, decision theory and probabilistic reasoning were introduced in the field, while uncertainty was represented more efficiently by adopting Bayesian networks. In the late 1990s, it became obvious that massive amount of data would be generated, given the significant developments of microchip manufacturing technologies and the concurrent growth of global Internet. The emerging era of big data, including electronic medical records, led to a new beginning of wide interest in AI.

---

### 4.3 Artificial Intelligence in Medicine

In 2012, convolutional neural networks came back to the forefront. Hinton’s research group at the University of Toronto, Canada, demonstrated a deep convolutional neural network (AlexNet) which was able to train more layers of neurons. Since then, deep learning-based methods have been used in several applications, including medical image diagnosis, with promising results [4].

In general, deep learning (DL) is a subset of ML that is composed of algorithms. The implementation of these algorithms aims to train the software to perform tasks, like image recognition, by exposing multi-layered neural networks to vast amount of data. On the other hand, ML is the subset of AI that enables machines to improve at tasks with experience, using abstruse statistical methods. Radiomics include ML techniques for the analysis of image features. Combined with AI approaches, radiomics could extract valuable information that is not perceivable by the human eye, or cannot be comprehended by the human brain. These advanced techniques can facilitate pattern recognition in images, analysis of biomarker data, and integration with non-imaging parameters [5].

Depending on the predicted outcome, medical ML can be classified as focused on regression (e.g. linear regression, polynomial, and support vector regression) or classification tasks (e.g. logistic regression and random forest) [5]. Regression methods are used for the prediction of continuous values, like biomarker levels and tumour volume reduction, while classification methods aim to predict a binary/categorical value, such as tumour recurrence and toxicity development. Additionally, Cox hazard regression incorporates the time-to-event together with a binary event (e.g. death).

---

#### **4.4 Artificial Intelligence in Oncology: Head and Neck Cancer**

In oncology, risk prediction of overall survival and tumour control after therapy represents the most evident example of AI in treatment decision-making, based on imaging data. Using model-based personalized strategies, cancer therapy could be tailored to the anticipated risk of failure before treatment. Toxicity development after chemo-/radiotherapy may represent another application of AI in oncology. On the other hand, auto-segmentation of tumour or organ at risk is a

voxel-based classification task that has already contributed in organ and tumour definition, decreasing delineation times [5]. Moreover, AI is being deployed for magnetic resonance imaging (MRI) deformation, improved image reconstruction, and MRI to pseudo-CT [5].

In HNC, the analysis of functional imaging data can contribute significantly not only to the diagnostic investigation but also to the evaluation of treatment response and the follow-up of the patients. Novel diagnostic and prognostic biomarkers could be developed through the extraction of high-dimensional sets of quantitative descriptors (radiomic features) from medical images, including PET images. These high-dimensional data can be analysed using ML algorithms and AI methods, offering information complementary to the conventional clinical predictors. Notably, radiomics features commonly refer to shape, intensity (histogram), and texture characteristics. Previous studies demonstrated correlations between diagnostic or outcome variables and radiomics features since they represent biological characteristics of the tissues, such as cellularity, heterogeneity, and necrosis [6]. Moreover, radiomics features have been also correlated to genomic and molecular characteristics of malignant tumours (radiogenomics).

Based on the analysis of such relationships, a more personalized form of cancer care could be implemented, using ML and AI approaches. The value of radiomics data is expected to be higher when combined with clinical variables, serum markers, and additional conventional biomarkers. Given their significant statistical power, ML methods can offer efficient analysis and development of predictive models, using high-dimensional data. Recently, several classification and regression models have been applied in the field of HNC, aiming at the prediction of molecular markers, genomic identification, diagnostic differentiation of suspected tissue, survival prognostication, and prediction of treatment response [6]. PET studies aiming at the investigation of outcome prediction using radiomics are presented in Table 4.1 [7–18].

## 4.5 Conclusions

The development of novel multivariate diagnostic and prognostic biomarkers is now more feasible, given the increasing numbers of publicly available mega-data and open-source ML algorithms. These tools could integrate radiomics features and clinical parameters for risk stratification, outcome prediction, and personalized treatment planning in HNC patients. In the future, radiomics analysis may provide a fast, low-cost, and comprehensive tumour and tissue characterization, in combination with the conventional clinical testing and prognostication. However, despite the exponential growth of radiomics and AI research studies in medicine, most of the prediction models have not reached a level of clinical usability. Effective interpretability to the end user seems to be of great importance for clinical implementation. Therefore, apart from the fact that models must be reliable, results should be presented in a manner adequately interpreted by the clinicians who are responsible for therapy decision-making.

## PET-CT in Lung Cancer

# 5

Roxani D. Efthymiadou

An appropriate staging of lung cancer is of great value for patient's management and prognosis. The evaluation includes, except the detailed clinical examination, a variety of laboratory tests and imaging methods. PET-CT has much promise as an aid to the noninvasive evaluation of lung cancer. In fact, lung cancer is one of the main and well-established indications of the method [1].

As a product of the advanced technology in imaging, PET-CT combines in one single method the detailed anatomic information provided by CT with the functional data provided by PET. PET-CT has many applications but is widely used in lung cancer because of its superiority, compared to other imaging modalities, in the detection of nodal and metastatic disease. The radiotracer used for PET is  $^{18}\text{F}$ -FDG, which is a glucose labeled with  $^{18}\text{F}$ , a radionuclide with relatively long half-life—of almost 110 min—and small photonic energy of 0.64 MeV.  $^{18}\text{F}$ -FDG is the most widely used in oncology radiotracer because cancer cells have increased metabolic activity and exclusively use glucose as a source of energy [2]. After an appropriate preparation, the scan is performed following well-predefined instructions. One hour after the  $^{18}\text{F}$ -FDG injection, both a PET and a CT are obtained. The procedure covers the whole body and lasts about

40 min. The amount of radiotracer trapped in cancer sites can be quantified by using methods such as the SUV (the standardized uptake value). The PET, CT, and fused PET-CT images are studied by specialists (radiologists and nuclear medicine doctors) in order to combine all the provided data.

$^{18}\text{F}$ -FDG PET-CT currently is indicated for the characterization of lung lesions, staging of non-small cell lung carcinoma (NSCLC), detection of distant metastases, diagnosis of recurrent disease, planning radiotherapy, and for treatment monitoring [3].

One of the main indications of PET-CT is the evaluation of the solitary pulmonary nodule (SPN). SPN is an opacity in the lung parenchyma that measures up to 3 cm and that has no associated mediastinal adenopathy or atelectasis. CT is considered an excellent tool for the evaluation of the nodule but is characterized by poor specificity (58%).  $^{18}\text{F}$ -FDG PET-CT provides complementary information about the metabolic activity of a nodule that cannot be obtained by radiographic methods. The development of  $^{18}\text{F}$ -FDG PET-CT has taken the evaluation of solitary pulmonary nodules beyond anatomic and predictive analyses to functional and metabolic analyses of disease. PET alone has been described as a better predictor of malignancy than clinical and morphologic criteria combined. A study showed that when an SUV equal to or greater than 2.5 was used for detecting malignancy, the sensitivity, specificity,

---

R. D. Efthymiadou (✉)  
CT, MRI and PET-CT Department, Hygeia Hospital,  
Attiki, Greece

and accuracy of PET-CT were 97%, 82%, and 92%, respectively [4]. The negative predictive value of the method is high enough to avoid a biopsy. However, PET-CT may be false negative in small nodules with a diameter less than 8–10 mm. It may also be negative in malignancies with low metabolic activity such as focal bronchioalveolar cell carcinoma or carcinoid. A hypermetabolic nodule needs further investigation as increased  $^{18}\text{F}$ -FDG is not specific and may represent a malignant as well as an inflammatory lesion [4].

Conventional chest radiography, computed tomography (CT), magnetic resonance imaging, radionuclide scintigraphy, and positron emission tomography (PET) all have been used for NSCLC staging. TNM staging is of great importance for determining the therapeutic strategy [5].

Although CT, until now, has been widely used for the evaluation of tumor size and infiltration of adjacent structures, PET-CT is much more accurate in determination of T staging, as the accuracy of the method is 82% while the accuracy of CT is 68%. One of the main advantages of PET-CT is the ability to differentiate the hypermetabolic central neoplasm from the non-metabolic postobstructive atelectasis. PET-CT may also reveal subtle areas of invasion which are not occult on CT.

Lymph node status (N staging) is of great importance in determining the resectability of a tumor; PET-CT has been shown to be substantially more sensitive and specific in the detection and characterization of metastases to mediastinal lymph nodes: PET has a sensitivity of 83% and a specificity of 94%, while CT has 63% and 73%, respectively. By combining anatomic and functional data in a one single imaging method, dual-modality PET-CT represents the most efficient and accurate approach to NSCLC staging, with a profound influence on therapeutic management and patient prognosis [6]. The use of PET-CT results in further improved N staging compared with the use of CT. The limitations of size-based node characterization system in CT studies are well documented. In CT a lymph node is considered to be abnormal if its short-axis diameter is more than 1 cm. However, a large percentage

(44% according to one study) of small lymph nodes (measured less than 1 cm) is metastatic, whereas an even larger percentage (77% according to the same study) of enlarged nodes (measured more than 1 cm in the short axis) is proved to be nonmetastatic. PET-CT reveals not only the presence and morphology but also the metabolic activity even of small nodes (<1 cm) [1]. The method is characterized by 78% accuracy and 94% negative predictive value in the detection of mediastinal lymph nodes. Although mediastinoscopy remains the gold standard, PET-CT is the best noninvasive imaging procedure for N staging in NSCLC. The high negative predictive value of PET-CT in the evaluation of mediastinal lymph node involvement led to the avoidance of invasive methods, such as mediastinoscopy, in most of the PET-CT negative patients.

M status defines the presence or absence of a tumor spread to distant lymph nodes or organs. Lung cancer may metastasize to almost every organ of the body but mainly to the brain, the adrenals, the bone, the liver, and the contralateral lung. Thirty percent of patients with NSCLC have occult distant secondary deposits at the time of presentation of the disease. Detection of distant metastasis (M staging) is another critical step in determining the resectability of the lung tumor. During the past few decades, CT has been used as the method of choice for the detection of metastatic disease in NSCLC. The addition of PET in the evaluation of NSCLC reveals metastatic sites in more patients [7]. PET-CT has a high sensitivity in the detection of adrenal metastases. Increased  $^{18}\text{F}$ -FDG uptake in an adrenal enlargement can differentiate a metastatic from a benign lesion. PET-CT has also been shown as a sensitive method for the detection of bone and pleural metastases. Although CT may reveal focal thickening at the pleura or the pericardium, PET-CT can confirm the diagnosis of malignancy showing increased FDG uptake at the suspicious sites. As a whole-body study, PET-CT may reveal distant unexpected metastases not found in conventional staging. Previous studies demonstrated the high accuracy of PET-CT in the detection of unsuspected extrathoracic metastases in up to 17% of patients. The preoperative use of PET has led to

avoid unnecessary thoracotomies in patients considered to be operable on the basis of CT and clinical criteria. Although PET-CT is superior to conventional imaging methods in detection of metastatic disease in the body, MRI of the brain remains the method of choice for detecting metastatic disease.

The ability of PET-CT to detect both intra- and extrathoracic metastatic sites in one single examination with a better accuracy than conventional procedures has a potential impact on patient's management. The PET in Lung Cancer Staging (PLUS) trial and the American College of Surgeons Oncology Group trial confirmed that PET-CT—when added to the standard work-up of patients with NSCLC—led to upstage up to 25% of them and to improve selection of patients who can benefit from curative surgical resection.

PET-CT is an excellent tool for radiotherapy planning. PET-CT-guided planning devices will further refine three-dimensional conformal radiotherapy. PET-CT can demonstrate more accurately the sites of active tumor, which may probably have an impact on radiation therapy volume delineation in NSCLC. PET-CT provides safe delivery of high dose of radiation to the neoplastic site protecting the normal tissues, as it can differentiate tumor from nontumor lesions such as atelectasis, consolidation, or scar tissue. According to a study of 26 patients with stages I through III of NSCLC, Bradley et al. found changes in radiation therapy planning in over 40% of patients after integrated PET-CT in comparison with CT-guided treatment [8].

Although PET-CT is the best noninvasive imaging method for the evaluation of NSCLC, numerous pitfalls exist. The most frequently observed false-positive findings are due to brown fat, foci of infection, benign tumors like adenomas, post-therapeutic thymic hyperplasia, attenuation-related artifacts, recent trauma, surgery, or radiotherapy but also to sites with physiologically increased  $^{18}\text{F}$ -FDG uptake such as the brain, the myocardium, the vasculature, the bowel, and the collecting urinary system [5]. False-negative findings can be found in tumors with low metabolic activity such as the bronchioalveolar cell carcinoma and the carcinoid, in

cases of hyperglycemia but also in very small pulmonary nodules (with a short-axis diameter less than 8 mm).

Many studies have established the role of  $^{18}\text{F}$ -FDG PET-CT in lung cancer restaging, concerning the detection of residual or recurrent tumor and the response to first-line therapy. With the use of  $^{18}\text{F}$ -FDG PET-CT, residual or recurrent disease should, when possible, be differentiated from therapy-related changes in the lungs.  $^{18}\text{F}$ -FDG PET-CT has prognostic value and correlates strongly with rates of survival of patients with treated NSCLC meaning that patients with positive  $^{18}\text{F}$ -FDG PET-CT results have a significantly worse prognosis than patients with negative results [6, 9]. It was found that a reduction in metabolic activity correlated closely with the final outcome of the therapy. An early metabolic response (drop in SUV more than 50%) predicted better survival while as poor response predicted progression of the disease.

Despite its high cost, PET-CT—when properly used—has proved to be a cost-effective method in the evaluation of lung cancer [10]. In about 35% of cases first staged with CT, the stage of the disease has changed—in most cases the disease is upstaged—after subsequent PET-CT, with resultant changes in patient's management.

According to NCCN practice guidelines, PET-CT is recommended in NSCLC for:

- (a) Diagnosis in patients with one or two pulmonary nodules.
- (b) Initial staging except if multiple distant metastases exist.
- (c) Restaging stage III or IV after 2–3 months after treatment or before surgery.
- (d) Restaging in patients with symptoms suggestive of recurrence.
- (e) Radiation therapy.

Small cell lung cancer accounts for 15% of all lung cancers and is characterized by rapid growth and early spread to regional lymph nodes and to distant sites. The role of PET-CT in the evaluation of SCLC is still under study [3, 11]. SCLC is  $^{18}\text{F}$ -FDG avid at the primary site and at metastatic sites. PET-CT may be used in staging patients

with SCLC in order to select potential candidates for the addition of thoracic radiation therapy to chemotherapy. PET-CT may also lead to upstaging or downstaging of patients and to alteration of radiation fields due to the detection of additional sites of nodal involvement.

By combining anatomic and functional data in a single imaging method, dual-modality PET-CT represents the most efficient and accurate approach to NSCLC staging, with a profound influence on therapeutic strategy and patient prognosis. It also represents a useful and promising method for SCLC management (Figs. 5.1, 5.2, 5.3, 5.4, and 5.5).

Artificial intelligence (AI) is an expanding era of research promising valuable aid in the diagnosis and the management of oncologic patients [12]. On the other hand  $^{18}\text{F}$ -FDG PET-CT is a noninvasive functional imaging method with an established important role in routine imaging work-up of lung cancer. Many published studies, most of them related to lung cancer, discussed the possible applications of AI in  $^{18}\text{F}$ -FDG PET-CT imaging, regarding the diagnosis, the staging, the restaging, the response to therapy, and determination of prognosis [13].

Artificial intelligence techniques such as machine learning (ML) and deep learning can

**Fig. 5.1** Hypermetabolic SPN at the right lung on CT (a) and PET-CT images (b) proved—on biopsy—to represent primary lung cancer

**Fig. 5.2** Fused PET-CT images: primary tumor at the right lung (a) with hypermetabolic lymph nodes at the mediastinum (b, c)

**Fig. 5.3** Hypermetabolic metastasis at the iliac bones and the sacrum (b) which are not obvious or have subtle appearance on CT images (a) in NSCLC restaging

**Fig. 5.4** Whole-body PET image: widespread metastatic NSCLC

provide efficient analysis of the huge amount of information pertaining to the lung conditions [14]. The automated analysis allows better characterization of pulmonary lesions, such as pulmonary nodules as well as earlier detection of lung cancer [15].

Early detection is important in all types of cancer. Among the cancer-related deaths worldwide, lung cancer is the most frequent cause. A noninvasive and high performing method

**Fig. 5.5** Secondary deposit at the left adrenal on CT (a) and PET-CT images (b) in an NSCLC patient

should be ideal to screen lung cancer in early stage.

Artificial Intelligence emerges as a promising advancement [16]. Almost all the related studies show that the incorporation of AI in imaging can improve patient care by earlier and accurate detection of the disease, which is related with a good prognosis. Due to the better evaluation of the majority of lung nodules, undiagnosed cancers can be reduced [13, 15].

Artificial intelligence provides radiologists the ability to manage in an efficient way the data load of lung cancer screening provided by computed tomography. AI techniques target different aspects of lung cancer imaging including characterization of malignant pulmonary nodules, tumor detection, differentiation of lung cancer subtypes, lung cancer staging, and response assessment. In addition, AI-based models promise added value in predicting tumor behavior, response to therapies, and estimation of patients' survival [17].

Despite the potential benefits of AI in cancer imaging, the routine application of AI-based models according  $^{18}\text{F}$ -FDG PET-CT in clinical practice is limited at least partially due to lack of standardized, reproducible, generalizable, precise techniques [18]. Standardization of imaging data is required for the clinical and widespread use of computer-based automated examinations. More studies are needed regarding validation of AI models in the future, so that they can be incorporated in the healthcare system and proved beneficial in daily practice [12, 18].

## Breast Cancer: PET/CT Imaging

# 6

Vasiliki P. Filippi

PET/CT is a hybrid method that combines anatomical imaging with metabolic information in a single examination. The combination of these two methods has the advantage of precise localization of foci of pathologically increased metabolic activity. Pathological metabolic activity in malignant tissue often precedes anatomical changes, and in some cases, due to previous surgery or radiotherapy, anatomical findings alone are not specific for recurrence or dissemination of disease.

Fluorodeoxyglucose (FDG) is a tracer, analog to glucose, that is mainly used, currently, for PET and PET/CT imaging. FDG uptake by metabolically active tissue is related to the fact that malignant cells have proportionally increased demand for glucose [1].

FDG PET has a limited role in the detection of primary breast cancer (Fig. 6.1). The overall sensitivity of the method is 64–96% and specificity is 73–100%. The reported accuracy is 70–97%, the positive predictive value is 81–100%, and the negative predictive value is 52–89% [2].

The limitations of the method are due to the low sensitivity of the method in detection of small lesions (<1 cm) and to low FDG uptake in specific histological types (such as lobular carcinomas and ductal carcinoma in situ) and well-

differentiated tumors. Taking into account these limitations, as well as the low availability and the high cost, FDG PET is not currently indicated as a screening test for breast cancer [3].

In order to improve the efficacy of the method, the development of dedicated breast positron emission mammography (PEM) units seems promising. Possible applications of PEM are detection of small primary breast tumors, local staging and restaging, and evaluation of tumor response to therapy. So far, the method is not validated in large trials [4].

Accurate locoregional staging of the disease is very useful in patient management, as it is related to patient prognosis. For early-stage breast cancer patients, FDG PET has relatively low sensitivity in axillary staging and is not recommended by the literature for this purpose. However, in patients with advanced disease, FDG PET may provide additional information such as distant occult metastases or pathological internal mammary lymph nodes [4].

FDG PET may be useful in assessment of tumor response to therapy, since metabolic changes precede morphological regression. A decrease in the level of FDG uptake—compared to the baseline scan—following even the first or second cycle of chemotherapy, can predict response to chemotherapy treatment (accuracy 64–91%). Nonresponders are obviously benefited by avoiding useless, toxic treatment [5].

---

MRI, CT and PET/CT Departments, Hygeia and  
Mitera Hospitals, Maroussi, Greece

**Fig. 6.1** (a) CT image within normal limits. (b) PET/CT image shows an area with increased metabolic activity in the left breast (*arrow*), finding suspicious for malignancy, as an incidental finding

On the basis of scientific results obtained to date, there is not enough evidence to substitute anatomical imaging methods with molecular imaging modalities. However, FDG PET may play a complementary role in assessment of possible disease progression [6].

Recurrence of disease is frequent in patients with breast cancer, after completion of initial treatment. Early detection of tumor recurrences is beneficial for breast cancer patients and is associated both with prognosis and appropriate treatment choice. Estimation of the true extent may sometimes be quite challenging, due to occult recurrences. This may be correlated to the small size of a lesion that is considered normal with anatomical–morphological criteria, e.g., a lymph node, or inconclusive findings in areas that coexist with posttreatment findings, e.g., scar tissue post-radiotherapy (Fig. 6.2).

FDG PET has been shown to be effective in early accurate restaging of patients with breast cancer, as it detects pathologic metabolic activity of tumors, which usually can be detected earlier than anatomic–morphologic alterations. FDG PET is considered an effective diagnostic tool and is recommended in the follow-up of breast cancer patients. Isasi et al. estimated the diagnostic performance of FDG PET using meta-analysis. Among the studies with patient-based data,

median sensitivity was 92.7%, and median specificity was 81.6% [7].

The higher sensitivity of the method, compared to computed tomography, especially in detecting lymphatic dissemination of the disease is the main advantage of the method [8].

FDG PET/CT has an even greater diagnostic accuracy compared to PET alone, since lesions are better localized and false-positive findings, attributed to physiological FDG uptake, are avoided.

Moreover, FDG PET/CT is of great importance in patients with elevated tumor markers and negative or equivocal findings on conventional imaging techniques, as it provides information about the disease status in terms of localization of recurrence. In these patients it seems that although tumor marker levels may strongly indicate that there is occult tumor recurrence, conventional imaging methods cannot always estimate the true extent of the disease. FDG PET/CT in this population has a sensitivity of 86.8%, specificity of 87.5%, and accuracy of 86.9% (Figs. 6.3 and 6.4). The positive prognostic value is 97% and the negative prognostic value 58.3% [9].

Bone metastases are very common in breast cancer patients. FDG PET and bone scintigraphy are methods complementary to each other, since

**Fig. 6.2** Patient with suspicious recurrence in the right breast after surgery. CT images show abnormal soft tissue at the surgical region (**a**, *arrow*) and a borderline left internal mammary lymph node (**b**, *arrow*). PET/CT images

confirm the local recurrence (**c**, *arrow*) and additionally show increased uptake in the left internal mammary lymph node (**d**, *arrow*)

FDG PET is more sensitive in detection of lytic and intramedullary secondary deposits and bone scintigraphy is superior in detection of osteoblastic lesions [10].

FDG PET has an important clinical impact in the management of breast cancer patients. By altering, which is more often upgrading, the stage of the disease, clinical management decisions are usually influenced. FDG PET has been shown to change the clinical stage of the patients examined in 36%. Even if the stage of the disease is not changed by FDG PET results, information about the true extent of the disease provided may result in differentiation in treatment options. Physicians

seem to rely on FDG PET results, thus altering clinical management in 58% of cases. This fact is of proof that FDG PET is already considered as an important diagnostic tool among physicians [11].

Currently, FDG is the radiopharmaceutical in clinical use. New tracers like fluorothymidine (FLT), fluoroestradiol, methionine, and choline seem promising, especially in the field of monitoring tumor response to therapy [12].

In conclusion, the role of FDG PET/CT is complementary to conventional imaging methods and should not replace them. The main indication currently is to provide additional

**Fig. 6.3** (a) Equivocal findings on CT (obliteration of the left paracolic fat, *arrow*) in a patient with breast cancer history and elevated tumor markers. (b) PET/CT image

shows a focus of increased metabolic activity (*arrow*), suspicious for peritoneal implantation

Additionally, in the same image (b), a hypermetabolic focus (*arrowhead*) is seen in the anterior aspect of the 11th thoracic vertebra

information in selected cases in the restaging of breast cancer patients and in evaluation of response to treatment (Fig. 6.5).

Nowadays, a new era has been introduced in medical imaging. Artificial intelligence is a growing and promising tool in early and accurate detection and precise and personalized management of patients with cancer. A possible applica-

tion of AI in  $^{18}\text{F}$ -FDG PET imaging is the management of breast cancer patients in terms of early detection, differentiation malignant from benign lesions, accurate staging, early response to treatment assessment, and prognosis determination [13].

However, there are not enough data yet, to introduce the method in clinical practice.

**Fig. 6.5** CT image (a) shows no abnormal findings. PET/CT image (b) shows a lesion of increased uptake in the left ilium (arrow), consistent with bone metastases

## 7.1 PET/CT with [<sup>18</sup>F]FDG in Cervical Cancer

### 7.1.1 Initial Diagnosis and Prognosis

Imaging with [<sup>18</sup>F]FDG-PET/CT is not routinely used for the initial diagnosis of cervical cancer although the primary tumor is generally [<sup>18</sup>F]FDG avid, because of the lack of precise anatomic information which limits its clinical utility.

[<sup>18</sup>F]FDG uptake of the primary cervical tumor, as measured by SUVmax, provides valuable prognostic information for predicting lymph node involvement, treatment response, and overall survival. Although there is no standard SUVmax cutoff value defining the prognosis in patients with cervical cancer, cervical tumors with a higher SUVmax are more likely to be poorly differentiated and have an increased risk of lymph node involvement. Median preoperative SUVmax values in the primary tumors were significantly higher in patients with higher FIGO stages ( $p = 0.0149$ ), pelvic lymph node metastasis ( $p = 0.0068$ ), parametrial involvement ( $p = 0.0002$ ), large (>4 cm) tumor size ( $p = 0.0022$ ), presence of lymphovascular space

invasion ( $p = 0.0055$ ), and deep cervical stromal invasion ( $p < 0.0001$ ) [1].

A recent study that classified cervical cancer into two major histological types, squamous cell and non-squamous cell carcinoma, such as adenocarcinoma and adenosquamous carcinoma, showed that pretreatment [<sup>18</sup>F]FDG-PET provided different prognostic implications between histological subtypes [2]. Metabolic tumor burden (metabolic tumor volume (MTV) and total lesion glycolysis (TLG)) could be beneficial for the prognostic prediction of patients with squamous cell carcinoma, whereas metabolic intensity (SUVmax) could be beneficial for non-squamous cell carcinoma [2].

Radiomics allows a high-throughput extraction of multiple features from images with artificial intelligence (AI) approaches and develops rapidly worldwide [3]. They are statistical or model-based metrics to quantify tumor intensity, shape, and heterogeneity, which have been shown to reflect intratumoral histopathological properties and provide prognostic information in several malignancies [4, 5].

Radiomics on pretreatment PET/CT have been shown to predict response to therapy and risk of pelvic recurrence. Studies have shown that radiomics features on <sup>18</sup>F-FDG-PET/CT have significantly higher prognostic power than clinical parameters with accuracy of 94% for predicting recurrence and 100% for predicting lack of

loco-regional control (versus ~50–60% for clinical parameters) [4].

### 7.1.2 Initial Staging

Most primary tumors over 1 cm are easily detectable with [<sup>18</sup>F]FDG-PET/CT, but due to the relatively poor spatial resolution of this modality, it is not considered suitable for T staging. However, [<sup>18</sup>F]FDG-PET/CT is quite helpful in delineating the margins in cases that an invasive tumor extends superiorly into the uterine cavity and inferiorly into the vaginal cuffs.

[<sup>18</sup>F]FDG-PET/CT has an important role in staging cervical cancer, and it aids particularly in identifying the involvement of lymph nodes and distant metastases. Although the assessment of lymph nodes is not a part of the FIGO staging, it is generally performed during the initial workup of patients with cervical cancer as an important component of treatment planning, since the survival rates for patients with nodal metastases are significantly lower than those without. Recently, PET/CT scan has been increasingly used for staging workup [6–8]. [<sup>18</sup>F]FDG-PET/CT shows a significant benefit to assess the metabolic activities of the tumor, especially for distant metastases, taking advantage from the whole-body cross-sectional images. [<sup>18</sup>F]FDG-PET/CT demonstrates a specific benefit to assess the pelvic and paraaortic lymph node involvement with equivocal size and morphology on CT or MRI.

In studies where [<sup>18</sup>F]FDG-PET/CT was evaluated in patients with negative CT/MR, the sensitivity and specificity of [<sup>18</sup>F]FDG-PET/CT for detection of metastases have been found 83.3–85.7% and 94.4–96.7%, respectively [9, 10]. In recent meta-analyses, [<sup>18</sup>F]FDG-PET or [<sup>18</sup>F]FDG-PET/CT showed the highest pooled sensitivity (79–84%) and specificity (95–99%), compared with 47–50% and 92–97%, respectively, for CT and 56–72% and 90–96%, respectively, for MR imaging [11–16]. [<sup>18</sup>F]FDG-PET/CT positivity for lymph node metastases correlates well with survival and is highly predictive of

progression-free survival. A multivariate analysis demonstrated that the most significant prognostic factor for progression-free survival was the presence of positive paraaortic lymph nodes as detected by PET imaging ( $p = 0.025$ ) [12]. Concerning paraaortic nodal disease, [<sup>18</sup>F]FDG-PET/CT demonstrated a sensitivity of 100% and specificity of 99% despite another study that demonstrated lower values (50% and 83.3%, respectively) [17, 18].

According to American College of Radiology appropriateness criteria, [<sup>18</sup>F]FDG-PET/CT with concurrent abdominopelvic CT is considered highly appropriate in assessing nodal disease at stage II or higher and in patients with suspected tumor recurrence [19]. Also, for detecting distant metastases, [<sup>18</sup>F]FDG-PET/CT demonstrated a sensitivity of 100% and specificity of 94% [18].

### 7.1.3 Radiotherapy Planning

[<sup>18</sup>F]FDG-PET/CT has been shown to impact external-beam radiotherapy planning by modifying the treatment field and customizing the radiation dose. This particularly applies to detection of previously uncovered paraaortic and inguinal nodal metastases.

[<sup>18</sup>F]FDG-PET/CT-based brachytherapy optimization allows improved tumor volume dose distribution and detailed 3D dosimetric evaluation of risk organs.

Furthermore, [<sup>18</sup>F]FDG-PET/CT-guided intensity-modulated radiation therapy (IMRT) allows delivery of higher doses of radiation to the primary tumor and to grossly involved nodal disease while minimizing treatment-related toxicity. IMRT use in cervical cancer has been demonstrated to produce equivalent or better results [20].

### 7.1.4 Restaging after Treatment

The current literature supports the use of [<sup>18</sup>F]FDG-PET/CT for evaluating response after chemoradiation for locally advanced carcinoma

of the cervix. The optimal timing to obtain  $^{18}\text{F}$ -FDG-PET/CT to assess for treatment response is at least 6 weeks after surgery and 3 months after completion of concurrent chemoradiation therapy. The posttreatment metabolic response seems to be predictive of both cause-specific and progression-free survival after chemoradiation for cervical cancer.

A study showed that the ratio of SUV<sub>max</sub> at posttherapy to SUV<sub>max</sub> at pretherapy of  $<0.33$  correlated with tumor pathologic response ( $P < 0.001$ ) and a 35% improvement of 6-month progression-free survival (PFS) ( $P = 0.004$ ) in advanced-stage IB2-IVA patients [21]. A prospective cohort study demonstrated that  $^{18}\text{F}$  FDG-PET/CT can provide reliable long-term prognostic information and may be used to guide early interventions for patients with less than a complete metabolic response [22].

$^{18}\text{F}$ FDG-PET/CT can be used to monitor treatment response during treatment as the change in  $^{18}\text{F}$ FDG uptake during chemoradiation therapy is associated with response to treatment [21].  $^{18}\text{F}$ -FDG-PET/CT seems to be superior to MRI for posttherapy evaluation in patients with advanced cervical cancer 2–3 months after definitive concurrent chemoradiotherapy. A study showed that the sensitivity, specificity, and accuracy of PET/CT were 60%, 100%, and 89% versus those of MRI 27%, 100%, and 80%, respectively [23].

Abnormal  $^{18}\text{F}$ FDG uptake in the cervix or lymph nodes after completion of radiotherapy is associated with poor survival outcomes. The optimal timing to obtain  $^{18}\text{F}$ FDG-PET/CT scans during RT for cervical cancer is unclear. FDG activity tends to show an initial increase followed by a steady decline after treatment. Early elevation of FDG activity may be associated with acute inflammation in normal tissue or elevated metabolic activity within the tumor cells; the later reduction in FDG uptake is a reflection of a decrease in the number of viable tumor cells or a reduction in tumor metabolic activity.

### 7.1.5 Tumor Recurrence

$^{18}\text{F}$ FDG-PET/CT appears to have an acceptable diagnostic performance in suspected recurrent cervical cancer, and it may affect patient management. Furthermore, FDG avidity may predict the prognosis of recurrent cervical cancer (Figs. 7.1 and 7.2).

For the detection of combined local and metastatic recurrence of cervical cancer, according to several studies, the sensitivity of  $^{18}\text{F}$ FDG-PET/CT ranges from 92% to 93%, the specificity from 81 to 100%, and the accuracy from 87 to 96% [24–27].  $^{18}\text{F}$ FDG-PET/CT was strongly predictive of overall survival [24]. Patients with negative  $^{18}\text{F}$ FDG-PET/CT for recurrence had a significantly better 2-year disease-free survival (DFS) rate compared to patients with positive PET/CT (85.0% vs. 10.9%, respectively,  $P = 0.002$ ) [28]. The results of another study were in accordance with the above, and  $^{18}\text{F}$ FDG-PET/CT for the evaluation of local recurrence showed sensitivity, specificity, positive predictive value, and negative predictive value of 93%, 93%, 86%, and 96%, respectively, and for metastatic disease showed sensitivity, specificity, positive predictive value, and negative predictive value of 96%, 95%, 96%, and 95%, respectively [29].

The low rate of false-positive results and high prognostic value suggest that  $^{18}\text{F}$ FDG-PET/CT is an important diagnostic tool for detecting recurrent cervical cancer in clinically equivocal patients. For treatment planning, it is reported that  $^{18}\text{F}$ FDG-PET/CT may change management in 23.1–48% of cases in suspected recurrent cervical cancer [24, 25]. Because of its high sensitivity and positive predictive value,  $^{18}\text{F}$ FDG-PET/CT should be the imaging technique of choice for evaluating extrapelvic disease prior to performing pelvic exenteration. It seems to be useful in identifying recurrent cervical cancer in both asymptomatic and symptomatic patients with elevated tumor markers and negative imaging findings (squamous cell carcinoma antigen  $>1.5$  ng/mL) [30].

**Fig. 7.1** A 56-year-old woman, with previously treated cervical cancer, presenting with increased serum tumor markers and equivocal findings in conventional imaging.

$[^{18}\text{F}]$ FDG-PET/CT showed increased  $[^{18}\text{F}]$ FDG uptake in multiple lesions in the liver

**Fig. 7.2** A 51-year-old woman, with previously treated cervical cancer presenting with elevated CEA serum levels and negative findings on CT and MRI imaging.  $[^{18}\text{F}]$

FDG-PET/CT showed several areas of increased metabolic activity in the peritoneum (peritoneal implants)

### 7.1.6 Conclusion

[<sup>18</sup>F]FDG-PET/CT provides pretreatment prognostic information concerning the aggressiveness of cervical tumors which may contribute to optimizing and individualizing patient therapy. Although [<sup>18</sup>F]FDG-PET/CT is not considered suitable for T staging, it has an important role in staging cervical cancer, and it aids particularly in identifying the involvement of lymph nodes and distant metastases. In this context, it is helpful in targeted radiotherapy planning. Finally, [<sup>18</sup>F]FDG-PET/CT is an important diagnostic tool for detecting recurrent cervical cancer in clinically equivocal patients.

## 7.2 PET/CT with [<sup>18</sup>F]FDG in Endometrial Cancer

### 7.2.1 Initial Diagnosis and Prognosis

Like most neoplasms, endometrial carcinoma does demonstrate an increased rate of glycolysis and takes up [<sup>18</sup>F]FDG. Imaging with [<sup>18</sup>F]FDG-PET/CT may play a role as a prognostic factor in endometrium cancer. Several studies have shown that there is a statistically significant correlation between SUVmax and FIGO stage, histological grade, depth of myometrial invasion, lymph node metastasis, lymphovascular space involvement, and tumor size. Also, they have demonstrated that high SUVmax was an independent prognostic factor for both disease-free survival (DFS) and overall survival (OS),  $p < 0.05$  [31–33]. The analysis of survival ROC curve revealed SUVmax cutoff value of 17.7 to predict high risk of recurrence. Endometrial cancer patients with SUVmax higher than 17.7 were characterized by worse prognosis and lower overall survival [34].

### 7.2.2 Initial Staging

There have been several reports demonstrating the accuracy of [<sup>18</sup>F]FDG-PET/CT for detecting lymph node metastasis in endometrial cancer.

The referred sensitivity and specificity of [<sup>18</sup>F]FDG-PET/CT on region-specific analyses are 36–72% and 88–99%, respectively, and that corresponding values for patient-based analyses were 41–100% and 56–100%, respectively [35–43]. It seems that [<sup>18</sup>F]FDG-PET/CT tends to show low sensitivity and higher specificity. Studies have shown that the negative predictive value of [<sup>18</sup>F]FDG-PET/CT is very high (96–98%) [44, 45]. So, the combined high specificity and high negative predictive value confirm that [<sup>18</sup>F]FDG-PET/CT is presently the most promising imaging method to potentially exclude lymph node metastases and thus help avoid potentially harmful lymphadenectomy for staging.

But there is still a major limitation, the inability of the method to detect microscopic metastasis. As tiny lymph nodes tend to show smaller SUV than real values due to the partial volume effect, it is difficult to use the usual cutoff point (2.5–3.0) for differentiating malignant from benign lymph nodes [46]. A study has shown that in metastatic lymph nodes with a short axis diameter of 4 mm or less, [<sup>18</sup>F]FDG-PET/CT had a detection sensitivity of 12.5%; with a diameter between 5 and 9 mm, the sensitivity was 66.7%; and with a diameter of 10 mm or greater, it was 100.0% [36].

A recent study that compared the diagnostic performance of [<sup>18</sup>F]FDG-PET/CT, MRI and two-dimensional ultrasound (2DUS) found that all three methods were comparable in predicting myometrial invasion [44]. For cervical invasion and lymph node metastases, however, [<sup>18</sup>F]FDG-PET/CT was more accurate [44]. It seems that compared to MRI, [<sup>18</sup>F]FDG-PET/CT has a limited role for local staging of primary cancer, whereas it is a useful technique for assessing distant metastases throughout the whole body in a single examination in patients with advanced-stage disease [47].

### 7.2.3 Tumor Recurrence

Unlike conventional imaging modalities which provide morphological information, PET with [<sup>18</sup>F]FDG is able to identify viable tumor lesions

based on the increased glucose metabolism of malignant tissue. [<sup>18</sup>F]FDG-PET/CT can detect recurrent lesions otherwise missed or misinterpreted on conventional imaging studies and several studies support this.

A recent meta-analysis of the literature and several studies demonstrated that the patient-based sensitivity and specificity for detection of endometrial cancer recurrence were 91–100% and 83–100%, respectively [27, 36, 46, 48–50]. A previous study showed that the overall lesion site-based sensitivity and specificity of [<sup>18</sup>F]FDG-PET/CT were 94.7% and 99.5%, respectively [27]. The lesion site-based sensitivity and specificity of [<sup>18</sup>F]FDG-PET/CT for the detection of pelvic recurrence were 92.3% and 97.3%, while for the detection of extrapelvic recurrence, the indices were all 100% [27].

## 7.2.4 Conclusion

[<sup>18</sup>F]FDG-PET/CT has a limited role for local staging of primary cancer, whereas it is a useful technique for assessing lymph node and distant metastases throughout the whole body in a single examination in patients with advanced-stage disease. Its main role is in detecting recurrent lesions otherwise missed or misinterpreted on conventional imaging studies.

## 7.3 PET/CT with [<sup>18</sup>F]FDG in Ovarian Cancer

### 7.3.1 Initial Diagnosis: Differentiation Between Malignant and Benign Ovarian Tumors and Prognosis

The role of [<sup>18</sup>F]FDG-PET/CT for differentiating between malignant and benign ovarian tumors remains controversial, and false-negative and false-positive cases have been reported. Concerning the prognostic value of [<sup>18</sup>F]FDG-PET/CT, there have been reports that a high (>13.15) pretreatment SUV<sub>max</sub> of the primary tumor in patients with ovarian cancer was associ-

ated with a poor prognosis [51]. The SUV<sub>max</sub> of the primary tumor had a statistically significant association with stage ( $p = 0.010$ ) and histology ( $p = 0.001$ ) [51].

Intratumoral heterogeneity of PET/CT has been proved to be a prognostic predictor for many malignancies and the radiomics features extracted from PET/CT images allow the assessment of intratumoral and metabolic heterogeneity quantitatively [52, 53].

Radiomics signatures of PET seem that can improve the diagnostic accuracy and provide complementary prognostic information compared with the use of clinical factors alone or combined with CT components [52].

### 7.3.2 Initial Staging

In ovarian cancer [<sup>18</sup>F]FDG-PET/CT has an effective role in staging patients with advanced disease, providing useful information about extrapelvic sites, such as supraclavicular and paraaortic nodular involvement, peritoneum and omentum implants, and bone and muscle metastases. A recent meta-analysis, including data from 882 patients with ovarian cancer, showed that [<sup>18</sup>F]FDG-PET or [<sup>18</sup>F]FDG-PET/CT was a more accurate modality for detecting metastatic lymph nodes [54]. Approximately 70% of metastatic lymph nodes and 97% of negative lymph nodes could be correctly diagnosed by [<sup>18</sup>F]FDG-PET or [<sup>18</sup>F]FDG-PET/CT. Though significantly better than those of CT and MR imaging, the sensitivity of [<sup>18</sup>F]FDG-PET or [<sup>18</sup>F]FDG-PET/CT was moderate [54]. A possible explanation is that this method can only detect lesions with sufficient malignant cells to change the glucose metabolism and that FDG uptake may not be increased in low-grade tumors.

The main effect of [<sup>18</sup>F]FDG-PET/CT seems to be the detection of metastases outside the pelvis as it may detect distant metastasis in the liver, pleura, mediastinum, and supraclavicular lymph nodes that had been missed on CT imaging. It has been shown that [<sup>18</sup>F]FDG-PET/CT may increase the pretreatment staging accuracy to 69–87% compared with 53–55% with CT alone [55, 56]. [<sup>18</sup>F]FDG-PET/CT is particularly useful in distin-

guishing patients with stages III–IV cancer from those with stages I–IIIB. For this classification, the specificity, sensitivity, and accuracy of  $^{18}\text{F}$ FDG-PET/CT was 91%, 100%, and 98%, respectively, in comparison with 64%, 97%, and 88% for CT [57].

Although fusion PET/CT shows higher staging accuracy, mostly by identifying extra-abdominopelvic disease, it has not been widely adopted, as evidence that this capability alters treatment is lacking [58].

### 7.3.3 Radiotherapy Planning

In the literature, there is only one report about the role of  $^{18}\text{F}$ FDG-PET/CT on intensity-modulated

radiation therapy (IMRT) planning that showed that  $^{18}\text{F}$ FDG-PET/CT information seems to change gross tumor volume (GTV) delineation in 35% of cases. In these patients, the average increase in GTV was 21.6%, due to the incorporation of additional lymph node metastases, minimal recurrent nodularity, and extension of the metastatic tumor beyond the frame defined by CT [59].

### 7.3.4 Restaging After Treatment

Several studies have demonstrated that  $^{18}\text{F}$ FDG-PET/CT-derived parameters, including SUV and percentage change, have the potential to predict response to therapy in patients with ovarian cancer (Fig. 7.3).

**Fig. 7.3** A 78-year-old woman posttreatment for ovarian carcinoma, presenting with rising tumor serum markers and negative findings on recent CT imaging.  $^{18}\text{F}$ FDG-

PET/CT revealed increased  $^{18}\text{F}$ FDG uptake in the peritoneum and in bilateral inguinal lymph nodes

When an arbitrary SUV of 3.8 was taken as the cutoff for differentiating between responders and nonresponders after therapy, [<sup>18</sup>F]FDG-PET/CT showed a sensitivity of 90% and specificity of 63.6%. When an arbitrary percentage change of 65% was taken as the cutoff, the sensitivity was 90% and specificity 81.8% [60].

### 7.3.5 Tumor Recurrence

Potential advantages of the use of integrated [<sup>18</sup>F]FDG-PET/CT for evaluation of recurrent ovarian cancer include increased lesion detection with the use of a metabolic tracer, simultaneous acquisition of anatomic reference points to determine the exact location of lesions, and, in most cases, differentiation of disease processes from physiologic processes. Moreover, [<sup>18</sup>F]FDG-PET/CT may survey the entire body in one examination. These superior qualities may help identify which patients are eligible for secondary surgical cytoreduction. There have been many reports discussing the usefulness of [<sup>18</sup>F]FDG-PET/CT for detecting ovarian cancer recurrence. When the gold standard was clinical follow-up including radiological imaging, the diagnostic accuracy of [<sup>18</sup>F]FDG-PET/CT was very high with 73–100% sensitivity, 71–100% specificity, and 83–100% accuracy in patient-based analysis [57, 61–71]. However, when the gold standard was histopathology by surgery, the diagnostic accuracy of [<sup>18</sup>F]FDG-PET/CT tended to be poorer, and it was reported that the sensitivity, specificity, and accuracy of patient-based analysis were 53–83%, 40–86%, and 63–82%, respectively [72–74]. The discrepancies in these values between the clinical follow-up and the surgical histopathology as a gold standard may partly depend on the resolution of the [<sup>18</sup>F]FDG-PET/CT systems used and partly on the size of microscopically small lesions. The spatial resolution of PET is approximately 6–10 mm;

therefore, its sensitivity for depicting lesions smaller than 1 cm is lower than that for larger lesions [75] (Figs. 7.4 and 7.5).

Several studies and a meta-analysis have compared techniques for detection of recurrence and demonstrated that [<sup>18</sup>F]FDG-PET/CT was better (sensitivity 91% and specificity 88%) than CT (sensitivity 79%, specificity 84%) or MRI (sensitivity 75%, specificity 78%) [57, 62, 68, 76, 77]. In addition, [<sup>18</sup>F]FDG-PET/CT had the highest positive predictive value (89–98%) for recurrence of ovarian cancer when compared with other modalities [78, 79].

A major indication for [<sup>18</sup>F]FDG-PET/CT is the evaluation of ovarian cancer recurrence after first-line therapy in patients in which CA-125 levels are rising and conventional imaging studies show negative or equivocal findings [61, 80]. Investigators have reported that [<sup>18</sup>F]FDG-PET or PET/CT has a sensitivity of 96% for localizing recurrent disease in patients with rising CA-125 levels and that PET evidence of recurrent ovarian cancer preceded CT findings by 6 months, allowing earlier reintroduction of therapy [81, 82]. In accordance with the results of recent studies, [<sup>18</sup>F]FDG-PET/CT has a higher predictive value than the CA125 serum marker in the detection of disease recurrence [83].

Concerning the detection of peritoneal implants in a recent study, the sensitivity and specificity of [<sup>18</sup>F]FDG-PET/CT were 97.5% and 100%, whereas those of MRI were 95% and 85.7%, respectively. For the small-to-medium-sized (0.5–2 cm) peritoneal implants, diagnostic accuracy values of [<sup>18</sup>F]FDG-PET/CT were significantly better than those of MRI ( $p < 0.05$ ) [84].

As reported in the literature, the change in management of patients with ovarian cancer recurrence who have undergone [<sup>18</sup>F]FDG-PET/CT ranges between 25% and 58% [57, 64, 65, 83, 85].

**Fig. 7.4** A 52-year-old woman with a history of bilateral ovarian carcinoma presenting with slight but persistent elevation of tumor marker serum levels and negative findings on MRI imaging. [<sup>18</sup>F]FDG-PET/CT revealed two [<sup>18</sup>F]FDG avid lesions in the peritoneum

**Fig. 7.5** A 66-year-old woman, status posttreatment for ovarian carcinoma, presenting with progressively elevated CA-125 antigen and negative conventional imaging evaluation.  $^{18}\text{F}$ FDG-PET/CT revealed several foci of

increased  $^{18}\text{F}$ FDG uptake in the peritoneum. Abnormal metabolic activity was also present in a small left paraaortic and a small left common iliac lymph node

### 7.3.6 Conclusion

$^{18}\text{F}$ FDG-PET/CT has an effective role in the detection of metastases outside the pelvis as it may detect distant metastasis in the liver, pleura, mediastinum, and supraclavicular lymph nodes that may be missed on CT imaging. Another major indication of the modality is the evaluation of ovarian cancer recurrence after first-line therapy in patients in which CA-125 levels are rising, and conventional imaging studies show negative or equivocal findings.

# PET-CT Staging of Rectal Carcinoma

8

Maria G. Skilakaki

## 8.1 Introduction

Rectal cancer comprises over 1/3 of cases of all colorectal cancers and is one of the most frequent causes of cancer-related mortality in Western countries. The expectation of cure strongly depends on the local extent of initial tumor, infiltration of lymph nodes, and presence of distant metastatic disease. Accurate initial staging, early recognition of recurrence, and assessment of residual masses after treatment are mandatory for optimal management of patients with rectal cancer. Although contrast-enhanced multi-detector CT of the chest, abdomen, and pelvis and pelvic MRI are the modalities of choice for preoperative staging of rectal cancers, appropriate imaging for the diagnosis and management of these tumors remains a topic of current investigation.

Fusion imaging with combined positron emission tomography (PET) and computed tomography (CT) has been introduced in clinical practice since 2001. The glucose analog,  $^{18}\text{F}$ -fluorodeoxyglucose ( $^{18}\text{F}$ -FDG), due to its ability to accumulate in highly metabolic lesions, is the most widely used radiotracer for PET tumor imaging. As a noninvasive whole-body imaging modality able to provide metabolic and anatomic information,  $^{18}\text{F}$ -FDG-PET/CT has been exten-

sively used in the evaluation of patients with rectal carcinoma [1–3].

In recent years AI has emerged as a very promising tool in improving many aspects of medicine, including cancer imaging and management. Radiomics, a new field in imaging of clinical oncology, use AI methods to extract and analyze a large number of features from radiographic images to optimize technical factors, improve tumor characterization, quantification and staging, assess treatment response, and predict survival. Limited, preliminary data show that PET/CT-derived radiomics can increase method's accuracy and be of potential value in the evaluation of patients with rectal cancer [4–6].

## 8.2 Diagnosis and Initial Staging

Although most rectal tumors are FDG avid, PET/CT is not generally recommended for the initial diagnosis and staging of rectal cancer because it has a low sensitivity for locoregional staging due to its limited spatial resolution combined with the intense FDG uptake by the primary tumor and its inability to detect microscopic lymph nodal disease.

However, several studies in the literature that have investigated the specific impact of PET/CT on management of patients with locally advanced and low rectal tumors found FDG-PET/CT to be superior to contrast-enhanced multi-detector CT

M. G. Skilakaki (✉)

e-mail: [skmaria@otenet.gr](mailto:skmaria@otenet.gr)

in identifying both intrahepatic and extrahepatic metastatic disease with a high (>90%) sensitivity and specificity. Additionally, these studies reported a change in treatment strategy in 12–31% of cases. This is mainly due to more accurate tumor volume delineation for preoperative radiation treatment planning, discrimination of responders from nonresponders to chemoradiotherapy, and detection of abnormal metabolic activity in inguinal lymph nodes, a common place of metastasis in patients with low rectal cancer (Fig. 8.1) [2, 7, 8].

Moreover, an intense FDG uptake before therapy seems to be a bad prognostic factor related to reduced overall survival. It is therefore currently widely acceptable the use of FDG-PET/CT in the initial staging of patients with locally advanced rectal carcinomas who will receive chemoradiation preoperatively [9–11].

In recent years, whole-body FDG-PET/MRI has been reported as a promising tool for the evaluation of advanced rectal cancer. Hybrid PET/MRI combines the high soft tissue contrast and functional information of MRI and the metabolic information provided by PET. The current evidence suggests that PET/MRI is superior to PET/CT in T staging, whereas in N staging both modalities have similar diagnostic accuracy [12, 13].

**Fig. 8.1** A 58-year-old male with low rectal cancer. Axial fused PET/CT at the level of the pelvis shows abnormal metabolic activity in the primary tumor and in inguinal lymph nodes

### 8.3 Detection and Staging of Recurrent Disease

Locoregional recurrence and hepatic metastatic disease are the most common sites of relapse in patients with rectal carcinoma and usually occur in the first two years after resection of the primary tumor. Early diagnosis of local recurrence at the level of the anastomosis and identification of liver metastases are very important for patient care because surgery is the only curable option. One of the most challenging matters in post-therapy patients with locally advanced primary tumors is differentiation of surgical scarring and radiation fibrosis from viable tumor. PET/CT performed 3–6 months after radiotherapy is able to diagnose tumor recurrence by detecting abnormal metabolic activity in the presacral surgical bed and has been noted to have a sensitivity of 84–100%, specificity of 80–100%, positive predictive value of 76–88%, and negative predictive value of 92–100%. Thus, on this aspect PET/CT is superior to multi-detector CT and MRI [10, 14–16] (Figs. 8.2, and 8.3).

Moreover, FDG-PET/CT with its whole-body imaging capabilities has a significantly higher sensitivity (92%) for detection of extrahepatic metastatic disease than does CT or MRI and can play a crucial role in determining whether patients are suitable candidates for curative surgery. It seems that incorporation of PET/CT into the preoperative investigation of patients with recurrent disease and potential resectable local or hepatic lesions leads to reduced morbidity due to futile surgery and probably also to a considerable cost saving [14, 15, 17].

Another situation in which PET/CT is very helpful is the evaluation of patients with progressively elevated carcinoembryonic antigen (CEA) and no identifiable lesions on conventional imaging modalities (Figs. 8.4, and 8.5). In this patient population FDG-PET and PET/CT have reported sensitivity, specificity, positive and negative predictive values for detection of recurrence 79–100%, 50–83%, 89–95%, and 85–100%, respectively [15–17].

Additionally, several studies have shown that PET/CT may also be useful for detecting recur-

**Fig. 8.2** (a), (b) A 62-year-old patient with rectal carcinoma, status post-surgery, and chemoradiotherapy. Sagittal CT and fused PET/CT images reveal increased FDG uptake in a presacral mass representing local recurrence

**Fig. 8.3** (a), (b) A 72-year-old patient with rectal carcinoma, status post-surgery, and chemoradiotherapy. Sagittal CT and fused PET/CT images reveal no FDG uptake in presacral soft tissue representing post-radiation fibrosis

**Fig. 8.4** (a), (b) A 68-year-old man status post-treatment for rectal cancer presenting with rising CEA serum levels and negative results on CT imaging. Axial PET and cor-

responding fused PET/CT image of the abdomen show diffuse infiltration of the anterolateral peritoneum

**Fig. 8.5** (a), (b), (c) A 63-year-old patient with rectal carcinoma, status post-surgery, and chemoradiotherapy, with rising CEA serum levels and negative results on CT

imaging. Axial fused PET/CT images of the pelvis show infiltration of the right sciatic nerve

rence in patients with suspicious clinical findings and/or radiologic features regardless of the CEA level [8].

### 8.4 Monitoring Treatment Response and Planning of Radiation Therapy

Although the gold standard for assessing the tumoral response to therapy is histopathological analysis, interest in imaging for post-treatment response assessment is growing. Traditionally,

cancer response to therapy is based on comparison of tumor sizes visualized on conventional imaging modalities (most commonly CT) before and after treatment. According to response evaluation criteria in solid tumors (RECIST) a tumor is considered responding when there is at least a 30% decrease of its largest diameter. Although the RECIST criteria are widely accepted in current clinical practice, there is a weak correlation between changes in tumor size and patient outcome. Moreover, biologic response to therapy may precede morphologic changes and residual masses may lack any malignant activity. Several

recent studies and meta-analyses show that the combined functional and anatomical information provided by FDG-PET/CT seems to be very helpful in monitoring therapeutic activity [1, 8, 14, 15, 18–21].

Preoperative chemoradiotherapy in locally advanced rectal tumors has been noted to downstage the disease and allow sphincter preserving surgery in selected cases. Furthermore, it has been reported to increase the rate of complete surgical resection and reduce the risk of local recurrence, compared with postoperative treatment [1, 15, 22, 23]. The tumoral response to this neoadjuvant chemoradiotherapy is very heterogeneous and ranges from complete response, seen in 8–31% of the patients, to no response at all, while most patients (54–75%) achieve a partial response. Discrimination of responders from nonresponders with FDG-PET/CT has based on several predictive parameters including visual response, standardized uptake value (SUV), percentage SUV reduction (Response Index = RI), total lesion glycolysis (TLG), and metabolic tumor volume (MTV). The most studied PET parameter in therapy response prediction is the RI, which expresses the relative change in SUV measured before and after treatment and reflects a semiquantitative estimation of FDG activity within a selected lesion [8, 18–21].

However, there is a substantial variability among different studies in selecting optimal time for imaging and defining a minimum post-therapeutic SUV reduction indicative of response. In addition, hypermetabolic inflammatory changes that may be present after radiation therapy can cause issues with image interpretation and limit the accuracy of FDG-PET/CT in assessing tumor response [10]. Thus, although the available data suggest that  $^{18}\text{F}$ -FDG-PET/CT may be a very useful contribution to the conventional imaging modalities in the assessment of treatment response, the international guidelines still state that PET/CT should not be used to monitor progress of neoadjuvant therapy [18]. Further investigation with multicenter studies is needed to define the role of  $^{18}\text{F}$ -FDG-PET/CT imaging for predicting response to neoadjuvant therapy in patients with rectal cancer.

Another field, in which FDG-PET/CT can provide additional information, is the early detection of residual malignancy after targeted therapies in patients with unresectable liver metastases. Treatment choices for these patients include local radiofrequency ablation, selective internal radiation therapy, and transcatheter arterial chemoembolization. Identification of increased focal metabolic activity in the area of a treated lesion is considered as persistent disease. The reported negative predictive value of PET/CT scans performed at 1–4 weeks and at 3–11 months after targeted therapy is 100%, whereas the positive predictive value ranges from 80 to 88% [8, 10, 15]. Moreover, because the aim of many locoregional therapies is to stabilize disease rather than reduce tumor size, measuring both metabolic and anatomic response by PET/CT is preferable to measuring anatomic response alone by CT or MRI [8].

There are limited data in the literature supporting the use of FDG-PET/CT in radiotherapy planning for rectal cancer. PET/CT is reported to provide useful information for identification of more aggressive tumor subvolumes that should receive higher doses of radiation leading to accurate delineation of tumor volume, more effective local tumor control, and decreased toxicity [8, 11]. Although the NCCN is increasingly recognizing the effectiveness of PET/CT on tumor delineation for radiotherapy planning, the impact of PET on patient outcomes has yet to be established [8].

---

## 8.5 PET/CT Radiomics in Rectal Cancer

PET/CT-based radiomics literature in rectal cancer is rather limited with most of the studies analyzing colorectal cancer patients in general and, thus, mixing different kind of malignancies. There are only a few publications mainly targeted to the prediction of tumor response to neoadjuvant treatment in patients with locally advanced rectal cancer [5, 24–26].

Intratumoral heterogeneity and tumor genetic mutational status are the parameters that have

mostly been investigated with controversial results [27–29]. Bang et al., [28] in their study of 74 patients, that investigated 50 textural parameters for predicting tumor responses to neoadjuvant chemoradiotherapy failed to show significant associations between any of these features and treatment response, whereas Shen et al., [29] in their study of 169 patients with newly diagnosed, locally advanced rectal cancer, that evaluated 68 textural features using a different AI technique reported high accuracy in prediction of pathological complete response. Obviously, multi-center, larger, prospective, clinical studies and independent validation of existing artificial intelligence techniques are needed before clinical use in personalized treatment planning.

## 8.6 Conclusions

FDG-PET/CT can be reliably used in the evaluation of patients with rectal carcinoma, particularly for the assessment of residual presacral masses after treatment, the localization and staging of recurrent disease before surgery, and the investigation of cases with progressive elevation of serum CEA and negative findings on conventional imaging techniques. The available data suggest that PET/CT is very useful in assessing neoadjuvant therapy response in patients with locally advanced rectal cancer and targeted therapies in patients with unresectable liver metastases. There may also be a potential role of PET/CT in planning of radiation therapy, but NCCN has not yet officially recommended it. Finally, PET/CT-based radiomics is a new, increasingly explored and promising field in modern oncologic imaging but its implementation in every day clinical practice is limited mainly due to lack of standardization and reproducibility of AI techniques.

# Advances in Neuroendocrine Tumor Imaging, Including PET and Artificial Intelligence (AI)

Dimitrios Fotopoulos, Kapil Shirodkar,  
and Himansu Shekhar Mohanty

## 9.1 Introduction

Although neuroendocrine tumors (NET) can arise from various neuroendocrine cells containing tissues, in clinical practice, they arise majorly from the gastroenteropancreatic (GEP) sites and the lungs.

Gastrointestinal neuroendocrine tumors (NET) range over a broad spectrum of aggressiveness and differentiation, including well-differentiated tumors and poorly differentiated carcinomas. They are classified according to WHO based on cell proliferation, Ki index, and the number of mitoses, assigned designation from G1 to G3.

The inherent limitations of conventional cross-sectional imaging techniques like CT and MRI in detecting lesions smaller than 2 cm and tumors without discernible arterial phase enhancement (Up to 20%) are prone to false negatives. Hence, hybrid imaging with PET-CT has overtaken CT and MRI in identification and staging.

Recent advances in computer technology, improved computational power of chipsets, along the acquisition of large radiology datasets have provided opportunities for machine learning and optimization of diagnostics using deep and machine learning algorithms and deep neural networks to unlock the true potential of imaging data into meaningful insights aimed at better lesion detection, optimization of image acquisition, and better targeting of therapy. These improved insights or “consensus-derived experience” from machine learning can then be used for further deep learning to design neural networks with the ultimate goal of improving diagnostic and treatment techniques.

Currently, various research studies are published in the public domain, which aids in detection, segmentation, classification (radiophenomics), characterization (radiomics), and statistical classification (prediction/prognosis).

## 9.2 SSTR-Based Imaging

Conventional CT is better at detecting lung lesions. Diffusion-weighted imaging (DWI) allows better lesion detection in the liver and pancreas than CT. PET/CT and PET/MR combined metabolic and structural imaging to further improve imaging studies’ diagnostic accuracy.

Ghaziabad, Delhi NCR, India

Somatostatin receptors (SSTR) are expressed in a majority of NETs and are responsible for the shift from conventional image acquisition to molecular imaging for both diagnostic and targeted therapy.

SSTR imaging gives up to 50% improved sensitivity and up to 30% improved specificity in primary tumor detection compared to multiphase contrast CT.

SSTR imaging with gallium has revolutionized the diagnostic approach to neuroendocrine tumors. The agents currently used are Ga-68 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-Phe1-Tyr3-Octreotide (TOC)/Tyr3-Octreotide (TATE)/NaI3-Octreotide (NOC)/lanreotide PET/CT or <sup>99m</sup>Tc-hydrazinonicotinyl (HYNIC)-TOC/<sup>111</sup>InDOTA-TOC/lanreotide scintigraphy, 4,14–17 among others—referred to onwards as Ga-68 SSTR [1].

The agents used for SSTR imaging (SRI) can be either agonists or antagonists. The majority of the clinically used tracers are somatostatin agonists (68 Ga-DOTATE, 69 Ga-DOTATOC, and 68Ga-DOTANOC); however, antagonists (68Ga-NODAGA-JR11) have shown higher tumor uptakes, improved lesion detection, better image contrast, and overall higher sensitivity in preclinical settings. However, further research is required to ascertain whether antagonist tracers could be used instead of traditional agonists in the clinical diagnostic setting (Fig. 9.1).

**Fig. 9.1** Axial fused image of Gallium-68 DOTATOC scan showing uptake in NET of prostate

Gallium has shown 4–8 times more affinity for SSTR2 receptors than yttrium or indium derivatives. Although <sup>68</sup>Gallium has been traditionally used due to its wider availability, its limited availability from a generator source and higher half-life (68 min) has always been a technical limitation. <sup>64</sup>Copper has recently challenged this with a half-life of 12.7 h and better spatial resolution. <sup>64</sup>Cu-DOTATATE has been recently approved by the US-FDA for clinical use and has shown some promising results by detecting more additional true positive lesions and greater SUVmax in tumors and the background organs. However, higher beta-radiation and limited physical availability, limits the use of <sup>64</sup>Cu in the current settings.

The hallmark of the well-differentiated (G1) and intermediate differentiated group (G2) is the lower expression of SSTR. The higher the SSTR expression in NET, the lower the tumor's grade and vice versa. These receptors can be targeted by modifying a small portion of the somatostatin peptides for artificially increasing the affinity for specific receptor subtypes.

Ga 68 SSTR imaging comes into its own in identifying tumors with SSTRs—generally, higher tumor differentiation is associated with lower SSTR detection. SSTR2a is the most expressed receptor subtype, followed by SSTR3 and SSTR1. Different octreotide chelator complexes have different affinities for the receptors, and the clinically relevant SSTR-based imaging targets these receptors.

The Krenning scoring system is a visual assessment of Ga-68 SSTR uptake on a 0–4 scale using liver uptake (up to 2) and splenic uptake (up to 4) as reference points. Most probably, Ga-68 TATE is the agent of choice when a primary neuroendocrine tumor is suspected, based on a combination of clinical symptoms pointing to an underlying gastroenteropancreatic neuroendocrine tumor with a relevant biochemical profile.

The superiority of PET NET imaging compared to gamma scintigraphy techniques has been well documented in previous research

**Fig. 9.2** (a) Axial fused image of CECT Abdomen showing enhancing mass in the cecum. (b) Corresponding Gallium-68 DOTATOC scan showing uptake in the cecal mass

papers, and they provide higher sensitivity and have the most significant impact on clinical decision-making. Lower radiation dose than CT is another advantage; however, longer acquisition times are a strong deterrent (Fig. 9.2).

Also, false positives of Ga-68 PET/CT can arise due to many causes. These include the (1) uncinata process of the pancreas (well-established area of false-positive uptake); (2) intra-abdominal splenosis-related pseudo-nodules in Post-Splenectomy states (as splenectomy is frequently employed in the therapeutic operative regimen of NET tumors and residual splenic parenchyma in the splenosis manifests Ga-68 uptake); (3) osteophytes, because of SSTR2 expression in osteoclasts; (4) pituitary, thyroid, kidneys, and adrenals; and (5) sites of inflammation [2].

### 9.3 Ga-68 SSTR-vs. F18-FDG

In comparison between the two, Ga-68 SSTR PET/CT outperforms F18-FDG PET in disease sensitivity, although they have similar specificity; however, the combination of both maximizes the detection rate.

F-18 PET-FDG is more sensitive to high-grade tumors and less likely to express SSTRs. As high-grade tumors are more metabolically active, they are more likely to engage glycolytic energy-generating metabolic pathway which FDG-PET/CT better detects.

In comparison, Ga-68 TATE is more efficacious for highly differentiated tumors, retaining their original ability to express SSTRs, prone to selective Ga-68 uptake, albeit metabolically less active.

The arrival of SSTR-specific PET imaging has not rendered F-18 PET/CT imaging obsolete; on the contrary, a study by Binderup et al. showed that low sensitivity of F-18 FDG-PET studies is associated with a prolonged survival rate [Binderup et al.] (Fig. 9.3).

F-18 FDG/PET remains a highly reliable study for the prognostication of disease progression [Garin et al., Rodrigues et al.].

Additional value of F-18 FDG/PET is that it is an excellent prognosticator of survival when negative in a patient with SSTR expression—in particular, high values correlate with decreased overall survival.

A particular group (Binderup et al.) went so far as to define a cut-off value of SUV 9 as a prognosticator of greater mortality.

These studies render the use of F18-FDG-PET/CT and Ga-68 SSTR PET/CT not mutually exclusive but rather complementary. They serve to identify different populations of cells, depicting different identities, including levels of cell differentiation, thereby facilitating guided biopsy targeting different phenotypes. Therefore, it is self-evident that this would directly impact both proper tumor grading and tumor prognostication, as blind biopsies might miss a tumor subsite har-

**Fig. 9.3** (a) Axial NCCT images of pelvis showing mass in the urinary bladder. Histopathology photograph showing high-grade NET. (b) Postoperative gross specimen

image showing the NET. (c) Insignificant uptake on corresponding PET images

boring different cell populations, hence underestimating tumor grade, directly affecting its therapy and patient prognosis.

One additional advantage of Ga-68 SSTR PET/CT compared to F-18 FDG/PET CT is that the former can identify subcentimeter lesions thanks to its high target-to-background contrast, a property especially true of GaTate (exemplified by the fact that SUV of GaTate is significantly higher than FDG). Ga-68 outperforms FDG PET for the identification of bony secondary deposits.

It is advised to perform F-18 FDG/PET initially and in cases where Ga-68 SSTR PET/CT shows progression.

Furthermore, it should be reminded that since the introduction of checkpoint inhibitors, the mere application of RECIST criteria does not apply to accurate follow-up, as size reduction is not applicable for tumor response assessment. Instead, iRECIST criteria should be employed. Identifying this tumor subgroup with a high concentration of SSRs has been paramount since introducing peptide receptor radionuclide therapy.

## 9.4 Theragnostics in Neuroendocrine Tumors

Theragnostics (hybrid of the two Greek words Therapeutics and Diagnostics) is the principle of tailoring a specific therapeutic regimen to a patient deemed suitable for this therapy through diagnostics.

The principle of PRRT (peptide receptor radionuclide therapy) exploits the hypothesis that targeted high doses of radiation, mediated by agents specifically attached at high-affinity sites with an abundance of somatostatin receptors, allow for locally administered higher radiation dose. PRRT is far more efficacious than an external radiotherapy beam, on the condition that the concentration of SSTR receptors is high and is accomplished by specifically binding beta-emitting particles with a peptide that attach to SSTR.

Radiolabeled somatostatin analogs can be used for therapy in patients with refractory disease, provided the tumors express SSTRs on their

surface. Yttrium-90 ( $^{90}\text{Y}$ ) and Lutetium-177 ( $^{177}\text{Lu}$ ) are the most frequently used radionuclides, with different emitted particles, energies, and tissue penetration.

If therapy-related systemic complications, particularly hematologic, are factored in, it is inferred that careful selection of patients is mandated, based not only on identification of somatostatin receptors expression but also on imaging-related quantified parameters.

However, no uniform agreement has been reached so far in the current literature to set a specific SUV cut-off value.

The introduction of PRRT has necessitated the principle of somatostatin analog dosimetry, in the interest of both patient safety and therapeutic efficacy, particularly by evaluating quantitative parameters about tumor texture, known as radiomics, to create an individualized tumor profile that might prognosticate potential tumor response. However, no imaging study currently has validated this attempt in neuroendocrine tumors.

This is further compounded by the fact that efficacy of PRRT treatment cannot be relied upon RECIST criteria, as tumor size does not correlate well with overall survival prolongation—in up to almost one-third of PRRT therapy, the overall tumor size might even increase (without adverse implications for patient prognosis). This further exemplifies the fact that conventional imaging alone is not sufficient for response assessment [3].

---

## 9.5 Tentative Approach to AI in PET/CT Regarding Neuroendocrine Tumors

Artificial intelligence (AI) is a computer-based entity that tries to emulate and even surpass human intelligence with pinpoint accuracy based on algorithmic computational models, deep learning (DL), machine learning (ML), and deep neural networks (DNNs) to facilitate clinical decisions and treatment. Using complex algorithms to post-process complex multiparametric morphological and functional imaging data, AI has enormous potential to facilitate improved

image acquisition, improved lesion detection, overall improved diagnostic accuracy, improved imaging workflows, and improved targeted therapy, making it a hot commodity in the field of oncology.

It also allows new opportunities for treatment response assessment and survival prognostication using complex algorithms for automated post-processing of images acquired in routine clinical practice to extract standard quantitative parameters (currently done manually like size, percentage contrast enhancement, and SUV values) as well as analyze information beyond standard parameters to generate more insights into tumor burden assessment, disease response patterns as well as dose reduction and attenuation correction.

However, the literature regarding Artificial Intelligence in neuroendocrine tumor imaging is either sparse, not clinically validated, or not yet out in the public domain.

A study by Huejiao Han et al. [4] concerned itself with AI application in differentiation between pancreatic cystadenoma and pancreatic neuroendocrine tumors, but without reference to PET-CT.

The latest meta-analysis study by Ephraim Partouche et al. [5] conducted to standardize imaging practices in pancreatic neuroendocrine tumors identified a host of factors that constitute barriers towards effective integration of AI in neuroendocrine imaging studies. These include discrepancies between clinical and radiologic studies, geographic non-uniformity of studies, non-conformity to the proposed guidelines (e.g., ENETS 2017), and under-representation in the available literature of novel PET/CT imaging methods when compared to their conventional CT (and MRI) counterparts. This inhomogeneity will have to be addressed to achieve standardization of data towards ensuring pooled data use.

Ignat et al. [6] tried to preoperatively grade pancreatic NETs based on CECT imaging and validation of deep learning using convoluted neural networks. The challenges they raised include the complexity of data, difficulties with mathematical interpretation, signal differentiation from noise, and the complexity of the bio-mathematical

models. They suggested mathematical integration of functional imaging, circulating transcriptomics, and “omic” clustering amalgamated with master regulator tumor interrogation to provide the basis for a new discipline of neuroendocrine Oncotheranomics.

Zimmerman et al. [7] tried to use machine learning techniques to provide better decision support/decision trees to reduce NET misdiagnosis using a combination of factors (e.g., abdominal pain, and endoscopic/biopsy procedure, vomiting) or longer times to diagnosis (e.g., asthma diagnosis with visits to >6 providers) to increase the probability of NET detection.

Schwytzer et al. [8] explored the possibility of using machine learning algorithms to analyze PET CT imaging data to allow automated lung cancer detection using very low radiation doses to improve the specificity of lung cancer screening tests.

Koong et al. [9] described how machine learning could detect and predict treatment outcomes of pituitary neuroendocrine and other sellar tumors by utilizing machine learning of MRI radiomic data of the sellar region.

Wei et al. discussed in their review paper the various application of sophisticated image processing and machine learning algorithms to PET/CT imaging in several applications, including segmentation, reconstruction, and outcome modeling, with a special focus on the oncological radiotherapy domain areas and image-based prediction of treatment outcomes.

Zheng Q et al. [10] published a paper about utilizing AI algorithms for radiology imaging to provide equivalent or improved NET tumor metastasis detection than healthcare professionals.

Niazi et al. [11] developed deep learning methods to reduce pathologists’ workload by identifying tumor boundaries in images of Ki67-stained NETs using transfer learning techniques.

Hirai et al. [12] used deep learning AI to classify subepithelial lesions on EUS images with higher diagnostic performance than expert endoscopists leading to an improved clinical diagnosis.

Trebeschi et al. [13] explored the possibility of using AI algorithms to auto-quantify noninvasive radiomic biomarkers to assess response to immunotherapy in both neoadjuvant and palliative oncology settings for improved patient stratification.

Partouche et al. [14] advocated standardization of PNETs imaging to accumulate extensive homogenous imaging pooled data to enable AI data mining to identify new imaging biomarkers for treatment effectiveness, ultimately leading to better PNET treatment optimization.

Other potential application examples of AI in NET imaging which are currently being researched include:

1. Hyperplane or decision boundary separation to better classify imaging data
2. Decision support tool giving decision algorithms based on machine learning
3. Automated image detection and segmentation
4. Pattern recognition for classification of benign from malignant masses
5. Better 3D extrapolation of 2D imaging volume data
6. Pre-processing of imaging data for artifact reduction and automatic imaging protocol selection
7. 3D and 4D segmentation of dynamic contrast MR data

The hurdles of various AI studies for integration into daily clinical practice include (1) standardization of results, (2) robust validation by regulatory authorities, (3) reproducibility, (4) lack of gold reference standards, (5) absence of consensus of results or cross-study comparisons, (6) availability of abundant anonymized open clinical and imaging data sharing for research purposes due to strict patient safety and confidentiality issues, and (7) lack of harmonization between various AI guidelines [15].

However, AI is continuing to gain traction in the last decade and hopefully will overcome the various discovered and undiscovered digital, physical, financial, statistical, human, and mental

limitations to become better integrated into the healthcare systems with the ultimate goal of better patient care. However, for AI to reach its full potential, high-quality data, including outcome information, is mandatory to train the sophisticated AI algorithms on large prospective trials using standardized examinations.

# PET/CT in the Evaluation of Adrenal Gland Mass

# 10

Alexandra V. Nikaki

## 10.1 Introduction

Adrenal glands serve as potential sites for secondary infiltration of various cancers. Moreover, primary tumors can arise, either from the cortex or from the medulla of the glands. Single-photon emitters with g-camera procedures have long been used for the evaluation of primary tumors with high sensitivity and specificity. F-18-FDG-PET/CT has mostly been evaluated as a diagnostic tool in detection of adrenal metastasis, while other positron radiopharmaceuticals have been used for the identification and evaluation of disease extent in primary adrenal tumors.

## 10.2 PET/CT in Evaluation of Adrenal Masses in Cancer and Noncancer Patients

Although adrenal masses incidentally discovered in general population are usually benign and diagnosis is usually achieved by CT and MRI, they are common cause of differential diagnostic problems when conventional imaging is indeterminate in noncancer patients or when they consist of the only site of potential metastasis in cancer patients [1–5]. In the first case scenario, with sensitivity and negative predictive value of

up to 100% [1], PET/CT may be helpful and should be considered [6].

Common primary tumors that metastasize in adrenal glands are from non-small cell lung cancer, gastrointestinal tract cancer, and melanoma. Sensitivity, specificity, and accuracy of FDG-PET/CT in identification and characterization of adrenal masses in cancer patients have been demonstrated to be high (Figs. 10.1 and 10.2). Qualitative analyses, using liver [2] or aorta uptake [7] as a reference standard, quantitative measurements using SUVmax cutoff values [2] or target to adjacent tissues' and organs' ratios, and a variety of interpretive criteria and scanning protocols have been proposed in order to augment the method's diagnostic capabilities. According to Jana et al. [2], visual interpretation is enough for discriminating between benign and malignant formations in cancer patients, while the utility of PET is invaluable for CT indeterminate adrenal lesions. Utilizing quantitative measurements, SUVmax 3.4 was reported to yield 95% sensitivity and 86% specificity [2], tumor-to-liver SUV ratio of 1.68 corresponds to 90, 91.1, and 90.4% sensitivity, specificity, and accuracy, respectively [4], while in a meta-analysis of 21 eligible studies, including 1391 lesions, reported sensitivity, specificity, accuracy, positive and negative likelihood ratio for characterizing adrenal masses as malignant or benign are 0.97, 0.91, 0.98, 11.1, and 0.04, respectively [3]. The method's high negative and

**Fig. 10.1** (a), (b) Adrenal metastasis in a patient with non-small-cell lung cancer—high FDG uptake

**Fig. 10.2** (a), (b), (c) Adrenal myelolipoma in a patient with non-small-cell lung cancer—FDG uptake lower than liver uptake

positive predictive values of ~93% are also confirmed in a later prospective study [8], and FDG uptake is reported as a significant predictor for malignancy [9]. Further, newer PET/CT device with advanced technology, i.e., time-of-flight PET/CT detectors or addition of CT histogram analysis from PET/CT-derived data, may add to the, anyway high, method's diagnostic potentiality, regardless of qualitative or quantitative measurements [7, 10, 11]. Thus further exploration

of adrenal masses with other imaging techniques is considered unnecessary. However, mild uptake, equally increased metabolic activity in both adrenal glands, and size of less than 1 cm should be dealt with caution, as they might provoke false interpreting results [3, 7]. Lipid-poor and generally benign adrenal adenomas, hyperplasia as well as pheochromocytomas (PCCs), and tuberculosis constitute causes of false-positive results [2, 7, 9, 12].

### 10.3 PET/CT in Primary Tumors' Evaluation

Primary tumors of the adrenal glands arise either from the cortex, called adrenocortical carcinomas (ACC), or from the medulla, the most common being pheochromocytoma (PCC).

PCCs are paragangliomas (PGs) that arise from adrenal medulla and are usually diagnosed by their biochemical-functional profile in addition to a CT scan or MRI that reveal an adrenal mass. I-131- or I-123-MIBG complements further diagnostic approach, while somatostatin receptor scintigraphy has also been used [13]. Current approaching strategies if PCC is suspected may include gene profile expression and specific radiopharmaceutical utilization, according to the mutations detected. Although studies are scattered and patient sample is small in most of them, several positron emitting radiopharmaceuticals have been used in PCC investigation, summarized in a review of Havekes et al. [13] with F-18-dihydroxyphenylalanine (FDOPA) to present higher diagnostic accuracy in detection of PCCs as compared to I-123-MIBG. In addition, PET radiopharmaceuticals can be used for multifocal and metastatic disease detection or exclusion and recurrence assessing [13]. In a small sample of 12 patients with suspected or known relapse of PG, FDOPA-PET was reported superior to I-123-MIBG in assessing the burden of disease and changed therapeutic management in one patient [14]. Positive and negative predictive values of FDOPA-PET for the detection of PCCs-PGs are reported 94% and 85%, respectively, yielding an accuracy of 91%, with false results in Von Hippel-Lindau (VHL) and succinate dehydrogenase subunit B (SDHB)-related paraganglioma [15]. FDOPA uptake is not significantly different among the various genotypic tumor mutations [15]. In a direct comparison of FDOPA with MR/CT angiography, the authors highly recommend FDOPA-PET/CT as a diagnostic approach in patients with clinical symptoms of head and neck PG recurrence in the absence of somatostatin Ga-68-labeled agents [16].

Somatostatin analogs, such as DOTATOC, DOTATATE, and DOTANOC, labeled with positron emitting radionuclides—Ga-68—have also been used for evaluation of metastatic disease [13]. In a prospective study, Naswa et al. [17] demonstrated the superiority of Ga-68-DOTANOC over I-131-MIBG in evaluation of PCCs-PGs, concluding in alteration of therapeutic management of six patients. Evaluating the role of Ga-68-DOTATATE in PCCs-PGs at initial staging and follow-up, the authors proposed the utilization of this radiopharmaceutical in high-risk patients and patients with mutations correlated with familial syndromes [18]. However, during the process of dedifferentiation, tumors may lose their primary molecular characteristics, and therefore less specific radiopharmaceuticals, such as F-18-FDG, may be more suitable for imaging. In metastatic SDHB-associated PGs, FDG was reported to yield the highest sensitivity of the modalities used, up to 100% [19]. FDG-PET was also demonstrated to have higher sensitivity, as compared to I-123-MIBG and CT in the evaluation of metastatic disease in biochemically established PCCs and PGs, with a specificity of 90.2% [20].

Adrenocortical carcinoma is a rare tumor, with poor prognosis and high rates of recurrence. Metomidate (MTO), the methyl ester of etomidate, with its high and specific adrenocortical binding, labeled with the positron emitting C-11, has been evaluated in adrenal glands' pathology. Although C-11-MTO-PET could not differentiate between malignant and benign lesions, reported sensitivity and specificity for distinguishing adrenocortical versus non-adrenocortical pathology reach 89% and 96% compared to histopathologic findings [21]. A tumor-to-normal gland uptake cutoff ratio of 1.4 is associated with a risk of 99.5% for adrenocortical tumor [21]. Higher SUV values were reported for aldosterone-secreting tumors, compared to nonfunctional adenomas and to adrenocortical carcinoma [21, 22]. False-negative results were reported for lesions <1 cm and large necrosis [21]. C-11-MTO could potentially serve as complementary to CT and MRI for evaluation of adrenal pathology [22, 23]. Razifar et al. [24] reported improve-

ment of image quality, reduction of image noise, and increase of structure contrast by using principal component analysis—masked volume wise (MVW). Medication, such as adrenal steroid inhibitors and chemotherapeutic agents, may reduce C-11-MTO uptake both in adrenocortical carcinoma lesions and in normal tissues [25]. While C-11-MTO-PET is specific to adrenocortical versus non-adrenocortical pathology evaluation, FDG-PET has been proposed for discriminating benign versus malignant lesions in adrenal glands. FDG-PET, with a sensitivity of ~90%, is proposed to be used complementary to CT for detection of recurrent and metastatic adrenocortical carcinoma. High mitotic rate is found to significantly relate to FDG uptake [26]. Although authors report that FDG avidity and FDG uptake volume are significantly correlated with overall survival [26] in their group of patients, such correlation between FDG uptake in the primary tumor with overall survival (OS) neither in metastatic nor in the non-metastatic patients is verified for initial staging patients in another study [27] and further investigation needs to be carried out. C-11-MTO and F-18-FDG may be utilized supplementarily, since they answer specific and different clinical questions. Further studies are required until both find their exact position in adrenocortical pathology evaluation.

Neuroblastoma consists of the most frequent extracranial tumor in children. Imaging modalities used during the workshop of neuroblastoma include ultrasound, CT, MRI, and bone and MIBG scintigraphy. Although neuroblastoma tumors usually concentrate FDG, FDG-PET could likely be reserved for non-MIBG avid neuroblastoma and perhaps for early response assessment if baseline FDG-PET showed at least moderate FDG uptake, as well as for follow-up [28, 29]. As compared to I-123-MIBG scintigraphy, FDG-PET appears less effective in evaluation of neuroblastoma disease burden; thus it cannot replace I-123-MIBG scintigraphy in everyday practice. However, FDG-PET bears significant prognostic value, since (a) FDG uptake higher than the respective MIBG uptake, (b) high tumoral SUV<sub>max</sub>, and (c) identification of bone disease in PET are all correlated with

lower survival interval in refractory or recurrent neuroblastoma patients going to receive I-131-MIBG therapy [30]. F-18-FDOPA has also been evaluated in advanced stage neuroblastoma at initial staging and during follow-up in suspicion of recurrence; the authors reported sensitivity and accuracy of 90% in a lesion-based analysis, higher than the respective values of I-123-MIBG, thus proposing FDOPA as potential radiopharmaceutical for neuroblastoma exploration either at initial staging or at restaging of the disease, as well as in inconclusive MIBG results [31].

---

## 10.4 Towards Artificial Intelligence

Artificial intelligence (AI) is a long-living term which describes the potentiality of computers to perform tasks that otherwise would need human intelligence to be achieved. Imaging acquisition as well as imaging interpretation could benefit from AI algorithms providing higher quality services in oncologic patients. Hybrid systems, PET/CT and PET/MRI are considered data-rich methods, which make them excellent tools for AI models application [32]. A systematic review [33] was attempted for AI implementation in FDG-PET imaging in oncologic patients. Although most of the studies concerned lung cancer, AI models may help in tumor detection, staging and restaging as well as in evaluation of patients' prognosis. Further investigation is required in order to implement Deep Learning (DL) techniques in clinical practice.

---

## 10.5 Conclusion

F-18-FDG-PET/CT in the evaluation of adrenal glands' tumors is currently widely applied in cancer patients, in search of metastatic adrenal lesions, particularly in non-small cell lung cancer patients; in rare cases in noncancer patients and suspicion of cancer, it may serve as a complementary tool in cases of inconclusive CT and MRI. For the exploration of primary adrenal tumors of the medulla, several radiopharmaceuti-

cals, such as FDOPA and Ga-68-somatostatin receptors' analogs, have been used, while C-11-MTO is specific for distinguishing adrenocortical versus non-adrenocortical pathology. However, further research is required so as the above-described positron emitting radiopharmaceuticals reach their definite applications. Of interest would be the application of AI algorithms in the investigation of adrenal gland mass lesions, either it may concern the cortex or the medulla, primary or metastatic, using several different radiopharmaceuticals.

Alexandra V. Nikaki

## 11.1 Introduction

The incidence of renal cell carcinoma (RCC) at all stages is rising, with clear cell histologic type being the commonest [1]. However, it has been reported that 15% of small renal masses are benign [2]. Partial or total nephrectomy is the current treatment for RCC. Contrast-enhanced computed tomography (CECT)-renal protocol [3] is the imaging modality of choice in the detection and differentiation of solid renal masses versus cystic ones, even small ones of size <2 cm; however, it faces certain limitations consisting of its lower ability to differentiate between benign and malignant lesions, as well as indolent from aggressive phenotype [2, 3]. The role of magnetic resonance imaging (MRI) is currently mostly restricted to characterization of equivocal computed tomography (CT) findings, evaluation of perirenal fat and venous cava thrombosis. The urge of functional characterization of renal masses has brought the utilization of PET/CT in the foreground [2, 3].

## 11.2 18F-FDG-PET for Renal Cancer Investigation

### 11.2.1 Renal Mass Characterization and Initial Staging

Although FDG-PET has an established or promising role in initial staging and restaging of the majority of malignancies, results are less optimal when renal masses are validated. Primarily physiologic renal excretion of the radiopharmaceutical and secondary inflammatory or indolent processes can provoke false positive results. Moreover, the variable degree of FDG uptake by the renal masses as well as the spatial resolution of PET scanners can mislead to false negative diagnosis [2, 4].

Studies concerning the exploration of the value of FDG-PET imaging procedure in initial staging and restaging patients with renal cancer are only scattered, occupying a small sample of patients and the majority of them reveal no or little added information as compared to conventional imaging procedures. Although differences in FDG uptake in the means of SUV values between high- and low-grade clear cell RCC, as well as between high-grade clear RCC and normal kidney tissue are demonstrated [5], the reported sensitivity for RCC diagnosis and staging varies in the range of 32–100% and 47–75%, respectively [2, 4].

A. V. Nikaki (✉)  
Docrates Cancer Center, Helsinki, Finland

First promising results for the utilization of FDG-PET in the exploration and characterization of RCC, with a reported sensitivity of 94% [6], equal to that of CT, were not verified in more recent studies, although it should be mentioned that studies are subjected to referral bias, since most patients were only referred to PET examination, if they were to be treated with surgical excision after CT and/or MRI indication [3, 6–8]. Aide et al. [7] demonstrated the high number of false negative PET examinations in evaluating suspicious renal masses, thus reporting a sensitivity of 47%, however a higher specificity (80%); the authors also reported the discordance between high FDG uptake by small low-grade renal malignances and low FDG uptake by large high-grade renal malignances, although the median size of visualized tumors was actually higher than that of nonvisualized ones. The last was also confirmed by Ozulker et al. [8] reporting an average  $8.3 \pm 4.3$  cm for FDG-PET visualized tumors versus  $3.5 \pm 1.3$  for nonvisualized ones; however, the authors also reported statistically significant higher Fuhrman grade in visualized tumors as compared to nonvisualized malignances. Accuracy was ~50%.

FDG-PET is reported to have a good sensitivity in characterizing the extent of disease, especially in detecting distant metastasis, thus showing higher accuracy than CT, concerning, more frequently, bone [7, 9, 10] and adrenal metastasis [7], renal vein and inferior vena cava infiltration, and tumor thrombus [8]. Advanced local disease, lymph node assessment, and predominantly distant metastasis are well identified by FDG-PET with higher sensitivity than CT and bone scintigraphy, thus concluding in alteration of patients' management in 9–13% of cases, or even more according to more optimistic studies [6–10]. FDG avidity in metastatic lesions is demonstrated to be higher as compared to the primary site of the tumor, possibly indicating different biology and GLUT expression [3, 9]. Sensitivities in detecting metastatic disease range between 64% and 100%, more closely to 100% (for a review see Lawrentschuk et al. [4]). False results may occur in oncocytomas [6, 8]. Sensitivity could, likely, be improved by delayed imaging or

with the use of diuretics; however, there are conflicting results and further investigation needs to be carried out.

High SUVmax either at the primary or at the metastatic foci as well as increased number of FDG-avid lesions before treatment in metastatic or recurrent RCC patients has been reported to have prognostic significance and to be correlated with reduced overall survival [11, 12]. Further, in a multivariate analysis of 139 RCC patients, Nakajima et al. demonstrated that the total lesion glycolysis (TLG) and the metabolic tumor volume (MTV) along with high pathologic TNM stage were the significant factors for predicting progression-free survival [13].

<sup>18</sup>F-FDG-PET has been investigated in a small pediatric population sample with Wilms tumor and was reported to correctly identify the primary site of the tumor and lymph node invasion and to accurately rule out distant metastasis; the authors reported that although it could be suitable for imaging Wilms tumor, it does not actually offer added information [14].

### 11.2.2 Relapse and Evaluation of Treatment Response

The role of FDG-PET is perhaps more decisive in the evaluation of possible renal bed recurrence or metastatic disease in restaging patients with renal cell carcinoma, especially considering the post-treatment changes that may influence CT interpretation. Regarding that FDG-PET is not subject to such alterations, it has been found accurate and useful in this portion of patients. Reported sensitivity is 74–100% [6, 15–19]; specificity [15–19] and accuracy [15, 18, 19] are 71–100% and 79–90% respectively (partially varying according to the usage of per-patient or per-lesion evaluation), while prognosis is better for PET negative patients. Lymph node invasion, local relapse, and adrenal metastasis were identified as relapse or metastatic lesions. During surveillance, Park et al. [16] demonstrated positive and negative predictive value of FDG-PET 77.3% and 92.6%, respectively, with an overall accuracy of 85.7% in evaluating possible recurrence and

**Fig. 11.1** (a) 18F-FDG-PET-MIP imaging reveals multiple metastatic lesions in a patient with renal carcinoma, who underwent surgical resection of the left kidney and had received multiple schemes of chemo and targeted therapy. (b), (c) Nodule at the right lung (b) with 18F-

FDG uptake (c), indicative of pulmonary metastasis. (d), (e) Osseous distortion at CT imaging (d) with high 18F-FDG uptake at PET (e), compatible with osseous secondary invasion

metastatic disease; however, the reported results did not overweight those of other conventional modalities (Fig. 11.1a–e). More recently FDG-PET/CT is demonstrated to influence therapeutic strategy in 43% of patients and to correlate both with overall survival and progression-free survival [19]. SUVmax is considered as an independent factor of survival in advanced RCC cases, recurrent and stage IV [20].

Apart from radical or partial nephrectomy, current therapeutic strategies for renal cancer, especially in advanced or recurrent cases, include tyrosine kinase inhibitors which target VEGF signaling, as well as mTOR inhibitors. However, these approaches do not result, at least initially, in massive tumor shrinkage and size changes, since they act more as cytostatics rather than cytotoxics [3]. On the other hand it would be of great importance to determine which patients mostly benefit from targeted therapies. FDG-PET has been evaluated in the assessment of renal cell cancer

response to tyrosine kinase inhibitors—sunitinib and sorafenib. Correlation with overall survival has also been reported. Ueno et al. [21], in their prospective study, demonstrated that SUVmax reduction of >20% early in the course of targeted treatment (~30 days after the initiation of treatment) was correlated with longer progression-free interval. Moreover, when patients were categorized in good and intermediate responders according to SUVmax reduction >20 or <20% in non-increasing masses according to CT criteria, both progression-free and overall survival were statistically significantly different. Therefore, FDG-PET potentially could complement CT in evaluation of response to kinase inhibitors treatment and further discriminate patients with CT findings of stable disease [21]. However, Kayani et al. [11] reported prognostic significance of FDG-PET only 16 weeks after initiation of treatment with sunitinib, and not early in the course of therapy, although FDG-PET may provide infor-

mation about tumors' biologic nature and sunitinib resistance according to the writers.

As for pediatric population with Wilms tumor, FDG-PET bears a potential role in post-treatment setting and in evaluating pretherapeutic relapse [14].

Conclusively, FDG-PET is likely not used in determining renal malignancy; however, it could play a role in selected cases of suspected distant metastasis during initial staging. Its role is more prominent in providing functional prognostic information and evaluating response to treatment and recurrent disease.

---

### 11.3 Non-FDG Radiopharmaceutical for RCC Imaging

Considering the limited value of FDG-PET in determining renal cell carcinoma especially in the means of monitoring small renal masses, efforts have been made so as other imaging biomarkers to be manufactured. Carbonic anhydrase IX is a cell surface antigen, highly expressed in >95% of clear cell renal cell carcinoma (ccRCC). Girentuximab (cG250), a chimeric antibody, labeled with I-124 (positron emitting radionuclide) binds with carbonic anhydrase IX and has been proposed for the evaluation of ccRCC [2]. After promising initial results in a small sample of patients [22], a multicenter open-label study was carried out, in which I-124-cG250-PET was performed in patients with renal masses, who were planned for surgical removal. With excellent interobserver agreement, reported average sensitivity and specificity are 86.2 and 85.9 versus 75.5 and 46.8%, respectively, for CECT, while accuracy ranges between 85.6 and 86.9% and higher than the respective reported for CECT and at least comparable to that of biopsy. Positive and negative predictive values are demonstrated 93.9–94.7 and 68.8–70.3%, respectively. Interestingly, I-124-cG250-PET could detect even small lesions of less than 2 cm. I-124-cG250-PET has been characterized as the first molecular imaging procedure which bears specific prognostic information for a specific solid

tumor [23]. Despite, however, the first encouraging results, girentuximab-labeled tracers have not gained wide acceptance.

Other radiopharmaceuticals have, also, been proposed for the evaluation of renal masses and RCC. 18F-Fluoromisonidazole, a marker of hypoxia, has been evaluated to define possible oxygen-derivative alterations during sunitinib treatment and baseline 18F-Fluoromisonidazole was found to be linked to progression-free survival in RCC patients treated with sunitinib, however not with overall survival [24]. 18F-Fluorothymidine, a proliferative marker, and 18F-Fluoroethylcholine, a membrane synthesis marker, were also validated in RCC patients receiving tyrosine kinase inhibitor treatment, consisting of a category of potential imaging agents in renal cell carcinoma [25–27]. Nakanishi et al. reported significantly higher AUC, sensitivity, and accuracy for 11C-choline PET compared to 18F-FDG-PET, concluding that RCC patients may benefit more from choline-PET imaging than FDG-PET for staging and restaging [28]. Imaging RCC patients with PSMA-PET is considered less optimal; however metastatic patients may benefit [29]. For bone metastasis evaluation in RCC patients 18F-NaF-PET is reported to be significantly more sensitive than bone scan and CT, a fact which could further have an impact in treatment decisions [30]. However, all these radiopharmaceuticals are under investigation and further validation is required until they gain a role in daily imaging of renal cell carcinoma.

---

### 11.4 Towards Artificial Intelligence

Artificial Intelligence (AI) is currently invading in PET/CT imaging instrumentation, data acquisition, data processing, and final reporting. Huge efforts have already been made towards algorithms development for machine learning (ML) and imaging interpreting concerning a variety of tumors or nontumor lesions imaged with PET. A systematic approach [31] was attempted for AI FDG-PET imaging in oncologic patients. The majority of the studies concerned lung cancer,

followed by head and neck tumors. ML models may serve as useful assistance to physicians for tumor detection, segmentation, staging, prognosis, and evaluation of response. Despite, however, the promising results, AI in PET imaging is still in its early stages and more effort is required in order to implement Deep Learning (DL) techniques in everyday practice. Considering RCC imaging, AI may be even more useful, as current approaches are in some cases of limited value and new radiopharmaceuticals are being explored.

# PET/CT Findings in Testicular Cancer

# 12

Chariklia D. Giannopoulou

A glucose analog, 18F-fluoro-2-deoxy-D-glucose (FDG), is the most used PET tracer in testicular cancer. In general, increased FDG tumor uptake is due to the increased number of glucose transport molecules and the increased activity of hexokinase isoenzymes, making FDG a probe for imaging tumor metabolism, aggressiveness, and viability. FDG-PET/CT provides functional information about the metabolic activity of disease sites, and especially about viability in residual masses that cannot be correctly predicted by anatomical, conventional imaging.

Non-FDG-PET tracers have also been used in testicular germ cell tumors (CGTs) such as 39-deoxy-39-18F-fluorothymidine (18F-FLT)—a probe for imaging cellular proliferation—[1] and radio-labeled integrins [2].

Seminomatous germ cell tumors (SGCT), including their metastases, show high FDG uptake and express significantly greater FDG avidity than nonseminomatous germ cell tumors (NSGCT), whereas mature teratomas have low FDG uptake [3].

False-positive findings are due to the fact that FDG is not a tumor-specific tracer; normal and benign cells may also accumulate it. Apart from the normal distribution (brain, kidneys, and bladder) sites of inflammation, granulomata, and tis-

ues in certain other non-malignant conditions may concentrate FDG. Post-radiotherapy inflammatory reactions, as well as post-chemotherapy metabolic flare may also be responsible for non-specific FDG uptake resulting in false-positive studies.

On the other hand, false-negative findings may be due to lesion's size (foci smaller than 1 cm are at the limits of systems' resolution), to tissue histology: a mature differentiated teratoma has low FDG uptake, or to short time elapsed after chemotherapy.

It is evident that special care should be taken about the timing of PET/CT that should be performed not earlier than 6 weeks post-chemotherapy, in order to obtain maximum accuracy.

---

## 12.1 Initial Staging: Early Detection of Micrometastases

There is not enough evidence supporting the value of FDG-PET in the staging at presentation of patients with either SGCTs or NSGCTs.

The predictive value of FDG-PET at the initial staging of patients with clinical stage I/II GCTs has been a question of dispute, as it affects patients' management, i.e., the selection of surveillance against primary retroperitoneal

---

C. D. Giannopoulou (✉)

Hospital, Athens, Greece  
e-mail: [harisg@otenet.gr](mailto:harisg@otenet.gr)

lymphadenectomy for NSGCTs, or surveillance versus radiation therapy for SGCTs.

CT is the established method of staging patients with SGCTs. However, the great percentage of false-negative CT results—due to its inability to detect microscopic metastases in approximately 30% of patients—hampers the accurate diagnosis of early-stage disease, and the correct differentiation of stage I from stage IIA NSGCT patients [4].

Anatomical imaging (CT) findings are solely based on lymph node (LN) size and morphology, whereas FDG uptake reflects the metabolic LN status: relatively small LNs may harbor active disease and enlarged LNs may be reactive. Another PET advantage over CT, improving PET sensitivity, is standard whole-body scanning covering areas that are not routinely scanned by CT. On the other hand, PET resolution of about 10 mm may limit sensitivity for the detection of small volume disease; however, newer PET/CT systems may achieve a resolution of 5 mm or less.

FDG-PET/CT could be useful for small-volume metastatic disease diagnosis in patients with early-stage II NSGCT and inconclusive conventional imaging studies.

In a paper from a German multicenter trial, studying the predicting value of FDG-PET in primary staging of retroperitoneal LN metastases in patients with newly diagnosed early-stage NSGC, the PPV and NPV of FDG-PET were 95% and 78%, while for CT, PPV and NPV were 87% and 67%, respectively. The authors concluded that FDG-PET as a primary staging tool for NSGCT yielded slightly better results than CT and that false-negative findings were more frequent with CT, rendering FDG-PET mostly useful as a diagnostic tool in case of inconclusive CT scan [5]. These results are in keeping with those of previous studies [6].

However, an earlier UK study of patients with clinical stage I NSGCT examining the ability of FDG-PET to identify patients without occult metastatic disease was stopped prematurely, because of the high number of FDG-PET false negatives: Of 88 patients with negative PET scans, 33 patients relapsed with an estimated

one-year relapse-free rate of 63.3% [7]. In a recently published paper FDG-PET was helpful in the initial staging of 16 patients with equivocal CT studies; however it was not able to predict relapse in the group of high-risk patients [8]

In conclusion, although FDG-PET/CT does not have a distinctive role in staging of patients with SGCTs or NSGCTs, it could be useful for small-volume metastatic disease diagnosis in patients with early-stage II NSGCT and inconclusive conventional imaging studies.

---

## 12.2 Response to Treatment Assessment: Residual Mass Characterization

Assessing residual disease after treatment in both seminoma and nonseminomatous germ cell tumors of the testis is of great importance in patients' management, as it contributes to patient selection for surgical resection, especially those with masses greater than 1 cm.

---

## 12.3 Seminomatous GCTs

After seminoma resection, patients with seminomatous testicular GCTs are generally followed up with CT. Surveillance using serum tumor markers is unreliable, because of its limited sensitivity—only 30% of seminoma relapses are marker positive [9].

In patients with post-chemotherapy residual masses, FDG-PET due to its ability to differentiate between necrosis/fibrosis and residual or recurrent viable tumor has been proved sensitive as well as specific for detecting recurrent disease and selecting those patients who could thereafter be treated surgically (Figs. 12.1 and 12.2).

In a large, prospective, multicenter trial [10], FDG-PET was performed in 51 patients with metastatic seminoma and post-chemotherapy residual masses greater than 1 cm, detected by CT. FDG-PET findings were correlated with the histological findings as to tumor viability, or to clinical or radiological (CT) evidence of progressive disease. In that study it was shown that

**Fig. 12.1** (a) FDG-PET/CT, axial fused image showing residual retroperitoneal mass without increased FDG uptake, in a patient with seminoma, 2 months after the

completion of chemotherapy. This is a true negative study, as there was no evidence of active disease after 3 years of follow-up. (b) Corresponding CT axial image

**Fig. 12.2** (a) FDG-PET/CT, axial fused image of a 56-year-old patient with stage IIb seminoma, 7 weeks after first-line chemotherapy completion, showing intense

FDG uptake in the residual retroperitoneal mass. After surgery, histology revealed viable tumor in the resected mass. (b) Corresponding CT axial image

FDG-PET can identify viable tumor with a specificity of 100%, a sensitivity of 80%, a positive predictive value of 100%, and a negative predictive value of 96%, versus CT's respective values of 74% specificity, 70% sensitivity, 37% positive predictive value, and 92% negative predictive value. The authors conclude that FDG-PET performed within 4–12 weeks after chemotherapy can accurately predict viable residual tumor. In patients with residual lesions greater than 3 cm and negative FDG-PET, surgery can be omitted, whereas if PET is positive, residual lesions, even smaller than 3 cm, can be considered as harboring viable tumor; hence surgery can be of benefit [10].

These results are in keeping with a prospective study in 48 patients with metastatic seminoma

and CT-documented residual mass after chemotherapy, investigating whether FDG-PET predicts viable tumor. FDG-PET had a sensitivity and specificity of 80% and 100%, respectively, compared with CT sensitivity and specificity being both 73%. In conclusion, in patients with post-chemotherapy seminoma residuals, a positive PET is highly predictive for the presence of viable tumor. A negative PET scan can accurately exclude disease in lesions >3 cm, with a slightly higher sensitivity than CT, thus contributing to avoid unnecessary additional treatment for these patients [11].

In a study by Hintz, the ability of FDG-PET for predicting residual tumor viability was evaluated in 20 patients with seminoma following chemotherapy for advanced disease.

Histopathological findings were correlated with PET results. All patients with viable tumor were identified correctly by FDG-PET. No false-negative results were observed, but nine patients had false-positive PET results. FDG-PET had an overall sensitivity of 100% and specificity of 47% in detecting residual viable tumor [12].

In a recent meta-analysis of nine studies by Treglia et al. [13], FDG-PET was proved as an accurate diagnostic imaging method in the post-chemotherapy management of patients with seminoma—in particular in patients with recurrent/residual lesions >3 cm.

However, the PPV of FDG-PET has been challenged by a retrospective study done in 2018: in a cohort of 90 patients with metastatic seminoma and FDG/PET positive residual retroperitoneal tumor mass, the PPV was only 23%. False-positive FDG has been associated mainly with necrosis, or with sarcoidosis, fibrosis, inflammation, and benign tumors. The authors recommend closely monitoring patients with repeated imaging in order to avoid unnecessary overtreatment [14].

An interim FDG-PET study, after two cycles of cisplatin, etoposide, and bleomycin (PEB) treatment, has been proposed in patients with metastatic seminoma and was compared with a CT study after three or four cycles of therapy. There has been found a significant association between metabolic PET response and tumor shrinkage in patients, resulting in predicting those who do not need additional treatment, in order to reduce toxicity, and in timely identifying cases hard to treat [15]. Similarly, a recent prospective observational study by Raggi et al. in 75 patients with advanced stage seminoma, an interim FDG/PET study after 2 cycles of PEB or EP, showed that those patients with no residual FDG uptake had better relapse-free survival. The authors also concluded that an early interim FDG/PET study may also contribute to optimizing the prognostic risk groups definition [16].

In conclusion, in patients with post-chemotherapy seminoma residuals, a positive PET is an indicator of residual active—viable tumor regardless of lesion size. A negative PET scan can accurately exclude disease in lesions

>3 cm. In order to enhance specificity, reducing the incidence of false-positive results, the PET scan should be performed at least 6 weeks after the completion of chemotherapy [17].

In keeping with international guidelines [18–21] PET-CT study is recommended in the post-chemotherapy management of pure seminoma patients, in order to assess whether residual viable tumor is present. In patients with a residual mass > 3 cm, normal levels of serum markers, and negative PET, no further treatment is needed and close surveillance is recommended. If PET scan is positive, surgical resection could be considered, along with biopsy or surveillance.

---

## 12.4 Nonseminomatous Germ Cell Tumors

Most patients (70%) with advanced metastatic NSGCT will show complete response to first-line chemotherapy, with subsequent normal serum markers and mass disappearance. In the rest 30%, who show partial response to treatment with negative marker levels and persistent residual masses, the major imaging diagnostic challenge is to differentiate, in a noninvasive way, between fibrosis and necrosis, that occurs in approximately half of those patients, from either mature or immature teratomas—that have to be operated upon as they are chemotherapy resistant, tend to grow, and undergo malignant transformation—or viable/active disease.

FDG-PET cannot reliably distinguish mature teratoma from benign residual mass, because mature teratoma has low FDG uptake and cannot be differentiated from fibrotic or necrotic tissue (Fig. 12.3). In a prospective multicenter study of 121 patients with stage IIC or III NSGCT, with histological confirmation [22] FDG-PET predicted correctly tumor viability with a 56% accuracy, comparable to CT accuracy (55%). Sensitivity and specificity of FDG-PET were 70% and 48%. With viable carcinoma as the unique malignant finding, the negative predictive value was 83% for FDG-PET. Authors conclude that this trial demonstrated that FDG-PET cannot add a clear clinical benefit to the standard diag-

**Fig. 12.3** (a) sFDG-PET/CT, axial fused image of a 34-year-old patient with mixed nonseminomatous germ cell tumor 40 days after the completion of cisplatin-based combination chemotherapy. There is no increased FDG

uptake noted in the residual retroperitoneal masses shown on corresponding CT axial image (b). This is a false-negative study: after surgery, histology revealed mature cystic teratoma in the resected masses

nostic procedures—CT and serum tumor markers—in the prediction of tumor viability in residual masses.

However, in a previous prospective study, Kollmannsberger et al. [23] demonstrated that FDG-PET could correctly characterize residual masses with a specificity of 92% and a sensitivity of 59% in a high-risk population of 45 patients with nonseminomatous germ cell tumors, concluding that positive PET is highly predictive for the presence of viable carcinoma.

Possibly, FDG-PET could contribute to defining the lesions worth operating, i.e., those with high FDG uptake most likely to harbor viable tumor, in patients with multiple residual masses.

In conclusion, current evidence does not support the use of FDG-PET/CT in the management of patients with nonseminomatous germ cell tumors [24] as FDG-PET has no clear additional role in predicting residual mass histology in patients with advanced metastatic NSGCT after the completion of chemotherapy.

## 13.1 Introduction

The evolving role of nuclear medicine and particularly of PET/CT over time in prostate cancer is represented by the expansion of applications of already used radiopharmaceuticals in everyday clinical practice, by newly utilized radiopharmaceuticals, as well as by the introduction of new imaging modalities such as PET/MRI. Radiopharmaceuticals used for prostate cancer imaging include  $^{11}\text{C}$ - and  $^{18}\text{F}$ -Choline,  $^{18}\text{F}$ -Fluciclovine,  $^{18}\text{F}$ - and  $^{68}\text{Ga}$ -Bombesin,  $^{18}\text{F}$ -Dihydrotestosterone,  $^{89}\text{Zr}$ -STEAP monoclonal antibody,  $^{18}\text{F}$ -Sodium Fluoride,  $^{18}\text{F}$ -Fluorodeoxyglucose, and finally  $^{68}\text{Ga}$ - and  $^{18}\text{F}$ -Prostate-Specific Membrane Antigen (PSMA).

## 13.2 Imaging of Prostate Cancer with PET/CT

The role of  $^{11}\text{C}$ -Choline, an FDA and NCCN guideline-approved radiopharmaceutical, is quite established in the era of prostate imaging, particularly with regard to Choline-PET/CT utilization in the investigation of biochemical relapse where

high detection rates are demonstrated. Pooled sensitivity and specificity of  $^{11}\text{C}$ -Choline-PET for recurrent prostate cancer including 1270 participants is demonstrated 89% in a recent meta-analysis [1]. However, for preoperative lymph node evaluating, as with diffusion-weighted imaging, moderate sensitivity ~70% is reported [2]. PET-guided treatment, oligometastatic therapeutic planning, radiation delineation, and dose escalation are some of the newer applications that Choline-PET is investigated. Castellucci et al., evaluating a large series of patients, propose the performance of  $^{11}\text{C}$ -Choline-PET in biochemical recurrence patients aimed for salvage therapy, particularly in cases of increased PSA-doubling time, in order to exclude extrapelvic malignant lesions [3]. Besides, confirmation of oligometastatic disease is of great importance as it largely affects the therapeutic strategy. Choline-PET may lead to a treatment change in ~40% of prostate cancer patients [4]. Furthermore,  $^{11}\text{C}$ -choline-PET has been suggested for neoadjuvant treatment evaluation in high-risk or locally advanced prostate cancer cases [5].  $^{11}\text{C}$ - and  $^{18}\text{F}$ -Choline-PET has been used for radiation treatment contouring in prostate cancer patients, providing added value to MRI scheduling alone in the era of escalated radiation therapy to specific recognized targets (Dominant Intraprostatic Lesions, DILs). Several thresholds and manners for identification of DILs using PET have been described. Automatic delineation using a cutoff

of 60% of SUVmax has been demonstrated as the preferable approach [6, 7]. Although, for visual analysis, PET is suggested to be performed before the initiation of anti-androgen treatment [6], further investigation is still required. Performance of Choline-PET is associated with PSA and PSA-doubling time values as well as Gleason scores [8].

A new FDA-approved radiopharmaceutical, a leucine amino acid derivative **<sup>18</sup>F-fluciclovine** (anti-<sup>18</sup>F-FACBC), has been developed for prostate cancer imaging with, also, promising results. Uptake is clearly observed in cancer sites in newly diagnosed prostate cancer patients. Moreover correlation with 3 T MRI is demonstrated, as well as good tolerance of the radiopharmaceutical, good image quality and correlation of SUV and radiopharmaceuticals' kinetics over time [9], although overlap between malignant and benign lesions was recorded in primary prostate cancer [10]. Positive findings are reported to correlate with PSA and PSA-doubling values [11]. For prostate/prostatic bed investigation, sensitivity, specificity, accuracy, positive and negative predictive value for anti-3-[(18)F]FACBC are, respectively, 90.2%, 40.0%, 73.6%, 75.3%, and 66.7%, while the respective values for extra-prostatic lesions are 55.0%, 96.7%, 72.9%, 95.7%, and 61.7% [12]. FACBC-PET is demonstrated superior to CT in prostate cancer relapse patients [13]. In a direct comparison with <sup>11</sup>C-Choline-PET imaging in recurrent prostate cancer patients <sup>18</sup>F-FACBC seems to have slightly higher specificity, sensitivity, and positive predictive values with a statistically significant difference as far as TP, TN, FP, and FN results are concerned, while <sup>18</sup>F-FACBC seems to perform better in cases of low PSA ( $p = 0.0001$  for PSA <1 ng/mL). Among others the authors also favorably comment the physical properties, production feasibility, and tracer distribution within the body and tumor uptake [14]. Furthermore fluciclovine-PET is investigated in radiotherapy treatment contouring with so far positive results [15].

**PSMA**, a transmembrane protein, was identified as a potential target for prostate cancer imaging, as it is overexpressed in prostate cancer cells,

as well as may serve as a target for therapy in the thera(g)nostics era ([16] for a review see Hofman and Irvani). Ga-68 and F-18 labeled PSMA compounds are the most utilized in Europe. Advantages of Ga-68 are its physical characteristics and its in-site production through <sup>68</sup>Ge/<sup>68</sup>Ga generators. But, although some differences have been described between different PSMA tracers for PET imaging, there is no clear proof to date that one of those radiopharmaceuticals has actually improved diagnostic characteristics compared with another and therefore when we refer to PSMA-PET we in fact refer to any of the PSMA-PET tracers [17]. Schwenck et al. [18] directly compared the PSMA-PET with <sup>11</sup>C-choline-PET in a group of 123 initial and biochemically relapsed prostate cancer patients. In the relapse group abnormal lesions in prostatic bed/prostate, lymph nodes, and bones showed significantly higher uptake of PSMA than of choline; the detection rate of pathologic lymph nodes ( $p < 0.001$ )—particularly smaller ones—and bone metastasis (98% vs. 64%) was significantly higher for <sup>68</sup>Ga-PSMA. In a per-patient and in per-regional-lymph-node basis detection rate differences were also observed. Notable was the fact that the discrepancy in the detection rate of lymph nodes concerned more low-PSA (<1 ng/mL) prostate cancer cases in favor of PSMA-PET. Altogether <sup>68</sup>Ga-PSMA-11 PET presented with 83% detection rate of at least one metastatic lesion vs 79% for <sup>11</sup>C-choline-PET. Concentrating on TNM staging and oligometastatic disease, PSMA-PET imaging was found to have a higher impact in N and M staging compared to that of Choline-PET. As far as the initial staging group is concerned, higher uptake of <sup>68</sup>Ga-PSMA was observed, as well as more lymph nodes and bone lesions detected, although no difference in per-patient basis.

PSMA-PET tracers are, thus, gaining acceptance in prostate cancer patients imaging during staging and restaging. Specificity, negative and positive predictive values of <sup>68</sup>Ga-labeled PSMA ligand HBED-CC in a retrospective study of 319 recurrent prostate cancer patients in a lesion-based analysis are 100%, 91.4%, and 100%, while the detection rate in per patient analysis is 82.8%

[19]. Pooled estimated positivity for  $^{68}\text{Ga}$ -PSMA-PET, in a recent meta-analysis, is 42% for PSA levels  $<0.2$  ng/mL reaching 76% for PSA 1.0–1.99 ng/mL and 95% for PSA  $>2$  ng/mL, while similar findings are reported for PSA-doubling time [20]. In ProPSMA trial, a multicenter randomized trial, for staging high-risk prostate cancer patients, PSMA-PET had 27% greater accuracy than that of conventional imaging [21]. PSMA-PET is the most sensitive modality for depicting metastatic disease; however prognosis based only on metastases found in PSMA-PET is missing [22]. It is reported that the detection rate of 50% of lymph nodes requires  $>2.3$  mm lymph node diameter and of 90%  $\geq 4.5$  mm [23]. Discussion exists about the necessity of baseline PSMA-PET when evaluating treatment response. Figure 13.1 shows PSMA-PET/CT before and after hormone therapy in a prostate cancer patient with favorable outcome.

Biochemical recurrence, oligometastatic disease, and imaging after androgen deprivation therapy are only a few questions regarding the performance of PSMA-PET, and numerous studies are currently evaluating its value in prostate cancer patients. New guide recommendations have been proposed for PSMA-PET imaging. For initial staging high score (appropriate) indication includes unfavorable intermediate-, high-risk, or very-high-risk prostate cancer  $\pm$  negative or equivocal or oligometastatic disease conventional

imaging. For biochemical recurrence indication includes the increase or persistence of PSA after radical prostatectomy or after definitive radiotherapy. Last, for Castration-resistant cancer high score indication includes negative conventional imaging [17]. Figures 13.2 and 13.3 show the incremental contribution of PSMA-PET/CT in biochemical recurrence.

Consensus criteria were recently established proposing the use of PSMA-PET/CT for investigation of metastatic disease at any stage of the screening process, as well as for biochemical recurrence investigation, while it should be omitted in low-risk cases. PSMA-PET/CT can lead to stage alteration, directing to further consideration and perhaps to alternative clinical treatment decisions [22]. Concern is expressed about how deprivation therapy has an effect on the interpretation of PSMA-PET imaging results. Hormone therapies may have an impact on PSMA uptake including flare phenomenon, and Fanti et al. being particularly careful propose at least 3-month initiation of therapy before performing a PSMA-PET [22, 24]. A molecular imaging TNM (miTNM) has been proposed [25] for standardization of reporting local disease, pelvic and extrapelvic involvement, as well as for improving diagnostic confidence when reporting using a five-point scale. Blood pool, liver or spleen, and parotid uptake function as thresholds for reporting PSMA expression [25].

**Fig. 13.1** CT (upper row) and  $^{68}\text{Ga}$ -PSMA-PET/CT fused images (lower row) before (a) and after (b) hormone therapy in a prostate cancer patient—favorable outcome

**Fig. 13.2**  $^{68}\text{Ga}$ -PSMA-PET/CT fused images. Biochemical recurrence after prostatectomy, Gleason Score 9, PSA 20.35. Multiple skeletal lesions and a left pelvic lymph node

**Fig. 13.3** Ga-68-PSMA-PET/CT. (a): MIP image, (b): transverse PET/CT. A 68 years old patient with history of surgery because of prostate adenocarcinoma [Gleason score 6 (3 + 3)]. PSA levels were elevated to 0.3 ng/dL. A small (4 mm) left pelvic lymph node uptake is noted

(arrows) (SUVmax 9.2). Radiotherapy and 3 months later no detectable PSA levels (<0.001 ng/dL). Ga-68-PSMA-PET/CT can detect site of recurrence even in cases with low PSA levels

### 13.3 Artificial Intelligence in the Service of Prostate Cancer Patients

The term Artificial intelligence (AI) has been in use for long time to describe the ability of computers to do tasks that would require human intelligence to be performed. In practice, artificial intelligence in imaging device and processing, meaning the application of computer algorithms for image interpretation, is currently widely applied and investigated both in the acquisition processing and in the reconstruction phase, gaining growing acceptance in the imaging field. For PET instrumentation modern AI refers essentially to the time-of-flight and the localization of photon interaction [26]; for radiopharmaceuticals it stands for the development of new tracers/radiopharmaceuticals using computing AI technology [27], while radiomics directs to the transformation of the image to measurable data, through which information about the tumor/lesion biology or further about the patient's prognosis can be derived [28]. The advantage of hybrid PET/CT or PET/MR systems is that either one or both the anatomic and the functional compartment can be used for machine training and validation. Using textural analyses and radiomic features derived from the CT component of the hybrid PET/CT systems, as well as MR parameters derived from PET/MR systems several investigators developed and/or used AI CT or MRI-derived methods to detect tumor lesions concerning the primary tumor, the lymph nodes, and distant metastases in prostate cancer patients [29–31], concluding that AI tools may serve at least comparable to expert physicians [30]. Furthermore, radiomic features, derived from any imaging method, can be used for machine learning or in neural network systems in order to create predictive models (deep radiomics) [28].

Several challenges are confronted every day in the effort to implement AI in everyday practice. These are even more in prostate cancer imaging, correlated to the organ's proximity to the bladder—which yields high activity measurements, or derived from the small or the multiple or the non-avid cancerous foci in the prostate, as well as

the physiologic distribution of tracer uptake [32]. Still being at its outset, a few studies have been published using AI and Deep Learning (DL) for the primary tumor segmentation and quantification, lymph node and metastasis evaluation, as well as outcome and survival prediction.

Mortensen et al. developed and trained a convolutional neural network (CNN) algorithm for prostate segmentation using data from both the PET and CT compartments of the PET/CT device with the utilization of F-18 choline (FCH). Researchers compared PET values such as SUVmean, SUVmax, TLU, and Vol<sub>abn</sub> derived from manually drawn prostate areas to CNN automatic derived prostate areas and found a good match between them [33]. Polymeri et al. [34] evaluated DL CNN-based algorithm obtaining training data from one PET system and apply it to a validation group scanned by a different PET device, thus showing that algorithms, when trained properly, may be used in a larger scale. This was even evaluated in a larger cohort for lymph node detection using different PET systems in different hospitals [35]. Using choline-PET, differences were reported between observers and automated systems, yet correlation between quantification values and survival was mentioned; lastly, concerning prostate volume evaluation, the automated method tended to overestimate the small prostates while overestimate the large ones [34]. Yi et al. developed and validated radiomics methods in order to predict the probability of an invisible Ga-PSMA-PET prostate area to be cancerous, thus avoiding further biopsies or pointing to biopsy necessitation [36]. The investigators used the 10 more profound predictive radiomic features derived from standard and delayed PET images for machine training and external testing. Reported AUCs in the validation group of trained model was 0.903 for the standard images, 0.856 for the delayed ones, and 0.925 for both, all of which significantly higher than that of PSA Density, while accuracies ranged between 79.4% and 87.0%. Taking into account that the measurements may be applied for the right and left prostate lobe separately, further application of this prediction model could be the evaluation of the “negative” prostate site in known one-sided pros-

tate cancer. Zamboglou et al. using different approach applied AI radiomic features from PSMA-PET in the investigation of primary tumor to discriminate cancerous from noncancerous prostate tissue [37].

Detecting lymph nodes using AI methods is considered even more challenging, as lymph nodes do not concern a specific organ easily segmented in CT and secondly the higher percentage of nonspecific uptake of the radiopharmaceutical leads to more false-positive findings. These obstacles need to be surpassed before AI algorithms become a routine in daily practice. However lymph node status depicted by AI CNN-based tools is demonstrated to be related to survival in prostate cancer patients. Furthermore AI can perform as good as a physician, although overestimating lymph node involvement, and AI tools can be trained for better performance. These initial tools can serve as the basis for more advanced ones and/or for other tracers' utilization [35]. Capobianco et al. reported that it is possible to train a convolutional neural network to find Ga-68-PSMA uptake lesions in the entire axial body and further classify them according to the PROMISE miTNM system, showing agreement with the expert's estimation and opinion. In addition, the authors showed that it is possible to use information from other PET tracers such as FDG for training the system, which actually may lead to improvement of the performance of the system [38]. Evaluating the pelvic area including bone and lymph node lesions using a developed deep neural network a precision and recall of 99% was reached for skeletal detection and 94% and 89% respectively for lymph node involvement estimation on Ga-68-PSMA-PET/CT [39].

Using a developed automated software ("aPROMISE—automated Prostate Molecular Imaging Standardized Evaluation") bearing deep learning methods so as to segment the organs in low-dose CT and further to measure the uptake of the radiopharmaceutical in these organs, high accuracy of the method for organ segmentation is reported. Also high sensitivity is demonstrated of 91.5%, 90.6%, and 86.7%, respectively, for regional lymph node detection in high-risk local-

ized disease patients, for all lymph nodes, and skeletal metastasis [40]. Finally, AI and CNN models can be applied in prostate cancer patients with biochemical recurrence undergoing  $^{18}\text{F}$ -fluciclovine-PET imaging. Analyzing pelvic images, AUC for the slice-based approach 2D-CNN is 0.971. AUC for the case-based approaches using the 2D-CNN and the 3D-CNN was respectively 0.750 and 0.699 [41].

Alongi et al. developed ML radiomics algorithm to discover features for high-risk prostate cancer progression estimation derived from FCH-PET imaging. From the 106 features initially extracted out of 4876 features analyzed, the combination of 13 was found to express the highest sensitivity, specificity, and accuracy in DA classification [42]. Further, in another study, using ML feature selection, from manual tumor delineation, a prognostic model was trained using features that mostly related to patients risks. The investigators used discriminant analysis (DA) for classification of features according to TNM as well as in the whole cohort to predict the presence of progressive disease during follow-up and although different features were depicted for better tumor, nodal, and metastatic prognostication, the fact is that such ML models are feasible and may be useful for PD prediction in this group of patients with a similar level of risk [43]. In a prospective study evaluating risk stratification in prostate cancer patients undergoing  $^{18}\text{F}$ -DCFPyL PET-CT using radiomics extraction and machine learning-based algorithms the authors concluded that the PSMA expression metrics derived from the primary tumor was a good marker for predicting tumor's histopathology and metastatic propensity. Different features were identified for a variable of predictions, i.e., Gleason score or lymph node disease with a variable association to SUV metrics, with intensity-based features to be more important for lymph node invasion prediction and textural ones for Gleason score. Reported AUCs were 0.86–0.76 for predicting Gleason score, extracapsular extension, lymph node, and distant metastasis. The authors demonstrated the role of partial volume correction to the radiomics estimations as well as the threshold set for the metrics [44].

**Theranostics**, in Nuclear Medicine, is a term which arises from the combination of the words therapy and diagnosis, to describe the utilization of the same target for radiopharmaceutical manufacturing for both imaging and therapeutic purposes. For prostate cancer the use of F-18 or Ga-68 PSMA for PET/CT imaging and Lu-177 PSMA for treatment is the epitome of a “theranostics” example. The introduction of Lu-177 PSMA in the treatment strategies for prostate cancer patients is supported by several trials, as well as by the increasing number of ongoing ones. The VISION trial, which randomized metastatic castration-resistant prostate cancer patients receiving either 177Lu-PSMA-617 plus standard care or standard care alone, showed that radiographic progression-free survival (PFS) was improved to 8.7 months in the first group of patients versus 3.4 months for the second one (hazard ratio 0.40), while overall survival respectively was 15.3 versus 11.3 months (hazard ratio 0.62). Patients in the 177Lu-PSMA-617 plus best standard of care group were reported to have a diminished death risk of 38% [45]. The TheraP trial (PSMA radionuclide therapy vs. cabazitaxel) demonstrated that radiolabeled PSMA treatment was associated with higher PSA response, longer PFS, and fewer high-grade adverse events [46].

Personalized treatment takes into account patient’s special characteristics such as age, body mass, or comorbidity, as well as tumor’s characteristics such as Gleason score, PSMA expression, or PSA values in prostate cancer cases. For radionuclide therapy dosimetric calculations constitute the basis for individualized treatments. AI models may serve as an immense assistance in every step during radionuclide diagnostic- based personalized radionuclide therapy [for a review see 47]. Specifically such models may be implicated in quantitative imaging acquisition, during registration of the images, and segmentation of the organs as well as of the abnormal and normal tissues and the assessment of time-activity curves; Radiomics and Deep Learning models may be used for dosimetric calculations and prediction of the absorbed dose so in the tumoral tissues, as in the organs that need

to be spared. Finally algorithms may be used for the prediction of the treatments’ outcome and patients’ prognosis [47].

As newer radiopharmaceuticals and technologies appear in oncologic patients’ service, further assessment is required until each is applied in the most useful manner. AI can become an undisputed tool in PET/CT imaging and radionuclide therapy providing objective quantitative assessment within seconds, assisting both experienced physicians and beginners.

# The Role of $^{18}\text{F}$ FDG-PET/CT in Malignant Lymphomas Clinical Implications

Theodoros P. Vassilakopoulos,  
Athanasios Liaskas, Alexia Piperidou,  
Maria Ioakim, and Vassilios Prassopoulos

## 14.1 Introduction

PET/CT has a key role in final response assessment after treatment in most types of malignant lymphomas, as well as in baseline staging and interim (mid-treatment) evaluation [1, 2]. Its application is widely established in Hodgkin lymphoma (HL) and aggressive B cell lymphomas, including diffuse large B cell lymphoma (DLBCL), primary mediastinal large B cell lymphoma (PMLBCL), and other related subtypes. Although recent recommendations suggest the use of PET/CT for baseline staging and response assessment in follicular lymphomas, mantle cell lymphoma (MCL), Burkitt lymphoma, and “nodal” T cell lymphomas [anaplastic large cell (ALCL), peripheral T cell (PTCL), and angioimmunoblastic T cell lymphoma (AITL)], the accumulated clinical experience with these subtypes is considerably less [1–7]. The role of PET/CT is much more controversial in non-follicular low-grade lymphomas and primary extranodal lymphomas other than DLBCL [6, 8].

The various lymphoma subtypes are not equally FDG-avid and this mainly depends on their histologic features, aggressiveness, and biologic characteristics. “Routinely FDG-avid lymphomas” include HL, DLBCL, and other aggressive B cell lymphomas, lymphoblastic and Burkitt lymphoma, follicular and MCL, nodal marginal zone lymphoma, and systemic ALCL, since they are almost invariably  $^{18}\text{F}$ -FDG-avid (>90% and usually >95–100% of the cases) [1, 2, 9, 10]. Other aggressive T cell lymphomas, mainly the non-ALCL “nodal” types, such as PTCL and AITL as well as extranodal NK/T cell lymphomas, are typically but not invariably  $^{18}\text{F}$ -FDG-avid (>80–100% of the cases in various studies) [1, 2, 9, 10]. In contrast, other indolent lymphomas are even more “variably  $^{18}\text{F}$ -FDG-avid.” Thus, several forms of extranodal lymphomas, including MALT and cutaneous B and T cell lymphomas, small lymphocytic, splenic marginal zone lymphoma as well as some rare lymphoma subtypes, may not be satisfactorily evaluated by PET/CT, displaying frequencies of FDG avidity between 50% and 80% [1].

## 14.2 PET/CT in Initial Staging

The rationale of using FDG-PET in the initial staging of lymphomas is based on its improved accuracy in determining disease extent, as compared to conventional imaging [1, 2]. PET/CT is

more sensitive than CT, mainly because it can detect disease in normal-sized lymph nodes or facilitate the evaluation of extranodal disease [1, 2]. The extent of disease upstaging or—less frequently—downstaging varies according to histology and will be discussed later. Further to more accurate staging, baseline PET/CT can facilitate the interpretation of the end-of-treatment (EOT) PET/CT response assessment serving as a basis for comparison. Finally, baseline PET/CT may provide new prognostic factors related to tumor burden and metabolic activity, which are increasingly evaluated in detail, although they have not yet become standard prognostication tools.

### 14.2.1 Role of PET in the Initial Staging of Lymphomas

Baseline PET/CT is strongly recommended for initial staging of the routinely FDG-avid lymphomas [1, 2] (Figs. 14.1a, 14.2a, 14.3a, 14.4a, 14.5a, 14.7a). In HL, the number and density of

Hodgkin-Reed-Sternberg cells in the tumor vary and FDG uptake occurs mainly by the inflammatory tumor microenvironment. PET/CT identifies 25–30% more lesions and leads to upstaging an average of 18% of patients in various studies compared to conventional staging [2]. Conversely, up to 10% of the patients (average 4% in various studies) [2] can be downstaged [1, 2, 11, 12]. Such changes might lead to major treatment modification in up to 1/4 of the patients (average 11% in the studies reviewed by Barrington et al.) [2]. In a more common scenario, the identification of more disease sites may affect radiotherapy (RT) fields, even in the absence of stage shift [12]. However, most of the knowledge on treatment approaches is based on conventional staging [11, 12]. Thus, it is not yet clearly proven that stage shift according to PET/CT should guide treatment decisions in HL. In addition, the clinical benefit to be gained from the widening of the RT fields to include anatomically subclinical disease sites may be of concern with respect to potential long-term sequelae. This is becoming

**Fig. 14.1** (a) Baseline staging in a patient with Hodgkin lymphoma. Intense FDG uptake is shown in a bulky mediastinal mass. Right cervical and right epiphrenic nodal involvement is also shown. (b) Post chemotherapy evaluation revealed a residual mediastinal abnormality with FDG uptake higher than the mediastinal blood pool but

not exceeding that of the liver. This would have been interpreted as positive, i.e., suggestive of residual active disease based on the 2007 IHP criteria. However, interpreted as Deauville 5-point scale score 3 (Table 14.1), it is now considered compatible with complete metabolic response based on the 2014 Lugano criteria (Table 14.2)

**Fig. 14.2** (a) Baseline staging in a patient with diffuse large B-cell lymphoma. Disseminated lymphadenopathy including a left pelvic mass and multiple focal osseous/bone marrow lesions suggestive of bone marrow involve-

ment are consistent with stage IV disease. (b) Interim PET after two cycles of R-CHOP is completely negative. (c) Post R-CHOP evaluation is also negative, as correctly predicted by the negative interim examination

**Fig. 14.3** (a) Baseline staging in a patient with Hodgkin lymphoma, indicating cervical and mediastinal involvement. Conventional staging had revealed mildly enlarged paraortic nodes, which were not demonstrable by PET/CT. Thus, the patient was downstaged from clinical stage IIIA to PET-stage IIA. (b) PET/CT at the time of relapse in the same patient. PET/CT had been normalized follow-

ing ABVD  $\times$  6. Three months after the completion of involved field radiotherapy the patient presented with lumbar pain and elevated ESR and C-Reactive Protein levels. MRI revealed osseous abnormalities, which were confirmed by PET/CT. PET/CT normalized again after IGEV salvage chemotherapy and BEAM with autologous stem cell support

**Fig. 14.4** (a) Baseline staging in a patient with Hodgkin lymphoma. The patient had disseminated nodal disease, including a mass at the hepatogastric junction, and a positive bone marrow biopsy (stage IVB). (b) Interim PET after two cycles of ABVD revealed complete resolution of FDG uptake except of the hepatogastric mass, which was reduced in size and had residual FDG uptake just above that of the liver. Interim PET was interpreted as positive,

Deauville score 4. The patient received intensified chemotherapy with six cycles of BEACOPP-escalated. (c) Negative end-of-treatment PET in the same patient. He remains in complete remission 8.5 years after the positive interim PET/CT (Courtesy of Drs Datsaris I and Rondogianni Ph, Department of Nuclear Medicine and PET/CT, Evangelismos General Hospital, Athens, Greece)

particularly relevant, given the trend to adopt smaller RT fields and doses or even omit RT in appropriately selected patients.

The situation is similar in DLBCL, the commonest form of aggressive B cell lymphomas, and PMLBCL, in which PET/CT is also strongly recommended for initial staging [1, 2]. However, the effect on treatment decisions with standard rituximab-based chemoimmunotherapy may be less important, with the potential exception of abbreviated immunochemotherapy regimens in localized DLBCL. The effect on potential RT fields may not be so relevant in DLBCL, since RT is not routinely applied in the majority of patients in many centers.

In other routinely FDG-avid lymphomas, especially follicular lymphomas and MCL, PET/

CT is also recommended for initial staging [1, 2]. However, a meaningful impact on treatment strategy is not expected, since the disease is already disseminated in the vast majority of cases. In the unusual cases of early stage disease, mainly seen in a minority of patients with follicular lymphoma (less frequently in NMZL and even more rarely in MCL), PET/CT may confirm that the disease is indeed localized and potentially curable with involved field or regional RT. Baseline PET evaluation is generally not recommended in lymphoma subtypes which are not routinely FDG-avid (Fig. 14.6) [1, 2].

PET/CT may also contribute to the identification and histologic confirmation of transformed disease in patients with known indolent lymphomas. The degree of FDG uptake has been pro-

**Fig. 14.5** (a) Baseline staging in a patient with Hodgkin lymphoma demonstrating stage IIB disease with extensive supradiaphragmatic nodal involvement. (b) Interim PET revealed a residual left axillary abnormality with FDG uptake above the surrounding background but below the mediastinal blood pool. Interim PET was interpreted as negative, Deauville score 2. The patient continued on

ABVD. Posttreatment PET/CT was negative. Following involved field radiotherapy, the patient remains in complete remission 8 years after the negative interim PET/CT (Courtesy of Drs Datseris I and Rondogianni Ph, Department of Nuclear Medicine and PET/CT, Evangelimos General Hospital, Athens, Greece)

**Fig. 14.6** Extranodal marginal zone lymphoma of the left eye. A mass with increased FDG uptake is shown. Marginal zone lymphomas are not routinely FDG-avid.

PET/CT is not routinely recommended either for baseline staging or for posttreatment evaluation in this entity

posed to be correlated with tumor grade, proliferative activity, and aggressiveness and to be of prognostic value [9]. Studies using semi-quantitative measurements based on SUVmax suggest that SUVmax >10 is usually seen in aggressive or transformed indolent lymphomas

[9]. The optimal threshold to detect Richter transformation in chronic lymphocytic leukemia (CLL) may range between 5 and 10 with varying effects on sensitivity, specificity, positive and negative prognostic value and may differ in the era of novel agents [13, 14].

**Table 14.1** 2014 Revised criteria for response assessment in malignant lymphomas

	Complete response (CR)	Partial response (PR)	No response/stable disease (SD)	Progressive disease (PD)
<i>Pet-Based Criteria<sup>a</sup></i>				
Lymph nodes	D5-PS score 1, 2, or 3 ( $\pm$ residual masses)	D5-PS score 4 or 5—but reduced compared to baseline—and residual mass(es) of any size <ul style="list-style-type: none"> <li>•At interim evaluation: responding disease</li> <li>•At final evaluation: residual disease (treatment failure)</li> </ul>	D5-PS score 4 or 5—but no significant change in FDG uptake compared to baseline (applicable at both interim and final evaluation)	D5-PS score 4 or 5 and increase in FDG uptake compared to baseline (applicable at both interim and final evaluation) AND/OR New FDG-avid lesions consistent with lymphoma (applicable at both interim and final evaluation) Biopsy or follow-up PET encouraged if lymphomatous nature of the lesion(s) is uncertain
Extralymphatic sites	D5-PS score 1, 2, or 3 ( $\pm$ residual masses) <sup>b</sup>			
Non-measured lesions	Not applicable	Not applicable	Not applicable	
Organ enlargement	Not applicable <sup>b</sup>	Not applicable	Not applicable	
Bone marrow	No FDG-avid disease <sup>b</sup>	Residual uptake higher than normal marrow but less than baseline (diffuse uptake permitted) <sup>c</sup>	No change from baseline	New or recurrent FDG-avid foci
<i>Conventional (CT) Criteria<sup>a</sup></i>				
Target lymph nodes/masses and/or extralymphatic sites	Nodal regression to LDx $\leq$ 1.5 cm AND No extralymphatic sites	Up to 6 sites in total: $\geq$ 50% decrease in SPD <sup>d</sup>	Up to 6 sites in total: $<$ 50% decrease in SPD and no progressive disease criteria met	PPD progression of $\geq$ 1 individual node/lesion, which should be abnormal (all the following): <ul style="list-style-type: none"> <li>• LDx <math>&gt;</math>1.5 cm and.</li> <li>• Increase by <math>\geq</math>50% from PPD nadir and.</li> <li>• Increase of LDx or SDx (compared to nadir) by 0.5 cm or 1.0 cm for lesions <math>\leq</math>2 and <math>&gt;</math> 2 cm respectively.</li> </ul> AND/OR new sites, defined as: <ul style="list-style-type: none"> <li>• Regrowth of previously resolved lesions.</li> <li>• New node <math>&gt;</math>1.5 cm in any axis.</li> <li>• New extranodal site <math>&gt;</math>1.0 cm in any axis; if <math>&lt;</math>1.0 cm, it should be unequivocal and attributable to lymphoma</li> </ul>

**Table 14.1** (continued)

	Complete response (CR)	Partial response (PR)	No response/stable disease (SD)	Progressive disease (PD)
Non-measured lesions	Absent	No increase (regressed or absent/normal)	No increase falling into the definition of progression (see below)	Clear progression or new lesions
Organ enlargement	Regression to normal	Spleen regression by >50% (in its length beyond normal)	No increase falling into the definition of progression (see below)	<ul style="list-style-type: none"> <li>•Prior splenomegaly: Increase of splenic length by &gt;50% of the extent of its prior increase beyond baseline</li> <li>•No prior splenomegaly: Increase <math>\geq 2</math> cm from baseline</li> </ul>
Bone marrow	Morphologically normal; negative IHC, if indeterminate	Not applicable	Not applicable	New or recurrent involvement

*PET* positron emission tomography, *D5-PS* Deauville 5-point scale, *CT* computed tomography, *FDG* fluorodeoxyglucose, *IHC* immunohistochemistry, *LDx* longest transverse diameter of a lesion, *MRI* magnetic resonance imaging, *PET* positron emission tomography, *PPD* cross product of the *LDx* and perpendicular diameter, *SDx* shortest axis perpendicular to the *LDx*, *SPD* sum of the product of the perpendicular diameters for multiple lesions

Terms used throughout this table: (1) Target lesions (target lymph nodes/masses and/or extralymphatic sites) or Measured Dominant Lesions: They include the dominant lesions, i.e., those which are the major determinants of response. They should include up to 6 of the largest nodes/nodal masses or extranodal lesions, being representative of the total tumor burden. Further selection criteria include: a. to be clearly measurable bidimensionally; b. to be located at as much as disparate anatomic regions as possible, including both mediastinal and retroperitoneal areas, if involved. Measurable nodes and extranodal lesions should have an *LDx* of >1.5 cm and >1.0 cm respectively. (2) Non-Measured Lesions: They include: a. any nodal or extranodal disease, which has not been selected as “Measured Dominant Disease” according to the above definition; b. lesions considered abnormal, but failing to fulfill the requirements for measurability; c. any site of suspected disease, which is assessable but is difficult to be followed by quantitative measurements (serous effusions, bone lesions, leptomeningeal disease, etc.)

<sup>a</sup>PET-based criteria are recommended for FDG-avid lymphoma subtypes (defined in Chap. 4). Conventional (CT) criteria are recommended for non-FDG-avid lymphoma subtypes (defined in Chap. 4)

<sup>b</sup>An uptake higher than mediastinum or liver can be compatible with complete metabolic response, if observed at sites that might have high physiologic uptake or high uptake due to “activation” (i.e., chemotherapy or growth factor-induced), such as the Waldeyer’s ring, GI tract, spleen, or marrow. In such cases, FDG uptake at sites of initial involvement should not exceed the surrounding normal tissue, even if this is “physiologically” high

<sup>c</sup>Caution: Persistent focal lesions might be further evaluated by MRI, biopsy, or a new PET

<sup>d</sup>Further instructions to assess partial response, when small residuals are present, are provided in the corresponding article (see below). Adapted and modified from Cheson BD, Fisher RI, Barrington SF, et al. Recommendations for initial evaluation, staging and response assessment of Hodgkin and non-Hodgkin lymphoma: The Lugano classification. *J Clin Oncol* 2014; 32:3059–3067; (Table 3). Reproduced from “PET/CT in lymphomas: A case-based Atlas”, Springer 2016, by the same Editors

Finally, baseline PET/CT may be used to determine the metabolic tumor volume (MTV) and total lesion glycolysis (TLG), which is a combined eval-

uation of both tumor burden and metabolic activity. These parameters—and other radiomic markers—can be of prognostic significance, as described later.

**Table 14.2** Summary of selected studies evaluating the outcome of EOT-PET-negative patients with Hodgkin lymphoma after the completion of chemotherapy and prior to any radiotherapy

Author, year, ref	Pts	Stages	Chemotherapy	Definition of negative EOT-PET	Radiotherapy	Relapse (progression) free survival
<i>Localized stages</i>						
Fuchs [84] HD16, RT arm	328	I/II, few EORTC unfavorable <sup>a</sup>	ABVD × 2	D5PS score 1–2	100%	93% at 5 years (PFS)
Radford [83] RAPID, RT arm, per protocol	183	I/IIA, no bulky mediastinum	ABVD × 3	D5PS score 1–2	100%	97% at 3 years (PFS)
Borchmann [85] HD17, RT arm	274	I/II with ≥ 1 r.f. but not IIB E or bulky	BEACOPP-esc × 2 plus ABVD × 2	D5PS score 1–2	100%	98% at 5 years (PFS)

Barrington [88] RAPID, RT arm, ITT	209	I/IIA, no bulky mediastinum	ABVD × 3	D5PS score 1–2	88%	96% at 5 years (EFS)
Barnes [81]	83	I/II A/B, non-bulky	ABVD × 4–6	“neg or likely neg for neoplastic disease”	≤ 56% <sup>b</sup>	94% at 4 years (PFS)
Barrington [88] RAPID, no RT arm, ITT	211	I/IIA, no bulky mediastinum	ABVD × 3	D5PS score 1–2	1%	90% at 5 years (EFS)
Radford [83], 2015 RAPID, no RT arm, per protocol	209	I/IIA, no bulky mediastinum	ABVD × 3	D5PS score 1–2	0%	91% at 3 years (PFS)
Fuchs [84] HD16, RT arm	300	I/II, few EORTC unfavorable <sup>a</sup>	ABVD × 2	D5PS score 1–2	0%	86% at 5 years (PFS)
Borchmann [85] HD17, RT arm	323	I/II with ≥ 1 r.f. but not IIB E or bulky	BEACOPP-esc × 2 plus ABVD × 2	D5PS score 1–2	0%	96% at 5 years (PFS)
<i>Advanced stages</i>						
Vassilakopoulos [79]	56	III/IV	ABVD × 6–8	IHP criteria	12%	80% at 4 years (RFS) (88% versus 69% for stages III vs. IV)
Engert [80, 87] HD15, CR/CRu (no or < 2.5 cm residual); no PET evaluation	884	IIB X/E, III/IV	BEACOPP-esc × 6 or 8 or BEACOPP-14	IHP criteria	not planned	92% at 4 years (PFS) AND 85% at 10 years (PFS)
Engert [80, 87] HD15, PET-negative residual ≥ 2.5 cm	548	IIB X/E, III/IV	BEACOPP-esc × 6 or 8 or BEACOPP-14	IHP criteria	1%	93% at 4 years (PFS) AND 88% at 10 years (PFS)

<sup>a</sup>Early stages according to GHSG definition, but few early unfavorable according to the EORTC definition because of bulk definition and age

<sup>b</sup>Among 96 patients, 56% received radiotherapy but 13/96 had a positive PET and presumably received RT more frequently (decision based on physician's choice)

## 14.2.2 PET in the Assessment of Bone Marrow Involvement

Numerous studies have investigated the role of PET in the assessment of bone marrow (BM) involvement. The comparative accuracy of PET/CT and bone marrow biopsy (BMB) highly depends on the specific lymphoma subtype under evaluation.

### 14.2.2.1 Hodgkin Lymphoma

According to current recommendations, bone marrow biopsy (BMB) can be omitted in HL, if baseline PET/CT is performed [1, 2]. The omission of BMB in this setting is also proposed by the latest version of the ESMO guidelines at a level of evidence III (from prospective cohort studies) and grade B strength of recommendation (generally recommended) [15]. However, a BMB still remains necessary in cases with no baseline PET/CT available. Indeed, PET/CT uncovers more cases of BM involvement [11, 16–19] while treatment decisions are not typically affected in the rare cases with a positive BMB but a negative PET/CT, as analyzed below. Patients with BM involvement by PET/CT may have similarly poor outcomes irrespective of BMB status, but this information is still based on rather limited data [16, 18]. Notably, PET/CT is suggestive of BM involvement only if focal lesions are present. In contrast, diffuse increased uptake, even with intensity >liver, is due to reactive BM changes caused by the cytokine milieu present in HL and should not be confused with BM involvement [1, 2, 16–18, 20].

In a large study of 454 HL patients, who were staged by both PET/CT and bone marrow biopsy [16] (Fig. 14.4a), 6% (27 patients) had BM involvement. However, more than twice (13% or 59 patients) had multi- ( $n = 31$ ), bi- ( $n = 9$ ), or unifocal ( $n = 19$ ) PET/CT bone lesions and a negative BMB. No cases of BM involvement were detected among patients with diffusely increased 18-FDG uptake. Only 4/454 patients (<1%) had a positive BMB in the absence of PET/CT evidence of BM disease, and BMB did not lead to treatment modification, since all of them had already advanced disease (stage shift from III

to IV). The experience of the German Hodgkin Study Group (GHSG) in the HD16–18 trials was similar [19]. Only 20/832 (2.4%) patients had a positive BMB but five fold more patients ( $n = 110$ ) had a PET/CT evidence of BM disease. The negative predictive value was 99.9% as only 1/703 patients without BM disease on PET/CT had a positive BMB. In both studies, patients with both positive PET/CT and BM biopsy had much more frequently multifocal lesions, suggesting that among patients with PET/CT-based evidence of BM involvement, those who also have positive BMB have more extensive BM disease. Similarly, only 1.1% of patients with HL and a negative BM PET/CT had a positive BMB in a meta-analysis of 955 patients, including the first previously mentioned study [21] while the overall frequency of a positive BMB in the presence of a negative PET/CT was 1.9% in a study of 1085 patients [22]. Our experience, based on 172 patients, is very similar, further demonstrating that there is not even a small high-risk subgroup [17, 23], in which BMB could offer additional information. Furthermore, it appears that the outcomes of patients with positive BMB and those with PET/CT evidence of BM involvement but negative BMB are equally poor, but this should be further confirmed [16–18]. Thus, the biologic and prognostic significance of BM involvement detected by means of PET/CT only appears to be similar to that of histologically proven BM disease in HL [16–18]. Finally, PET/CT might facilitate the identification of foci of increased uptake in order to guide bone marrow biopsy, since bone marrow involvement can be patchy and incremental information could be lost.

### 14.2.2.2 Diffuse Large B Cell and Primary Mediastinal Large B Cell Lymphoma [24–33]

In DLBCL the frequency of BM involvement is 10–15% and PET/CT is again suggestive of BM involvement only if focal lesions with increased uptake are present (Fig. 14.2a). BM involvement may be either concordant (large cell) or discordant (small cell) compared to lymph node histology with an almost equal frequency [24].

This phenomenon, which is of prognostic significance, cannot be effectively demonstrated by PET/CT [25].

According to the 2014 Lugano recommendations, BMb could be safely omitted in DLBCL staged by PET/CT, because the probability of a positive BMb is low in the absence of focal BM lesions on PET/CT and, even in such cases, treatment strategy is not typically affected [1, 2]. However, a BMb was still indicated for the detection of discordant histology in DLBCL, if this was relevant for patient management or required by a clinical trial [1, 2]. Extending these thoughts, current ESMO and NCCN guidelines propose to omit BMb if PET/CT is suggestive of BM involvement but keep BMb in staging procedure in case of a negative PET/CT in order to detect discordant or low-volume (<10–20%) BM involvement [34, 35]. The scientific basis for these recommendations is analyzed below.

Although BMb might be omitted in the majority of DLBCL patients, it is more informative compared to HL, because more patients may have positive biopsies with negative PET/CT. PET/CT reveals on average twice more cases of BM involvement than BMb in DLBCL [26–32].

However, in contrast to HL, approximately 1/3 of patients with positive BMb (range, 14–50%) have a negative PET/CT, accounting for 1.5–8% of the total DLBCL population in various studies [26–31, 33, 36]. If BMb is omitted, several cases of BM involvement may be overlooked, but most of them have already features of advanced disease and management is not affected (see Lugano recommendations [1, 2]). This was recently shown clearly in a combined analysis of the PETAL and OPTIMAL trials [33]. However, PET+/BMb- cases may have a better prognosis than BMb + cases, so that BM involvement could be an adverse prognostic factor only if demonstrated at the histologic level [27, 29–32]. Thus, although of limited value, the exact role of BMb in DLBCL remains to be further investigated [31, 32, 37]. Special caution should be taken in patients with no evidence of BM disease on PET/CT and apparently limited stage, who are scheduled for abbreviated immunochemotherapy regimens, in whom a BMb would be most useful [15, 35].

In PMLBCL, the baseline probability of BM involvement is extremely low and it would be reasonable to omit BMb in the absence of relevant findings in PET/CT, especially because a positive result would not alter treatment strategy [32, 38, 39]. However, there is no formal recommendation on this for the time being.

#### 14.2.2.3 Other Lymphoma Subtypes

In indolent lymphomas, including follicular lymphomas and MCL, BM biopsy remains the gold standard for the evaluation of BM disease, which is much more prevalent than in HL and DLBCL. PET/CT may not reveal bone marrow involvement by low-grade lymphoma [9] and BMb cannot be omitted [1, 2].

### 14.2.3 Potential Prognostic Impact of Baseline PET Parameters

The calculation of total metabolic tumor volume (TMTV) by baseline PET/CT may provide a better estimation of the true tumor burden compared to conventional imaging. Furthermore, total lesion glycolysis (TLG) provides a combined evaluation of both TMTV and intensity of metabolic activity (SUV mean of each lesion) [40]. These parameters, which are derived from baseline PET/CT, may provide important prognostic information in individual lymphoma subtypes.

Further to rather small studies in which TMTV was demonstrated as an independent prognostic factor for PFS [41] and OS [41, 42] in HL, the impact of TMTV and TLG has been significant in the context of randomized trials or larger patient series as well, both for early stage disease [43, 44] and for advanced disease, where TMTV may stratify patients with a negative interim PET into distinct prognostic subgroups [45–48].

Similarly, small or medium-sized studies (<200 patients) have shown the prognostic impact of TMTV [49–53] and TLG [54, 55] in DLBCL, which appears to be independent from conventional prognostic systems and molecular profiling. In addition, a very recent large study of >1000 patients clearly demonstrated the additive impact of TMTV to the IPI in DLBCL in the form of International Metabolic Prognostic Index [56]. TMTV and TLG were also independent

prognostic factors after adjustment for IPI and cell-of-origin within the large population (>1000 patients with DLBCL) enrolled in the GOYA trial comparing CHOP plus rituximab or obinutuzumab [57]. Furthermore, within the REMARC randomized clinical trial which included only patients with a response to R-CHOP (and consequently more favorable prognosis), baseline TMTV still remained a strong independent prognostic factor and this was independent from the administration of lenalidomide maintenance or not [58].

In PMLBCL, for which established and reproducible prognostic factors are generally lacking, baseline PET parameters may also be valuable: Within the IELSG26 study, 103 patients were treated predominantly with R-MACOP-B (84%) or R-CHOP (16%), both followed by RT [59]. Baseline SUVmax, MTV, and TLG of the mediastinal disease were associated with outcome, but only high TLG, observed in 1/3 of patients, was an independent prognostic factor, overcoming the significance of the other PET parameters, bulky disease, and other conventional prognostic factors. The 5-year PFS and OS for patients with low vs. high TLG were 99% vs. 64% ( $p < 0.0001$ ) and 100% vs. 80% respectively ( $p = 0.0001$ ) [59]. The prognostic significance of TMTV was confirmed by a LySA study as well as by MD Anderson and Dana Farber data under R-da-EPOCH chemotherapy [60, 61].

Other baseline PET-derived metabolic parameters may also provide important prognostic information in HL and aggressive B cell lymphomas. The distance between the 2 lesions that are farthest apart (Dmax or lesion dissemination), a measure of tumor dissemination, may add to the prognostic significance of MTV or even overcome it in DLBCL and cHL [62–64]. Metabolic heterogeneity refers to the intratumoral distribution of <sup>18</sup>F-DG uptake, which reflects the glucose metabolism of both the tumor cells and their microenvironment as well as other processes, such as necrosis, apoptosis, proliferation, and angiogenesis. High metabolic heterogeneity confers adverse prognosis in PMLBCL in addition to TLG [65]. In DLBCL, high metabolic heterogeneity does not correlate with TMTV and may also confer an adverse impact on prognosis [66, 67].

Baseline PET parameters have also been evaluated in other lymphoma subtypes. A high MTV predicted the outcome of high-tumor burden follicular lymphomas independently from the well-established FLIPI2 prognosticator in a pooled analysis of 3 multicenter studies [68], while it predicted outcomes independently from cell-free DNA in another study [69]. In contrast, neither baseline MTV nor TLG or SUVmax predicted the outcome of follicular lymphoma patients treated within the GALLIUM study with Obinutuzumab or rituximab plus chemotherapy (predominantly bendamustine) followed by antibody maintenance [70]. In MCL, baseline MTV and TLG—but not SUVmax—were independent predictors of PFS in a series of 87 patients [71]. Baseline MTV also predicted PFS and OS in “nodal” T cell lymphomas independently from other clinical factors and had a synergistic prognostic impact with the T cell prognostic index (PIT) [72], while it was subsequently shown to offer prognostic information independent from interim PET as well [73]. Similar data were recently published for TLG in peripheral T cell lymphomas [74]. Finally, a similar prognostic effect for TLG (and SUVmax) was shown in patients with extranodal NK/T cell lymphomas [75].

Although interesting, all this information deserves further prospective evaluation in large-scale studies along with many established clinical and biological prognostic factors before implemented in clinical practice. Standardization of the procedures is also essential for reliable clinical application.

### 14.3 PET/CT in Response Assessment After Completion of Therapy

#### 14.3.1 Criteria for Response Assessment and Definitions of PET Positivity

The most important information provided by PET, as far as response evaluation is concerned, is the differentiation between viable lymphomatous tissue and necrotic or fibrotic tissue within residual masses, which are apparent on CT. Furthermore,

EOT-PET/CT may uncover occult disease in normal-sized lymph nodes or bone marrow disease, which may not be demonstrable by trephine biopsy. In 2005, Juweid et al. published a retrospective study in patients with aggressive NHL, predominantly DLBCL, who underwent PET and CT after 4–8 cycles of chemotherapy [76]. They noticed that patients otherwise categorized as CRu (Complete Remission unconfirmed) based on Cheson's 1999 criteria were usually PET-negative, and, overall, had a favorable outcome with PFS similar to that of the CR group. Patients in partial remission (PR) had strikingly different outcomes when PET was negative or positive. In the "early" PET era, response assessment had been traditionally based on the International Harmonization Project (IHP) criteria described in 2007 [77, 78]. According to that set of criteria, a positive PET at the EOT was defined in relation to the size of the residual lesion: For residuals <2 cm, any focal or diffuse FDG uptake above the background in a location not compatible with normal anatomy/physiology was considered positive. However, for residuals  $\geq 2$  cm a mild uptake above background was still compatible with CR, i.e., PET positivity was defined as FDG uptake exceeding that of the mediastinal blood pool structures (Figs. 14.1b, 14.2c, 14.4c, 14.7c).

More recently, the EOT response criteria were revised, adopting the Deauville 5-point scale (D5PS), which had been initially used for interim response assessment (Table 14.1). The D5PS was incorporated in the currently used Lugano criteria [1, 2]. According to current recommendations any FDG uptake up to that of the mediastinal blood pool (corresponding to D5PS 1–2) is considered compatible with CR irrespective of the size of the residual mass. Furthermore, a low-grade positivity, higher than the mediastinal blood pool and up to the uptake of the liver (D5PS 3; Table 14.1), is also considered as a favorable response. Thus, clear PET positivity at the EOT is defined as any uptake above that of the liver, corresponding to D5PS 4 or 5 (Figs. 14.1b, 14.2c, 14.4c, 14.7c). It should be noted that the D5PS score should be determined visually; the classification should not be relied on simple SUVmax comparisons between the uptake of the lesion and that of the liver or the mediastinal blood pool.

The currently used set of criteria for the evaluation of response in malignant lymphomas incorporating both PET/CT and anatomic findings are summarized in Table 14.1 [1, 2, 32] (Figs. 14.1b, 14.2c, 14.4c, 14.5c, 14.7c).

**Fig. 14.7** (a) Baseline staging in a patient with Hodgkin lymphoma: Extensive supradiaphragmatic as well as infradiaphragmatic involvement consistent with stage IIIB disease. (b) Interim PET after two cycles of ABVD revealed persistence of multiple nodal sites on both sides of the diaphragm with FDG uptake markedly greater than that of the liver. A new focal osseous lesion is also seen.

Interim PET was interpreted as positive, Deauville score 5. The patient continued on ABVD. (c) End-of-treatment PET after a total of six ABVD cycles demonstrated further progression. The patient had progressive disease by conventional restaging as well. (d) Further progression later on, during disease course in the same patient. Multiple focal splenic lesions are noted

### 14.3.2 Who Should Have an EOT-PET-Based Response Assessment and When?

PET/CT is routinely used for final response assessment in patients with HL and aggressive B cell lymphomas. It is also currently recommended as the optimal tool for final response assessment in all other FDG-avid subtypes, especially in follicular lymphomas. However, the accuracy parameters related to EOT-PET depends on the precise histologic subtype, being highest for HL but lower for aggressive non-Hodgkin lymphomas. Although clearly recommended for final response assessment, PET/CT may not be so informative in low-grade follicular lymphomas and MCL, since these diseases are incurable and a negative PET/CT is merely reflecting an improved PFS and prolonged survival but not “true” disease eradication. When used in variably <sup>18</sup>F-DG-avid histologic subtypes, which is not recommended as a general rule, it is essential to have a baseline PET/CT available in order to confirm that the tumor is <sup>18</sup>F-DG-avid (Fig. 14.6).

EOT-PET/CT evaluation should preferably be performed 4–6 weeks (and at least 3 weeks) after chemotherapy and immunotherapy and 8–12 weeks after RT, in order to avoid false positive findings due to inflammatory processes and false negative due to stunning from cytostatic drugs [1, 2, 77, 78]. As far as interim PET is concerned it should better be performed as close to the next chemotherapeutic cycle as possible (see next topic).

### 14.3.3 Clinical Data in Individual Lymphoma Subtypes

As already stated, accuracy parameters, i.e., positive and negative predictive value (PPV, NPV) of EOT-PET/CT, depends on the histologic subtype (Hodgkin lymphoma vs. individual subtypes of non-Hodgkin lymphomas), but also on the chemotherapy regimen applied (standard or intensive) and the a priori probability of relapse, as reflected by clinical stage or other prognostic factors.

#### 14.3.3.1 Hodgkin Lymphoma

The long-term outcome of patients with HL who achieve a PET-negative status at the end of first-line chemotherapy, depends on stage, chemotherapy regimen, and use of RT, as summarized in Table 14.2 [79–88]. A negative PET/CT after standard ABVD chemotherapy predicts a 5-year relapse-free survival (RFS) of ~95% in stages I/II, where ABVD is typically followed by RT (Fig. 14.5c), and ~80% in stages III/IV, in which only few patients are irradiated (Fig. 14.4c) [79].

Within the RAPID trial, patients with non-bulky clinical stage I/IIA and a strictly negative PET (D5PS 1 or 2) after ABVD×3 were randomized to receive 30 Gy involved field (IF)-RT or no further treatment, achieving a 3-year PFS of 97% versus 91% respectively ( $p = 0.026$ ) [83]. In the German Hodgkin Study Group (GHSG) HD16 trial of patients with localized, favorable HL (early stages) treated with ABVD×2, the 5-year PFS was 93% versus 86% who received consolidative IF-RT or not, if EOT-PET was strictly negative (D5PS 1 or 2) [84]. Within the GHSG HD17 trial of patients with localized, unfavorable HL (intermediate stages) treated with intensified therapy (BEACOPP-escalated ×2 plus ABVD×2) consolidative RT could be omitted without clinically meaningful loss of efficacy, if EOT-PET was strictly negative (D5PS 1 or 2). Even among patients with bulky disease, the 5-year PFS was 97% regardless of the administration of consolidative RT. [86] These data may have important implications for the design of follow-up strategies [89].

Regarding advanced HL treated with ABVD, the HD607 trial demonstrated that RT can be omitted in patients who achieve a negative PET status, defined as D5PS score 1–3, both at the interim and EOT evaluation despite the presence of bulky disease  $\geq 5$  cm [90]. The 6-year PFS was 92% versus 90% for irradiated and non-irradiated patients and the difference was not significant whatever the definition of bulk (5, 7, or 10 cm) [91]. If advanced stage patients are treated with more aggressive chemotherapy such as BEACOPP-escalated or variants, the 5-year RFS for patients with a residual mass of  $>2.5$  cm and

a negative post-chemotherapy PET/CT is approximately 90% without RT [80], falling to 88% at 10 years [87]. Within the HD15 study of the GHSG, this was comparable to the 85% observed as 10-year PFS in patients with conventional CR or residual masses <2.5 cm, who did not undergo EOT-PET/CT evaluation [87].

Despite additional RT, early stage patients who remain PET/CT-positive after ABVD chemotherapy have a 5-year RFS of 40–65% (Fig. 14.1b) [81, 82, 88, 92]. Higher 18-FDG uptake is predictive of treatment failure in this setting and could have an impact on therapeutic strategies, but this needs further clarification [88, 92]. In the above-mentioned RAPID trial, patients with favorable (defined as non-bulky) stage I/IIA HL who remained PET-positive (D5PS 3, 4 or 5) after ABVD×3 received one more ABVD cycle and IF-RT. The outcome was favorable for those with D5PS 3–4, but it was dismal for those with D5PS 5: The 5-year PFS was 95%, 88%, and 62% for patients with D5PS score 3, 4, and 5 respectively [88]. This difference was translated to overall survival difference as well. In the GHSG HD16 trials of early (favorable) stages, among patients receiving ABVD×2 plus IF-RT, the 5-year PFS was 93%, 88%, and 81% for patients with D5PS score 1–2, 3–4, or 4, respectively, while the corresponding figures were 98%, 94%, and 82% within the HD17 trial after BEACOPP-escalated ×2 plus ABVD×2 plus consolidative RT. [84, 86] This suggests that D5PS score  $\geq 4$  is an unfavorable prognostic factor despite additional RT (caution to be exercised to the definition of score 4; cases with conventional D5PS score 5 may have been included in the absence of new lesions).

In advanced stages, the figures are similar to early stages after ABVD, but it appears that, after more intensive chemotherapy such as BEACOPP-escalated, RT to >2.5 cm PET-positive residuals may be much more efficient for disease control with long-term RFS just below 85% [87]. The degree of conventional radiographic response appears to correlate with disease control after BEACOPP-based therapy and RT: Patients whose residual masses had been reduced by >40% in

their largest diameter compared to baseline had similar outcomes with PET-negative patients with 4-year PFS of 92%. The prognosis was worse for patients with reductions  $\leq 40\%$ , who had a 4-year PFS of 73% [93].

#### 14.3.3.2 Primary Mediastinal Large B Cell Lymphoma

A negative PET/CT after R-CHOP, R-MACOP-B, or R-da-EPOCH is associated with 90–95% cure rates in PMLBCL, even when RT is omitted in many patients [38, 39, 94–98]. According to the Vancouver experience, even patients with D5PS score 3 after R-CHOP may enjoy a > 90% long-term disease control rate without consolidative RT [97], which is similar to the outcomes achieved with RT in all these patients [98].

If irradiated, PET/CT-positive residual masses are effectively controlled in 65–70% of cases provided that the disease is responsive by conventional imaging [39, 95, 96, 98, 99]. In particular the rate of long-term disease control in patients with D5PS score 4 following R-CHOP (or R-MACOP-B) is exceptionally high in the range of 80–87% [39, 97, 98]. Among the latter patients, those with D5PS score 4 and “lower” FDG uptake may have equally favorable outcomes compared to PET-negative patients with long-term PFS >90%, while those with higher SUVmax (for example  $\geq 5$ ) probably have significantly inferior outcomes [99, 100]. Although patients with D5PS score 5 have inferior outcomes [39, 98–101] >40% of them can achieve long-term disease control with consolidative RT if they have achieved PR by conventional imaging [98]. However, salvage chemotherapy intending to autologous transplant is preferable for patients with D5PS score 5 and conventionally defined stable or progressive disease [98].

If patients are treated with the more intensive combination R-dose adjusted-EPOCH (R-da-EPOCH), EOT-PET/CT can be interpreted more conservatively. Patients with D5PS scores 1–2 are not candidates for consolidative RT, but RT is also omitted in patients with D5PS 3 and 4. Serial PET/CT evaluation typically shows regression or stability even in D5PS score 4 during follow-up

with no further intervention [102–104]. The few patients with D5PS score 5 after R-da-EPOCH can be effectively salvaged with RT if they have achieved PR by conventional methods but should be again forwarded to salvage chemotherapy intending to autologous transplant if they have conventionally defined stable or progressive disease [105].

Because of the considerable curative potential of RT, patients with PMLBCL should not be referred for high-dose therapy and autologous transplantation solely based on a positive PET/CT after immunochemotherapy and this is especially true if the uptake is not marked [94]. It should be also noted that certain patients who have low-grade positivity after immunochemotherapy remain PET/CT positive at a similar degree after RT as well without experiencing disease progression, suggesting that mild positivity (at the lower range of D5PS score 4) may be compatible with cure in this entity [99, 101, 102]. Finally, the question whether RT could be safely omitted in PET-negative patients after immunochemotherapy (other than R-da-EPOCH) is currently evaluated by the IELSG-37 randomized trial.

### 14.3.3.3 Diffuse Large B Cell Lymphoma

A negative PET/CT after R-CHOP carries a lower NPV in DLBCL compared with HL and PMLBCL [106–113]. The long-term event-free survival (EFS) in these patients after a negative PET/CT post R-chemotherapy is roughly 70–85% (Table 14.3) and the probability of relapse may depend on their baseline relapse risk, as reflected by the International Prognostic Index (IPI) and its components [106, 109, 110], the cell of origin [106] as well as on the depth of conventional radiographic response (CR versus PR) (Fig. 14.2c), the size of the residual mass, and the number of residual lesions [108].

Recently, two large studies including patients with predominantly advanced DLBCL evaluated EOT-PET after R-CHOP (or obinutuzumab-CHOP) using the D5PS [112, 113]. Both demonstrated a 3-year disease control rate of 82–83% without consolidative RT. Within the GOYA trial

including >1000 patients, a positive EOT-PET (D5PS score 4–5) was an independent prognostic factor after adjustment for IPI or the cell-of-origin. Unexpectedly, among patients with complete metabolic response (D5PS score 1–3), those with IPI 0–2 had inferior 2.5-year PFS to those with IPI 3–5 (77% versus 88%,  $p < 0.0001$ ), while ABC DLBCL expectedly fared worse than their GCB counterparts (2.5-year PFS 80% versus 89%,  $p < 0.05$ ) [112]. According to the British Columbia experience on 723 patients, the 3-year disease control was 83% and inferior outcomes were predicted independently by baseline B-symptoms and BM involvement. The individual IPI factors were not independently associated with the outcome but the IPI per se and the cell-of-origin were not assessed. Interestingly, the outcome of patients with a negative EOT-PET was the same in the presence of bulky disease or not and independently of the presence of skeletal or craniofacial involvement, which were traditionally irradiated in some institutions [113]. The feasibility to omit RT in patients with bulky disease who achieve a PET-negative status following R-CHOP-based therapy was also confirmed in the setting of the OPTIMAL randomized trial, which was limited to elderly DLBCL patients [114].

Patients with DLBCL who remain PET/CT-positive after R-CHOP have a < 40–50% probability to remain disease-free [107–110], but even this figure suggests that false positive findings are not infrequent (Table 14.3). Within the GOYA trial only 12% of the 1092 patients had a positive EOT-PET defined as D5PS score 4–5 and still enjoyed a 3-year PFS of 49% [112]. IPI was not predictive in this subgroup, but ABC DLBCL remained worse than GCB (44% versus 63% disease control). Unfortunately, there was no mention of the potential impact of the exact D5PS score (4 versus 5), which may be critical for the outcome.

The British Columbia group also focused on the EOT-PET-positive subgroup and the role of RT. Among 723 patients with advanced DLBCL (stage III/IV or I/IIB or bulky) treated with R-CHOP, the rate of EOT-PET positivity was much higher reaching 25% (178/723) [113]. The

**Table 14.3** Summary of selected studies evaluating the role of EOT-PET after the completion of full-course rituximab-based chemioimmunotherapy

Author, year, ref	Pts	IPI ≥3	Chemotherapy	Radiotherapy	End-of-treatment PET positivity		Progression Free Survival			Prognostic factors for the outcome of PET-neg patients/ other comments

<sup>a</sup>Among 215 consecutive DLBCL patients, 125 were included based on EOT-PET availability; 20% had indeterminate results and were analyzed together with PET-neg patients (similar outcomes)

<sup>b</sup>169 further patients were excluded, because they had received radiotherapy after chemotherapy (possible positive selection)

<sup>c</sup>Selected on the basis of advanced stage [III/IV (74%) or II either B or bulky (26%)] AND the presence of >2 cm residual mass but no primary progression (possible negative selection). PET interpreted according to IHP criteria between 2005 and 2014 and the D5PS thereafter. RT was given almost exclusively to PET-positive patients. In the subgroup of patients evaluated by the D5PS the 3-year TTP was 83%, 69%, and 33% for PET-neg, PET-pos irradiated, and PET-pos not irradiated

<sup>d</sup>Selected on the basis of conventional radiographic response (CR/CRu/PR) and PET/CT availability. RT was given mainly in selected PET-positive patients (percentage not provided). Deaths of any cause in remission were not considered as events

<sup>e</sup>According to investigator's assessment, patients were randomized to receive everolimus maintenance or placebo

<sup>f</sup>Patients had to be PET-negative after R-chemotherapy, before randomization to everolimus versus placebo (no difference detected)

study was focused on patients who had not experienced disease progression until the time of EOT-PET, so that they were considered as responders with residual disease. Among the 178 patients with a positive EOT-PET defined as D5PS score 4–5, 86 received RT and achieved a 3-year time-to-progression (TTP) of 69%, which was only slightly inferior to EOT-PET-negative patients (83%). This impressive success rate should be further confirmed, since it depends on optimal patient selection. In contrast, the 3-year TTP for the 92 patients that had disease not amenable to RT was only 33%. However, even in this unfavorable setting, 1/3 of the patients remain without disease progression. Notably, despite some overlap, the median SUVmax of progressors was substantially higher to that of the minority of patients who remain in remission [16.3 (up to 36.0) versus 4.5 (up to 18.1)] [113].

#### 14.3.3.4 Follicular Lymphoma

EOT-PET carries prognostic significance for patients with FL. Dupuis et al. reported that a positive EOT-PET after 6 cycles of R-CHOP significantly affected PFS regardless of iPET status and FLIPI score [115]. A pooled analysis using EOT-PET/CT scans from 439 patients enrolled in three landmark studies (PRIMA, PET-FL, and FOLL05) showed that D5PS >4 was associated with significantly lower PFS (16.9 vs. 74 months for EOT-PET-positive and -negative patients respectively) [116]. Also, the secondary analysis of PET results from GALLIUM study reported that patients who achieved complete metabolic response had better PFS and OS irrespective of whether they received rituximab- or obinutuzumab-based treatment, or whether they achieved CR in conventional imaging [117]. Currently, restaging with EOT-PET is recommended for prognostication, but not for treatment modification decisions or patient surveillance.

#### 14.3.3.5 Mantle Cell Lymphoma

EOT-PET is considered optional in patients with MCL and its role remains unsettled, as treatment

strategies in patients with MCL are heterogeneous. A study of 32 cases treated with Rituximab-Bendamustine demonstrated that patients who achieved complete metabolic response by D5PS had significantly higher PFS [118]. Similarly, in a study of 72 patients treated with alternating R-CHOP/R-high-dose cytarabine, a positive EOT-PET (D5PS score 4–5) was associated with worse PFS [119]. The LyMA-PET project demonstrated that SUVmax and D5PSS in iPET and EOT-PET had not prognostic significance; however SUVmax in iPET and  $\Delta$ SUVmax (reduction of SUVmax between iPET and EOT-PET) in EOT-PET were associated with OS and PFS, respectively [120].

#### 14.3.3.6 T Cell Lymphomas

The utility of EOT-PET in T cell lymphomas remains rather poorly defined, as T cell lymphomas consist of various histological subtypes with diverse clinical and biological characteristics and heterogeneous treatment approaches. In a study of 114 patients with PTCL, iPET had not prognostic significance but a positive EOT-PET (D5PS score 4–5) was significantly associated with worse PFS and OS [121]. In another study of 140 patients with PTCL treated mainly with CHOP or CHOP-like regimens, the authors aimed to explore the role of interim (after 2 or 3–4 cycles of chemotherapy) and EOT-PET/CT. PET positivity was again defined as D5PS score 4–5. Patients with positive interim PET had significantly compromised 2-year PFS and OS. EOT-PET was also predictive as the 2-year PFS and OS were 83% and 94% vs. 6% and 27% for EOT-PET-negative and -positive patients, respectively.

---

## 14.4 Interim Response Assessment

Early prediction of response to therapy is of major importance, not only as a powerful prognostic factor but also as a potential basis for early treatment modification. Functional changes that

precede the anatomic ones could potentially be more accurate in predicting treatment response early in the course of therapy.

#### 14.4.1 Who Might Benefit from Interim PET-Based Early Response Assessment?

Early response assessment has provided a major prognostic clue for patients with advanced HL or localized HL with adverse prognostic factors [122, 123] and provides a useful tool for early treatment intensification. The prognostic effect of interim PET (iPET) is less marked, although still significant, for patients with DLBCL, but it cannot be used for early treatment modification in the absence of effective alternative chemotherapy. In the specific setting of PMLBCL, the outcomes according to iPET appear to be conflicting [124]. Data on other lymphoma subtypes, including T cell lymphomas, are sparse. Relevant studies regarding iPET are discussed below.

The D5PS was initially described for the evaluation of iPET and remains the standard tool for this purpose in HL [1, 2]. In DLBCL, the D5PS is less reproducible and is associated with inferior prognostic discrimination. An approach based on the reduction of SUV<sub>max</sub> between baseline and iPET ( $\Delta$ SUV<sub>max</sub> at a cutoff of 66%) is prognostically superior and sufficiently reproducible. Thus, the calculation of  $\Delta$ SUV<sub>max</sub> is the recommended approach for iPET interpretation in the specific setting of DLBCL (see below) [1, 2].

#### 14.4.2 Clinical Data in Individual Lymphoma Subtypes

##### 14.4.2.1 Hodgkin Lymphoma

According to the D5PS (Table 14.1), a negative iPET may not be nominally negative: Any positivity in previously involved sites with 18-FDG uptake up to that of the liver is acceptable as a

favorable interim response (D5PS scores 1,2,3) and this assessment should be made visually (Fig. 14.5b). Any uptake higher than the liver is considered positive (scores 4,5) (Figs. 14.4b, 14.7b). Using the D5PS, the International Validation Study demonstrated that, under ABVD chemotherapy, the 3-year PFS for patients with negative and positive iPET was 95% vs. 28% [125]. Such figures may apply not only to advanced HL, but also to intermediate stage HL (localized stages with  $\geq 1$  unfavorable features). However, the outcome of iPET-positive patients with localized disease and no adverse factors, especially no bulky disease, may be much better than the ~30% reported above [82, 122, 126]. Furthermore, the excellent outcome for iPET-negative patients with intermediate, and particularly advanced, stages has not been reproduced in subsequent studies using ABVD, as discussed below.

Under BEACOPP-escalated, the NPV of iPET is also very high, with >90% of iPET-negative patients achieving continuous CR. Nevertheless, the PPV is much lower compared with ABVD-treated patients: Large datasets within the context of randomized trials have recently revealed PFS rates between 70% and > 90% with continued BEACOPP-escalated for a total of 6 cycles in case of iPET positivity after the second cycle [127–130]. In the HD18 trial of the GHSG, 46% of advanced stage patients remained iPET-positive after BEACOPP-escalated  $\times 2$  (defined loosely as D5PS  $\geq 3$ ) and ~ 54% of them were still positive by the current definition of D5PS  $\geq 4$  [131]. The 3-year PFS for all these patients was ~93–94%; it was 91% for patients with D5PS  $\geq 4$ .

##### 14.4.3 Is It Reasonable to Modify Treatment of HL in Response to Interim PET Results?

In order to justify treatment modification in response to iPET result, two conditions must be

met: Firstly, the outcome of iPET-positive patients could be possible to improve by an alternative therapy, and, secondly, the NPV should be sufficiently high to avoid relapses in the vast majority of iPET-negative patients.

Regarding the first condition, there are overwhelming data indicating that treatment intensification may produce long-term PFS rates of ~65% (vs. ~30% expected based on historical data with continued ABVD) in patients with advanced or even intermediate (early unfavorable) stage HL, who remain PET/CT-positive after 2 ABVD cycles (Fig. 14.4b) [90, 91, 132–137]. This is typically achieved by switching chemotherapy from ABVD to BEACOPP-escalated for at least 4 cycles [90, 91, 132–136, 138] but early salvage therapy and autologous stem cell transplantation may also produce similar results [139]. These data are summarized in reference #138.

Although clinical trials are mainly investigating PET-adapted therapy for advanced disease, the only randomized evidence for the superiority of treatment intensification with BEACOPP-escalated in HL comes from the H10 trial for localized stages [140]. In H10, 361/1925 (19%) of patients had persistent PET/CT positivity after ABVD×2, loosely defined according to the IHP criteria and roughly corresponding to D5PS score  $\geq 3$ . Only 97/361 (27%) had no adverse factors, while 264 (73%) had  $\geq 1$  risk factor. These 361 patients were randomized to receive: (1) 1 or 2 further ABVD cycles (according to the absence or presence of risk factors) plus 30 Gy involved node RT (standard arm) or (2) 2 cycles of BEACOPP-escalated plus 30 Gy involved node RT (experimental arm) irrespective of risk factor classification. PFS was improved by only 2 cycles of BEACOPP-escalated with 5-year rates of 91% versus 77% in the experimental and the standard arm respectively ( $p = 0.002$ ). Importantly, a marginally significant but clinically meaningful improvement was noted for 5-year OS as well (96% versus 89%,  $p = 0.062$ )

[140]. However, in a subsequent analysis presented in abstract form, it became evident that the benefit of switching to BEACOPP-escalated was limited only to patients with D5PS score 4–5, while those with D5PS score 3 were effectively treated by ABVD×2 plus RT. [141]

In the specific setting that first-line therapy is based on BEACOPP-escalated instead of ABVD, the long-term PFS of iPET-positive patients may be in the range of 70 to >90%, as stated above [128, 131]. In this setting, improvement of the outcome of iPET-positive patients appears difficult. For example, the addition of rituximab was not successful in improving the outcome of iPET+ patients after BEACOPP-escalated ×2, in the GHSG HD18 trial [131].

While the first of the required conditions is partially fulfilled, the second one is becoming particularly important for the final success of iPET-directed therapy: Although major early studies had shown that the NPV of iPET could be >90% under ABVD, more recent studies and maturing data suggest that it may not be so perfect as initially thought in patients with truly advanced HL: In the US S0816 trial, the 2-year PFS of 271 patients with stage III/IV HL treated with ABVD×6 was 82% (and was projected to be reduced to ~70–75% at 4–5 years!) and did not differ according to the D5PS score (80%, 84%, and 81% for scores 1, 2, or 3) [134, 137]. In the RATHL trial, the 3-year PFS for iPET-negative patients with continued ABVD or AVD was 84–86%, but it was only 82% for younger (<60 years old) stage III/IV patients [133]. Within the HD0801 trial (81% stage III/IV), the 2-year PFS was 81% [139], while the 3-year PFS was 87% in the HD607 trial, which included only 67% stage III/IV patients [90]. Smaller studies also provided similar results with long-term PFS for iPET-negative patients clearly <90% and as low as 71–77% [135, 136, 142]. These data have been extensively reviewed in reference #138. It is not currently known if there is a reproducible

subgroup of iPET-negative patients after ABVD who remain at a high risk of failure.

The a priori risk of failure as reflected by stage IV (or extranodal involvement) or other prognostic factors may affect the NPV of iPET and should be further investigated [133, 136, 143]. A large mediastinal mass  $\geq 7$  cm was predictive of relapse in iPET-negative patients in another retrospective study [144]. The significance of any bulk  $\geq 5$  cm was also demonstrated in strictly iPET-negative, non-bulky stage I/IIA patients in the RAPID trial [145]. Serum lactate dehydrogenase elevation was the only predictor of conversion from iPET-negative to EOT-PET-positive and anemia was modestly associated with PFS in the HD0801 study [146, 147], while only the IPS predicted—albeit loosely—treatment failure in iPET-negative patients of the HD0607 trial [148]. Within the latter trial, baseline TMTV and IPS could define 3 groups of iPET-negative patients with highly diverse outcomes: TMTV  $< 471$  mL and IPS 0–1 (7% of patients), either elevated (80% of patients) and both elevated (TMTV  $\geq 471$  mL and IPS  $> 1$ ; 13% of patients) with 3-year PFS of 98%, 85%, and 56% [46]. Similarly, within the H10 trial for localized HL, TMTV  $> 147$  mL (observed in only 16% of iPET-negative patients) was associated with significantly, but numerically slightly inferior outcome with 5-year PFS of 82% versus 95% for those with lower TMTV [43]. Biological prognostic factors may also be relevant, such as high content of CD68+ tumor-associated macrophages plus diffuse or rosetting PD1+ cells in the microenvironment or STAT1 negativity of tumor cells [149]. Persistence of residual TARC levels  $> 800$  pg/mL after ABVD  $\times 2$  may also discriminate a rather small subgroup (19% of iPET-negative patients) with inferior outcome (4-year PFS 74% versus 89%) [150]. Despite all these data there is no evidence that any prognostic factor or combination can define a sizeable subgroup of iPET-negative patients with sufficiently poor outcome to justify a different approach from the beginning.

Apart from starting with ABVD and escalating to BEACOPP, an alternative iPET-driven strategy can be starting with BEACOPP-escalated and de-escalating chemotherapy in case of a negative iPET.

Very promising results have been reported by the LySA 2011 trial, in which this reverse iPET-driven strategy was applied to 823 patients with advanced stage HL according to the GHSG definition, i.e., stage III/IV or IIB with mediastinal bulk and/or extranodal involvement [127, 128]. The standard arm consisted of fixed treatment with BEACOPP-escalated  $\times 6$  and the experimental arm consisted of BEACOPP-escalated  $\times 6$  in case of a positive iPET after 2 cycles or BEACOPP-escalated  $\times 2$  plus ABVD  $\times 4$  if iPET was negative. The study had a non-inferiority design with a margin of 10%. The experimental arm was not inferior to the standard one with 5-year PFS rates of 86.7% versus 87.5% [128]. The 5-year PFS for iPET-negative patients was similar for the two arms reaching  $\sim 90\%$ . For iPET-positive patients it was  $\sim 71\%$ . It should be noted that iPET positivity was defined as metabolic activity exceeding 140% of the liver activity and only 12–13% of the patients remained iPET-positive after BEACOPP-escalated  $\times 2$  [127].

In the GHSG HD18 trial (again advanced stages according to the GHSG definition) the standard arm consisted of fixed treatment with BEACOPP-escalated ( $\times 8$  or  $\times 6$  in a subsequent amendment) and the experimental arm consisted of BEACOPP-escalated ( $\times 8$  or  $\times 6$  in a subsequent amendment) in case of a positive iPET after 2 cycles or BEACOPP-escalated  $\times 4$  (total cycles) if iPET was negative [130]. The definition of iPET positivity was D5PS score  $\geq 3$  and 48% of the patients remained iPET-positive. The 5-year PFS after BEACOPP-escalated  $\times 4$  or  $\times 6$  in patients with D5PS score 1–2 (iPET-negative) was  $\sim 91\%$  in both arms and overall survival was numerically better with the abbreviated 4-cycle regimen [129]. The 5-year PFS for the iPET-positive popula-

tion was ~88% (numerically higher in case of D5PS score 3 compared to  $\geq 4$ ) in sharp contrast with the 71% observed in the AHL 2011 trial with the same treatment. However, the rate of iPET positivity was 48% versus 12–13% in the two trials due to the different thresholds used and this is the possible explanation for this large discrepancy.

#### 14.4.3.1 Diffuse Large B Cell Lymphoma

In DLBCL, iPET is also predictive of the outcome after R-CHOP or similar immunochemotherapy, but differences are not so marked compared with HL. The use of iPET to guide treatment decisions is not currently recommended [1, 2] because there is still no proven salvage therapy capable of improving the outcome of patients with a positive iPET, while the NPV of iPET is rather low.

As stated above, the D5PS is not so widely accepted in this setting, because of their moderate reproducibility and prognostic capacity [151] (Fig. 14.2b). Alternatively, a satisfactory iPET response can be defined by a  $> 66\%$  reduction in SUVmax between baseline and interim assessment [1, 2, 151]. In the NHL International Validation Study, based on 114 DLBCL patients treated with standard R-CHOP-21 or intensified R-CHOP-14 or R-ACVBP-14, where no PET-driven treatment modification was made, the 3-year PFS was 79% vs. 44% in patients with  $>66\%$  and  $\leq 66\%$  SUVmax reductions after 2 cycles of immunochemotherapy [151]. The 66% SUVmax reduction criterion was superior to the D5PS in a subanalysis of the CALGB 50303 trial (R-CHOP-21 or R-da-EPOCH), as well as in the UKCRN-ID 1760 and the SAKK 38/07 trials (both adopting R-CHOP-21 or R-CHOP-14), in which no treatment modification was made according to iPET results [152–154].

In the LNH-2007-3B trial, higher risk, young DLBCL patients randomly received either R-CHOP-14 or R-ACVBP-14 and underwent iPET assessments after 2 and 4 cycles,

which modified subsequent treatment strategy. The study confirmed that visual analysis was not accurate enough. The cutoff for SUVmax reduction was set at 66% for PET-2 and 70% for PET-4 [155]. The 4-year PFS according to PET-2 was 80% vs. 56%, while it was 84% vs. 35% according to PET-4 [156]. The prognostic significance of iPET using the 66% SUVmax reduction criterion was also confirmed in the PETAL randomized trial and a GELTAMO phase 2 trial, both of which included treatment intensification for iPET-positive patients [157]. In the PETAL trial, 2-year PFS was 79% for iPET-negative versus 46% for iPET-positive patients despite treatment intensification in the latter ( $p < 0.0001$ ). Using the D5PS the difference was much less marked and the corresponding figures were 79% versus 71% ( $p = 0.0068$ ). Neither the addition of 2 rituximab infusions in iPET-negative patients nor treatment intensification in the form of a Burkitt protocol resulted in any improvement in the outcome of patients with aggressive lymphomas [158]. The corresponding 2-year OS rates were 88% versus 59% ( $p < 0.0001$ ). The prognostic significance of iPET was independent from that of IPI [158, 159].

Overall, the use of the SUVmax reduction criterion over the D5PS score in DLBCL is supported by the results of studies of fixed or PET-driven modified treatment as well as by expert opinions [151–161].

The prognostic significance of iPET in DLBCL in various studies using either or both of the above criteria, either under the same continued treatment or after treatment escalation, is summarized in Table 14.4 [111, 124, 151, 153–159, 162–167].

#### 14.4.3.2 Primary Mediastinal Large B Cell Lymphoma

At present, existing data are too limited to support the recommendation of interim response assessment and iPET-based treatment modification in PMLBCL [168–170]. However, data on

Author, year, ref	Pts	Initial treatment	iPET positivity		Escalation regimen	Progression (or event) free survival			
			Time-point	Definition		Frequency # (%)	iPET-neg	iPET-pos	At n-years
Li 2019 [222]	129	CHOP x4 or R-CHOP x4	4 cycles	$\Delta\text{SUVmax} < 74\%$	Treatment unchanged	84%	31%	2 years	0.001
Zhang 2015 [223]	197	R-CHOPx2 or R-CHOPx2 + RT	2 cycles	IHP criteria	Therapy was performed as planned and was not altered due to IPET findings unless progression occurred	75.8%	38.2%	3 years	<0.001
Zhang 2015 [223]	197	R-CHOPx4 or R-CHOPx4 + RT	4 cycles	IHP criteria	Therapy was performed as planned and was not altered due to IPET findings unless progression occurred	75.3%	24.7%	3 years	<0.001

<sup>a</sup>The  $\Delta\text{SUVmax}$  was however the only PET factor associated with overall survival

<sup>b</sup>After retrospective review according to D5PS, the 2-year PFS was highly different between D5PS score 4 and D5PS score 5 patients (88% versus 33%,  $p = 0.0002$ ), given that treatment intensification was actually performed in the majority of them

<sup>c</sup>The 4-year PFS was 83% for the 12 patients (8%) with indeterminate result in iPET

<sup>d</sup>But only 57% for the 7% of patients with D5PS score 5, defined as uptake  $>3\times$  liver and/or new lesions ( $p = 0.01$ ). Interestingly, 13% of patients had D5PS score 5, defined as uptake  $>2\times$  liver and/or new lesions and had a 2-year PFS ~67% (derived from survival curves)

<sup>e</sup>5-year PFS 70% versus 54% ( $p = 0.01$ ) for patients with D5PS score 1–4 versus 5; the latter defined as uptake  $>2\times$  liver and/or new lesions. Only 12% of the patients had D5PS score 5

iPET under R-CHOP-21 in PMLBCL are only derived from a small subgroup analysis of the PETAL trial [158]. A study from Memorial Sloan Kettering Cancer Center failed to show any impact of iPET on the outcome of PMLBCL, when treatment was modified in patients with positive findings: In detail, 51 patients received 4 cycles of accelerated R-C<sub>1000</sub>HOP-14 and underwent iPET, which was negative in 53% of them [169]. A significant number of patients underwent biopsies of the iPET-positive mass, which were always negative [124]. Patients subsequently received non-cross resistant therapy with 3 cycles of ICE with or without rituximab and no additional RT. No difference in PFS emerged according to iPET result irrespective of the criterion used to define positivity. Similar results were reported by Lazarovici et al. in a study of 36 patients, in which 16/17 patients with positive iPET had negative biopsies [171]. However, none of the iPET-positive patients had D5PS score 5 and treatment (mostly R- or G-ACVBP) was modified according to iPET result.

In a retrospective study of 30 patients, R-VACOP-B ( $n = 19$ ) or 11 R-CHOP ( $n = 11$ ) was continued irrespective of iPET result without consolidative RT. [170] A positive iPET was observed in 47% of patients. Their 3-year PFS was 57% versus 94% for those with a negative iPET ( $p = 0.015$ ). However, there was a trend towards inferior prognostic performance of iPET after R-VACOP-B. In another Chinese retrospective study of 49 patients treated with R-da-EPOCH or R-CHOP, the rate of iPET positivity was 37% and 10/18 iPET-positive patients had D5PS score 5. Treatment was modified in 7/10 patients with score 5 and 1/8 with score 4. The 2-year PFS rate was 93% versus 69% versus 20% for patients with D5PS score 1–3, 4, and 5 respectively, with only score 5 conferring a clearly inferior outcome despite frequent treatment modification [172].

Finally, the previously described PETAL trial included a small subgroup of 42 patients with PMLBCL. Using the  $\Delta$ SUVmax criterion, only 12% remained iPET-positive after R-CHOP $\times$ 2. The 2-year FFTF was clearly superior for iPET-

negative patients (89% versus 40%) despite treatment intensification in case of iPET positivity; however, the 2-year OS was virtually the same (97% versus 100%) [168]. Obviously, the effect of Burkitt-like treatment intensification could not be adequately evaluated with only 5 iPET-positive patients [168].

#### 14.4.3.3 T Cell Lymphomas

Interim PET positivity by the  $\Delta$ SUVmax criterion is also a strong prognostic factor in patients with T cell lymphomas. The rarity of these subtypes has not permitted the development of separate trials. In a subgroup analysis of 76 patients with peripheral T cell lymphomas (ALCL, AITL, or PTCL-NOS) enrolled in the PETAL trial, 25% remained iPET-positive after CHOP $\times$ 2 by the  $\Delta$ SUVmax criterion. This percentage was 33% for PTCL, AITL, and ALK-ALCL combined, but only 1/21 patients with ALK+ ALCL had a positive iPET [173]. In the subgroup of 55 patients with PTCL, AITL, and ALK-ALCL, the SUVmax reduction criterion provided the best discrimination in terms of PFS at the cutoff of 50% (and not 66%) with 4-year PFS rates of 50% versus 0%. The same criterion at the cutoff of 66% and the D5PS (5 versus 1–4) provided very good, but slightly inferior discriminative capacity [173]. The extremely small number of events precluded an analysis in the 21 patients with ALK+ ALCL. However, treatment intensification with a Burkitt protocol failed to improve the outcome of iPET-positive patients, but this conclusion was based on the analysis of less than 20 patients and should be interpreted with caution [173, 174]. In extranodal NK/T cell lymphomas, iPET is also prognostically relevant [75], but data on potential treatment modification are lacking.

---

## 14.5 Impact of Interim and EOT-PET on Clinical Practice: Randomized Trials

Although the prognostic significance and the diagnostic accuracy of EOT-PET/CT have already been firmly established, studies evaluating PET-guided treatment decisions are only few

[83–86, 90, 91, 129–131, 140, 158, 175]. Evidence-based strategies for the implementation of iPET and/or EOT-PET are available only for HL and aggressive B cell lymphomas.

## 14.5.1 Hodgkin Lymphoma

### 14.5.1.1 Radiotherapy Questions

Four recent randomized trials have focused on the possibility of omitting RT in localized stage HL after a negative PET/CT. The non-inferiority EORTC H10 has been the most informative of them [140, 175]. The published results of H10 suggest that RT cannot be safely spared after ABVD $\times$ 2 in patients with stage I/II HL, who become strictly PET/CT-negative by the IHP criteria [77, 78] (roughly corresponding to D5PS scores 1–2), especially in those without adverse risk factors: In H10, patients who became PET/CT-negative after ABVD $\times$ 2 were randomized to receive: (1) 1 or 2 further ABVD cycles (according to the absence or presence of risk factors) plus 30 Gy involved node RT (standard arm) or (2) 2 or 4 further ABVD cycles (according to the absence or presence of risk factors) without RT (experimental arm). The study was prematurely terminated due to excess relapses in the no-RT arms [175]. More mature results revealed a clear difference in terms of 5-year PFS for patients without adverse risk factors (99% versus 87%, hazard ratio 15.8 with 95% CI 3.8–66.1), but a non-significant one for those with  $\geq$ 1 adverse factors, including bulky mediastinal masses (92% versus 90%, hazard ratio 1.45 with 95% CI 0.84–2.50). In any case however, non-inferiority of ABVD compared with combined modality could not be demonstrated for patients with a negative PET after ABVD $\times$ 2 [140]. The design of the other 3 trials, namely RAPID, HD16, and HD17, rather resembled to an interim PET- than an EOT-PET-driven trial [83–86].

Overall, all published trials suggest that RT cannot be omitted after 2, 3, or 4 cycles of ABVD in patients with early favorable disease (stage I/II—no adverse prognostic factors) and a strictly negative PET after 2 or 3 ABVD cycles without relevant loss in disease control (generally

10–15% at 5 years; Table 14.2), although overall survival is not affected at all. Furthermore, it is not clear if omission of RT will be associated with an increased rate of very late relapses observed  $>$ 5 years from initial diagnosis, which are typically not captured during the mid-term follow-up of randomized clinical trials [176]. On the contrary, in patients with early unfavorable disease (stage I/II and  $\geq$  1 adverse factors) the benefit from consolidative RT in case of a strictly negative iPET (D5PS scores 1–2) appears to be minimal. Thus, surprisingly, RT can be omitted in this unfavorable subgroup—even in patients with bulky disease—with minimal loss in disease control and no impact on overall survival, provided that a total of 6 ABVD cycles are given. After more intensive chemotherapy consisting of BEACOPP-escalated  $\times$ 2 plus ABVD $\times$ 2, RT can be omitted if EOT-PET is strictly negative without any loss even in disease control [85].

Whether RT can be omitted in patients with an iPET D5PS score 3 is unclear, since these patients were irradiated in the above randomized trials. However, both the RATHL [133] and the HD607 randomized trial [90, 91] included a considerable percentage of patients with early unfavorable stages and the outcomes without consolidative RT appeared to be comparable in the D5PS score 1–3 (iPET-negative) subgroup irrespective of the exact classification as 1, 2, or 3, again provided that 6 A(B)VD cycles were given. However, in the CALGB 50604 trial, after only 4 ABVD cycles and no consolidative RT, patients with non-bulky stage I/II HL with an iPET D5PS score 3 had numerically lower 3-year PFS compared to D5PS score 1–2 (77% versus 94%) [177].

In advanced stage HL, RT is not considered in EOT-PET-negative patients without bulky disease, while it can be omitted in case of iPET and EOT-PET negativity (D5PS score 1–3) after ABVD  $\times$ 6 in patients with bulky disease defined as  $d_{max} \geq$ 5 cm [90, 91]. It appears that this is independent from the size of bulky disease (even if  $\geq$ 10 cm) although HD607 was not powered enough to address this specific subgroup question. As already mentioned, RT can be spared irrespective of the initial bulk in advanced HL patients with a negative PET and  $>$  2.5 cm resid-

ual abnormalities (and obviously in those with smaller or no abnormalities), if this response has been achieved by intensive chemotherapy with BEACOPP-escalated or similar regimens, because >88% of them remain disease-free at 10 years [80, 87].

### 14.5.2 Chemotherapy Questions

Treatment intensification in the form of BEACOPP-escalated is recommended in patients with a positive iPET after ABVD ×2. There is clear evidence from the H10 trial that BEACOPP-escalated ×2 improves PFS and marginally overall survival in early unfavorable HL compared to ABVD ×2 plus the same consolidative RT. [140] Although not tested in any randomized trial of advanced HL, switching to 4–8 cycles of BEACOPP-escalated clearly improves PFS in iPET-positive patients with stages III/IV (or unfavorable II) [90, 91, 132–138]. The RATHL approach using BEACOPP-escalated ×4 or BEACOPP-14 ×6 appears reasonable in terms of preserved efficacy with the least possible toxicity.

Apart from starting with ABVD, another iPET-driven strategy involves starting with BEACOPP-escalated and de-escalating chemotherapy in case of a negative iPET. However, 2 different methods of de-escalation have been tested, as described above (sect. 14.4). Collectively, both the AHL 2011 and the HD18 trial suggest that, if BEACOPP-escalated is the initial choice, 6 cycles should be given to strictly iPET-positive patients, while de-escalation can be either a total of BEACOPP-escalated ×2 plus ABVD ×4 or a total of BEACOPP-escalated ×4. The optimal threshold to define iPET positivity (more strict or looser) needs to be defined further.

Overall, iPET-adapted therapy appears attractive and has been adopted in everyday practice in many institutions. Randomized trials are not yet mature enough to examine the presence of a potential overall survival benefit over ABVD. Whether an ABVD-first and escalation or BEACOPP-first and de-escalation is preferable is not clear [138].

## 14.5.3 Aggressive B Cell Lymphomas

### 14.5.3.1 Radiotherapy Questions

Few prospective trials have evaluated the omission of RT after abbreviated chemoimmunotherapy regimens in DLBCL. Lamy et al. reported that RT can be omitted in patients with non-bulky (<7 cm), localized (stage I/II) DLBCL if a strictly negative PET was achieved after R-CHOP-14 ×4. Overall patients received 4 or 6 cycles of R-CHOP-14 according to baseline risk classification. The 5-year EFS was 92% vs. 89% for patients who were randomized to receive RT or not and relapse rates were similar [178]. Interestingly, PET positivity was defined visually as “<sup>18</sup>F-FDG uptake above the mediastinum or surrounding background in a location incompatible with normal anatomy or physiology,” which is a very strict criterion for PET-negative status. In another prospective trial of 132 patients with non-bulky (<10 cm), localized (stage I/II) aggressive B cell lymphoma (mostly DLBCL), the rate of PET positivity, defined as D5PS score ≥ 4, was 11%. RT was omitted in patients with a negative iPET after R-CHOP-21 ×3 (D5PS score 1–3), who received R-CHOP ×4 in total without RT, while patients with positive iPET received involved field RT and subsequent radioimmunotherapy with ibritumomab tiuxetan. The 5-year PFS was 89% versus 86% for patients with iPET-negative or positive respectively after R-CHOP-21 ×3 [179]. Similarly, indirect comparison of the OPTIMAL>60 and the RICOVER60 trials suggests that RT can be spared in elderly patients with bulky DLBCL (>7.5 cm) who achieve a PET-negative status after R-CHOP-14-based immunochemotherapy with a 2-year PFS for all bulky patients of 79% (irrespective of PET status or RT) [114].

All the above data suggest that RT can be spared in localized, non-bulky DLBCL even after abbreviated immunochemotherapy in case of a negative PET after 3–4 cycles of immunochemotherapy. It can also be probably spared in bulky, PET-negative patients irrespective of stage, as has been suggested by the British Columbia retrospective experience as well [113].

In PMLBCL RT can be spared after R-da-EPOCH in patients with D5PS score 1–4 after

R-da-EPOCH based on the excellent results of a prospective trial [102, 103]. The results are also very encouraging after R-CHOP if RT is spared in patients with D5PS score 1–2 [97–99] or even score 3 [97]. However, there is still no evidence on this RT question from a randomized trial. The IELSG-37 trial is expected to shed light on this issue [180].

#### 14.5.3.2 Chemotherapy Questions

The only randomized trial in the field of aggressive lymphomas is PETAL, which failed to demonstrate any impact of intensified treatment in iPET-positive patients with aggressive lymphomas under initial treatment with R-CHOP [158]. In a recently published GAINED trial treatment was modified according to PET-2 and PET-4 results. The outcomes were similar for PET-2-negative/PET-4-negative patients who received intensive conventional immunochemotherapy and PET-2-positive/PET-4-negative patients, who received consolidation autologous stem cell transplantation, with 2-year PFS 90% versus 84%. The 2-year PFS was 62% for PET-4-positive patients. Although the above results suggest some improvement based on PET-driven therapy, this is not a randomized comparison of treatment strategies [181]. Thus, there is no established “more effective” treatment for iPET-positive patients with DLBCL, who have inferior outcomes.

### 14.6 PET in the Setting of Autologous Stem Cell Transplantation (ASCT)

The evaluation of PET in patients with lymphoma undergoing ASCT was introduced early in the course of utilization of PET in clinical practice. Generally, published studies have included mixed (HL and NHL) patient populations: Patients with positive pretransplant PET have inferior outcomes than those with negative studies. Pretransplant PET appears to be an independent predictor from established clinical risk scores at the time of relapse/progression [182]. In a meta-analysis of 12 studies, incorporating 630 patients

with HL and aggressive NHL who underwent ASCT and had been evaluated with pre-high-dose chemotherapy PET examination, Terasawa et al. reported a summary sensitivity of 69%, summary specificity 81%, similar prognostic accuracy among studies, and shorter PFS for patients with positive PET scan [183]. Another meta-analysis reported hazard ratios of 3.2 (for disease progression) and 4.5 (for death) for patients with positive vs. negative pretransplant PET [184].

In relapsed/refractory HL, patients who become PET-negative with salvage chemotherapy and undergo ASCT have a long-term remission rate of 80–85% vs. 40–50% for those who remain PET-positive [185, 186], although the range for these figures among several published studies is much wider, as suggested in a another, more recent meta-analysis [187] (Fig. 14.8). These results demonstrate that failure to achieve a PET-negative status does not preclude ASCT in patients with HL, especially if they are chemosensitive by conventional imaging. However, more standardized protocols are required for evaluation of pretransplant PET/CT in patients undergoing ASCT: It is not clear whether pretransplant PET should be evaluated by the D5PS, SUVmax-based, or other criteria. As a general rule, the decision to proceed to ASCT in relapsed/refractory HL should be based rather on conventional chemosensitivity criteria than on PET evaluation.

The D5PS has been evaluated in several studies with patients with scores 4—and particularly those with score 5—carrying a worse prognosis [185, 188–191]. In addition the baseline MTV at initiation of salvage therapy is a strong prognostic factor [189], while the residual pretransplant MTV may also provide independent prognostic information within the unfavorable group of pretransplant PET-positive patients [188, 191]. The outcomes of PET-positive patients with low residual MTV are closer to those with a negative pretransplant PET than to patients with more bulky residuals [188, 191]. Although such sophisticated methods may provide very promising risk stratification, they are

**Fig. 14.8** (a) 18 FDG-PET before autologous stem cell transplantation in a patient with relapsed Hodgkin lymphoma: hypermetabolic lymph nodes at the upper mediastinum. (b) 18 FDG-PET 4 weeks after autologous stem

cell transplantation: negative. (c) Relapsing disease 6 months later. (d) The patient received additional radiation therapy and reached CR (PET negative)

not yet applicable in clinical practice and need further standardization and validation.

The probability of further progression after ASCT remains high in relapsed/refractory HL. As shown in the AETHERA trial, the probability of progression in high-risk patients can be significantly decreased by consolidative treatment with brentuximab vedotin, an anti-CD30 monoclonal antibody linked to a microtubule poison. Brentuximab vedotin consolidation was highly beneficial in patients with a positive PET prior to ASCT but had minimal or no effect on those who had already achieved a PET-negative status [192]. These data should be interpreted with caution because pre-ASCT PET was not required by the protocol and, therefore, it was not performed in all patients and was not centrally and uniformly evaluated. Although this information was derived from an unplanned subgroup analysis, pre-ASCT PET might provide a clue to the optimal use of post-ASCT consolidation and should be further evaluated.

## 14.7 PET in the Era of Novel Agents

### 14.7.1 Programmed Death-1 (PD-1) Inhibitors

The introduction of Programmed Death-1 (PD-1) inhibitors nivolumab and pembrolizumab has provided very promising results in heavily pretreated patients with relapsed/refractory HL during the last few years [193–198]. Promising results have also been reported for PMLBCL [199, 200]. Apart from producing a high objective response rate with several durable remissions (>5 years) [197, 198] (Fig. 14.9a, b), PD-1 inhibitors may result in a transient tumor flare or pseudoprogression. For this reason, an attempt was made to modify the criteria for response assessment to PD-1 inhibitors by describing the LYRIC classification [201]. The description of these revised criteria is beyond the scope of this review.

However, pseudoprogression appears to be a rather rare problem in relapsed/refractory HL, while new lesions may be also due to immune-related adverse events [202, 203].

As expected, PET/CT is superior to CT for response assessment during PD1 inhibitor treatment for relapsed/refractory HL uncovering more patients with complete metabolic responses [204, 205]. Responses are evident during the initial 2–3 months and correlate with PFS and overall survival [193, 195–198]. Based on the analysis of

the KEYNOTE-087 trial for pembrolizumab the classification of responses appears to be similar irrespective of the use of the Cheson 2007 or the Lugano 2014 criteria [206]. Finally, it should be noted that some patients do not achieve an objective radiographic or PET-based response, but continue to receive clinical benefit for variable time periods despite episodes of disease progression [195]. This strategy of “treatment beyond progression” was formally assessed within the protocol of the CHECKMATE-205 trial of nivolumab.

**Fig. 14.9** (a) Fifty-two year old male with stage IIA classical Hodgkin lymphoma diagnosed on 2006, 10 years prior to this image, had a slow progression after ABVD × 6 + RT. He achieved a PR to IGEV salvage chemotherapy but declined ASCT approximately 5 years ago. Further ESHAP was too toxic and discontinued after 1 cycle. Brentuximab Vedotin was then instituted but the disease remained stable. The patient was initially unwilling and later ineligible for ASCT and remained on palliative therapy awaiting for a clinical trial with PD-1 inhibitor. Prior to PD-1 inhibitor initiation he had a very unusual disease localization with extensive esophagealgastric hypermetabolic mass (SUVmax 17.2), which caused dysphagia (left panel), regional small hypermetabolic lymph nodes (SUVmax 4.6) and hypermetabolic osseous/bone marrow involvement of the L4 vertebra. After the fourth PD-1 inhibitor infusion (pembrolizumab every 3 weeks) the patient had achieved a complete remission with a negative PET (second image from left, 3/2016). The patient remains in complete metabolic response (CMR) 27 months after the introduction of pembrolizumab (third and fourth images on the right, dated 6/2016 and 3/2017). (b) A 32 year old female with classical Hodgkin lymphoma, stage IIA, was diagnosed on 2012, 3 years prior to this image. After ABVD × 6 + RT she achieved a PR and subsequently relapsed. Although she did not respond to ESHAP salvage chemotherapy, she underwent ASCT, but progressed rapidly thereafter. She further received brentuximab vedotin, bendamustine and gemcitabine-vinorelbine with rapidly progressive disease after each modality. Prior to PD-1 inhibitor initiation she had very extensive disease with generalized hypermetabolic lymphadenopathy, bulky mediastinal (SUVmax 9.6) and

left lung localization (SUVmax 6.6) and multiple bone marrow hypermetabolic foci (SUVmax 7.2) associated with a positive bone marrow biopsy and B-symptoms (left panel). After the fourth PD-1 inhibitor infusion (pembrolizumab every 3 weeks) the patient had achieved a complete metabolic response (CMR) with a negative PET (right panel). The patient remains in CMR 27 months after the introduction of anti-PD-1 therapy with pembrolizumab. (c) A 62 year old female with stage IIISXB nodular sclerosing classical Hodgkin lymphoma, was diagnosed approximately 2 years prior to this image. Despite a negative interim PET after ABVD × 2, she developed progressive disease after the seventh ABVD cycle. She failed to respond to IGEV and ESHAP salvage chemotherapy, always developing progressive disease with B-symptoms, pruritus and worsening anatomic findings, thus being unable to undergo ASCT. She also failed to respond to Brentuximab Vedotin and rapidly developed symptomatic progressive disease after 2 cycles of BEACOPP chemotherapy. On March 2016 she was started with the PD-1 inhibitor Nivolumab (3 mg/kg every 2 weeks). Serial CT and PET evaluations demonstrated lack of response, with some anatomic sites responding and others enlarging. However, the patient is asymptomatic and inflammatory markers (ESR, CRP and thrombocytosis) have been completely normalized. This type of sustained clinical response had never been achieved with conventional chemotherapy and Brentuximab Vedotin. It is now increasingly recognized that PD-1 inhibitors may induce relatively durable periods of meaningful clinical benefit in patients who have anatomically stable or slowly progressive disease [195]

### 14.7.2 Chimeric Antigen Receptor (CAR) T cells

CAR-T cells are autologous T cells, modified *ex vivo* to express receptors which combine antigen-binding and T cell activation properties. Currently CAR-T cell therapy is the most innovative and promising treatment approach for relapsed/refractory DLBCL and related aggressive lymphomas. Several studies have evaluated the prognostic role of PET/CT in the CAR-T cell treatment setting. Vercellino et al. highlighted the prognostic significance of TMTV, and aimed to create a prognostic model for early progression after CAR-T cell infusion by combining TMTV ( $>80 \text{ cm}^3$ ) and clinical characteristics related to tumor burden, at the time of treatment [207]. Another study aiming to explore the prognostic role of different baseline quantitative metrics also showed that high TMTV ( $\geq 25 \text{ cm}^3$ ) was associated with inferior PFS, whereas SUVmax was not of prognostic significance [208]. More studies are needed to define the optimal time point and prognostic role of PET/CT in patients treated with CAR-T cells.

## 14.8 Artificial Intelligence in F-FDG-PET/CT Scan

The recent applications of Artificial Intelligence (AI) in the field of medical imaging have created great expectations in cancer diagnostics and personalized treatment approaches. Machine Learning (ML) is a branch of AI that creates applications which learn “on their own” by recognizing patterns in input datasets. AI/ML in medical imaging encompasses a variety of applications (e.g., Convolutional Neural Networks—CNN) which aim to eliminate the various biases that may affect image interpretation by humans and produce results comparable to expert radiologists. As extensively discussed in this chapter, F-FDG-PET/CT imaging has been broadly used in staging and response assessment in malignant lymphomas. Until today, just a few studies related to the applications of AI in PET imaging of lymphoma have been published, but definitely, sig-

nificant progress will be made during the forthcoming years.

Different methods and quantitative metrics (e.g., SUVmean, TMTV, TLG, etc.) in PET/CT have been used in order to quantify tumor burden, evaluate treatment response, and estimate prognosis. AI is expected to better manage these tasks, as its applications may permit automatic quantification and register multiple parts of the body at the same time [209]. The main tasks of AI applications in PET/CT image processing are detection, segmentation, and classification. Detection refers to localization of an area within a medical image which contains an object of interest [210]. Examples include automatically characterizing lymphoma lesions or defining areas of High Normal Activity (Hina) such as bladder and kidneys [211]. Furthermore, the use of radiomics in PET-CT scan has shown great results in separating sites with HiNA, inflammatory nonmalignant lesions, and malignant lesions as shown from Anunziata and Lartizien’s results [212, 213]. Segmentation is the process of demarcation and specific detection of the margins of an object of interest. Segmentation improves the ability of precise estimation of quantitative parameters and improves the methods of exact specification of tumor burden. It is very important to estimate the risk stratification of each patient and predict the therapy response. In order to accomplish this, radiomic features such as standardized uptake value (SUV) and total metabolic tumor volume (TMTV) are used [58, 214]. For example, TMTV and TLG could possibly be better estimated and in less time, through this procedure [215, 216]. Classification refers to the assignment of medical images into diagnostic or prognostic groups. Radiomics are usually used for this purpose in order to characterize lesions as normal or abnormal, or defining different histologic subtypes of lymphomas [216]. Classification could also lead to better prognostication, especially in procedures which highly depend on individual viewer’s experience, such as D5PS estimation [212].

The application of Delta radiomics, which compare the changes of a lesion before and after treatment may be a useful tool in order to esti-

mate the therapy response and the prognosis of the patient [217]. It is crucial for the world's institutions to contribute to everyday clinical practice's amplification with AI algorithms in PET imaging [218].

Concluding, AI may provide promising and innovative tools for image processing, medical decision making, and prognostication. It is sure that several subjective and time-consuming procedures will be held automatically in the future. However, more time is needed to evaluate AI applications and produce reliable and robust results. Currently physician's critical thinking remains invaluable beyond any doubt.

## 14.9 The Role of PET/CT in the Follow-Up of Lymphomas

Once a negative PET/CT has been achieved, routine follow-up of patients with HL and aggressive B cell lymphomas with PET/CT is not recommended, because it does not affect survival and the risk of false positive findings outweighs any potential benefit of "earlier" identification of relapse and will lead to many unnecessary invasive procedures to exclude relapses. There is also no role for PET/CT in the follow-up of other lymphoma subtypes.

Information regarding PET/CT restaging for relapsing or refractory lymphoma is rather limited (Fig. 14.3b). PET/CT may have a particular role in patients, mainly those with HL, who could be candidates for local treatment with curative intent.

## 14.10 Conclusions

FDG-PET is a unique tool for the assessment of malignant lymphomas, demonstrating high accuracy and strong prognostic significance. The implementation of PET/CT has altered the definition of response to treatment and has already a major impact on staging and the design of treatment strategies. Although data are rapidly accumulating, the exact role of PET/CT in guiding

treatment decisions, especially in the mid-treatment (interim) setting, needs to be defined by randomized trials, many of which are ongoing. Questions under investigation include the role of PET to decide about consolidation radiotherapy, the potential of improving outcomes by early treatment intensification in interim PET-positive patients, or conversely, the possibility of treatment reduction in patients with negative interim PET. Although some answers have already been obtained, evidence-based data on the appropriate use of PET in lymphomas are expected to be available shortly.
