Clinicians should also consider the effects of an EFA on client responding within the broader context of their client's past experiences. Clients with a history of trauma (e.g., threat of death, see DSM-V) or repeated exposure to extremely stressful conditions (e.g., bullying) may respond differently to FA procedures than clients without a trauma history. Exposure to long extinction periods or extended alone conditions, for example, may evoke similar responding that occurred under past conditions of neglect. Additional choices for participants (e.g., whether or not to participate), safety precautions (e.g., reinforcing early), and collaborations with caregivers (e.g., soliciting input) will be necessary to ensure that clients are not re-traumatized during the assessment and treatment process (Harris & Fallot, 2001). To prevent potential re-traumatization, conversations about the potential effects of EFA procedures on client responding with all relevant stakeholders should be occurring continuously throughout the design and implementation of an EFA. It should also be made apparent that the client or any stakeholder has a right to withdraw assent or consent from the EFA process at any time.

One final consideration clinicians should make before conducting an EFA is to understand how the procedures and outcomes of that EFA will fit into the system of care that surrounds each client. Even though the EFA is brief, the client's family, clinical staff, school or residential facility, and community may all be impacted by the outcomes of this analysis. Clinicians should evaluate how well the EFA's procedures align with the values and goals of each client's care system, as well as the amount of preparation required for the EFA to run smoothly. Questions clinicians may ask themselves to begin this evaluation process include, but are not limited to: *Why are we conducting an EFA? Are caregivers and implementers* *on the same page about the EFA's procedures? How do my procedures promote the safety and well-being of my client? Do these EFA procedures meet the values and needs of the family? Are implementers sufficiently trained to conduct the EFA? How are we planning to use the results of the EFA?* Continuously and critically evaluating EFA procedures in this manner may improve buy-in with relevant stakeholders as well as ensure a safe and productive analysis.

Conclusions

Decades of research on EFA technology have led to a (a) solidified process for understanding environmental contributors to problem behavior and (b) a rich set of modifications and procedures that have helped to spur continuous research and practical applications. In fact, EFA has long been informed by practitioner-relevant elements, including concerns of safety, efficiency, and acceptability of procedures. The core components of the EFA will continue to be modified in the endless empirical search of a programmatic behavioral technology that produces meaningful improvements in problem behavior.

27 Standard Tests and Interviews for Functional Assessment

Johnny L. Matson and Megan Callahan

Functional assessment has become a standard methodology and one of the core elements of applied behavior analysis. The experimental functional analysis (EFA; Hanley et al., 2003) was the first type of procedure developed for conducting a functional assessment. The many studies conducted on the topic were instrumental in establishing the primary maintaining variables of alone, escape, social, and tangible. Each of these four factors helps explain what is reinforcing the problem behavior and ensuring it will continue and, in many cases, continue to strengthen. A number of refinements and variations of this methodology have been developed over the years. It is an important methodology and one which will likely continue to evolve while being used frequently.

Problems exist with the EFA, as with any method. All methods have strengths and weaknesses. So, we make this statement out of a recognition of the complexities in assessing and treating human behavior versus criticism of the EFA. First, many authors have referred to the EFA as a direct assessment and checklists as an indirect assessment. In our view, and the context of the broad array of assessment methods available in Applied Behavior Analysis and psychology, we prefer the terms analogue and standardized (more on this later) assessments. Direct assessment would be an observation of a target behavior in a naturalistic setting. Analogue, conversely, involves the implementation of maintaining conditions in a contrived setting, with a structured, predetermined means of manipulating conditions by therapists who do not work with the client normally. This set of factors describes EFA and has been used to treat a range of behaviors, such as the treatment of social skills, which dates back to before the development of the EFA (Matson et al., 1980). In studies of this type, contrived vignettes are developed and provide the client an opportunity to provide a social response. Specific target behaviors such as eye contact, voice volume, tone of voice, and content of speech are assessed. The client is then given performance feedback, instruction, and reinforcement. Thus, there is a good possibility, but not definitive, that analogue data will translate to naturalistic settings.

The EFA is more suitable for high-rate behaviors. Thus, low-rate behaviors may be hard to observe since the response may simply not occur in the allotted time in the assessment room. Usually, to rise to a clinical priority, these low-rate behaviors must be of high intensity. It is possible in some instances to "induce" the target behavior. However, this presents possible issues due to concerns about injury to the staff and/or client. Another potential concern is that once rates of maladaptive behavior have been

increased, the behavior(s) may persist well after the session has been terminated.

There are many advantages of EFA over other methods of functional assessment. This topic has been covered in detail in other chapters of this volume. The purpose of pointing out limitations here is to build a rationale for increasing the number of options in the toolbox of functional assessment. The most researched alternatives are standardized tests, which will be covered next.

Standardized Tests

Standardized assessments have a long history in the field. These tests have a set number of items and a norm group based on a population similar to the person being evaluated. In 1905, Alfred Binet and Theodore Simon developed a standardized test that became the precursor to the current intelligence tests (Siegler, 1992). This measure of intelligence set a standard for many tests that came later and was a major building block in the development of the field of psychology. Standardized tests spread out to the measurement of academic skills and the broad field of psychopathology. General measures such as the Child Behavior Checklist were followed by more specific measures for ADHD, autism, anxiety, and depression, among others. Measures for challenging behaviors such as aggression, property destruction, and self-injury were also developed. Thus, the development of standardized measures to evaluate variables that maintain challenging behaviors was a natural progression with considerable historic momentum.

Standardized assessments provide an added dimension to the toolbox of functional assessment (Matson & Minshawi, 2007). Different circumstances will dictate multiple methods and/or different approaches to assessment. Therefore, the more valid and reliable methods that are available, the better. Standardized tests of functional assessment are based on maintaining variables such as escape, attention, alone, and tangible established earlier with the EFA (Iwata et al., 1982). It is the case that standardized tests of functional assessment are the easiest method to administer and are the most frequently used method of functional assessment (Ellingston et al., 1999). And, these measures have been used the most with special needs children. However, its use has expanded to other groups of children, adolescents, and adults more recently. Applications have occurred in mental health clinics, schools, and work settings (Austin et al., 1999; Sterling-Turner et al., 2001).

Motivation Assessment Scale (MAS)

The MAS and Questions About Behavior Function (QABF) are by far the most heavily researched standardized measures of functional assessment. Chronologically, the MAS appeared earlier, therefore, it will be discussed first.

The psychometrics of the MAS are mixed. Durand and Crimmins (1988) developed and first described the scale. The questionnaire has 16 items and, in the authors' words, was designed to identify "situational determinants (more recently called maintaining variables) of self-injurious behavior of persons with special needs." They asked 50 teachers about agreement on these items for persons with developmental disabilities. Teachers were tested again 30 days later. The authors report good reliability and present the MAS as an addition to, or replacement for, an EFA.

Soon after this study appeared, other authors also addressed the reliability of the MAS. Newton and Sturmey (1991) assessed 12 adolescents and adults with severe/profound intellectual disabilities. They found low correlations of items and subscale scores. Conversely, internal consistency of subscales and total scores was high. Kearney (1994) evaluated direct care staff members who evaluated 42 adults. He found moderately significant reliability across raters.

Zarcone et al. (1991) also addressed the reliability of the MAS in two groups of persons with developmental disabilities (institutionalized and school samples). A total of 55 individuals were assessed independently by either two staff or a teacher and a teacher's aide. They used the same correlation methods as Durand and Crimmins

(1988) as well as interrater reliability. Only 15% of the correlation coefficients were above .80. None of the interrater percent agreements were above 80%, the accepted minimal criteria. Thus, reliability was uniformly poor. Unacceptable interrater reliability was found on 42 topographies of five children. Also, very low levels of interinformant agreement were found.

Sigafoos et al. (1994) also reported disappointing reliability for the MAS. Maintaining factors for the aggressive behavior of 18 adolescents and adults with severe or profound intellectual disability were reported. The interrater reliability of two independent raters produced 44% reliability, which is very low. The authors concluded that the "MAS may not represent a viable alternative to more formal functional analysis procedures."

Spreat and Connelly (1996) found mixed results on reliability measures. Similarly, moderate-to-low intrarater and interrater reliability was found by Conroy et al. (1996). In their study, 20 people with intellectual disabilities with 19 raters participated.

Validity has also been addressed with the MAS. Duker and Sigafoos (1998) looked at reliability, internal consistency, and construct validity. Ninety ratings of challenging behaviors for 86 people with intellectual disabilities were reported. Reliability was poor. The structure initially established by Durand and Crimmins (1988) differed from the four factors these authors found. Thus, Duker and Sigafoos (1998) conclude that the construct validity of the MAS was ambiguous. Another study also failed to support the factor structure of the MAS. Joosten and Bundy (2008) used a Rasch analysis on data from 246 MAS tests on 67 children with autism or intellectual disabilities or both. The data failed to support the proposed unidimensional construct of the original four-factor structure. Thus, a failure to replicate the factor structure was reported (Kearney et al., 2006). Three hundred and thirty-five people with severe intellectual disabilities produced a three-factor solution versus the original four factors.

Not all of these factor analytic studies of the MAS have been negative. Bihm et al. (1991) did validate the initial MAS factor analysis with 118 people who were predominately functioning in the severe to profound range of intellectual disabilities. As with the original factor analysis, sensory, escape, attention, and tangibles were the four categories of maintaining variables. Singh et al. (1993) assessed staff of 60 residents, and teachers of 96 students in schools were evaluated. Target behaviors fell into the general area of self-injury. These authors concluded that the original MAS factor structure was "robust." One study was published that used the MAS as a means of determining the change in self-injurious behavior when Naltrexone was administered as a treatment. They found no change in self-injury and correlations on the MAS.

Well, the data on the psychometric properties are mixed. From our view, the MAS has worth, should be considered as a viable measure, but when used, should be part of a functional assessment battery. For those interested in the MAS, some modification in the items on the scale seems to be in order. Also, the developers deserve credit for establishing the first widely used standardized measure of behavior function.

Questions About Behavior Function (QABF)

The rationale for developing the QABF is to build on the experimental functional analysis with a simpler, faster way to achieve similar results in identifying maintaining variables of identifying challenging behaviors. A number of standardized scales have been developed to achieve this goal. In this writing, the most frequently studied scale with the best psychometrics is the QABF (Matson et al., 2012).

The first published paper on the QABF was by the Matson group (Matson is the first author of this chapter, as a point of transparency). Paclawskyj et al. (2000) assessed 34 adults with intellectual disabilities living in an institutional setting. The first author, who was a PhD student in clinical psychology at the time, interviewed a staff member who knew the client for 6 months or longer. Test–retest data were collected. The scale consists of 25 items, 5 items for each of the 5 subtests: attention, escape, nonsocial, physical, and tangible. The scale can be completed in about 20 minutes. Reliability for all items was good to excellent.

Bienstein and Nussbeck (2009) studied the properties of a German version of the QABF. These authors looked at reliability. Cronbach alphas were run and were good (.84–.62) Interrater reliability was fair, with intraclass correlations of .65–.58. Also, a factor analysis was conducted. A five-factor solution identical to that reported in the original study was found. In a study on the Spanish version, factor analysis also mapped onto the five original factors noted in Paclawskyj et al.'s (2000) study. Also, good test–retest was found. This study was a large one, with 300 participants with intellectual disabilities and 328 challenging behaviors.

The psychometric properties of the QABF have also been studied by Freeman et al. (2007). They studied an outpatient sample of 91 children with intellectual disabilities. Problem behaviors they displayed included physical aggression, self-injury, and property destruction. They found that the QABF had fair-to-good internal consistency, strong corrected item-total correlations, and acceptable interscale correlations.

Nicholson et al. (2006) also studied the psychometric properties of the QABF. They addressed 118 challenging behaviors of 40 young people with severe intellectual disabilities. Interrater reliability, internal consistency, and construct validity were addressed. Interrater reliability for individual items and subscale score was modest. However, interrater reliability of rankings of subscale scores was excellent, exceeding that reported by other similar measures. Interrater agreement was higher for higher rates of behavior and lower for maladaptive versus disruptive behaviors. Internal consistency was high for total score and all of the subscale scores. Factor analysis yielded the same five factors established in the original study. A single item on the repetitive nature of challenging behaviors did not fit into the five-factor solution. The authors conclude that the QABF presents specific advantages over other standardized measures for functional assessment.

Matson et al. (1999) studied the validity of the QABF with 398 people in a developmental center who evinced intellectual disabilities. These adults exhibited one of these challenging behaviors: self-injurious behavior (n = 118), aggression (n = 83), or stereotypies (n = 197). Professionals conducting the evaluations had a master's degree in clinical psychology and experience working with people who displayed intellectual disability. The focus of Experiment 1 of this study was to determine the percentage of people who had a clear function, which was defined as subscales with a minimum score of 4 out of 5 items on a given factor. Also, of the remaining 4 subscales, a sufficient number of item endorsements to meet the 4 out of 5 criteria were needed to establish a second function. Eighty-four percent of the total sample had a clear function. Target behavior percentages were 83% for self-injury, 74% for aggression, and 93.3% for stereotypies. In Experiment 2 of this study, 180 people from the original 398 individuals were evaluated. Half of the sample, 90 people, were in the treatment group, and 90 individuals were randomly assigned to the control group. The treatment group had behavioral plans that were based on the maintaining variables established with the QABF. For example, challenging behaviors that were maintained by attention included teaching communication skills, while challenging behaviors maintained by nonsocial elements were treated with environmental enrichment and social skills. Controls were administered as an intervention consisting of interrupting the challenging behavior, blocking, and redirection. The treatment group showed statistically significant improvements for self-injurious behaviors, aggression, and stereotypies after 6 months of intervention. Participants displaying self-injury showed a 66% decrease in the treatment group and 21% for controls. For aggression, a 59% decrease was noted for the treatment group and 19% for controls. People displaying stereotypies had a 54% decrease for the treatment group and 15% for the controls. All three comparisons showed a statistically significant difference between groups. And, to our knowledge, this was the first large-scale controlled study to demonstrate the superiority of interventions based on functional analysis. These data are more impressive when one considers that these were adult clients with long-standing high rates of these three maladaptive behaviors.

Other efforts to establish the validity of the QABF have also been published. Watkins and Rapp (2013) compared an experimental functional analysis to QABFs completed by parents of people with autism spectrum disorder who evinced challenging behaviors. With five of the six participants, the experimental functional assessment and the QABF identified the same function, and for the sixth client, both assessments identified a dual function.

Twenty-seven adults living in a developmental center and exhibiting intellectual disability served. All of the clients had problems of sufficient severity to warrant a treatment plan (Smith et al., 2012). Twelve people had one challenging behavior and 15 evinced two target behaviors. The QABF and MAS were given for each target behavior, thus for 15 individuals, 2 QABFs and 2 MAS were administered. One hundred and thirteen staff who had worked at least six months at the center severed as evaluators/informants. Typically, five respondents evaluated each target behavior. Twenty-five graduate students were trained to administer the QABF and MAS. Reading and discussing the test manuals, role-playing administration procedures, and receiving feedback on their performance were included. Staff and student ratings were compared. The QABF resulted in a slightly better agreement.

For experiment two, eight individuals from study one were selected for inclusion. In addition to the QABF and MAS data, experimental functional analyses were conducted. The EFA was similar to Iwata et al. (1982). All eight clients were administered three conditions: attention, alone, and demand. All participants were also exposed to a play/control condition, and six of the participants were administered a tangible condition. One to six sessions occurred daily. The sequence was alone, attention, play, tangible, and demand. Sessions were 10 minutes in length and occurred three to five times per week. A total of 20–25 sessions were conducted for each individual. For the seven people who had clear functions established with the EFA, six corresponded to the QABF, while EFA results corresponded to four people based on MAS scores. Thus, the QABF proved to be the superior standardized measure of maintaining variables.

Fee et al. (2016) have also compared QABF and MAS results to an EFA and also a functional assessment interview. Twenty-four children who were between 2 and 12 years of age participated. Target behaviors in the analysis included screaming, aggression, stereotypies, hand flapping, teeth chattering, and elopement. The brief functional analyses were carried out in an exam room of an outpatient hospital clinic. The room had a camera and one-way mirror for observation. The QABF and MAS were sent to the children's homes five weeks before the functional analysis interview. These interviews were conducted with caregivers by phone.

The Brief Functional Analysis conditions lasted five minutes and included tangible, attention, and demands. When QABF results were compared to the Brief Functional Analysis, agreement was 67% and was 65% for the MAS. Results are not in line with the previous study and may be due to using a different type of EFA and using phone versus direct interviews with the standardized scales.

In another study comparing multiple methods of conducting functional assessments, 13 people with profound intellectual disability were served. Target behaviors included self-injury, aggression, tantrums/verbal aggression, and stereotypies (Paclawskyj et al., 2001). The EFA was based on the methods described by Iwata et al. (1982). Five conditions were presented: attention, demand, tangible, alone/ignore, and toy play. The alone condition was not employed for the three people who were aggressive. The therapist sat next to or behind the client, and one or two observers collected data from the far side of the room. Observers did not interact with the participant until the session had been terminated. In the attention condition, the therapist sat near the client reading a magazine. Verbal and physical attention followed the occurrence of a target behavior. For the toy play condition, preferred items were available, and the therapist provided attention once every 30 seconds contingent on no target behaviors for 5 seconds. For the demand session, the therapist asked the client to fold towels or stack cups, for example. There was a three-step series of prompts going from verbal, modeling, and physical guidance. For the alone sessions, the therapist sat behind the client or out of his/her sight. Target behaviors were ignored. A preferred object was given to the client for two minutes prior to initiating the tangible condition. The item was then removed and then given to the client for 30 seconds every time a target behavior occurred. The QABF and MAS were administered one month or less after the completion of the experimental functional analysis by a PhD student in clinical psychology. The QABF and experimental functional analysis were in agreement 56% of the time, and the experimental functional analysis and MAS were in agreement 44% of the time.

A psychometric study comparing the QABF and the MAS was reported by Shogren and Rojahn (2003). They tested 20 adults with intellectual disabilities. Problem behaviors displayed by these clients included aggression, property destruction, and self-injury. Test–retest, internal consistency, and interrater reliability were calculated. The authors concluded that both scales had good psychometrics, and that the psychometrics were similar across scales.

May et al. (2014) looked at the psychometrics of the QABF and found negative results. They evaluated the problem behaviors of 45 students in a K-12 school for children with developmental disabilities. The children and adolescents were 7–19 years of age and had attended school for at least a year. Problem behaviors assessed with the QABF were off-task behavior, noncompliance, verbal aggression, and physical aggression. Each target behavior was assessed by the classroom teacher and two paraprofessionals. The teachers had been working with the students for at least 6 months. One teacher had a master's degree and the remainder had bachelor's degrees in special education. Paraprofessionals had high school to associate degrees. Item correlations ranged from weak to strong. Their data did not support a five-factor solution. The authors conclude that formal training may be needed to produce reliable and valid results. We concur and argue that any functional assessment approach would require formal training, with experimental functional analysis requiring much more training than standardized assessment methods, such as the QABF. This point would seem to be particularly relevant with raters who have high school educations. The fact that the current data are at odds with numerous other studies by multiple research teams would seem to underscore this point.

Various parameters of maintaining challenging behaviors have also been evaluated using the QABF. Matson et al. (2005) addressed pica, rumination, food stealing, food refusal, aggression, and self-injury at mealtime. Informants for 125 with feeding problems and severe to profound intellectual disabilities served. Behavior functions most commonly associated with problematic feeding were identified. These data are important for treatment implications since they provide the most important maintaining variables to focus on initially.

In another paper, severe challenging behaviors of adults with intellectual disabilities were assessed with the QABF. Self-injurious behavior, stereotypies, aggression, pica, and rumination were evaluated. With the exception of aggression, nonsocial was the most commonly identified function (Applegate et al., 1999). High-rate and low-rate behaviors and the effect of frequency of self-injury and aggression were assessed. Because of the difficulty to employ experimental functional analysis with very severe and/or very low-frequency behavior. The focus on standardized measures such as the QABF is beneficial in these instances.

At the time of this writing, the standardized measure with the most and best empirical support is the QABF. Very good reliability and validity have been established. Additionally, data have been replicated across multiple research teams in various settings with multiple participant groups. However, no one method will work in all instances for these complex problems. Thus, several additional methods have been developed and are needed. They will be reviewed next.

Functional Assessment Checklist (FACTS)

The FACTS is a semi-structured FBA interview for use by teachers in school settings (March & Horner, 2002). The measure was a streamlined version of a large manual that was not empirically validated: the Functional Assessment Observation (O'Neill et al., 1997). The interview allowed for event-based measurement of problem behaviors and the identification of antecedents such as presenting tasks and consequences such as teacher attention and task removal. Data analysis involved identifying frequently occurring antecedents and consequences. FACTS interviews from 63 informants for nine student target behaviors were collected for this chapter.

A series of reliability and validity measures were obtained. Thirteen of 63 informants were evaluated on test–retest reliability, with the FACTS being readministered from 5 to 7 days after the initial assessment. Strong test–retest reliability was established for antecedent, functions, and total statements. Moderate reliability was noted for setting events. All 63 students had FACTS completed by five to eight staff members. Moderate reliability of .50–.88 was obtained. Interobserver agreement was obtained for nine students. One-hundred percent agreement was found.

Validity was also addressed in this study. Some of their validity was based on an eye test. McIntosh et al. (2008) contend that content validity is established by noting that the format and items are similar to what is found in other functional behavior assessment interviews. Process validity was noted as another valuable construct. But, this methodological approach has not been addressed with the FACTS. Convergent validity, however, was addressed. Good convergent validity was reported. These data are certainly helpful. However, a big need exists for additional research. The measure does not have sufficient empirical support to recommend it at this point.

Functional Analysis Screening Tool (FAST)

The FAST is a 16-item scale measuring antecedent and consequent events of challenging behaviors. Four categories were established: (1) social-positive reinforcement, such as access to tangibles and attention; (2) social-negative reinforcement in the form of escape; (3) automatic reinforcement/self-stimulation; and (4) automatic-negative reinforcement (e.g., escape pain and/or discomfort). These conditions were based on a review the authors had done looking at maintaining conditions discovered in numerous empirical studies. They combined the tangible and attention conditions that are separate in the MAS and QABF. A copy of the scale is available in Iwata et al. (2013).

The initial reliability data were for 151 people with ID or autism. Some of the participants had more than one target behavior. As a result, 196 behaviors were assessed by parents, relatives, teachers, teacher aides, and direct-care staff. Education of the evaluators ranged from high school to a master's degree. The authors calculated observer agreement based on item-by-item comparisons between pairs of informants. They note 80% agreement as the minimal acceptable standard. With the FAST, 71.5% agreement was obtained. The authors characterize this reliability as moderate at best. As noted by Iwata et al. (2013), without acceptable reliability, validity cannot be established.

In a second study examining the FAST, it was compared to the QABF and FACT (more on the FACT later). Zaja et al. (2011) evaluated 130 adults who attended a day program in the United States. Clients had been diagnosed with ID and other physical and mental health problems. Senior day program staff ($n = 29$) were the raters. All three scales were completed for each target behavior. The reliability for the QABF and the FACT was acceptable to good. The FAST has poorer reliability scores than the other two measures. Convergent and discriminant validity were better between the QABF and FACT than results for the FAST compared to the other two instruments. Thus, given the disappointing psychometrics of the FAST, it cannot be recommended for use at this time.

Functional Assessment for Multiple CausaliTy (FACT)

The FACT is a 35-item measure developed to identify a hierarchy of behavioral functions for persons with ID, autism, and other developmental disorders. This is significant since it is the only functional assessment measure to help establish the order in which multiple functions for behavior are included in treatment for a given person. Of course, this is not an issue for a client who displays only one function for a target behavior. Thus, the FACT would not be used in all instances where maintaining variables are identified.

A forced-choice procedure is used with the FACT. Each item gives the informant two choices, with each representing a different function. Items are rotated so that each item has been paired with all items. Frequency of endorsement shows the overall validity of each item. Relative frequency of endorsements is used to establish treatment priorities.

Psychometric qualities of the FACT were established by Matson et al. (2003). Participants were 297 persons with ID and/or autism. They ranged in age from 9 to 85 years old. The FACT was completed for each significant behavior problem, which ended with 409 completed scales. FACTs were administered to direct care staff by master's level mental health professionals. Factor analysis produced five factors: escape, self-stimulation, attention, tangible, and physical. A second-factor analysis was then replicated with a second sample with 197 people with ID and/or autism. This sample ranged in age from 16 to 85 years old. In this study, 307 FACTs were completed. This replication study yielded the same five factors established in Study 1. Internal consistency was also very good with .88–.92. This study is particularly rigorous. While future research would certainly be warranted, at present there are sufficient data to recommend the FACT for use.

Questions About Behavioral Function in Mental Illness (QABF-MI)

The same 25 items from the QABF were used in the current study. The difference was the population studied. One hundred and thirty-five direct care staff from three inpatient psychiatric facilities with serious and persistent mental illness were assessed. The participant-to-item ratio was just over 5 to 1, which is optimal for a factor analysis. A principal component procedure was used for factor extraction. The QABF-MI items corresponded 100% to the QABF. Thus, based on the QABF and these data, the QABF-MI appears to be a methodologically sound functional analysis scale.

Teacher Functional Behavioral Assessment Checklist (TFBAC)

The TFBAC was evaluated with 89 first through third graders. Good-to-excellent agreement was found for teachers' multiple ratings of problem behaviors. The authors conclude that the scale was reliable for identifying problem behaviors. There was evidence of convergent validity of problem behaviors, although a lack of evidence for the validity of the purported maintaining functions of these behaviors was found.

Functional Analysis Checklist (FAC)

The FAC is another checklist developed to establish and maintain variables (Sturmey, 2001). The study was conducted with individuals in behavior therapy programs in a state school population. Interrater and test–retest reliability was uniformly poor.

Descriptive Functional Assessment

The focus of this study was to identify low-rate, high-intensity behaviors using descriptive data (Radford & Ervin, 2002). These authors note that aggression and violence are typical in school settings. Only one participant, a 13-year-old male with ADHD, served. He had exhibited low rates of aggression toward peers in his school. Methods and procedures were multifactorial. A comprehensive review of archived data including office referrals for aggression and previous school records. Also, data were assessed to determine if the target behavior was more likely to occur in unstructured parts of the school day such as recess. Also, data were assessed to see if negative peer interactions such as teasing, name-calling, or physical aggression resulted in higher rates of the target behavior. These data were used to develop intervention plans.

A less structured approach was also described by Hoff et al. (2005) in a school classroom for an adolescent who had been diagnosed with attention deficit hyperactivity disorder (ADHD) and oppositional defiant disorder (ODD). Assessment methods included teacher interviews, student interviews, and direct observation in the classroom. An intervention, that the authors reported was successful, was based on the information derived from these evaluations.

In another study, using informal functional assessment, Toogood and Timlin (1996) found poor agreement with the experimental functional assessment. These authors looked at the function of 121 challenging behaviors of 20 people with ID. They also make the point, which is still pertinent, that staff training is very important to ensure accurate functional assessment.

Love et al. (2009) evaluated 32 children ages 2–12 years who were diagnosed with autism, Asperger's syndrome, or Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS). Data were collected at a university outpatient clinic over a four-year period. Two methods of assessment were used initially: the FAST (It has already been noted in this chapter that the FAST does not have acceptable reliability) and a semi-structured interview. A caregiver was included to discuss information about antecedents and consequences and about when challenging behaviors typically occurred. Next, caregivers were trained to record environmental events based on professional committees' establishment of maintaining variables using the FAST and the interview described above. Each instance of the low-rate challenging behavior, caregivers recorded the environmental events that occurred at the same time in a narrative format. One of two doctoral-level psychologists reviewed these narrative descriptions and established a maintaining variable or variables. Attention from others proved to be the maintained variable in most cases.

Another study where multiple functional assessment methods were used by Stage et al. (2006). They evaluated three schoolchildren in kindergarten, first grade, and ninth grade. Measures and methods included the Functional Assessment Checklist for Teachers, the Student-Directed Functional Assessment Interview, the Functional Behavior Assessment Checklist, and an Adaptive Functional Assessment Interview. Experimental conditions were manipulated in the classroom setting to establish maintaining variables as well. The scaling methods varied in reliability but proved useful in establishing and maintaining variable to consider during the classroom manipulations.

Scatterplots

Another method that can be helpful in establishing patterns of behavior and maintaining variables is the scatterplot. First described by Touchette et al. (1985), it consists of a grid. The vertical axis lists time in segments (hours, half hours, minutes), while the horizontal axis represents successive days. After the data are plotted, empty cells represent no occurrence, and a filled-in cell indicates the occurrence of the target behavior. The authors warn that the data that are visually presented need to be accurate and easily interpreted. In the text of the chapter, the authors give examples of how the scatterplot can be used. For those interested in this methodology, it is recommended that they consult this article.

One example is a 14-year-old girl, Joan, with aggression dating back a decade. She lived in a residential facility for adolescents with autism. Her challenging behaviors were severe enough that she had to be removed from ongoing activities. The focus of the scatterplot was to establish maintaining events. Joan was monitored for aggression during all waking hours, seven days a week. Over a three-week period, assaults typically occurred from one to four in the afternoon, Monday to Thursday. During these hours, Joan was in prevocational and community living classes. She was involved in one-to-one training in the morning. The authors concluded from this data that demands were not a trigger. Thus, her afternoon group activities were changed to one-to-one. Activities such as listening to stories and trying on cosmetics were provided and changed every 15 minutes. This approach proved to be effective in decreasing challenging behaviors.

Kahng et al. (1998) note that the scatterplot is a frequently used method of establishing patterns of challenging behaviors. In their study, 20 people living in residential settings participated. Clients' programming consisted of vocational or academic classes, speech or physical therapy, and other constructive activities. Self-injurious behaviors were recorded as occur or does not occur during 30-minute intervals. Visual inspection was made to identify patterns of problem behavior across days. Various maintaining variables were noted, such as sensitivity toward specific staff or activities. The authors caution that for all-day assessments, interval recording for all day should be at least 30 minutes in length. An additional modification of the scatterplot is described by Bosma and Mulick (1990). They contend that data can be evaluated more efficiently by using see-through slides of individual scatterplots that can be overlaid. They conclude that important relationships, which might otherwise be overlooked can be visually detected in this manner.

Scatterplots were also used in a study by Maas et al. (2009). They evaluated seven adults with ID. Depending on each individual's living arrangement, target behaviors were recorded by direct care staff or parents. Cells were intervals of two hours with data collected on 28 consecutive days. These seven people with confirmed Prader–Willi syndrome were compared to a control people of five people with ID who had no known genetic conditions, epilepsy, or use medication that may have an effect on daytime sleepiness and functioning. People with Prader–Willi syndrome displayed more excessive daytime sleepiness than controls. The target behaviors were more likely to occur when daytime activities were not scheduled.

Another study using largely informal methods is described by Linville et al. (2010). They had 148 participants who were rated longitudinally. The focus was on relationships between couple relationships, parenting methods, parental depression, and their children's challenging behaviors. The child's behavior was evaluated twice, one year apart. Each child and an adult were videotaped while engaging in standardized tasks: free play (15 minutes), a clean-up task (5 minutes), a delay of gratification task (5 minutes), four teaching tasks (3 minutes for each of the four tasks), a second free play session (4 minutes), a second clean-up task (4 minutes), the presentation of two inhibition-inducing toys (2 minutes each), and a task involving making lunch. Problem behaviors were assessed on the following criteria: parent gives child choices for behavior change where possible, parents use clear language regarding behavior change, the caregiver uses a calm voice, parent adjusts situations to enhance interest, success and comfort by the child, when the child misbehaves or is off task the parent redirects to more appropriate behavior, and verbal instructions are used to make tasks more manageable. When these data were used to inform treatment, better effects were found relative to controls.

Another functional assessment is described by Todd et al. (2008). Four elementary school-aged boys served as participants. They were chosen due to frequency of office visits, teachers affirming that the child's problem behaviors frequently disrupted classroom activities as well as parental and student assent. A 20–40-minute interview was conducted with each child's primary teacher. The FACTS (which was discussed earlier) interview helped identify problem behaviors, antecedent events that correlate highly with the occurrence or nonoccurrence of challenging behaviors. Direct observations were also used with an ABC chart (antecedent-behavior-consequence). Data were confirmed when the FACTS and ABC information matched. Target behaviors were being in the wrong location, talking out, noncompliance, talking to peers, being disruptive, and having negative physical or verbal interactions. These data were used to inform treatment, which was effective.

Final Remarks

The focus of this chapter has been functional assessment methods that fall outside the realm of experimental functional analysis. Obviously, researchers and clinicians see a need for these various methods, given the number of authored papers and the range of strategies that have been described. Unfortunately, there is no systematic data that have been collected regarding how often these methods are used in an applied setting. Nonetheless, it is likely that these methods are in widespread use. Also, given many discussions with teachers and psychologists, it is often the case that those people administering the measures may have inadequate expertise/training in these methods of assessment. Given the level of expertise and the labor-intensive nature of EFAs, they will be confined largely to university settings. Thus, a research focus on how to train and monitor methods other than EFAs in applied settings should be a top priority.

To date, functional assessment has been limited largely to special populations and challenging behaviors. Children and adolescents have also been studied much more frequently than adults. The focus should be oriented to more populations and more problems (e.g., anxiety, PTSD). What is referred to as “triggers” with mental health problems may in fact be maintaining variables conceptualized a bit differently. In any event, data to this point are promising, but much is still to be learned.

28 Quantifying Outcomes in Applied Behavior Analysis Through Visual and Statistical Analyses: A Synthesis

Javier Virues-Ortega, Mariola Moeyaert, Maithri Sivaraman, Aida Tarifa Rodríguez, and Belén Fernández Castilla

Five adults with intellectual disabilities who attended a day-training center were prescribed with physical exercise. Krentz et al. (2016) aimed to increase walking in these adults. The authors began with a baseline phase in which they recorded the number of laps completed in one hour by each adult. During the treatment phase, the adults earned tokens for each lap completed and could exchange these tokens for a preferred item at the end of the one-hour session. The researchers observed an increase in the number of laps by each adult during the token reinforcement phase relative to baseline. After a few treatment sessions, baseline conditions were reinstated, i.e., the adults stopped receiving tokens. The authors observed that the laps completed by each adult decreased until their frequency was comparable to the one observed during the initial baseline. The study was completed with a return to the treatment phase in which participants again received tokens for walking laps. The results showed that walking was low during the baseline phase, increased during the treatment phase, decreased during the return to baseline, and increased once again during the final treatment phase for all participants. The authors concluded that token reinforcement was effective in increasing walking among their adult participants.

The study described above exemplifies a reversal design involving repeated and frequent measures of behavior (i.e., number of laps walked), the experimental manipulation of an independent variable (i.e., introduction and withdrawal of token reinforcement for walking), and replications within and across subjects (see chapter on single case design in this volume). Single-case experimental designs (SCED) allow the practitioner to evaluate the effects of an intervention using repeated behavioral measurements across sessions and conditions. This is in sharp contrast to group designs that often focus on the aggregated effect of a treatment on an entire group. A single-subject approach allows the

practitioner to monitor individual performance on a session-by-session basis, potentially drawing cause–effect links between experimental manipulation (i.e., treatment) and behavior (What Works Clearinghouse, 2020). Single-subject designs are particularly well-suited to practitioners and clinicians as they engage in practice-oriented research. Single-subject designs can accommodate large between-subject variations commonly encountered in practice (e.g., level of baseline performance, dataset size, topographical variations across participants, etc.). In addition, intervention procedures and SCED may be modified on an ongoing basis in the event of limited or no improvements in performance (Kratochwill & Levin, 2014; Kratochwill et al., 2010).

Single-subject designs have been criticized for being subject to selection bias, relying on visual analysis for treatment outcome evaluation, and not accommodating to mainstream inferential statistics. Moreover, there has been no methodological requirement for reporting on all participants initially screened or selected for participation in behavior–analytic studies. Some have criticized that this practice may have led to publication bias, whereby positive results are more likely to be reported and published. This threat was confirmed by Sham and Smith (2014), who observed that the effect size in a selection of applied studies was on average 20% greater in published relative to unpublished studies. Recent suggestions for extending methodological standards borrowed from the medical sciences, including consecutive client admission (Hagopian, 2020) and intention-to-treat analysis (see for example Taylor et al., 2019), provide the tools for overcoming patient selection bias in SCEDs.

The reliance on visual analysis has been criticized as an unreliable and pre-quantitative approach to data analysis (e.g., DeProspero & Cohen, 1979). A major justification for visual analysis lies on the *effective* dimension of the field of applied behavior analysis (Baer et al., 1968). In the hopes of prioritizing socially valid interventions, behavior analysts have traditionally focused on interventions producing large effects that can be evident from the visual inspection of the time series and are less likely to induce Type I errors (false positives). Moreover, statistics were seen at the time as a distracting sophistication due to the frequent mismatch between clinical and social significance (see for example Michael, 1974). These factors led to a decades-long rejection of mainstream inferential statistics in applied behavior analysis.

These concerns are now gradually coming to the fore as behavior analysis produces service models that ought to be weighted and prioritized by health and policy decision makers, causing a need for quantitative and widely intelligible summaries of scientific evidence. Visual analysis allows a good understanding of emerging patterns in the data, whereas statistical analysis can help to quantify the magnitude of effects, study co-variables, and synthesize evidence from multiple individuals and studies. In addition, structural visual analyses and visual aids minimize subjectivity and Type-I errors while visually analyzing SCED datasets.

In this chapter, we will briefly review the various approaches to quantifying outcomes in SCED and how new developments in statistics can support the process of *mainstreaming* SCEDs into the outcome research literature by combining visual and statistical analyses. In the next sections, we will describe techniques to evaluate SCEDs using visual and statistical analyses and also outline the potential synergies between the two for the purposes of quantifying, comparing, and pooling treatment effects. We recommend that the reader is familiarized with Chaps. 24 (Single-Case Designs), 29 (Treatment Integrity), and 30 (Social Validation). Concepts from these sections will be used throughout the current chapter.

Visual Analysis

How Does It Work?

Session-by-session SCED graphs provide the most common basis for conducting a visual analysis. While there are numerous graph formats in applied behavior analysis (e.g., line graphs, bar graphs, cumulative record, scatter plot), the line graph is predominant in applied behavior analysis for displaying non-cumulative behavior recordings over time. In a line graph, the *y*-axis represents the dependent variable (i.e., the behavior of interest) and the *x*-axis typically represents time (i.e., sessions, days). Letters in alphabetical order are often used to denote the various conditions in a SCED and its graphic display. For example, an ABAB design represents two A conditions and two B conditions. *A* typically refers to the baseline condition, whereas *B*, *C*, … denote successive treatment conditions. A transition from one condition to another is represented using a phase change line on a graph (see a set of guidelines for graph construction to minimize bias in Cooper et al., 2019; Kubina et al., 2017; see also Chap. 24).

Data graphing and visual analysis go hand-in-hand throughout a behavior change project and they are considered essential processes for both ongoing clinical decision-making and evaluation of the intervention effect. Specifically, a major aim of a visual analysis is to identify whether there was a change in the behavior of interest and whether that change could be reliably attributed to the intervention. Intervention effects in SCEDs are primarily evaluated for their clinical significance[1] (i.e., focus on large effect sizes *à la* Baer et al., 1968). A visual analysis involves the evaluation of data patterns both within and across phases or conditions.[2] In the following sections, we will revise the main dimensions of within- and across-phases visual analysis.

Within-Phase Visual Analysis

Treatment effects are assessed relative to baseline. As a first step, the visual analyst would evaluate *steady-state responding* in the initial baseline phase. During steady-state responding the dependent variable is expected to present low variability and no discernable trends. The presence of high variability and/or trend within baseline threatens the baseline logic and may result in the researcher extending the baseline phase (until steady state is attained) or modifying the study procedures in order to ensure baseline stability. In order to allow for timely phase change decisions, it is recommended that visual analyses are conducted on a continuous basis following the data collection process as closely as possible.

A visual analyst focuses on three major dimensions of the visual display of the data within a phase or condition: (a) *level*, the average amount of behavior; (b) *trend*, directional movement of the data over time; and (c) *variability*, data variation across the time series that cannot be attributed to trends. In effect, the visual analysis will provide information about how much behavior occurs (level), how the behavior changes over time (trend), and how much change do we see in the behavior that cannot be clearly attributed to the independent variable or to existing trends. The What Works Clearinghouse standards (2020) suggest that a minimum of five data points in each phase or condition are needed before introducing a new phase in order to properly appreciate level, trend, and variability (see also Maggin et al., 2013).

Level

The level is the overall or average amount of behavior within a condition with reference to the *y*-axis (Barton et al., 2018). *Floor* (zero), *low*, and *high* are common qualifiers of the level of behavior (see Fig. 28.1a). The level within an SCED phase is often estimated using the mean or median (see Fig. 28.1b). The mean is highly sensitive to outliers. Therefore, in the presence of outliers or significant variability, the median is recommended. However, computing phase level may be informative only to the extent that the data has no trend and relatively low variability. Behavior analysts are mostly concerned with changes in level that may be revealed over the course of an intervention, whereas the mean (or

[1]This is in sharp contrast to group designs, which often focus on statistical significance and abstract effect size metrics.

[2]We will use the terms phase and condition interchangeably. *Phase* may be more appropriate for independent variable manipulations comprising a continuous time series, whereas *condition* may be more appropriate for multielement designs where treatments are implemented briefly as part of discrete alternating sessions.

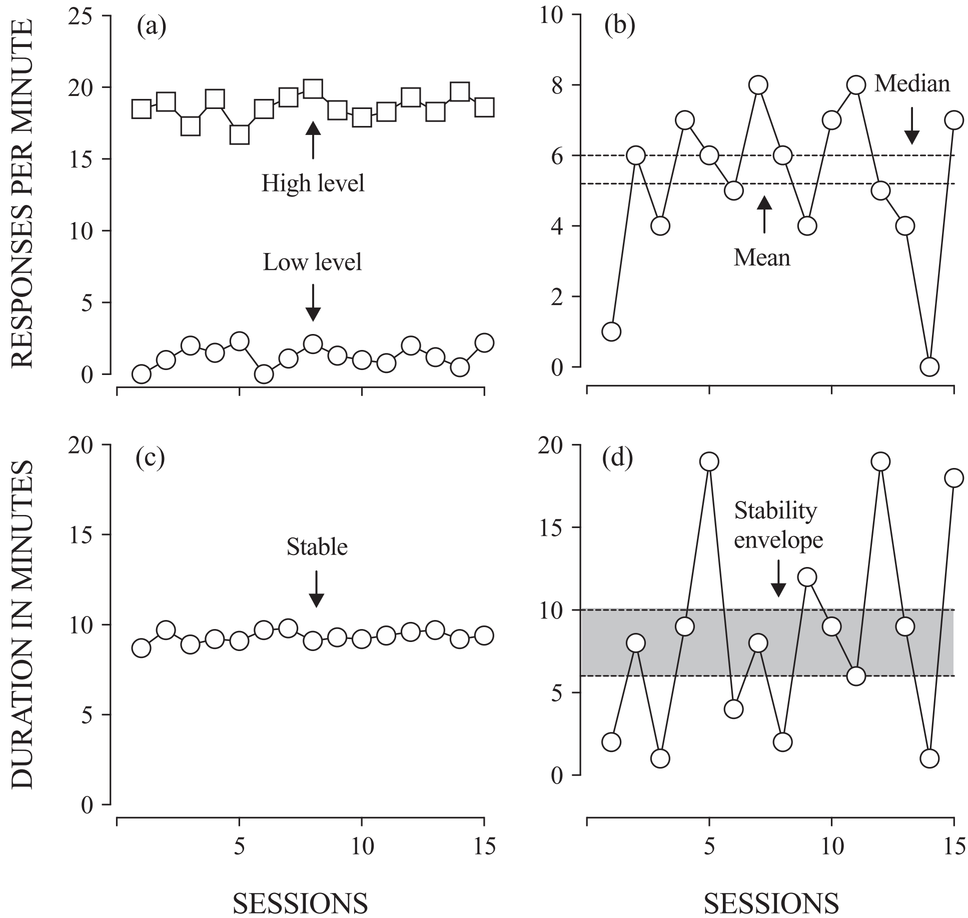

Fig. 28.1 Some graphical examples of common visual analysis scenarios

median) change in level may have little practical relevance.

Trend

Trend refers to the directional movement of data over time. Trend may be *accelerating, decelerating*, *increasing*, *decreasing*, *therapeutic, counter-therapeutic,* or *null* if absent. Visually detecting trends within a condition can offer information about the progressive improvement (or worsening) of the target behavior, and it may be the basis for phase change decisions. For example, (a) a therapeutic trend during baseline (i.e., a trend in the expected direction of the intervention) may indicate that the introduction of treatment is premature or unnecessary, (b) a counter-therapeutic trend during baseline (i.e., a trend opposing the expected direction of the intervention) or no trend may warrant the introduction of treatment, and (c) a therapeutic trend during treatment may indicate that the treatment is having the intended effect and that termination of treatment before its effect becomes asymptotic may be premature.

Fig. 28.2 (upper panel) presents a decreasing trend of vocal requests during baseline followed by an increasing trend after the onset of the treatment phase. While data stability is considered optimal before making a phase-change decision (i.e., steady-state responding), a baseline phase composed of a counter-therapeutic trend may be acceptable on occasions when it is not practically possible to wait for steady-state responding. The inception of an opposing trend immediately after treatment implementation is a form of effect demonstration—even though comparing mean levels would suggest no effect. Steep localized trends

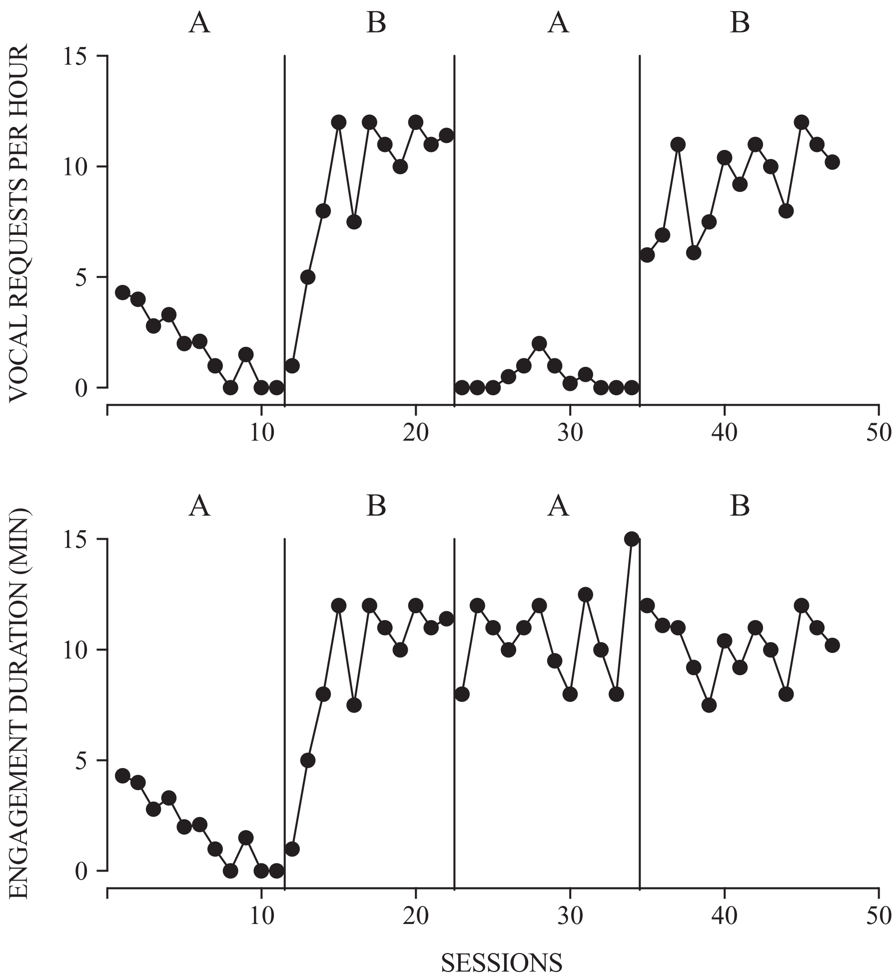

Fig. 28.2 Examples of local trend (first B phase) and non-reversibility (second A phase, lower graph)

observed upon the implementation of treatment (or the reversal to baseline conditions), as the ones shown in Fig. 28.2 (first B phases), are sometimes called *transition trends* and should not affect the ascertainment of behavior level once the trend is replaced with steady-state responding.

Discontinuing a study phase with an ongoing trend, while compatible with effect demonstration, may limit the researcher's ability to assess the intervention maximum effect and the stability of the intervention effect. Phase change or cessation decisions may be pre-determined by socially valid mastery criteria. For example, educational interventions focusing on behavior accuracy may require two successive sessions or blocks of trials with 80% of correct responses or more as a mastery criterion. This criterion can be portrayed in the graph as a horizontal mastery criterion line aiding visual analysis.

Trend can be appreciated visually or estimated through trend lines. A variety of techniques can be used to calculate trend lines, including the split-middle line method or a simple regression line. Most graphing software packages (e.g., Prism GraphPad, SigmaPlot, SPSS) can compute regression trend lines seamlessly. The split-middle method (Cooper et al., 2019, pp. 149–150) relies on the median and is therefore less sensible to outliers than linear regression lines.

Variability

In the context of a visual analysis, variability may be defined as the extent to which the data points within a condition vary randomly. It may also be defined as the fluctuation of data around the trend or level line (Barton et al., 2018). It can be referred to as *stable* or *variable*.[3] Fig. 28.1 presents examples of stable and variable baselines. As is the case with level and trend, variability can be ascertained by visually inspecting the data. Crying duration in Fig. 28.1c seems fairly stable upon visual inspection. Variability may be augmented or minimized by the scale of the *y*-axis. In order to prevent a false appreciation of variability, it is recommended that the graph scale reflects the range of socially relevant variations of the dependent variable. In addition to visual analysis, some authors recommend computing a *stability envelope* to visually portray variability. According to Ledford et al., 2018, on occasions when ≥80% of the data points are within ±25% of the median, the data may be described as stable. For example, for the time series in Fig 28.1(d) (*Me* = 8), the stability envelope would range from 6 and 10. There are only five values within the envelope (33%); therefore, the time series may be considered variable. For time series with an increasing or decreasing trend, the stability envelope may be calculated around the trend line, instead of the median. Similarly, Hagopian et al. (1997) suggested using criterion lines below and above the control condition as the basis for identifying intervention effects (see section "Visual Analysis: A Case Study" later in this chapter).

Within-phase variability is indicative of weak experimental control (i.e., weak functional relationship between the treatment and the target behavior). Therefore, variability in the data will hamper our ability to draw conclusions from it. Variability may also be interpreted differently in different experimental designs. For example, a greater level of variability is to be expected in a study with few data points per condition, where steady-state responding is unlikely. Similarly, multielement designs typically present greater variability than study designs where the independent variable is not quickly alternated, and are, therefore, less vulnerable to carryover effects. Whenever possible, it is recommended to identify the sources of unexplained variability, for example, by using different data paths for sessions conducted at home vs. sessions conducted in the community or sessions conducted by different therapists, etc.

A visual analysis of variability often weights more observations conducted relatively later in a particular phase (i.e., towards the right of the graph). Namely, variability occurring before steady-state responding is attained can, to some extent, be ignored if it can be reasonably attributed to the gradual effect of the baseline or intervention conditions (e.g., gradual effect of discrimination, reinforcement, habituation, and extinction processes). By contrast, continued unexplained variability over an extended period of time suggests that key sources of variation remain unidentified, which could take the researchers back to the drawing board. The research setting may also affect the visual analyst judgment of variability. For example, we would expect more unexplained variability in studies conducted in ecological settings (e.g., classroom, home environment), where the opportunities to produce the target behavior may vary greatly (see for example Valbuena et al., 2015).

Visual Analysis Across Phases

Conducting a visual analysis across study phases can help to establish (a) whether there was a change in the target behavior across conditions and (b) whether this change was caused by the intervention. The What Works Clearinghouse standards (2020) offer specific criteria to evaluate a treatment effect. For example, the standards require at least three demonstrations of the intervention effect by considering changes in level, trend, and variability across adjacent phases in a reversal designs (or across participants, behaviors, or contexts in a multiple-baseline design). In the following sections, we will consider immediacy, overlap, and consistency as specific dimensions of a visual analysis comparing side-by-sade phases.

Immediacy

Immediacy may be defined as the amount of time elapsed since the implementation of treatment (or

[3] Bailey and Burch (2017) use the terms high and low *bandwidth* to denote high or low variability during visual analyses.

the reversal to baseline conditions) to an identifiable change in behavior. Immediacy may be defined with reference to either the initial change of the dependent variable and/or the maximum change of the dependent variable. Visual analysts focus on the first few sessions after the implementation of treatment to assess immediacy. For example, in multi-element designs, lack of immediacy could result in frequent dips in the intervention effect, or worse, undifferentiated data paths across conditions.

Abrupt changes in behavior upon the introduction of a new condition may seem ideal. However, abrupt or gradual changes in behavior are both acceptable from an internal validity perspective assuming the delay in behavior change is minimal (see several examples in the phase transitions of Fig. 28.2). Moreover, abrupt changes in a behavioral time series may be partially attributable to the degree of data aggregation. For example, computing responses per minute in 5-min sessions can more easily result in a gradual phase transition than computing responses per hour in 12-hour sessions (Fahmie & Hanley, 2008). Also, the nature of the underlying behavioral process may be key to obtaining gradual or abrupt changes in behavior (e.g., discriminated change in behavior allocation vs. shaping).

Overlap

Overlap refers to the extent to which the level and range of behavior are comparable across adjacent conditions. The greater the overlap, the lesser the confidence in a functional relation between treatment implementation and changes in behavior. Presence of variability during baseline and treatment phases greatly increases the likelihood of overlap. Overlap can be computed quantitatively by way of the percentage of non-overlapping data points (PND) and similar indices (see section on Non-overlap and Other Non-parametric Indices). On occasions when overlap is present, it is important to evaluate whether it changes along local transition trends or whether overlap affects the entirety of the phases under analysis. In the latter scenario, our confidence in identifying a functional relation will diminish. For example, the reversal design in Fig. 28.2 (lower graph) presents a failed baseline reversal (i.e., the second baseline phase fails to verify the level of behavior found in the initial baseline). The overlap between the treatment phases and the second baseline implies lack of experimental control. However, the level of overlap in this particular scenario does not suggest an absence of effect, but rather a failed replication or *non-reversibility event*. Experimental control can be restored by accompanying non-reversible effects with between-subject replications (cf. multiple-baseline design across participants, see Chap. 24).

Consistency

Consistency refers to the extent to which the level of behavior in a particular phase can be verified in subsequent phases featuring the same treatment and the extent to which treatment effects can be replicated through multiple within-subject and between-subject replications. For example, in an ABAB reversal design, the transition between baseline and treatment is repeated. Therefore, the ABAB design provides an opportunity to *verify* baseline and treatment levels and to *replicate* the effect of treatment. Specifically, the ABAB design allows for the evaluation of the effectiveness of the intervention at three different moments in time: transition from first baseline to first intervention, from first intervention to second baseline, and from second baseline to second intervention. The closer the treatment effect across replications, the greater the consistency. Highly consistent intervention effects enhance our ability to identify a functional relation. For example, the treatment replications in the upper graph of Fig. 28.2 are reasonably consistent, whereas the replication was unsuccessful in the lower graph.

Non-reversible behavior changes, such as language acquisition, are not amenable to within-subject replications (e.g., reversal design). Yet, it is still possible to assess treatment consistency across participants. For example, the consistency across participants is high in the first baseline-to-treatment transition for both datasets in Fig. 28.2, even though the treatment effect was not reversible for the lower dataset.

Reliability of Visual Analysis

While visual analysis is the most common method for analyzing SCEDs in applied behavior analysis, studies on its reliability and validity have been limited. Ninci et al. (2015) conducted a meta-analysis and a moderator analysis of SCED studies reporting the interrater reliability of visual analysts. Overall, they found a moderate level of interrater reliability (0.76). Their moderator analysis suggested that the visual analyst's level of expertise did not improve interrater reliability, whereas providing consistent interpretation instructions, visual aids, and consistent training enhanced interrater agreement. In addition, Kahng et al. (2010) found consistent interpretations of SCED line graphs among well-trained visual analysts. However, they utilized relatively simple low-variability line graphs in their study. Other studies are less optimistic about the reliability of visual analysis (see for example Wolfe et al., 2016).

Consistently with Ninci et al. (2015), the use of structured guidelines for visual analysis may increase its reliability and reduced the potential for Type I errors. For example, Hagopian et al. (1997) proposed a set of guidelines for visually analyzing multielement designs used in the functional analysis of problem behavior. Their guidelines have been used in several reviews, allowing visual analysts to attain over 90% interrater agreement (see for example Cox & Virues-Ortega, 2016). Moreover, Fisher et al. (2003) developed the dual-criteria (DC) and conservative dual-criteria (CDC) method to aid visual inspection of SCEDs. Broadly defined, the DC method involves calculating the mean and trend lines for baseline data and extending these lines over the subsequent phases. Next, the number of points in the successive data path(s) that fall above or below both lines is counted and compared to a cut-off value based on a binomial distribution. The CDC is a more stringent variation of the DC method, wherein the mean and trend lines are increased or decreased by one-fourth of a standard deviation (Fisher et al., 2003). The DC and CDC methods are intended to provide a more objective and reliable basis to conduct visual analyses. In yet another example, J. M. Ferron et al. (2017) have proposed the *masked visual analysis* as a means to minimize the risk of Type I errors (i.e., probability of finding an effect when there is none). We discussed masked visual analysis in the section on statistical analyses that produce a *p* value as the main outcome (p. 529). In addition to using structured criteria, using automated tools to ascertain level, trend, and variability may also enhance the reliability of visual analysis (see for example De et al., 2020; Manolov, 2020). More research is needed to validate the various approaches that have been proposed to enhance the reliability of visual analysis, including supplementing visual analysis with statistical analyses discussed later in this chapter.

Visual Analysis: A Case Study

We will illustrate the use of structured criteria for visual analysis with the guidelines proposed by Hagopian et al. (1997) for functional analysis of problem behavior. These criteria have been revised by Cox and Virues-Ortega (2016). We will apply these revised criteria to four multielement SCEDs reported by Conners et al. (2000) (a fully re-graphed version of the data is available in Fig. 28.3). Before implementing these criteria, the visual analyst would draw in the functional analysis graphs the upper criterion line (UCL), defined as the mean plus the standard deviation of the play (control) condition; and the lower criterion line (LCL), defined as the mean minus the standard deviation of the play condition (Fig. 28.3). The revised Hagopian et al. criteria are summarized in Table 28.1. Table 28.2 presents a synthesis of the revised criteria as used with the participants in Conners et al. (2000). Below, we combine the structured visual analysis with some commentary on the within-phase (level, trend, variability) and across-phase (immediacy, overlap, consistency) dimensions of visual analysis.

The only test condition in Annette's functional analysis that met the criterion for differentiation was attention (*D1: observations above the UCL minus observations below the LCL*

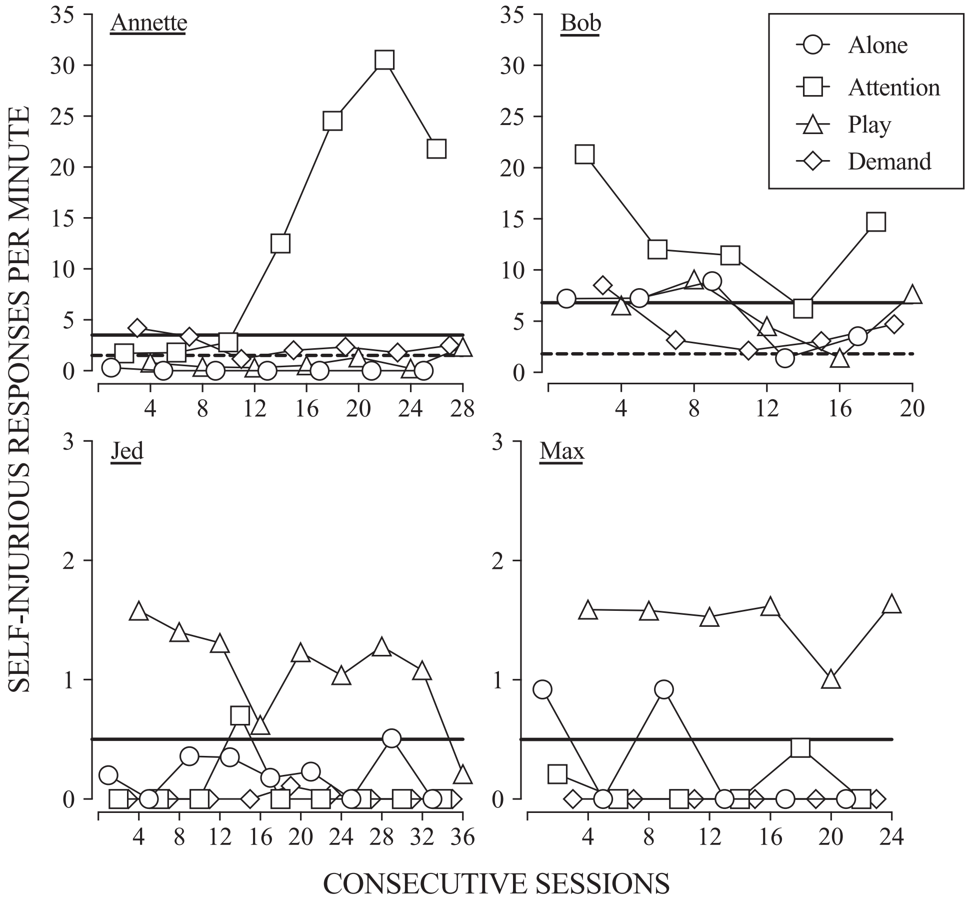

Fig. 28.3 Cases of attention-maintained (Bob and Annette) and escape-maintained (Max and Grey) self-injury. *Notes.* Solid and broken horizontal lines denote the upper and lower criterion lines for the play condition (Hagopian et al., 1997). Originally re-graphed data (Source: Conners et al. (2000))

equal at least half of the observation in the time series). In addition, attention met the criteria for an upward differentiated trend (*T2: all observations above the UCL are in the second half of the assessment*). Therefore, the outcome of the visual analysis is *attention*. The visual inspection shows that alone, play, and demand, all present steady-state responding at zero or near-zero levels. The variability and overlap of the effect of attention (and its lack of immediacy and consistency) may be almost completely attributed to a local transition trend, possibly following the discriminative learning process present in functional analysis.

For Bob's functional analysis, both alone and attention met the D1 criterion for differentiation. Yet, alone also met the criterion for a downward undifferentiated trend (*T1: among the observation above the UCL, fewer than 2 data points [or 20% of the time-series] occur in the second half of the assessment*). Therefore, alone should be discarded as a differentiated test condition. The outcome of the assessment is *attention*. In sharp contrast with Annette's functional analysis, Bob's presents a U-shaped trend that is identifiable to various extents in all conditions. This trend may explain some of the variability in the assessment in addition to the partial overlap of the fourth attention session. Variability is also evident by

Table 28.1 Structured criteria for the visual analysis of a multielement design functional analysis. (according to Hagopian et al., 1997, Cox & Virues-Ortega, 2016)

General criteria	
D1	Criterion for differentiation: points above the UCL line minus points below the LCL ≥ 5
D2	If play LCL is 0 or lower, zeros counted as below the lower line.
D3	If the play's UCL is below 0.5, draw the upper criterion line at 0.5.
D4	If no play/control condition and the highest condition is attention, demand, or tangible (or any two-term combination of these) set LCL and UCL to 0 and 0.5, respectively.
D5	For % of intervals or % of session duration, the maximum UCL is 100%, any 100% data point will be considered above the UCL.
D6	If there are less or more than 10 data points per condition use criteria proportionally, e.g., 50% of data points above UCL vs. 5 data points above UCL. Invoke D6 only if there are at least 2 data points per condition. (D1 is relevant to A3, T1, and T2.)
Automatic reinforcement	
A1	Alone is the highest and is significantly higher than play (is the highest condition in most series).
A2	Behavior is higher in conditions with lower external stimuli (one or more of alone, attention, tangible) relative to those with higher stimuli (one or more of play, demand).
A3	All conditions are high and relatively stable with no overall trends (mean of all conditions is above 1.5 per min [or 15% intervals] and less than 5 zero points).
Trends	
T1	Downward trend (undifferentiated): If less than two data points above the UCL occur in the second half of the assessment. This rule does not apply to demand and tangible if responding adapts to an efficient rate (e.g., every 30 s in demand).
T2	Upward trend (differentiated): All 5 data points above the UCL are in the second half of the assessment, ignore points below the LCL.
T3	Overall trend (differentiated): condition that is consistently higher than play.
Low rate or magnitude	
LR	1. Most of the data points are low across all conditions AND 2. More than half of the high sessions occur in a test condition AND 3. More than half of the behaviors occur in the same condition as #2 AND 4. At least one of the high points in the condition identified in #2 should occur in the second half of the assessment.
LM	Condition meets criterion for differentiation (D1) by a small amount, then raise UCL by 20%. LM1 can be used only if T2 is not applicable.
Multiple control	
M1	Multiple meet criterion for differentiation and alone does not have the highest mean.
M2	M1 applies to all test conditions, then ignore alone.
M3	Two differentiated conditions and alone are the lowest (compute means); outcome: multiply controlled (i.e., automatic plus a social contingency).

Notes: Series = every alone-attention-play-demand sequence; *LCL* = lower criterion line (play condition mean minus its standard deviation); *UCL* = upper criterion line (mean of the play condition plus its standard deviation)

the relatively wide range defined by the LCL and UCL. Otherwise, the effect of attention is immediate and consistent.

Table 28.2 Structured visual analysis for Annette, Bob, Jed, and Max

	Revised Hagopian criteria		
	General	Specific	Outcome
Annette	D6		Attention
Alone			
Attention		D1, T2	
Demand			
Bob	D6		Attention
Alone		T1	
Attention		D1	
Demand			
Jed	D2, D3, D6		Demand
Alone			
Attention			
Demand		D1	
Max	D2, D3, D6		Demand
Alone			
Attention			
Demand		D1	

On occasions when the UCL is below 0.5, the UCL is arbitrarily set at 0.5 (D3). This is the case for Jed and Max. For both of these participants, only demand met the criterion for differentiation (D1), making this condition the outcome of the functional analysis. Attention, demand, and play present steady-state responding at near-zero levels for both datasets. The effect of demand is more consistent and demonstrates less overlap for Max. By contrast, Jed's demand time series presents two *dips* that overlap with some of the undifferentiated conditions. This lack of consistency may be attributed to the effect of demand being less immediate for Jed—to explore this possibility further, the effect of longer demand sessions or the presence of within-session trends could be evaluated. Even though the effect of demand is differentiated in both participants, the relatively low rate of problem behavior could have easily become undifferentiated in the presence of higher response variability in the other conditions of the assessment.

Synergy Between Statistical and Visual Analyses

Arguments for and Against

Applied behavior analysts moved away from inferential statistics in part due to the treatment of within- and between-subject variation as residuals (error). By contrast, variation is often meaningful in applied behavior analysis. Specifically, the continuous analysis of a time series at the individual level is critical to deliver services in applied behavior analysis. For example, one participant may respond to a reinforcement-based intervention (e.g., token reinforcement) within one session, whereas another may require 10 sessions for the intervention to reach its peak, yet a third participant may show no effect whatsoever prompting a swift change in course on the part of the interventionist (e.g., conducting new preference or reinforcer assessments, changing the ratio requirement of the token economy, etc.). An idiographic approach requires a continuous feedback loop between intervention effect monitoring and procedural adjustments. This continuous process may not be possible solely by evaluating aggregated effects *after* the intervention.

Another argument against statistics in applied behavior analysis poses that statistical significance is heavily influenced by sample size, data variability, and data distribution. These three aspects made traditional inferential statistics ineligible for small-*n* experimental designs. Specifically, the modest number of participants in single-subject experimental designs negates *significant* results, even for hugely effective interventions. Moreover, analyzing trends as well as variability as a form of random variation or error can penalize bona fide effects of behavior–analytic interventions, where variability can be attributed to the gradual effect of the independent variable (i.e., trends) or procedural fine-tuning (i.e., ideographic approach).

Finally, single-subject datasets cannot accommodate traditional data distributions including the normal distribution due to the limited number of observations often reported in SCEDs. Fortunately, statistical developments over the last few decades can help to address some of these concerns.

Statistics are needed to enter the high-stakes outcome research literature upon which decisions for treatment policy and treatment prioritization are often made (see for example Keenan & Dillenburger, 2011, for a discussion). Effect size metrics and inferential statistics are sorely needed in applied behavior analysis, if not to compete, at least to achieve a common language with randomized controlled trials (RCT) and other group-based designs. On the other hand, statistical analyses should acknowledge the ideographic, hierarchical, and longitudinal nature of behavior–analytic interventions.

Statistical Techniques

Statistical techniques in SCED remain an active area of study where widely accepted methodological recommendations are lacking. In the following section, we evaluate a selection of the most promising (and a few of the most popular) statistical techniques that have been developed for SCEDs. In the interest of brevity, we have classified the analytical techniques and effect size metrics for SCEDs in four groups: non-overlap and other non-parametric indices, mean-based effect sizes, analyses producing a *p* value as the main outcome, and regression-based analyses (a more detailed classification has been proposed by Manolov & Moeyaert, 2017). Below, we present samples of the most commonly used analyses within these groups. Systematic comparative summaries of these techniques can be found in Tables 28.3 and 28.4.

Non-overlap and Other Non-parametric Indices

Non-overlap indices focus on a key feature of across-phase visual analysis by quantifying the extent to which the range of variation in baseline and treatment phases overlap. The greater the overlap, the less confident one can be in the treatment effect. These indices are easy to compute, require minimal training, and have been widely used in the literature. In addition, they do not impose data distribution assumptions (e.g., normality). Yet, they are subject to numerous sources of bias. First, some of these indices are computed on the basis of a selection of the observations. For example, the percentage of non-overlapping data points (PND) is obtained by computing the percentage of data points during treatment that is above the highest baseline data point. Second, with few exceptions, the value of a non-overlap index is not indicative of the magnitude of the effect but simply of the level of overlap. For example, an intervention increasing the level of baseline responding by 100 can produce a relatively lower non-overlap index compared to another intervention increasing responding by 1.5, assuming that the former incurs on greater overlap. Moreover, outliers can easily bias these indices as they often cause overlap. Additional limitations to non-overlap indices include their limited use in meta-analysis or moderator analysis (other than by averaging). They are not amenable to inferential statistics, or the analysis of co-variables, and they do not produce *p* values, although it is possible to obtain confidence intervals for some of them (Parker & Vannest, 2009). Moreover, there has been limited research on what represents a small, medium, or large non-overlap index. Parker and Vannest (2009) obtained percentiles of common non-overlap indices, providing some basis to ascertain effect magnitude (Table 28.3). Some non-overlap indices are less biased than others. For example, the NAP (non-overlap of all pairs), the PAND (percentage of all non-overlapping data points), and the Tau-*U* include all the values in the time series in the calculation process and are less vulnerable to the effect of outliers.

The log-response ratio is a non-parametric effect size index based on proportional change of rates of behavior across contiguous study phases (Pustejovsky, 2015). Log-response ratio effect sizes do not rely on often unverified parametric assumptions, setting them apart from mean-based effect sizes. Unlike non-overlap indices, it has been proposed to be fully amenable to meta-analysis (Pustejovsky, 2018).

Mean-Based Effect Sizes

The standardized mean difference (SMD) is the difference between the intervention level and baseline level in standardized units. In other words, the difference between the intervention and baseline mean is divided by the pooled within-case standard deviation (or the standard deviation of baseline). This is similar to Cohen's *d* developed for group studies (Cohen, 1992). Cohen's *d* can be corrected for small sample size bias (the standard deviation for each group is weighted by the sample size), which is Hedges' *g*. A version of Hedges' *g* was developed for use with SCEDs and is known as the *between-case standardized mean difference* (BC-SMD;

Table 28.3 Key characteristics of selected single-subject effect size metrics and analytic techniques

	Concept	Range of usable values	Key references
Non-overlap and other non-parametric indices			
NAP	*Non-overlap of all pairs*, percentage of data that improve from the baseline phase to the intervention phase	$P_{10} = 50\%$; $P_{25} = 69\%$; $P_{50} = 84\%$; $P_{75} = 98\%$; $P_{90} = 100\%$	Parker and Vannest (2009)
PND	*Percentage of non-overlapping data*, ratio of number of Phase B data points above the lowest/highest data point in Phase A divided by Phase B total data points	Range, 0–100%; >70% effective intervention; 50–70%, questionable effectiveness; <50% no observed effect.	Parker and Vannest (2009), Scruggs and Mastropieri (1998)
PAND	*Percentage of all non-overlapping data, m*inimum number of data points removed from Phase A and/or Phase B to eliminate all overlap between phases.	$P_{10} = 60\%$; $P_{25} = 69\%$; $P_{50} = 82\%$; $P_{75} = 93\%$; $P_{90} = 100\%$	Parker et al. (2007), Parker and Vannest (2009)
Tau-*U*	Non-overlap index that accounts for changes in level and trend in Phase B. It has the ability to correct for baseline trend	$P_{25} = 0.56$; $P_{50} = 0.84$; $P_{75} = 1.00$ (with baseline trend correction)	Brossart et al. (2018), Parker et al. (2011), Tarlow (2017)
Log-response ratio	Metric based on proportionate change	Not available	Pustejovsky (2015)
Mean-based effect sizes			
WC-SMD	*Within-case standardized mean difference*, difference between the baseline and treatment means divided by the baseline standard deviation	Range, $-\infty$ to $+\infty$; very small, 0.01–0.19; small, 0.20–049; medium, 0.50–0.79; large, ≥0.80	Busk and Serlin (1992)
BC-SMD	*Between-case standardized mean difference*, difference between treatment and baseline means divided by the square root of the sum of the variance of observations within cases plus the variance of observations between cases	Range, $-\infty$ to $+\infty$; very small, 0.01–0.19; small, 0.20–049; medium, 0.50–0.79; large, ≥0.80	Hedges et al. (2012), Pustejovsky et al. (2014)
Analyses producing a p value as the main outcome			
Randomization test	Probability of the rank of the actual baseline and treatment observations relative to all possible permutations of ranks	Same as a one-tailed Type I error probability. If $p \leq 0.05$, then the distribution of higher (or lower) treatment observations is statistically significant	Heyvaert and Onghena (2014)
Masked visual analysis	Probability that an independent visual analyst correctly guesses the true intervention sequence order	Same as a one-tailed Type I error probability. If $p \leq 0.05$, then the distribution of higher (or lower) treatment observations is statistically significant	Ferron and Jones (2006)
Regression-based analyses			
Hierarchical linear modeling and Cohen f^2 effect size	Variance explained by purposely selected hierarchical factors (e.g., behavior, subject, treatment). The Cohen f^2 effect size can be computed by comparing a target model with a reference model	Range, $-\infty$ to $+\infty$; small, 0.02–0.15; medium, 0.15–0.34; large, ≥0.35	Lorah (2018), Van den Noortgate and Onghena (2003)

Notes: Major single-subject designs include reversal, multielement, multiple-baseline, and changing-criterion designs. Parenthesis indicate that the standard can be met if modelled. Local trends denote carryover effects, multiple-treatment interference, and phase transition trends. *BC-SMD* = Between-case standardized mean difference; *HLM* = Hierarchical linear modeling; *LRR* = Log-response ratio; *MVA* = Masked visual analysis; *NAP* = Non-overlap of all pairs; *PAND* = Percentage of all non-overlapping data; PND = Percentage of non-overlapping data; *RT* = Randomization test; *WC-SMD* = Within-case standardized mean difference

Pustejovsky et al., 2014). BC-SMD can also be characterized as a regression-based metric, as it is estimated using a two-level hierarchical linear model; Level 1 is a within-case regression model and Level 2 is between-case variation in regression coefficients (Pustejovsky et al., 2014). Because the difference between the baseline and intervention data is standardized using both the within- and between-case standard deviation, BC-SMD is assumed to be on the same scale as group designs, therefore, Cohen's *d* scale can be used for interpretation. Two additional SCED metrics standardized mean difference are the mean phase difference (MPD; Manolov & Solanas, 2013) and mean baseline reduction (MBLR; Campbell, 2004). Both formulas for MPD and MBLR are similar to Cohen's *d* but without the standard deviation denominator. Thus, they are unstandardized mean difference metrics.

Analyses Producing a *p* Value as the Main Outcome

We have selected the non-parametric randomization test and masked visual analysis to illustrate this category. The randomization test estimates the probability of the observed sequence in level changes across phases, relative to the null hypothesis (i.e., no changes in level across phases). Levin et al. (2012) provide a practical example:

> [S]uppose that there are 8 alternating A and B phases (i.e., an ABABABAB design), each consisting of one or more outcome observations per phase. Further suppose that it had been predicted that the intervention (B) phases would yield generally higher outcome observations than the baseline (A) phases. With 8 total phases, 4 A and 4 B, there are 8!/4!4! = 70 possible assignments of 4 observations (or means based on multiple observations per phase) apiece to two groups, A and B. For each possible assignment, the mean difference between the B and A observations is calculated, yielding a permutation distribution of 70 mean differences. Now suppose that the actual mean difference (i.e., the mean difference produced by the study's 4 actual B phase observations and 4 actual A phase observations) turned out to be the third largest of all 70 mean differences. Assuming that the 70 mean differences are all equally likely, the probability of obtaining a mean difference as large as or larger than the one actually observed is 3/70 = 0.043, with a pre-designated one-tailed Type I error probability (α) of 0.05, would be a statistically significant result. (p. 604)

Ease of calculation, fitness to all major SCEDs (including the multielement design), and lack of data distribution assumptions are distinct advantages of randomization tests. However, the power of randomization tests is diminished in multielement designs using a fixed condition alternation order (Levin et al., 2012), which is a common approach to functional analysis (e.g., Hammond et al., 2013). In addition, a randomization test is fully compatible with other statistical techniques, including non-overlap effect sizes, mean-based effect sizes, and regression-based analyses (see a practical illustration of this combined approach in Heyvaert & Onghena, 2013).

Ferron and Jones (2006) have proposed using randomization strategies as part of a masked visual analysis process with the aim of reducing Type I errors (see also Ferron et al., 2017). For example, in a multiple-baseline design with four participants, the experimenter would hide phase transitions in the graph and randomize the order of the participants within the graph. The experimenter would then ask an independent visual analyst to guess the time points at which the intervention started for each participant. In this example, the probability of correctly guessing the order in which the intervention started for each participant by chance equals $\frac{1}{n!} = \frac{1}{24} = .042$, where n is the number of participants in the multiple baseline design. Therefore, if a visual analyst correctly identifies the order of the intervention sequence, this would ensure that the Type I error is below 0.05. Moeyaert et al. (2020) have developed a user-friendly mobile app to conduct masked visual analysis.

Regression-Based Analyses

Different types of regression-based approaches have been used for SCEDs such as ordinary least squares (OLS; Huitema & McKean, 2000), generalized least squares (GLS; Swaminathan et al., 2014), and multilevel models (Van den Noortgate & Onghena, 2003). OLS is a parametric approach that can quantify the change in level between baseline and intervention phases, as well as the change in trend (Huitema & McKean, 2000). Additional parameters can be added to the model depending on the research question (e.g., it can be used to estimate the baseline level at the start of data collection, the trend during baseline, and the changes in trend and/or level). However, OLS makes several assumptions, including the assumption of normality, homoscedasticity (equality of variances across conditions), and independence of errors. In instances where these assumptions may be inappropriate to make (e.g., if heteroscedasticity or autocorrelation is present), the GLS approach is a more viable and appropriate alternative. GLS is similar to OLS, except that it can reflect count data such as frequency or rate (Declercq et al., 2019) and account for autocorrelation by adjusting the residuals (Swaminathan et al., 2014). Like OLS, GLS is able to reflect both change in slope and change in level together in one model and provide separate estimates of these regression parameters.

Hierarchical linear modeling is an extension of single-level regression analysis and accounts for the nesting of measurement occasions within participants. This modeling approach can be used to estimate change in level and/or slope for individual participants and across participants. As such, HLM is able to estimate between-case differences in intervention effectiveness. If a large amount of between-case variance is found, moderators can be added in an effort to explain variability in intervention effectiveness between participants.

Dataset produced in behavior–analytic studies can be characterized as having a hierarchical or multilevel structure. Levels can be construed as key aspect of the data source that may determine different aspects of the variability. For example, in a study including several multiple baseline designs across behaviors for three participants, some of the differences observed in the behavior may be explained by differences within participants across sessions (i.e., variability across time points) and by differences between participant characteristics (variability across subjects). In addition, subject personal characteristics (e.g., diagnostic group, age, standardized outcomes) may also be included as covariates within the multilevel analysis.

An exciting aspect of multilevel analysis is its flexibility. It is possible to add as many levels to the analysis, as it would be conceptually and statistically appropriate.[4] It is also possible to add a *study* level in order to generalize intervention effectiveness across similar studies, thereby conducting a meta-analysis (Moeyaert, Ferron, et al., 2014a). It is also possible to compute the effect size of key predictors in HLM (e.g., treatment status) and to compare the goodness of fit of various models (Lorah, 2018).

Statistical Analysis: A Case Study with a Two-Level Hierarchical Model

Among the various statistical approaches described to evaluate treatment effects in single-subject data, multilevel analysis or hierarchical linear modeling (HLM) has various distinct advantages. First, acknowledging the hierarchical nature of SCED data can, potentially, minimize unexplained variance and effect underreporting (Baek et al., 2014; Moeyaert et al., 2014a, 2017). In addition, the ability to add predictors can account for characteristics of SCED, which have been ignored in alternative approaches. For example, few of the traditional effect size metrics discussed here have been adapted to multielement designs; one of the most common research designs in applied

[4] Adding a specific level might have conceptual sense, but if that factor has few units, then the estimates could be biased and it might be preferable to omit that level.

behavior analysis (Virues-Ortega et al., 2016). The case study below illustrates the use of multilevel analysis in the functional analyses by Conners et al. (2000) and exemplifies the synergistic use of visual and statistical analyses in SCEDs (see section "Visual Analysis: A Case Study").

We will consider two hierarchical levels: measurement occasions (Level 1) are nested within subjects (Level 2). *Behavior* refers to the amounts of behavior measured in responses per minute. *Subject* identifies each of the four participants. The key predictor for the behavior level is *treatment status*. For the purposes of this analysis, the differentiated conditions of the functional analysis (attention for Annette and Bob, and demand for Jed and Max) are considered as target treatment conditions, whereas undifferentiated conditions (i.e., alone, play, and demand for Annette and Bob; and alone, attention, and play for Jed and Max) will be considered nontarget treatment conditions. Therefore, we created the variable *treatment status (tts)* as a dummy variable, coded as 1 for the sessions of differentiated conditions and 0 for the sessions of undifferentiated conditions. *Session* refers to the ordinal session number for each participant. The behavior level, Y_{ij}, is the behavior level of participant (j) at measurement occasion (i). The independent variable, tts_{ij}, is a dummy variable, indicating the treatment status of participant (j) at measurement occasion (i). Therefore, β_{0j} indicates the expected behavior level for participant j during the undifferentiated condition and β_{1j} indicates the expected change in behavior level between the undifferentiated and differentiated condition for participant j. The within-participant errors (e_{ij}) are assumed to be homogeneous and normally distributed, with a lag1 autocorrelation. A lag1 autocorrelation indicates that two consecutive errors are correlated, which is likely in repeated measures design. The level 1 model is displayed in Eq. 28.1:

$$\text{Level 1 (within participants)}:$$
$$Y_{ij} = \beta_{0j} + \beta_{1j} D_{ij} + e_{ij} \text{ with } e_{ij} \sim N\left(0, \sigma_e^2\right) \quad (28.1)$$

The level 1 parameters (at the right side of the equation sign in Eq. 28.1) are allowed to vary at the second level as it is to be expected that behavior levels during the undifferentiated treatment (β_{0j}'s), as well as changes in level between the undifferentiated and differentiated treatments (β_{0j}'s), vary between participants. Therefore, these parameters are a function of an overall average effect across participants (reflected by the θ's) and individual differences (reflected by the u's). This is reflected in the Level 2 model, displayed in Eq. 28.2:

$$\text{Level 2 (across participants)}:$$
$$\begin{cases} \beta_{0j} = \theta_0 + u_{0j} \\ \beta_{1j} = \theta_1 + u_{1j} \end{cases}$$
$$\text{with} \begin{bmatrix} u_{0j} \\ u_{1j} \end{bmatrix} N\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} \sigma_{u_0}^2 & \\ \sigma_{u_0 u_1} & \sigma_{u_0}^2 \end{bmatrix} \right), \quad (28.2)$$
$$\text{and } e_{ij} \sim N\left(0, \sigma_e^2\right)$$

θ_0 refers to the overall behavior level during the undifferentiated condition across the J participants. The deviation of participant j from the overall level θ_0 is indicated by u_{0j}. These deviations are assumed to be normally distributed around 0 with a variance of u_{0j} As such, $\sigma_{u_0}^2$ represents the between-participant variance of the behavior level during the undifferentiated conditions of the functional analysis. Similarly, θ_1 refers to the overall change in behavior level between the undifferentiated and differentiated conditions across the J participants. u_{1j} refers to the deviation of participant j from the difference in level. These deviations are assumed to be normally distributed with an average of 0 and variance $\sigma_{u_1}^2$. Thus, $\sigma_{u_1}^2$ represents the between-participant variance of the change in level. Likewise, the within-participant errors, e_{ij} are assumed to be normally distributed around 0 with a variance of σ_e^2. Therefore, σ_e^2 indicates the within-participant error variance. The within-participant errors (i.e., e_{ij} 's) are assumed to be correlated. By substituting the Level 2 equations into the Level 1 equation, the combined two-level hierarchical linear model can be written as:

Table 28.5 Design matrix for one participant

Name	Participant	Treatment status (tts)	Session	Behavior (beh)
Bob	1	0	1	7.21
Bob	1	1	2	21.32
Bob	1	0	3	8.52
Bob	1	0	4	6.53
Bob	1	0	5	7.26
Bob	1	1	6	12.01
Bob	1	0	7	3.17
Bob	1	0	8	9.10
Bob	1	0	9	8.91
Bob	1	1	10	11.44
Bob	1	0	11	2.14
Bob	1	0	12	4.52
Bob	1	0	13	1.39
Bob	1	1	14	6.24
Bob	1	0	15	3.06
Bob	1	0	16	1.43
Bob	1	0	17	3.55
Bob	1	1	18	14.72
Bob	1	0	29	4.70
Bob	1	0	20	7.65

$$y_{ij} = \theta_0 + u_{0j} + \left(\theta_1 + u_{1j}\right) D_{ij} + e_{ij} \text{ with } \begin{bmatrix} u_{0j} \\ u_{1j} \end{bmatrix} N\left(0, \Sigma_v\right), e_{ij}\ N\left(0, \sigma_e^2\right) \quad (28.3)$$

The basic two-level HLM approach introduced in Eq. 28.3 is promising and its appropriateness in summarizing SCED data has been empirically validated through large-scale Monte Carlo simulation studies (e.g., Ferron et al., 2010).

We evaluated the current multilevel model (presented in Eq. 28.3) using the statistical package *R* for Mac (Urbanek et al., 2020). Table 28.5 presents the coding of the design matrix for one randomly selected participant (i.e., Bob). For a detailed discussion on how to appropriately setting up the design matrix, see Moeyaert, Ugille, et al. (2014b). The *R* code for the proposed analyses is displayed and described in Fig. 28.4. The results of the two-level HLM analysis are presented and described in Fig. 28.5. The output indicated that the difference in behavior level between the target and non-target conditions is estimated to be 5.86, and is statistically significant, $\hat{\theta}_1 = 5.86$, $t(103) = 2.07$, $p = 0.04$. This analysis provides a quantitative indication of functional analysis differentiation in this context. However, the same analysis could be used to quantify treatment effects. We encourage the interested reader to check Becraft et al. (2020) for a tutorial on using multilevel models and Rodabaugh and Moeyaert (2017) for additional information.

Conclusion

Some researchers have argued that the use of visual inspection alone as a standard for demonstrating functional relations may inhibit communication with researchers from other fields unaccustomed to this methodology (Falligant et al., 2020). The modest interrater agreement indices reported in the literature (Ninci et al., 2015), in addition to other sources of bias present in SCED, call for more stringent methodological standards for visual analysis in SCED as applied

```
install.packages ("nlme")
library("nime")

regl_AR_HE<-Ime(beh ~ tts, random=~tts |name,data=raw, na.action="na.omit",
            correlation=corAR1(form=~ 1|name),weights = varIdent(form = ~1 |
tts),
            control=list(opt = "optim",
            optctrl = list(method = "REML ")))

summary (regl_AR_HE)
```

In order to run the two-level hierarchical linear model, the R package *"nlme"* needs to be installed *[install.packages("nlme")]* and loaded *[library ("nlme")]*. The package *"nlme"* allows running a linear mixed effects model. The function *"lme()"* is called and between the brackets the specific model is defined, together with some optional arguments. The behavior outcome score (*"beh"*) is regressed on the dummy coded treatment variable (*"tts"*, or the dummy coded variable indicating the undifferentiated versus differentiated condition). The intercept and *"tts"* are allowed to vary between participants (indicated by random =*~tts|names*). The argument *"data=raw"* indicates that we are using the data saved in the dataframe *"raw"*. The next argument *"na.action="* is needed in case there are variables with a missing score (na = not applicable). The *"correlation=corar1"* argument indicates that we are modelling a lag1 autocorrelation per participant (*"|name"*). The "weights" defines that the within-participant variance is heterogeneous (i.e., a different amount of variance in the treatment versus non-treatment condition is modeled). Lastly, the control and *optCtrl* define that the restricted maximum likelihood estimation approach is used (which is recommended when working with a small number of observations). The obtained output is saved in *"reg1_AR_HE"* (but any other name can be chosen) and a display of this output is obtained by running *"summary(reg1_AR_HE)*. The obtained output is included in Figure 5.

The first part of the output provides goodness of fit indices (i.e., AIC, BIC and the Log Likelihood). These indices can help to choose between multiple competing nested models. The smaller the values for the fit indices, the better the model fit. The hierarchical liner model is very flexible. For instance, different functional forms for the trend (e.g., linear trend, quadratic trend, etc.) and/or autocorrelation can be specified. The model can also be expanded by including participant-specific covariates (e.g. gender, age, etc.). Competing models can be compared using these fit indices. The next part of the output indicates the random components estimates, i.e., the estimate of the between-participant variance of behavior level in the non-differentiated condition (i.e., $\sigma^2_{u_0} = 2.44^2$), the between-participant variance of changes in behavior level (i.e., $\sigma^2_{u_1} = 5.03^2$), the covariance between the non-differentiated and differentiated condition ($\sigma_{u_0 u_1} = 2.44 \times 5.03 \times 0.60$), and the within-participant variance. The within-participant variance is estimated separately for the non-differentiated (i.e., $\sigma^2_e = 1.35^2$) and the differentiated treatment condition [i.e., $\sigma^2_e = (5.13 \times 1.35)^2$]. This indicates that most variance is due to difference in behavior level between-participants, and within the treatment condition. The next lines in the output provide an estimate of the lag1 autocorrelation (Phi = 0.29). This value indicates that there is a decent amount of correlation between two consecutive errors. Next, the fixed effect parameter estimates are provided. The estimated behavior level during the non-differentiating condition is 1.67 and not statistically significantly different from 0 [$\hat{\theta}_0 = 1.67$, $t(103) = 1.35$, $p = .18$]. The difference in behavior level between the non- differentiating and differentiating condition is estimated to be 5.86, and is statistically significant at the .05 level [$\hat{\theta}_1 = 5.86$, $t(103) = 2.07$, $p = .04$]. The within-participant standardized residuals indicate that the median error is close to 0, and that there are no significant outliers (as the standardized errors range from -2.85 to +2.87). The last line of code indicates that there is a total of 108 observations, nested within 4 participants.

Fig. 28.5 *R* output for a two-level hierarchical linear model with lag1 autocorrelation and heterogeneity of variances behavior analysis enters the high-stakes outcome research arena.

We expect that the status of visual analysis and SCED as mainstream methods of treatment evaluation and data analysis will be established more firmly as progress continues in the following fronts: (a) widespread evaluation of methodological quality in SCED (as it is customary for RCTs), (b) widespread evaluation of the interrater reliability of visual analysts (as it is the case for interobserver agreement or treatment fidelity), (c) widespread use of intention-to-treat analysis and/or consecutive case reporting, (d) widespread use of structural guidelines for visual analysis (e.g., Hagopian et al., 1997; Fisher et al., 2003), and (e) widespread use of statistical analyses and meta-analysis-compatible effect size metrics *in conjunction with* visual analysis.

Progress in these various fronts would require a level of consensus in the field that is yet to be achieved. However, the basic elements to attain these standards are already well understood. A challenge of particular importance for incorporating statistical analysis in SCED results from the limited sensitivity of the available statistical techniques to the logic of SCEDs. For example, practically no statistical technique properly models steady-state responding, weights within-subject replications, or provides an estimate of carryover effect (Table 28.4). These SCED-specific features ought to be modeled in a unified theory of SCED data analysis. In this respect, hierarchical models offer the greatest flexibility to researchers and practitioners to assess these various effects. The practical conjunction of statistical and visual analyses may depend on the theoretical consistency of these two approaches to data analysis and data interpretation.

29 Precursor Behaviors to Severe Challenging Behaviors

Devon Ramey, Emma Craig, Ciara Gunning, and Jennifer Holloway

Introduction

Challenging behavior in children is common during various developmental stages. While most children will outgrow these issues, behavioral intervention is required when a challenging behavior persists or occurs at such a high frequency or intensity that it has serious repercussions for the individual (Powell et al., 2006). However, there are some challenging behaviors that present a number of safety risks to the individual and/or caregivers during assessment and treatment. These severe challenging behaviors can be more difficult to address due to their intensity, frequency, or harmful nature. To minimize potential risks, practitioners often intervene on the precursor behaviors that reliably precede episodes of severe challenging behavior. Precursor behaviors are considered milder or innocuous behaviors that belong to the same response class as the severe challenging behavior, meaning they have the same maintaining contingency (Smith & Churchill, 2002). By assessing for and treating these precursor behaviors, severe challenging behaviors can be reduced or eliminated altogether (Fritz et al., 2013).

This chapter will first provide a brief overview of challenging behavior and give examples of more severe challenging behavior observed in individuals with developmental disabilities. Next, the ethical and practical considerations of treating severe challenging behavior will be examined. Precursor behaviors will then be defined, and the theoretical perspectives behind these behaviors will be discussed. Strategies for identifying precursor behaviors, including the precursor functional analysis, will be evaluated. Finally, this chapter will review some of the function-based treatments for precursor behaviors that have been successfully demonstrated within the literature.

Challenging Behavior

All individuals have engaged in challenging behavior at some point in their lives. In fact, it is developmentally normative for children and adolescents to engage in certain forms of challenging behavior at various stages of development (Ogundele, 2018). Infants and toddlers, for example, will exhibit tantrums, hyperactivity, non-compliance, and even aggression as they are still acquiring social–emotional competence and self-regulation (Powell et al., 2006). On the other hand, it is not uncommon for adolescents to act

defiant and demonstrate more risk-taking and impulsive behaviors due to pubertal development and increased peer pressure (Milkman & Wanberg, 2012). While many behavioral topographies are part of typical childhood development, it is the "persistence, intensity, and pervasiveness" of challenging behavior that becomes a cause for concern and can result in the need for professional support and intervention (Powell et al., 2006, p. 26).

During the early childhood years, it can be tricky for some practitioners to differentiate between challenging behaviors that are developmentally appropriate and those that are more worrisome (Dunlap et al., 2006). When identifying a challenging behavior, it is important to consider how the problem behavior impacts the person's physical well-being, socialization, and educational outcomes (Gore & Umizawa, 2011; McTiernan et al., 2011). In view of this, two definitions of challenging behavior have been proposed. Smith and Fox (2003) defined challenging behavior as "any repeated pattern of behavior, or perception of behavior, that interferes with or is at risk of interfering with optimal learning or engagement in pro-social interactions with peers and adults" (p. 5). Another commonly recognized definition of challenging behavior comes from Emerson (2001). He defined challenging behavior as:

> Culturally abnormal behavior(s) of such intensity, frequency or duration that the physical safety of the person or others is likely to be placed in serious jeopardy or behavior which is likely to seriously limit use of, or result in the person being denied access to, ordinary community facilities. (p. 3)

These definitions are more useful than a topographical list of behaviors (e.g., aggression, elopement) because they define challenging behavior by its impact on the quality of life of the person and others (Oliver et al., 2003).

While it is estimated that 10%–15% of typically developing preschoolers engage in some form of mild-to-moderate challenging behavior (Campbell, 1995), research has found that individuals with developmental disabilities are at a greater risk for displaying challenging behavior that is more severe and persistent over time (Lory et al., 2020). In fact, studies have shown that children with intellectual disability (ID) are three to seven times more likely to engage in challenging behavior when compared to their neurotypical peers (Alimovic, 2013; de Ruiter et al., 2007). The higher rates of challenging behavior among individuals with developmental disabilities are thought to be associated with communication and social challenges in this population (Buschbacher & Fox, 2003; Holden & Gitlesen, 2006; Sigafoos et al., 2003). For individuals with ID, prevalence estimates of challenging behavior have ranged from 48% to 60% (Simó-Pinatella et al., 2019). However, this prevalence rate increases substantially with a secondary diagnosis of autism spectrum disorder (ASD; McCarthy et al., 2010; McClintock et al., 2003). As a matter of fact, challenging behavior occurs far more frequently among autistic individuals than individuals with other developmental disabilities (Gregori et al., 2020). The reported prevalence of challenging behavior among individuals with ASD varies, but it has been found to be as high as 82% (Murphy et al., 2009) to 94% (Jang et al., 2011; Matson et al., 2009).

Severe Challenging Behavior

Among the various topographies of challenging behavior, there are some forms that are more dangerous than others because they pose a risk to the health and safety of the individual and caregivers. These severe challenging behaviors can cause physical harm to the individual or others, and they are estimated to be present in 10%–15% of the developmental disability population (Lowe et al., 2007). An operational definition of severe challenging behavior proposed by Qureshi and Alborz (1992) includes any behavior that:

(a) Has at some time caused more than minor injuries to [the individual] or others
(b) Has at some time resulted in the destruction of the [individual's] immediate living or working environment
(c) Behaviour [sic] occurring *at least weekly* which either:

(i) Places [the individual] in physical danger
(ii) Requires intervention by more than one member of staff for control
(iii) Causes damage which cannot be rectified by immediate care staff
(iv) Causes at least an hour's disruption
(d) Has caused disruption lasting more than a few minutes at least daily. (p. 139)

Severe challenging behaviors are often easy to recognize because they are highly disruptive, harmful, and/or destructive (Chandler & Dahlquist, 2014). Examples of severe challenging behavior include, but are not limited to, aggression (e.g., hitting, pinching, scratching, biting, pulling hair), self-injurious behavior (e.g., head banging, self-hitting, self-biting, bruxism, eye gouging or poking, hair pulling), property destruction (e.g., window breaking, throwing furniture or objects, breaking or hitting objects), inappropriate sexual behavior (e.g., public masturbation, touching or grabbing the genitalia of others), pica or coprophagy, and vomiting or rumination (Lowe et al., 2007; Lydon et al., 2015).

Beyond the risk of injury to the individual and those around them, severe challenging behavior can have a number of other deleterious effects. First, severe challenging behavior will often prevent an individual from being fully integrated into the general education classroom or community (Agran et al., 2018). Individuals with severe challenging behavior are also more likely to experience intrusive and restrictive practices such as seclusion or restraint (Webber et al., 2011). Sadly, these aversive practices can result in emotional trauma, injury, or even death to the individual receiving such treatment (Ferleger, 2008; Tilli & Spreat, 2009). In addition to this, the misuse of medication as a form of chemical restraint to manage severe challenging behavior can lead to adverse side effects such as agitation, nausea/vomiting, lethargy, and tics (Matson et al., 2000). Severe challenging behavior can also have a negative effect on the emotional well-being of those close to the individual. Research has found that these behaviors in children with developmental disabilities are a strong predictor for parenting stress, which can lead to parent depression, poorer physical health, and family or marital problems (Neece & Chan, 2017). It has also been discovered that severe challenging behavior is a strong predictor of stress and burnout among support workers (Ryan et al., 2019). Overall, these findings would suggest that severe challenging behavior has a negative impact on the quality of life of individuals with developmental disabilities and their caretakers.

Treatment and Assessment Considerations

Without effective intervention, challenging behavior is likely to persist across the lifetime of an individual with developmental disabilities, which in turn can hinder their socialization, education, and inclusion (Matson & Rivet, 2008). Two commonly used approaches for treating severe challenging behavior are function-based intervention and crisis management (Stevenson et al., 2019). Crisis management, or emergency intervention, is the use of restrictive procedures in response to an episode of severe challenging behavior that is typically not included within the individual's Behavior Intervention Plan (Webber et al., 2011). While crisis intervention strategies have been shown to be effective for some individuals, there is a lack of research demonstrating their effectiveness for individuals with developmental disabilities (Stevenson et al., 2019). There are two possible reasons for this. First, crisis management procedures often include language-intensive activities such as debriefing or planning sessions, which may be difficult for individuals with language delays (Stevenson et al., 2019). Furthermore, crisis interventions rarely take into consideration the function of the severe challenging behavior, so they will often inadvertently reinforce the behavior rather than reduce it (Ryan et al., 2007). Research has found that function-based interventions are more effective in diminishing challenging behavior than non-function-based approaches (Ingram et al., 2005; Hurl et al., 2016).

Function-based intervention is considered the best practice for treating severe challenging behavior, and there are decades of empirical research to demonstrate its efficacy across a wide range of behaviors, diagnoses, and settings (Weddle & Carreau, 2018). Function-based approaches are effective in reducing challenging behavior because they acknowledge and address the idiosyncratic variables that are maintaining the behavior (Hurl et al., 2016). To identify these variables, a variety of indirect and direct assessments can be implemented within a systematic process known as the functional behavior assessment (FBA; O'Neill et al., 2015). While some studies have demonstrated that indirect and direct assessments can accurately determine the maintaining function of challenging behavior (Lewis et al., 2015), there is other evidence to suggest that direct or descriptive assessments have low validity, although they are commonly used in clinical practice (Tarbox et al., 2009; Wightman et al., 2014). Of the various FBA methodologies, the experimental functional analysis (EFA) is considered the most accurate assessment and is generally considered the "gold standard" for determining behavioral function (Hanley et al., 2003).

The EFA is the most precise method for informing function-based intervention because it is the only assessment that can provide an empirical demonstration of the causal relationships between challenging behavior and environmental variables (Lerman & Iwata, 1993). During the EFA, the practitioner systematically manipulates antecedent and consequent events within highly controlled conditions to determine which variables are maintaining the challenging behavior (Iwata et al., 1982/1994). During the assessment, the individual is exposed to a variety of test conditions, in which the maintaining variables are present, and a control condition, where these variables are absent (see Chap. 26). There is a substantial corpus of research that has demonstrated the validity of the EFA for evaluating challenging behaviors and developing effective function-based treatments (Beavers et al., 2013; Hanley et al., 2003).

Despite the proven effectiveness of the EFA for identifying functional relations, there are some ethical and practical considerations with its use for severe challenging behavior. First, the traditional EFA approach may not be appropriate for high-intensity, severe challenging behavior that occurs so infrequently (e.g., once per day), that it is unlikely to be evoked during the EFA sessions (Fahmie & Iwata, 2011). While some researchers have attempted to address this issue by extending the duration of the sessions (e.g., all-day functional analysis; Kahng et al., 2001), this is not always ethical or feasible. This modification might be considered unethical because the individual is exposed to states of deprivation (e.g., social attention withheld) for extended periods of time (Tarbox et al., 2004). Furthermore, this adaption to the EFA may not be practical within organizations where resources are limited (Tarbox et al., 2004).

Another ethical consideration with the use of the traditional EFA is that the severe challenging behavior is purposefully evoked and reinforced during the test conditions. While this is necessary to demonstrate a functional relationship, temporary increases in the severe challenging behavior pose a safety risk to the individual and others (Smith & Churchill, 2002). In a retrospective review, Kahng et al. (2015) found that the rate of injuries to individuals tended to be higher during EFA sessions than outside of them. Considering this, parents or schools may be reluctant to approve such procedures (Najdowski et al., 2008). To mitigate the potential risks associated with the traditional EFA, a number of variations have been developed. These include the brief functional analysis, functional analysis with protective equipment, latency functional analysis, and trial-based functional analysis (Lydon et al., 2012). Another strategy is to apply the experimental contingencies to more benign topographies of behavior that are members of the same response class as the severe challenging behavior (Smith & Churchill, 2002). Research has shown that the assessment and treatment of these innocuous behaviors can help to reduce or prevent severe challenging behavior (Fahmie & Iwata, 2011).

Precursor Behaviors

Early studies have demonstrated that if one topography of challenging behavior is punished or placed on extinction, collateral increases in other forms of problem behavior may be observed (Goh & Iwata, 1994; Lerman et al., 1999; Sprague & Horner, 1992). This response variability could suggest that the challenging behaviors are members of the same response class, meaning that they are maintained by the same consequence (Catania, 2013). There are at least a dozen studies to illustrate that different topographies of challenging behavior often belong to the same response class (Warner et al., 2020). Members of a response class covary, meaning that the probability of one behavior being emitted is directly related to the probability of the other behaviors occurring (Sprague & Horner, 1992). This would imply that the behaviors form a response class hierarchy, where the ordering of each topography is determined by response effort, schedules of reinforcement, and the probability of punishment (Lalli et al., 1995).

The hierarchical nature of challenging behavior has been demonstrated by several researchers using extinction analyses (e.g., Harding et al., 2001; Lalli et al., 1995; Lieving et al., 2004; Magee & Ellis, 2000; Richman et al., 1999). In these studies, when extinction was applied to milder topographies of a response class, there were predictable increases in more severe topographies. Similarly, when the milder behaviors were reinforced, the likelihood of the individuals engaging in severe challenging behavior was reduced. In summary, different topographies of challenging behavior belonging to the same response class tend to occur in a predictable temporal order. By applying contingencies to initial, milder members of the response class hierarchy (e.g., crying), subsequent and more severe members (e.g., self-injury) can be reduced or eliminated (Dracobly & Smith, 2012).

While this research supports the theory that milder forms of challenging behavior are earlier members of a response class hierarchy, there is another possible explanation for this phenomenon. It is also feasible that some of these preceding topographies are initial links within a response chain (Heath & Smith, 2019). Simply put, these early behaviors do not produce the maintaining consequence themselves, but they serve as discriminative stimuli for the severe challenging behavior that produces reinforcement. This was demonstrated by Hagopian et al. (2005), who used a conditional probability analysis to show that stereotypy reliably occurred before episodes of eye poking. When the stereotypy was blocked, eye poking was substantially reduced, but when eye poking alone was blocked, both behaviors continued to occur in more than a third of the intervals. This indicated that stereotypy was the earlier link within the response chain, and by interrupting this response, the probability of the terminal response (i.e., eye poking) was reduced.

From both theoretical standpoints, the treatment of initial milder topographies is hypothesized to prevent or alleviate episodes of more severe challenging behavior. These lesser problematic behaviors are often referred to as precursor behaviors. Smith and Churchill (2002) defined precursor behaviors as "behaviors that are observed to frequently precede the problem behavior" (p. 126). For a behavior to be classified as a precursor, it must have a "temporal and probabilistic relation" to the challenging behavior of concern (Fahmie & Iwata, 2011, p. 993).

Precursor behaviors can vary from person to person. Nevertheless, Fahmie and Iwata (2011) revealed that the most common precursors reported in the literature were unintelligible vocalizations, object-directed movements, and self- or non-directed movements (Fahmie & Iwata, 2011). This was supported by Silbaugh and Falcomata (2018), who found that the majority of reported precursors were non-vocal and vocal responses. Regarding precursor-target relations, Fahmie and Iwata (2011) discovered that unintelligible vocalizations were most likely to occur before aggression and property destruction. Property destruction was also likely to be preceded by non-specific vocalizations. The most common precursors to self-injurious behavior were self- or non-directed movements (Fahmie & Iwata, 2011). However, despite these findings, practitioners should not rule out the potential for other precursor topographies. Like all operant behaviors, precursor behaviors are idiosyncratic to the individual, and there is a wide range of possible topographies. Before a practitioner can treat precursor behaviors, it is first necessary to identify their form and function to determine if they belong to the same response class as the more severe challenging behavior.

Identification of Precursor Behaviors

Progress has been made in recent decades in developing and validating assessment methods for response class hierarchies. Such assessments provide information regarding the structure of a response class hierarchy, including the relative probability of class members, the range of topographies, and the strength of each behavior (Silbaugh & Falcomata, 2018). Using these assessments, practitioners can investigate the hierarchical nature of challenging behavior in order to identify the precursors that reliably precede other members within the response class and the relative severity of topographies across the response class (Silbaugh & Falcomata, 2018). Understanding the structure of response class hierarchies and identifying precursor behaviors can help to improve intervention outcomes, minimize the recurrence of challenging behavior, and prevent unwarranted changes to treatment to address previously unseen topographies (Silbaugh & Falcomata, 2018). Furthermore, by empirically investigating response class hierarchies, more severe topographies of challenging behavior can be identified, and interventions targeting milder topographies can be developed, thereby limiting the occurrence and reinforcement of severe challenging behavior during assessment and treatment (Lalli et al., 1995; Langdon et al., 2008).

Until recently, it has been suggested that limited synthesis and examination of this research has impeded the application of these assessments in practice. To address this limitation, Silbaugh and Falcomata (2018) evaluated the current literature on methods for identifying and characterizing response class hierarchies and precursor behaviors. Based on the defining features of these assessment procedures, the authors developed a classification system for the methods and examined the evidence base for each. Methods were classified as either indirect assessments, direct descriptive assessments, structured consequence-based assessments, or experimental analyses.

Indirect Assessments

Indirect assessments involve interviewing respondents to obtain information about the precursor behaviors. These informants should be individuals who know the person well and are familiar with their behavior of concern, such as caregivers (e.g., Fritz et al., 2013; Smith & Churchill, 2002) or teachers (e.g., Herscovitch et al., 2009; Langdon et al., 2008). During these assessments, precursor behaviors are explained to the respondents using non-technical language (e.g., "warning signs that problem behavior is likely to occur"; Langdon et al., 2008, p. 808). Then, respondents are asked to identify these behaviors; if there is more than one topography, they may be required to rank these behaviors as primary, secondary, or tertiary precursors (e.g., Herscovitch et al., 2009).

According to Silbaugh and Falcomata (2018), there are a few benefits to indirect precursor assessments. First, these assessments are relatively straightforward to complete, with limited time or training resources required. Furthermore, in contrast to other methods, indirect precursor assessments do not require the systematic programming of contingencies for the precursor behaviors. While this method can provide valuable information to the practitioner, indirect precursor assessments are not without limitations.

There are only a few examples of indirect precursor assessments within the literature, and it has been suggested that this method is susceptible to inaccuracies (Herscovitch et al., 2009). Some precursor behaviors, for example, may be subtle or bear limited resemblance to the challenging behavior, making them more difficult for the informants to identify (Fritz et al., 2013). In addition, if a response occurs at such a high rate (e.g., stereotypy) that it precedes multiple different behaviors, it may incorrectly be identified as a precursor to the challenging behavior. Informants may also be influenced by particularly salient or recent instances of severe challenging behavior and are less inclined to remember precursors during episodes where the more severe topography was absent (Dracobly & Smith, 2012). While consulting with multiple respondents may ameliorate some of these challenges, this would increase the time and resources required to conduct such assessments.

Direct Descriptive Assessments

Direct descriptive assessments involve collecting data on the severe challenging behavior and any precursor behaviors that occur immediately before it. This may be done during planned direct observations of these behaviors or through the secondary analysis of data collected during an EFA or treatment evaluation (Silbaugh & Falcomata, 2018). Many of these methodologies evaluate the temporal relationships among members of a response class by calculating the probabilities that the challenging behavior and precursor behaviors will occur during specified time frames.

Comparative Probability Analysis

Comparative probability analyses examine correlations between potential precursors and the challenging behavior by calculating the conditional probability of each behavior. These assessments can be employed alone (e.g., Apamo-Gannon, 2016) or in conjunction with other precursor assessments (e.g., Dracobly & Smith, 2012). Each occurrence of the challenging behavior and precursor behavior is an anchor point from which these probabilities are calculated (Borrero & Borrero, 2008). The probability of a precursor given the challenging behavior is calculated by observing whether the precursor behavior occurs within a predetermined number of seconds before the anchor point of the challenging behavior (e.g., 10 s; Borrero & Borrero, 2008). Similarly, the probability of the challenging behavior given a precursor is calculated by observing whether the challenging behavior occurs within the same number of seconds after the anchor point of the precursor behavior. These probability values are calculated for each episode of precursor behavior and challenging behavior, and from these, an overall conditional probability percentage is determined.

Lag-Sequential Analysis

Lag-sequential analyses examine similar response–response correlations. These assessments calculate the second-by-second probability of a precursor behavior occurring within a specific time frame immediately prior to and following an episode of challenging behavior (e.g., 60 s; Dracobly & Smith, 2012). Within this time frame, each 1-s interval is scored for the presence or absence of the precursor behavior. The number of intervals with the precursor behavior is divided by the total number of intervals with the challenging behavior to determine the conditional probability value. A similar analysis is also conducted to determine the second-by-second probability of the challenging behavior occurring during each 1-s of the given time frame immediately before and after an episode of precursor behavior.

Within lag-sequential analyses, conditional probabilities are compared to unconditional probabilities. The unconditional probability of the challenging behavior is calculated by dividing the total number of challenging behavior episodes by the number of opportunities to engage in the challenging behavior (Borrero & Borrero, 2008). In comparison to this unconditional probability, an increase in the probability of the precursor during intervals immediately prior to the challenging behavior and a subsequent decrease in the probability during intervals immediately following the challenging behavior suggest that the response is a reliable precursor behavior (Borrero & Borrero, 2008). Similarly, an increase in the probability of the challenging behavior during intervals immediately following the precursor and a decrease in the probability during intervals immediately prior to the precursor suggest that the challenging behavior reliably occurs after the precursor behavior (Borrero & Borrero, 2008).

Transitional Probability Analysis

Transitional probability analyses examine the relationship between precursor behaviors and challenging behavior within the context of daily activities (Langdon et al., 2008). Data are collected during direct observations of the individual engaging in activities that are reported to evoke the challenging behavior. Each observation is divided into a series of equal intervals of time, and five transitional probabilities are calculated. With each episode of precursor behavior, a new observation interval begins, and the following probabilities are calculated: (a) the likelihood the precursor is immediately followed by the challenging behavior, (b) the likelihood the precursor is immediately followed by another precursor, and (c) the likelihood the precursor is immediately followed by any other behavior (Langdon et al., 2008). Similarly, with each episode of challenging behavior, a new observation interval begins, and the following probabilities are calculated: (a) the likelihood the challenging behavior is immediately followed by another challenging behavior, and (b) the likelihood of the challenging behavior occurring when neither the precursor nor another challenging behavior was seen in the previous observation interval (Langdon et al., 2008).

The previous three analyses are considered more accurate precursor assessments than other descriptive or indirect assessments because they identify precise temporal relationships between behaviors within a response class hierarchy (Silbaugh & Falcomata, 2018). Thus, they can provide more valuable information regarding specific response–response correlations. However, while there is no requirement to program contingencies for the precursor behaviors, these assessments still require extensive time and resources to complete. Furthermore, it is important to note that the descriptive information generated by these precursor assessments is only correlational in nature and may warrant further validation through experimental analyses (Silbaugh & Falcomata, 2018).

Relative Latency Assessment

The relative latency assessment can also be employed to identify the temporal relationships between the topographies of challenging behavior within a response class hierarchy. In this assessment, the relative latency until each topography of challenging behavior is recorded following the initiation of a trial with the relevant establishing operation (e.g., a demand; Richman et al., 1999). To evaluate the temporal relationships between different behaviors, the responses are ranked based on their average latency until occurrence.

Silbaugh and Falcomata (2018) reported several benefits of the relative latency assessment. First, various topographies comprising the response class hierarchy can be identified through this assessment. Another benefit of using this method is that it can characterize temporal relationships between behaviors during or after an ongoing EFA or treatment evaluation, which can save time and resources. Furthermore, unlike consequence-based assessments, there is no requirement for programmed contingencies within this assessment. Limitations of the relative latency assessment include the indirect nature of relative latency as a measure, and the potential need to video record sessions to ensure accurate data collection (Silbaugh & Falcomata, 2018).

Structured Consequence-Based Assessments

Structured consequence-based assessments of precursor behavior involve the direct manipulation of antecedents and consequences and the subsequent analysis of data (Silbaugh & Falcomata, 2018). The various topographies within a response class are observed and analyzed within reinforcement and extinction conditions, providing an empirical demonstration of the response class hierarchy. These assessments differ from experimental analyses in that they do not display data in equal-interval graphs in order to identify the function of the precursor behavior using visual analysis (Silbaugh & Falcomata, 2018). Rather, bar graphs may be used to display the absolute latencies of various topographies, supporting the visual inspection of temporal relationships between behaviors (e.g., Lalli et al., 1995). Alternatively, data may be displayed in an equal-interval line graph, but only to characterize the nature of the response class hierarchy (e.g., Lieving et al., 2004), to assess the response covariation among mild and severe behavior responses (e.g., Shukla-Mehta & Albin, 2003), or to assess the response covariation between precursors and challenging behavior (e.g., Langdon et al., 2008).

Extinction Analysis

The extinction analysis and its variations are commonly employed within the literature and are effective for identifying the hierarchical relationship among topographies within a response class (Lalli et al., 1995). Prior to the extinction analysis, the topographies of the response class and its hypothesized function are identified through a functional assessment. The response topographies are then ranked in terms of frequency, from most frequent to least frequent. Extinction is first applied to the most frequent response topography, while all other topographies are reinforced until a reduction in the most frequent behavior is observed. Extinction is then applied sequentially to the other response topographies based on their relative frequencies (e.g., Magee & Ellis, 2000). By examining the changes in the frequency of each behavior while contingencies are systematically manipulated, the practitioner can empirically confirm the presence of a response class hierarchy (Richman et al., 1999).

A benefit of the extinction analysis is that a hypothesis regarding the organization of the response class hierarchy is not required prior to assessment. This method is also useful because it can be employed as a function-based treatment for severe challenging behavior (Silbaugh & Falcomata, 2018). By identifying and reinforcing early members of a response class while simultaneously placing the challenging behavior on extinction, the individual is less likely to engage in the more severe topography. However, this intervention does not teach any new skills, so it would be inappropriate when a replacement behavior needs to be taught. Due to the nature of this method, it can be used to examine within-session patterns of resurgence among behaviors placed on extinction (Silbaugh & Falcomata, 2018).

Latency-Based Extinction Analysis

The latency-based extinction analysis examines the latencies of different topographies within a response class to determine if the behaviors are hierarchically related (Silbaugh & Falcomata, 2018). During the assessment, one topography is reinforced at a time, while the remaining topographies are placed on extinction. The latency to the first occurrence of each member of the response class is recorded. If a hierarchical relationship exists between the topographies, the earlier responses will occur in a hierarchical sequence during the sessions where the last response is reinforced (Lalli et al., 1995). Similarly, when applying the contingency to responses earlier in the sequence, subsequent topographies are less likely to occur as reinforcement is taking place earlier in the sequence (Lalli et al., 1995). A benefit of this method is that it can be completed in only a few brief sessions. It can also identify more appropriate responses to reinforce during treatment, which can help to reduce the overall time of intervention (e.g., DeRosa et al., 2013). A limitation of the latency-based extinction analysis is that it cannot control for sequence effects, therefore, its internal validity may be threatened (Silbaugh & Falcomata, 2018).

Brief Latency-Based Extinction Analysis

Within the brief latency-based extinction analysis, reinforcement is arranged for one topography during a single session, while the other topographies are placed on extinction. The latency to the first occurrence of each topography is recorded, and a different topography is reinforced within each subsequent session (Mace et al., 2011). A response class hierarchy is identified if there is an escalating sequence of topographies when reinforcement is made contingent upon the last response. In contrast, when reinforcement is provided for earlier responses in the hierarchy, escalation is less likely to occur (Mace et al., 2011). An obvious benefit of this method is that it can be completed in a brief number of trials, so there are only a few instances of challenging behavior being reinforced. It is also suggested that this method can shorten the time to the initiation of treatment, as the findings can be used as a baseline (Mace et al., 2011). Like the extinction analysis, this assessment does not require a prior hypothesis of the hierarchical organization of the response class (Silbaugh & Falcomata, 2018).

Severity-Based Extinction Analysis

The severity-based extinction analysis assumes that more severe topographies of behavior are likely to follow less severe topographies. It employs an extinction analysis to assess the response covariation among members within a response class hierarchy (Silbaugh & Falcomata, 2018). Initially, reinforcement may be provided for all topographies within the response class. Then, during subsequent sessions, reinforcement is only delivered contingent upon more severe topographies, while less severe topographies are placed on extinction (Shukla-Mehta & Albin, 2003). A response class hierarchy is demonstrated if there is differential responding under these circumstances (e.g., higher frequency of severe topographies when less severe topographies are placed on extinction).

The extinction analysis and its variations can provide useful information regarding the full range of topographies within a response class, the position of these topographies within the hierarchy, and the covariation among these behaviors (Silbaugh & Falcomata, 2018). However, a limitation among these four methods is that challenging behavior is reinforced, including more severe topographies, which can present ethical concerns. These methods may also require video recording of the sessions to obtain more accurate measurements of the behaviors, which may require more time and staff resources (Silbaugh & Falcomata, 2018).

Precursor Analysis

A precursor analysis is employed to experimentally demonstrate the relationship between a precursor behavior and challenging behavior (Langdon et al., 2008). During this assessment, sessions mimic the environmental settings likely to trigger the challenging behavior (e.g., instructional demands, lack of attention), and an extinction contingency is differentially applied to the precursor behavior across phases. For example, Langdon et al. (2008) conducted a precursor analysis across two phases. In the first phase, both the precursor and challenging behaviors were reinforced. In the second phase, only challenging behavior was reinforced, and the precursor behavior was placed on extinction. In Phase 1, the precursor behavior occurred more frequently, while in Phase 2, the challenging behavior occurred more frequently. This indicated that both behaviors were maintained by the same consequence.

The precursor analysis can be useful in identifying various topographies within a response class and potential targets for intervention. By confirming that a precursor behavior belongs to the same response class as the challenging behavior, an appropriate function-based treatment can be developed to prevent escalation from the precursor to the more severe topography (Silbaugh & Falcomata, 2018). Another benefit of the precursor analysis is that it involves fewer conditions and sessions than both the EFA and precursor functional analysis. Nevertheless, this assessment may reinforce severe challenging behavior, and this method cannot empirically demonstrate the behavioral function of the precursors or challenging behavior, only that they belong to the same response class (Silbaugh & Falcomata, 2018).

Trial-Based Structured Precursor Assessment

The trial-based structured precursor assessment is an objective and brief method for identifying precursor behavior (Silbaugh & Falcomata, 2018). At the beginning of the assessment, caregivers are asked to identify the severe challenging behavior and any potential precursor behaviors. The assessment itself is conducted in a discrete trial format, with conditions similar to those within an EFA. As most challenging behavior is maintained by either positive or negative reinforcement, attention and demand conditions are typically presented within the assessment (Fritz et al., 2013). However, based on the caregiver's reports, a tangible condition may also be included if necessary. Contingent on the first instance of severe challenging behavior, the trial-specific consequence is delivered, and the trial is terminated. Once the behavior has not been observed for 30 s following the delivered consequence, or the behavior does not occur within 5 min, the next trial begins (Borlase et al., 2017). The duration of each trial is 5 min or until the first instance of severe challenging behavior. The criterion for the completion of the assessment is 10 trials with the challenging behavior. Where challenging behavior occurs within all 10 initial trials, additional trials with non-contingent access to reinforcement (i.e., play condition) are conducted to obtain a comparison (Fritz et al., 2013).

To ensure accurate analysis, all trials are videotaped, and the videos are used to identify and define potential precursors and to score their occurrence/non-occurrence during each trial. The following four conditional probabilities are then calculated: (a) the probability of the precursor given the challenging behavior, (b) the probability of the precursor given the absence of the challenging behavior, (c) the probability of the challenging behavior given the precursor, and (d) the probability of the challenging behavior given the absence of the precursor (Borlase et al., 2017; Fritz et al., 2013). Unconditional probabilities for both the precursor and challenging behavior are also calculated. A response is identified as a precursor behavior if it meets the following criteria. First, the probability of the challenging behavior given the precursor behavior must be greater than both (a) the probability of the challenging behavior given the absence of a precursor behavior and (b) the unconditional probability of the challenging behavior. Additionally, the probability of the precursor given the challenging behavior must be greater than both (a) the probability of the precursor behavior given the absence of a challenging behavior and (b) the unconditional probability of the precursor (Borlase et al., 2017; Fritz et al., 2013).

According to Silbaugh and Falcomata (2018), the trial-based structured precursor assessment is time-efficient, especially for low-rate challenging behavior, and it may be better than other precursor assessments for minimizing the occurrence and reinforcement of challenging behavior. Additionally, a wide range of topographies within the response class hierarchy can be identified, including precursor behaviors that have been underreported or inaccurately reported. However, the trial-based structured precursor assessment may be relatively resource intensive, and like the other assessments, there are ethical concerns with the reinforcement of severe challenging behavior (Silbaugh & Falcomata, 2018). This method may also yield false positives for some individuals (Fritz et al., 2013).

Summary of Assessments

In summary, the practice guidelines suggested by Silbaugh and Falcomata (2018) are as follows. Regarding the time available to complete a precursor assessment, indirect precursor assessments and the brief latency-based extinction analysis are considered highly efficient. The latency-based extinction analysis and the trial-based structured precursor assessment are considered moderately efficient, while all the direct descriptive assessments, the precursor analysis, the extinction analysis, and its variations are considered to have low efficiency. In relation to internal validity, the extinction analysis and its variations, the precursor analysis, and the trial-based structured precursor assessment are all considered to have medium-high to high validity. The direct descriptive assessments have moderate internal validity, and the indirect precursor assessments have low internal validity.

Overall, the current research suggests that direct descriptive assessments and structured consequence-based assessments are useful for identifying response class hierarchies and precursors to severe challenging behavior. However, given the correlational nature of their outcomes, these precursor assessments can only provide preliminary evidence of behavioral function (Heath & Smith, 2019). To confirm maintaining contingencies and demonstrate functional equivalence among precursor behaviors and challenging behaviors, practitioners should consider employing an experimental analysis (Silbaugh & Falcomata, 2018).

Precursor Functional Analysis

While the assessments described above are effective for identifying precursor behaviors and their temporal relationships among other members within a response class, they cannot demonstrate a maintaining contingency (Silbaugh & Falcomata, 2018). The EFA is the only assessment that can yield empirically based conclusions regarding the function of challenging behavior (Lerman & Iwata, 1993). A functional relation is demonstrated when the behavior is reliably evoked during at least one test condition for which the maintaining contingencies are present, while it is absent during the control condition for which the contingencies are absent (Fahmie et al., 2013). Using the results of an EFA, the practitioner can develop an appropriate function-based treatment to address the severe challenging behavior. Research has shown that treatments based on EFA outcomes are the most effective at decreasing or eliminating challenging behavior (Beavers et al., 2013; Hanley et al., 2003).

While the results of the EFA permit the design of such treatments, ethical concerns are raised when conditions are arranged to evoke severe challenging behavior (Hastings & Noone, 2005). Another concern is the possibility of strengthening severe challenging behavior during the EFA process. Studies have illustrated an increase in the rate of challenging behavior outside of the EFA setting as the result of this assessment (Call et al., 2012, 2017; Hastings & Noone, 2005; Shabani et al., 2013). Due to the concerns surrounding the reinforcement of such topographies, researchers have endeavored to address these challenges through adaptations to the traditional EFA methodology (Hanley, 2012). One such variation is the precursor functional analysis (PFA).

The PFA was first implemented by Smith and Churchill (2002) as a means to reduce the risks of conducting an EFA for self-injurious behavior and aggression. Initially, the authors conducted a traditional EFA with the participants to identify the maintaining function of their severe challenging behaviors. Then, these procedures were replicated during the PFA. The test conditions of the PFA modeled the conditions first outlined by Iwata et al. (1982/1994). Like the traditional EFA, these test conditions (i.e., alone, attention, demand, tangible) were systematically arranged to create an establishing operation for the challenging behaviors. However, during the PFA, the contingencies for each condition were placed on the earlier and less severe topographies within each participant's response class (e.g., screaming, crying, vocalizations). For example, during the demand condition, when Participant A engaged in foot stomping, screaming, grabbing, and/or falling, the task was removed, and the trial ended.

The results of this study suggested that the function of the precursor behaviors could be accurately identified through the PFA and that these maintaining contingencies matched the identified function of the severe challenging behaviors (Smith & Churchill, 2002). Thus, the precursors and challenging behaviors identified for each participant shared a common maintaining contingency, and functional equivalence was demonstrated. Furthermore, by providing the maintaining reinforcer for the precursor behaviors, the more severe topographies were greatly reduced or eliminated during the PFA (Smith & Churchill, 2002). These findings are pivotal because they indicate that the PFA presents a sound methodology for identifying the operant function of severe challenging behavior while simultaneously reducing the risks to clients and practitioners (Heath & Smith, 2019).

Several studies have replicated these findings in both schools and clinics, and across individuals with various developmental disabilities, thereby establishing the external validity of such procedures (Borlase et al., 2017; Borrero & Borrero, 2008; Dracobly & Smith, 2012; Fritz et al., 2013; Herscovitch et al., 2009; Najdowski et al., 2008). Among these studies, all but two (i.e., Dracobly & Smith, 2012; Najdowski et al., 2008) validated the findings of their PFAs by also conducting traditional EFAs that identified the same maintaining function for a majority of their participants. Beyond the reduction in risks associated with EFA procedures, the PFA has several other benefits. First, it has been suggested that the PFA can be used to clarify the results of undifferentiated EFAs. For example, Slaton et al. (2017) conducted traditional EFAs with nine participants with ASD and found that the outcomes were only differentiated for four participants, meaning that the function of their challenging behavior had been clearly identified. When the authors implemented additional PFAs, the function was identified for an additional two participants. Another potential benefit of the PFA is that this method can expediate the assessment process by producing rapidly differentiated outcomes (Heath & Smith, 2019).

Despite its merits, the PFA also has notable limitations. First, the PFA is considered resource intensive, given the time it takes to complete, and the required training needed to implement the test conditions (Silbaugh & Falcomata, 2018). The PFA can also unintentionally add other topographies of challenging behavior to the response class if these responses are incorrectly hypothesized as precursors and subsequently reinforced during the PFA process (Silbaugh & Falcomata, 2018). And like the structured consequence-based assessments, the PFA is not appropriate when the reinforcement of severe challenging behavior is unacceptable (e.g., episodes of life-threatening self-injurious behavior). It is also important to mention that the PFA can only make inferences about the contingencies maintaining severe challenging behavior, as they cannot provide a direct demonstration of functional relations for more severe topographies (Heath & Smith, 2019). Similarly, unless an EFA for severe challenging behavior is conducted alongside the PFA, the functional equivalence of the precursor behaviors cannot be confirmed (Silbaugh & Falcomata, 2018). For this reason, any PFA-based conclusions regarding a common contingency among the response class members should be made with caution unless an EFA is also conducted. Finally, the PFA can sometimes give rise to false negatives when the precursors meeting the reinforcement contingency end up masking other precursors within the response class (Fritz et al., 2013).

Interestingly, there is a lack of PFA research on precursor behaviors maintained by the access to attention or automatic functions. In their review, Silbaugh and Falcomata (2018) found that most PFAs (63%) identified an escape function for their participants, while 32% identified a tangible function. Notably, only 13% of the PFAs identified an attention function, and this could be explained by the logistics of conducting this test condition. The establishing operation for this condition is the absence of social attention. Consequently, it may be difficult for a practitioner to both withhold attention for non-target behaviors while simultaneously observing the individual for more subtle precursor behaviors (Silbaugh & Falcomata, 2018). The alone condition was tested among nine participants, but an automatic function was not identified for any of these individuals. This finding is not surprising given that it is unlikely that a more benign topography can provide the same automatically produced consequence as the more severe challenging behavior. Thus, a response class hierarchy would not develop (Fahmie & Iwata, 2011). Similarly, there is no need for an individual to proceed through a response class hierarchy to obtain reinforcement that is freely available for the least effortful and most probable response (Silbaugh & Falcomata, 2018). With this in mind, it is not feasible or even efficient to include an alone condition within the PFA.

In summary, there is a small literature base to show that the PFA is a highly valid assessment for identifying the maintaining contingencies of precursor behaviors. Using this information, the practitioner can make reliable conclusions regarding the function of severe challenging behavior without needing to implement a traditional EFA, thereby reducing the risk of harm to the individual and others. As such, effective interventions matching the theorized function of the severe challenging behavior can be developed. One treatment option is to directly intervene on the precursor behaviors that belong to the same response class as the challenging behavior. Research has shown that function-based interventions that target precursor behaviors can be effective in reducing or eliminating severe challenging behavior (Dracobly & Smith, 2012).

Treatment for Precursor Behaviors

Understanding the response covariation between precursor behaviors and challenging behavior can be profitable in the design of interventions to reduce maladaptive behaviors (Harris, 1980; Voeltz & Evans, 1982). Behavior analysis provides the technology (e.g., comparative probability analysis) by which to identify this relationship, and the methodology (e.g., PFA) to confirm the function of the precursor behaviors under consideration. Such information is invaluable for practitioners in the design of interventions, as different behaviors are often maintained by the same consequence (Harding et al., 2001; Magee & Ellis, 2000; Richman et al., 1999; Smith & Churchill, 2002).

Understanding the relationship between a precursor and challenging behavior has important treatment implications. Careful consideration must be taken when identifying a precursor behavior as either an earlier link within a response chain or a member of a response class hierarchy. As explained by Dracobly and Smith (2012), reinforcing an earlier member of a response class could diminish later topographies, while reinforcing an earlier link within a response chain could strengthen later topographies. To assess whether a response is a class member or a link within a chain, the practitioner can prevent the behavior from occurring, and observe the effects of this procedure on the next response within the sequence. If temporarily blocking the earlier topography eliminates the next behavior in the response sequence, this may suggest a response chain. If, however, this leads to an increase in the next response, this would indicate a response class hierarchy (Dracobly & Smith, 2012).

Research has suggested that precursor behaviors to automatically maintained challenging behavior are unlikely to be members of the same response class; rather, these behaviors are more likely to be linked within a response chain (Heath & Smith, 2019). For these precursor behaviors, response blocking is an empirically validated treatment that can lead to collateral reductions in the severe challenging behavior. For example, Rettig et al. (2019) found that the pica (i.e., the consumption of inedible items) of five autistic children was maintained by automatic reinforcement. The researchers implemented a response-blocking procedure for the identified precursor behaviors of each participant (e.g., approaching an item, bending over). By blocking the precursor behaviors, the researchers effectively decreased the severe challenging behavior without needing to block the pica directly. These procedures replicated an earlier study by McCord et al. (2005). This study demonstrated similar reductions in pica by implementing a blocking procedure that was only effective when applied earlier in the response chain. In other words, when the researchers blocked the precursor behavior (i.e., touching items), there were greater reductions in the challenging behavior than when they attempted to block the pica itself.

Blocking the earlier links of a response chain for automatically maintained self-injurious behavior has also proven to be effective. For instance, Hagopian et al. (2005) limited the number of intervals with eye-poking once they blocked the precursor of stereotypy. Blocking stereotypy was also found to lessen the response effort of the practitioner, as the number of episodes of challenging behavior that required blocking was greatly reduced. A similar study was conducted by Deaver et al. (2001), who used non-contingent application of mittens at bedtime and nap time for a young girl with ASD. The mittens effectively decreased the girl's hair twirling, which was identified as a precursor to automatically maintained hair pulling. The authors noted, however, that it was unclear whether this procedure was successful because it interrupted the response chain or because it resulted in sensory extinction.

While these studies demonstrated the efficacy of response blocking for precursor behaviors that precede automatically reinforced challenging behavior, the results were not always clear for participants who had multiple identified functions (e.g., automatic and social-positive reinforcement). Rettig et al. (2019) discovered that physical attention was a secondary function for one of their participants, so the blocking procedure inadvertently reinforced the child's pica. While blocking the precursors to automatically maintained challenging behavior can be effective, alternate interventions must be considered if there are different or multiple functions. This highlights the importance of identifying the function of challenging behavior prior to treatment. To confirm whether a severe challenging behavior is automatically maintained, it is recommended to begin the EFA with a single extended alone condition (Smith & Churchill, 2002). If the response continues to occur without social reinforcement, it is more than likely an automatically maintained behavior, and an appropriate function-based treatment can commence. However, if the response shows signs of extinction (e.g., burst then reduction), it is likely maintained by social reinforcement and further assessment of the precursor behaviors can be initiated (Smith & Churchill, 2002).

For precursor behaviors theorized to be members of a response class hierarchy, it is important to first conduct precursor assessments to ensure that these topographies and the challenging behavior are maintained by the same consequence. If precursor behaviors to severe challenging behavior are confirmed as members of the same response class, it is presumed that the treatment of these precursors will result in the reduction or prevention of the more severe topography (Langdon et al., 2008; Najdowski et al., 2008). Due to their functional equivalence, similar approaches for reducing challenging behavior have effectively been applied as interventions for precursor behaviors. A number of these interventions have been evaluated in the literature and will be subsequently presented. While this is not an exhaustive list, it will highlight some of the more important findings.

Researchers have suggested that challenging behavior is a form of communication (Carr & Durand, 1985). Accordingly, functional communication training (FCT) is a commonly employed intervention that aims to replace the communication system representative of the challenging behavior with one that is functionally equivalent and more socially valid. In fact, FCT is one of the most frequently published function-based treatments for challenging behavior (Gerow et al., 2018). During FCT, an appropriate communicative response is taught to the individual during evocative situations using prompting methods (Carr & Durand, 1985). Once taught, this response is differentially reinforced with the same maintaining consequence as the challenging behavior, while the challenging behavior is placed on extinction.

During FCT for precursor behaviors, the occurrence of a known precursor serves as a cue to the practitioner to prompt the communicative behavior (Langdon et al., 2008). There are multiple examples of the use of FCT for precursors to treat challenging behavior. In Najdowski et al. (2008), individualized FCT interventions were developed following PFAs that suggested the participants' precursor behaviors were maintained by access to attention or tangibles. During related evocative situations (i.e., diverted attention, toy removal), the functional communicative response was prompted following instances of the precursor behaviors. This FCT intervention was found to eliminate the precursor behaviors altogether and prevent episodes of severe challenging behavior for all three participants (Najdowski et al., 2008).

Challenging behavior maintained by negative reinforcement (i.e., escape and avoidance) is often difficult to treat with FCT, as the learning opportunity is often embedded within the occurrence of the challenging behavior. However, by implementing FCT on precursor behaviors, the functional communicative response can be taught within the given situation before the challenging behavior has an opportunity to occur. Thus, the FCT intervention acts as a proactive approach for preventing the occurrence of maladaptive behavior (Langdon et al., 2008). Langdon et al. (2008) demonstrated the positive impact of FCT on precursor behaviors by minimizing challenging behavior maintained solely by negative reinforcement. The authors found that prompting the participants to ask for a break following instances of precursor behaviors was an effective approach for reducing the challenging behavior.

Based on these findings, Langdon et al. (2008) noted that the implementation of FCT for precursor behaviors warrants consideration. It is often the case that practitioners teach communication responses based on environmental conditions (e.g., diverted attention, then prompt request for attention). For example, Lalli et al. (1995) prompted their participants to say "No" following the first instruction, then provided a 30-s break. The problem with this approach is that it does not take into consideration the individual's sensitivity to the aversiveness of the situation (Langdon et al., 2008). Just because demands are being presented, does not mean the individual should immediately be prompted to request a break. If, however, the FCT intervention is designed to respond to the emittance of precursor behaviors, then practitioners can be more sensitive to the presence of individual motivating operations and not prompt a response simply because of the presence of certain environmental stimuli.

FCT is a form of differential reinforcement of alternative behavior (DRA). Like FCT, an appropriate, alternative behavior is reinforced while the challenging behavior is placed on extinction during DRA procedures. The difference between these two procedures, however, is that the replacement behavior in DRA does not need to be a form of communication (Tiger et al., 2008). There is some research to suggest that reinforcing existing topographies within a response class can increase the efficiency of DRA procedures because the practitioner does not need to teach a novel response to reinforce (e.g., Grow et al., 2008). In the case of precursor behaviors, DRA may be particularly useful, as these behaviors are already within the individual's repertoire and often occur in the context of the challenging behavior (Heath & Smith, 2019). When DRA methodology is applied to these earlier topographies within the response class, the individual does not need to engage in the challenging behavior to meet the reinforcement contingency. An example of DRA for precursor behaviors was demonstrated by Dracobly and Smith (2012). The authors found that when contingent attention was provided for the precursor behavior (i.e., head up) of an individual with ID, his self-injurious behavior was eliminated. Interestingly, while the DRA treatment was implemented in the participant's workplace, a cessation in self-injurious behavior was also seen in his home. This demonstrates both the efficacy and social validity of DRA for precursor behaviors.

Treatment packages to address challenging behavior are also widely used in clinical practice and have been demonstrated within the precursor literature (Apamo-Gannon, 2016; Fritz et al., 2013; Wrigley et al., 2010). In a study by Apamo-Gannon (2016), a multi-component treatment package that included differential reinforcement, FCT with extinction, and response interruption and redirection was implemented to treat the precursor behaviors of a 20-year-old female with ASD. This intervention package was found to gradually reduce the participant's precursor behaviors, self-injurious behavior, and aggression to low levels. In addition, her use of functional communication increased, and results were replicated across three settings, further supporting the social validity of the intervention package.

Fritz et al. (2013), on the other hand, used the results of a PFA to guide the development of a function-based treatment that included noncontingent reinforcement (NCR), followed by the thinning of the NCR schedule with the addition of DRA. The authors found that this intervention package was a viable treatment option for reducing precursor behaviors and severe challenging behavior that were maintained by both positive and negative reinforcement contingencies. Additionally, this treatment package improved the participants' use of functional communication, demonstrating that the individuals had shifted their responding from challenging behavior to more appropriate behavior (Fritz et al., 2013).

Another notable treatment package was implemented by Wrigley et al. (2010). The authors employed a multi-component intervention to treat rumination (i.e., regurgitation and swallowing of previously consumed food) of a woman with severe disabilities. As the rumination was theorized to be automatically maintained, the first component of the intervention was the interruption of her precursor behaviors (e.g., bending over, rocking). The intervention package also included alternating periods of "walk and work" and noncontingent attention, together with differential reinforcement of other behavior for the absence of rumination. The treatment greatly reduced the participant's rumination, and an additional component analysis determined that all intervention components were necessary for treatment success. The findings of this study are important because they showed that life-threatening rumination could be diminished without the use of aversive procedures such as contingent aversive stimulation or extreme food satiation.

There are a few other examples of function-based treatments for precursor behaviors that have demonstrated positive outcomes in the reduction of challenging behavior among the literature. For instance, Kuttler et al. (1998) effectively used Social Stories™ (Gray & Garand, 1993) to reduce the precursor behaviors of a child with multiple diagnoses who engaged in severe tantrums during transitions or when he had to wait. The use of Social Stories™ reduced the precursor behaviors (i.e., vocalizations, dropping to the floor) to zero or near-zero levels. In turn, tantrum behaviors were eliminated.

This section provides evidence of the utility of designing interventions that focus on the behaviors that precede challenging behavior. In fact, there is some literature to suggest that precursor behaviors can be treated more easily than challenging behaviors themselves (e.g., Hagopian et al., 2005). The most important consideration to be extracted from the literature is that a systematic approach should be used to determine the existence of precursor behaviors and to confirm their functional equivalence with the challenging behavior. Using this information, a function-based intervention can be developed to address these precursor behaviors. Given the functional equivalence between precursor behaviors and challenging behavior, the treatment of precursors is thought to result in similar outcomes as those associated with the treatment of the more severe topography. The difference is that these treatment outcomes can be achieved more safely and efficiently with the precursor-based intervention. However, due to the limited number of studies in this area, further research is necessary to confirm whether this is the case (Silbaugh & Falcomata, 2018).

There are many advantages to intervening on precursor behaviors for both the target individual and the practitioner. In the first instance, some severe challenging behavior (e.g., self-injurious behavior) can place the individual and others in high-risk situations, and by applying interventions to the precursor behaviors, the practitioner may eliminate some of that risk (Hagopian et al., 2005; Harding et al., 2001; Harris, 1980; Richman, 2008). By intervening on precursor behaviors, practitioners can prevent the escalation to more severe challenging behavior (DeRosa et al., 2013; Lalli et al., 1995; Richman et al., 1999). That is to say, when reinforcement is provided for earlier topographies within the response class hierarchy, it becomes unnecessary for the individual to engage in the severe topography, which may also require more of a response effort and result in more physical pain (Najdowski et al., 2008). The prevention of severe challenging behavior can, in turn, reduce the use of aversive reactive strategies such as seclusion or restraint (Pritchard et al., 2011).

Furthermore, the application of interventions to precursor behaviors permits more time to deliver treatment, which may not always be available when the individual is frequently engaging in the challenging behavior. By intervening on precursor behaviors before the escalation to the target behavior, the practitioner can teach more appropriate, functionally equivalent responses that result in the same reinforcement as the challenging behavior (e.g., Langdon et al., 2008).

Some authors have also suggested that response redirection contingent upon the occurrence of precursor behavior can be used as an opportunity to teach more appropriate behaviors such as leisure activities (Rettig et al., 2019). By focusing on precursor behaviors during function-based intervention, practitioners can conduct treatments more safely and with a high level of procedural fidelity (e.g., Apamo-Gannon, 2016).

Conclusion

In conclusion, challenging behavior can lead to a number of deleterious and life-long effects for an individual without effective intervention (Matson & Rivet, 2008). Function-based intervention is considered the best practice for treating challenging behavior because it is a data-driven method that directly addresses the operant contingencies maintaining the challenging behavior (Hurl et al., 2016). While the FBA is commonly used to identify the contingencies maintaining challenging behavior, this methodology may be clinically contraindicated when the target behavior is a high-risk challenging behavior (Smith & Churchill, 2002). To address this ethical dilemma, practitioners have turned to the analysis and treatment of precursor behaviors that reliably precede the severe challenging behavior.

Understanding the role of precursor behaviors within response chains and response class hierarchies is important for clinical practice. First and foremost, by identifying precursor behaviors and characterizing their relationship with severe challenging behavior, appropriate interventions can be developed to target these more innocuous behaviors. By intervening at the precursor level, practitioners have a proactive approach that can prevent the occurrence and reinforcement of severe challenging behavior during assessment and treatment (Lalli et al., 1995; Langdon et al., 2008). Based on the findings of Silbaugh and Falcomata (2018), there are a wide range of assessment methods for identifying and classifying precursor behaviors. These methods vary in efficiency and validity, but research suggests that the PFA is a highly valid and viable approach for testing the hypotheses regarding the function of challenging behavior without risking the safety of the individual and others (Heath & Smith, 2019).

In turn, the results of precursor assessments can be used to develop individualized function-based treatments that are responsive to the behavioral cues of the individual (Langdon et al., 2008). These precursor-based interventions can lead to similar reductions in challenging behavior as treatments that directly target the problem behavior. This could save time and resources in the long run, especially when severe challenging behavior is more difficult to treat (Silbaugh & Falcomata, 2018). Furthermore, these precursor-based treatments allow practitioners to teach appropriate, replacement behaviors within the context of the challenging behavior, without having to wait for episodes of the challenging behavior to occur. As both the precursors and replacement behaviors result in the same reinforcement contingencies as the challenging behavior but require less of a response effort, the problem behavior becomes irrelevant (Najdowski et al., 2008).

However, despite the promising findings for precursor-based treatment, there are a limited number of studies that have evaluated function-based interventions for precursor behaviors. Notably, in Silbaugh and Falcomata (2018), only 10 of the 17 studies implemented some form of treatment based on the results of the precursor assessments. Even then, some of these procedures were implemented as a way to further verify the results of the precursor assessments (e.g., Magee & Ellis, 2000), rather than to treat the challenging behavior. This clearly demonstrates a gap within the literature regarding the clinical application of precursor-based treatment and more research in this area is necessary.

30 Function-Based Treatment

Denice Rios, Rebecca R. Eldridge, Rebecca L. Kolb, Marlesha Bell, and Kimberly M. Peck

Introduction

When assessing and treating challenging behavior using behavior analytic principles, research shows that using a function-based treatment is more effective than a treatment not based on function (Ingram et al., 2005). The Behavior Analyst Certification Board Professional and Ethics Code for Behavior Analysts (BACB ECBA) requires behavior analysts to use treatments supported by research (BACB, 2020, 2.13-2.14). To determine function, behavior analysts will conduct a functional behavior assessment (FBA), which is often comprised of the following components: a record review, interviews, direct observation, and functional analysis (Cooper et al., 2020).

Once a function is determined, the behavior analyst reviews the literature for treatments that match the function and designs a treatment plan using the best available evidence in conjunction with client preference and contextual variables (BACB, 2020, 2.09c; Benazzi et al., 2006; Spencer et al., 2012). At this point, the behavior analyst will conduct a treatment analysis, which means implementing the treatment for an amount of time long enough to determine its effects on behavior. If behavior changes in a desirable direction, the behavior analyst will then utilize some experimental method (such as reversal, multiple baseline, or multielement design) to show that the intervention is indeed what has caused the desirable change in behavior. The behavior analyst will present treatment results to the client and/or caregivers and incorporate feedback into the intervention plan. Treatment will continue in this fashion with frequent progress monitoring until the behavior reaches acceptable levels and support can be faded. However, if the treatment does not have a desirable effect on the behavior of interest, the behavior analyst will go back to the literature and select a different function-based treatment that fits the client context. This process of assessment and progress monitoring will continue until a desirable outcome is reached.

As mentioned above, in addition to function, behavior analysts are also professionally and

ethically obligated to consider contextual variables (BACB, 2020, 1.07 & 2.19). These variables should include, but, are not limited to culture, language, age, setting, and resources. Later in this chapter, we will further expand on these contextual variables. In addition to the ethical responsibility to consider these variables, research also shows that when client context and preference are considered, caregivers are more likely to implement intervention procedures with fidelity (Benazzi et al., 2006).

Finally, once function, client context, and preference are considered, behavior analysts are also required to take their own experience and expertise into consideration when selecting treatments. The BACB ECBA requires that behavior analysts practice within their scope of competence (BACB, 2020, Introduction, 1.05). This means that if a particular function-based treatment has shown desirable effects in the literature and the client and caregiver have agreed to its appropriateness and fit to their context, but the behavior analyst has no training or experience with it, then that behavior analyst must seek training and supervision or refer the client to someone with that experience. Further, if a behavior analyst is working with a client for whom they are unfamiliar with the culture, the behavior analyst should practice cultural humility (which we will discuss below) and, when possible, seek collaboration with someone who is familiar with that culture. These steps will ensure the treatment is implemented consistently with the norms and values of that culture and client.

Treatment selection for challenging behavior is an important and complex process that requires careful data collection and analysis, communication and collaboration with the client and/or caregivers, and the knowledge and expertise to implement. This chapter will break down each of these components in more detail to equip students in behavior analysis with decision-making tools and considerations for the safe, effective, and ethical practice of applied behavior analysis.

Contextual Factors and Cultural Variables

Treatment for problem behavior is provided in many places but is most commonly conducted in the context in which the individual spends a majority of their time. For example, services may be provided in an individual's classroom at school (among teachers, other students, and teaching assistants), in their home (among parents and extended family), or in the community (among community members). These everyday life settings include idiosyncratic contextual variables. Contextual variables are stimuli (e.g., people, objects, activities) and contingencies (e.g., schedules of reinforcement, punishment, and extinction) in the client's environment (Detrich, 1999; Slocum et al., 2014). The stimuli and contingencies may vary from situation-to-situation depending on the contextual variables present. For example, there are different contingencies that exist in the classroom, a grocery store, place of worship, a library, and a person's home. It is important to consider the entire context when planning for the intervention process if the behavior analyst's goal is to produce socially significant change that will maintain over time.

Treatment procedures are implemented with a diverse group of individuals, which includes various age groups, cultures, settings, socioeconomic status, citizenship, and cultural values. The make-up of populations that are served continually shifts, and behavior analysts should adapt to the needs of the families that they serve. For example, racially and ethnically diverse groups currently make up about 28% of the population (Humes et al., 2011). However, minoritized groups will make up more than half of the American population by 2044 (Colby & Ortman, 2015). A family's identity is part of the context and should be considered due to the potential variations in contingencies in their environment.

Behavior analysts and researchers are beginning to examine how they can best consider cultural variables when providing services. Frameworks are systems that describe a concept or process and are used to assist with considering culture during the assessment and treatment process. Cultural humility, a framework described by Wright (2019), is a process of "self-evaluation and critique to address power imbalances and develop mutually beneficial and non-paternalistic partnerships with communities" (p. 1)." An additional definition provided by Hook et al. (2013) is the "ability to maintain an interpersonal stance that is other-oriented (or open to the other) in relation to aspects of cultural identity that are most important to the [person]" (p. 2). A behavior analyst is never expected to learn everything about every context or culture but should be aware that there are differences and should respond to each context in a way that best fits the family's goals. The process will be ongoing, uncomfortable (for some), but it is important to always practice cultural humility in order to create the most meaningful change for the client.

Every behavior analyst, in a sense, enters services in a position of power; meaning they provide a service for a family and the loss of those services could be detrimental to the well-being of the individuals they serve. Additionally, if the behavior analyst is, for example, a white, heterosexual, male, cisgender, American citizen, serving a family from a historically marginalized group, there is an added layer of power or privilege (Bohonos 2021). It is important that behavior analysts consider how their position of power or privilege impacts treatment. The easiest way to describe privilege is the absolution of worry about things that others have to worry about on a daily basis. For example, a person who is from an upper- or middle-class socioeconomic status does not need to worry about keeping their lights on or their next meal, whereas someone from a low socioeconomic status will carry this burden. A person who is born in America or has citizenship in the United States does not have to worry about allowing professionals in their home that could jeopardize their safety in the country, leading to separation from their family. Practicing cultural humility is even more imperative when the behavior analyst/therapist is cross-cultural. Wright (2019) recommended a self-assessment on an individual level and an organizational level. Examples of some questions include, "What are my cultural identities?", "How does my own cultural background help or hinder my connection to clients/communities?", "What are my initial reactions to clients, specifically to those that are culturally different than me?", and "How much do I value input from my clients?". Furthermore, Horner (1994) published a commentary paper on the advances of functional assessment technologies. In the paper, Horner discusses that clinicians should consider culture when moving from a functional assessment to clinical intervention. Horner encourages readers to use both behavioral function and family features to develop contextually fit interventions. A contextual fit might include the culture of the family, especially if that family follows cultural practices different from those of the behavior analyst. Horner describes key features such as skills, schedules, resources, and values of the people who will be implementing the procedures.

Pritchett et al. (2020) also discuss the importance of context and understanding. One of their recommendations for behavior analysts is to practice perspective-taking to neutralize power imbalances. Perspective-taking skills allow historically marginalized groups the space to describe the history of their lived experiences. From a behavior analytic perspective, "lived experiences" are synonymous with histories of contingencies. The family reporting topographies of problem behavior, frequency, intensity, common antecedents, common consequences, and previous treatments all provide insight into the contingencies of that context. Thus, it is imperative that behavior analysts are actively listening and providing opportunities for the family to describe all contingencies present in their context (cultural context included). Missing the contingencies in the environment may prevent or create barriers for the behavior analyst's effectiveness. The literature is beginning to gain more information about how to best consider contextual and cultural variables. The following sections will discuss some examples (but not an exhaustive list) of contextual variables that are important to consider during treatment for problem behavior.

Culture

A contextual factor that is commonly overlooked is culture. Skinner defines culture in *Beyond Freedom and Dignity* as behavior that is shaped by a set of contingencies that a group of individuals follows for the survival of that group, meaning the behavior is reinforced by the group (Skinner, 1971). For example, some cultural groups share responsibilities across nuclear and extended families. The shared responsibilities across all of their family members allow for individuals' care, financial responsibilities, household chores, and emotional support. An individual is always part of a culture in some aspect. Examples of cultural variables include, but are not limited to, race, ethnicity, gender identity, sexual orientation, religion, socioeconomic status, geographic location, language, and citizenship. An individual receiving treatment can have overlapping identities which influence their behavior and contingencies around whether their behavior will continue or stop. Skinner (1971) states that social environments and culture contribute to the success of a practicing group. Because adherence to cultural practice is associated with reinforcement within a cultural community, interventions that jeopardize that reinforcement may not be adopted. Thus, behavior analysts should consider the social environments and culture of the families when treating the behavior of an individual and their family system.

Identifying these cultural variables is important in behavior analysis, particularly in the treatment process. The goal of behavior analysis is to improve the quality of life of that individual, which includes the family or surrounding contexts (Baer et al., 1968). For example, in some cultures, direct eye contact is considered aggressive and could be interpreted as disrespectful. Teaching an individual to make direct eye contact with every request may be punished or extinguished in their everyday life. Thus, behavior analyst should be tailoring the interventions to the context in which these behaviors will be reinforced and utilized day-to-day. Evaluating cultural variables in the context of the treatment process is a new and growing area. Much of the literature evaluating cultural variables is centered on language. Next, we will review some interesting ways that language can affect the treatment process.

Language Language is verbal behavior that communities use to communicate with each other. Environmental variables functionally control the acquisition of language (Skinner, 1957). Language is part of a group's culture. Every culture uses some form of language to communicate, and these languages vary across cultures. The verbal community that surrounds the individual reinforces different words. Brodhead et al. (2014) define cultural and linguistic diversity as "the social (cultural) differences between groups that may control verbal behavior" (p.2). For example, different communities reinforce different words, which ultimately is how linguistic diversity is shaped over time. Additionally, behavior analysts serve a linguistically diverse population. In fact, the US Census (2011) reports that 23,060,040 people residing in the United States speak a language other than English. Half of this population (11,116,194) speaks Spanish, and this number continues to grow. In the next section, we will discuss modifications in the treatment process that consider language when they are implemented with linguistically diverse populations.

Treatment Outcomes Language has shown to have an effect on aspects of treatment outcomes. Aguilar et al. (2016) conducted a study to identify the language preference of instructions for children with autism receiving services. The authors presented the participants with multiple language options to evaluate their preference for English or Spanish instructions. The children were given a choice of the language of instruction by presenting different microswitches. Each microswitch represented either English instructions, Spanish instructions, or no instructions. Results indicated that the participant preferred to receive instructions in Spanish.

Research has not only indicated that the language of instruction matters, but there can also be a difference in reinforcing value. Clay et al. (2020) conducted a study to evaluate the preference and reinforcing efficacy of language. The authors conducted a paired stimulus preference assessment for language followed by a reinforcer assessment to evaluate the reinforcing value of praise in English and Spanish. The preference assessment showed that there was limited to no preference for praise in one language over the other; however, when a reinforcer assessment was conducted, one participant showed slightly more responding in Spanish than in English. Slightly higher responding could indicate a slightly higher reinforcing value for praise in Spanish. The findings of the above two studies are important because if there is a preference or higher reinforcing value for one language over the other, the differences can have an effect on increasing a behavior using more salient reinforcers.

Language is also being evaluated in the context of communication responses and problem behavior. Kunze et al. (2019) conducted a study where they observed the frequency of communication responses from a speech-generated device in English and Spanish. The authors found that there were more mands evoked in Spanish than in English. The number of mands evoked and the language of the mand are important because in order for problem behavior to stay low, a mand needs to occur to access a reinforcer. For example, the mand in Spanish may have a higher likelihood of being reinforced if the mand is in the primary language that the family speaks. Now, it may be the case that the family would prefer the individual to learn the mand in the secondary language and that is okay. The family's preference takes priority. It will be important to let the family know the specific mand you are teaching so they can reinforce the mand consistently in their environment. This type of flexibility shows cultural humility while still practicing behavior analysis in an effective manner. Another study was conducted by Neely et al. (2020), which evaluated resurgence of problem behavior in bilingual individuals. The participants were taught English and Spanish mands, followed by a resurgence test. The resurgence test could simulate conditions for a learner who uses one language in one context and a different language in another context. The results showed that functional communication responses in English (taught first) resulted in resurgence of problem behavior when the communication responses were extinguished in a different context. Meaning, problem behavior may increase in another context if the languages spoken in each context don't match. The authors demonstrated that two participants needed additional teaching in Spanish in order to mitigate problem behavior. One of the participants did not require additional teaching. In summary, it is not about choosing one language over the other; rather, it is important to recognize a cultural variable such as a language cannot be ignored because it can influence the intervention process. The responsibility is on the behavior analyst to consider these variables and create an intervention plan that will best fit the needs of the individuals and family's cultural context.

Setting

Another contextual consideration for treatment is the client's setting. Individuals receive treatment in a variety of different contexts including in homes, clinics, schools, and community settings. Each setting has features that can enhance as well as create barriers for treatment implementation. As such, careful consideration of the physical environment where treatment takes place is important when developing function-based treatments. To illustrate, consider treatment that occurs in-home versus in a clinic. Given families live in their homes, we can expect more distractions and unpredictability (e.g., family members present or easily accessible toys and other non-treatment items). While we might consider these potential barriers, treatments that are successful in natural environments require less programming for generalization. Similarly, having siblings or other family members present can facilitate training on interventions for all relevant stakeholders in the child's life. In comparison, the clinic offers a much more controlled space where distractions and nontreatment items can be managed more easily. Treatment in-home may require more advance planning to ensure sessions work around family routines and schedules, that specific reinforcers (e.g., toys or edibles), program materials, and data collection materials are available that may be more readily available in clinics. It's also essential to consider the safety risks posed by the treatment context, particularly when treating problem behavior. For example, in schools, it is critical for teachers and clinicians to consider classroom safety globally. This includes the safety of the client as well as other students in the same space, and the variety of materials (including furniture, etc.) that are accessible and could become dangerous during episodes of problem behavior.

Age

In addition to culture and setting, behavior analysts must always consider the chronological and cognitive age of their client when examining context to ensure the most appropriate treatment selection. For example, offering emphatic praise and high-fives to an attention-loving preschooler will likely serve as high-quality reinforcers, but the use of those same reinforcers with an older adult who prefers a quiet space would be absolutely misguided. As with all behavior analytic treatment, there is no one-size-fits-all approach, and the consideration of client age in treatment selection is paramount. Behavior analysts have the potential to serve individuals across the lifespan, meaning they may encounter early learners as young as 18 months old (Vietze & Lax, 2020) to older adults over 65 years old (Burgio & Burgio, 1986).

Behavior analysts should be thoughtful about the variations and modifications to assessment and treatment for their clients based on their age. This includes but is not limited to the types of instructional materials, examples, reinforcers, job aids, goals, and treatment environments chosen for each client. Consider a 17-year-old client diagnosed with a mild intellectual disability receiving services to assist with their transition into adulthood. The behavior analyst should choose examples relevant to that client's cognitive skill level, as well as age-appropriate interests (e.g., these could include going to college, finding paid employment, making friends, dating, etc.). Another important consideration is the developmentally relevant milestones to a client's chronological age (for the example above, factors such as hormone and body changes, emotional impulsivity, or the ability to make decisions could contribute to the client's context; Corchado & Martínez-Arias, 2022).

It likely goes without saying that priorities and preferences change as individuals age. A person-centered approach will pave the way for behavior analysts to ensure their treatment priorities align with their clients' values (Holburn, 2001; Slocum et al., 2014). Think about your own priorities at the age of 5, 12, 18, 25, and beyond. Consider how your own priorities may change based on your decade of life, your physical and mental abilities associated with that age, your ability to wait patiently or concentrate on a difficult task, or how your physical senses have changed over the course of your life. All of these factors, and more, play a role in a client's contextual environment related to their age. As behavior analysts approach differently aged clients across the lifespan, we encourage you to get creative. Ask questions. Consult the literature. Seek insight from your team members and colleagues to help you consider the best and most supportive treatment for your client of any age.

Resources

One final contextual factor to consider in treatment selection is the availability (or lack) of resources at the behavior analyst's and their clients' disposal. Research shows that variables like treatment cost, insurance coverage, socioeconomic status, geographic location, neighborhood, school district, and access to technology can greatly affect treatment outcomes for our clients, as well as their access to treatment at large (Nieuwenhuis et al., 2017; Wilson et al., 2018). These barriers are further intensified by systems that allow for racism, classism, and other prejudices that ultimately prevent access to healthcare, adequate nutrition and education, and childcare for individuals from historically marginalized groups as well as low-income families (Cogburn, 2019; Gee & Ford, 2011; Nieuwenhuis et al., 2017).

As stated earlier in the chapter, the behavior analyst's awareness and education around these barriers will allow for more equity in treatment for all of their clients. Other resources to consider in treatment selection are the availability of staff to implement treatment, access to a variety of reinforcers and instructional materials, physical space of the treatment environment, and whether the client has reliable transportation. Once the behavior analyst has taken a thorough inventory of the available resources, they will be empowered to advocate and facilitate removing any barriers to treatment for their clients (BACB, 2020, 2.19; Carr & Lord, 2016).

One final resource consideration is the ability to adapt in times of crisis. As we author this book, we are living through the COVID-19 pandemic. This global emergency has demanded our society to change the way we do just about everything, especially education and treatment of our clients. Educators, clinicians, and behavior analysts have been challenged with the task of delivering their services via telehealth or other technological mediums (Rodriguez, 2020). This poses a large treatment barrier to clients without regular access to technology (e.g., computers, tablets, or smart phones), reliable internet, a quiet learning space, or family to help support treatment in the home. As behavior analysts continue to navigate this crisis and future unexpected events in our ever-changing world, they should remain cognizant of their clients' values and the stressors they face daily. Behavior analysts have the technology and training to make treatment feasible and accessible to their clients and families no matter what their contextual environment is (Coyne et al., 2021; Szabo et al., 2020).

Treatment Based on Function of Problem Behavior

As mentioned previously, function-based interventions are more effective than non-function-based interventions (Ingram et al., 2005). In the following sections, we will discuss treatment for four main functions of problem behavior: (a) attention, (b) automatic reinforcement, (c) access to tangibles, and (d) negative reinforcement (escape).

Problem Behavior Maintained by Access to Attention

In this section, we will discuss treatment for attention-maintained problem behavior. These behaviors are defined as those shown through a functional analysis to be maintained by social positive reinforcement in the form of attention from another person (Cooper et al., 2020). In other words, if a behavior increases when followed by attention from another person, it is likely maintained by attention. Several literature reviews have been conducted on the incidence of different topographical response classes and functional relations of problem behavior. Two reviews in particular are noteworthy. Hanley et al. (2003) found that 25.3% of problem behavior reported in the functional analysis literature was shown to be maintained by social positive reinforcement in the form of attention. More recently, Beavers et al. (2013) found that 17.2% of problem behavior reported in the literature was shown to be maintained by social positive reinforcement in the form of attention. Further, both studies also reported behaviors between 14.6% (Hanley et al., 2003) and 24.3% (Beavers et al., 2013) to be multiply maintained, which may also encompass attention as a functional reinforcer. Because of its prevalence in the literature, it is likely that behavior analysts will encounter behavior maintained by attention and thus need to be aware of various treatments and contextual considerations when selecting treatment. Before we get into the treatment of attention-maintained problem behavior, we will first discuss common antecedents and types of attention.

Functional Antecedents

For attention-maintained behavior, we must first consider antecedents that can serve as triggers to problem behavior. The most obvious antecedent is the removal of attention. For example, let's say that Maria's whining at bedtime is maintained by access to attention from her mother. Every time her mother leaves Maria's bedroom, she begins to whine, and Maria's mother always comes back in to check on her and assure her things are okay. The removal of attention could function as an antecedent which is evoking whining. Diverted attention can be another antecedent to attention-maintained problem behavior. Diverted attention is when the attention is removed and specifically diverted to something or someone else. For example, when Maria is playing in the kitchen with her mother, the phone rings. Maria's mother goes to answer the phone, and Maria begins whining. Maria's mother tells the person on the phone she will have to call them back and returns attention back to Maria. In this example, Maria's mother's attention has been diverted to someone else (i.e., someone on the phone). For some individuals, the simple removal of attention does not function as an antecedent for problem behavior; however, someone else getting the attention from another individual may function as an antecedent. For example, Maria's mother could be in a room with Maria without directly giving her attention and without Maria engaging in any problem behavior. However, if another person walks into the room and gets the mother's direct attention, this may serve as an antecedent for Maria to engage in problem behavior. For all attention-maintained problem behavior, the perceivable presence of another person functions as a discriminative stimulus that attention is available. In this way, attention-maintained problem behavior generally does not occur when the individual is alone but only in the presence of other people that could deliver attention.

Types of Attention

There are also different types and topographies of attention to consider when selecting treatment for attention-maintained problem behavior. When we describe attention-maintained problem behavior as the behavior that is maintained by social positive reinforcement, this does not mean positive or "good" attention. It simply means the addition of attention to a previous lack of or minimal attention situation. The attention received contingent on problem behavior could be both positive or negative or "bad" attention (reprimand). In fact, researchers have found that variations in the topography of attention show differentiated effects for both attention-maintained and escape-maintained problem behavior (Gardner et al., 2009; Kodak et al., 2007). When evaluating the types of attention, there are several different topographies of attention to consider: vocal, physical, proximity, eye contact, and body language. Vocal attention is a stimulus change in the environment that consists of a vocalization from one person to another, usually perceptible to the ears. It can be in the form of praise statements, reprimands, conversations, noises, expressions of annoyance, or attempts to soothe, just to name a few. Physical attention is a stimulus change in the environment that involves touch from one person to another, usually perceptible to the skin. Physical attention could be a pat on the back, a handshake, a high five, holding hands, or even a physical restraint. Proximal attention is a stimulus change in the environment that involves the nearness of one person to another, usually perceptible to the eyes. Sometimes the mere approach of someone can be the form of attention. Consider the waitress coming toward your table to take your order. Finally, eye contact and body language are also types of attention that involve a stimulus change in the environment that is perceptible to the eyes. Most of us can remember the feeling we got when we made eye contact with a crush in our adolescent years. Similarly, body language, such as gestures, can be a form of attention and a form of nonvocal verbal behavior. In addition to varying topographies of attention, behavior analysts should also consider duration when evaluating the quality of attention delivered. By manipulating these aspects of attention, we can increase or decrease the overall quality of attention provided, contingent on appropriate or inappropriate behaviors.

Treatment for Behaviors Maintained by Attention

When we look at function-based treatments for attention-maintained problem behavior, they fit into two categories: antecedent-based interventions and consequence-based interventions. The theory behind function-based interventions for attention-maintained problem behavior is somewhat simple. If attention functions as a strong reinforcer for the individual, then we can use the motivation for attention to decrease the inappropriate behavior and increase appropriate behavior (Cooper et al., 2020). For antecedent interventions, we are generally providing attention prior to onset of the target behavior. For consequence-based interventions in general, we are either providing attention for a different behavior or no longer providing attention for the target behavior, or both. The interventions described below utilize the theory of using functional motivation, and research shows these interventions have significant effects on attention-maintained behavior.

Antecedent-Based Interventions

Noncontingent Attention One of the quickest ways to reduce attention-maintained problem behavior is to reduce the motivation for attention. By providing noncontingent attention, the individual may become satiated with attention, thus reducing the value of attention as a reinforcer and the likelihood of engaging in behaviors that produce attention (Cooper et al., 2020). This strategy is usually used on a timed schedule (either fixed or variable), where attention is delivered at a preset time, regardless of the behavior that the individual is exhibiting. The risk of noncontingent attention is that delivering attention on a fixed time schedule may mean delivering attention following problem behavior and thus inadvertently reinforcing problem behavior. In our example of Maria, whose whining has been determined to be attention-maintained, we might use noncontingent attention by giving Maria verbal praise, smiles, or winks every 5 min throughout our phone call with our friend. This way, Maria is getting attention on a fixed time schedule, thus reducing the motivation for attention.

Consequence-Based Interventions

Extinction Withholding reinforcement for a previously reinforced behavior is one of the more researched consequence-based strategies for attention-maintained problem behavior (Cooper et al., 2020). For attention-maintained behaviors, it means withholding attention following the target behavior. It is important to identify the topography of attention that is maintaining the problem behavior, as even a quick reprimand or furrowed brow could serve to reinforce the problem behavior. It is also important to withhold attention only for the target behavior. Usually, extinction is used in combination with another consequence-based strategy, such as differential reinforcement of alternative behavior (see below). During the initial implementation of extinction, implementors often see an extinction burst, which is defined as a sudden increase in the target behavior following extinction (Cooper et al., 2020). Implementors of extinction need to be prepared for this, so as not to inadvertently reinforce the behavior at its highest magnitude or intensity. Further, implementors of extinction also need to consider the harm of not being able to implement extinction with 100% integrity. This can result in intermittent reinforcement of the target behavior, which can actually strengthen the response and make it resistant to extinction procedures. For example, let's go back to Maria, who is whining at bedtime to get her mother's attention. Let's say that Maria's mother decided to use an extinction procedure to reduce whining at bedtime. On Monday night, Maria begins whining around 8:30 and continues into a full-on tantrum with screaming, crying, and pounding on her bedroom door. Maria's mother knows about extinction bursts, so she bought some ear plugs to be able to withstand the noise. Around 9:30, Maria fell asleep on her bedroom floor. On the second night, Maria whined just a little but fell asleep in her bed around 8:45. This pattern continues with whining decreasing and sleep time increasing until Friday night. Maria's mom had a long day at work and didn't get home until after dinner. Maria went to bed at 8:30 and whined because she missed her mom at dinner. Maria's mother tried to stay strong but went to check on her at 9:00 because she was worried that Maria was going to make herself sick with whining. Unfortunately, this intermittent reinforcement could strengthen Maria's whining in the long run, and because Maria's mom went in after 30 min, it could have also increased the duration for which Maria will whine until she "gives up." For this reason, it is good to give parents' options when implementing extinction, and if they want to implement it, ensure they pick days and times in which they are likely to be successful.

Differential Reinforcement of Alternative Behavior (DRA) Differential reinforcement of alternative behavior is usually used when we have identified the function of the problem behavior and are able to select a functionally equivalent replacement behavior. When selecting a replacement behavior, it is important that the alternative behavior is more efficient and effective than the problem behavior (Cooper et al., 2020). In other words, it has to be less effortful and result in a greater amount of the reinforcer more often than the problem behavior. In DRA and any differential reinforcement procedure, behavior analysts want to ensure that the behaviors they want to see increase are competing for reinforcement with the behaviors they want to see decrease. Using the competition analogy, the winning behavior (in this case, the replacement behavior we want to see increase) is one that is faster and produces greater rewards than the losing behavior (in this case, the target behavior we want to see decrease). Going back to Maria, who wants her mom's attention when her mother is on the phone, a replacement behavior for whining could be writing her mom a note. However, in order for note writing to be an effective replacement, it has to result in mom's attention more often than the problem behavior. Thus, mom must respond immediately to the note and every time Maria writes a note. Eventually, once an individual is consistently engaging in the replacement behavior and the problem behavior has reduced to zero or near-zero levels, the schedule of reinforcement can be thinned to intermittent reinforcement and a delay can be systematically introduced. In the note-writing example, Maria's mom could give a signal, like holding up her pointer finger, to Maria indicating that she will respond in a minute. This provides Maria with two things, attention in the form of validation that mom is aware Maria is communicating, and an indication that there will be a slight delay to reinforcement. This is one way we can successfully thin a schedule of reinforcement to one that is more naturally occurring and manageable.

Differential Reinforcement of Other Behavior (DRO) Another way to treat attention-maintained problem behavior is to provide attention to other behaviors. In other words, reinforcement can be provided for any and all behaviors *other* than the problem behavior (Cooper et al., 2020). Sometimes DRO procedures can be difficult to maintain due to the sheer magnitude of other behaviors you would be reinforcing, so behavior analysts must determine whether they are going to set an interval or momentary DRO schedule. In an interval schedule, the target behavior must not occur for a set amount of time before reinforcement is delivered. This requires the behavior change agent to be actively monitoring the client through the entire interval. Alternatively, in a momentary schedule, the behavior must not occur at a specific moment in time. While interval DRO may be more effective at reducing the problem behavior, momentary DRO may be a more manageable way to reinforce other behaviors (Cooper et al., 2020). Similar to NCR, in an interval DRO you would select an amount of time, usually less than the current inter-response time (IRT) (i.e., time between instances of problem behavior), and once the time had elapsed, you would reinforce the first instance of *other* behavior that occurred. In setting the time less than the current IRT, the behavior analyst is ensuring that the other behavior is reinforced at a rate higher than the problem behavior, thus making it more effective for gaining attention than the problem behavior. For example, let's go back to Maria, who engages in whining behavior while her mom is on the phone. Her current IRT is averaging 6 min. So, you set your interval at 5 min. The first behavior that occurs after the 5 min elapse is any behavior other than whining would get attention. The key difference with DRO (compared to NCR) is that if problem behavior occurs, you do not provide reinforcement. The reinforcement is contingent on the absence of the problem behavior.

Treatment Selection

It may sometimes be difficult to identify the best treatment option for any given situation given the number of different function-based interventions available to behavior analysts. However, the BACB's Ethics Code for Behavior Analysts (ECBA; BACB, 2020) gives behavior analysts recommendations for doing so. Specifically Code 2.14 states, "Behavior analysts also consider relevant factors (e.g., risks, benefits, and side effects; client and stakeholder preference; implementation efficiency; cost effectiveness) and design and implement behavior-change interventions to produce outcomes likely to maintain under naturalistic conditions." Grow et al. (2009) provide behavior analysts with a simple decision tree to aid in treatment selection for attention-maintained problem behavior. In addition, there is a host of research on evidence-based practices, which means to "integrate the best available evidence with client values/context and clinical expertise in order to provide services for their clients" (Slocum et al., 2014, p. 41). Earlier, we outlined specific contextual variables such as culture, values, setting, resources, age, and family preferences when selecting treatments. In order for function-based interventions to be effective and generalized, it is imperative that they are selected and designed specifically for the context of the individual we are serving.

Problem Behavior Maintained by Automatic Reinforcement

When individuals engage in behaviors to get access to the stimulation created by that very same behavior, those behaviors are said to be maintained by automatic reinforcement. In the review by Beavers et al. (2013), 16.9% of cases resulted in an automatic function. Behaviors maintained by automatic reinforcement present many challenges for behavior analysts (Vollmer et al., 1994). Specifically, because the behaviors produce their own reinforcers, it is often difficult to manipulate and separate the reinforcer from the behavior without using intrusive interventions, such as blocking. For example, if an individual engages in skin picking that is automatically maintained, without blocking the behavior itself, the individual will continue to access the reinforcer each time they engage in skin picking. Another challenge with behavior maintained by automatic reinforcement is that it is often difficult to identify the specific reinforcer for the behavior. For instance, when self-injurious behavior, such as biting, is found to be maintained by automatic reinforcement, it is unclear during the functional analysis if the specific reinforcer is the stimulation created on the skin from the bite or if the reinforcer is the stimulation felt in the individual's teeth. Given these difficulties, identifying functional antecedents to better predict and prevent the behavior and creating function-based interventions can be challenging.

Functional Antecedents

As mentioned before, the reinforcers that maintain automatically reinforced behaviors are difficult to identify. As a result, identifying the specific antecedents that evoke these behaviors is extremely challenging. However, behavior analysts can make predictions about the specific antecedents that may trigger problem behavior through the manipulation of different types of stimulation. Typically, there are five types of stimulation that a behavior produces: (a) tactile, (b) visual, (c) olfactory, (d) auditory, and (e) thermal. As a result, any event that either removes or presents any of these types of stimulation can evoke the problem behavior. In a study by Patel et al. (2000), researchers conducted antecedent assessments to identify the specific sensory stimulation that triggered problem behavior for two participants. During the assessments, the researchers presented and removed various types of stimulation during different conditions and measured the rate of problem behavior. The researchers successfully identified common triggers to the problem behaviors and were able to create function-based interventions for each participant.

Treatment for Behaviors Maintained by Automatic Reinforcement

Similar to other types of problem behavior, automatically maintained problem behavior can be approached through either antecedent-based or consequence-based interventions. However, given the difficulties with identifying specific reinforcers, interventions for behaviors maintained by automatic reinforcement more often involve antecedent manipulations rather than consequence-based interventions.

Antecedent-Based Interventions

The most common treatment for problem behavior maintained by automatic reinforcement is noncontingent reinforcement (NCR). During NCR, the client is given access to known reinforcers on a fixed or variable time schedule independent of behavior (Cooper et al., 2020). A common form of NCR used for automatically maintained problem behavior is environmental enrichment (Gover et al., 2019). During environmental enrichment, clients are given access to tangible items and/or activities on a fixed or variable time schedule. The goal of this intervention is to abolish the motivating operation for the reinforcers that maintain the problem behavior in order to decrease the probability that the behavior will occur. Research has shown that in order for environmental enrichment to be effective, the stimuli provided should successfully compete with the behavior (Berg et al., 2016; Piazza et al., 1998). Stimuli are said to successfully compete with the behavior if there are low levels of the behavior when the client manipulates the stimulus. For example, if an individual's levels of hand flapping decrease while playing with blocks, the blocks successfully compete with the behavior. These data are typically collected during a preference assessment. During the preference assessment, the behavior analyst presents the client with a number of stimuli and allows them to manipulate each one. The behavior analyst then records the levels of the automatically maintained behavior across all items and/or activities. Preferred stimuli that produce the lowest levels of problem behavior during the assessment are then used in the environmental enrichment intervention. The effects of this intervention are enhanced when the sensory stimulation produced by the preferred stimuli matches the sensory stimulation produced by the behavior (Piazza et al., 1998, 2000). For example, if a client engages in pica in order to get access to oral stimulation, behavior analysts could use edible items during environmental enrichment. Behavior analysts can identify these stimuli by conducting a matched stimulus assessment (Love et al., 2012; Piazza et al., 1998, 2000). During a matched stimulus assessment, behavior analysts present the client with various stimuli that are both preferred and match the sensory stimulation produced by the problem behavior. Additionally, stimuli from all other sensory categories are included and presented to the client during the assessment. For example, if behavior analysts believe that the hypothesized reinforcer for the behavior is a result of some sort of oral stimulation, during the matched stimulus assessment, the behavior analyst presents stimuli that produce oral stimulation and stimuli that produce other types of stimulation, such as tactile, auditory, visual, and thermal stimulation.

Consequence-Based Interventions

Another strategy that enhances the effectiveness of environmental enrichment is the use of reinforcement-based strategies. For example, behavior analysts can reinforce appropriate manipulation of objects and appropriate engagement in activities during environmental enrichment by delivering socially mediated reinforcers. Clients can earn tokens, praise, and other tangible or edible reinforcers for appropriate manipulation. For example, during environmental enrichment, the behavior analyst could deliver praise contingent on the individual playing appropriately with the items provided. However, sometimes individuals may not have the necessary skills to effectively manipulate the various objects in the room. The behavior analyst may sometimes have to implement a skill acquisition program that focuses on increasing play skills. Using this intervention, behavior analysts could prompt and reinforce appropriate manipulation of the items during environmental enrichment.

Occasionally, reinforcement-based strategies in combination with environmental enrichment are not effective at decreasing problem behavior maintained by automatic reinforcement. The reinforcer resulting from engagement in the problem behavior is much too strong and may not compete with other stimulation. When this occurs, behavior analysts may need to implement consequence-based interventions that are specifically targeting the problem behavior. The most intrusive approach is to use punishment-based interventions, such as the use of reprimands, response cost, overcorrection, physical or mechanical restraint, response blocking, and response interruption and redirection. Overcorrection can be used during environment enrichment as a consequence-based intervention. Specifically, contingent on problem behavior, the client is asked to engage in effortful behavior that is related or similar to the problem behavior (Cooper et al., 2020). Delivering verbal reprimands during environmental enrichment includes the behavior analyst making statements such as “Stop that!”, “No,” and “Don’t do that” contingent on problem behavior. Response cost can be used during environmental enrichment by removing access to the preferred objects and/or activities contingent on problem behavior. The use of physical or mechanical restraint during environmental enrichment can involve many things. For example, if the automatically maintained problem behavior involves the client engaging in skin picking, the behavior analyst can hold the client’s hands down contingency on the occurrence of the behavior. However, another option would be to use a mechanical restraint contingency on problem behavior, such as belts, to keep the client’s hands down for a specified duration of time. For example, contingency on the occurrence of skin picking, the behavior analyst could place the client’s hands into the mechanical restraint for 1 min during environmental enrichment. Response blocking involves the behavior analyst physically blocking the client from engaging in the problem behavior as soon as the behavior occurs throughout the duration of environmental enrichment. For example, if the behavior is hand-mouthing, behavior analysts can block the client by putting their hands over the client’s mouth as soon as the client engages in the problem behavior. Finally, response interruption and redirection is a variation of response blocking where behavior analysts interrupt an instance of problem behavior and redirect the client to engage in a more appropriate response. For example, if a client engages in hand-mouthing, behavior analysts can block the client from engaging in the behavior as soon as the behavior occurs and immediately redirect the client to clap their hands.

Treatment Selection

According to a recent review by Gover et al. (2019), a combination of both antecedent and consequence-based treatment is the most effective approach for decreasing behaviors maintained by automatic reinforcement. Specifically, environmental enrichment is most effective when a combination of both reinforcement and punishment-based interventions is used. However, using punishment-based interventions poses several issues for clients who are receiving treatment. For instance, treatments based on punishment are aversive and can often evoke emotional responding on the part of the client. These procedures would not be accepted well by both clients and their families. Given that our ethical compliance code requires us to ensure client and caregiver acceptability of our treatments, it would be difficult to reach acceptability with aversive interventions. Even more, using aversive interventions will make it less likely that caregivers or teachers will continue the treatment with fidelity outside of the treatment sessions. As a result, behavior analysts should go through the evidence-based practices that are based on reinforcement, such as using matched stimuli preference assessment and skill acquisition interventions, to avoid punishment-based strategies unless absolutely necessary.

Problem Behavior Maintained by Access to Tangibles

When clients engage in problem behavior in order to get access to goods, leisure items, or activities, they are said to be maintained by access to tangibles. In the review by Beavers et al. (2013), 17.2% of cases resulted in a tangible function. Similar to behaviors maintained by attention, when behaviors are found to have multiple functions, it is very likely that access to tangibles is one of those maintaining variables. For example, when individuals engage in escape-maintained behaviors, they usually do not escape to nothing. Typically, when individuals are given a break from work, they also gain access to preferred items and/or activities. As a result, it is very common for behaviors to be maintained by both escape and access to tangibles. Behavior analysts must ensure that they take into account all antecedent- and consequence-based variables when identifying function-based interventions for behaviors maintained by access to tangibles.

Functional Antecedents

The most common antecedent for behaviors maintained by access to tangibles is the removal of a preferred item or activity. For example, an individual may engage in problem behavior anytime their preferred items (such as food or their iPad) are removed. However, other antecedents that may trigger problem behaviors maintained by access to tangibles include denied access to the tangible items in the first place. For example, an individual may engage in problem behavior anytime their caregivers deny them access to preferred items, such as toys and/or activities. While both antecedent events are functionally similar, the treatment approach will vary depending on which antecedent event triggers the most problem behavior. For example, if an individual engages in more problem behavior when denied access to items than when the items are removed, the behavior analyst may need to focus treatment on teaching that individual to accept "No" rather than teaching them to ask for items appropriately. On the other hand, if an individual engages in more problem behavior when items are removed than when they are denied access to those items, the behavior analyst will need to focus treatment on teaching the individual to ask for the item back in a more appropriate way, such as "Can I have more time?" or "Can I have it back?"

Treatment for Behaviors Maintained by Access to Tangibles

Function-based treatments for behaviors maintained by access to tangibles generally involve reinforcing a more appropriate response for accessing the tangible items. However, as mentioned before, the type of response taught will depend on the specific antecedents evoking the problem behavior. Either way, like many other types of problem behavior, the most effective treatment approach for behaviors maintained by access to tangibles involves a combination of both antecedent and consequence-based interventions. Specifically, treatment should involve creating an environment that decreases the establishing operation for the problem behavior while also disrupting the relationship between the problem behavior and the tangible reinforcers. Below, we will talk about how to address each approach.

Antecedent-Based Interventions

A common approach to the treatment of many problem behaviors is functional communication training (FCT). This procedure involves teaching an appropriate communicative response in order to access the specific tangible item. FCT is often used when the individual cannot mand for items or activities. The first step in FCT is to identify the form of the communicative response. The behavior analyst will include the family and client in deciding whether they will teach a vocal response, a picture card, an augmentative device, a microswitch, or any other form of language. Once a form is identified, the behavior analyst will then begin the process of teaching the communicative response.

The behavior analyst will base the specific communicative response to teach during FCT on the specific antecedent event that evokes problem behavior. Sometimes, the communicative response is a specific item, food, and/or activity, such as "Skittles" or "Go outside." Other times, the behavior analyst may choose to teach a more general communicative response, such as "I want my way," in order to capture multiple items and/or activities. Finally, as mentioned above, sometimes the communicative response that is targeted during FCT is a tolerance response such as "Ok" in response to a caregiver saying "No" or denying access to item.

Although FCT is an effective intervention used to decrease problem behaviors maintained by access to tangibles, there are a few things that behavior analysts should consider. First, during FCT for access to tangibles, individuals may become obsessed with the tangible item and/or activity. As a result, the frequency of the communicative response may increase to levels that may interfere with learning. This can be alleviated by doing a variety of things. For example, the behavior analyst could schedule noncontingent access to the tangible item in order to decrease the motivating operation for the item Another option would be to provide other preferred stimulus based on a preference assessment. Finally, behavior analysts could use what is called a "safety spot" where the individual loses access to the item or activity but can still see it in the room. With this procedure, behavior analysts identify a "safety spot" in the room where the individual can place the item when their time with it is up. A second barrier that may come up during FCT for access to tangibles is that learners may have a restricted range of actions they perform with the item. For example, an individual may learn to ask for their iPad appropriately; however, when they get access to their iPad, they watch short segments of videos over and over again. Behavior analysts could address this by scheduling specific times where the individual could engage in this restrictive behavior and times where they must do other things on their iPad. A final barrier that may come up during FCT for access to tangibles is the availability of the tangible item or activity. Specifically, an individual's preferred item or activity may only be available during restricted times. For example, if an individual's preferred activity is playing outside, access to playing outside is restricted to days where it is safe to go outside. If there is any inclement weather that prevents the individual from going outside (i.e., too cold, raining, etc.), access to that preferred activity is no longer an option and the behavior analyst can no longer use it as a reinforcer. A way to address this issue is to identify multiple items and/or activities that the individual can access contingent on appropriate requests. For example, instead of teaching an individual to appropriately request one specific item, the behavior analyst could teach them to request multiple items. This can be done by either teaching a general request such as "I want Max time" or by teaching the individual to ask for multiple items (Reichle & Wacker, 2017).

Consequence-Based Interventions

Once an individual can successfully ask for a tangible item, behavior analysts switch from FCT to differential reinforcement of alternative behaviors (DRA). During a typical DRA procedure, behavior analysts reinforce an appropriate request for a tangible item and put the problem behavior on extinction (Cooper et al., 2020). That is, they no longer deliver the tangible item contingent on problem behavior and instead only deliver the tangible item contingent on an appropriate request such as "Can I have skittles?" or "I want skittles." For example, if a client engages in physical aggression that results in access to an iPad during a DRA procedure, behavior analysts will no longer deliver the iPad contingent on physical aggression and instead only deliver the iPad if the client says, "Can I have my iPad?"

Despite its effectiveness in decreasing problem behaviors, barriers can arise when implementing extinction during DRA. For example, there are some behaviors that are too dangerous to withhold reinforcement. Specifically, in order to keep the client and others safe, it is necessary to continue to reinforce the behavior. For example, if a client engages in aggression that is maintained by access to tangibles, it would be dangerous to withhold the reinforcer while allowing them to continue to aggress toward others. Another example is when the behavior involves self-injurious behaviors. If an individual engages in head hitting in order to get access to tangible items, it would be extremely dangerous to allow the behavior to occur without delivering a reinforcer. Additionally, complete extinction of a problem behavior can be extremely difficult for both behavior analysts and caregivers. Extinction bursts commonly follow the onset of extinction interventions. Extinction bursts occur when the behavior increases in magnitude or intensity as a result of withholding a reinforcer. This increase in magnitude and/or intensity can become extremely aversive for the caregivers and/or behavior analysts who are implementing the intervention. As a result, treatment fidelity may decrease if the caregiver and/or partitioner can no longer tolerate the behavior.

Recent reviews on DRA suggest that using extinction is not always necessary to decrease problem behavior. Given the many barriers that arise from using extinction during DRA, an alternative approach is to use DRA without extinction (Peck et al., 1996). Specifically, behavior analysts could continue to reinforce the problem behavior but at a lower rate or with a thinner schedule of reinforcement. This procedure can be delivered in many different ways. For example, one approach would involve delivering the highest quality reinforcer contingent on appropriate requests for tangible items and delivering a low-quality and/or less preferred tangible item contingent on problem behavior. For instance, if an individual engages in tantrums in order to gain access to their computer (i.e., high preferred item), behavior analysts can allow access to the computer contingent on the client saying, "Can I play on my computer?" At the same time, the behavior analyst can deliver blocks (i.e., low preferred item) contingent on tantrums. Another approach would be to change the schedule of reinforcement based on appropriate and inappropriate behaviors. For example, if an individual engages in physical aggression in order to gain access to food, the behavior analyst could allow access to food for each response of "I want food" (i.e., FR1). However, if the individual engages in physical aggression, the behavior analyst will only deliver food after five instances of physical aggression (i.e., FR5). Finally, behavior analysts can also change the magnitude of the reinforcer for both appropriate and inappropriate behaviors. Specifically, if the individual above were to engage in physical aggression, the behavior analyst might deliver a small portion of a food item while delivering large portions for appropriate requests.

Treatment Selection

Combinations of DRA, like the ones mentioned above, are frequently used in the literature to address behaviors maintained by access to tangibles. Some considerations for effective implementation of the procedures above include ensuring that you have conducted frequent preference assessments and ensuring that you identify an array of multiple tangible items. Regardless of what moderation of the DRA procedure you use, the ultimate goal is to teach the individual a more appropriate way to access the tangible items and activities they need.

Behaviors Maintained by Negative Reinforcement (Escape)

When negative reinforcement (escape) is identified as the function of problem behavior, the consequences for problem behavior are either the removal or delay of an aversive task or activity. Behavior maintained by negative reinforcement can involve either an escape or avoidance contingency. When the removal or termination of an aversive task or activity maintains problem behavior, we refer to that contingency as escape, and the behavior as escape maintained. For example, a student who swipes materials off their desk after beginning a math worksheet will almost certainly have work terminated for a short time (e.g., while the teacher gathers the materials off the floor). If the student continues to swipe materials off the desk more often moving forward, this is conceptualized as an escape contingency; in other words, the student swipes materials because it results in a temporary removal of the math work. On the other hand, if a behavior is either preventing a task from being presented all together or delaying it, we refer to this as avoidance. For example, a student who hits a peer after recess (right before math instruction begins) and is sent to the office or resource room, avoided contact with instruction altogether. In this scenario, because the behavior resulted in the prevention of the aversive task presentation, we may conceptualize this behavior as avoidance (if behavior occurs more often in the future). Both escape and avoidance (i.e., negative reinforcement) are the most common functions of problem behavior among individuals with intellectual and developmental disabilities (IDD), including those with autism spectrum disorder (ASD; Beavers et al., 2013), and the percentage observed is even higher in classroom settings (Llyod et al., 2016). Problem behavior that occurs during instruction is especially disruptive to learning as it interferes with the ability to acquire academic and other important skills. Given the importance of skill building for individuals with ASD, effective treatments for escape-maintained problem behavior are critical for successful long-term outcomes.

Functional Antecedents

Whether an individual is behaving to escape or avoid an aversive situation, what constitutes what is aversive will be idiosyncratic across individuals (Langthorne et al., 2014). This is an important consideration when deciding and designing treatments. We commonly think of individuals escaping from academic work; however, research has demonstrated escape or avoidance may occur with a variety of other stimuli including aversive aspects of the environment (e.g., noise; Kettering et al., 2018; Dupuis et al., 2015), attention or physical proximity (e.g., Hagopian et al., 2001; Oliver et al., 2001), as well as nonacademic tasks (e.g., daily living routines). Correspondingly, very specific stimuli associated with an aversive task or activity may evoke escape or avoidance behavior while others may not. Consider that particular academic work topics (e.g., math), or types of work (e.g., word problems), may evoke escape or avoidance when others (e.g., reading or numeral problems) may not. Identifying the specific stimulus conditions evoking escape may be important for designing the most effective and least restrictive intervention (Call et al., 2004) and can be evaluated using treatment analyses (e.g., Cooper et al., 1992) or structural analyses (e.g., Hagan-Burke et al., 2015).

To illustrate, imagine a child in a special education classroom who engages in aggression during instruction, we'll call her Luna. A functional analysis demonstrated negative reinforcement is the function of Luna's aggression, and the descriptive assessments suggest it's most likely to occur during math instruction. This may sound like a straightforward case of escape-maintained problem behavior that most function-based interventions could resolve. But as it turns out, math work itself is not what Luna is actually seeking to escape; she's seeking to escape the physical prompts involved during number block lessons (e.g., graduated guidance) that are not present in other academic tasks. Although a less individualized intervention may reduce aggression, if we know that Luna is actually engaging in aggression to remove physical prompts, a simple antecedent change in the type of prompting could reduce behavior without the need for a more restrictive intervention. Further, if that type of prompting during instruction will be temporary, the aggression is tolerable, and she's showing mastery, we may decide not to intervene at all. Although this level of analysis may not always be necessary or feasible to implement, the more fine-grained analysis should be prioritized when an FBA evaluating standard escape conditions is inconclusive, or when problem behavior occurs during control conditions (Langthorne et al., 2014). As behavior analysts, we are ethically bound to provide the most effective and least intrusive intervention, so careful consideration of context in this manner should not be dismissed (BACB, 2020).

Treatment for Behaviors Maintained by Negative Reinforcement (Escape)

A variety of function-based interventions have been established as effective for reducing negatively reinforced problem behavior. These treatments can be divided into two broad categories: those that intervene on variables present prior to the problem behavior (antecedent-based interventions) and those that occur after (consequence-based interventions). As noted above, contextual factors related to the individual need to be considered when selecting an intervention. It is crucial that our interventions match not only the problem behavior function but also match the intervention context, requiring thorough consideration of all relevant variables described previously (e.g., cultural factors, preference, setting, etc.). The sections that follow describe an overview of intervention procedures and considerations for choosing function-based interventions for escape-maintained problem behavior. Given that escape-maintained problem behavior often occurs in instructional contexts (Llyod et al., 2016), the examples presented will be specific to behavior to escape or avoid instructional tasks.

Antecedent-Based Interventions

Instructional Modifications Similar to attention-maintained behavior, the first thing to consider when deciding a treatment for escape-maintained behavior is the context in which the behavior is occurring. After reading that last sentence, you might be saying "Well of course it is! Evaluating and changing the context is what we do!". You'd be right, of course, but there are contextual variables we often overlook, particularly when we're acting as consultants who are not typically part of the natural environment. The contextual variable most relevant to escape-maintained problem behavior during instruction is the current instructional situation. In particular, assessing the instructional level of tasks, the way instructions are being delivered, the availability of support for the student while completing tasks, and whether or not the student has the skills to recruit any needed support. The purpose of assessing instructional level is to ensure the skills of the student match the instructional materials they're expected to engage with. A mismatch in instructional level can include both tasks that are too difficult or tasks that are too easy, and in both cases can result in decreased academic engagement and problem behavior (Sanford & Horner, 2012). The most straight forward way to assess instructional level is to evaluate student accuracy on the task. Literature suggests an accuracy level between 70% and 80% is ideal during the acquisition of new material (Archer & Hughes, 2011; Engelmann, 1999; Kestner et al., 2019). If learner accuracy is too low, instructional modifications should be considered. These might include providing the student supplemental materials to increase accuracy that can be faded over time (e.g., a number line or calculator to assist with math; McComas et al., 2000), support during the task (e.g., prompting), or adjusting the instructional target (e.g., reducing task difficulty or teaching required prerequisite skills). If making support available during instruction is used as an intervention, it's important to evaluate the learner's ability to recruit that support. Recruiting assistance during instruction will be discussed more in depth in the section on functional communication training (FCT). Other changes to instruction that may reduce challenging behavior include decreasing the number of problems on worksheets (Ellis & Magee, 1999), changing the modality tasks are presented (e.g., paper vs. iPad; Neely et al., 2013), and adjusting how instructions are provided (e.g., 1-step instead of multistep directives; Richman et al., 2001; Boelter et al., 2007).

Activity Choice Incorporating learner choice within the instructional context is a simple evidence-based antecedent intervention. A variety of choice situations have been evaluated and shown to be effective including choice of the task itself (e.g., Rispoli et al., 2013), choice of the sequence of tasks (e.g., Kautz et al., 2018; Stayer Smeltzer et al., 2009), and choice of task materials (e.g., choice of two types of matching materials; Ulke-Kurkcuoglu & Kircaali-Iftar, 2010). For activity choice, learners are typically provided a choice between all available instructional activities. After a choice is made, the learner is required to complete the activity and then a choice between the remaining activities is provided (e.g., Romaniuk et al., 2002; Rispoli et al., 2013). For example, if a learner's choices were math, spelling, and reading, and they first choose to complete reading, the next choice would be between spelling and math. This process continues until all activities have been completed. Providing individuals choices in the sequence of tasks is very similar, but instead of choices being presented after each task is completed, the learner chooses the order of all tasks up front and is then required to complete tasks in that order (e.g., Kautz et al., 2018; Stayer Smeltzer et al., 2009). Although an antecedent intervention, choice of activity or sequence of activities is considered a function-based intervention for escape-maintained problem behavior because the learner has the ability to delay an aversive task by choosing to complete less aversive tasks first. Choice of activity materials has also demonstrated improvement in problem behavior (e.g., Koegel et al., 2010), but less research has evaluated its effectiveness compared with other activity choice approaches.

Noncontingent Escape (NCE) A final antecedent intervention considered evidence-based practice is noncontingent reinforcement (NCR; Ritter et al., 2018). As mentioned earlier in this chapter, NCR involves presenting the functional reinforcer on a time-based schedule independent of behavior (e.g., Waller & Higbee, 2010). For negatively reinforced problem behavior procedurally, this involves providing escape (i.e., noncontingent escape [NCE]) from the task (e.g., breaks) after a specific time interval (i.e., fixed-time schedule), or after an average number of minutes (i.e., variable-time schedule). For example, during math instruction, a student may get a break every 1-min regardless of what work has been done during that time. Because NCE doesn't require the learner to engage in a specific behavior to obtain the reinforcer, it's considered an antecedent intervention. Conceptually, NCE is likely effective because frequent access to the reinforcer acts as an abolishing operation that reduces motivation to engage in the problem behavior. Noncontingent reinforcement is often used in conjunction with other interventions (e.g., DNRA or DNRO; Fritz et al., 2017; Kodak et al., 2003). Advantages of NCE include that it's easy to implement, is effective on its own, and problem behavior is likely to be reduced quickly because the functional reinforcer is provided as part of the procedure. Disadvantages include the disruption it can cause to the natural environment as dense reinforcement schedules are typically used initially, that BCBA oversight may be required to successfully fade the intervention, and the potential to accidentally reinforce problem behavior (Waller & Higbee, 2010). Simple adjustments in procedures, such as increasing the interval if undesirable behavior is occurring, can avoid inadvertently reinforcing the target behavior.

Consequence-Based Interventions

Escape Extinction (EE) When behavior is under extinction conditions, reinforcers that had been previously provided contingent on problem behavior are withheld. Extinction procedures result in a decrease in future behavior because the response–reinforcer relationship that previously maintained the behavior is broken. Procedurally extinction is different depending on the function of the behavior; for negative reinforcement, the aversive stimuli are continuously presented without allowing escape until the relevant demand is completed (e.g., escape extinction). In other words, to implement escape extinction you would not allowing the learner to escape or avoid the aversive situation. For example, if a learner swipes instructional material off the table when a demand to complete work is presented, escape extinction might involve immediately representing the instructional materials every time materials were swiped until the learner completes the demand. While escape extinction can be used alone (Tereshko & Sottolano, 2014), it is most often combined with other interventions (e.g., instructional fading; Pace et al., 1993). Despite its effectiveness, escape extinction is not appropriate for all problem behaviors or settings, given the procedures can be labor intensive and involve adverse side effects that make it less likely to be implemented with high levels of treatment fidelity (Geiger et al., 2010; Lerman et al., 1999). When treatment fidelity of escape extinction is low, problem behavior can be inadvertently strengthened or intensified in magnitude. Escape extinction is best implemented with mild problem behaviors or in settings with high levels of control over the environmental setup and sufficient staffing. Further, implementing escape-extinction alone is not preferable given an appropriate behavior is not taught as part of the intervention. If escape-extinction is being used, ensuring programming for strengthening other behaviors in place is best practice. Given the potential constraints for the implementation of escape extinction, exploring treatment options that combine extinction with other procedures or remove it entirely is important for effectively matching the evidence-based treatment to both the individual and context.

Differential Reinforcement One treatment that often involves extinction as one component is differential reinforcement. When differential reinforcement is implemented as function-based intervention for negatively reinforced behavior, the reinforcer provided is escape (i.e., Differential Negative Reinforcement of Alternative Behavior [DNRA]). DNRA and variations of it are one of the most common interventions utilized for escape-maintained behavior. A standard DNRA procedure involves providing reinforcement (i.e., escape) for an alternative behavior while problem behavior is placed on extinction. For example, if a learner (let's call him Mateo) screams when instructions are provided, you may implement procedures so reinforcement (e.g., escape) is provided when Mateo says "not now" or "I want to do something else" after a task demand and withheld (e.g., instruction continues) when he screams. DNRA with extinction may be preferable to escape extinction alone because it involves teaching an alternative response in addition to the suppression of the problem behavior.

DNRA has been successfully implemented without the use of extinction (Briggs et al., 2019) but requires manipulating dimensions of reinforcement in favor of the alternative response (e.g., quality and/or duration; Trump et al., 2020) or other treatments added (e.g., NCR) to be successful (MacNaul & Neely, 2018). Vollmer et al. (2020) have recently made a call to redefine differential reinforcement procedures as increasing reinforcement along some dimension for one behavior and minimizing it along some dimension for another behavior. For the purpose of this chapter, interventions that manipulate dimensions of reinforcement across concurrent operants to reduce problem behavior are described in the section on choice-making treatments.

Another differential reinforcement procedure successful in reducing escape-maintained problem behavior is Differential Reinforcement of Other Behavior (DNRO; Kodak et al., 2003). In DNRO, escape is provided when a specified amount of time elapses without the occurrence of the problem behavior. Similar to using EE alone, DNRO may be a less preferred intervention because it doesn't include increasing an adaptive response. DNRO may be more appropriately considered when the stimuli individuals are escaping are not related to instruction (e.g., wearing a medical bracelet; Cook et al., 2015), are difficult to manipulate (e.g., automatic reinforcement), or when they cannot be feasible identified (e.g., due to setting constraints; Jessel & Ingvarsson, 2016).

Function Communication Training (FCT) As mentioned previously, FCT is a variation of a DRA procedure that involves teaching an alternative communicative response to obtain the reinforcer that's maintaining problem behavior. FCT is the most commonly implemented treatment for problem behavior and has a vast literature base to support its use (Falcomata & Wacker, 2013; Tiger et al., 2008). Similar to DRA procedures, FCT is most often implemented with extinction (Hagopian et al., 1998) and is often combined with other intervention procedures (e.g., noncontingent reinforcement; Doughty & Anderson, 2006; Rooker et al., 2013). If possible, implementation with extinction is recommended as it is most effective with extinction added (Hagopian et al., 1998; Tiger et al., 2008), and in some cases, punishment has been required to obtain clinically significant behavior reduction (Fisher et al., 1993; Hanley et al., 2005). However, in situations where extinction is not feasible, recent research suggests that when combined with other interventions, FCT may be successful without extinction (e.g., instructional fading; Davis et al., 2018).

For escape-maintained problem behavior, there are two main communicative responses taught: request for a break and request for assistance. Requests for assistance should be taught when an activity is too difficult or cannot be completed independently by the learner. Alternatively, requests for break should be taught when the learner can successfully complete the activity but is either habituated or satiated with the activity (Reichle & Wacker, 2017). For example, if a student, Hiroshi, reliably starts and completes part of a writing lesson but then engages in property destruction, teaching him to request a break would be more appropriate than teaching him to request assistance because he is able to complete the task without assistance. Diya on the other hand, is a learner who is just learning to write and requires prompts to complete the lesson. Diya swipes her materials when the teacher is not immediately available to assist her. In Diya's case, teaching a request for assistance would be more appropriate. Whichever communicative response is necessary, it should be established in the learner's repertoire before implementing FCT in the instructional context. Main benefits of FCT include that it teaches an appropriate communicative response to obtain the functional reinforcer, is low cost and easy to implement and client focused. Drawbacks include that fading reinforcement for the communicative response may require careful BCBA oversight and that extinction is often included as a component and may not be feasible in some contexts.

Choice-Making Interventions Choice-making interventions for problem behavior maintained by negative reinforcement involve presenting two or more concurrently available options (i.e., operants), each with separate schedules and/or dimensions of reinforcement altered. Some authors have proposed using "differential reinforcement with asymmetrical choice options" to describe these interventions. This type of intervention is used to reduce target behavior similar to DRA but doesn't fit current definitions of DRA because they don't always include an extinction component and may involve more than two concurrently available operants

(Kestner et al., in press). A growing body of literature supports these interventions as successful to reduce escape-maintained problem behavior with extinction as one of the operants (e.g., McComas et al., 2002; Peck Peterson et al., 2005) and also without extinction when dimensions of reinforcement are altered to favor alternative responses (e.g., Piazza et al., 1997; Davis et al., 2012). Dimensions of reinforcement including duration of the break, quality of the break (e.g., positive reinforcement added), or a combination of both have been successful in shifting responding from problem behavior to more adaptive behavior. Recent research evaluating the magnitude of escape required for interventions to be successful suggests that large differential magnitudes are preferred (Rogalski et al., 2020).

To illustrate what this intervention may look like let's imagine a teenager named Bandile who engages in severe aggression during instruction in his special education classroom. Given Bandile's size and severity of behavior, escape extinction would not be appropriate in a school setting with limited staff and other students present. This makes differential reinforcement with asymmetrical choice options a good match for both the client and the setting. Dimensions of reinforcement like the duration and quality of the break could be varied to favor either work completion or appropriately requesting a break while continuing to provide comparably minimized reinforcement for the problem behavior. During instructional tasks, Bandile could be provided two options with cards associated with each: He could take a short break (choose the break card) or work and have a longer break with access to his iPad (choose the work then break card). Bandile can also engage in problem behavior, a third available operant. These cards would be presented to Bandile at the start of every work session, and he'd be given the opportunity to choose. If he chooses to work, after completing the task he'd receive the long high-quality break (e.g., 5 min with iPad). If he chooses to request a break, work materials would be removed immediately and he'd receive a short break (e.g., 1–2 min), and if he aggressed toward the teacher, a very short break (e.g., 15–30 s) would be provided before work was again presented.

Demand/Instructional Fading In the previous example, given problem behavior is severe and the individual is older, the school setting may not be able to tolerate even low levels of the behavior. As such, combining the concurrent operant DRA intervention with an intervention that reduces the likelihood inferring behavior will occur may be needed. One evidence-based intervention likely to result in the reduction of problem behavior when combined with other interventions is demand/instructional fading (also called stimulus fading but henceforth referred to as instructional fading). In instructional fading, demand requirements are initially reduced significantly or to zero levels and then increased slowly over time based on learner success (Zarcone et al., 1994; Piazza et al., 1996). Ideally, instruction is increased (faded in) gradually enough that problem behavior is avoided altogether or significantly minimized. Instructional fading has almost exclusively been evaluated in combination with other interventions (e.g., FCT; Davis et al., 2018), but larger decreases in problem behavior are observed when it's added. Instructional fading is simple intervention to implement and combine with other approaches. In addition, it offers the benefit of reducing the likelihood undesired behavior will occur at all but may require very small increases in demand requirements to do so. This may limit the acceptability of this intervention in some instructional settings where delays to engagement with instruction cannot be tolerated.

Inclusion Positive Reinforcement Some studies have demonstrated that the addition of positive reinforcement to the instructional context can effectively compete with negative reinforcement. The addition of both attention (e.g., Cooper et al., 1992) and edibles (e.g., Carter, 2010; Lomas et al., 2010; Slocum & Vollmer, 2015) has shown a reduction in problem behavior even when it continues to result in escape. Given the relatively few studies demonstrating these effects in isolation without other interventions, and some that suggest a combination of both positive and negative reinforcement may be most effective (Bouxsein et al., 2011), the inclusion of positive reinforcement may be best as an addition to other evidence-based interventions.

Treatment Selection

The literature on treatment of negatively reinforced problem behavior resoundingly supports the use of function-based interventions whenever possible, and treatment packages that combine multiple interventions may be most effective. Given there are many evidence-based interventions available to choose from and combine, deciding on a specific intervention can be daunting. Geiger et al. (2010) developed a decision-making tool to assist practitioners in selecting interventions for escape-maintained problem behavior that may be of use. Although this tool can be helpful as a starting place and provides a helpful overview of interventions, caution is advised when using the tool in isolation. Validation studies on the Geiger et al. (2010) decision-making tool have been mixed (Hoffmann et al., 2022; Saini et al., 2017), and further research is needed to identify conditions under which it will result in the effective identification of a successful intervention. Although some considerations have been outlined in this section, the importance of individualized intervention cannot be overstated. We are bound by our ethics code as BCBAs to match our interventions to the individual and context they behave in, and doing so will ensure we implement the most effective and least restrictive intervention. Often we may have multiple matched evidence-based options available, and under these circumstances, it's crucial that we consider the individual receiving treatment and their care providers' preference.

Practical Considerations for Treatment

As demonstrated in this chapter, there is no shortage of evidence-based interventions at the behavior analyst's disposal when selecting function-based treatments for problem behaviors. Our hope is that following this chapter, the savvy practitioner will have added a few more tools to their toolbox. Remember that there are a handful of cardinal rules when selecting function-based treatments for your clients. First, determine your client's priorities. As a behavior analyst, it can be easy to get bogged down in the multitude of interventions you'd like to implement to increase the skills and quality of life of your clients. The reality is that we are most effective when we prioritize and focus on tackling those priorities systematically. Create a list of questions you might ask yourself as you begin treatment planning (e.g., "How will this improve my client's life?", "Is this goal aligned with their values and culture?", "Will this intervention increase independence?", "Is this goal aligned with the client's goals?"). Consider drafting questions relevant to your scope of clinical practice and client population.

Next, remember that context matters. Clients and their families bring a lifelong history of experiences, triumphs, disappointments, skills, and deficits to the table when we meet them. To thoughtfully and aptly serve them, we must consider all of the cultural variables and contextual factors that have shaped their behaviors and influenced their lives before they met us. Their environmental context and culture will impact all aspects of their treatment and its subsequent success. Brainstorm ways to keep context at the forefront of treatment selection. Consider your client's experience and history, and seek support as needed. We can only hope to educate others through our own awareness and education.

Finally, make it feasible. Be thoughtful about who might be implementing the treatments you select and the environment in which they will be trained. Think about the reading level of your behavior plans—are they accessible to all of the staff, teachers, caregivers, or other individuals who might be implementing treatment? Consider the barriers and resources that are presented to your clients. Are there ways to advocate, empower, or remediate barriers for our clients? As mentioned earlier in the chapter, don't be afraid to get creative or ask for advice from colleagues. From the literature (and experience), we know that a feasible treatment is a successful treatment. No matter what, as long as you keep your client's success as the focus of every treatment plan, you will undoubtedly demonstrate the safe, effective, and ethical practice of applied behavior analysis.

Part V

Treatment Methods

31 Token Economies

Iser G. DeLeon, Tracy Argueta, Nathalie Fernandez, Samantha Castano, Gabbriella Henderson, Lauren Shoemaker, and Crystal Williams

Most behavior–analytic interventions rely on the careful, systematic arrangement of reinforcement contingencies—a given consequence is delivered contingent upon a desirable response under conditions in which that response would be appropriate and the consequence would be valuable to the individual. That response is "strengthened" insofar as it becomes more probable under future similar circumstances. A token economy is a specific kind of flexible arrangement of reinforcement contingencies, used frequently in therapeutic and instructional contexts, in which the delivered consequence is a conditioned reinforcer, a token, that is later exchangeable for other reinforcers. The reference to "economies" derives from its resemblance to how we all learn to exchange earned arbitrary symbolic units (e.g., coins and paper money) for goods and services. That is, earned tokens are exchanged for backup reinforcers in much the same way that money is exchanged for goods and services in conventional economic systems.

Token economies offer several advantages over other reinforcement systems that rely on the direct delivery of the backup reinforcers (discussed below). For example, tokens are easy to administer and provide learners with a salient marker that represents their progress. As such, they have become common across many settings. In a survey of 406 professionals who serve people with developmental disabilities, Graff and Karsten (2012) found that tokens were the second most delivered programmed reinforcer, following only verbal praise. Token economies can be implemented in the same structured format for multiple individuals in a given setting. They can also be individualized for each client, as there are essential components that can be adjusted to suit each individual's needs and circumstances. In what follows, we provide a detailed description of these components of a token economy. We follow with an elaborated description of the advantages afforded by these systems over other reinforcement arrangements, advantages that resulted in their widespread adoption. We further describe the history and use of token economies, touching upon the multiple contexts in which token economies have been used. We end with a variety of additional considerations, including embedding punitive outcomes within a token system and concerns that have been expressed about the use of token systems.

Components of a Token Economy

Although descriptions vary, most agree that token economies consist of seven essential components (e.g., Miltenberger, 2012; Hine et al., 2017; Ivy et al., 2017) that can be individualized for each participant or setting and can be adjusted based on performance. These components include (1) identification of the target behaviors, (2) identification of the stimuli used as tokens, (3) identification of backup reinforcers, (4) arranging the token-production schedule, (5) arranging the exchange-production schedule, (6) arranging the token-exchange schedule, and (7) token-training procedures. Below, we address each component by providing a description of the process and product, supplemented by research on best practices when available.

Identifying Target Behaviors

Prior to implementing a token economy, one must identify and operationally define the target behavior(s) that will result in token delivery. Target behaviors should be socially significant (Miltenberger, 2012) and appropriate for the client's repertoire and treatment goals. Examples of potential target behaviors include communication responses (e.g., Mason et al., 2015), daily living activities (e.g., Paul & Lentz, 1977), alternatives to problem behavior (e.g., Christensen et al., 2004), and health-related behaviors (e.g., DeLuca & Holborn, 1992; Patel et al., 2019). Tokens have also been delivered contingent on the absence of problem behavior, for example, by arranging token delivery on a differential reinforcement of other behavior (DRO) schedule (e.g., Didden et al., 1997; Donaldson et al., 2014). Problem behaviors may also be directly targeted when response cost is incorporated into a token system, as discussed in greater detail below.

As in all behavioral interventions, a critical issue is careful specification of the operational definitions of the target behavior(s). Loose descriptions of the behavioral criteria that result in token delivery (or token removal) can result in suboptimal performance within the token economy. For example, Moore et al. (2001) conducted an informal component analysis of an ineffective token economy in an inpatient psychiatric facility and identified two critical problems. One involved the delay in exchanging the tokens. Another was that the target behaviors had not been operationally defined. The latter was addressed by more clearly specifying the behavior(s) that would result in token delivery. Prior to the modification, the criteria were loosely defined as "follow directions," "be nice," and "be where you are supposed to be." These definitions were clarified for both staff and children. For example, "be nice" was transformed into "remaining at least two feet away from another child" because the key issue seemed to be participants invading each other's personal space. Although the other modification (altering the delay to token exchange) ultimately had a greater impact, simply modifying the operational definitions had a clear and consistent influence on the number of tokens earned collectively by the participants.

Identifying Stimuli Used as Tokens

In most cases, the tokens themselves are initially behaviorally neutral stimuli. That is, they have little pre-experimental or pre-therapeutic value or stimulus function but acquire value or stimulus functions through token training. The tokens themselves can vary along several dimensions, and common examples include poker chips, laminated images, plastic coins, and check marks. Token system developers must consider several factors when selecting stimuli to use as tokens. First, tokens should be safe to manipulate and should not pose a choking hazard, particularly when working with children and individuals with neurodevelopmental disorders. In addition, tokens should be items that clinicians can easily transport and deliver quickly, such that they immediately follow the occurrence or nonoccurrence of the target behavior. Relatedly, tokens should be stimuli that clients can easily carry, accumulate, and exchange. Tokens should also be durable because they will likely be used throughout the course of an intervention. Clinicians should also avoid using items that are readily available in the environment to prevent learners from bootlegging or counterfeiting tokens. For example, star stickers may be placed on a chore chart in a school-based token economy, but the stickers should not be available elsewhere in the classroom and some marking might be added to differentiate them from stickers that are available in stores or at home.

Clinicians should also consider whether tokens should be manipulable or nonmanipulable. A manipulable token is an item that is physically handled by the learner during token production and exchange (e.g., a poker chip), whereas a nonmanipulable token is a stimulus whose delivery and exchange are mediated by the practitioner (e.g., a check mark on a board or virtual tokens on an iPad). Physical token manipulation may increase the saliency of the response–reinforcer contingency (Leaf et al., 2012). On the other hand, manipulable tokens may occasion token-directed behavior (e.g., playing with the tokens, tapping tokens on a table) that can interfere with learning by increasing the time between learning trials and decreasing overall instructional time. Sleiman et al. (2020) compared relative rates of responding when manipulable or nonmanipulable tokens were provided for academic task completion in three children with autism spectrum disorder (ASD). One participant engaged in higher rates of responding in the nonmanipulable token condition, while the remaining participants engaged in similar rates across both conditions. All three participants demonstrated a preference for manipulable tokens in a preference assessment. In the absence of functional differences, clinicians should consider the client's preference. However, if the learner engages in token-directed behavior that interferes with learning, nonmanipulable tokens should be considered. Nonmanipulable tokens may also be beneficial when an exchange response cannot be trained (Hine et al., 2017) or if the client is likely to engage in problem behavior related to token exchange. This may be particularly relevant in a response-cost system if learners are asked to relinquish tokens contingent upon undesirable behavior.

When selecting stimuli to use as tokens, clinicians must also decide whether to use novel or preferred stimuli (i.e., interest-based tokens). An example of an interest-based token is using laminated images of Mickey Mouse as tokens for a client known to be particularly fond of Mickey Mouse. The advantage of novel stimuli is that the clinician controls the learner's history with tokens via token training. However, token training can be time-consuming. Alternatively, stimuli that are already preferred by the learner might already function as conditioned reinforcers and, thus, might require less training time. Fernandez (2021) recently completed an internet survey of token economy practices among clinicians involved in early intervention for learners with autism spectrum disorder and found that roughly 70% of clinicians reported using interest-based tokens in clinical practice. Charlop-Christy and Haymes (1998) found that using stimuli with which children were often preoccupied (i.e., an object of obsession) as tokens resulted in more correct responding and less problem behavior than novel tokens. However, it is unknown whether participants engaged in token-directed behavior outside the definition of problem behavior that might have produced longer intertrial intervals. Nonetheless, when using interest-based tokens over extended periods of time, preference for the stimulus being used as a token may diminish and reduce the tokens' effectiveness. However, this is unlikely to occur if the interest-based token is exchangeable for valuable backup reinforcers. Thus, clinicians should regularly evaluate the effectiveness of backup reinforcers and not rely solely on the previously existing conditioned reinforcing properties of an interest-based token.

Identifying Backup Reinforcers

Backup reinforcers are the stimuli or activities for which clients exchange their tokens (Hackenberg, 2018). The nature of viable backup reinforcers will vary, of course, depending on the population and what is readily available in the setting. Examples of backup reinforcers often used in token economies for children with neurodevelopmental disorders include edible reinforcers, leisure items (e.g., access to a tablet, toy cars), outdoor playtime, and escape (i.e., break from demands). Notably, one can also include reinforcers that are "free" and readily available, such as opportunities for social interactions with caregivers. By contrast, several studies have used token economies to support desirable behavior in workplace settings with typically developing adults (e.g., Camden et al., 2011; Vergason & Gravina, 2020), where the sorts of reinforcers listed above would clearly be less relevant. Simonian et al. (2020) conducted a systematic review of methods used to identify effective reinforcers for employees in organizational settings. Common candidate back-up reinforcers included items such as gift cards (themselves, characterizable as tokens), coupons, opportunities to leave work early, opportunities to choose work assignments, and preferred parking.

Independent of the population or setting, when selecting backup reinforcers, clinicians should select preferred items, activities, or privileges identified via a preference assessment and demonstrated to support appropriate behavior. Ideally, one should conduct direct preference assessments, which involve the systematic presentation of stimuli and observation of the learners' approach, selection, and/or consumption responses. Researchers have developed and evaluated several methods of conducting systematic preference assessments. Options include single-stimulus presentation methods (DeLeon et al., 1999; Pace et al., 1985), paired-stimulus presentations methods (Fisher et al., 1992), and multiple-stimulus presentation methods (DeLeon & Iwata, 1996; Hanley et al., 2003; Roane et al., 1998). A detailed description of these methods is beyond the scope of the current chapter, but the reader is directed to Virues-Ortega et al. (2014), who describe each of these methods and provide guidance on selecting the most appropriate preference assessment method under varying circumstances.

For time-based backup reinforcers (e.g., playtime, tablet, and escape), the duration of access should be directly related to the number of tokens exchanged for that activity. For example, if each token is exchangeable for 30 s of tablet access, the client should receive 5 min of tablet time in exchange for 10 tokens. Therefore, clinicians should consider whether they can easily control access to backup reinforcers (i.e., remove when access time expires). Clinicians should also consider selecting backup reinforcers that can be restricted to the token economy, such that the learner can only access the item by exchanging tokens (i.e., a closed economy). Several authors have observed that free access to reinforcers outside of the context in which they must be earned (i.e., an "open economy") can reduce levels of responding within the earning context (e.g., Kodak et al., 2007; Roane et al., 2005). Thus, access to backup reinforcers outside of the context of the token economy might suppress motivation and responding, limiting the system's effectiveness.

Setting the Token-Production Schedule

The token-production schedule specifies how and when target behaviors will produce tokens, or in other words, "the rule that describes the specific response requirements and environmental conditions that must be satisfied for token delivery" (Ivy et al., 2017, p. 723). Token-production schedules can theoretically mirror any arrangement that has been studied in behavior–analytic research (see DeLeon et al. (2013), for a description of schedule variations in applied settings) and vary necessarily depending on the clinical target. However, in practice, most clinical researchers adopt a fixed-ratio (FR) or variable-ratio (VR) schedule of reinforcer delivery (Fernandez, 2021). In a FR schedule arrangement, the token is delivered following the emission of a fixed (unvarying) number of target responses, whereas a VR schedule implies that the number of required responses can vary but is anchored to a mean (e.g., a VR 3 schedule implies that a token would be delivered after a mean of 3 responses, but delivery of any single token might occur following a number of responses that ranges between 1 and 5). That said, Ivy et al.

(2017) reported finding examples of FR schedules, VR schedules, differential reinforcement of alternative behavior (DRA) schedules, differential reinforcement of incompatible behavior (DRI) schedules, and DRO schedules as token-production schedules in their review of token research.

Token-production schedules seem to result in response rates and patterns typical of schedules of direct reinforcement (Hackenberg, 2018). For example, DeLuca and Holborn (1992) found that successively increasing a variable-ratio (VR) token-production schedule produced response rate increases as would be expected based on what is known about the relation between schedule values and performance on VR schedules in basic research. When setting token-production schedules, one should therefore consider the goals of the intervention. Still, during initial training, clinicians and researchers generally begin by delivering tokens on a very dense schedule (e.g., FR 1) to establish a consistent relation between the response and delivery of the token. Once the target response meets a mastery criterion, the schedule for that response may be thinned to an intermittent schedule for practical purposes. When selecting an intermittent schedule, clinicians should consider the natural schedule under which the target response will be maintained as well as optimal response rates. In some instances, different intermittent schedules may be similarly effective (e.g., Repp & Dietz, 1975). In such cases, one should consider the client's preferences when selecting the token-production schedule. One should directly train, or verbally describe, the response requirements to produce tokens (Ivy et al., 2017).

However, one should approach increasing the token-production schedule with caution. In token systems in which the amount or duration of backup reinforcers is directly tied to the number of tokens earned, increasing the token-production schedule necessarily increases the ratio of responses to reinforcers (i.e., the unit price), such that more responses are required for each reinforcer delivery. For example, Hackenberg (2018) describes that doubling the token-production schedule doubles the ratio of responses required to produce one reinforcer. As such, clients might demonstrate decreased responding indicative of ratio strain, a situation in which the targeted performance ceases to occur because the behavioral cost of each token has become too high. Thus, Hackenberg (2018) recommends holding the token-production constant and increasing the exchange-production schedule instead. However, if the token-production schedule will be changed, one should consider gradually thinning the schedule to prevent ratio strain (e.g., Ackerman et al., 2020).

A further important consideration about token-production schedules is the immediacy of token delivery. Tokens should be delivered immediately after the target behavior, as delays in token delivery tend to decrease task compliance (Boerke & Reitman, 2011) and response rates and increase latency to responding (Leon et al., 2016). Leon et al. (2016) found that delays to token deliveries as brief as 3- to 6-s produced decrements in responding relative to immediate delivery. Moreover, clinicians should consider and evaluate unprogrammed delays in token delivery (i.e., failures in treatment integrity) as a possible explanation for decrements in responding that may emerge throughout the course of the intervention and for initially low levels of responding that cannot be explained otherwise.

Setting the Exchange-Production Schedule

The exchange-production schedule specifies how and when the client will exchange earned tokens for backup reinforcers. Calling this a "schedule" in the same sense as the token-production schedule, seemingly implies that a specific number of tokens must be earned before an exchange opportunity is arranged. This is accurate in some cases, but in actual practice, exchange-production schedules can take numerous other forms. For example, in an instructional context for learners with ASD, the clinician might arrange an exchange opportunity (1) after a certain number of tokens have been earned, (2) at the end of the instructional session independent of how many tokens have been earned, or (3) at the end of the day (or even at the end of the week) during a convenient time for exchange. The last exemplifies a time-based exchange-production schedule rather than a response-based exchange-production schedule. Ivy et al. (2017) reported that 60% of the studies they reviewed employed time-based exchange production schedules; they seemingly have become the norm. The timing of opportunities to exchange can have a significant impact on the effectiveness of a token economy. Field et al. (2004) reported meaningful improvements in token economy effects in initially "nonresponsive youth" by changing the frequency and immediacy of access to back reinforcers. By increasing exchange opportunities from once a day to twice a day and by halving the number of tokens (or points in their case) that a child needed to earn access to preferred consequences, the authors observed clear increases in the frequency of earning backup reinforcers and corresponding decreases in "intensive behavioral episodes."

Backup reinforcers may be displayed in a "token store," for example, by using either a menu format or in a room in which individuals can make their purchases. In time-based schedules, individuals should only have access to the token store at designated times, which may include predetermined store hours (e.g., from 1:00 pm to 4:00 pm). Of course, the time and place where token exchange will occur must be decided in advance. When first establishing a token economy, the token store should be available frequently, but exchange-production schedules could be thinned across time and become available more intermittently for practical purposes (Cooper et al., 2020). McLaughlin and Malaby (1976) assessed the effects of fixed-time (FT) and variable-time (VT) exchange-production schedules on assignment completion of a fifth- and sixth-grade class. Both schedules were equal to 5 days, with token exchange occurring between 3, 5, 7, and 9 days under the VT schedule. Although the FT schedule produced between 88% and 100% assignment completion, the VT schedule produced less variable responding (i.e., 100% assignment completion). Thus, variable exchange-production schedules may produce more consistent responding during token production.

Arranging response-based exchange-production schedules may require careful consideration owing to second-order effects. That is, responding in the token-production schedule may be affected by the exchange-production schedule. Nonhuman research has shown that FR exchange-production schedules can produce decreased response rates and longer postreinforcement pauses (PRP) on the token-production schedule than equivalent VR exchange-production schedules (Bullock & Hackenberg, 2006; Foster et al., 2001). However, Argueta et al. (2019) found that FR and VR exchange-production schedules did not significantly affect responding on an arbitrary task in a child with ASD. Both schedules also produced similar pause-reinforcement pause (PRP) durations, with the exception of the VR2 schedule, which produced slightly longer PRPs and decreased relative to FR2. The differences observed in PRP may be an artifact of the backup reinforcer used in the study (i.e., videogames on an iPad). Given that each token was exchangeable for 15 s of access to the iPad, exchanges occurring following the accumulation of one token may have produced an aversive context in which access to the backup reinforcer was brief and distributed. Distributed reinforcement arrangements have been shown to produce decreased levels of responding and to be less preferred (see DeLeon et al., 2014). Therefore, it is also important to consider whether the reinforcer potency of the backup reinforcer is enhanced by accumulated access when determining the exchange-production schedule.

Regardless of whether the exchange-production schedule is time- or response-based, the schedule should be dense initially to maximize contact with backup reinforcers. Over time, the scheduled can be thinned. If the client stops responding during schedule thinning, the clinician may consider returning to a previous, denser schedule as decreased responding may be indicative of a different kind of ratio strain—a situation in which the targeted performance ceases to occur because the opportunities to exchange have become too few and far between.

Setting the Token-Exchange Schedule

The third schedule to consider is the token-exchange schedule, which specifies how many tokens must be exchanged for a given backup reinforcer or the "price" of each backup reinforcer. For example, each token could be exchanged on a one-to-one ratio for a preferred edible reinforcer or 30-s access to an iPad. There are no explicit rules on how to set the prices of backup reinforcers, and researchers have adopted several strategies. One method is to set the price of all backup reinforcers at the same number of tokens (Akin-Little & Little, 2004). For example, all high, moderate, and low preferred backup reinforcers cost five tokens. Alternatively, the price of each backup reinforcer may vary based on the learner's preferences or reinforcer availability. For example, the learner's highest preferred item is set at 10 tokens, while a moderately preferred and low-preferred items are set at 5 and 1 tokens, respectively. Leaners may then accumulate tokens to access higher priced backup reinforcers (Ackerman et al., 2020). Fernandez (2021) reported that 48% of clinicians determined the price of backup reinforcers based on learner's preferences. In this case, presumably, more preferred items are set at higher prices as a means of promoting motivation to earn tokens, but no research is available to our knowledge to endorse this practice.

The learner's level of functioning may also be an important consideration when selecting a strategy to set the price of backup reinforcers. While higher functioning learners may be able to effectively accumulate and distribute tokens among a variety of differently priced backup reinforcers, lower functioning learners may benefit from a token store in which all the backup reinforcers have the same price. Clinicians must also consider how many tokens the learner can produce and accumulate before exchange, or lose if a response cost is implemented, to ensure that the learner can access reinforcers. Like with the other schedules, the price of backup reinforcers should initially be low before systematically thinning the schedules. For example, initially, each token could be exchanged for one unit of the selected backup reinforcer, after which the token exchange schedules could be adjusted for practical purposes. Once again, the token system developer may need to be cautious about setting the prices too high. Backup reinforcers that are functionally unobtainable because of a high token-exchange value may cease to motivate targeted responding.

Token Training: Common and Best Practices

Token training refers to procedures used to establish tokens as conditioned reinforcers. Although this step necessarily precedes the execution of other token economy components, sequentially, we describe it last because the description requires an understanding of the other components. Recommendations for token training vary depending on the learner's repertoire. For clients with intact verbal abilities, it may suffice to provide verbal instructions (e.g., vocal, written) that explain the token-production and exchange contingencies (Cooper et al., 2020; Kazdin, 1977). Ivy et al. (2017) reported that when token conditioning procedures were reported at all, 76% of studies provided a verbal description of the token economy contingencies. For clients who are less responsive to instructions, recommendations typically suggest some sort of pairing procedure to establish a relationship between tokens and backup reinforcers, thus "imparting value" upon the tokens (Doll et al., 2013; Hackenberg, 2018; Hine et al., 2017).

There are multiple pairing procedures from which to choose, the simplest of which is stimulus–stimulus (S–S) or direct pairing, in which tokens are delivered noncontingently and are immediately followed by a backup reinforcer (Doll et al., 2013). The most common pairing procedure reported by practitioners is response–stimulus (R–S) pairing (Fernandez, 2021), in which, contingent on a target response, a token is delivered and immediately followed by an established reinforcer. Kazdin (1977) suggested another procedure, hereinafter referred to as stimulus–exchange–stimulus (S–E–S) pairing, which involves noncontingently delivering tokens and then prompting an exchange response, contingent on which backup reinforcers are delivered. Last, another alternative is to combine R–S and S–E–S pairings by delivering tokens contingent on responding and delivering backup reinforcers contingent on exchanging delivered tokens (e.g., Argueta et al., 2019; DeLeon et al., 2014). However, applied researchers have not directly evaluated the general and relative effectiveness of these procedures for pairing tokens. To the extent that findings with other stimuli and species generalize to tokens, clinicians should use pairing procedures that require an exchange response (e.g., S–E–S training) and, more generally, those that require response–contingent pairings (e.g., R–S pairing; Hackenberg, 2018).

In addition to pairing, token system managers must often also teach token exchange and production responses, the topography of which should be carefully considered. Exchange responses refer to handing in tokens for backup reinforcers. Examples of exchange responses include handing a completed token board (e.g., Leaf et al., 2012) or individual tokens (e.g., Argueta et al., 2019) to a therapist, depositing tokens into a slot (e.g., Smith, 1972), or verbally indicating which backup reinforcer is desired. When selecting an exchange response, one should be mindful that some exchange responses might not be physically possible or might be too effortful for some clients (Hine et al., 2017). If an appropriate exchange response is not identified, clinicians should consider exchanging tokens for the client (Hine et al., 2017) until a suitable response is available. However, clinicians should be mindful that exchange responses are indispensable if one plans to teach learners to accumulate and exchange tokens at their discretion (Hine et al., 2017).

Production responses are those which result in token delivery (i.e., the target behaviors). The topography of production responses can vary widely and can include acquisition or mastered targets. However, to minimize demand- and delay-related problem behavior, mastered and low-effort responses are preferable during initial training. To the extent that unmastered tasks are aversive, their use during training might compromise the reinforcing value of tokens. Production and exchange responses may be trained using a variety of procedures, including but not limited to verbal instructions (Doll et al., 2013; Kazdin, 1977), errorless learning (e.g., Leaf et al., 2012), prompting (e.g., Argueta et al., 2019; DeLeon et al., 2014), and chaining (Hackenberg, 2018). Practitioners' most common default strategy for training production responses is akin to forward chaining, in which learners earn the first token in the terminal token-production schedule and subsequent tokens are added gradually (Fernandez, 2021). The second most common default strategy for practitioners training production responses is akin to backward chaining (Fernandez, 2021). Note that prior to training production responses, exchange responses should be trained to establish the relationship between tokens and backup reinforcers (Hackenberg, 2018).

After exchange and production response training, clinicians may include accumulation training to teach clients to compile and save tokens. Accumulation allows individuals to access more (Hine et al., 2017) or higher cost and more preferred backup reinforcers at each exchange. However, the increased availability of reinforcers via accumulated tokens can weaken clients' motivation to engage in token-earning behavior (Hackenberg, 2018). Thus, the decision to allow for token accumulation must be carefully weighed. If clients can accumulate tokens, clinicians should consider restricting accumulation, such as by limiting how many tokens clients can accumulate (e.g., Yankelevitz et al., 2008) or setting expiration dates for tokens. Clinicians can also restrict the quantity of tokens that learners can or must exchange at each exchange opportunity. Accumulation training can employ procedures like those for training exchange and production responses. However, additional training might be required to establish discriminative stimuli that signal when accumulation is available. Prior to training, one must also decide where and how clients will store accumulated tokens.

History and Use of Token Systems

Hackenberg (2009, 2018) provided a detailed history of the development of token economies, beginning with its roots in nonhuman experimentation. In what follows, we cover some of the highlights of that history. Wolfe (1936) and Cowles (1937) were among the first to systematically evaluate tokens in the laboratory. Both researchers used poker chips as tokens and chimpanzees as subjects to investigate response patterns across various token arrangements and to compare the reinforcing effectiveness of tokens to primary reinforcers. In a series of experiments, both Wolfe and Cowles demonstrated that establishing a token–reinforcer relationship (i.e., pairing) is central to tokens' effectiveness. Specifically, Wolfe (1936) found that chimpanzees preferred tokens that were paired with food over those that were not paired with food. Cowles (1937) found similar results, including that paired tokens supported the acquisition of matching-to-sample discriminations with levels of accuracy comparable to but lower than those supported by food. Following Wolfe's and Cowles's experiments, token research lagged until a series of experiments conducted by Kelleher (1956, 1957, 1958). Investigating reinforcement schedules, Kelleher (1956) found that responding for tokens under various simple schedules of reinforcement generally conformed to the typical patterns of responding observed when the reinforcers delivered were food. However, Kelleher (1958) found that higher FR token-production schedules produced longer pauses in responding early on in sessions than those typical of food production schedules.

A spike in applied token research was spurred by Ayllon and Azrin's (1965) seminal study evaluating the effects of a token economy on the self-help and vocational behaviors of adults with psychosis hospitalized in an inpatient facility. Across six experiments, Ayllon and Azrin demonstrated that participants' performance improved as a function of the token economy, an effect that was lost when the token system was disrupted. The value of Ayllon and Azrin's study was in the social significance of the behaviors and population included (Hackenberg, 2018). Kazdin and Bootzin (1972) and Kazdin (1982) addressed the increase in applied token research and identified practical areas (e.g., staff training, generalization, procedural fidelity) warranting further analysis. In the ensuing years, researchers also began applying token economies across a broad range of settings and circumstances. Matson and Boisjoli (2009) suggested that tokens system have been used most often in inpatient psychiatric settings and school-based programs, the descriptions below exemplify the variety of contexts in which token economies have been successfully implemented.

Preschools Token economy research has been conducted in preschool settings to proactively address behavior management in young children. Filcheck et al. (2004) implemented a class-wide levels system managed by the teacher, in which, in lieu of dispensing tokens, children's names were moved up and down seven levels contingent on meeting the specified criteria associated with each level. This type of economy removed the effort of the teacher to dispense tokens and did not require the students to count, track, or exchange tokens. It also allowed all students to participate and earn reinforcers without "singling out" the children with behavior management issues.

Elementary Schools In elementary schools, token economies may be used to identify and diagnose the children with behavior problems and learning disabilities while cultivating peer relationships and social skills. Anhalt et al. (1998) evaluated the ADHD Classroom Kit to increase prosocial behavior and decrease disruptive behavior in classrooms. The Kit was designed for kindergarten through sixth-grade classrooms and involved splitting the class into groups so as not to single out children with ADHD or other behavior management issues. Groups and individuals earned tokens for desirable behavior and received an opportunity to correct disruptive behavior following verbal warnings. The Kit required students to rely on each other, increased accountability within groups, and allowed for peer modeling of prosocial and on-task behaviors. Additionally, the Kit has been shown to increase appropriate behavior in children with problematic behavior or disabled learning and has been used in numerous case studies (Anhalt et al., 1998).

Middle and High School Token economies have been evaluated with adolescents in middle schools to improve the accuracy and variety of academic skills. For example, Swain and McLaughlin (1998) used a point system in a classroom of adolescents diagnosed with behavioral disorders to improve their math accuracy. Truchlicka et al. (1998) successfully used a token economy with a response cost component to improve the performance of adolescents in a special education classroom on spelling tests. Token research in high schools is sparse and often takes place in special education classrooms. One consideration for the lack of use in high schools may be that teachers do not find token economies socially valid at this level. They may also not be feasible in classrooms where students attend one class a day before moving to the next.

University/College Token research in university and college settings may be more common than in high schools. Boniecki and Moore (2003) successfully used tokens to increase college students' participation during class by distributing tokens for answering questions correctly during lecture, and they were exchangeable for extra credit points. Nelson (2010) conducted a similar study, but instead, students earned tokens by asking questions in class. These studies used tokens to increase participation during class toward the aim of improving students' performances during evaluations. This expands the literature on token use to large, diverse groups and beyond the use to address disordered behavior and psychiatric conditions.

Residential/Community Facilities Token economies have been successfully implemented in residential and community facilities. For example, Phillips (1968) implemented a token economy at a residential rehabilitation center for predelinquent boys. The adolescents earned points (i.e., tokens) for appropriate behaviors (e.g., self-care, prosocial behavior, academic achievement) and lost points for inappropriate behaviors (e.g., aggressive speech, failing schoolwork, arguing). Phillips reported significant improvement with all the participants. Similarly, Adams et al. (2002) described the implementation of a camp-wide token economy to increase prosocial behaviors at a pediatric burn summer camp. Nastasi et al. (2020) used a token economy to increase physical activity in a residential home for adults with IDD.

Organizational Settings There have also been applications of token economies within a variety of organizations to reinforce employees' desired behaviors. Fox et al. (1987) used stamps as tokens to reinforce miners behaving safely in an open-pit mine. They reduced the time and money lost by the company due to injury. Camden et al. (2011) decreased employee absenteeism and rescheduling by almost half through a credit reward system. Vergason and Gravina (2020) successfully had guests and confederates provide tokens to employees at a zoo for appropriate greeting behavior. These applications show the versatility of token economies across several contexts.

Therapy Settings Token economies have also been implemented in therapy settings. For example, Ingham (1982) evaluated the effects of a token system for reducing the stuttering of adults. However, the results were inconclusive but provided initial evidence that token programs might be an effective intervention for this behavior and population. In general, token economies implemented with patients with schizophrenia have been effective (Dickerson et al., 2005). However, research with this population published since

1994 has not been reviewed and evaluated. Thus, the current effectiveness of recent studies is unknown and cannot be compared to previous research. After all, it is possible that the level of care provided in older research differs from that provided in contemporary studies. Although behavior analysts report using token economies often and although tokens are the second-most common consequence delivered by staff working with people with IDDs, research elucidating the efficacy of tokens with other populations is lacking. As such, studies with populations and in therapy settings with which we do not typically evaluate token economies are needed to better understand the efficacy of token economies in differing therapies.

Several authors have noted a marked decline in the quantity and change in the nature of token economy research. Hackenberg (2018) observed that most recent applied research has generally focused on practical and clinical concerns rather than elucidating the processes underlying token systems' effectiveness. Thus, recent applied token research has generally not been informed by basic research and has declined significantly since the 1970s. In fact, in applied publications including token economies, token systems are usually a component of treatment packages rather than the focus of the interventions or the research themselves.

Matson and Boisjoli (2009) discuss several reasons why applied token economy research might have declined. At the height of applied token research in the 1970s and 1980s, much of the research involved psychiatric inpatients. However, once the deinstitutionalization movement began, the demand for token economies in institutions declined, and thus related research also declined (Liberman, 2000). Additionally, Hackenberg (2018) posits that the successful widespread application of token economies might have contributed to their decline in applied research. Both as a primary intervention and as a component of treatment packages, token economies have been successfully implemented to change behavior across a variety of settings, subjects, responses, and procedural modifications. Consequently, researchers may have had little motivation and reason to evaluate token economies in their own right or to investigate variables that impact their effectiveness.

Mechanisms Underlying Token Effects

Tokens increase responses upon which they are contingent, but the mechanisms by which they do so are not well understood. One account is that tokens function as conditioned reinforcers that strengthen responses due to their relationship to backup reinforcers (Hackenberg, 2009, 2018). For example, Smith (1972) and Moher et al. (2008) demonstrated that contingent tokens differentially increase children's responding when the tokens are paired with backup reinforcers compared to when they are not. Moher et al. (2008) further observed that paired tokens maintained levels of responding similar to those maintained by the backup reinforcers themselves, suggesting that the acquired value of tokens is commensurate to that of the backup reinforcers for which they are exchangeable. Wolfe's (1936) and Cowles's (1937) findings that tokens maintained similar levels of responding to food also supported the conceptualization of tokens as conditioned reinforcers. Relatedly, tokens are typically conceptualized as generalized conditioned reinforcers when they are paired with more than one backup reinforcer. Supporting the conceptualization of such tokens as generalized conditioned reinforcers, Moher (2008) found levels of responding are less susceptible to fluctuations due to changes in motivating operations (MOs) when tokens are paired with multiple vs. one backup reinforcer.

Another account posits that tokens do not increase responding because they function as conditioned reinforcers that directly strengthen the responses they follow, but that they increase responding much like discriminative stimuli in that they signal that reinforcement is forthcoming and, thus, guide responding much like signs on roadways direct drivers to their destination (Shahan, 2010). For example, Bullock and

Hackenberg (2015) compared pigeons' rates of responding to identical tandem and token schedules for food (i.e., FR 200) in which the token schedule also produced tokens on a FR 50. If tokens were conditioned reinforcers, rates of responding should have been greater during the token schedule because it produced more reinforcers. However, rates of responding were lower during the token schedule, suggesting that tokens have a discriminative or signaling function and, thus, resulted in more efficient responding. In addition, rates of responding toward the end of the token requirement approximated rates at the end of the tandem requirement, indicating that early token delivery signaled a delay to the terminal reinforcer (i.e., food) and, thus, suppressed responding. Bullock and Hackenberg's results indicated that tokens have discriminative functions when token schedules produced lower rates of responding relative to identical tandem schedules for food, even though the token schedule resulted in four times as many reinforcers (i.e., tokens) for every food delivery on the tandem schedule.

To our knowledge, researchers have not conclusively evaluated the mechanisms responsible for token effects with applied populations, and therefore, it is unclear which mechanisms account for their effects on human behavior. Regardless, tokens' exchangeability for backup reinforcers appears to be critical to their effects (Hackenberg, 2009, 2018; Shahan, 2010).

Benefits/Advantages of Token Reinforcement

Token economies have many advantages relative to other reinforcement systems. First, tokens are typically discrete and easy to store (Ivy et al., 2017) and transport across environments (Ayllon & Azrin, 1968). Additionally, token systems allow for immediate reinforcement without interrupting ongoing responses or activities in the way that directly delivering other reinforcers (e.g., toys) can (Kazdin & Bootzin, 1972). The ability to reinforce responding immediately is an especially important benefit given findings that delays to reinforcers as brief as 6- to 10-s can negatively impact skill acquisition by reducing instructional efficiency and effectiveness (Carroll et al., 2016; Majdalany et al., 2016). Relatedly, token accumulation facilitates continuous, uninterrupted access to backup reinforcers (e.g., 10 min access after 10 tokens are exchanged), which researchers have found supports more responding and is preferred by learners than distributed (e.g., 1 min access after one token is exchanged) access (DeLeon et al., 2014).

Another benefit is that tokens can be established as generalized conditioned reinforcers and, thus, can be less susceptible to satiation effects. When tokens are paired with multiple backup reinforcers, they can continue to support similar levels of responding even when the client is satiated on one of the backup reinforcers (Moher et al., 2008). By contrast, satiation inevitably renders actual reinforcers delivered as direct consequences less effective. To maximize resistance to satiation, tokens should be paired with at least two to three reinforcers (Moher et al., 2008), and the classes (e.g., edible vs. leisure items) of those reinforcers should vary (Becraft & Rolider, 2015).

Further, each component of token systems can be individualized and tailored to a range of circumstances and treatment objectives (Ivy et al., 2017). For example, differential reinforcement can be easily embedded into a token system by arranging for different target responses to produce different quantities of tokens (Miltenberger, 2012). Similarly, response cost can be incorporated into a token system. Contingent removal of earned tokens can reduce problem behavior when appropriate (see later section on "Response Cost"). Moreover, each schedule in a token system can be readily adjusted to promote optimal responding for each client as the environment and their repertoire change.

Additionally, token economies have large-scale applicability; they can be used to change the behavior of group members (e.g., Fox et al., 1987). A good example is money, which functions as a token reinforcer because it can be exchanged for goods and services and is typically earned (and lost) by engaging in specific behaviors. Money functions as a token reinforcer for most individuals in a society and, therefore, influences the behaviors of many. Relatedly, because token economies mirror societies' monetary systems, they can be used to teach saving and spending behaviors.

Additional Considerations

Response Cost in Token Economies

Response cost is a negative punishment procedure whereby the tokens one already possesses are removed contingent upon undesirable behavior. Response cost is essentially a modification of the token-production schedule (Hine et al., 2017). It is incorporated into token economies when one of the aims of the token economy is to decrease undesirable behavior, and simply reinforcing appropriate behavior has not achieved this aim (Miltenberger, 2012). Therefore, in practice, token economies do not typically begin with response cost, but they may be added when other attempts to decrease undesirable behavior through positive reinforcement have been thoroughly exhausted. Response cost can be implemented in varying ways. For example, individuals might be given some number of tokens at the beginning of an intervention period (noncontingent token delivery). By contrast, the individual may have to earn the tokens that are later removed contingent upon inappropriate behavior (Conyers et al., 2004).

Results of studies that compared token economies with and without response cost in decreasing problem behavior have found mixed results (Conyers et al., 2004; DeJaeger et al., 2020; Phillips et al., 1971), although some evidence indicates that response cost is just as effective, if not slightly more than symmetrical reinforcement-based procedures for reducing undesirable behavior. Interestingly, when given a choice between the procedures, many study participants have expressed a preference for response cost over the reinforcement-based alternative (Donaldson et al., 2014; Jowett Hirst et al., 2016).

Insofar as response cost is a punitive procedure, several considerations are important in deciding whether to incorporate it into a token economy. Punishment can be associated with undesirable side effects (e.g., emotional responding, punishment-induced aggression), so care must be taken to ensure that implementing response cost does not, in fact, occasion more undesirable behavior than it decreases. Although some studies suggest that token response cost may be relatively benign in this respect relative to other punitive procedures (see Iwata & Bailey, 1974; McGoey & Dupaul, 2000), we know of no direct comparisons between response cost and other kinds of positive or negative punishment procedures.

Another important consideration in the use of response cost is whether it would be difficult to remove tokens from an individual that does not particularly want to relinquish them. Removing tokens under some circumstances may result in a struggle, and under other circumstances may result in a sort of delay to the punitive operation. Delayed punishment has been shown in some cases to have diminished effects relative to more immediate punishment (e.g., Abramowitz & O'Leary, 1990).

Other important considerations involve questions regarding how many tokens should be removed contingent on an undesirable response. On the one hand, the amount lost must be sufficient to offset what is gained from engaging in the target response. That is, the relative value of the loss incurred through response cost must outweigh the gain achieved by engaging in the undesirable behavior. On the other hand, it is important that the individual not lose access to all tokens through response cost, thereby establishing a condition in which no further penalty could be imposed for additional instances of undesirable behavior. In other words, losing all of one's tokens "might produce a segment of time in which contingencies for appropriate behavior are vague, perhaps creating an establishing operation for problem behavior." (Hine et al., 2017; see also Miltenberger, 2012).

Fading a Token Economy

Fading a token economy refers to the methods employed to transfer control of target behaviors from the token system to natural contingencies in a manner that promotes response maintenance. In most cases, fading token systems will be necessary to facilitate clients' transitions from treatment to natural environments. As such, prior to implementing a token economy, one should ensure that fading the token program will be feasible. Otherwise, one should consider alternative interventions to prevent possible decrements in responding resulting from removing the token economy without fading. Additionally, one should establish criteria for initiating fading while developing the token system, and one should also develop fading procedures well before the client meets said criteria.

There are two general approaches to fading a token system: (a) changing the contingencies and schedules of the token system while it remains in effect and (b) gradually eliminating the token economy in its entirety. Paul and Lentz (1977) utilized the former method to fade a type of token economy known as a level system that targeted psychiatric patients' daily living skills (e.g., bed making). Participants began at Level 1 and moved on to other levels by meeting predetermined criteria. As participants accessed higher levels, the schedules were faded such that the contingencies more closely resembled those in the natural environment outside of the hospital. For example, when participants moved to Level 2, token delivery was delayed such that they received large quantities of earned tokens at once, much like a "pay day" (Boerke & Reitman, 2011). Participants at Level 4 could purchase backup reinforcers without restrictions if they continued to meet applicable response requirements and purchased a card that unlocked this privilege. In this manner, Paul and Lentz faded the token economy and promoted self-management skills (e.g., planning, self-monitoring) required in the natural environment.

The other method of fading involves gradually eliminating the token program and transferring control solely to the natural environment. For example, Petursdottir and Ragnarsdottir (2019) completely faded a token reinforcement system that had successfully changed the disruptive behavior and academic engagement of elementary school students. The researchers faded the token program by systematically (a) pairing token delivery with social reinforcement, (b) increasing delays to token and backup reinforcer delivery (i.e., token-production and exchange-production schedules), (c) raising performance criteria (i.e., increasing the token-production schedule), and (d) increasing the token-exchange schedule (i.e., higher prices for backup reinforcers). Ultimately, participants had to engage in target behaviors for progressively longer intervals to earn tokens, earn a greater proportion of all possible tokens to access the same backup reinforcers, and wait long periods for opportunities to exchange tokens. Eventually, the researchers were able to thin these schedules such that they were able to eliminate the token system entirely while maintaining responding at desirable levels.

Evidence suggests that the treatment effects of a token economy may persist for several years after the system is removed (Kazdin, 1982; e.g., Paul & Lentz, 1977). Variables associated with such maintenance include individualized instruction, smaller classroom sizes, parental involvement, and home-based reinforcement (Kazdin, 1982). However, sometimes the treatment effects of faded token systems are not maintained, and this loss may be the result of individuals operating in environments that do not support the behaviors targeted in the token economy. Alternatively, the environment might support the behaviors, but if the token system was not appropriately faded, individuals might experience ratio strain resulting in response decrements. To promote response maintenance once a token program is removed, Kazdin (1982) recommends incorporating the procedures described by Stokes and Baer (1977) for facilitating generalization. More specifically, Kazdin (1982) suggests fading in reinforcers (e.g., praise) that occur naturally in the environment, increasing delays to and schedules of reinforcement, involving peers and caregivers in delivering reinforcers, and conducting training across environments and stimulus conditions to encourage generalization.

Potential Limitations of Token Economies

Token economies harness much of what we know about arranging effective instructional and therapeutic contingencies, as verified by hundreds of studies. Still, in relation to other behavior change systems, they do incur some costs, which warrants a consideration of their relative benefits and costs in relation to other contingency arrangements.

Unlike the simple provision of immediate tangible reinforcers, token economies require one to train the recipients of intervention to use the token system. This added time detracts from instructional time during which the client might otherwise be acquiring skills via direct tangible reinforcement. Thus, training might result in a delay in the onset of intervention for some behaviors, especially those the token economy will target. However, time spent in training might reduce time that could potentially be spent managing problem behavior related to the use of nontoken reinforcers (e.g., unprogrammed delays to reinforcement, immediate unavailability of reinforcers).

Also, when used to their greatest potential, token systems require continuous monitoring and frequent adjustment of many moving parts (e.g., schedules, backup reinforcers). One generally starts a token system with a dense schedule of contrived reinforcement that bears little resemblance to the circumstances under which that performance is expected to persist in the future. To eventually approximate the target natural contingencies, one is required to change the system based on performance and the changing needs of the client's repertoire and environment. Additionally, if responding in a token economy begins to degrade, there are many potential components to evaluate and manipulate to restore responding. Among the possible issues are whether one or more of the backup reinforcers are no longer potent, whether one of the three schedules has been thinned too rapidly, and whether treatment integrity has been compromised.

Matson and Boisjoli (2009) outlined several criticisms launched against the use of token economies. One involves potential ethical concerns surrounding the use of response cost within a token system, which carries the same risks as any other punishment procedure. As such, it is possible that the individuals managing the token economy (e.g., teachers, therapists) might find implementing response cost negatively reinforcing, which might result in an overuse of response cost and similar punishment procedures. Thus, a response cost embedded within a token economy can result in the same negative side effects as any other punishment procedure, including aggression, emotional responding, and discriminated avoidance of individuals and stimulus conditions associated with the procedure. However, Matson and Boisjoli point out that few token economies include a response cost component.

Another criticism is that ethical and clinical standards of care for psychiatric patients have changed, and there is a possibility that tokens are not considered appropriate for this population. They may also be difficult to maintain by staff and thus are not feasible. As such, Glynn (1990) posed that the efficacy of token economies in these settings was not properly disseminated, but also that the ethical and feasibility barriers may have been too great to implement in these settings.

Others have expressed concerns that token systems, like all other contrived reinforcement systems, might reduce internal motivation to engage in the targeted activity (i.e., overjustification effect; Deci, 1971; Kohn, 1993). However, researchers using single-subject designs have repeatedly demonstrated that there is little evidence that external reinforcement systems like token economies, as used in applied behavior analytic research, produce a systematic decline in targeted behavior (Levy et al., 2017; Peters & Vollmer, 2014). Even so, teachers and parents who are unaware of such research may be unlikely to collaborate on or consent to token research, respectively. As such, these and other such reservations about token economies might have further contributed to the decline in applied token research.

Such concerns and limitations are genuine and require attention. Despite the above-noted decline in token-oriented research, a variety of questions clearly remain to be addressed. Nonetheless, token economies have been found to be effective across numerous settings and circumstances. The rich literature on their use has shown that they can be successful in diverse applications that can be tailored to suit individual therapeutic and educational needs. As summarized by Matson and Boisjoli (2009), "the technology is powerful, efficient, and largely has been able to deal with critical comments. Thus, we see no substantial clinical justification for the decreased use of token economies."

32 Discrete Trial Instruction

Evan H. Dart, Jordyn Martin, Christley McGirt, Talia Shuman, Jennifer Hodnett, Faith Reynolds, Tegan Graff, Courtney Claar, Nicolette Bauermeister, Ashley Dreiss, and Hannah Mennes

Discrete trial instruction (DTI), also called discrete trial training (DTT; e.g., Tarbox & Najdowski, 2008), is an instructional paradigm rooted in behavior analysis first proposed as a method for teaching verbal language to individuals with autism spectrum disorder (Lovaas, 1977; Lovaas & Smith, 1989). It has since been expanded to promote the acquisition of a wide variety of skills, including verbal and nonverbal communicative behaviors (e.g., Koegel et al., 1988), academic skills (e.g., Carroll et al., 2016), and adaptive behaviors (e.g., Downs et al., 2007). DTI is built upon the foundation of operant conditioning (Cooper et al., 2020), which posits that the consequences following our behaviors shape their future likelihood and those behaviors that contact pleasurable consequences (i.e., reinforcement) are more likely to be exhibited again. Whereas more traditional instructional paradigms rely on naturalistic contingencies of reinforcement for their success, DTI takes a more intentional approach by providing learners with many more opportunities to respond (OTRs; e.g., Haydon et al., 2012) and ensuring each opportunity ends with the learner contacting reinforcement for accurate responding.

In DTI, each OTR is labeled a trial, which represents the smallest unit of learning within the instructional paradigm. Sessions of DTI involve the delivery of many consecutive learning trials and it has sometimes been referred to as "massed-trial instruction" for this reason (e.g., Majdalany et al., 2014). There is evidence to support the notion that higher rates of OTRs are linked to increased academic engagement and student learning (e.g., Common et al., 2020). As we will describe later, instructional pacing and inter-trial intervals are important variables within effective DTI programs. Although it is typical to deliver blocks of massed trials targeting a single skill or behavior in order to create behavioral momentum (Nevin et al., 1983), it is not uncommon to rotate through several target skills within a single treatment session by devoting each new block of trials to a different skill. Selecting which skills to target within a DTI paradigm is also very important and involves a combination of indirect assessments (e.g., interviews, rating scales) and direct assessment (e.g., observations, skill probes). A learner's current target skills and future planned targets comprise their instructional program, which can be likened to an individualized curriculum. Goals and objectives can be set based on this curriculum, allowing instructors and stakeholders to make data-based decisions about learners' progress through their program. In sum,

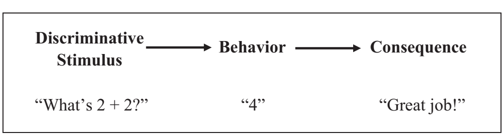
DTI represents a data-based instructional paradigm through which instructors can model small changes in learner behavior to inform instructional modifications and drive socially desirable change.

The remainder of this chapter will expand on the preceding two paragraphs to provide readers with a deep understanding of DTI and the literature supporting it as an instructional strategy. We begin with a brief overview of the behavior analytic principles underlying the effectiveness of learning in a discrete trial format. Next, we review several critical considerations for effective DTI related to the structure and process of treatment sessions, data collection, and program evaluation. Third, we provide a broad review of the literature supporting DTI across a variety of environmental and learning characteristics, such as setting, population, and behavioral target as well as potential barriers to effectiveness (e.g., training requirements, generalization). We conclude with an example of DTI program development and implementation.

Behavior Analytic Principles

As mentioned previously, DTI is built upon the principles of operant conditioning and behavior analysis. Specifically, each trial within DTI is comprised of three distinct components: (1) an antecedent prompt (i.e., discriminative stimuli) signaling to the learner that a specific response is requested; (2) the response exhibited by the learner; and (3) positive reinforcement contingent upon the response. These three components make up the three-term contingency (e.g., Albers & Greer, 1991) and we have provided a visualization of how this is conceptualized within an instructional environment. Each of these components is described in more detail below.



Discriminative Stimuli

Discriminative stimuli (abbreviated S^D) are antecedent stimuli that signal to an organism that a specific behavior is likely to be reinforced (e.g., Cooper, Heron, & Heward, 2020). In the example above, "What's 2 + 2" serves as the S^D for the response of "4." One non-academic example is an "OPEN" sign in the window of a storefront, signaling that your attempted entry into said store will be reinforced. In naturalistic settings, S^Ds are not perfect indicators that reinforcement is available. For example, the "OPEN" sign may have accidentally been left facing the street when in fact, the store is closed and the door is locked. Similarly, answering the question "What's 2 + 2?" with "4" may not always result in a reinforcing consequence (i.e., "Great job!"). Instead, there may be no apparent consequence at all, or a punitive one (e.g., "Duh, everyone knows that"). It is also important to note that specific stimuli do not universally function as S^Ds for all organisms. Instead, they are shaped into S^Ds through repeated pairings with a consistent consequence or shared through the specification of verbal contingencies (e.g., "If the sign says 'OPEN' the door should be unlocked"). Thus, it is our unique learning histories that form three-term contingencies and the stimuli that signal their availability.

This is important to keep in mind when considering DTI as an instructional paradigm. Each skill or behavior targeted within DTI will be associated with a specific antecedent prompt. The purpose of DTI is to establish new three-term contingencies through repeated pairings (i.e., massed trials) of the prompt, the response, and a reinforcing consequence. The goal is to shape the antecedent prompt from a neutral stimulus into an S^D that signals to the learner that engaging in the skill or behavior will result in reinforcement. Furthermore, because the aim of DTI is to promote skill acquisition across a variety of settings, it is important to choose an antecedent prompt that learners are likely to encounter outside of the teaching environment. For example, consider the social skill of greeting others (e.g., making brief eye contact and saying "Hello"). It would not be appropriate to select "Show me how to say hello" as an antecedent prompt for this behavior. Even though it may appear appropriate within the context of learning and is likely to evoke greeting behavior from most individuals, it is not contextualized within a social interaction and does not represent the likely S^D for this behavior in naturalistic settings. In other words, a learner is unlikely to hear "Show me how to say hello" outside of the instructional setting and would likely not respond to a more naturalistic greeting (e.g., "Hi, [NAME]") because it was not introduced during the learning process. Instead, selecting something like "Hi, [NAME]." as an antecedent prompt for greeting behavior is likely to result in opportunities to exhibit the behavior in naturalistic settings.

There is some debate about whether to use a range of antecedent prompts (e.g., "What's your name?" and "Who are you?") or one prompt for a single skill. The single prompt proponents suggest that too much variability in the form of antecedent prompts may prohibit learning by slowing the establishment of clear three-term contingencies (e.g., Grow & LeBlanc, 2013). Other suggest that while variability in prompt form may impede initial acquisition, it is critical if learners are expected to exhibit the skills learned in DTI across the wide variety of settings and naturalistic stimuli, they are likely to encounter once instruction concludes (Leaf et al., 2016). The most practical recommendation is to begin instruction of a new skill with a single prompt and allow the learner to demonstrate mastery with that prompt before introducing variability using multiple exemplars (Stokes & Baer, 1977).

Response

Because DTI is used primarily to promote skill acquisition, the behaviors targeted within an instructional program are unlikely to be within a learner's repertoire and a response to a target skill's antecedent stimulus, if one occurs at all, is likely to be incorrect. A response that does not occur cannot be reinforced, leaving DTI instructors repeating the antecedent prompt over and over again waiting endlessly for an opportunity to reinforce the learner's correct responding. Fortunately, the antecedent prompt is only the first in a hierarchy of prompts provided to learners, allowing instructors to implement a DTI program with more fluidity than otherwise would be possible.

Prompting hierarchies establish a progression of additional prompts exhibited by the instructor should the learner fail to exhibit a correct response following the initial antecedent prompt. Prompts can be classified into topographical categories, the most common of which are verbal, gestural, model, and physical. Within DTI, verbal prompts include any verbal stimulus provided subsequent to the initial antecedent prompt. For example, given the antecedent prompt "What's the capital of Florida?", a subsequent verbal prompt might be "T-," "Tal," or "Tallahassee." Gestural prompts include any gesture (e.g., pointing, facial orientation, nodding) by the instructor to indicate to the learner the correct response. For example, when presented with an array of two colored cards, one red, one green, and the antecedent prompt of "Touch green." A subsequent gestural prompt might involve the instructor pointing toward the green card. A model prompt involves the instructor exhibiting the correct response for the learner to observe. For example, given the antecedent prompt "Clap your hands," a subsequent model prompt would see the instructor clapping their hands to show the learner what the expected behavior looks like. Finally, physical prompts involve the instructor using hand-over-hand guidance to assist the learner in exhibiting the correct response. For example, given the antecedent prompt "Clap your hands," a subsequent physical prompt would have the instructor gently taking the hands of the learner and clapping them together. Physical prompts can be partial or full, meaning that the instructor provides some physical guidance (e.g., brings learners hands up and ready to clap) or complete physical guidance (e.g., the learners hands are clapped for them).

Within DTI, prompts are typically arranged in hierarchies (e.g., most-to-least or least-to-most) by their level of intrusiveness. For example, a least-to-most hierarchy might arrange prompts in this order: (1) gestural prompt, (2) model prompt, (3) partial physical prompt, and (4) full physical prompt, whereas a most-to-least might have them reversed. Learners who do not respond correctly to the initial antecedent prompt would receive the next prompt in the hierarchy, continuing through each prompt type until they responded correctly. Learners requiring a full physical prompt to exhibit a behavior are still considered to have provided a correct response, just with a very intense level of prompting required. As we will discuss later, it is important to record which prompt type was necessary to evoke a correct response from the learner as progress within DTI programs is often exhibited by demonstrating increases in the percentage of trials in which a learner responded correctly and independently (i.e., no prompts required in addition to the initial antecedent prompt); however, progress may also be exhibited by demonstrating that a learner who previously required full physical prompts to respond correctly now only requires a model or gestural prompt.

Research investigating the relative effectiveness of the different prompt types and prompting hierarchies within DTI suggests that any differences are idiosyncratic (e.g., Seaver & Bourrret, 2014). For all prompt types, it is very common for the initial antecedent prompt to be repeated with whichever prompt is being used. In this way, the initial antecedent prompt is still paired with the correct response and subsequent reinforcement. In addition, instructors can build a fixed or progressive time delay into their prompting procedures, meaning that learners are given a brief period of time (e.g., 3 s) to exhibit the correct response before a subsequent prompt is provided. This time period is meant to reduce learner dependence on prompts and allow them to contact reinforcement more quickly should they exhibit the response independently compared to waiting for the next prompt (e.g., Soluaga et al., 2008).

Consequence

The final component of the DTI trial is the reinforcing consequence. When a learner exhibits a correct response following a prompt from the instructor, their response is reinforced to strengthen the three-term contingency. Often, and especially when a new skill is introduced, the schedule of reinforcement is very thick or continuous (e.g., FR1), meaning that each correct response by the learner contacts' reinforcement. As a learner acquires a skill and begins to exhibit it more reliably and with less intrusive prompts, an instructor may consider thinning the schedule of reinforcement (e.g., FR2, FR5) and switching to a variable schedule that approximates naturalistic conditions. When considering the stimuli that will be used for reinforcement, instructors have several options.

First, it is often recommended that DTI instructors attempt to condition their presence and attention as a reinforcer. This process is known as pairing and Lugo et al. (2017) describe a systematic pairing process that includes close physical proximity, frequent verbal praise, reflections of the learner's verbalizations, imitation of the learner, description of the learner's play behavior, and initiation and creation of play with the learner. Pairing allows the instructor to use differential delivery of praise and other attention to the learner as reinforcement instead of tangible or edible stimuli that may not be feasible or appropriate. With that being said, preference assessments and reinforcer assessments (e.g., Cannella et al., 2005) of tangible and edible stimuli can provide insight into what stimuli may be used within a DTI program to reinforce correct responding. Finally, token economies (Matson & Boisjoli, 2009), in which arbitrary stimuli (i.e., tokens) acquire reinforcing properties because they can be exchanged for primary reinforcers (i.e., edible or tangible stimuli), have been used frequently to establish and maintain DTI programs (Haq et al., 2015).

Considerations for Implementation

Successful DTI implementation depends on first clearly defining the learning objective. Skills and behaviors that are appropriate for DTI typically display a clear beginning, middle, and ending. An example of a suitable behavior for DTI intervention might be writing at least five words on a sheet of paper with a pen or pencil when asked to start writing. Notice that we can identify a clear antecedent to the target behavior for this example—in this case, the verbal prompt to begin writing. As mentioned previously, antecedent prompts are typically explicit, succinct verbal instructions. Once the target behavior and its antecedent(s) are clearly identified and operationally defined, a specific criterion for mastery must be established as well (Bogin et al., 2010). We might stipulate mastery of the writing skill to be complete when the individual writes at least five words, at three out of four (75%) opportunities in a single week, across two or more teachers.

What distinguishes the DTI framework from other instructional methods is its emphasis on "chunking," or breaking down complex skills and behaviors into small steps that can each be taught independently. Progress in a DTI intervention resembles ascent on a stairwell with each step progressing from a simpler task toward a more advanced skill set. A task analysis is typically performed to determine what steps a task should be divided into (Cohen et al., 2006; Eikeseth et al., 2002). To return to our previous example, we might break the target behavior (writing five words when prompted) down into the steps outlined below. Note that the same criterion for mastery (e.g., *learner performs task at 75% of opportunities in a single week across two or more teachers*) should be implemented at each step before progressing to the next level:

1. Learner puts pencil to paper when provided multiple prompts.
2. Learner puts pencil to paper when verbally prompted once.
3. Learner writes 1 or more words when provided multiple prompts.
4. Learner writes 1 or more words when verbally prompted once.
5. Learner writes 3 or more words when verbally prompted once.
6. Learner writes 5 or more words when verbally prompted once.

DTI is typically administered by a single teacher who works one-on-one with a learner. Discrete trials are usually kept short and follow the same pattern: teacher cues for target behavior, prompts if necessary, and immediately reinforces the learner's response (Smith, 2001). After a short pause (i.e., inter-trial interval; e.g., 3–5 s), the instructor provides another antecedent prompt for the response again. Each trial has a definitive beginning (i.e., initial prompt) and end (i.e., delivery of reinforcement), and is typically followed by a brief break before beginning an additional trial or set of trials. The inter-trial interval between the end of one trial and the beginning of the next trial should be kept relatively short to maintain a steady pace of instruction. It is recommended to deliver trials in a rapid manner, with about 2–3 s between each trial (Koegel et al., 1980). In this way, the learner is given frequent OTRs, repeated reinforcement for correct responding, and behavior momentum is built. Longer pauses between trial deliveries (i.e., breaks) can be given after entire blocks of trials are completed.

DTI interventions' time- and content-intensive nature makes organizing materials a key priority in successfully carrying out teaching sessions. There should be very little time elapsed between a learner's correct response to a previous prompt and a teacher's prompt for the following response. Moreover, data must be collected trial by trial by the teacher or, if possible, by an independent observer. For each trial, instructors should note whether a correct response was produced by the learner as well as the level of prompt necessary to produce a correct response. These data are then converted to the percentage of trials in which an independent correct response was produced. It is recommended that data collection sheets be tailored to the specific set of behaviors being taught and specific prompting method and hierarchy employed (Bogin et al., 2010). DTI's intensive format provides for many learning opportunities for the learner, up to 10 or 12 per minute. The pattern of continuous, repetitive reinforcement of correct responding is theorized to strengthen target behaviors through operant conditioning. In addition, since instructors and learners typically work one-on-one, DTI interventions can be constructed explicitly by tailoring prompts and reinforcers to meet individual students' needs. These characteristics make DTI a particularly effective way to teach students new behavioral repertoires in an accelerated fashion (Smith, 2001).

Evaluating Progress and Determining Mastery

As with any instructional method, it is of interest to the DTI instructor to determine how effective they have been in promoting skill acquisition within a learner. Fortunately, DTI's objective instructional procedures are conducive to data collection and allow instructors to examine even small changes in learner behavior over time. To evaluate acquisition and mastery of a skill, it is important to have a data collection tool and method to evaluate the learners' progress. Data collection sheets should include information on the target skill, date of target introduction, date of each probe, date of mastery, and level of prompting for target response (see Fig. 32.1 for an example). Data collection should take place following each probe of a target skill for the session. For example, if the learner independently emits the correct response with no prompting within 3 s following the S^D, the instructor would record that trial as a correct independent response. If the learner does not emit the correct response within 3 s following the S^D and requires further prompting, the level of prompt needed for the learner to exhibit a response would be recorded. An incorrect response can include any response other than the target response, the target response chained with another response, a self-corrected response, no response at all, or the target response with a latency longer than 3 s. Defining what constitutes a correct and incorrect response requires the instructor to consider what variations in responses, if any, would be functional outside of the learning environment.

As mentioned previously, data collection during DTI may be as simple as recording the level of prompt necessary for a learner to exhibit a correct response for each trial. Acquisition goals will often be set on this indicator of performance and progress toward these goals can be reflected through a linear graph with the percentage of trials with correct independent responding on the *Y*-axis and sessions on the *X*-axis. Figure 32.2 provides an example of what these data would look like for a single skill probed ten trials each session. For this method, a minimum of five or ten trials should be run for each skill per session. Because DTI sessions typically involve conducting many more than five trials per skill per session, it is common to use the first few trials (e.g., five or ten) of the session as the evaluation probes. These are known as "cold probes" and are thought to best represent the learner's performance outside of the learning environment and before they have been given the opportunity to "warm up" to the session. After all evaluation probes for the skill have been conducted, the percentage of correct responses should be calculated. A common acquisition mastery goal is 90% or more trials with correct independent responding across two or three sessions. Of course, these goals can be changed to accommodate the idiosyncrasies that each learner will bring to DTI session; however, it is important to set goals stringent enough to ensure that the learner has in fact acquired the skill. All data on skill acquisition should be graphed to represent at least weekly progress in order to evaluate the number of skills acquired and consider the need for modifications in the programming. Learners should be making reasonable progress based on their developmental level and number of service hours being provided.

Beyond mastery, target skills should be probed periodically for maintenance over time. Maintenance probes can occur on a less frequent schedule (e.g., once per week, once per month). If the data indicate a decrease in accuracy, the target should be added back into the learner's

DTI - Data Collection Sheet

instructional programming. It is also important for mastered target skills to be probed for generalization. The target should be probed in various settings (e.g., classroom, playroom, outside), with different individuals (e.g., teacher, parent, other adult), using multiple exemplars (e.g., different pictures, physical objects, different materials), and with various instructions (e.g., point to yellow, show me yellow, which one is yellow). If the data suggest that a skill is exhibited by a learner accurately in one setting but not others, more intentional generalization strategies can be employed (see section "Limitations" below).

Empirical Support

There is a large body of literature supporting DTI as a generally effective instructional strategy; however, it is almost exclusively used with individuals with autism spectrum disorder, intellectual disabilities, and other developmental disabilities. Several meta-analytic studies have

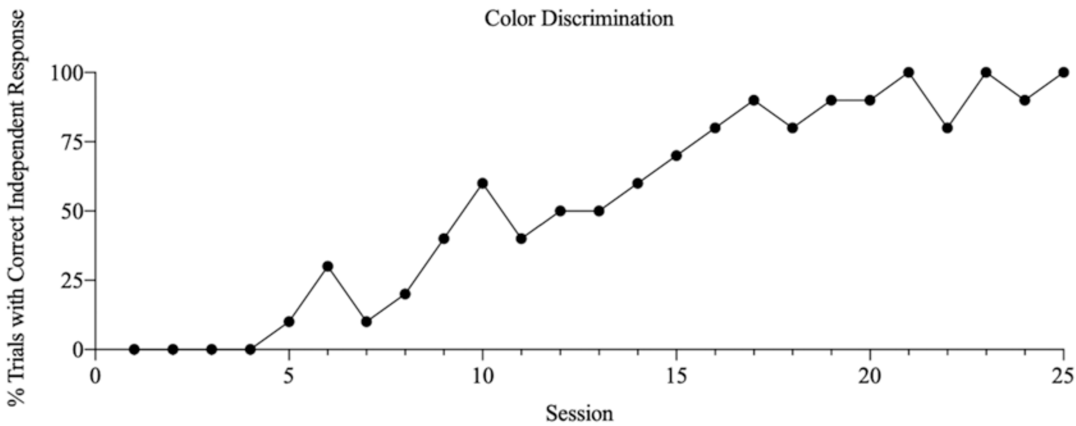

Fig. 32.2 Sample linear graph of a learner's progress toward accurate color discrimination

investigated the effectiveness of DTI and reported positive outcomes in these populations. For example, Kane et al. (2010) evaluated the effectiveness of spoken language interventions developed for children on the autism spectrum. The meta-analysis compared 22 different studies composed of either contrived teaching approaches (e.g., DTT) or naturalistic approaches in terms of their effects on the generalization and maintenance of learned skills. The meta-analysis results indicated that both methods were considered effective, but that DTI-like approaches demonstrated greater generalization effects in the children with ASD, suggesting a preference for teaching style in this population to generalize learned skills (Kane et al., 2010).

Virués-Ortega (2010) examined the effectiveness of long-term, comprehensive ABA interventions in populations of children with autism or pervasive developmental disability not otherwise specified. In this meta-analysis of 22 studies, the researchers synthesized the literature supporting intensive behavior analytic treatment programs based on DTI (e.g., one-to-one format, individualized intensive intervention). They found medium-to-large positive treatment effects for DTI interventions "in terms of intellectual functioning, language development, acquisition of daily living skills and social functioning in children with autism" (Virués-Ortega, 2010, p. 387). Another meta-analysis by Peters-Scheffer et al. (2011) evaluated the effectiveness of early intensive behavioral intervention (EIBI) in children with ASD. EIB is based on ABA methods and includes DTI practices. The researchers found that, across 11 studies, experimental groups that received EIBI "outperformed the control groups on IQ, non-verbal IQ, expressive and receptive language, and adaptive behavior" (Peters-Scheffer et al., 2011, p. 60). In sum, it is clear that DTI is an effective instructional method to promote skill acquisition and intellectual functioning within these populations.

Regarding the types of skills targeted by DTI, it is often used to promote "fine and gross motor skills, recreation, self-care, cognitive, and academic skills" (Bogin et al., 2010, p. 1). One of the most common targets of DTI is communication, either verbal or nonverbal, reflecting one of the primary deficits and diagnostic features of ASD. Paul et al. (2013) compared the effectiveness of a DTI approach to a more naturalistic approach for spoken language acquisition in preschoolers with ASD. They found that although both treatments performed similarly in terms of overall effectiveness, the DTI method resulted in larger treatment effects for those children with poorer receptive language. In addition to language and communication, DTI has been used to promote learners' social behavior (e.g., Jennett et al., 2008), academic skills (e.g., Carroll et al., 2016), and adaptive behaviors (e.g., Downs et al., 2007).

DTI has also shown to be effective across various settings, such as in-home, school, and community settings (e.g., Devlin & Harber, 2004). Moreover, researchers demonstrate the utility of DTI in both individual and small group settings. For example, Devlin and Harber (2004) incorporated DTI in one-to-one settings. The researchers first implemented structured DTI sessions in the students' home and school settings. Upon mastery of the targeted skills, the DTI sessions were carried over into the student's natural environment in the greater community. Students who received this intervention showed improvement in various skills related to attention, imitation, receptive and expressive language, pre-academic, and self-help (Devlin & Harber, 2004). Similarly, Taubman and colleagues' (2001) study incorporated DTI in small group settings. This study was conducted in a preschool classroom of eight developmentally disabled children and extended one-on-one discrete trial teaching to an environment with group instructions. The findings showed that the group DTI method was useful in establishing various educational skills, such as language and pre-mathematics skills (Taubman et al., 2001).

Finally, because of the relative simplicity of DTI's core procedures compared to other therapeutic or instructional methods, individuals require only basic training to become effective DTI instructors. Sarokoff and Sturmey (2004) demonstrated that a behavioral skills training (BST) package consisting of instruction, modeling, roleplay, and feedback was sufficient to improve the fidelity of three teachers' implementation of DTI to an average of 98%. Similarly, Radley et al. (2015) used behavioral skills training to teach high school seniors how to implement a DTI program with their peers to teach functional skills and adaptive behaviors. Leaf et al. (2019) conducted a systematic review of 51 studies examining techniques to train DTI instructors and found that students, therapists, paraprofessionals, parents, and individuals with ASD were all capable of becoming proficient instructors within a DTI framework (Leaf et al., 2019). Therefore, although long-term implementation of DTI may appear complex and intensive, the literature supports it as a feasible strategy due to the relatively low training demands compared to more complex psychological treatments.

Limitations

Despite its widespread implementation and effectiveness, there are several limitations of DTI that warrant consideration. First is the lack of authenticity within the learning setting. The environment in which DTI is conducted is in itself unnatural, or contrived, and highly controlled (Smith, 2001). This could make it difficult for the behaviors learned through DTI to transfer into natural situations (i.e., generalization). Generalization of the skills learned in DTI is important to ensure the skill will be used in a variety of settings to increase student functioning in areas other than a controlled setting. Making DTI sessions more like the natural conditions the learner will experience will help increase student practice of the skills, and hopefully utilize the skill taught in DTI in more than just one specific prompt (Cowan & Allen, 2007). An emphasis on the generalization of skills is also one aspect that is representative of an effective intervention with children who have ASD (Steege et al., 2007). In DTI, generalization has to be explicitly taught or the student will only respond to the prompts they have been working on in the previous sessions. Naturalistic approaches use natural consequences, diversity in training, and the incorporation of mediators of training to help increase generalization of the skill taught in DTI (Cowan & Allen, 2007). Using naturalistic modifications to DTI can help increase the generalizability of skills taught within sessions (Cowan & Allen, 2007; Steege et al., 2007). Some naturalistic approaches that have been used alongside DTI are incidental teaching, pivotal response training, and script-fading (Cowan & Allen, 2007).

Implementing DTI also requires a significant amount of resources from staff members. According to Smith (2001), it is not uncommon for DTI programs to be implemented for up to 35–40 h per week. DTI is a core component of early intensive behavioral intervention (EIBI) for children with ASD (e.g., Reichow et al., 2012), which, true to its name, is very time intensive, often being implemented for 20 or more hours each week. DTI allows instructors to provide a large amount of material to most accurately meet a learner's needs, but this individualization takes a large amount of the student's time. Staff members are also limited to the resources available, including availability of time, space, and materials. Although the core concepts of DTI are not complex, instructors may be required to undergo more intensive training to increase their understanding of the more nuanced aspects of DTI, including how to chunk trials appropriately and how to provide appropriate reinforcement. For these reasons, it is most common to see DTI programs implemented in a clinical setting, as opposed to a school and instructor burnout becoming a more frequent topic of study (e.g., Griffith et al., 2014).

Example of DTI Program Development

We conclude this chapter with an example of how DTI can be implemented programmatically and have intentionally selected verbal behavior as a point of example due to its popularity within the DTI community. Verbal behavior DTI programs are frequently developed to address the broad domains of functional language, or verbal operants. Specifically, individuals rely on both receptive and expressive language objectives as they expand their ability to communicate with others. Practitioners are tasked with examining the presence and absence of skills across receptive and expressive verbal operants as they design verbal behavior programs, which begins with conducting skill assessments. Data collected from comprehensive verbal behavior evaluations can allow the development of a curriculum tailored to the needs of the individual learner. Verbal behavior assessments provide stakeholders insight into skills that need to be taught or targeted and areas of proficiency for the learner.

Verbal behavior skill assessments evaluate linguistic milestones of an individual. By determining if an individual has reached a specific developmental benchmark, practitioners can assess if the individual is primed for advancing forward. A practical approach to understand more about an individual's language skills is to systematically examine their abilities across the verbal operants. An individual's ability to make requests, or manding repertoire, can provide insight into the potency of reinforcement and personal motivation for emitting verbal behavior. Armed with knowledge of how establishing operations impact language, gathering knowledge regarding the ability to imitate sounds can influence subsequent assessments (e.g., Speech Sound Assessments; Articulation Assessments). Sundberg and Michael (2001) highlight a learner's demonstration of tacts as being related to "the nature and extent of nonverbal stimulus control over verbal responses, and a systematic examination of the receptive and intraverbal repertoires will show the control by verbal stimuli" (p.706). Practitioners can further define areas of concern by discovering the presence of "splinter skills." Specifically, individuals presenting high functionality in one area may be masking deficits in another area, which can potentially have long-term impacts on overall language competency.

An iconic example is Sundberg's (2007) Verbal Behavior Milestones and Placement Program (VB-MAPP). Purposed to evaluate children from 0 to 48 months, practitioners can identify gaps in a child's functional language development. This criterion-referenced assessment can provide instructors with insight into the skills of their learner and the skills of a learner acquiring language typically in their natural environment. This comprehensive evaluation tool consists of three individual assessments investigating a child's current verbal repertoire, barriers that may be impeding progress for the child, and areas that may impact meaningful progress. In addition, practitioners can consult numerous task analyses to guide skill tracking for programming targets. Stakeholders can also obtain guidance for recommending individualized educational program (IEP) goals. Progress monitoring is built into this tool through quarterly administrations, making program evaluation an essentially embedded component.

Although individuals exposed to verbal behavior programming demonstrate promise and perhaps even progress with each correct response during DTI, these are not synonymous with mastery of a skill. An individual can demonstrate skill mastery through fluency and generalization of the skill outside of the learning environment. In addition, proficiency is measured as an individual continues to reliably demonstrate the skill over time. Establishing regular data collection procedures explicit to determining mastery of target skills being taught and skills recently acquired is considered best practice. On a weekly basis, reviewing the current targets across single trials, often called probes, prior to provide any teaching can inform an individual's level of mastery. More specifically, practitioners can analyze responding during weekly probes, across time to guide decisions regarding introducing new targets, and the need for teaching modification when targets are resistant to mastery.

Identifying barriers impending with skill acquisition is vital to continued progress throughout verbal behavior programs. Practitioners could conduct formal assessments to determine which behaviors or individual deficits may be contributing to a lack of growth. Recognizing specific obstacles can directly inform individual interventions or strategies necessary for skill acquisition. For example, if an individual is overly dependent on prompts for correct responding when presented a target, the stakeholder can examine prompt fading to move closer to skill acquisition.

Teaching procedures of DTI follow a highly structured format that allows for complex skills to be broken down into sub-skills that can then be targeted and mastered (Tarbox & Najdowski, 2008). Sub-skills are categorized by student responses which allow for intensive support to be provided based on individual need paired with repeated practice for effective teaching. For example, a student would be presented with a given stimulus and then has an opportunity to respond to that stimulus. The student's response is then paired with the appropriate consequence. A correct response would receive immediate reinforcement that can come in multiple different forms based on student preference (praise, tangible items, etc.). Incorrect responses or failures to respond are paired with the absence of a reinforcer and this can look like inattention to their response, offering feedback on their response, or just simply not giving them a reinforcer at all (Tarbox & Najdowski, 2008). DTI is considered unique in its ability to use direct, explicit instruction that focuses on skill development within a process and targets individual needs at the most basic level to then attain the complexity of the skill.

To effectively use DTI, it is crucial to acknowledge the environment in which the teaching will take place and refrain from any aversive factors that may occur. As an explicit instructional paradigm that is informed through student responses, the environment should maximize student engagement while isolating the specific consequence that is paired with the response. It is also critical that those who engage with DTI are proactive when pairing a student with a teacher and environment and provide careful consideration for external factors that may impact the outcomes of the student (Haydon et al., 2012).

Mands are responses dictated by the desired reinforcement (Skinner, 1957). Specific reinforcement is the response consequence, while the establishing operation serves as the controlling variable when learners emit a mand. Despite being commonly described as a request for an item, mands can also demand information or the removal of nonpreferred stimuli. A learner that can effectively request stimuli demonstrates a level of control over their own environment; as such, this operant is often addressed first. Skinner (1957) suggests that by demonstrating the utility of verbal behavior to the learner through mand training, the value of emitting verbal language increases for the learner. Another reason to begin programming around mands pertains to the ease with which motivation can build using preferred items (e.g., toys, candy, snacks).

Verbal stimulus without point-to-point correspondence or formal similarity is considered an intraverbal. Following this type of response, the learner is provided nonspecific reinforcement, or a generalized conditioned reinforcer (e.g., tangible item, adult attention, break from demand). Finishing a verse of a nursery rhyme, providing remaining elements of a sequence (e.g., "Ready, Set, ___"), and XXX are all examples of intraverbal responses.

The controlling variable for the echoic verbal operant is verbal stimulus with point-to-point correspondence and formal similarity. More simply, when an individual imitates a sound, word, or phrase, they have emitted an echoic response. This verbal operant is met with a nonspecific reinforcement during teaching trials.

When using DTI, teachers should also mix prompts or tasks given to the student. In behavioral momentum theory, there is an emphasis on "building momentum" of a behavior by asking students to do tasks that often come before the more complex task (Podlesnik & Shahan, 2010). In this theory, students tend to comply with difficult and low-probability instructions by building momentum through easy and high-probability instructions that the student has already mastered. Using tasks the student has already mastered will help scaffold as well as reduce frustration of starting an entirely new task. When using these previously mastered tasks, it is also important to continue reinforcement to reduce the ratio strain. When there are large gaps of time without reinforcement, the student may not have any response. To avoid this, teachers using DTI should be prompting and reinforcing at a regular rate that is developmentally appropriate for the student they are working with.

Conclusion

DTI is a popular and effective instructional paradigm, particularly for teaching verbal behavior and other communicative skills to individuals with ASD and other developmental disabilities; however, because it is rooted in basic behavior analytic principles, DTI's effectiveness transcends the population and target skills for which it is typically used. With the primary goal of establishing and maintaining functional three-term contingencies between naturally occurring antecedent stimuli, adaptive behaviors and skills, and reinforcing consequences, DTI is clear in its purported mechanism of change. Due to this, DTI has been incorporated into large-scale programmatic treatment efforts to address developmental delays in young children (e.g., EIBI, UCLA model) and has proven successful in doing so. Although efforts to promote generalization of learned skills outside of the instructional environment have been effective, it remains one of the primary concerns of the long-term viability of DTI.

33 Group-Based Instruction

Nicholas A. Gage, Rachel Kaplan, Kaci Ellis, and Brittany Batton

Introduction

In 1948, B.F. Skinner published his utopian novel, *Walden Two*. It describes a commune in the rural American East developed and sustained entirely through behavioral engineering. Through the first-person account of Professor Burris, we learn about Walden Two from Frazier, the founder of Walden Two. Over the course of the story, Frazier describes how experimental behavior analysis was used to create a community that encourages "people to view every habit and custom with an eye to possible improvement. A constantly experimental attitude toward everything" (p. 82). As a result, Walden Two is a community of intelligent, caring, artistic, and content individuals living very happy and healthy lives together. As Frazier notes, "the potency of behavioral engineering can scarcely be overestimated. It makes one wonder why the techniques haven't been put to better use long before this" (p. 399).

Although fictional and, without a doubt, utopian, Skinner used *Walden Two* to describe the potential value, behavior analysis can have on large groups of individuals; how the principles of behavior, with a commitment to experimental analysis, can meaningfully improve collective outcomes for all. Setting aside Skinner's radical behaviorism and any desire to reimagine society, there is an important lesson to be gleaned from *Walden Two*: the principles of behavior can be successfully used with groups of individuals to meet desired outcomes. It is the overly simple summation that we shall explore in this chapter, namely, how the principles of behavior, as enacted through applied behavior analysis, have been used to change the behavior of groups of individuals. Below, we will provide a brief rationale for working with groups and the benefits of doing so. We will then describe research in a variety of applied areas, with a focus on school settings and children. Overall, our goal is to highlight how applied behavior analysis has been applied to groups and the subsequent resulting benefits.

Rationale

There is overwhelming evidence that socially important behaviors can be changed (e.g., Hanley et al., 2003). In fact, Baer et al. (1968) note in the first sentence of their seminal paper that "the analysis of *individual behavior* [emphasis added] is a problem of scientific demonstration… reasonably well understood" (p. 91). As such, the unit of analysis in most applications of ABA is the individual and their behavior. For example, Lang et al. (2010) used functional analysis to develop a treatment to reduce elopement behaviors demonstrated by a 4-year-old boy with high

functioning autism. The authors, experimentally manipulated attention, access to a tangible reinforcer, and free play in two settings. Based on functional assessment, the authors found that an attention-based intervention was most salient in a resource-room setting, while a tangible-based intervention was most salient in a classroom setting. The functional analysis was conducted one-on-one with the boy and a therapist, while the interventions based on the functional assessment results were implemented by a teacher. Collectively, the assessment and intervention required extensive staff time and attention.

Elopement is a behavior that may require an individualized intervention, given the dangers the behavior poses and the unique contingencies triggering and maintaining its occurrence. Yet, many other behaviors may not require the same level of intensity and/or specificity. These behaviors can likely be addressed through group-based assessments and interventions. For example, Rasmussen and O'Neal (2006) used a fixed-interval schedule of positive reinforcement by a teacher to reduce verbal classroom disruptions of three students with emotional and behavioral disorders (EBD) in an alternative school. The authors conducted individualized functional analyses and determined that the function of the verbal disruptions for all three students was teacher social attention and developed individualized interventions for each student. Alternatively, Groves and Austin (2017) use interdependent and independent group contingencies class wide to reduce verbal disruptions of four students with EBD in an alternative school. The authors did not evaluate each students' function, but instead evaluated the effect of the group intervention on individual student behaviors. Both studies established a functional relation between the intervention and verbal disruptions. However, one was more efficient, as it was applied class wide.

Group-based applications of ABA are distinct from individualized interventions in that the unit of analysis of the independent variable is a group. We define group broadly to include two or more individuals, and group-based as assessment or intervention focused on a group. For example, a teacher implementing an interdependent group contingency, such as the Good Behavior Game (GBG) (Barrish et al., 1969), conducts the intervention with all of the students in her class. She may be using the intervention to reduce problem behaviors class wide or the problem behavior of an individual student. Regardless, the independent variable is applied to the whole group.

Application of an assessment or intervention to a collective group has a number of advantages. First, group-based ABA can be resource efficient. Well-trained staff, such as Board Certified Behavior Analysts (BCBA), can impact a collective group, increasing the number of individuals and their behaviors impacted by a single staff member. Group-based ABA can also save time. There is no doubt that identifying and experimentally manipulating the function of an individual's behavior will increase the likelihood of behavior change. Yet, when applying practices to a group, conducting individualized functional analyses may not be necessary for all group members. Returning again to the interdependent group contingencies example, the teacher does not know the function of all her students' behaviors and may not have them under stimulus control. Yet, the application of the interdependent group contingency may decrease student behaviors, particularly low intensity problem behaviors, by capitalizing on the natural reinforcers in the classroom (Barrish et al., 1969). Furthermore, applications of more low-intensity group-based interventions by fewer well-trained staff can be used to rule out potential environmental confounds on the intractability of a target behavior and screen individuals within the group in-need of more intensive support. For example, two students in a class exhibit very aggressive physical and verbal aggression toward peers during large group instruction. The teacher then implements a group-based intervention, this time a class wide token economy. One of the students significantly reduces their aggressive behaviors, while the other does not. By first conducting the group-based intervention, the teacher found that for one student, increasing access to reinforcement during large group instruction changed the target behaviors, meaning that the teachers' classroom management may have been the reason for the aggressive behaviors. However, for the other student, access to the class-wide reinforcement was not salient and indicates that the student may need more individualized assessment and intervention. Thus, the token economy was able to identify one student, not two, in need of more intensive supports, thereby saving time and resources. This process is, in fact, the central premise and motivation for school-wide positive behavior interventions and supports (SWPBIS; Sugai & Horner, 2020), a multitiered prevention and intervention framework grounded in ABA and designed to be efficient and effective.

Group-based applications of ABA can also reduce costs. When services are delivered at the group level, the costs of individual behavior change are spread across all involved. For example, Greenberg and Martinez (2008) examined the cost-effectiveness of an ABA-based early intervention model in preschools across 1 year of implementation. The author implemented a group-based discrete trial training using learning units and natural environment teaching (NET) to increase preschool children's correct learning units. The authors found reduced costs per learning unit by delivering the intervention in groups instead of individually. Intuitively, this should be the case for most group-based applications. By reducing resources, saving time, and spreading the individual benefit across the group, significant money saving can be attained.

There are many examples of group-based ABA assessment and intervention procedures. For our purposes, we categorize these procedures by the characteristics of the group. Specifically, research has demonstrated group-based behavior change for large groups, such as whole schools or facilities, and smaller groups, such as classrooms or social skills groups of three to five individuals. Further, group-based ABA procedures have been used with young children in preschool settings and school-aged students in public, private, and alternative schools. Given the myriad applications, we provide a brief overview and review of research in each of these contexts below. Our goal is to simply survey different applications of group-based ABA procedures and suggest that research has demonstrated socially important behavior change.

Example Group-Based ABA Procedures

School-Wide Positive Behavior Interventions and Supports (SWPBIS)

SWPBIS is a three-tiered framework for implementing positive behavior support (PBS) school-wide. PBS is a technology with four core features: (a) application of research-validated behavioral science; (b) integration of multiple intervention elements to provide ecologically valid support; (c) commitment to substantive, durable outcomes; and (d) implementation of support within organizational systems that facilitate sustained effects (Carr et al., 2002; Dunlap et al., 2009). SWPBIS uses an MTSS approach for improving social and academic student outcomes school-wide by integrating school data, systems, and practices. SWPBIS is not a packaged program, but rather a framework of data driven and research-based practices which support all students across the school. The framework consists of core features which allow a school leadership team to use data to create a personalized plan for their school with consideration for the school's organizational structure, resources, and cultural needs (Horner & Sugai, 2015; Sugai & Simonsen, 2012). Core features include a team-driven approach to sustainable systems' change throughout the school, universal screening for all students, ongoing progress monitoring, school-wide expectations, a continuum of procedures to reinforce those expectations, a continuum of strategies to address problem behaviors, implementation fidelity, and continuous professional development for all staff (Anderson & Kincaid, 2005; Sugai & Simonsen, 2012). Research, including meta-analyses, suggests that SWPBIS has a positive and meaningful impact on all student behavior (Gage et al., 2018) and the behavior of under-represented students (McDaniel et al., 2020).

As noted, there are three SWPBIS tiers. Tier 1, or universal, provides proactive, preventative support to all students. Critical features of Tier 1 include establishing, teaching, and reinforcing school-wide behavioral expectations. Reinforcement is often, but not always, delivered through a school-wide token economy system. An additional component is implementation of evidence-based classroom management practices in the classroom, as well as throughout the school. School-wide data, such as office discipline referrals, are used for identifying students non-responsive to Tier 1 prevention, and in need of more intensive, Tier 2 supports. Tier 2 is often provided in small groups of students and includes self-management, self-regulation, social skills, and/or academic support. Intervention decisions should be informed by hypothesized functions of behaviors. Tier 2 supports are monitored through on-going data collection. Students non-responsive to Tier 2 support receive Tier 3 individualized interventions based on a functional behavior assessment (FBA). The goal across all three tiers is to efficiently deliver evidence-based behavior supports, grounded in PBS and ABA, to all students and increase the intensity of those supports for students in need. Below, we highlight a few specific group-based components of SWPBIS.

Behavioral Expectations A core primary prevention practice in SWPBIS is establishing, teaching, and reinforcing school-wide expectations. Teaching rule-governed behaviors increases the likelihood students will respond effectively to specific environmental triggers without having a history of contacting the contingencies (Skinner, 1969). School teams establish three-to-five broad behavioral expectations and then define those expectations across all school settings and routines, typically using a behavioral matrix. For example, a school may define their school expectations as be safe, be respectful, and be responsible. Then, specific expected behaviors are defined by setting for each of the school-wide expectations and, most importantly, directly taught to all students. Rules are developed for all settings of school (e.g., walking through the hall, standing in the cafeteria, entering, sitting in, and exiting a bus, areas of the playground, and a variety of classroom settings). Once students are taught the expectations and rules, pre-corrections are used to verbally and gesturally prompt students to demonstrate the expected behaviors throughout the school.

Consequences of Behavior Consequence-based interventions can include any interventions intended to respond to a behavior either through reinforcement to increase its future occurrence or punishment to decrease its future occurrence. By pairing these contingencies to their function, school teams are able to consider appropriate school-wide consequences (Skinner, 1969). Once students have learned the expectations, school staff create two systematic and consistent continuums to provide consequences for student behavior. First is a continuum of positive procedures to encourage and acknowledge students for following the expectations. This continuum is linked to the school-wide expectations, used across all school settings, and accessible to all students. School teams chose the research-based components of this continuum based on the student need and school resources. Some evidence-based reinforcement procedures frequently implemented include behavior specific praise, group contingencies, behavioral contracting, and token economies (Simonsen et al., 2008). The token economy is a system in which students earn tokens, ideally paired with behavior specific praise, contingent upon the display of expected behaviors. Students trade in the tokens for backup reinforcers, including edibles (e.g., candy, chips), tangible items, (e.g., small toy, stickers) social reinforcers (e.g., attention from a teacher, playtime with a friend), and special privileges (e.g., extra recess, time on the computer). The tokens can be provided to students and exchanged for back up reinforcers on a variety of schedules in order to meet the different developmental needs of the students (Maggin et al., 2011). For example, access to reinforcement latency may be shorter in elementary schools or early elementary school grade levels and longer in secondary school settings.

Strengths and Weaknesses There is a large evidence base supporting the effectiveness of SWPBIS reducing student disciplinary actions and improving organizational health. Lee and Gage (2020) conducted a systematic review and meta-analysis of the SWPBIS literature and included studies that (a) focused on the school as the unit of analysis, given that SWPBIS is a group-based approach aimed at improving the behavior of all students in a school and (b) used an experimental group design (i.e., a treatment group and a comparison group). The authors identified 32 studies that included almost 9000 schools and estimated that schools implementing SWPBIS significantly reduced disciplinary exclusions, including suspensions, increased academic achievement, and increased organizational health. Although the evidence is positive, it is unclear which features of SWPBIS implementation are critical for actualizing positive student behavioral outcomes. Most studies include a measure of fidelity of implementation, quantitatively documenting that SWPBIS was implemented as designed. Unfortunately, those measures are global and do not provide insight beyond a total score. Therefore, to date, it is unclear which components and interventions are the most salient. Such information would increase understanding of the PBS technology and allow for more targeted professional development.

Classroom Management

All behaviors are functionally related to the teaching environment, and therefore, teachers can alter the occurrence of desirable and undesirable behaviors by changing the teaching environment. Research suggests that teachers using ABA-based classroom management strategies, defined as function-based (Hershfeldt et al., 2010), have better control of their classrooms and prevent and effectively respond to student behavior (Conroy et al., 2014). Classroom management focuses on how teachers establish and maintain school and classroom expectations rules, and routines, as well as how teachers respond to and restore desired behavior patterns when they are disrupted (Brophy, 20). The goal of classroom management is to ensure students are on-task and engaged in the curriculum and instruction and equip students with desired learning outcomes. Below, we describe some of the evidence-based classroom management strategies teachers use.

Antecedent Strategies Antecedent strategies are directed at changing the teaching environment before behavior occurs. Thus, these strategies are considered preventative in nature. Antecedent strategies applied to a group of students (i.e., classroom management) include as previously mentioned classroom expectations and routines, as well as providing choice and implementing visual schedules (Conroy et al., 2014; Dunlap et al., 2001). Teachers clearly communicate what is expected (i.e., follow teacher directions the first time, stay in your learning area, have all needed materials), and then, students role-play examples and appropriate non-examples and practice modeling each expectation. Teachers regularly provide precorrections and prompts for the expectations throughout the day. Expectations are retaught if regular problem behaviors occur. In order to ensure that students have exposure to explicit modeling and multiple opportunities to practice each of the classroom expectations, teachers use the I do, we do, you do teaching sequence.

Instructional choices can be offered to select the order of academic tasks, choice of reinforcer when task is completed, and within task choices (i.e., materials to use, location to work, partners). Providing choices has been found to increase academic engagement, student self-esteem and self-determination (Royer et al., 2017). Establishing predictable routines and providing visual schedules can help all students, but particularly students with autism spectrum disorders, transition between daily activities and tasks (Sevin et al., 2015). A visual support system uses images or photographs in a sequence for the activities of the day and allows all students to see the order of events. An icon can be used to indicate when a change in routine is expected to happen (i.e., assembly, picture day, field trip). Language like “first we will independently read, then we earn a movement break” can be used to break down multi-step instructions and reminds students of earned reinforcers.

Consequence Strategies A number of consequence-based classroom management strategies are used to reinforce appropriate behaviors. As noted above, these include, behavior specific praise, group contingencies, behavior contracts, and token economies (Simonsen et al., 2008). Group contingencies are often used to provide group rewards when the group or individual student meets a pre-determined goal. Data toward the goal can be tracked using a compliment chart or token jar. Teachers can be creative by tailoring these data collection systems to match students' interests. For example, if the student with more frequent problem behaviors really likes unicorns, a teacher might design the data collection system using a unicorn theme. While explicitly stating how the group earned a step toward their goal, teachers can visually add a flower to the garden, piece to Captain America, or a marble in a jar. Teachers can make the goal more attainable or more challenging by changing the number of required items to earn the reward. "Secret student" can be played by the teacher predetermining a student for the chosen time block. The teacher will remind the class that the secret student needs to follow a specific rule(s) for the class to earn the reward. When the time block is over, the teacher announces if the secret student met or did not meet the goal. It is important to know which students like to be praised publicly and which prefer to not have attention on them. To minimize peer pressure and retaliation, it is critical that the secret student is not named prior to the time period ending, or if the student did not meet the goal. If the student does not make the goal, a teacher might say "our secret student did not earn a prize because they did not stay in their area. Remember we stay in our area by sitting at our table. We will try again next time."

A positive version of the Good Behavior Game can also be played. Teachers select a short block of time to play and students are divided into teams. The teacher explicitly states how students can earn a point (i.e., raising a quiet hand, staying in area, focusing on assigned work). When students from a team demonstrate one of these expectations, their team is given a point. At the end of the time block, the team with the most points wins. To connect the game to already established group contingencies, the whole class can earn a marble if both teams earn a predetermined number of points. Rewards that students earn can be cost effective or free. Teachers can determine students' preference in reinforcers by observation, interview, or using a preference assessment. Teachers can facilitate building relationships with trusted adults in a variety of ways, like hosting mystery guest parties with the principal, school counselor, or specials teachers. Teachers can mail post cards home or send an electronic version through email or text recognizing appropriate student behavior. Reinforcement is a group-based intervention that if implemented effectively can decrease student problem behavior in the classroom.

Strengths and Weaknesses A number of systematic reviews and meta-analyses have examined the evidence base of classroom management generally, as well as evidence of specific interventions. Oliver et al. (2011) completed a meta-analysis on the impact of classroom management on disruptive and aggressive behavior, findings that classroom management has an average effect of 0.80 ($p < 0.05$) standard deviation units. Put differently, classroom management significantly and meaningfully reduces disruptive and aggressive behaviors in a classroom. Marzano et al. (2003) found similarly large effect sizes ($d = 0.90$, $p < 0.05$) but also found a significant and positive effect size of 0.52 ($p < 0.05$) for academic achievement. With regard to specific classroom management strategies, reviews have found similar outcomes. Royer et al. (2019) reviewed research focused on behavior specific praise, MacSuga-Gage and Simonsen (2015) reviewed research on teacher-directed opportunities to respond, and Gage et al. (2020) reviewed active supervision research, to name a few. All found positive and significant improvements in student behavior when each practice was implemented. That being said, there are some weaknesses. First, the literature does not always clearly distinguish specific, discrete classroom management strategies, such as behavior specific praise, from classroom management interventions, such as group contingencies or token economies. Second, studies have not determined which specific discrete behaviors are most salient and what combination of discrete teacher behaviors and classroom interventions are most effective for increasing student engagement and reducing problem behaviors.

Direct Instruction Curricula

Research consistently demonstrates that explicit and systematic instruction, based on ABA principles, has a direct and meaningful impact on student academic achievement. One such approach, Direct Instruction curricula (DI; Engelmann & Colvin, 2006), has an extensive evidence base with demonstrations of positive impacts on learning for more than 50 years. DI is based on the assumption that students learn with well-designed instruction that is contingent on students mastering prerequisite knowledge and skills. Students receiving DI begin with assessment to determine current academic skills levels to identify what skills have been mastered and what skills need to be mastered. Students are then grouped by skill level and the curriculum is enacted. The target skills are then introduced slowly, ensuring that students achieve mastery through repeated practice. All details of the instruction are controlled to ensure accuracy of delivery and effect of instruction. The instructors also provide regular positive reinforcement of demonstrated mastery behaviors, celebrating student successes at regular intervals (Engelmann, 2014).

A recent systematic review and meta-analysis evaluated 50 years of DI research (Stockard et al., 2018). The authors included 328 research studies evaluating the impact of DI on student achievement in reading, math, language, and spelling, as well as impacts on affect and perceived ability. Across almost 4000 effect sizes from the total corpus of studies, the authors found large effect sizes for all academic areas ($d > 0.50$) and moderate effect sizes for affect and ability ($d > 0.30$), with all effects favoring DI. DI, an ABA- and group-based approach, has a significant, positive, and meaningful impact on student academic achievement and other outcomes.

Strengths and Weaknesses Strengths of the DI literature base are both shear volume and consistent positive impact. Yet, a number of criticisms have been levied against DI, particularly the rigidity of the curriculum and the exclusive focus on skill mastery and not higher order concepts, such as reading comprehension. There has also been concerns that DI is only effective for young children or children with extensive needs. These concerns do not align with the meta-analysis results, which indicate that DI is effective for all students. Nonetheless, even in the face of clear and consistent evidence, DI is not broadly implemented across the nation. Therefore, more work is needed to increase the social acceptability of DI as an accessible instructional model.

Preschool/Early Childhood Settings

Although similar to K-12 school settings, preschools and early childhood settings, including in-home day care and center-based care, have unique needs and developed its own literature-base separate from school-based research. The size of groups in these settings varies. The American Academy of Pediatrics recommends an adult-to-child ratio of no more than 1:8; however, the laws are left up to each state in which the maximum ratio reaches upward of 1:20 for 4-year-old children, and as of 2011, 11 states did not have any required regulation for preschool group sizes. Some of the most widely used and least intensive group strategies in preschool and early childhood settings include antecedent interventions, natural environment teaching, and the use of group contingencies.

Antecedent Interventions As noted above, antecedent interventions are defined as a manipulation of the environment or events that occur prior to a behavior's occurrence (Smith, 2011). Antecedent strategies serve as a proactive approach to ensure a safe and positive environment that is structured to promote desired behaviors and limit the opportunity for problem behaviors. Antecedent strategies can be broadly classified into two different categories of intervention: default interventions (in which the teacher/caregiver is manipulating the environment in which problem behavior may occur) and function-based interventions (in which the teacher/caregiver is manipulating a previously identified contingency which maintains the problem behavior) (Smith, 2011). These could include well-defined classroom centers, visual schedules, and opportunities for movement and choice. One popular antecedent intervention is antecedent exercise. Research shows that antecedent exercise decreases disruptive behavior (Allison et al., 1995). Specifically, with preschool children, Webster et al. (2015) found that following a classroom physical activity break, students on task behavior increased and the most off task preschool children's behavior increased by an even greater margin following exercise. The creation of an enriched environment is an additional default antecedent strategy in which noncontingent access to reinforcement is available (Cooper et al., 2020). In a preschool classroom, this could include whole class or small group access to toys and games or opportunities for socialization.

Two function-based antecedent interventions that have been effective in preschool and early childhood settings are noncontingent reinforcement (NCR) and high probability instruction (high-p) (Cooper et al., 2020). Though these interventions are typically used in individualized instruction, they can be used in group settings. Following the recommended steps from Coy and Kostewicz (2018) for implementation of NCR, teachers collect data to establish context, identify reinforcers, deliver reinforcers continuously, create a formal plan, and then implement and evaluate the effectiveness of their plan. While this is designed for individual use, the steps could be adapted to evaluate whole class adherence to expectations and rules and reinforced on a fixed or variable schedule via class wide work breaks, access to edible reinforcers, or teacher attention. High-p or behavior momentum has been studied specifically in the preschool context. Austin and Agar (2005) found that the use of high probability command sequences was effective in increasing compliance in pre-kindergarten and kindergarten classrooms with typically developing children. Jung et al. (2008) used high-p in combination with peer-modeling to increase social interactions in 5- and 6-year-old children with autism.

Natural Environment Teaching Natural environment teaching (NET) in preschool settings is implemented to teach children in natural settings, allowing for more interaction with their peers, less one-on-one instruction, and greater generalization of skills. Two variations of NET typically used in preschool settings include incidental teaching and milieu teaching. Milieu teaching incorporates incidental teaching, as well as modeling, mand-prompting, and time-delay (What Works Clearinghouse, 2012). Both incidental teaching and milieu teaching are methods designed to increase functional language of young children building upon the processes outline by Hart and Risley (1975). There are mixed reviews of the effectiveness of these interventions. A 2009 review on milieu teaching reported increases in children's communication, while a U.S. Department of Education, What Works Clearinghouse has reported no evidence for milieu teaching due to a lack of research meeting their standards of rigor (Mancil, 2009; What Works Clearinghouse, 2012).

Group Contingencies Group contingencies are one of the least intensive strategies for acknowledging appropriate behavior in the preschool and early childhood settings. The three types of group contingencies include independent ("to each his or her own"), interdependent ("all for one"), and dependent ("one for all") (Simonsen et al., 2008). A review of group contingencies with preschool-aged children found positive effects for all three types of group contingency interventions, though the majority of studies evaluated interdependent contingencies in which all members of the group must meet the required expectation, so that all children receive the agreed upon consequence (Pokorski et al., 2017). The Good Behavior Game (GBG) is an example of a widely used interdependent group contingency, including in preschool and early childhood settings. An evaluation of the GBG in preschools found that the use of visual and vocal feedback during the GBG resulted in significant decreases in the level of disruptive behaviors displayed by young children (Wiskow et al., 2019).

Strengths and Weaknesses The literature describing group-based interventions grounded in ABA implemented in preschool and early childhood settings include many practices used with older students but adapted for the unique context. Many of these adaptations are clear. For example, milieu teaching does not necessarily have to be an early childhood intervention, but much of the research has focused on early childhood settings. Yet, although many ABA- and group-based interventions are implemented in preschool and early childhood settings, more rigorous research is needed. Returning again to milieu teaching, many studies have been conducted, but most do not meet rigorous evidence standards.

Juvenile Justice and Detention Centers

Incarceration is a form of punishment. However, it is only a true consequence if it reduces the probability of the future occurrence of behavior. If incarceration acts as an operant punishment, then we would expect the rate of recidivism and amount of criminal behavior in the United States to be low; however, that is not the case (Apel & Diller, 2016). Research shows that the effectiveness of punishment-based interventions varies based on the intensity, the probability of contacting punishment, the immediacy of the punishment, the strength of the reinforcement contingency that sustains the behavior, and any competing reinforcers. Incarceration may be more effective when paired with intervention, including group-based interventions.

The state of Oregon used an approach based on behavior analysis in their "Supermax" detention center. Specific behaviors were targeted in a behavior action plan, based on systematic assessment. In order to be released from the unit, the individuals had to finish the program assigned to them and were not allowed to display any rule violating behavior. Data were regularly collected on both appropriate and inappropriate behaviors of all inmates, and the inmates earned positive reinforcement for displaying appropriate behavior, including access to visitors and tangible reinforcers. As a result, the program found overall decreases in problem behavior displayed across the prison (Webb, 2003).

Contingency management programs have also resulted in positive outcomes in detention settings. Based on operant conditioning, these programs provide reinforcement to individuals immediately contingent upon the appropriately exhibited behavior and are associated with prisoner's behavior gains in a variety of areas. These programs can include token economies, response cost, behavior contracts, time out, and overcorrection. The token economy is the most common contingency management program in detention center, and it is also notable because it is a positive reinforcement. A token economy allows individuals to earn tokens or points when they display appropriate behavior, then later exchange those tokens for backup reinforcers (Gendreau et al., 2014).

A growing evidence-base is combining many of these practices and organizing them into a multitiered system of support framework for juvenile justice and detention centers. The approach, known as facility-wide positive behavior interventions and supports (FW-PBIS; Sprague et al., 2020), adapts SWPBIS for juvenile justice settings, leveraging PBS practices, and, importantly, defining behavioral expectations and positively reinforcing demonstrations of those expectations. A recent review by Grasley-Boy and colleagues (2021) identified 19 studies of FW-PBIS conducted in juvenile justice and alternative school settings. Overall, the review found that FW-PBIS reduced restraints and seclusions of incarcerated youth, and, for some youth, improved behavior and academic achievement.

Strengths and Weaknesses Juvenile justice and detention centers are difficult contexts. Yet, there is a growing evidence-base that ABA-based interventions, delivered facility-wide, can be used to improve problem behavior and, importantly, reduce the need for restraints and seclusions. That being said, it is important to acknowledge that the literature is still developing and more experimental studies are needed. The Grasley-Boy et al.'s review could not include a meta-analysis because of a number of design limitations. Thus, more studies establishing experimental control, either through single-case experimental designs or group-based designs with a control group, are necessary to establish these ABA- and group-based practices as evidence-based in juvenile justice and detention centers.

Concluding Thoughts

Our goal was to briefly describe research areas evaluating the implementation of group-based instruction. Across all of the settings, interventions, and strategies, accumulated evidence demonstrates that socially important behavior can be successfully changed. The examples focused exclusively on children and youth, yet there are other examples that could be described. For example, one area left out is organizational behavior management, which is the application of behavior analysis to organizational settings, such as health care, sports, and manufacturing. Thus, it is clear that group-based interventions grounded in ABA are widely implemented, effective, and efficient.

It is worth noting that across all of the group-based contexts, a few specific themes emerged. First, most research on ABA- and group-based strategies focuses on prevention, creating high structured environments to teach behavioral expectations and reinforce displays of those expectations. Reinforcement was often structured through a token economy, but also included contingent praise when expected behaviors were displayed. The second theme was the broad use of group contingencies, particularly the Good Behavior Game. Finally, the application of multi-tiered systems of support, leveraging PBS, is expanding beyond the K-12 setting. SWPBIS and FW-PBIS are, in essence, frameworks for delivering prevention and intervention practices using a tiered approach. Thus, the framework could continue to expand, potentially into the organizational behavior management context. Regardless, the growing evidence-base situates SPWBIS as an evidence-based group implemented framework for improving behavior.

The utopian vision Skinner described in *Walden Two* provides a fictional exemplar for how ABA could improve society. Practically, the myriad group-based interventions and strategies described here may not actualize any utopian dreams, but, when implemented as designed, can have real and meaningful impacts on the lives of children, youth, and adults. We believe that expanding the use of these strategies can save time, resources, and money while simultaneously meaningfully improving outcomes, including socially important behaviors of groups and individuals.

34 Caregiver Training

Rebecca K. Dogan

According to National Alliance for Caregiving and AARP (2015), in the United States, approximately 43.5 million informal caregivers provide support each year, not including parents or caregivers of non-biologically related children. Fifteen percent of those caregivers provide services for more than one individual. In addition, these caregivers are estimated to have an increasing economic value of $470 billion in 2013, compared to $375 billion in 2007, with close to 50% coming from caregivers of individuals with Alzheimer's disease or dementia. For some caregivers, such as parents or guardians, this role is a full-time and long-term job, while other caregivers may only care for an individual a few hours a week in a private home or care facility, such as a senior who requires minimal assistance or an adult with a physical, medical, or mental disability. On average, caregivers spend 19 days a month providing basic necessities, such as shopping, meal preparation, transportation, housekeeping, monitoring medication, and self-care support (e.g., grooming, bathing, assistance with toileting, dressing, etc.) (National Alliance for Caregiving & AARP, 2015).

The roles of a caregiver vary enormously based on the needs of the care receiver, the care-related tasks that are required, and the skills of the caregiver (e.g., experience, training, education) (Kavanaugh et al., 2019). In general, caregivers are expected to not only provide basic necessities (food, shelter, medical needs, etc.) but also encourage and support socially appropriate behaviors that allow individuals to be as independent as they are capable of being. This is no small feat and a role that can be complicated even more by the thousands of books and resources available, many of which are conflicting and change with new popular psychology theories. Some parents, for example, may be struggling with a child who has severe behavioral issues. The role of caregivers who have children or adolescents with these conditions often needs more focus on caregiver training/education that teaches skills not only to improve prosocial behaviors (e.g., compliance) but also to learn strategies to manage and reduce undesirable behaviors (e.g., defiance, aggression). Caregivers responsible for individuals with developmental challenges may have far more complex roles requiring caregiver training/education in addition to more specific skills training in areas such as social and communication skills. Other caregivers who provide support for individuals with physical, neurocognitive, or medical diagnoses, such as traumatic brain injury, dementia, stroke, or cancer, require more advanced, specific skill development in several key areas such as communication skills, treatment of behavioral issues (e.g., aggression, wandering), in addition to broader, long-term self-care skills (e.g., ambulating independently).

For caregivers who provide support for those individuals with complex chronic care issues, that caregiver may provide roughly 96% of assistance with activities of daily living (ADLs), such as dressing, shopping, transportation, and managing hygiene (National Alliance for Caregiving & AARP, 2015). Each diagnosis presents with its own confronts, all of which alter and complicate the role of the caregiver who is ultimately responsible for helping the care receiver develop the skills necessary to lead productive, inclusionary lives. Caregivers face many challenges in several common areas including teaching novel skills to address deficits (e.g., behaviors that occur too infrequently) and managing behavioral excesses (i.e., behaviors occurring too often). Caregiver training attempts to assuage these issues by providing guidance to managing both.

Behavioral Parent Training

In caregiving training literature, the preponderance of empirically based studies is in the areas of behavioral parent training for children with specific diagnoses. According to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), the category disruptive, impulse-control, and conduct disorder (CD) includes oppositional defiant disorder (ODD) and CD, formally referred to as part of the disruptive behavior disorders category in the DSM-IV-TR (American Psychiatric Association [APA], 2000). Neurodevelopmental disorders are a category that encompasses conditions with onset occurring in the developmental period such as attention–deficit/hyperactivity disorder (ADHD) and autism spectrum disorder (ASD). Behavioral parent training has long been recognized as an evidence-based treatment for children diagnosed with ADHD, ODD, and CD (Danforth, 2016; Carr, 2014; Bearss et al., 2015). With well over 100 studies expanding over several decades, behavioral parent training has emerged as one of the most successful interventions and has well-established its effectiveness (Booth et al., 2018; Cohen et al., 2010; Kaehler et al., 2016) and even its efficacious impact over other forms of treatment (Carr, 2014). For example, 60–70% of children whose parents participated in parent training showed improvements in child behavior and gains were maintained at reassessment during a 1-year follow-up (Carr, 2014).

According to the Center for Disease Control and Prevention (CDC), approximately 1 in 6 children meet criteria for a mental health disorder (CDC, n.d.-a). The more common childhood disorders include ADHD (9.4%), behavior disorders (7.4%), anxiety (7.1%), and depression (3.2%) (CDC, n.d.-a). Children with ASD represent about 1 in 54 children in the United States (CDC, n.d.-b). Forms of child mental illness are ubiquitous across the globe, but prevalence rates vary due to under-reporting, especially in countries with limited diagnostic and treatment resources (Our World in Data, n.d.). In many US states and across countries worldwide, services for individuals with special, explicit needs and their caregivers are still not available, accessible, or affordable (Lord & Jones, 2013) and as many as 75% of children and adolescents will not receive evidence-based treatment services (Kaehler et al., 2016). Access to treatment services for children with disruptive behaviors is often impacted by ethnicity and socioeconomic status (Lesch, 2015). When considering the global restriction of services and barriers to treatment in addition to the efficacious results and wealth of research supporting parent training, additional work still needs to be done to make this intervention more accessible, affordable, and sustainable to those who can benefit.

Most parent training programs (PTPs), commonly referred to as PTPs, are designed and studied for children with a specific mental health disorder (e.g., ADHD, ODD, CD, ASD) and are delivered as a group treatment package that is highly structured, such as parent–child interaction therapy (PCIT), the incredible years (IY), and Triple P programs. The primary goal of these PTPs is to reduce childhood problem behaviors by enhancing parent behavior management skills (Zwi et al., 2011; Young & Myanthi Amarasinghe, 2010; Booth et al., 2018; Lessard et al., 2016). However, the term "parent training" goes by many names and is referred to throughout the literature as in-home training, parent-assisted training (Booth et al., 2018), parent education, parent-implemented, parent-mediated, and caregiver-mediated training (Bearss et al., 2015). In most cases, the term "mediated" is used when the caregiver is the agent of change, meaning the individual responsible for delivering treatment to their child. Mediated can be further defined as either primary or complementary, where the parent is part of a therapist led program (Bearss et al., 2015). Literature has also demonstrated benefits for caregivers who have participated in parent training such as experiencing a reduction of parental stress and improvement in parenting skills capability (Schultz et al., 2011). Over the years, variations of these training programs have been modified and adapted to address a wider range of psychiatric diagnoses (e.g., ASD, CD) as well as caregiver barriers, such as parental mental health issues (Charles et al., 2013; Gardner et al., 2010) and economic stressors (Carr, 2014; Danforth, 2016).

Over time, there has been a shift from working solely with the child to modify his or her behavior to incorporating the use of nonprofessionals (e.g., peers, parents) into caregiver training programs. Parents play a vital role in the development, generalization, and maintenance of their child's behaviors (Booth et al., 2018; Hsieh et al., 2011). Caregiver training allows parents to act as the agent of change and to be properly supervised during the practice of newly learned skills. In addition, trained parents can also be taught how to train other caregivers, such as a sibling or relative, which can boost generalization (Loughrey et al., 2014) and enhance maintenance of skills. Parents have a greater number of opportunities in the natural setting to have a substantial effect on learning since they spend the most time with their children. They also have more opportunities to have their child practice newly learned skills in novel settings and with an array of individuals. Parental involvement as an intervention agent is by no means a novel idea and was incorporated into Lovaas' work in the 1970s (Lovaas et al., 1973). Parental participation is a key component of PTPs and, more recently, a wider range of caregiver skills training programs that target specific skills sets such as discrete trail teaching (DTT; Eid, Aljaser, et al., 2017b; Subramaniam et al., 2017), manding (Loughrey et al., 2014; Suberman & Cividini-Motta, 2020), and arranging safe sleep environments (Carrow et al., 2020).

Attention-Deficit/Hyperactivity Disorder

Parent training is seen as an integral part of behavioral interventions for children and adolescents with ADHD (Daley et al., 2018; Danforth, 2016). ADHD is a chronic and pervasive neurodevelopmental disorder characterized by symptoms associated with inattention or hyperactivity/impulsivity, or a combination of both affecting roughly twice as many males as females (APA, 2013; Wolraich et al., 2019). It has been one of the most well-researched and studied disorders of childhood (Young & Myanthi Amarasinghe, 2010).

Common evidence-based treatment strategies for younger individuals with ADHD include contingency management, behavior therapy, and social skills training, all of which require multiple sessions, and in most cases, a caregiver is involved (Daley et al., 2018). For preschool children, the focus of parent training is education on ADHD (e.g., written materials, internet sources), addressing caregiver risk factors, and teaching parents how to improve their parenting skills. Specific skills targeted include identifying and learning to modify antecedents and consequences that impact their child's desirable and undesirable behaviors; in addition to learning to track and monitor behaviors (e.g., behavioral diaries), as well as enhancing caregiver ability to correctly reward appropriate behavior (e.g., compliance, good listening) while properly decreasing challenging behaviors (Young & Myanthi Amarasinghe, 2010). With very young children, most reward systems include praise and tangible rewards such as stickers and access to preferred items or activities. Antecedent-based strategies may include providing effective instructions or removing distractions prior to a demand, whereas consequence-based strategies can include the use of time-out, limiting parental attention (i.e., planned ignoring for attention maintained behaviors), temporary removal of preferred items or activities, or rewards for demonstrating desirable behaviors. Researchers and physicians are in agreement that for young children, the first line of treatment should be on caregiver education and training rather than pharmacological interventions (Young & Myanthi Amarasinghe, 2010).

For school-age children, very similar strategies are used but modified to be developmentally appropriate. For instance, the use of monetary allowance would be chosen rather than parent play time; likewise, grounding would be more appropriate than time-out. The training program also concentrates more on generalization of skills learned at home that should now be transferred to the school setting or the program may implement concurrent school-based interventions. Goals would likely shift from parenting goals alone to child academic, social, and behavioral goals. Contingency management interventions for school-age children often involve the use of a Daily Report Card, where the teacher monitors and tracks the student's behavioral goals, determines if the student meets his/her daily goal, and then a reward is provided at home or school. Goals may include behaviors such as completing in class work on time, raising a hand to share information, or remaining seated. Other areas to target for this age group include teaching time management skills, enhancing social skills, and helping teachers modify the school setting to allow for more opportunities to be successful (Young & Myanthi Amarasinghe, 2010). For instance, goals and strategies may include independently using timers, learning to accept criticism, and relocating the student away from distractions such as a window or close peer.

A significant amount of research, supported by the National Institute for Health and Clinical Excellence, has been conducted with the school-age population that endorses parent training for children with ADHD (Young & Myanthi Amarasinghe, 2010). This wealth of research concurs that parent training for school-age children with ADHD demonstrates an increase in positive parent-specific skills, a reduction in child symptoms, and overall lower levels of family distress. However, Young and Myanthi Amarasinghe (2010) also reported that research is less ample for studies that included parents whom themselves have ADHD and studies targeting other ADHD-specific symptoms besides externalizing behaviors such as noncompliance and aggression. Despite positive outcomes for school-based interventions, additional research is still needed to create a sufficient evidence base for child-centered academic interventions (e.g., modification of instructions or materials and environmental manipulations), cognitive–behavioral therapy, and social skills training, in the absence of parent training (Young & Myanthi Amarasinghe, 2010).

Middle and high school adolescent parent training goals work toward maintaining and generalizing skills learned as school-age children. For instance, the Daily Report Card, which was previously monitored daily or several times a day, can now be assessed weekly. Individualized training is focused on specific academic challenges such as test taking, skills associated with executive functioning, and problem-solving skills, as well as continued practice and development of more complex social skills (e.g., dealing with peer pressure), self-management, and self-reinforcement strategies. Parent involvement is ongoing, but less direct and issues are addressed as they arise (Young & Myanthi Amarasinghe, 2010). Tweens and teens with ADHD may present with more complicated symptoms due to comorbidities such as depression, anxiety, and substance use, as well as transformation of their own ADHD symptoms. For instance, many school-age children and adolescents with ADHD show fewer or less intensive symptoms associated with hyperactivity as they get older and inattentiveness increases (Martel et al., 2016). It is important for clinicians to not only assess and treat the core ADHD symptoms but also comorbidity issues impacting this age group in the home, community, and school settings.

Although under-represented, the focus of fathers as the primary participant in PTPs suggests that fathers of children with ADHD are as equally as responsive as mothers to PTPs; however, maintenance and generalization of skills need to be further researched to ensure that these areas are thoroughly addressed (Fabiano et al., 2012). Frank et al. (2015) used a survey and focus group with a large sample of fathers to gather insight into approaches that may enhance promotion of PTPs to fathers and content fathers may be more inclined to show interest in or notice. It was suggested that fathers prefer programs that emphasize trained practitioners, include personalized content, and for the mode of delivery to be T.V., internet-based, or a fathers only group. For school-age children and adolescents with ADHD, additional research needs to investigate alternative non-pharmacological interventions, specifically working with parents, teachers, counselors, and adolescents collectively to make treatment decisions and target skills required to successfully transition to adulthood (Young & Myanthi Amarasinghe, 2010).

There is a vast amount of research in support of pharmacological treatments and behavioral interventions for specific age groups of individuals with ADHD, but few studies have specifically tackled the challenges of identifying the order or combinations in which these two treatments should be provided and what exact factors demonstrate the highest degree of managing symptoms with the fewest side effects (Pelham Jr et al., 2016). It is estimated that two-thirds of children and adolescents with ADHD are taking medication and 50% have participated in behavioral interventions (Wolraich et al., 2019). The American Academy of Pediatrics (AAP) has suggested diagnostic procedures and treatment guidelines based on approximate age of the client. The AAP suggests that preschool children should receive parent training/behavior management training first, and only if those methods fail to show clinically significant improvements should methylphenidate be considered. For children ages 6–12, medications approved by the US Food and Drug Administration (FDA) in combination with parent training/behavior management, including classroom interventions, are recommended. For middle and high school students (ages 12–18), the suggestions focus on educational interventions, behavioral interventions, and medication with child assent (Wolraich et al., 2019).

Pelham Jr et al. (2016) investigated different initial treatment patterns by comparing individuals who received several treatment options categorized as the following: behavioral-medication (BM); behavioral-behavioral (BB); medication-behavioral (MB); and medication-medication (MM). For each group, participants were first randomly assigned to either the behavioral (BehFirst; 8-week low dosage behavior PTP with concurrent social skills training sessions, and Daily Report Card) or medication (MedFirst; 0.15 mg/kg/dose of immediate-release methylphenidate) group. At follow-up (8 weeks or later), those parent/child group members who were determined to be insufficient responders (i.e., child gains were not sufficient in the home or school setting) were once again randomly assigned to a secondary treatment program. These new groups included either a combined program (BehFirst plus additional behavioral support [BB] or MedFirst plus additional behavioral support [MB]) or medication program (MedFirst plus increased dosage [MM] or BehFirst plus initial low dosage [BM]). One-hundred forty-six children (ages 5–12) participated in this 1-year study. Results revealed that the best outcome was produced by the BM group, meaning that adding a secondary treatment of a low dosage of stimulant to an already existing low dosage behavioral program produced the best outcomes for home and school. The group that showed the poorest outcomes and low parent participation was the MB group. The authors suggested that this may have been related to poor motivation to engage in a higher effort intervention, compared to giving their child medication, after 8 or more weeks of inadequate improvement (Pelham Jr et al., 2016).

Daley et al. (2018) conducted a meta-analysis of current best practices in the use of parent training and other behavioral interventions for children and adolescents diagnosed with ADHD. Results confirmed that these interventions not only benefit the child (i.e., improvements in skill development and behavioral issues), but also improve parenting behaviors toward their own children as well as parent self-report regarding confidence in their own abilities, thereby indicating a high probability that these improvements benefit the parent–child relationship. More research is still needed to assess specific caregiver involvement (i.e., fathers), degrees of training and supervision for caregivers, ways to motivate caregiver participation and help-seeking behaviors, parental characteristics (e.g., mental health issues, intellectual ability), integrated home-school interventions, and the impact these factors have on treatment (Daley et al., 2018). In addition, in order for research and program development to be thorough, it must address the other symptoms associated with ADHD besides the externalizing problem behaviors (Daley et al., 2018; Zwi et al., 2011) as well as further evaluate supplemental components, such as mindfulness exercises (van der Oord et al., 2012).

Clinically, more focus is still needed on increasing awareness about ADHD symptoms and treatment options for those directly involved in young children's lives from an early start, including caregivers, teachers, and pediatricians. Moreover, continued critical assessment of diagnostic measures for those with more inattentive symptoms, enhanced monitoring and management for those utilizing both medication and non-pharmacological treatments, as well as additional research on skill building for the transition period from adolescents into adulthood is still deficient (Lesch, 2015). One barrier of parent training for the ADHD population is that an estimated 25% of parents involved will have either have received an ADHD diagnosis or are undiagnosed. Therefore, not only are parents trying to manage their child's symptoms, but they are also battling with their own challenges and limited coping abilities which can affect their ability to participate and meet the expectations of the program (Lesch, 2015). PTPs for this subgroup should include modules explaining and discussing adult ADHD, modeling and role-play of specific skills associated with adult symptoms, and regular check-ins as well as booster session options.

Autism Spectrum Disorder

ASD is a neurodevelopmental condition characterized by limitations in social-emotional reciprocity and use of nonverbal behaviors (e.g., facial expression, eye-to-eye gaze), impairment in communication, developmentally inappropriate peer relationships, or reduced share enjoyment of activities and interactions (APA, 2013). Many children with ASD also display dangerous or disruptive behaviors such as aggression, self-injury, and noncompliance (Postorino et al., 2017). According to the CDC (n.d.-a), the up-to-date first line of treatment for young children with ASD includes a multidisciplinary approach (e.g., occupational therapy, speech therapy, applied behavior analysis [ABA]) in addition to parent-mediated interventions as well as employing interventions to target specific skills area directly impacted by ASD. Specific areas of ABA recommended by the CDC and National Standards Project that are considered emerging or evidence-based treatments include the early start denver model (ESDM), DTT, early intensive behavioral intervention, pivotal response training (PRT), and verbal behavior intervention, some of which are highly individualized or standardized treatment programs. Other types of treatments noted by the CDC include less supported options that are not evidence-based. These include dietary modifications and complementary and alternative medicine (CAM), such as chelation and supplements (CDC, 2015). FDA-approved medications are also listed as treatment options to alleviate specific subsets of behavioral or mood excesses and deficits (e.g., obsessive–compulsive disorder, poor attention, aggression) and include selective serotonin re-uptake inhibitors, tricyclics, antipsychotics, stimulants, and anti-convulsants (CDC, n.d.-c; National Institute of Health, n.d.). However, some medications can have negative side effects such as weigh gain (Postorino et al., 2017).

Despite the many treatment options available, both science and snake oil, behavioral interventions such as those based on ABA are by far the most effective and recommended

(Booth et al., 2018; World Health Organization [WHO], 2019) but costly (Lord & Jones, 2013; Postorino et al., 2017). Implementing a parent-mediated training model is one way to help reduce costs, promote generalization, and lead to improved outcome gains, since many individual programs do not have the supervision necessary that will lead to the best outcome (Booth et al., 2018). In addition, the literature on parent training interventions, specifically ones in which the parent is an active behavior change agent, have repeatedly demonstrated positive outcomes for core symptoms of ASD (Lord & Jones, 2013; WHO, 2019) and are considered a crucial component of ASD treatment programs (Baharav & Reiser, 2010; Booth et al., 2018).

Research supports early intervention services for young children, showing the best trajectory outcomes with substantially larger gains in various skills (e.g., language, social, adaptive skills) when there are parent-mediated interventions (Lord & Jones, 2013; Shire et al., 2016). Given the challenges individuals with ASD have with regard to natural (untrained) generalization and maintenance of skills, it only seems logical to have caregivers involved in the treatment process (Lord & Jones, 2013). Similar to children and adolescents with ADHD and other behavioral challenges, parent training for children with ASD focuses on modifying contingencies to promote prosocial behavior and reduce undesirable or dangerous behaviors, all while improving the parent–child relationship. Yet, over the last 15 years, there has been a rising concern regarding specific interventions that address the greater needs of children with ASD as well as their families. Individuals with ASD present with additional struggles that impact the entire family unit and require specific, longer term skill building to address (Lord & Jones, 2013; Schultz et al., 2011). Most interventions target the core symptoms of ASD such as social communication skills (Bearss et al., 2015), but may not address larger family issues. Given the evidence of heightened levels of parental stress for caregivers with a child on the spectrum (Dababnah & Parish, 2014; Postorino et al., 2017) compared to other intellectual or medical diagnoses (Booth et al., 2018), parent training for these families may also involve more psychoeducation. This additional component can benefit caregivers by increasing a family's knowledge of their child's diagnosis, helping to give parents a stronger sense of empowerment in advocating for their child's treatment, and helping parents address their fears as well as learning to adjust their expectations to better fit the development of their child (Bearss et al., 2015; Connolly et al., 2018; Lord & Jones, 2013). Psychoeducation alone, focused on discussions rather than live coaching, does not appear to support the same robust findings that parent-mediated interventions produce (Shire et al., 2016).

In a 2011 review of research in this area, primary limitations included lack of fidelity measures, predominantly one-on-one training (versus a more cost-effective group option), limited parent outcome measures, and a lack of consistency with number of sessions or length of treatment and intensity (Schultz et al., 2011). In addition, the growing number of treatment packages with varying target behaviors, ages, formats, and context (e.g., online, group, individual) makes it extremely challenging for not only parents to know which will be successful for their family and has previously demonstrated to be effective (Booth et al., 2018) but also for professionals to determine the right dose of those treatments (Postorino et al., 2017). Seeing how costly, lengthy, and at times, inaccessible the treatment for ASD is, the development of more cost-effective PTPs for this population needs to be a high priority (Bearss et al., 2015; Postorino et al., 2017). However, the literature suggests that caregivers prefer one-on-one training to group training, likely because the clinician or behavior analyst can modify and create a skills programs tailored for that child or family based on their needs (Booth et al., 2018). Access to quality services globally is a noteworthy problem, so the development of online platforms to train caregivers such as "Simple Steps" and "Challenging Behavior" may pose a solution

(Booth et al., 2018). Pyramidal training (e.g., caregivers training other caregivers) can also benefit this population, and research has demonstrated that fathers have had success in learning skills associated with improved parent–child interactions (e.g., following child's lead, non-speech vocalizations) and are also highly capable of training mothers who were then also able to apply the same skills with their child (Elder et al., 2010). In areas where service providers are few or for families who lack insurance coverage or have financial burdens, these training options, if made easily accessible and affordable, could help reduce the strain between need and services.

Another limitation in the research is identifying specific moderators (e.g., subgroups) and components of parent training (Farmer et al., 2012; Lord & Jones, 2013; Schultz et al., 2011). Having professionals better define and categorize programs to notify and allow consumers to be aware if they are parent-mediated intervention (PMI) or parent supported, primary (parent is primary change agent) or complementary (therapist initially works with child and then provides coaching), and the focus of treatment (e.g., core symptoms, behavioral), is essential (Bearss et al., 2015). Bearss et al. (2015) developed a model for categorizing PTPs into one of the following: parent support-care coordination, parent support-psychoeducation, primary PMI for core symptoms, complimentary PMI for core symptoms, primary PMI for disruptive behavior, or complimentary PMI for disruptive behavior. For instance, the ESDM has been classified as a PMI-Complementary-for Core Symptoms. Other criticisms have been raised regarding labeling these interventions as "parent management training" because they can provide a false perception that parents are to blame and suggest hierarchical power of the practitioner with the parent simply being the "trainee" (Sanders & Burke, 2014). Sanders and Burke (2014) explain that these labels do not empathize with the collaborative nature of the parent–practitioner relationship and could in turn deter parent willingness to seek treatment.

General Limitations and Barriers of Caregiver Training

Specific barriers noted in the parent training literature include situational (e.g., practical issues such as transport, childcare, scheduling) and psychological factors (e.g., fear of being judged, stigma, and concerns with confidentiality), as well as parent challenges with implementation of strategies, and lack of awareness of treatment programs (Danforth, 2016; Koerting et al., 2013; Smith et al., 2015). According to Smith et al. (2015), potential ways to address some of these barriers include having a therapist provide a clear description of what is involved in the PTP and the expectations, specifically addressing motivational issues and caregiver confidence as part of treatment. Furthermore, offering support outside of session and techniques that will help parents follow through at home (e.g., modeling and practicing in session) can address some of these barriers. Research has also indicated that specific advertisement strategies (e.g., clear, easy to understand content, offering open/free events), direct recruitment, certain program factors (e.g., flexible, individually tailored, phone support), and therapist factors (e.g., extensiveness of their training) can all play a role to addressing barriers (Koerting et al., 2013).

In order for caregivers to successfully use behavioral interventions and apply skills with their children, they must attend and participate in the PTP; which is why caregiver adherence and barriers to treatment continue to be a focus in the literature. Jensen and Grimes (2010) advanced the literature in this area substantiating that when caregivers had a child enrolled in concurrent skills training programs that attendance rates increased up to 52%. Only a few PTPS today have both parent and child concurrent but separate run programs. Instead, parents typically need to enroll their child in a in independent child-specific groups (e.g., local social skill group). In a seminal article published by Allen and Warzak (2000), the authors proposed the use of a functional assessment to identify what environmental contingencies could be altered to increase adherence to behavioral parent training. This was the first study to investigate caregiver adherence from a behavior analytic perspective, a common approach in this field to assess treatment effectiveness (Allen & Warzak, 2000). The outcome of this study identified four behavioral principles and components affecting caregiver adherence (see Table 34.1). It was suggested that in order to maximize treatment gains and child outcomes, professionals must take these contingencies into consideration. Moreover, professionals should be mindful of their own behavior and the contingencies that impact their behavior during parent training sessions (Allen & Warzak, 2000). Stocco and Thompson (2015) expanded this area of research by reviewing child-effect studies and identifying positive and negative reinforcement contingencies for parent behavior. For instance, Patterson's negative reinforcement trap is an example of how caregivers' escape and avoidance of problem behavior over time can lead to use of corporal punishment and intensifying child problem behaviors. Similarly, Wahler's positive reinforcement trap describes how a caregiver may inadvertently reinforce child undesirable behaviors, for instance, a parent threatening but not following through with time-out and, instead, accepting hugging and apologizing child behaviors immediately after the initial misbehavior. Behavior analysts, therefore, have an opportunity to improve parent

Table 34.1 Adherence variables

training methods with functional analysis (FA) technology to further asses these contingencies influencing parent behavior. Stocco and Thompson (2015) also reviewed older literature on the success in training children to be the behavior-change agent to influence caregiver parenting behaviors. Despite multiple studies showing the impact that children, acting as change agents, can have on parents and teacher behavior, this does not seem to be implemented in PTPs and recent caregiver training literature.

The therapeutic process has multiple phases (i.e., initial interaction, assessment, skills training, and termination) regardless of duration of treatment. At each phase, the clinician is working to set the client up for successful outcomes. This may include explaining a treatment program and its benefits to gain parent commitment during the initial interaction, selecting appropriate achievable goals during the assessment phase, teaching strategies in a meaningful and functional way during the skills training phase, or equipping parents with the tools to generalize skills for sustainability of treatment effects during the termination phase. Practitioners must be highly cognizant during each phase and all interactions during the sessions to monitor their own behavior and parent responses to provide the best services that encourage active participation and address parent resistance. As shown in Tables 34.2 and 34.3, Sanders and Burke (2014) published a beneficial outline of common issues that can arise during the therapeutic process between practitioner behavior and parent response, as well as details regarding a guided participation model with four key processes for promoting positive change in clients.

Yet another barrier published in articles on parent training is the deficiency of detailed, thorough step-by-step procedures or specific protocols for parents and that the access to such information is often only available through training, certification, and purchase of standardized manuals for evidence-based programs (Sanders & Burke, 2014). Specifically, to address excessive skill complexity to improve caregiver treatment fidelity, Danforth (2016) suggested clinicians create and utilize flowcharts to serve

Table 34.2 Common process problems during parent consultation sessions

Type of problematic practitioner behavior	Parents immediate reaction	Clinical consequence	Alternative practitioner behavior
Practitioner sets difficult or impossible tasks	Parent non complies	Parent drops out	Practitioner negotiates a more achievable set of goals and tasks
Practitioner becomes defensive when challenged	Parent reciprocates with defensiveness	Parent drops out	Practitioner remains non-defensive and clarifies the parent's referents before responding
Practitioner's demonstration of skill is poor	Parent becomes confused and fails to develop necessary skills	Intervention fails	Practitioner demonstrates more appropriate example of the being used correctly
Practitioner's explanation of a skill is vague	Parent lacks a clear rationale to support a parenting practice	Parent can't explain what she is doing to significant others	Practitioners provide reviews parenting strategy and develops a more convincing rationale to explain a strategy or skill
Practitioner provides a poor or incorrect response to parents questions	Parent implements a strategy incorrectly	Child does not improve	Practitioner reviews procedure and provides the correct answer to specific question
Practitioner assumes a parent is refusing to try a new skill	Parent becomes angry or defensive; refuses to try the strategy	Parent drops out	Practitioner acknowledges the difficulties associated with making change
			Practitioner assists parent to anticipate setbacks and other difficulties as a normal part of the change process
Practitioner fails to recognize that the change effort is hard	Parent becomes disheartened, sees self as a failure	Parent drops out	Practitioner negotiates a more achievable set of goals and tasks
Practitioner rescues an emotional distressed parent	Parent may become dependent	Parent fails to change behavior or becomes self-regulated	Practitioner acknowledges parental distress through summarization or reflection, then refocuses (if appropriate) parent's attention to the task at hand
Practitioner provides vague positive feedback	Parent does not improve performance	Parent continues to perform inadequately	Practitioner writes down specific verbatim examples of what the parent did well
Practitioner provides negative judgmental nonspecific feedback	Parent feels criticized and gets angry	Parent drops out	Practitioner writes down specific examples of what constitutes correct and incorrect implementation of a skill or routine

as a visual prompt for caregivers to follow. This can serve as a supplemental element to the current components most evidence-based, structured programs contain such as instruction, modeling, role-play, and feedback. In Fig. 34.1, the author first created a task analysis of a parent response behavioral chain, and from this produced a 30-step flowchart that helps walk caregivers through a compliance training protocol. The protocol includes giving instructions, responding correctly to complaint or noncompliant behavior, warnings, appropriate use of time-out, and praise (see Fig. 34.1). Besides presenting parents with a simplified visual/written version of the strategies taught during the parent training sessions, what may be even more beneficial would be laminating or providing multiple copies of this flowchart so that parents can track, identify, and then discuss areas of difficulty during therapy. Afterward, if needed, more specific

Table 34.3 Guided participation model for promoting change

Practitioner assumptions, beliefs, and behaviors	Introducing change	Supporting change	Preventing and managing resistance
Be curious	Client-driven goal selling	Collaborative exploration and discussion of presenting problem and potential solutions/strategies	Recognize discomfort/ disengagement in client or practitioner
Assume positive intentions from clients	Offer tentative suggestions	Check goals are realistic	Recognize and attend to any threat to practitioner's own values
Acknowledge own values	Provide rationale for suggestions	Acknowledge inherent difficulty of change	Explore client ambivalence to change
Be non-judgmental	Active client involvement	Identify client and contextual factors that support change	Validate client perspective
Be empathic	Matching pace of change to client needs	Identify and problem solve client and contextual factors that impede change	Gently raise issue with client
Demonstrate hope/ optimism	Balancing push for change with support	Build client self-regulatory skills	Identify source
View client as expert on their life	Check in (for understanding, agreement, and commitment)	Validate client change efforts	Clarify meaning
Be non-defensive	Clarify meaning (client and practitioner)	Encourage self-reinforcement	Problem solve solutions
Parents are doing the best they can	Validate client experiences Summarize regularly		Develop goals for moving forward

steps can be discussed, modeled, and practiced addressing those precise struggles (Danforth, 2016).

Parent Training Programs (PTPs)

Three of the more well-known and researched PTPs include The IY, PCIT, and Triple P. These programs are based off of the Hanf-Model, created between the mid-1960s and 1970s by Constance Hanf, whose significant contribution of combining social learning theory, operant conditioning, and family systems theory led to the birth of this model and future PTPs (Kaehler et al., 2016). There is a plethora of other PTPs with moderate-to-extensive research that have been shown to produce positive outcomes including but not limited to Parent Management Training-Oregon Model, Helping the Noncompliant Child, and Community Parent Education.

The Incredible Years

The IY parent, teacher, and child series is well-established in the literature as an intervention for children diagnosed with behavior issues (Webster-Stratton et al., 2011). First introduced approximately 40 years ago, it is designed to both treat and prevent substantial behavioral challenges in addition to improve prosocial behaviors and parenting skills (Webster-Stratton & Herman, 2010). The IY offers three central program components: IY Child Program/Dinosaur School, IY Parent Program (BASIC and ADVANCED), and IY Teaching Program. IY Child Program/ Dinosaur School is a prevention curriculum to be used in the classroom (Classroom Dinosaur Child Prevention Program) or as a small group intervention program (Small Group Dinosaur Child Treatment Program) for children ages three to eight. For the classroom, there are over 60 lesson plans, and for a small group, it runs approximately 18–22 weeks (2-h sessions) with treatment

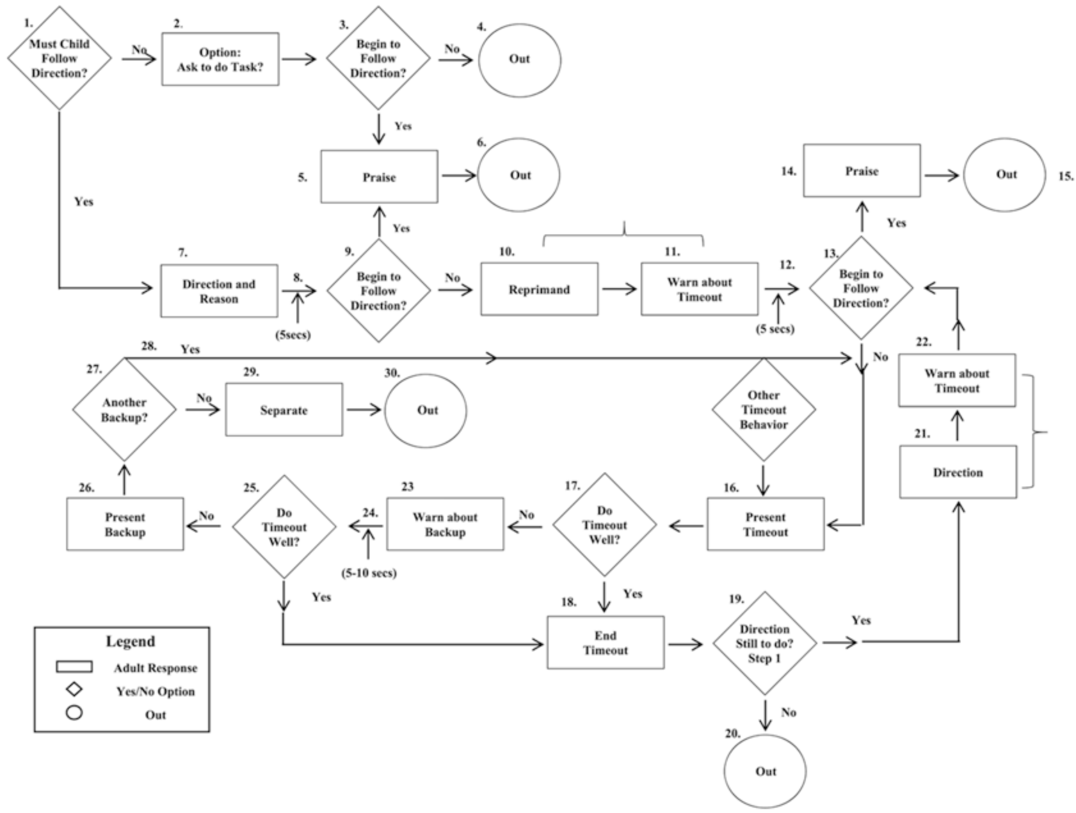

Fig. 34.1 Example of a behavior management flowchart

components, including video vignettes, roleplay, and addressing social as well as emotional competencies, such as following school rules, making friends, understanding feelings, and problem solving. The IY Parent Programs include the BASIC, which are separate programs based on child age (babies [0–1], toddlers [1–3], preschool [3–6], and school age [6–12]), and focus on enhancing the parent–child relationship, teaching appropriate ways to respond to undesirable behavior, and further developing prosocial skills (e.g., social skills, language skills). These run between 12 and 20 sessions (2–3 h per session). The ADVANCED IY Parent Program is an adjunct parent-focused treatment program targeting communication skills between caregivers. Auxiliary adjunct programs now offered include the School Readiness Program, Attentive Parenting Program, Autism Spectrum and Language Delays Program, and Well-Baby Program. Finally, the IY Teacher Program was created for educators of younger children (ages 3–8) to help teach classroom behavior management skills and promote prosocial behavior over monthly workshops, totaling 42 h. The IY also offers an Incredible Beginnings Program for day care providers and teachers of young children (ages 1–5) (The Incredible Years, 2013a).

The IY program comes at a hefty cost to its consumers at up to $4795 for the parent training series (Pidano & Allen, 2015), but is cost-effective when considering the expenditure of untreated antisocial behavior (e.g., crime and unemployment) on society (Charles et al., 2013; O'Neill et al., 2013). Of the IY programs, the parenting interventions have a rich body of literature. Webster-Stratton et al. (2011) reported that the research on the IY parent program is highly extensive, evaluating its effects on over 800 families with children (ages 3–7) diagnosed with

ODD/CD. Over the last decade, the literature has expanded greatly with multiple publications focusing on evaluating the IY parent program for other populations and ages. Specifically for the ADHD population, studies have compared the IY with medication (Lessard et al., 2016), preschool age children (Azevedo et al., 2013; Homem et al., 2015; Posthumus et al., 2012), the long term maintenance of effects (Drugli et al., 2010; Webster-Stratton et al., 2013) as well as the IY parent and teacher programs combined (Rimestad et al., 2018). Overall, these studies suggest that parents in an IY program versus medication group use more consistent and appropriate discipline strategies, that IY program effects can be seen up to 6 years after treatment, at-risk preschoolers are responsive as young as 3, and that combining parent and teacher IY programs is not more meaningful than parent training alone.

Fewer publications exist for the ASD population. An RCT and case study were completed in 2007 and 2008, respectively, but in the last decade, only a handful of articles have been published investigating the effects of the program on children with ASD (Dababnah & Parish, 2014) and children with a range of developmental disabilities (Kong & Au, 2018). Additional research with the ODD/CD populations have homed in on the impact effects of mediators and moderators, further advancing support of the IY. For example, studies have investigated its effects on children with heightened risk factors such as caregiver depressive symptoms (Boyd et al., 2017; Charles et al., 2013; Gardner et al., 2010), comparison of individuals with more severe emotional and conduct problems to those with fewer (Leijten et al., 2018a, b), shortened versions of the IY parenting program (Reedtz et al., 2011), cultural responsiveness (Lau et al., 2010), and high-risk and socially disadvantaged populations (Furlong & McGilloway, 2015; Menting et al., 2014; Scott et al., 2010; Sicotte et al., 2018).

The IY research has also demonstrated its efficacy with multi-cultural groups in various countries (e.g., Portugal, Russia, Finland) with exceedingly diverse populations (Maori tribes, Native Americans) (The Incredible Years, 2013b). The IY also continues to be supported with wide ranges of recipients and has demonstrated long-term maintenance of gains for many externalizing symptoms (Webster-Stratton et al., 2013; Drugli et al., 2010). However, less robust research has been produced for versions with fewer than the standard number of sessions when assessing child problem behaviors (Reedtz & Klest, 2016), the babies program (Jones et al., 2016), toddler and older children programs, in addition to research on component analysis, maintenance of skills beyond a 12-month follow-up (Pidano & Allen, 2015), combining programs (Rimestad et al., 2018; Webster-Stratton et al., 2011), and assessing transferability to non-US existing service delivery (Trillingsgaard et al., 2014). There is also a paucity of research on attrition in high-risk and socially disadvantaged populations as well as fidelity challenges (Furlong & McGilloway, 2015; McGilloway et al., 2012), as well as inconsistencies within the research on adjunct intervention strategies (Boyd et al., 2017) and effects on parental mental health (Charles et al., 2013; Leijten et al., 2018a, b).

Parent–Child Interaction Therapy

Another empirically supported intervention for families with children (generally ages 2–7) struggling with behavioral issues is PCIT. Developed over 40 years ago, this well-researched intervention is comprised of two phases and focuses on coaching sessions (in-vivo feedback) to teach parents how to manage and respond to behavioral issues as well as to teach skills that enhance the caregiver–child relationship. Similar to other PTPs, it is based on reinforcing desirable behaviors, not only of the child but as well as the parent during the "bug in the ear" coaching sessions, in addition to using behavioral strategies to decrease undesirable behaviors (e.g., tantrums, inappropriate attention seeking behaviors). The first phase of PCIT is child-directed interaction, where the parent is coached on how to respond and provide opportunities that foster more positive, healthy interactions between child and caregiver. Parent-directed interaction is the second phase in which the caregiver is taught how to discipline (e.g., time-out) in an appropriate, consistent, and nurturing way to decrease problem behaviors and improve compliance. PCIT typically takes place over 12–20 sessions in a clinic setting (PCIT International, 2015).

PCIT has also been adapted over the years to include group PCIT, home-based PCIT, teacher–child interaction training, infant behavior program (IBP), PCIT-ED (emotional development), PCIT with emotion coaching, intensive PCIT (I-PCIT), and PCIT-CALM. A third phase, referred to as bravery-directed interaction, can also be added for those children with separation anxiety (Lieneman et al., 2017). PCIT is internationally accepted, practiced, and researched in 11 countries and PCIT International provides training and certification (Lieneman et al., 2017).

Over the last decade, there have been continued advances with examining PCIT's effects on various communities and populations. Burgeoning research is with children diagnosed as having ADHD, anxiety (Carpenter et al., 2014), bipolar disorder, or depression (Luby et al., 2012). Multiple studies have also investigated treatment effects in community mental health centers both in the U.S.A. and internationally (Abrahamse et al., 2016; Bjørseth & Wichstrøm., 2016; Budd et al., 2011; Danko et al., 2016; Foley et al., 2016), domestic violence shelters and child-welfare agencies (Herschell et al., 2017; Keeshin et al., 2015; Lanier et al., 2014), foster homes (Mersky et al., 2016), correctional facilities (Scudder et al., 2014), and university-based outpatient clinics (Timmer et al., 2010). In addition, population-specific studies in the last decade have extended the literature and widened PCIT's applicability. For instance, modified programs targeting fathers (Bagner, 2013), socioeconomically disadvantaged populations (Fernandez et al., 2011; Nieter et al., 2013), and high-risk families (Chaffin et al., 2011; Galanter et al., 2012; Kimonis et al., 2014; Lyon & Budd, 2010), tailored treatment recommendations for children in foster care (Mersky et al., 2016), and children who are born preterm (Rodríguez et al., 2014). There have also been cultural adaptations for certain populations and groups, including ethnic minorities (McCabe et al., 2020, Chinese (Yu et al., 2011; Leung et al., 2017), Japanese (Hosogane et al., 2018), Latina/o (Niec et al., 2014; Ramos et al., 2017), Norwegian (Bjørseth & Wichstrøm, 2016), American Indian/Alaska Native (Bigfoot & Funderburk, 2011), Dutch, Mexican American, and caregivers in the military (Lieneman et al., 2017). For community populations, there is also evidence to suggest that a group format can be just as beneficial as individual, which has societal benefits as it can reduce discrepancies between the needs within some communities and access to services (Niec et al., 2016). Additional research, such as the article authored by Barnett et al. (2019), can assist by better identifying direct-to-consumer marketing techniques for certain culture groups. For instance, it is suggested that Spanish speaking caregivers may be more likely show intent to participate in PTPs when the advertisement is delivered by an actor therapist versus a parent.

In the last decade, the ASD research in this area has grown, with sustained positive outcomes. PCIT has also demonstrated its value when viewed as a preventative intervention with restricted but encouraging outcomes focused on counteracting child externalizing behaviors, prevention of maltreatment or reoccurring maltreatment (Kennedy et al., 2016), and developmental delays (Allen & Marshall, 2011; Garcia et al., 2014; Ros et al., 2016). PCIT literature continues to show several inconsistencies with maintenance of skills (e.g., young children may not require the same frequent follow-up) (Eyberg et al., 2014), caregiver characteristics (Lieneman et al., 2020), and parent outcomes (e.g., stress) (Fernandez et al., 2011). In a recent study, Woodfield and Cartwright (2020) investigated PCIT from a parental perspective, examining how parents' personal experiences throughout the program can help practitioners better understand component preferences and the possible impact of negative caregiver attributions (e.g., skepticism, doubt). Future studies should continue to assess newer adaptations such as the IBP (Bagner et al., 2015; Blizzard et al., 2018; Morningstar et al., 2019) and the I-PCIT (Graziano et al., 2015; Graziano et al., 2020) program, which have promising implications.

Triple P Program

The Triple P program is designed to be a population-based health approach, with the goal to serve as a preventative and treatment option for families with children displaying behavioral and emotional challenges. Triple P was developed in Australia, more than 40 years ago, and has grown to be one of the most extensively researched universal treatment programs available today. Triple P is based on the foundations of social learning theory as well as cognitive, behavioral, and developmental theories with the target being to reduce child behavioral and emotional issues by enriching parental knowledge, skills, and self-confidence. The primary program, Triple P, is designed for families with children in infancy up to age 12; however, there is also a teen version referred to as the Teen Triple P for ages 12–16. Similar to the IY and PCIT, adaptations have been made including specialist programs for families experiencing a separation or divorce (Family Transitions), children struggling with obesity (Lifestyle), children with disabilities (Stepping Stones), and Indigenous families (Indigenous) (Triple P International, n.d.-a).

Triple P has been determined to be cost-effective, culturally sensitive, and widely accessible, with parent resources that have been translated into 21 languages. It has been used in over 25 countries and data analyzed in over 980 studies and a plethora of published articles. The Triple P programs are offered as individual, group, online, or in a public seminar format to parents, teachers, and other paraprofessionals. Depending on the need of the consumer, Triple P offers a 5-level system in addition to the specialty programs. Level 1, also referred to as Universal Triple P, is a media-based information program designed to reach larger communities providing materials such as brochures, newspaper columns, and posters. The goal of Universal Triple P is to reduce stigma associated with support seeking behaviors, increase awareness of services, and counter negative messages in the media that suggest the caregiver is at fault (Triple P International, n.d.-b.). Level 2 is a basic, minimalist intervention for parents, offering short duration sessions ranging from 15 to 30-min consultations to three 90-min seminars for those caregivers seeking additional information, and has only general concerns about their child. The third level is for parents who have a child or teen with specific behavioral issues and can be delivered face-to-face, over the phone, or as small group sessions ranging from 2 to 4 h. Level 4 includes training in Triple P's 17 core positive parent skills and is intended for families with children experiencing severe problem behaviors. Delivery is in group format (five sessions and three follow-up consultants via phone), one-on-one (ten 1-h sessions), an internet-based service option, and a self-help workbook as well as weekly phone consultations options. Lastly, Level 5 is a rigorous support program for complex child and family issues offering two distinct formats based on family need. Formats include the Enhanced Triple P, offering three modules based on family explicit issues and include caregiver communication training and healthy adult coping skills in addition to addressing child-specific difficulties. The Pathways Triple P is designed to assist at-risk or vulnerable populations and includes anger management training (Triple P International, n.d.-b).

With the wealth of research evidence for this program, more recent studies have sought to investigate its effects on highly specific populations such as pediatric acquired brain injury, combinations of Triple P with other programs such as Acceptance and Commitment Therapy (ACT; Brown et al., 2015), further assessment of the Teen Triple P (Salari et al., 2014), and a community-based home visiting program targeting dietary intake (O'Sullivan et al., 2017). In addition, recent research has evaluated barriers to parental engagement (Eisner & Meidert, 2011), mode of delivery by context (Eisner et al., 2012), long-term follow-up (Hahlweg et al., 2010), and acceptability by culturally diverse parents (Morawska et al., 2011).

Despite the abundance of literature for these specific PTPs in general, there remains a scarcity in the literature investigating the effects on low- and middle-income countries (Hastings et al., 2012; Puffer et al., 2015), cultural adaptations (Baumann et al., 2015; Hamdani et al., 2017), programs for a wider range of child overall health issues, fathers as the primary participant (Sanders, 2012), treatment barriers (Lieneman et al., 2019), and further component analysis investigations (Lieneman et al., 2017; Pidano & Allen, 2015). There also remains need for more independent trials and replications with caution regarding investigator bias (Eisner et al., 2012; Sanders, 2012; Wilson et al., 2012). Surprisingly, even with attrition rates reported as high as 67%, a clear complication for many community-based PTPs, Lieneman et al. (2019) found that "drop out does not equate to failure" (p. 549). For instance, caregivers who attended at least four sessions prior to dropping out still had markedly higher improvements in child functioning. Timmer et al. (2010) found that mothers with depressive symptoms who generally tend to show high attrition rates showed meaningful gains after only the first phase of PCIT.

It is still crucial that clinicians assess for risk-factors and try to intervene to increase chances of success for caregiver and child (Bagner & Graziano, 2013). Evidence has been found that providing a post-training live video coaching session compared to a routine phone call can have an impact (Funderburk et al., 2015). Fowles et al. (2017) found that home-based treatment, compared to clinic-based, can indicate similar levels of positive outcomes, although a home-based program may be better for populations who tend to have poorer attrition (Fowles et al., 2017). Still, if these programs are to truly to become universal, researchers and developers have an obligation to work jointly and systematically with service-delivery professionals and policymakers (Pickering & Sanders, 2014).

Behavioral Skills Training

Caregiver training is now seen as an essential component to skills training programs in addressing limitations associated with generalization and maintenance of skills (Booth et al., 2018; Hsieh et al., 2011) and research has focused more specifically on the steps needed to teach caregivers these skills with long-term success. A training method that continues to gain interest in the ABA field is Behavioral Skills Training (BST; Crane, 1995). BST is an evidence-based teaching method typically comprised of four components: instructions, modeling, rehearsal, feedback (Ward-Horner & Sturmey, 2012; see Table 34.4).

Instructions often include providing a rationale for why a skill should be learned either verbally by an instructor or in written form. Handouts can be distributed on the steps required to complete the skill (i.e., task analysis) or what is expected from the learner. Next, the novel skill is modeled for the learner. This provides the learner with an opportunity to see the skills demonstrated correctly. Rehearsal or role-play provides an opportunity for the learner to practice using the new skill and it also gives an opportunity for the instructor to assess whether the skill is demonstrated correctly. The last step of the BST process involves providing feedback to the learner. Feedback has an informative component that can be delivered in the form of reinforcement (i.e., differential attention contingent upon correct performance), including tangible items, labeled (i.e., behavior-specific) or unlabeled praise, or corrective criticism to remediate incorrect performance. Overall, BST is a highly accepted and popular teaching procedure due to its ease of

Table 34.4 Components of BST

Teaching technique	Description
Instruction (tell)	State the name of the skill and provide a rationale (explain why the skill is important)
Model (show)	Demonstrate the skill either in person, through telehealth, or using video modeling
Rehearsal (practice)	Practice the skills with the caregiver or trainee in vivo and once mastered, practice in situ
Feedback (advise)	Give descriptive positive feedback (labeled/behavior-specific praise) and corrective feedback for incorrect responses

implementation. It is also recognized by the Behavior Analyst Certification Board (BACB) and is included as a requirement in the Supervisor Training Curriculum Online (2.0) (BACB, 2020).

Components of BST have been used to teach highly diverse populations (Hassan et al., 2018) such as children with or without a disability, staff, peers, young adults, adolescents, siblings, college students, and parents. BST has been used with a wide range of caregivers to teach diverse skills sets (e.g., safety skills, guided compliance, social skills) and reduce challenging behaviors (e.g., noncompliance) (Dogan et al., 2017). Within the last decade, the number of studies published supporting the positive effects of BST on caregiver skills training has increased substantially. Specifically, recent research has extended the literature in support of training caregivers to implement interventions to address food selectivity (Alaimo et al., 2017; Najdowski et al., 2010; Seiverling et al., 2012), social skills (Dogan et al., 2017; Hassan et al., 2018; Kornacki et al., 2013), DTT (Eid, Aljaser, et al., 2017b; Subramaniam et al., 2017), manding (Loughrey et al., 2014; Suberman & Cividini-Motta, 2020), incidental teaching procedures (Hsieh et al., 2011), PRT (Coolican et al., 2010), Natural Language Paradigm (NLP; Eid, Alhaqbani, et al., 2017a), parent responsiveness to improve language (Paul et al., 2013; Tsiouri et al., 2012), and behavior analytic strategies to decrease problem behaviors of children with ASD (Crone & Mehta, 2016). Furthermore, studies have proven positive results when teaching caregivers to implement a prompting procedure for noncompliance (Drifke et al., 2017), conducting functional assessments (Shayne & Miltenberger, 2013), arranging safe sleep environments (Carrow et al., 2020), training safety skills (Harriage et al., 2016; Ledbetter-Cho et al., 2019), daily living skills (Cruz-Torres et al., 2020), educators training parents to implement a tutoring program (Kupzyk et al., 2012), and parent training, specifically for single parents (Briggs et al., 2013).

Awarding caregivers even more liberty in the treatment process, Gabor et al. (2016) and Halbur et al. (2020) assessed parents' preference for various procedures, following BST to teach new skills. In the first study conducted by Gabor et al. (2016), five caregivers (four parents and one teacher) were taught how to implement noncontingent reinforcement (NCR), differential reinforcement of alternative behavior (DRA), and differential reinforcement of other behavior procedures (see Fig. 34.2). Following BST, caregivers participated in experience trials, where they practiced with their child until 90% integrity was established prior to moving onto choice trials. During choice trials, researchers used concurrent-chain arrangements to assess preferences and revealed that two caregivers distinctly selected DRA as the preferred choice and all but one participant had less definite preferences to the type of differential reinforcement but still more so than NCR.

Halbur et al. (2020; see Fig. 34.3) trained four parents, in five or fewer sessions, how to implement least-to-most, progressive-prompt delay, and most-to-least procedures to mastery. Once training was complete, parents were able to practice the procedures with their child in a quasi-random and counterbalanced order during experience sessions. Finally, parents participated in choice sessions, where researchers again used concurrent-chain arrangements to determine high-preference and moderate preference. All parents selected the least-to-most procedure as the high-preference intervention and the most-to-least procedure as the moderate preference. These studies are important because caregivers are beginning to take a greater role as the agent of change with their child in these types of training models. If more studies such as these are conducted to identify variables that influence preferences, this knowledge can then be used by behavior analysts to modify or create new procedures that are both effective and desirable to caregivers (Halbur et al., 2020), who ultimately, are the ones who will need to use these skills regularly in multiple settings with their child.

Beyond the basic four BST components, variations in more recent literature have included video review, structured observations (Pangborn et al., 2013), in-vivo feedback (Shanley & Niec, 2010), video modeling (Johnson et al., 2015), in-situ training (Hassan et al., 2018), and the

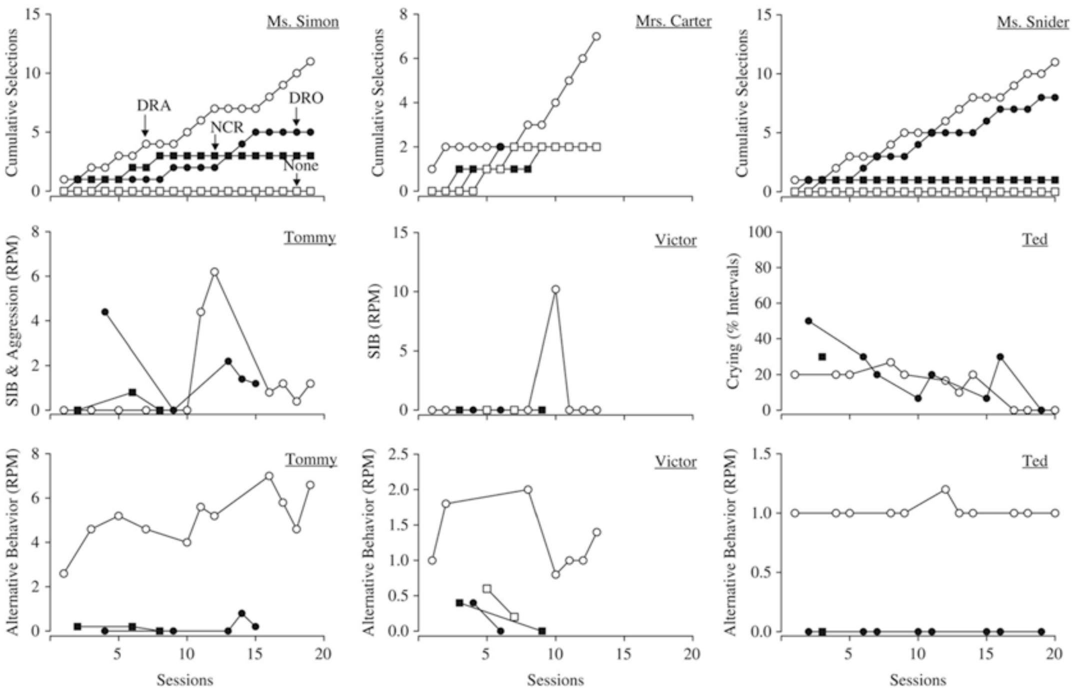

Fig. 34.2 Top graphs show cumulative treatment selections by caregivers during the choice sessions; the center and bottom graphs show problems and alterative behavior, respectively, exhibited by the child during each session. RPM responses per minute

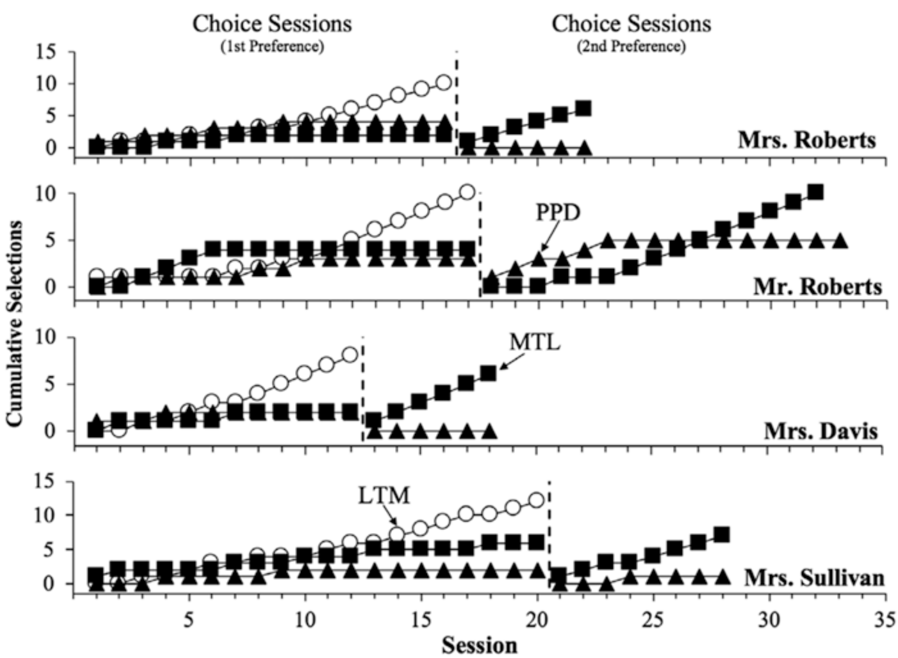

Fig. 34.3 Cumulative treatment selections for Mrs. Roberts (top panel) and Mr. Roberts (second panel), Mrs. Davis (third panel), and Mrs. Sullivan (bottom panel) during choice sessions. PPD progressive-prompt delay, MTL most-to-least, LTM least-to-most

addition of General-Case Training (GCT; Alaimo et al., 2017; Seiverling et al., 2010). According to Seiverling et al. (2010), GCT involves "training responses to the full range of discriminative stimuli in which responding should occur" (p. 55), and in combination with BST, it was found to be an effective package to train staff to conduct NLP room setup and procedures. In another study, Alaimo et al. (2017) also noted the benefits of BST and GCT, but suggested that ongoing feedback was not a necessary component to train caregivers to implement a feeding program; however, because a component analysis was not conducted, additional research is needed to see the role of other factors, such as multiple components beyond BST, or the addition of modifications (GCT).

Reoccurring weaknesses in the BST literature for caregiver training remain aimed toward identifying the fewest number of components and what formats (e.g., instructions provided as written vs. verbally) and promoting behavior change for both caregiver and child (Bachmeyer-Lee et al., 2020; Najdowski et al., 2010). In the 1980s, only three studies focused on conducting a component analysis of BST with findings suggesting instructions alone did not suffice and meaningful gains were only made with the addition of modeling and feedback (Ward-Horner & Sturmey, 2012). More recently, two additional studies produced inconsistent results with one noting that all steps were necessary for parents to meet the criteria (Drifke et al., 2017) and the other that feedback and modeling were the most effective (Ward-Horner & Sturmey, 2012). Pangborn et al. (2013) successfully taught caregivers to implement feeding protocols with a multicomponent treatment package using sequential application to evaluate essential steps. Of the seven steps included in the package, it was determined that instructions (written and verbal) were not sufficient. One parent only required an additional feedback component, another two parents required feedback plus video review, and the last participant required feedback, video review, modeling, and structured observation to meet criterion. These studies targeted different populations and behaviors, which suggests that researchers and practitioners should be cautious to draw far-reaching conclusions, and it would seem that individually tailored treatment options may be a way to provide efficient, effective training.

Current research has not drawn any firm conclusions regarding which components of BST produce the best results with various populations, settings, and behaviors; therefore, there will likely continue to be a growing number of studies that employ a limited number of BST steps as part of training new skills. For example, some researchers have examined BST without the modeling component. Forehand et al. (2011) achieved positive results for caregivers using instruction, discussion, and role-playing of child behaviors as part of a group curriculum based on the book *Parenting the Strong-Willed Child*. In a two-part study, researchers first examined the effects of a self-instructional manual, which included instructions, role-play (self-practice exercises), feedback (self-rated performance), and tests; adding video modeling for those parents who did not meet the mastery criterion. This was then compared to a more comprehensive package consisting of the self-instructional manual, video modeling, combined with role-playing with the experimenter as well as corrective feedback and if needed additional modeling conducted by the experimenter. The package with additional role-play/modeling/feedback with the experimenter produced far superior results (mean accuracy increased from 61.1% to 84.2%) compared to the manual and video modeling alone (mean accuracy increased from 43.4% to 64.5%) (Young et al., 2012). Vahidi et al. (2017) examined the effects of a PTP without the use of modeling, and moreover, feedback was only provided in the last (12th) session and results produced beneficial outcomes on child cognitive performance. Another PTP focused on a social communication intervention for children with ASD and found parent-implemented skills gains and encouraging child outcomes without a modeling component (Shire et al., 2015).

Studies have investigated the effects of BST without role-play. During group sessions, instructions, video modeling, and feedback were used to effectively teach parents PRT skills which led to an increase in child language (Boettcher Minjarez et al., 2011) and cognitive skills (Hardan et al., 2014). Landa et al. (2011) investigated the effects of a comprehensive intervention for parents and their children with ASD, including a 10 hour a week classroom teaching program, home-based parent training (modeling, feedback), parent education, instructional strategies, and a supplemental social curriculum. In addition, Radley et al. (2014) added to the literature on the value of training caregivers to be interventionists with the combination of social skills training (i.e., Superheroes Social Skills) and parent training without role-play (Radley et al., 2014). BST without feedback has also been examined. One study examined the effects of a brief behavioral intervention as part of a PTP; however, feedback was not incorporated, and booster sessions were optional for parents who reported continued problems with their child's behavior. Results revealed positive child and parent outcomes (Axelrad et al., 2013). Another study examined the effects of a brief PTP without feedback to improve parent knowledge and attitudes about adolescent sexuality in Ghana (Baku et al., 2017). Feedback was also not used when teaching parents how to implement activity schedules for children with ASD, but skills improved with instructions, role-play and video model alone (Gerencser et al., 2017). Finally, modeling, rehearsal, and feedback without clear instructions/rationale have been used to teach children with ASD fire-safety skills with success (Garcia et al., 2016).

Fewer than three of the four BST steps have also been assessed. Instruction (in baseline) and feedback (post baseline) alone were used for a feeding program with results, indicating that written instructions were not sufficient, but the added component of verbal feedback produced favorable results (Aclan & Taylor, 2017; Bachmeyer-Lee et al., 2020). Gerow et al. (2018) included only instructions (written and verbal) and feedback to teach parents to accurately implement functional communication training (FCT) with their child; however, one of the two parents who completed the generalization assessment required a self-monitoring booster session suggesting that these two BST components alone may not be sufficient. In addition, researchers have used instruction and rehearsal as part of a PTP for caregivers enrolled in the welfare system to reduce child behavioral issues (Greeno et al., 2016) and enhance the caregiver–child relationship (Li et al., 2013). Overall, across studies with modified or limited BST components, results have been somewhat inconsistent albeit hopeful for an even simpler training procedure, yet many studies fail to formally assess fidelity (Gengoux et al., 2015), and the lack of replication leaves professionals unaware if fewer BST steps can be used with a wider populations (ages, ability) or variations of behavioral targets. There are also a large number of PTP studies with what would seem to be BST components, but the specific techniques used were not explicitly stated or described, making replication insurmountable.

There is also a sizeable and important lapse in research applying BST to caregivers, other than the parents of younger children with behavior or developmental challenges. Caregivers working with individuals with physical or medical disabilities, such as dementia, often are not equipped with the skills needed to address behavioral concerns that arise (Buchanan et al., 2011); meanwhile, there is a significant demand and burden placed on these caregivers who would highly benefit from effective skill building. Numerous behavioral principles and techniques can be taught to individuals with dementia or Alzheimer's such as shaping to target remembering skills, errorless learning to teach face–name associations, use of external memory aids as well as role-play for improving communication skills, and modeling with rehearsal to recover ADL skills (Buchanan et al., 2011). Beyond the positive outcomes skills training would have on the care for the individual, these skills may also serve to reduce some of the negative consequences that can befall caregivers when they are overburdened (Kavanaugh et al., 2019).

Ninety dyads (caregivers and dementia patients) participated in a 5-day group residential training program, where caregivers were exposed to didactic sessions, modeling, and role-play focused on behaviors associated with reducing stress, use of coping techniques, behavior management, and problem-solving skills. Researchers revealed that caregivers reported an increase in needs being met, specifically relating to managing behavior, practical tasks, communication, and information, but level of burden and depression remained unchanged (Gresham et al., 2018). Potter et al. (2012) used an instructional DVD and diary log to reduce falling incidents among caregivers supporting individuals with cancer. Another study included a psychoeducation program, where caregivers of individuals with dementia were taught the TANDEM model, a communication training technique focused on the best ways to facilitate presentation, attention, comprehension of information, and finally, retaining that information. Once completed, participants engaged in role-play to practice newly learned skills and results demonstrated positive gains (Haberstroh et al., 2011). Similarly, Liddle et al. (2012) also used an instructional DVD to teach communication and memory strategies; however, modeling, role-play, and feedback were not noted. For caregivers of individuals with dementia, instructions, modeling, and role-play were used during a 2-h training to improve knowledge of ADL skills, yet caregiver burden and depression scores maintained (DiZazzo-Miller et al., 2017). Finally, two studies reported that the application of dialectical behavior therapy among other components, for caregivers of marginalized children and for caregivers of individuals with schizophrenia, suggested a reduction in mental health-related symptoms (e.g., distress, depression, and anxiety) (Behrouian et al., 2020; Woods-Jaeger et al., 2018). Unfortunately, many of these types of skills training publications do not provide detailed procedures; therefore, it is unknown if BST components were included. Still, it is probable that if BST were added, and it would further improve results.

Internet-Based Services

Telemedicine has been used for decades within the medical field and is defined as "the use of telecommunication and online technologies to provide healthcare at a distance" (Neely et al., 2017, p. 850). This service now goes by many terms including telehealth, telepractice, virtual-care services, and teletherapy, but for the purposes of this chapter, it will be referred to as telehealth. Distinguishing itself from other internet-based services or online training programs, telehealth involves online instruction and video conferencing connecting an interventionist, such as caregivers or teachers, with an expert (Neely et al., 2017). Over the last decade, to address the discrepancy between need and services provided due to geographic or financial barriers and long waitlists, telehealth research has flourished along with burgeoning publications that supports its effectiveness and societal benefits.

Telehealth has been shown to be cost-effective (Lee et al., 2015; Lindgren et al., 2016; Wacker, Lee, Dalmau, Kopelman, Lindgren, Kuhle, Pelzel, Dyson, et al., 2013b), time and resource efficient (Wacker, Lee, Dalmau, Kopelman, Lindgren, Kuhle, Pelzel, Dyson, et al., 2013b), and rated acceptable by participants (Bearss et al., 2018; Baharav & Reiser, 2010; Wainer & Ingersoll, 2015; Wacker, Lee, Dalmau, Kopelman, Lindgren, Kuhle, Pelzel, & Waldron, 2013a). Wacker, Lee, Dalmau, Kopelman, Lindgren, Kuhle, Pelzel, Dyson, et al. (2013b) completed a cost comparison for implementation of FAs and reported an average weekly telehealth cost of $58 per child compared to $335 for home-based services including travel expenses for the service provider. More impressive were the time and financial gains when telehealth was used for FAs and FCT combined (192 weekly sessions), indicating that the telehealth option was less expensive, with a savings of $44, 372 and saved services providers from spending over 1,000 hours of driving.

Online PTPs remain popular, especially for caregivers of children with behavioral issues (White et al., 2019). With rapidly developing technological advances, these programs are reaching further and with broader populations. For instance, Karr et al. (2017) connected the School for Global Inclusion and Social Development, University of Massachusetts, U.S.A. with parents in Bangladesh. Furthermore, the positive influence of gaming features (Bayley & Brown, 2015; Love et al., 2016), peer support (Wilkerson et al., 2020), and use of self-directed programs for various skills training such as PRT (McGarry et al., 2019) are trending. Blackman et al. (2020) compared the effectiveness of in-vivo and an online PTP and found both groups showed significant improvements in skills and knowledge. However, coaching is still encouraged, because a self-directed program may oversimplify treatment strategies (Irvine et al., 2015), which could have negative outcomes for families with more complex parent–child issues.

There have been a number of journal articles in support of behavior analytic interventions provided via telehealth (Suess et al., 2014), but many of the recent studies are focused toward individuals with developmental disabilities. This population has a clear need and substantial discrepancy between services needed and the availability and accessibility of services. Many recent studies have examined telehealth as a tool for teaching FCT and FAs. Wacker, Lee, Dalmau, Kopelman, Lindgren, Kuhle, Pelzel, and Waldron (2013a) used telehealth to coach parents to provide FCT to children with ASD displaying behavioral issues and found that not only were parents highly acceptable of the service but average reduction in problem behavior across children was approximately 93%. In addition, telehealth took an average of 16 sessions to meet the 90% criterion, whereas it took an average of 25 sessions for the same behavior improvements with a separate group of participants in a home-based program. The role of coaching has also been demonstrated as a favorable component of telehealth services for caregivers of individuals with disabilities (Benson et al., 2018; Ingersoll et al., 2016; Ingersoll & Berger, 2015; Simacek et al., 2017; Wainer & Ingersoll, 2015). For instance, Benson et al. (2018) demonstrated that telehealth with coaching was able to produce favorable outcomes even when targeting challenging behaviors such as self-injury while also increasing the use of mands.

Beyond parent training, a variety of online services have also been used in other caregiver settings, such as those caring for individuals with dementia. Kajiyama et al. (2013) assessed the program iCare (ICC), a web-based program designed to improve caregiver knowledge of dementia, relaxation skills to manage stress, behavioral activation strategies, effective communication skills, managing problem behavior of the care recipient, and health-related choices. While stress levels improved for the ICC group, dropout rates were high (31%). Online services may not serve as a replacement for in-vivo sessions but for some populations it could be a very advantageous adjunct service to address immediate geographic or financial barriers to accessing treatment (Blackman et al., 2020). Furthermore, in more rural communities, access to high-speed broadband may serve as yet another barrier to contact online services (Suppo & Mayton, 2014). As seen in Fig. 34.4, Lee et al. (2015) developed comprehensive guideline for technology when developing telehealth services and strategies to help address trouble shooting problems that may arise with connectivity, hardware, and software during behavior analytic interventions.

Future research for telehealth and internet-related caregiver training must continue to assess greater types of training opportunities and caregiver accepted interventions (Boisvert & Hall, 2014; Suppo & Mayton, 2014). Documenting and monitoring fidelity of implementation (Baharav & Reiser, 2010; Suess et al., 2014), technological issues such as challenges with headsets and viewing (Baharav & Reiser, 2010; Boisvert & Hall, 2014), and considerations for online programs such as lengthy videos compared to modules broken up into shorted durations (Ingersoll et al., 2017), are included as some of the areas that are still lacking sufficient data. In addition, the benefit of supplemental materials (Ingersoll & Berger, 2015), determining which subgroups of parents may be more responsive and accepting of telehealth (Ingersoll & Berger, 2015; Ingersoll et al., 2016; Suess

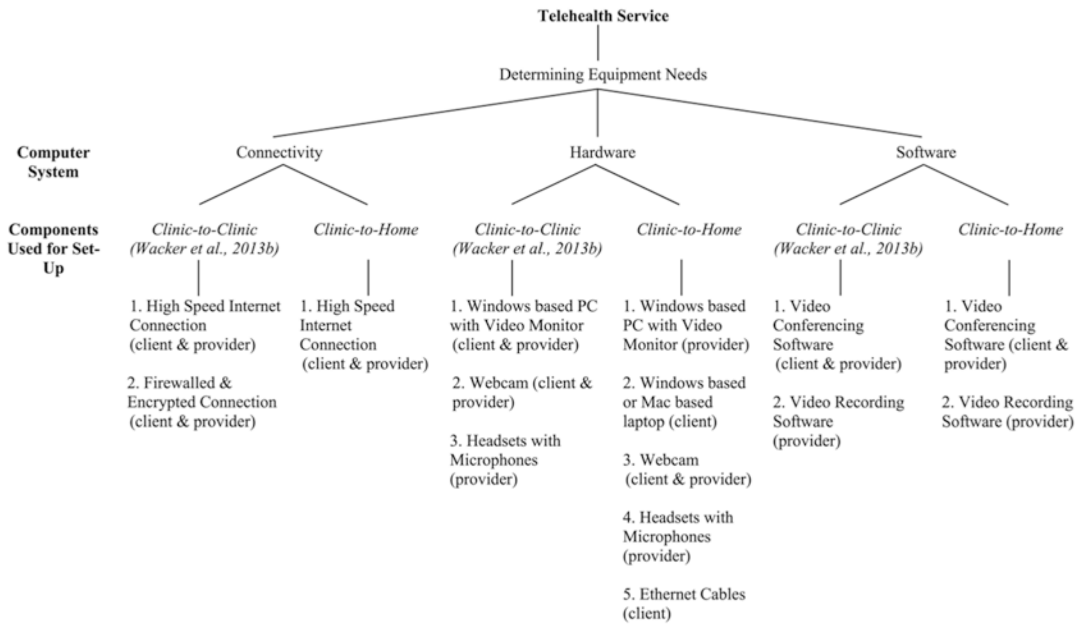

Fig. 34.4 Comparison of telehealth equipment needs between the clinic-to-clinic and clinic-to-home projects

et al., 2014; Wainer & Ingersoll, 2015; Vismara et al., 2012), and replication (Boisvert & Hall, 2014) must continue to be an area of focus for researchers.

Summary and Conclusions

Caregiver training has come a long way over the last several decades and now has earned universal recognition of its profound effect, on both caregiver and child behaviors. Development of caregiver training over the last decade has broadened its scope to new populations, improved ways of teaching, and equipped professionals and consumers with simpler, more efficient methods and tools. Caregiver training programs are nationally recognized in the U.S.A. and encouraged as part of state funded support systems; in addition to being globally applied as prevention models to reduce child maltreatment and boost societal gains. Given the advancement and accessibility of technology, telehealth options will continue to offer those individuals with situational barriers easier ways to get their family's needs met and will hopefully continue to magnify to reach populations across the globe, where psychological services are necessary but highly limited or nonexistent.

Without cures for cancer, Alzheimer's disease, and other degenerative conditions, and with mental health issues on the rise, caregivers demand our services and support. Particularly now more than ever, there is a worldwide necessity for access to telehealth services due to the coronavirus disease (COVID-19) pandemic that began making worldwide news in the early weeks of 2020 and continues to cause uncertainty regarding at what point face-to-face services options will return to normal. ABA and psychology researchers as well as service providers must continue to be zealous and efficient while continuing to develop, assess, and reevaluate the most accessible, affordable, as well as easy to implement caregiver skills training programs and resources. With cooperative actions between practitioners, researchers in the field, and policymakers, these assets can truly become universal for caregivers and care receivers, considerably adding to an improved quality of life.

35 Staff Training

Jason C. Vladescu and Kathleen E. Marano

Staff training is an area of focus that falls largely under the scope of organizational behavior management, a subdiscipline of applied behavior analysis. The focus of this chapter is on performance management as it related to training staff in human service settings. Readers interested in other areas of organizational behavior management (e.g., systems analysis, behavior-based safety) should refer to other sources (e.g., Daniels & Bailey, 2014; Gravina et al., 2018; Lebbon et al., 2011; McGee & Crowley-Koch, 2019; Wilder et al., 2009, 2017).

Individuals seeking the credentials of Board Certified Behavior Analyst (BCBA), Board Certified Assistant Behavior Analyst (BCaBA), or Registered Behavior Technician must pass certification examinations that cover a variety of areas. For example, the BCBA and BCaBA examinations require individuals to receive training in the basic concepts and principles that make up the science of applied behavior analysis, as well as have applied training in ethics, behavior assessment, behavior-change procedures, selecting and implementing interventions, and personnel supervision and management (Behavior Analyst Certification Board, 2017). Therefore, those who provide supervision and training to the individuals entering the field are responsible for training a wide variety of skills. Such skills include training staff to conduct discrete trial instruction (DTI), conduct stimulus preference assessments (SPAs) to assess consumer preference, conduct teaching designed to teach communication skills, and manage the performance of other staff. Therefore, it is important that staff receive effective training for a variety of target skills.

Effective staff training techniques are also necessary due to the importance of high treatment integrity when implementing behavioral technologies with consumers with developmental disabilities. Treatment integrity refers to the extent to which an intervention is performed accurately (Gresham et al., 1993). That is, treatment integrity measures are used to assess whether behavioral interventions are implemented as intended. For example, a certified behavior analyst who is responsible for training a direct-care staff member to conduct DTI would collect treatment integrity data on how accurately the staff member performs each step as the program was designed. Researchers studied the effects of treatment integrity errors to evaluate the impact of errors on the overall efficacy of the interventions. Results demonstrated that treatment integrity errors decreased the efficacy of the intervention (Carroll et al., 2013; Fryling et al., 2012). Researchers demonstrated that interventions designed to decrease challenging behavior and skill acquisition interventions were both less

effective when implemented with low treatment integrity. For example, Wilder et al. (2006) found lower compliance in children when treatment integrity levels decreased. Breeman et al. (2020) found that skill acquisition was slower when auditory-visual conditional discrimination training occurred with low integrity and faster under the high integrity condition. Given that errors in the implementation of behavioral technologies can have detrimental effects on the efficacy of an intervention, staff training techniques must ensure that individuals learn to perform skills with high levels of accuracy.

The purpose of this chapter is to provide an overview of staff training techniques with a focus on application in human service settings. We will discuss behavioral skills training (BST), the components that comprise BST, and potential modifications that trainers can make to traditional in vivo training procedures. In addition, this chapter will describe methods for training staff to provide training to others using pyramidal training strategies. The chapter will also provide a description of how to provide ongoing support after initial staff training, including a discussion of assessment tools trainers can use to identify the variables maintaining performance and indicate the best ways to improve performance.

Initial Approaches to Staff Training: Behavioral Skills Training

BST is considered one of the most effective staff training procedures (DiGennaro Reed et al., 2018). BST involves instructions, modeling, rehearsal, and feedback, which are provided until the trainee meets a predetermined mastery criterion. Typical BST training sessions begin with a trainer providing a rationale explaining why learning the skill is important, explaining how to perform the target skill, and providing descriptions and operational definitions for all steps that comprise the skill. Then, the trainer provides a model of correct performance of the target skill. Next, the trainee practices performing the skill, while the trainer observes and delivers positive and corrective feedback regarding performance. The rehearsal and feedback steps are then repeated until the trainee correctly performs the target skill (DiGennaro Reed et al., 2018; Parsons et al., 2012). Therefore, BST training requires both performance- and competency-based components.

BST Components: Instructions

Instructions involve providing staff with a description of the target skill, including operational definitions for each step and describing how to perform all steps (DiGennaro Reed et al., 2018). The purpose of instructions is to provide descriptions of individual steps and to describe the contingencies under which staff should perform the target behaviors. Providing these descriptions likely leads to staff developing rules for the appropriate responses to engage in under various scenarios (Gutierrez et al., 2019). Essentially, instructions provide explanations for staff about what to do and when to do it. Simple instructions involve only descriptions of the steps, whereas enhanced instructions may include relevant pictures or diagrams.

Trainers can choose from a variety of modalities for delivering instructions, including spoken and written instructions. Spoken instructions involve the trainer orally describing the steps that make up the task analysis for the target skill. Written instructions typically involve a brief summary of the target skill (DiGennaro Reed et al., 2018) or can consist of a written task analysis containing operational definitions. Trainers should ensure that the written instructions are written succinctly and focus specifically on the necessary steps, rather than being part of a larger and lengthier behavior plan (Parsons et al., 2012). Trainers should provide both written and vocal instructions when possible (DiGennaro Reed et al., 2018; Parsons et al., 2012).

DiGennaro Reed and Henley (2015) conducted a study designed to identify the various types of training and performance management procedures that are commonly used in clinical settings. The results of the study indicated that didactic approaches, including providing vocal or written instructions, are the most commonly used staff training procedure. However, many studies have demonstrated that using simple instructions alone is not typically effective for increasing staff performance to desired levels (DiGennaro Reed et al., 2010; Feldman et al., 1989; Hudson, 1982; Krumhus & Malott, 1980). For example, DiGennaro Reed et al. (2010) conducted a study designed to train teachers to accurately perform behavioral interventions. During baseline, the experimenters provided participants with written protocols that explained all the steps required to implement the intervention and verbally reviewed all steps. Then, participants completed a written post-test and the experimenters provided feedback to the participants regarding their written responses. Despite the delivery of the instructions, participants' performance of the behavioral interventions remained below desired levels of performance. Similar outcomes have been observed in other studies (e.g., Gutierrez et al., 2019; Marano et al., 2020a, b), suggesting that the inclusion of simple instructions often does not lead to substantial improvements in staff responding.

Although simple vocal and written instructions alone are not typically effective, researchers identified modifications to written instructions that can improve their efficacy. Common enhancements to written instructions include adding pictures and diagrams that correspond to each step, adding video models that demonstrate performance of each step in a task analysis, and adding descriptions of relevant antecedent stimuli and consequences of performing steps correctly. For example, Graff and Karsten (2012) used enhanced written instructions to train teachers to implement SPAs. During baseline, participants were given simple written instructions that described how to perform the assessments, which did not result in mastery-level performance. During training, the experimenters provided participants with a detailed data sheet and enhanced written instructions, which were written without technical jargon and supplemented with diagrams. The use of enhanced written instructions resulted in mastery level performance for all participants. Al-Nasser et al. (2019) expanded upon the work of Graff and Karsten (2012) by providing participants with textual information that was enhanced with visual cues (e.g., detailed examples, pictures), and also found that the enhanced written instructions were effective. Tyner and Fienup (2016) enhanced a task analysis that described how to create graphs in Excel by including descriptions of relevant antecedents (e.g., the colors, shapes, and locations of buttons) and consequences for each step (e.g., describing what the graph should look like after phase change lines are inserted). A comparison of the original and enhanced task analyses demonstrated that the enhanced task analysis resulted in more accurate graphing behavior. Therefore, although simple written instructions alone are not often effective, adding supplemental materials and information have been shown to increase efficacy.

Overall recommendations for delivering instructions include avoiding technical jargon and using a combination of written and vocal instructions (DiGennaro Reed et al., 2018; Parsons et al., 2012). For example, trainers may provide staff with a written task analysis and then verbally review it with the trainee. Trainers should also include enhancements to written materials whenever possible, such as including pictures of the required materials, describing the stimuli and conditions prior to and following the target behavior, and including diagrams.

BST Components: Modeling

The second component of BST is modeling, in which staff view someone else performing the target skill. The purpose of the model is to demonstrate the correct way to perform a behavioral technology so that staff perform the skill in the same way as the model when they are in similar situations. Trainers can choose to provide models either in vivo or through video (Catania et al., 2009; DiGennaro Reed et al., 2018; Lipshultz et al., 2015; Vladescu et al., 2012). In vivo models involve the trainer performing the skill live in front of the trainee. For example, Adams et al. (1980) modeled the delivery of positive reinforcement, while staff observed. Although in vivo models are often beneficial, because they do not require the use of any technology, they also have some limitations. In vivo models may result in inconsistent performance across demonstrations, which may result in the trainer modeling the skill with low treatment integrity (DiGennaro Reed et al., 2018). This is potentially problematic because it may result in the staff performing the skill with errors.

To ensure that the modeled performance is accurate, trainers can create and use video models. Video models involve staff watching pre-recorded performance of the target skill. For example, Lipshultz et al. (2015) used a video model depicting the experimenter performing SPAs to train staff to perform the assessments themselves. Trainers can also incorporate an instructional component into the videos by adding on-screen text or voiceover instruction. These enhancements increase the likelihood the viewer attends to the relevant aspects of the video. Video models offer potential advantages over in vivo models because they ensure accurate demonstration of the skill and multiple trainers can use the same video, potentially saving organizations time and money (DiGennaro Reed et al., 2018). Additionally, staff can view the videos from their own homes, which eliminates the need for a staff trainer, and allows for training to occur in rural areas or when there is a relative shortage of trainers available to provide in vivo training (Gerencser et al., 2019; Graff & Karsten, 2012; Karsten et al., 2015). Video modeling research indicates that video models are commonly used and effective for training a variety of skills. Researchers successfully used video models to train staff to conduct DTI (Catania et al., 2009; Vladescu et al., 2012), SPAs (Deliperi et al., 2015; Delli Bovi et al., 2017; Lipshultz et al., 2015; Weldy et al., 2014), problem-solving interventions (Collins et al., 2009), individual behavioral interventions (DiGennero Reed et al., 2010), the Picture Exchange Communication System (Martocchio & Rosales, 2017), mand training (McCulloch & Noonan, 2013), graph creation (Mitteer et al., 2018), functional analyses (Moore & Fisher, 2007), providing performance feedback (Shuler & Carroll, 2019), and guided compliance procedures (Spiegel et al., 2016).

Given the favorable results of video modeling research, there is likely a benefit to using videos when providing demonstrations of target performance. If trainers cannot provide video models and must provide models in vivo, trainers should model the skill in the intended context when possible, ensure that the model depicts accurate performance, and provide multiple examples of the skill (DiGennaro Reed et al., 2018). For example, a trainer who is demonstrating how to perform an SPA might show a video of someone performing the skill with a child that shows multiple examples of each step.

BST Components: Rehearsal

The third component of BST is rehearsal, which consists of the opportunity for staff to practice performing the target skill after instructions and models are provided. When rehearsing the target skills, staff can imitate the model's behavior and compare their own performance to the model's behavior. If the staff's behavior is similar to the model's performance, this may reinforce the staff's performance, resulting in future correct performance of the skill. Similar to the research on instructions alone, researchers found that rehearsal alone is not typically effective for training staff to perform behavioral technologies at mastery levels (Jenkins & DiGennaro Reed, 2016; Ward-Horner & Sturmey, 2012). Therefore, rehearsal should always be used in combination with the other BST components.

Staff can practice performing the target skill in either the natural setting or in an analogue setting. The natural setting refers to the location where staff will be expected to perform the skill. For example, a skill that will be performed in a school setting would be trained in the actual school. Lavie and Sturmey (2002) trained staff to conduct a paired-SPA using a BST package consisting of brief instruction, a video model, and rehearsal with verbal feedback. Participants conducted the assessments in a specialized school for with children. Analogue settings are designed to simulate the natural setting. For example, Pence et al. (2012) taught classroom teachers to conduct SPAs in a library setting but assessed generalization in real classroom or clinic settings.

Staff can also practice performing skills with either actual or simulated consumers. For example, Lavie and Sturmey (2002) required participants to perform the skill with actual children with autism spectrum disorder. Simulated consumers are played by confederates who serve the role of a consumer. Analogue settings often involve staff practicing the target skill with trainers serving as confederates. For example, Pence et al. (2012) required classroom teachers to practice running preference assessments while trainers played the role of confederate consumers and then assessed the generalization of participant performance with actual students in their classrooms. During sessions involving a confederate, the confederate engaged in a combination of typical (e.g., selecting one item, playing appropriately with toys) and atypical responses (e.g., selecting multiple items, not playing with items).

There are multiple reasons that trainers should consider opting to use confederates when requiring staff to rehearse target skills. First, using confederates prevent consumers from being exposed to errors that staff may make prior to learning to perform the skill at mastery levels. For example, if a trainee is learning to perform DTI, the trainee is likely to engage in errors. These errors may negatively impact consumer outcomes due to interventions being implemented with low procedural integrity (Fryling et al., 2012). Second, the use of a confederate ensures that staff are exposed to the full range of potential consumer responses during training. When practicing skills with actual consumers, these individuals may engage in only a subset of potential responses (e.g., correct responses only), although the staff must learn to respond to the full range of consumer responses (e.g., disruptive behaviors, errors). Therefore, trainers can provide confederates with scripts to follow that include all possible consumer responses staff will likely need to respond to in the natural environment. This allows trainers to better program training to facilitate generalization to the natural setting where the skill will occur. Therefore, trainers should provide rehearsal opportunities in analogue settings with confederate consumers using scripts whenever possible.

There is also some variation in the number of rehearsal opportunities researchers have provide during training. Rehearsal opportunities refer to the number of times staff are required to perform the target skill during training. There is no consistent number of rehearsal opportunities within BST research, with some researchers requiring as little as three rehearsal opportunities (e.g., Lerman et al., 2004) or up to 20 rehearsal opportunities (e.g., Matthews & Hagopian, 2014). To address the lack of a consistent recommendation regarding the number of rehearsal opportunities, Jenkins and DiGennaro Reed (2016) conducted a parametric analysis of rehearsal opportunities during BST. The researchers compared 1, 3, and 10 rehearsal opportunities while training participants to perform functional analysis procedures. Rehearsals improved performance, regardless of the number of rehearsals required. However, the one rehearsal condition resulted in the most efficient training. Therefore, it is possible that requiring fewer rehearsals may result in both effective and efficient training, although additional research is needed to identify optimal procedures for the rehearsal component of training.

BST Components: Feedback

The fourth component of BST is feedback, in which a trainer provides information to staff after a performance that specifies how well the staff performed the skill, which may lead to performance improvements in the future (Alvero et al., 2001). Feedback involves both positive and corrective components. Positive feedback specifies which steps were performed correctly, whereas corrective feedback specifies which steps were performed incorrectly and how performance should be improved in the future (Parsons et al., 2012). For example, a trainer delivering feedback on staff performance of DTI may say, "Great job delivering reinforcement immediately! When you delivered the instruction, the student was not attending to the materials. In the future, make sure the student is looking at the materials for at least three seconds".

Similar to the research on the efficacy of the other components of BST, research demonstrated that feedback alone does not improve performance for all individuals (Alvero et al., 2001; Sleiman et al., 2020). Alvero et al. (2001) conducted a review of the literature that assessed the effectiveness of performance feedback and identified the essential characteristics of feedback. Results indicated that feedback does not uniformly improve performance, and is more effective when combined with other procedures (e.g., instructions, modeling, rehearsal). In a meta-analysis of the literature on feedback, Sleiman et al. (2020) also found that feedback combined with antecedent interventions and behavioral consequences was effective, although effect sizes were also large for interventions consisting of feedback alone. In a component analysis of BST, Ward-Horner and Sturmey (2012) found that the feedback component of BST resulted in more robust performance improvements and is likely a necessary component of BST. Therefore, although feedback alone does not uniformly improve performance to mastery levels, feedback is an important component of staff training procedures.

Trainers can choose from a variety of modalities for delivering feedback to staff, including verbal, written, or visual feedback (DiGennaro Reed et al., 2018). Verbal feedback is usually delivered face-to-face and involves the trainer describing the correct and incorrect aspects of trainee performance. One advantage of verbal feedback is that it provides an opportunity for immediate feedback and discussion. Written feedback involves a textual description of staff performance, and is often provided via online communications (e.g., email) after staff reach mastery levels of performance. Visual feedback involves graphical depictions of staff performance. Visual feedback is beneficial because a permanent product is produced that demonstrates trainee performance improvements over time (DiGennaro Reed et al., 2018). Feedback is most effective when trainers use a combination of all feedback modalities (Alvero et al., 2001). For example, during initial training sessions, a trainer should provide immediate verbal feedback. Then, after mastery is achieved, trainers can email staff written feedback and include visual feedback in the form of graphed performance data.

An additional area of research within the feedback literature is how and when trainers should deliver feedback. This includes the format in which staff deliver positive and corrective feedback and the feedback delivery schedule. For example, Henley and DiGennaro Reed (2015) evaluated three feedback sequences (i.e., positive-corrective-positive, positive-positive-corrective, corrective-positive-positive) on participant performance of simulated office tasks. Some researchers have suggested that a "feedback sandwich" approach, in which corrective feedback is preceded and followed by positive feedback, may reduce discomfort and anxiety for both the feedback deliverer and recipient (Berger, 2013). However, Henley and DiGennaro Reed found that the corrective-positive-positive sequence was the most effective for participants who received feedback following performance. These results suggest that the commonly used feedback sandwich may not be the most effective approach and trainers should instead deliver corrective feedback, followed by positive feedback.

The literature also suggests that more frequently delivered feedback (e.g., weekly) is most effective (Sleiman et al., 2020). Research also suggests that it may be beneficial to deliver feedback immediately prior to subsequent performance, rather than consistently delivering feedback immediately after performance. For example, Aljadeff-Abergerl et al. (2017) suggest that delivering feedback prior to subsequent performance may function as an antecedent cue for appropriate responding. Therefore, future research is needed to identify optimal feedback sequences and delivery schedules.

Overall, recommendations for feedback delivery include using vocal feedback during initial training sessions, followed by written and visual feedback after achieving mastery. Trainers should deliver positive feedback after every rehearsal during training (DiGennaro Reed et al., 2018), should avoid using the feedback sandwich (Alvero et al., 2001), and should provide corrective feedback prior to subsequent performance (Aljadeff-Abergel et al., 2017).

BST: Component Analyses

Researchers also evaluated the individual components of BST to evaluate each component's influence on the efficacy of the BST training package. Ward-Horner and Sturmey (2012) found that instructions and rehearsal alone were ineffective, modeling was moderately effective, and feedback was most effective for training staff to conduct functional analysis procedures. Drifke et al. (2017) conducted a component analysis of BST while training parents to implement three-step prompting procedures. The researchers found that instructions with modeling improved participant responding, but did not lead to mastery levels of responding. The full BST package was necessary to achieve mastery-level responding. Therefore, it is possible that the feedback and modeling components are most important, although additional component analyses of BST are warranted.

BST: Potential Target Skills

There is a substantial research base supporting the efficacy of BST for training staff to perform a wide variety of target skills. Some primary areas within the literature include training staff to implement skill acquisition programs, assess consumer preference, conduct mand training, and conduct programs that target leisure activities. For example, Lerman et al. (2008) used a 5-day summer training program consisting of lectures, discussion, modeling, and role-play with feedback to train special education teachers to implement SPAs and direct teaching. The results of other studies also support the efficacy of BST for training staff to conduct SPAs and DTI (Pence et al., 2012; Sarokoff & Sturmey, 2007). Fetherston and Sturmey (2014) trained staff to implement DTI, activity schedules, and incidental teaching by providing participants with task analyses, models, rehearsal opportunities, and feedback. The results demonstrated that BST was effective for training staff to implement a variety of behavioral interventions, with generalization demonstrated with novel instructional programs. Additional research also demonstrated that BST is an effective procedure for training staff to conduct mand training (Nigro-Bruzzi & Sturmey, 2010). The overall results of BST research indicate that BST is an effective training procedure for a wide variety of skills and is likely applicable for training other skills not yet evaluated in the research literature.

BST: Asynchronous Modifications

Although in vivo BST is an effective training method, there are often circumstances in which it is not feasible or possible to deliver in-person training. The majority of behavior analysts are located in the United States, and rural areas have a relative deficit of available trainers (Gerencser et al., 2019). Therefore, alternative training methods are often needed for individuals in rural areas or areas outside of the United States. Even in areas where trainers are available for in vivo services, there is often a large number of staff who require training relative to the number of trainers (Graff & Karsten, 2012; Karsten et al., 2015). In addition, the rehearsal and modeling component of BST is typically delivered individually, which can result in lengthy training durations for each trainee (Gutierrez et al., 2019). Therefore, trainers must find alternative ways to provide training in such cases.

To address the need for potential modifications to standard BST procedures, researchers evaluated asynchronous staff training procedures, in which staff can complete training in the absence of a trainer. A comprehensive review of the asynchronous staff training literature is beyond the scope of this chapter, but interested readers are directed to published reviews (Gerencser et al., 2019; Marano et al., 2020a, b). One option for asynchronous training involves self-instruction that does not involve the use of technology, including manualized instructions, task analyses, and enhanced written instructions that include supplemental materials. For example, Tyner and Fienup (2016) compared the use of a written task analysis and a task analysis that was enhanced with information regarding the antecedent stimuli and performance consequences for creating graphs in Microsoft Excel. The enhanced instructions included descriptions of the colors and shapes of buttons on the computer screen participants should click on to complete each step, as well as descriptions of what the screen should look like after each step was completed. The enhanced written instructions were more effective for producing accurate graphing performance. Manualized instruction involves detailed descriptions of a behavioral technology and often includes pictures, diagrams, and flowcharts (Gutierrez et al., 2019). For example, Gutierrez et al. (2019) provided participants with a manual that described how to implement a token economy and found that the manual was effective for improving responding and resulted in generalization of responding from a confederate consumer to a child with autism spectrum disorder.

Another alternative to BST that is delivered in vivo is computer-based instruction (CBI), which typically requires staff to complete computerized modules that include the components of BST. Instructions and modeling are provided via on-screen text and videos, rehearsal occurs through questions that are embedded within the modules, and feedback is delivered based on participant responses to the questions. For example, Marano et al. (2020a, b) used a computer-based training procedure to train participants to conduct an SPA. The training module was created in PowerPoint and consisted of on-screen text that described how to perform each step, videos that depicted correct and incorrect performance of each step, and questions that required participants to score depicted performance as accurate or inaccurate. The module also provided feedback regarding whether participant responding was correct or incorrect. Computer-based training was also effective for training participants to identify appropriate procedural modifications to functional analysis procedures (Schnell et al., 2018), conduct DTI (Eldevik et al., 2013; Geiger et al., 2018; Gerencser et al., 2018; Higbee et al., 2016; Pollard et al., 2014), implement photographic activity schedules (Gerencser et al., 2017), and visually analyze graphs (O'Grady et al., 2018).

Telehealth is an additional alternative to in vivo BST that uses video and teleconferencing technology to share information and provide clinical care, education, and administrative services from a distance (Darkins & Cary, 2000). Telehealth allows for service delivery when in-person services are unavailable but is not considered asynchronous because it often involves a trainer providing live training via video conferencing software. Higgins et al. (2017) used a telehealth package consisting of a multimedia presentation, feedback from previously recorded sessions, and scripted role-plays with feedback to train direct-care staff to conduct SPAs. Knowles et al. (2017) also used a telehealth procedure to train staff. The researchers created online training modules, answered questions via text, email, and phone calls, conducted video observations, and emailed feedback to staff regarding their implementation of teaching procedures. Results of both studies suggest that telehealth is a viable training procedure when in-person services are not possible.

Train the Trainer Approaches

Pyramidal training offers an additional alternative to approaches in which one dedicated staff trainer provides training to multiple staff members. In a pyramidal training approach, an individual with experience with the target skills trains a subset of individuals, who then provide training to additional people (Pence et al., 2014). Pyramidal training is often called a "train the trainer" approach because it involves training someone to train other people. Pyramidal training was effective for training teachers to conduct SPAs to evaluate student preferences (Pence et al., 2012). A follow-up study demonstrated that pyramidal training was also effective for training teachers to conduct functional analysis procedures and to train others to implement the functional analysis procedures (Pence et al., 2014).

Pyramidal training is a valuable method for training staff to perform BST. Rather than requiring one staff member to train all of the remaining staff members, pyramidal training allows multiple individuals to train their coworkers and other staff members. Parsons et al. (2013) used a pyramidal approach to train ten human service staff to conduct BST training with other staff. Staff practiced performing BST in a simulated setting, and results showed that the training procedure was also effective for training staff to conduct BST with actual staff in their regular work setting. Erath et al. (2020) expanded upon the previous research by conducting pyramidal training in a one-time group-training format. Twenty-five human service staff attended a group training, in which the experimenters delivered didactic training by providing a general description of BST, three modeled exemplars of each step, and practice guidelines. Then, participants rehearsed and provided feedback to one another in peer dyads. The training procedure was effective for training participants to deliver BST and results generalized to using BST to train other behavioral technologies. Therefore, pyramidal training is a useful procedure for providing training for various behavioral technologies that does not require the continued presence of a dedicated staff trainer.

Providing Ongoing Support

Even after staff demonstrate mastery level performance during initial training, it is important to continue to provide ongoing support to ensure maintenance of the target skills and troubleshoot problems that arise. Trainers should continue to collect treatment integrity data on staff performance after mastery-level performance is achieved. Observations should occur more frequently immediately following training. Then, contingent on the maintenance of accurate performance over time, staff can begin to conduct observations less frequently (DiGennaro Reed et al., 2018; Parsons et al., 2012). DiGennaro Reed et al. (2018) and Parsons et al. (2012) also recommend that trainers tell staff why they are collecting data on their performance, which behaviors they will score, and when they will conduct observations. The purpose of informing staff of these details is to maintain good rapport with staff. However, staff may respond differently in the presence of a trainer due to reactivity (Brackett et al., 2007; Kazdin, 1979). That is, the presence of a trainer may influence staff performance, resulting in accurate data collection during observations. Therefore, trainers should consider conducting observations in ways that minimize their presence. For example, trainers can observe from behind a one-way mirror or record staff performance and score responding from video. Trainers can then provide written and visual feedback that staff can apply to future performance to again reach mastery level performance. To be most effective, such feedback should be delivered frequently (e.g., daily or weekly) and delivered by team leaders or experts (Sleiman et al., 2020).

If staff performance does not maintain at optimal levels and feedback is not sufficient for improving performance, trainers will need to take additional measures. Some of the most common reasons for non-proficient staff performance involve a lack of skills that are needed to perform the target skill, insufficient resources or time, a lack of motivation to complete assigned tasks, and incapability of performing the task (Reid et al., 2012). For example, if staff members are lacking the necessary skills, trainers can provide additional training to ensure that staff have all the required skills in their repertoire. Oftentimes, staff do not perform skills adequately due to a lack of resources, making them incapable of performing their work tasks. For example, if a staff member is expected to conduct a toilet training program by bringing the learner to the bathroom at specified time intervals, a potential reason for non-proficient performance is lack of access to a clock or timer. A potential remedy for this problem is to supply a timer to the staff member.

Trainers can also implement antecedent interventions, which are designed to evoke the correct staff behaviors, typically by telling staff what to do and signaling that reinforcement for correct responses is available (Wine & Pritchard, 2018). There are a variety of antecedent interventions that are commonly used to improve staff performance. For example, task clarification specifies job requirements, job aides prompt correct responses by making specific aspects of performance more likely to occur, and goals set standards for how well a task must be performed within a specific timeframe (Wine & Pritchard, 2018). Adding checklists of necessary job tasks or setting goals for how many tasks staff members must complete correctly each day can often improve performance.

Performance Diagnostic Checklist-Human Services

For situations where there is not an easily identifiable reason for poor staff performance, trainers will need to take additional measures to identify the variables responsible for inadequate performance. One option for identifying the variables that contribute to suboptimal staff performance is the Performance Diagnostic Checklist-Human Services (PDC-HS). Austin (2000) created the Performance Diagnostic Checklist, which is an informant assessment designed to pinpoint the variables impacting poor employee performance. The checklist proved effective for identifying the variables maintaining performance and is a useful tool for designing interventions that are based on the functions of current employee behaviors. However, the initial checklist was designed for the business industry, so it is not entirely applicable for human service staff. Therefore, Carr et al. (2013) created the PDC-HS, which is designed specifically for assessing the performance of human-service staff who provide care and services for other individuals. The PDC-HS is designed to identify the environmental factors that contribute to performance problems. Once those environmental factors are determined, behavior analysts can then identify specific targeted interventions that address those variables. The PDC-HS is a particularly useful tool for improving performance problems that are not resolved with simple solutions.

The PDC-HS is performed in an interview format, with a consultant or behavior analyst interviewing the supervisors and managers about the staff member's performance (Wilder et al., 2020). The assessment consists of 20 questions, which are divided into four sections. The sections include training; task clarification and prompting; resources, materials, and processes; and performance consequences, effort, and competition (Carr et al., 2013). The staff member's supervisor can answer the majority of the questions, while some questions require direct observation of the staff member. If multiple questions within one section indicate performance problems, that area is likely a good target for intervention. The PDC-HS has good predictive validity for identifying effective interventions for improving staff performance. For example, Bowe and Sellers (2018) used the PDC-HS to identify factors contributing to poor implementation of error correction procedures during DTI by paraprofessionals. Based on the results of the PDC-HS, the researchers then implemented an indicated intervention (i.e., an intervention based on the assessment's results) and a non-indicated intervention (i.e., an intervention that was not based on an area identified as problematic by the assessment). Results showed that indicated interventions resulted in more behavior change. This demonstrates that the PDC-HS is effective for identifying the variables related to poor staff performance and can indicate which interventions will be most effective for resolving performance issues that are not fixed with simple solutions.

When the focus of training staff is on staff behaviors related to safety, trainers can use the Performance Diagnostic Checklist-Safety (PDC-Safety), which analyzes the environmental events that contribute to safe and at-risk employee behaviors (Martinez-Onstott et al., 2016). The PDC-Safety is similar to the PDC-HS, but involves modifications that make it specific to safety behaviors. For example, Martinez-Onstott et al. (2016) used the PDC-Safety to identify the variables that contributed to unsafe equipment usage and used an intervention indicated by the assessment to improve participant behavior. Therefore, the PDC-Safety is an effective tool for identifying interventions that are most likely to be effective for improving at-risk staff behavior (Cruz et al., 2019; Martinez-Onstott et al., 2016).

PIC/NIC Analysis

If trainers are having difficulty with improving trainee performance, an alternative assessment option is to conduct a PIC/NIC analysis. A PIC/NIC analysis is a formal, but not scientific, method for looking at behavior from the perspective of the performer that allows for an analysis of the antecedents and consequences that affect behavior (Daniels & Bailey, 2014). The analysis requires that the trainer identify all antecedents and consequences for the target behavior and then categorize the consequences as positive or negative, immediate or future, and certain or uncertain. Positive consequences refer to positive reinforcers, whereas negative consequences involve punishers or aversive stimuli. Immediate consequences occur within seconds of the target behavior, whereas future consequences occur at any later time. Certain consequences are those that always follow the target behavior, whereas uncertain consequences have a lower probability of occurring. Consequences that are immediate and certain are more likely to affect behavior than those that are uncertain and future. For example, answering a phone call at work has a positive, immediate, and certain consequence of hearing a friend's voice and having a conversation. The potential consequence of being reprimanded by a supervisor for being off task is uncertain because it is contingent on a supervisor being nearby and attending to the staff's behavior when the phone call occurs. Therefore, the staff member is more likely to respond based on the positive, immediate, and certain consequence and engage in the off-task behavior of answering the phone.

Trainers must complete six steps when conducting a PIC/NIC analysis. First, the trainer must identify the problem behavior. Second and third, the trainer must identify all relevant antecedents and consequences. Next, the trainer categorizes each consequence as positive or negative. Then, the trainer categorizes each consequence as immediate or future. Finally, the trainer categorizes each consequence as certain or uncertain based on the probability that the behavior will produce a given consequence. For example, a trainer may identify the target behavior as staff tardiness. Antecedents for this behavior include traffic on the way to work, waking up late, and stopping for coffee on the way to work. Consequences include having coffee, getting more sleep, and getting reprimanded. Then, the trainer analyzes each consequence to determine whether they are immediate, certain, and positive or negative. The goal of the PIC/NIC analysis is to identify which consequences are impacting behavior so that consequences can be modified to facilitate improvements in staff behavior. For example, if staff members are late to work because they are stopping to get coffee, trainers may choose to provide coffee at work contingent on a specific number of days with all staff reporting to work on time.

Other Forms of Assessment

Wilder et al. (2017) conducted an analysis of the commonality and type of preintervention procedures used in the *Journal of Organizational Behavior Management* between the years of 2000 and 2015. Results indicated that only about one-quarter of the published literature included preintervention assessments. The most commonly used assessment was indirect, in which researchers gathered information from interviews or questionnaires without directly observing the behavior or the environment. Descriptive analyses, in which behavior was directly observed, but the environment was not manipulated, were the next most commonly used. Historical assessments, in which prior data were examined before a study was completed, and systems analysis, in which the researchers evaluated behavior in the context of a larger process or system, were used the next most frequently. The least commonly used form of assessment was experimental analysis, in which the environment is manipulated to determine the effects of the manipulation on a dependent variable. These results indicate that although conducting preintervention assessments is likely beneficial, they are not commonly used. Researchers and clinicians may benefit from increased use of assessments.

Areas of Intervention Based on Assessment

After conducting the PDC-HS and PIC/NIC analyses, trainers must then implement function-based interventions that are informed by the assessment results. That is, trainers should implement indicated interventions after conducting assessments or completing analyses of staff behavior. There are a variety of potential variables that may influence responding and each intervention must be individualized based on the specific variables. Below are some examples of solutions to common performance problems based on potential results of the PDC-HS.

If a trainer identifies that variables related to training are responsible for poor staff performance, the best solution is to provide additional training so that the staff member can perform all the required skills at mastery levels. For example, Bowe and Sellers (2018) completed the PDC-HS with paraprofessionals and determined that insufficient training was responsible for errors with implementation of error correction procedures during DTI. Therefore, the researchers used BST to provide additional training to improve performance. In addition, the researchers provided a non-indicated intervention (i.e., positing reminders). The results showed that only the indicated intervention was effective for improving staff performance.

When the indicated variables maintaining poor performance are related to task clarification and prompting, trainers can provide checklists or written prompts. For example, Merritt et al. (2019) found that a lack of task clarification and prompting were influencing staff tardiness. The researchers scheduled meetings with participants to review the organization's expectations regarding coming to work on time, provided written summaries of those expectations, and had participants sign a summary form indicating they understood. The researchers also gave participants an opportunity to ask questions.

If resources, materials, and processes are identified as the variables contributing to suboptimal performance, trainers must ensure that staff have access to all necessary materials. Wilder et al. (2018) conducted the PDC-HS and found that staff were not conducting teaching of verbal operants as frequently as required due to issues with accessing a timer. Therefore, the researchers made a Motiv-Aider device more readily available, which resulted in improvements in staff behavior.

The performance consequences, effort, and competition domain is the most commonly reported domain that results in poor performance (Wilder et al., 2020). The best solution when assessments identify this area as problematic is to modify the consequences of staff behavior. A common method for modifying consequences is to deliver feedback for staff performance (e.g., graphed, written, or verbal feedback). For example, Ditzian et al. (2015) used the PDC-HS to identify the variables responsible for inadequate security of client rooms, which indicated that insufficient consequences were affecting performance. Therefore, the researchers provided graphed and written feedback on participant performance to improve responding.

Staff Training Recommendations

Staff training is an important component of the field of applied behavior analysis due to the importance of providing high quality behavior analytic services (Fryling et al., 2012; Van Houten et al., 1988). Trainers should use BST to ensure that staff are receiving optimal training based on evidence-based procedures. When delivering instructions, trainers should begin by providing written descriptions of all steps, reviewing the correct way to perform each step with the trainee, and avoiding using technical jargon (DiGennaro Reed et al., 2018). Additionally, trainers should include detailed data sheets and supplemental pictures or diagrams when possible (e.g., Graff & Karsten, 2012). For the modeling component, trainers should ensure that the modeled performance does not include any procedural integrity errors and is modeled in the context where the target skill will occur (DiGennaro Reed et al., 2018). In addition, trainers should ensure that the models include multiple exemplars of the full range of consumer responses staff will likely encounter in the natural environment to best facilitate generalization (Moore & Fisher, 2007; Stokes & Baer, 1977).

Trainers can use video models to ensure that the modeled performance demonstrates all steps accurately and ensure that all possible consumer responses are included in the modeled examples. During rehearsal, trainers should require staff to meet a predetermined mastery criterion (e.g., two or three consecutive sessions with correct responding) before terminating training (DiGennaro Reed et al., 2018). It is also beneficial to include a confederate (e.g., Lipshultz et al., 2015) to ensure that staff are exposed to all potential consumer responses during training. Finally, trainers should deliver positive and corrective feedback to staff following their performance of the target skill, including a combination of written, verbal, and visual feedback (DiGennaro Reed et al., 2018).

Although BST is often conducted in vivo, there are often barriers to training, including limited availability of trainers in rural areas or locations outside of the United States (Gerencser et al., 2019) and a limited number of trainers relative to the number of staff who require training (Graff & Karsten, 2012; Karsten et al., 2015). Therefore, in situations where it is not possible to provide in vivo training to all staff, trainers should consider using telehealth (e.g., Higgins et al., 2017), CBI (e.g., Marano et al., 2020a, b), or self-instructional packages (e.g., Graff & Karsten, 2012). These asynchronous training procedures allow for training to occur in the absence of a trainer.

When initial training is not sufficient for maintaining the target skills, trainers must identify the variables maintaining poor performance and implement indicated interventions to address those variables. The PDC-HS (Carr et al., 2013) and PIC/NIC analysis (Daniels & Bailey, 2014) offer viable options for identifying the factors that contribute to poor staff performance and can help trainers determine the interventions that are most likely to be effective. Thus, trainers have many options available for training staff to perform new skills and can select the training options that best meet their needs.

There are some final overall recommendations for training and improving performance in human service settings. Trainers should consistently contact the research literature to remain informed about possible training techniques and the most current recommendations, function as scientist-practitioners using science to guide clinical practice, and assess social validity to ensure that staff members are satisfied with the goals, outcomes, and procedures of staff training (Wine & Pritchard, 2018).

Part VI

Health Issues

36 Enhanced Dental Care

Sara Kupzyk, Brianna Zey, and Keith D. Allen

Importance of Oral Health and Health Discrepancies

Individuals with intellectual and developmental disabilities (IDD) are less likely to access preventative, quality health care than those in the general population (Hosking et al., 2016). Unfortunately, this discrepancy is associated with higher rates of death, more than a third of which could have been potentially amenable to intervention (Hosking et al., 2016). Oral care is one area where there are significant discrepancies in care and outcomes for children with IDD (Hennequin et al., 2008). In fact, oral health care is the most prevalent unmet health care need of children with special needs (Lewis et al, 2005). This is concerning because this population is more prone to developmental defects, plaque build-up, untreated dental caries, infections (e.g., periodontal disease), dental traumatic injuries, malocclusion (poor fit between upper and lower teeth, overcrowding), and functional concerns (e.g., bruxism) (Camoin et al., 2020; Ferrazzano et al., 2020). When oral health problems are unmet, children might experience sleep disturbance, difficulty eating, and problems with self-esteem, which can lead to decreased overall quality of life (Anders & Davis, 2010).

The American Academy of Pediatric Dentistry (AAPD, 2018) recommends children have a dental home no later than 1 year of age. A dental home involves family-centered services for routine care, preventative health and education, dietary counseling, and referral to dental specialists. Children who have a dental home are more likely to receive routine dental care and less likely to require dental treatments and experience dental disease. Despite the value of establishing a dental home, 70% of parents of children with special needs report that their child had not visited a dentist for a routine appointment within the last year (Hendaus et al., 2020).

Barriers to Oral Health Care

Camoin et al. (2020) described three primary barriers to oral health care for children with IDD: socioeconomic, social, and medical-behavioral. First, families that have children with IDD frequently encounter financial difficulties due to the number of services required for their child's care and therapies. Given financial hardships, caregivers may have to make difficult decisions about whether or not to proceed with treatment. Those

who are uninsured are more likely to experience unmet dental needs (Newacheck et al., 2000).

Second, social barriers include difficulties finding providers that accept patients with disabilities. In one study, 35% of parents reported having difficulty finding a dentist to treat their child with special needs (e.g., cleft palate, cerebral palsy, seizure disorder) (Al et al., 2004). However, when children routinely see a medical doctor, they are more likely to have their needs met, which highlights the importance of comprehensive and coordinated care facilitated by children's pediatrician (Lewis et al., 2005). Although many dentists report willingness to provide care for individuals with mild special health care needs, fewer are willing to treat those with moderate-to-severe needs (Ziegler & Pilcher, 2020). Even when willing to provide care, many report the need to refer patients to other settings for various reasons (e.g., lack of confidence, lack of trained staff, lack of appropriate reimbursement; Abraham et al., 2019). Finding a qualified adult provider is even more challenging. In fact, many adults with IDD continue to receive care from pediatric dentists, which is problematic because pediatric settings are not typically equipped to provide adult-centered care (e.g., dentures, implants) and this decreases the number of appointments available for younger children (Chi, 2014).

Research suggests that dentists view this population as difficult to treat due to concerns with limited communication skills and uncooperative behavior as well as ethical concerns with consent for services, and inadequate reimbursement for the time required for procedures (Faulks et al., 2012). Many practitioners do not obtain adequate education or experience to effectively treat this population. In one survey, 75% of dental students reported little to no preparation in providing care to people with IDD (National Council on Disability, 2017). Limited preparation can influence the type of treatments prescribed (Faulks et al., 2012). For example, when dental practitioners were given clinical case scenarios that differed only in the child's disability status (i.e., cerebral palsy or not), practitioners were more likely to recommend tooth extraction for the child with the disability (54%) and a more conservative endodontic treatment for children without a disability (73%) (Camoin et al., 2020). In addition, when children present with uncooperative and challenging disruptive behaviors, dentists are more likely to use more restrictive means such as restraint or sedation (Casamassimo et al., 2004). In general, there are few incentives for dentists to use positive behavior management approaches that tend to require more effort and time (Newton, 2009). In response to the difficulty with finding a qualified provider, communities have developed web-based resources to connect individuals and caregivers with providers willing to treat children with special needs (Ziegler & Pilcher, 2020). Furthermore, specialized training programs are being developed to better prepare dentists to meet the unique needs of this population (see Holt & Barzel, 2020 for an overview of resources and programs available).

Third, individual medical and behavioral factors pose challenges to treatment. Specifically, children with IDD (a) have more difficulty understanding treatments and communicating their oral health needs, (b) demonstrate sensory sensitivities, (c) present with higher base rates of anxiety, and (d) are more likely to demonstrate uncooperative or noncompliant behavior during medical visits (Fallea et al., 2016; Pruijssers et al., 2014). For example, if communication skills are limited, children may not fully understand the reason or process involved in the treatment. As noted above, this can create challenges for providers with obtaining consent when needed and managing behavior. In addition, oral health problems might go unnoticed if children are unable to effectively communicate their discomfort or pain. Medical settings involve many sensory factors (e.g., bright lights, loud noises from equipment) that can be overwhelming for children with sensory sensitivities.

It is important to recognize that stimuli that commonly elicit fear in children are found in the dental care setting such as masks, unfamiliar settings and people, separation from caregiver, the dark, loud equipment, and injections. Although these fears are developmentally appropriate for young children (Gullone, 2000), individuals with

IDD present with higher prevalence of anxiety which is associated with increased pain perception and behavioral concerns or lack of cooperation with treatment. Anxiety and related behavior concerns are common in medical settings, particularly for individuals with IDD. For example, Fallea et al. (2016) administered the Dental Anxiety Scale to 700 patients with IDD. Overall, individuals with higher levels of intellectual disability and females reported more significant anxiety with dental treatments. In fact, 55% of individuals with moderate intellectual disability reported moderate-to-severe anxiety (21% severe anxiety, 19% high anxiety, and 15% moderate anxiety). In addition, younger individuals reported more anxiety. The difference in age may be related to the frequency or rates of exposure to dental treatments.

Concerns with limited understanding, sensory sensitivities, and anxiety are associated with higher rates of problem behavior in medical settings (Pruijssers et al., 2014). It is important to note that uncooperative behavior is common with young children. In fact, 23% of children ages 2–8 demonstrate negative acceptance during dental examination (Sharma et al., 2017). However, rates of noncompliance with medical treatment are higher for individuals with IDD. Taneja and Litt (2020) found that 39% of caregivers of children with autism spectrum disorder indicated uncooperative behavior as a significant barrier to accessing treatment. Uncooperative behavior increases the risk of injury and use of restrictive means of gaining compliance such as sedation and restraint (Camion et al., 2018). Additionally, the presence of significant problem behavior during medical appointments deters practitioners from providing services and parents from scheduling preventative or elective health care appointments (Lennox & Kerr, 1997).

Given the potential negative impact of noncompliance on access to oral health care services and daily hygiene, a conceptual analysis of these concerns is helpful for informing preventative strategies and treatment recommendations. The next sections provide an overview of conceptual considerations, followed by specific strategies to prevent and intervene to address behavioral concerns and thereby improve oral health of individuals with IDD.

Conceptual Considerations Related to Behavior Management Concerns

Conceptually, we understand fear responses as respondent events. Unconditioned stimuli in the dental care setting might include loud noises, prick of a needle, dark, and separation from caregiver. Although these stimuli are not a biological threat, they can elicit unconditioned responses including sweating, heat palpitations, shallow breathing, nausea, flinching or fainting. Through respondent conditioning, previously neutral, non-threatening sights (e.g., the dentists, room where services are provided) and sounds (e.g., whirring of the brush, clock ticking) in the dental care setting can become conditioned stimuli that elicit conditioned responses. Higher order conditioning can result in more previously neutral stimuli eliciting conditioned fear or emotional responding.

Conditioned emotional responses might also contact operant consequences that strengthen and maintain the behaviors. In particular, when individuals engage in emotional responses, the responses are often followed by escape or avoidance (negative reinforcement) from the feared stimuli. Behaviors maintained by escape or avoidance might include verbal (e.g., crying, moaning, complaining) and physical protests (e.g., pushing away, running away, biting, kicking, hitting, hiding). Unfortunately, because of repeated pairings of certain stimuli in the environment and the consequence of escape or avoidance, the previously neutral stimuli can acquire the ability to evoke noncompliant behaviors. Overall, this conceptual analysis suggests that the focus of treatment for medical noncompliance should center on respondent extinction of the fear responses, yet also consider strategies to address behavior maintained by consequences (operant conditioning). Therefore, it is not surprising that graduated exposure is one of the most common and important components of prevention and treatment (Kupzyk & Allen, 2019; Jennett &

Hagopian, 2008; Davis & Ollendick, 2006; Lydon et al., 2015).

Early Intervention Considerations and Strategies for Preventing Behavior Management Concerns

To begin, behavior analysts can become familiar with dental providers that have experience working with children with special needs (or a care team who is open to expanding their education) and help refer patients to establish a dental home (AAPD, 2018). Similar to questions related to medical care, questions upon intake in early intervention or behavioral health services should include those about oral health care. It is important for behavior analysts to be aware of financial and social barriers to oral health care in order to promote access to care and provide anticipatory guidance. For example, families might benefit from meeting with a social worker or family support personnel or advocate to explore programs to decrease the financial burden of proposed dental treatments. In addition, behavior analysts can provide caregivers with information about the important role they have in supporting their child's oral hygiene habits (e.g., limited juice, candy, regular brushing and flossing) to prevent the toothaches and dental caries.

The goal of prevention strategies is to provide children with positive experiences during home dental care and office visits and reduce the likelihood of conditioning fear and avoidance responses. Positive experiences can be accomplished by carefully preparing for appointments and using graduated exposure. To effectively prepare for an appointment, it is valuable to inform parents that most young children will experience some anxiety or negative acceptance when visiting the dentist so that they can be prepared to respond to such concerns (Sharma et al., 2017). Parents can be encouraged to expect that their child will be successful and show confidence in the dental care team. When an initial dental appointment is scheduled, parents can share information about their child with the provider so that they can best prepare for a successful visit/positive exposure (e.g., adaptive aids, communication modalities, preferences, potential triggers in the office and challenging behaviors). Parents can also request information about what will happen during the appointment (e.g., will the parent stay with the child, what procedures will be completed, how the child will be seated, positive behavior management strategies). This information can be used to help the family prepare and practice behaviors needed prior to the appointment.

Preventative graduated exposure strategies include establishing positive routines, providing instructions and modeling, reinforcing appropriate participation in care tasks, and using gradually introducing new care tasks and situations (see Allen & Wallace, 2013; Kupzyk & Allen, 2019, 2020). When developing routines, visual schedules can be used to add predictability, which can make the exposure more positive. Instructions and modeling allow the child to become comfortable talking about and seeing what the task will entail before engaging in the task themselves. This can include (a) a parent or sibling showing how to do a task (e.g., brush, floss), (b) reading books or watching videos that provide developmentally appropriate information about what daily oral health routines (e.g., brushing, flossing) or a visit to the dentist will entail, and (c) taking a tour of the dentist office. Therefore, when introducing a task, a graduated tell-show-do model can be followed. This involves verbally explaining what will be done, modeling the task with another person or a stuffed toy, and then completing the action with the child (Orellana et al., 2014).

Parents and other caregivers can also make positive statements about oral care (e.g., "Brushing our teeth makes our mouths healthy" "It is fun to brush while I listen to music) and reinforce cooperative behavior and completion of daily oral care tasks. Behavior analysts can aid parents in determining potential reinforcers to use during these tasks by completing a functional assessment and preference assessment. A likely function of uncooperative behavior is escape.

Therefore, providing brief, yet frequent breaks during tasks might decrease the value of escape. Preferred tangibles can also be provided to the child during the task to encourage relaxation (i.e., counterconditioning). Offering choices can also increase preference and value of engaging in the care tasks for some children. It is best if these choices are directly related to the exposure. For example, the parent or provider might ask questions such as: Do you want to lean back with the light on or the light off? Should I count your freckles first or your teeth? Do you want me to show you how the light turns on first or how this squirts water? Should I use a red or blue toothbrush?

When introducing a new oral care task, routine, or dental appointments behavior analysts can provide guidance in the use of graduated exposure. For example, when introducing tooth brushing, the parent might be advised to reinforce the small steps such as opening the mouth, then tolerating the toothbrush in the mouth, then movement of the brush, and then brushing for increased amounts of time. Approaching new tasks in this way might decrease the likelihood of a stimulus eliciting a fear response. Similarly, families can visit the dentist office for brief field trips. These trips are how counterconditioning and graduated exposure get accomplished. They may require recruiting a dentist and/or assistant to participate and understand that the point of the visit is not to get dental work done, but to make sure the child has a lot of exposure to the dentist, assistant, and office in small doses with lots of breaks and relaxing, positive experiences. Therefore, during these trips, parents can provide access to preferred items, attention, or activities to increase positive associations with the dentist office and staff. These visits might be very brief initially so that the visit is ended when the child is relaxed and enjoying themselves. Overtime, additional stimuli can be added to the environment (starting with those that are not aversive).

Interventions to Address Behavior Management Concerns

When preventative strategies are not successful or there is a history of uncooperative behavior during oral health care, more intensive intervention is warranted. Interventions may vary in type and form depending on the severity of the noncompliance. Similar to prevention strategies, the treatment for medical noncompliance should focus on its central respondent conditioning characteristics, with graduated exposure as an essential component. Table 36.1 provides a brief description of common evidence-based strategies used to treat medical noncompliance. It is important to note that the majority of intervention studies use a multi-component treatment package (see Kupzyk & Allen, 2019 for a review of the literature).

Respondent Conditioning Strategies

Graduated exposure Graduated exposure involves arranging exposure to steps in a procedure or a hierarchy of stimuli that have been conditioned in the past to elicit fear responses. The stimuli are commonly arranged in a hierarchy according to either (a) the order in which they would be encountered in the procedure or (b) reordered so less salient stimuli are presented first so that the initial exposures do not elicit fear or evoke avoidance behavior. Before starting treatment, a task analysis can be conducted to individualize the steps in the hierarchy. As treatment progresses, it may be necessary to revise or incorporate necessary substeps. See Altabet (2002), Cuvo et al. (2010), Carter et al. (2019), and Kupzyk and Allen (2020) for sample dental exam procedural steps and hierarchies that can be modified for individual clients.

Within the steps in the hierarchy, the salience and dimensions of a stimulus can also be varied by size of the stimulus (e.g., size of X-ray bite-

Table 36.1 Strategies to reduce the probability of behavior concerns and increase compliance with dental routines, visits, and procedures

Strategies to reduce the probability of behavior concerns	Description
Graduated exposure	The child is gradually exposed to steps in a procedure or a hierarchy of stimuli from least to most feared that have been conditioned in the past to elicit fear responses and escape behavior. The hierarchy is arranged so that less salient stimuli are presented first so that the initial exposures do not elicit fear or evoke avoidance behavior
Systematic desensitization	The child is taught relaxation responses or presenting stimuli associated with being relaxed to try to elicit positive responses to counter the fear response
Contingent reinforcement	A reinforcer (e.g., break, preferred activity, item, or token that can be exchanged) is given to the child for meeting specific expectations (e.g., compliance, opening mouth for a certain amount of time, completing a step). It is important to note that the expectations must be reasonable and gradually increased so that the child can receive the reinforcement Potential reinforcers can be identified through caregiver interviews or preference assessments
Noncontingent escape	The child is given brief breaks at regular time intervals during the procedure. The breaks are not contingent on the behavior displayed
Modeling and prompting	An in vivo model, video, pictures, or stories are used to demonstrate the step/what will happen for the child. For example, the provider might tell and show the child what will happen before administering the procedure
Behavioral Momentum	The child is given high-probability demands followed by low-probability demands.
Escape Extinction	The child's attempts to escape the procedure or setting are physically blocked or the child is guided to complete the task. Escape is only available when the child demonstrates cooperative, compliant behavior.

Modified from Kupzyk and Allen (2020)

wing; amount of toothpaste), distance from the stimulus (e.g., distance of light from dental chair), and/or duration of exposure (e.g., length of time with mouth open). Then, the salience of the stimulus exposures can be increased slowly so as not to elicit fear and avoidance responding. Hypothetically, when completed successfully, the graduated exposures result in respondent extinction, so that the conditioned stimuli no longer elicit a fear response and in habituation so that the unconditioned stimuli result in a less intense fear or emotional response. Increasing the frequency of graduated exposure sessions can help to achieve these outcomes more quickly (Szalwinski et al., 2019).

Systematic desensitization Graduated exposure can be enhanced by presenting the feared stimuli while the individual is relaxed. This form of graduated exposure is known as systematic desensitization (King et al., 2005). This requires either teaching the individual a relaxation response (e.g., progressive muscle relaxation) or evoking one by presenting stimuli that previously have been associated with being relaxed, such as watching a movie, holding a favorite blanket, or listening to music. This process of pairing relaxation with graduated exposure can result in counterconditioning, in which previously feared stimuli eventually come to elicit less intense fear responses and instead may even elicit pleasant, relaxed responses. For relaxation to be effective, the individual must be relaxed *before* the presentation of the feared stimuli and maintain the relaxed state during subsequent presentations.

Operant Conditioning Strategies

Given that uncooperative, noncompliant behaviors are also likely to be maintained by operant contingencies, additional evidence-based strategies can be combined with graduated exposure including contingent reinforcement, noncontingent escape, modeling/prompting, and behavioral momentum, and escape extinction.

Contingent reinforcement Contingent reinforcement involves delivery of reinforcement contingent on incompatible or alternative behaviors (differential reinforcement of incompatible or alternative behavior). Here, the delivery of reinforcement occurs *after* the presentation of the feared stimulus contingent on the individual's cooperative behaviors. Given that the uncooperative, noncompliant behaviors are likely to be maintained by escape or avoidance, brief breaks from the procedure may be one of the most potent reinforcers (i.e., contingent escape; Allen et al., 1992). Providing brief breaks is also more practical than delivering a tangible reward in the middle of treatment. For example, when the child demonstrates cooperative behaviors, the provider pauses the procedure to reinforce the behavior in the presence of the stimuli included in the graduated exposure hierarchy. Over time, the stimulus comes to signal that reinforcement is available for the cooperative instead of uncooperative problem behavior (if these behaviors have no longer been reinforced). In turn, this can decrease the likelihood of the stimuli to evoke problem behavior. After the individual has had success (i.e., regularly accessing reinforcement for appropriate behavior) with less aversive conditions in the hierarchy, the more threatening or fearful stimuli associated with a dental routine are introduced. Lastly, delivery of reinforcers can be faded contingent on participant compliance and speed of completion of the tasks to more closely represent rates of reinforcement possible in routine care (Carter et al., 2019).

Noncontingent ESCAPE In noncontingent escape, the child is provided brief breaks at fixed time intervals throughout the procedure. This differs from contingent reinforcement as the child is given the break regardless of the behavior they are engaging in at the end of the specified interval. For example, Allen and Wallace (2013) asked dentists to provide with breaks every 15 s at the beginning of a procedure with children ages two to nine and thin the schedule in 15 s increments every 3–5 min. Compared to a control group who received treatment as usual, the treatment group demonstrated significantly fewer physical and vocal disruptive behavior. Conceptually, this noncontingent escape might decrease motivation to engage in problem behavior because the reinforcer is freely available.

Modeling and prompting Other literature have used modeling and prompting to evoke the desired compliant and cooperative behaviors. Modeling can include the child watching someone else in person or via video demonstrate desirable behaviors during the procedure or watching themselves complete the procedure (Orellana et al., 2014). With improvements in technology, providers and staff can easily create brief video demonstrations of typical procedures including reinforcement for compliance that can be shared with families prior to a child's appointment (Hine et al., 2019). Some examples of prompts include visuals of each step in the procedure and social stories that show desired behavior during a medical procedure (Cavalari et al., 2013). Modeling and prompting might aid in helping the child understand and anticipate the steps that will be completed. Care should be taken, however, to make sure that the visual or social story does not elicit fear responses, which may happen if there is a significant history of discomfort associated with the images (Marion et al., 2016).

Behavioral momentum Behavioral momentum has also been used to increase compliance with medical procedures. Behavioral momentum focuses on delivery of high-probability demands, followed by more difficult, low-probability demands. Studies show that presenting high probability requests before a low probability request (e.g., the fear evoking request or stimulus) can increase compliance during medical procedures (McComas et al., 1998; Riviere et al., 2011).

Escape extinction Escape extinction involves physically blocking attempts to escape or physically guiding compliance (escape prevented). In other words, escape is only provided contingent on compliance with the routine. This approach works to further weaken undesirable behaviors by eliminating one of the main consequences assumed to be responsible for maintaining noncompliance. Although this procedure is effective, it is (a) challenging for dental practitioners to implement while also attending to the ongoing treatment and (b) can be dangerous to implement as extinction can result in "bursts" of intense escape behavior, which can further increase the risk of harm to individuals involved in the dental procedure (i.e., the individual, medical provider, and caregivers) (Allen & Wallace, 2013). Therefore, escape extinction should not be used in isolation; it should be accompanied by other procedures that allow the individual to contact reinforcement (e.g., contingent differential reinforcement of incompatible or other behavior).

In response to noncompliance or uncooperative behavior, practitioners can consider one of the following techniques (a) take small breaks from trials, ignore the problem behavior, and continue exposure trials (escape permitted for brief periods), (b) end the exposure trials when escape maintained behaviors occur (escape permitted that day), or (c) return to earlier steps in the hierarchy that are less likely to elicit fear responding and evoke noncompliance. In contrast with escape extinction, these approaches offer only temporary escape, which may be sufficient to maintain fear and noncompliance (Allen & Wallace, 2013). Again, regardless of the approach taken in response to noncompliance, these procedures should only be used in combination with other strategies described above.

Future Directions

Given the importance of dental care and the risk uncooperative behavior and noncompliance poses for all individuals involved in the dental procedures, additional research is needed to identify (a) ways to increase efficiency of treatment, (b) levels of generalization across providers, caregivers, and settings and maintenance of the effects of treatment, and (c) levels of satisfaction and acceptability of the procedures among children, parents, and providers (Carter et al., 2019).

Efficiency of treatment might be enhanced by only using necessary components and progressing quickly, yet successfully through exposures. Conducting a component analysis of common treatment packages may aid in determining the individual and summative effects of the components. The components that do not result in compliance may be omitted in future applications. Criteria for advancing to the next step in a graduated exposure hierarchy typically involves mastery with the current step for at least two or three sessions before advancing to the next step. In some cases, this may prevent more rapid completion of treatment. In other cases, two to three sessions may be insufficient for extinguishing the fear response even if the individual is compliant, which might result in later increases in conditioned emotional responding. However, it is unknown if asking practitioners to continue with exposures until more calm behavior is observed adds value to a protocol. Furthermore, the operational definition of "calm" is not clear; therefore, research that adds more objective measures of fear responses (e.g., heart rate) might be useful.

Unfortunately, little is known about the levels of generalization across providers, caregivers, and settings as well as maintenance of the effects of treatment (see Carter et al., 2019). Researchers are encouraged to conduct follow-up and generalization probes to more fully capture the effectiveness of treatment. Long-term studies would also provide valuable information about the timing and effects of treatment across an individual's lifespan. For example, increasing access to routine care and use of prevention and intervention strategies from an early age might help to decrease oral health care discrepancies for individuals with IDD. Indeed, effective prevention provides the greatest opportunity for improvement of oral health care for individuals with IDD (Anders & Davis, 2010).

More data are also needed to determine levels of satisfaction and acceptability of the procedures among children, parents, and providers. If procedures are too cumbersome with regard to time and effort, they are not likely to be used in routine practice especially if rates of reimbursement remain the same for providers. Interventions with poor contextual fit are also at higher risk for treatment integrity concerns. Therefore, it is important to involve relevant stakeholders in designing, implementing, and evaluating interventions.

Much of the intervention research targeting dental noncompliance in individuals with IDD has employed data-driven individualized interventions evaluated using single-case research designs. Within these studies, demonstrations of functional relations and internal validity are demonstrated (see Kupzyk & Allen, 2019). However, to improve generality and dissemination of treatment components or packages, a standardized or manualized approach would be useful. The manual could include guidance related to determining which components are needed and recommendations for progressing through steps in the graduated exposure hierarchy. A randomized controlled trial could provide additional demonstrations of the generality of the treatment (Barlow et al., 2009).

Conclusion

In summary, behavior analysts are positioned well to help decrease disparities in oral health care for individuals with IDD. Clinicians can incorporate questions related to oral health into routine intake procedures to determine if children have an established dental home and if they experience difficulties with daily oral hygiene. If a dental home is not established, behavior analysts can coordinate with health providers and social workers or advocates to increase access to care. In addition, they can provide parents with anticipatory guidance strategies to prevent uncooperative and other problematic behavior during appointments and daily care tasks at home. Lastly, when behavior management concerns interfere with dental care, behavior analysts can complete the following steps to increase compliance and decrease fear and emotional responding as well as escape-maintained behaviors.

1. Identify local dentists that are experienced and comfortable managing behavioral concerns and working with children with disabilities.
2. Coordinate with the dentist to conduct a task analysis to determine steps/stimuli to include in graduated exposures.
3. Conduct a functional assessment to identify consequences of uncooperative behavior and a preference assessment to identify tangibles and passive activities that can be used as reinforcers delivered contingent on desired behavior.
4. Design a treatment package that includes at a minimum graduated exposure (core component of treatment). Additional strategies may be incorporated as needed to enhance treatment (see Table 36.1). Clinicians might progress to the next step of the hierarchy when the child has shown success (compliant, calm) with a step. It might be necessary to back up to previous steps to establish success. In particular, if graduated exposure is completed in a clinic or home setting, it might be necessary to return to earlier steps in the hierarchy when implementing the procedure in the dentist office as the behavior may not generalize to the new setting.
5. Develop a plan for responding to problem behavior (e.g., brief break, end session, return to earlier step). Determine when escape extinction, restraint, or sedation might be necessary based on treatment necessity. Researchers have typically found success without the use of these more restrictive strategies, but treatment requires a more gradual approach that lengthens the course of treatment.
6. Plan for maintenance to encourage continued cooperative behavior during dental visits and home daily oral hygiene tasks. This might involve fading of reinforcers and periodic practices with the procedures.

37 Self-Care Skills

Kathryn M. Peterson, Vivian F. Ibañez, and Lisa A. Guerrero

Introduction

Self-care skills can involve many daily living routines, which are often necessary for individuals to carry out to maintain general health, hygiene, wellness, and safety (Centers for Disease Control and Prevention, 2016). For example, bathing, dressing, eating a meal, brushing one's teeth, washing the hands, and putting on shoes before leaving the house are just a few examples of the self-care skills and routines that we, as adults, must carry out on a daily basis. We acquire these skills over the course of our lives, with the more complex or chained tasks, such as driving a car to the pharmacy or cooking a meal, becoming relevant and routine later in life. First, we must establish critical prerequisite skills to become independent.

Taking a few steps back and a closer look into early childhood, normative studies have shown that children must first acquire important gross-, fine-, and oral-motor skills that will serve as the necessary prerequisites to develop self-care skills and routines later in life (Carruth & Skinner, 2002; Fauth et al., 2017). For example, infants learning to reach for and grasp a spoon or to open their mouth to accept solids comprise a few of the first skills needed for later development of the ability to self-feed. Young children learning to refrain from urinating in their diaper, displaying the correct fine-motor skills to grasp and pull down their pants, and the appropriate gross-motor strength to lift themselves to a toilet seat, are examples of the first steps required for appropriate, independent toileting.

Children typically acquire the skills necessary to carry out various self-care routines such as toileting, self-feeding, and general hygiene during their early toddler years. In most cases, this developmental sequence occurs over the course of several years, often as a result of different experiences, peer and adult models, or direct teaching (Schlinger Jr, 1995). Children begin to carry out self-care tasks with heavy guidance from caregivers. Over time, caregivers step back to allow the child greater opportunities to exercise autonomy. In some cases, caregivers may need to provide the child with guidance or additional practice to facilitate skill acquisition. These developmental progressions are also influenced by a number of other factors, such as culture, health status, and physical wellness (Churcher et al., 1993; Rosser & Randolph, 1989).

It is important for children to develop self-care skills to not only increase their general independence and reduce reliance on caregivers, but also to promote health and safety. Children identified as neurotypical may advance through more predictable developmental progressions. Children with autism or related disabilities however, may progress in a unique manner or require additional teaching strategies to directly intervene on self-care skill deficits. In fact, studies have shown that children with autism display more pronounced self-care skill deficits relative to same-age, typically developing peers (Flynn & Healy, 2012). Without the ability to carry out self-care routines independently, the child would likely require more constant support from adults or might be stigmatized by peers once they reach school age. If caregivers must guide or implement routines for the child, it could lead to problem behavior (e.g., elopement, aggression) which could pose risks to the child, caregiver, or others in the environment. A lack of independent self-care skills has been associated with a greater likelihood of child abuse, caregiver stress, and increased costs across the lifetime (e.g., Barrett et al., 2015; Macias et al., 2006; Sevlever et al., 2013). Alternatively, greater independence with self-care skills has been identified as an important indicator of positive outcomes for children with autism as they enter into adulthood (Klinger et al., 2015).

Children with Avoidant Restrictive Food Intake Disorder (ARFID) represent another group who may not develop important self-care routines according to a more typical progression. This particular diagnosis is defined as generally impaired oral intake that is not age appropriate and is associated with medical, nutritional, skill, or psychosocial dysfunction (American Psychiatric Association, 2013). Feeding disorders, such as ARFID, affect nearly 20–50% of children who are typically developing, and 80–90% of children with developmental disabilities (Benjasuwantep et al., 2013).

Children with ARFID and Self-Care Skill Development

Although the characteristic features of ARFID are principally associated with feeding and nutrient intake, related deficits often span across a variety of important domains. First, children with feeding difficulties are at greater risk for developing cognitive or learning delays (Freedman et al., 1999; Schreck et al., 2004), which could affect their acquisition of self-care skills similar to children with autism or related disabilities. Second, children with ARFID often have long and complex histories involving painful medical conditions and invasive medical interventions, some of which include aversive procedures to the face or mouth (e.g., naso-gastric tube placement, endoscopy; Goday et al., 2019; Ibrahim et al., 2009). It is likely that the same procedures or aversive stimuli that contribute to or are a result of the child's refusal to eat also affect the child's cooperation with or tolerance of other critical self-care tasks that involve the same areas of the body (e.g., tooth brushing, flossing, rinsing; taking medication by mouth; self-feeding and drinking; face washing). These challenges could worsen over time or result in missed opportunities for independence and skill acquisition, but also could lead to other behavioral concerns. For example, children who have learned that when a caregiver approaches them with an unfamiliar tool or utensil (e.g., toothbrush, nail clippers, spoon, syringe), it could be that a painful or uncomfortable procedure is impending. In these situations, the child may engage in learned behavior to escape or postpone the uncomfortable or aversive procedure (e.g., screaming, running away, aggression). If the behavior becomes sufficiently intense (i.e., frequent and severe), the caregiver may inadvertently reinforce the response by allowing breaks or providing soothing attention, which could result in the child developing a general repertoire of problem behavior during self-care routines. Third, children who have a long history of receiving inadequate nutrition also tend to suffer from painful conditions such as chronic constipation, diarrhea, or general gastrointestinal dysfunction (Goday et al., 2019; Manikam & Perman, 2000). These conditions could serve as the underlying reasons for the feeding difficulties and could be the result if the child's diet primarily consists of foods lacking in nutritional value and variety (e.g., diets high in sugar or lacking in fiber; Manikam & Perman, 2000). These adverse gastrointestinal problems could contribute to why the child has difficulty with independent or consistent toileting, another important self-care routine. For example, children who experience pain when they attempt to have bowel movements may begin to withhold or engage in challenging behavior when caregivers instruct them to sit on the toilet.

Given that the prevalence of feeding difficulties is so high among children with autism, it is also not surprising that some children with ARFID display change-resistant behavior during feeding or other self-care routines (Crowley et al., 2020). Although some type of routine is inherently necessary for many self-care tasks (e.g., fixed sequence of steps for tooth brushing before going to sleep), certain forms of rigidity can prevent children from being successful when unpredictable changes occur. A child's insistence on sameness might result in emotional outbursts when there are unexpected changes to a familiar routine that, for most, would be seemingly minor. For example, children with change-resistant behavior might avoid independently brushing their teeth if their caregiver presents them with a new toothbrush. Repetitive and change-resistant behavior also can affect the child's ability to develop and tolerate new self-care routines (e.g., getting haircuts, nail trimming) if the child insists on exclusively allocating their responding toward change-resistant behavior and routines.

The negative impacts of resistant to change in the context of self-care skills can lead to undesirable consequences such as poor personal hygiene (Conyers et al., 2004) and nutritional insufficiency (Crowley et al., 2020). Interestingly, some researchers have used brain-imaging techniques to understand why children with autism respond differently to changes in environmental stimuli (Bonnet-Brilhault et al., 2018). Results of these studies show neurophysiological markers that stand out in children with autism, which appear to be critical in our understanding of the etiology of change-resistant behavior (Gomot & Wicker, 2012).

Out team of researchers regularly assesses and treats feeding difficulties in children with and without autism. In our clinical setting, it is not uncommon for caregivers to report to us that their child either has concerning self-care skill deficits or exhibits behavioral challenges during self-care routines, especially those related to mealtimes or involving the mouth. This is concerning because there are long-term implications of self-care skill deficits relative to mealtime and eating if children with feeding disorders do not advance through typical progressions. Most major social, cultural, and religious events such as birthdays and holidays involve consumption of food; when a child's feeding disorder prevents the family from engaging in typical social activities, it can be stressful and problematic. Families report avoiding social events altogether or must carefully arrange their daily routines to avoid unexpected changes.

In the following chapter, we provide an overview of current research on teaching important self-care skills and routines to children with autism or related disabilities. Given our area of clinical and research expertise, we confined the focus of our review to specific self-care skills that are critical for children with feeding disorders to develop. We feel it is especially important to intervene on self-care skills in this population, given the unique history and environmental variables that contribute to the development and maintenance of pediatric feeding disorders. We organized the chapter according to self-care skill areas with a general review of current research for each topic. Given the limited research on teaching self-care skills to children with ARFID, we identify specific studies to highlight ways in which current research might extend to this population, and conclude by providing important implications for future research.

Feeding as Self-Care

Etiology and Overview

In part, the extent to which children successfully perform self-care skills that are near to or involve an oral route (e.g., self-feeding, oral medication taking) depends on their learning history with these tasks. Children with feeding disorders often have complex medical histories (Davis et al., 2010), including exposure to unpleasant tests and procedures. For example, some children might require a nasogastric tube as a temporary bridge to enable growth and hydration. Inevitably, placement of this feeding tube requires insertion through the nasal canal, which can be painful and distressing (Farrington et al., 2009). Moreover, a nasogastric tube often requires routine management and potentially ongoing aversive experiences like intermittent dislodgement (Northington et al., 2017).

In the case of self-care related to feeding, caregivers of children with persistent feeding difficulties report high levels of anxiety, stress, depression, social stigmatization (Graves & Ware, 1990), feelings of rejection, anger, and lack of self-confidence (Greer et al., 2008). Their stress can be a function of a lifestyle that requires frequent contact with medical personnel (e.g., gastroenterologist), and the unconventional feeding routines (e.g., nasogastric tube, serving foods on a specific plate) required to manage the child's medical and nutritional needs (Franklin & Rodger, 2003). Given that food is an unconditioned reinforcer for many children, caregiver prompts or guidance is rarely necessary to get them to eat. Caregivers of children with feeding difficulties, however, likely experience stress due to their child's over-reliance on them to carry out or prompt all feeding routines.

Non-self Feeding

Children who are identified as neurologically or developmentally typical often begin self-drinking between the ages of 12 and 36 months, and start self-feeding (e.g., with the fingers) by 12 months (Carruth & Skinner, 2002). One of the necessary prerequisite skills for children with feeding disorders to eventually eat independently is first to accept bites and drinks from another person in the absence of inappropriate mealtime behavior (e.g., head-turning, batting at the spoon). At first glance, it does not seem as though acceptance of food or liquid should require a specific or extensive skill set. However, based on the unique medical or behavioral history for children with feeding disorders, it can be critical to break each step down and teach the skills sequentially. Components of the feeding chain are different based on the activity, but generally consist of touching the feeding utensil to the lips or placing it in the mouth; using the lips to initiate or facilitate the process (e.g., closing the lips around a spoon to pull the food from the spoon); forming the food or liquid into a bolus; chewing, if necessary; elevating the tongue and propelling the food or liquid backward toward the pharynx; swallowing; and retaining the food or liquid (Arvedson & Brodsky, 2002). Disruptions can occur at any point in the chain of this process. Because children with feeding disorders often engage in challenging mealtime behavior, the early focus of intervention should be on building new, safe routines and developing the necessary strength and stamina before teaching more effortful or challenging skills.

Fortunately, there is now a wealth of empirical support for behavior-analytic interventions that promote acquisition of age- and developmentally appropriate feeding skills (Volkert & Piazza, 2012). Given that caregivers of children with feeding disorders have likely attempted a number of strategies in the past to get their child to eat (e.g., coaxing, offering rewards, providing breaks; Borrero et al., 2010), clinicians treating the feeding difficulties should first create a "clean slate" or a more predictable mealtime environment from which to build and teach new skills. One of the first important steps should be to structure the mealtime environment and create consistent routine surrounding meals. Structuring the meal might begin with something as simple as setting a regular meal schedule, creating a clean and appropriate feeding environment with safe seating, and setting time or volume caps or bite-pacing criteria (Peterson & Ibañez, 2018). If the mealtime environment is predictable and the same from day to day, the researcher or clinician can ensure that any change in child behavior is likely a result of the planned intervention and not another variable (e.g., difference in food type, time of day, or bite size). Creating a structured mealtime environment also provides a platform for systematically advancing to more independent feeding skills.

After implementing a structured meal routine, researchers can then assess the conditions in which a child refuses or accepts food, the variables that likely maintain inappropriate mealtime behavior (e.g., through use of functional analysis; Bachmeyer et al., 2009), and the function- or evidence-based interventions that will treat the feeding disorder (e.g., Groff et al., 2014; Patel et al., 2002; Peterson et al., 2016; Rivas et al., 2010). For example, Bachmeyer et al. (2009) showed that withholding the identified functional reinforcers for inappropriate mealtime behavior, escape and attention, was necessary to reduce inappropriate mealtime behavior and increase acceptance (i.e., escape and attention extinction). Even before the development of functional analyses of inappropriate mealtime behavior, numerous studies showed similar outcomes in that putative escape-extinction procedures (e.g., non-removal of the spoon; Cooper et al., 1995) were often necessary to treat pediatric feeding disorders.

Children who begin accepting bites and drinks by mouth without engaging in inappropriate mealtime behavior are then eligible to make gains in terms of increasing their overall independence during mealtime. For example, clinicians could begin to make tube reductions or eliminations, increase the variety of healthy options in the diet, reduce the number of restrictions in terms of where and when the child will eat, and take the initial steps toward promoting independent feeding behavior. Relatedly, with initial improvement in non-self-feeding routines, children can progress and develop important self-care feeding skills.

Self-Feeding and Self-Drinking

Ultimately, children will progress to become age- or developmentally appropriate feeders when they gain independence during mealtime. Researchers have evaluated a number of interventions to teach children more advanced feeding skills which includes, but is not limited to increasing (a) self-feeding and self-drinking skills (Peterson et al., 2015; Rivas et al., 2014), (b) chewing (e.g., Volkert et al., 2014) and other skills required to consume table-textured foods (e.g., appropriate tongue lateralization; Adams et al., 2020), (c) consumption of age-appropriate portion-based meals, and (d) the child's acceptance and tolerance of foods presented in their natural forms (e.g., presenting a hotdog in a hotdog bun). For example, Peterson et al. (2015) used differential reinforcement to increase self-drinking of formula from an open cup for two children with a feeding disorder. In this study, researchers started with a smaller amount of liquid in the cup and increased the amount after the child mastered self-drinking with the smaller amount. Developing appropriate and safe chewing skills is another necessary step toward increasing child independence. Volkert et al. (2014) evaluated a multicomponent intervention to increase chews per bite, increase mastication (i.e., the extent that food was broken apart into small pieces after chewing), and eliminate early swallowing (i.e., swallowing of whole bites before they were sufficiently chewed). This study was unique because caregivers served as feeders and used graduated verbal, model, and physical prompting to teach the child sequential steps that ranged from chewing on an empty strip of plastic airline tubing to chewing food placed inside the tube. Eventually, caregivers presented small, loose pieces of table-textured food to the child, which they systematically increased in size.

Medication Taking

In addition to food and liquid, children may need to acquire the skills and behavior necessary for taking medications by mouth. It is not uncommon for children with feeding disorders to take medications on a regular basis, especially given the high prevalence of comorbid medical conditions in this population (Rommel et al., 2003). It could be that a child dependent on tube feeds previously received medication parenterally (i.e., directly to the intestine through tube feedings). However, once the child begins consuming food and liquid regularly by mouth and the tube has been removed, the child will need to adopt a more typical route for medication consumption. In addition, children who are tube-fed may have insufficient opportunities to practice the skills associated with eating by mouth (Piazza, 2008), which likely extends to taking medication by mouth. If the child will consume some food or drink by mouth, caregivers still might observe challenging behavior when delivering oral medications (Schiff et al., 2011) due to insistence on sameness or oral aversions to medical supplies (e.g., syringe).

Outcomes of research have shown that stimulus fading along many dimensions can successfully increase child cooperation with numerous medical procedures (e.g., Birkan et al., 2011; Cuvo et al., 2010), including swallowing medication (Beck et al., 2005; Ghuman et al., 2004; Schiff et al., 2011). For example, Schiff et al. (2011) used differential reinforcement and stimulus fading in the form of increasing the complexity or response effort associated with the demands. Steps included empty syringe presentation, decreasing the proximity between the empty syringe and the participant, and gradually increasing the ratio of placebo liquid medication to water in the syringe. This intervention may be particularly relevant for increasing medication consumption, especially for children with feeding disorders. Using a similar arrangement to treat feeding difficulties, Groff et al. (2014) used a syringe to deposit bites and drinks into the mouth of a child who clenched his teeth during spoon presentations. Groff et al. then gradually increased the volume of solids and liquids in the syringe and faded from a syringe to a spoon for solids and a syringe to a cup for liquids. Presumably, clinicians could extend Groff et al. (2014) by replicating the intervention with liquid medication. In addition to targeting liquid medication, researchers have also explored methods to increase child cooperation with swallowing pills. Beck et al. (2005) developed a protocol which they referred to as a form of systematic desensitization. In this study, researchers established steps with placebo pills that progressively increased in size.

Cooperatione with oral-medication taking, especially for groups of children who might be at higher risk of having oral aversions, is an important area that requires additional research. If caregivers struggle to deliver important pain-relieving medications (e.g., lansoprazole for reflux), the child may continue to experience discomfort during meals which could have deleterious effects on their overall feeding progress (e.g., relapse in problem behavior during mealtime). In other cases, medications may be necessary to optimal maintain health (e.g., daily multi-vitamins) or are prescribed as vital to treat an illness. In addition, children must eventually develop the necessary medication-taking skills to become independent with this process throughout child- and adulthood. Without establishing prerequisite skills of medication acceptance and consumption, this transition will likely be much more challenging. Finally, when addressing these challenges in practice, clinicians must recognize the role that medical professionals play in the delivery or transfer of oral medications previously delivered parenterally. First, some medications cannot be liquidized, crushed, or mixed with other food or liquid; others can only be administered at certain times of day or under specific conditions (e.g., following a meal). In addition, some medication dosages may need to be altered when administered through a tube because of the additional steps required to flush and clean out the tube with water (Williams, 2008).

Hygiene and Medical Routines as Self-Care

Overview

When children have a history of frequent invasive and uncomfortable procedures, particularly near the face and mouth, the child may associate the presentation of any items to the face, mouth, or body with discomfort, pain, or both. From the child's perspective, a medication syringe, nail-clipper, or toothbrush may be indistinguishable from devices that medical professionals use during invasive procedures or tests. Caregivers of chronically hospitalized children have reported that medical procedures have affected their child's cooperation with non-feeding-related self-care activities. In addition, individuals with autism or related disabilities often have programmed therapeutic goals to increase their independence with self-care skills due to general deficits in this area (Flynn & Healy, 2012; Roane et al., 2016).

Self-care skills that involve maintaining proper hygiene and healthy management of medical concerns or status can span a wide range of tasks. We have streamlined our review of self-care skills in this domain to discuss routines that are near the face or mouth, or involve specific utensils, including brushing the teeth, routine grooming activities (e.g., hair brushing or cutting, nail clipping), and general medical procedures (e.g., blood draws or enduring painful or uncomfortable procedures). Many behavior-analytic studies have identified that some variation of stimulus fading, with or without differential reinforcement, is often efficacious in teaching these types of important self-care routines (Kupzyk & Allen, 2019).

Tooth Brushing

Children with a feeding or developmental disorder often display difficulties with tolerating or independently completing routine dental hygiene procedures. Jawadi et al. (2004) found that children with a gastrostomy tube were more likely to have plaque and calculus build-up in their teeth than children without gastrostomy tubes. Gum bleeding is also common among children with feeding disorders who are not conducting daily oral-hygiene routines, especially when those children have had prolonged exposure to diets lacking in Vitamin C (Swed-Tobia et al., 2019). For example, Ma et al. (2016) reported that five of the seven children in their study who were diagnosed with food selectivity and scurvy also had swollen or bleeding gums. In addition, Vajawat and Deepika (2012) found that children with autism had a higher rate of periodontal disease and difficulty with manual dexterity to accomplish high-quality tooth brushing. The researchers posited that perhaps oral hygiene was problematic in children with autism due to a preference for sweeter foods or pervasive issues with packing food in the mouth and not swallowing. Having poor oral hygiene is problematic because it may lead to caries, periodontal disease, and other serious health conditions over time (Vajawat & Deepika, 2012).

There is a critical need for interventions that teach children how to brush their teeth effectively, efficiently, and consistently, especially given that this is a common problem area for young children with autism or ARFID. For example, the Assessment of Functional Living Skills™ (AFLS; Partington & Mueller, 2012) is an assessment, skills-tracking system, and curriculum guide that clinicians often use for treatment planning. This tool has entire sections dedicated to assessing and designing goals to teach dressing, toileting, grooming, and other important self-care skills. Previous research has focused on teaching the tooth-brushing sequence using chaining techniques and varying reinforcement contingencies to break down the individual steps of the process until the child is proficient (Bishop et al., 2013; Bouter & Smeets, 1979; Horner & Keilitz, 1975; Poche et al., 1982; Snell et al., 1989; Wolber et al., 1987).

More recently, Bishop et al. (2013) evaluated a behavioral intervention targeting cooperation with tooth brushing, which included stimulus fading and reinforcement-based components. Bishop et al. created a 60-step hierarchy that began with the clinician presenting the toothbrush in front and within sight of the participant from approximately 61 cm away (step 1) and ended with the participant tolerating the clinician brushing the participant's teeth for up to 60 s (step 30). Participants had to reach 100% cooperation for each session before progressing to the next step and were provided access to a highly preferred item (e.g., toy) contingent on cooperation. Researchers also periodically probed tasks from several steps ahead in the hierarchy, to determine whether the participant was ready to skip steps in the progression. Bishop et al. determined that this combined chaining and differential reinforcement intervention was successful at increasing three participants' cooperation with tooth brushing with a clinician. More importantly, Bishop et al. conducted caregiver probes upon completion of the terminal step, during which, participants and their caregivers remained successful at 100% cooperation and integrity, respectively. The use of probes to evaluate if participants could skip unnecessary steps resulted in the elimination of about 50% of the total number of initially identified stimulus-fading steps, thereby resulting in a more efficient intervention.

Researchers should continue to evaluate these and other strategies for increasing tolerance of effective tooth brushing in children with autism or related disorders (e.g., ARFID). The terminal goal should be for children to engage in appropriate and thorough tooth brushing (at least 2 min per tooth-brushing event), in which all areas of the mouth are brushed sufficiently (American Dental Association, n.d.; Nguyen & Martin, 2008). This includes the front, back, and top areas of the teeth, gums, tongue, and roof of the mouth. It could be that some children require more intensive approaches (e.g., escape extinction) if their behavior is sensitive to negative reinforcement in the form of escape or that others require more intensive focus on skill acquisition or refinement (e.g., placement of the bristle-side of the brush on the tooth).

Researchers should also make plans to transition from non-self tooth-brushing routines to promoting child independence. Recently, our team of researchers began evaluating a backward-chaining intervention (similar to Bishop et al., 2013) that included differential reinforcement and three-step guided cooperation to teach children with feeding disorders to first tolerate non-self and then progress to independent tooth-brushing. To begin, clinicians identified each of the primary areas of the mouth that required thorough and regular brushing, and then gradually increased the duration and number of brush strokes per area that the child needed to complete. The child continued to advance until we observed 80% or greater cooperation with the full routine. If chaining alone was insufficient to increase tolerance of or cooperation with the full routine, researchers added differential reinforcement (e.g., access to iPad following successful steps) and provided guidance to ensure the child completed the step. Our team has found preliminary success and generally idiosyncratic outcomes with this intervention (e.g., some children only required backward chaining, others required the full sequence of backward-chaining steps plus reinforcement). Given these mixed results, we have not yet isolated which intervention component(s) is critical.

Other areas of future direction could include evaluating additional stimulus-fading interventions (e.g., fading from a preferred utensil to a non-preferred utensil, like the toothbrush) or treatments involving response-effort reductions (e.g., brushing only one area of the teeth and then removing the brush from the mouth) and reinforcement manipulations (e.g., magnitude or schedule adjustments). Additionally, researchers should attempt, when possible, to isolate the variables that contribute to a child's cooperation with tooth-brushing routines (e.g., determine whether specific putative aversive stimuli evoke challenging behavior, such as the bristles or the buzzing sound of the electric brush) to better inform treatment. Finally, tooth brushing is merely one component of the overall oral-hygiene skillset, albeit an important one due to the importance of preventive care. Researchers should evaluate interventions for other routine preventive dental care, such as flossing and rinsing, or regular attendance to and cooperation with dental visits and recommendations (e.g., Kupzyk & Allen, 2019).

Routine Medical and Grooming Tasks

In our clinical experience, caregivers of children with autism, feeding, or related disorders frequently report difficulties during their attempts to promote their child's cooperation or independence with routine medical care or daily grooming tasks. In addition, studies have shown that some children will display challenging behavior during routine medical procedures and appointments (Allen & Kupzyk, 2016). In these cases, it is not uncommon for medical professionals to use restrictive or sedative approaches if the child's behavior becomes too disruptive or challenging (Shabani & Fisher, 2006). Caregivers of children with autism also report having to physically restrain or use general anesthesia to get through medical or hygiene procedures with their child, such as dental visits, wellness checkups, or specific medical tests (e.g., dental surgery, procedures; Rada, 2013). Many children engage in uncooperative behavior (e.g., aggression, elopement) during routine grooming activities (Collado et al., 2008), such as when an adult applies lotion to the child's skin (Ellis et al., 2006) or when a child receives a haircut (Schumacher & Rapp, 2011). This behavior likely interrupts the grooming procedure, which then interferes with the caregivers' ability to help their child maintain appropriate hygiene and health, or might result in the caregiver avoiding the process altogether. Without treatment, these behavioral challenges could affect a child's overall health or medical management, leaving the child vulnerable to undiagnosed problems or safety risks (Collado et al., 2008).

In terms of increasing cooperation during routine medical procedures and appointments, studies often include treatment packages that have multiple components, such as escape extinction, differential reinforcement, stimulus fading, contingent escape, and modeling. For example, Shabani and Fisher (2006) implemented a stimulus-fading hierarchy with differential reinforcement to increase one child with autism's cooperation with blood draws. Shabani and Fisher (2006) were successful with increasing the child's cooperation, and the intervention resulted in behavior generalizing to natural settings (e.g., blood draws carried out in the nurse's station instead of a structured clinical setting).

The same conceptual interventions for routine medical procedures could be applied to routine grooming procedures. For example, Buckley et al. (2020) evaluated a graduated hierarchy of stimulus-fading steps along with a reinforcement contingency and determined that this package was successful at increasing two participants' tolerance of haircuts. Our team recently began investigating ways in which to reduce problem behavior during nail-clipping procedures. For this study, we first evaluated whether differential reinforcement of other behavior (DRO) alone would increase cooperation with fingernail clipping and reduce avoidance behavior for three children with autism. Avoidance behaviors were defined as the child (a) removing their hand from the therapist, (b) blocking or batting at the therapist, or (c) elopement. When we determined that DRO was insufficient to reduce challenging behavior, we applied a similar stimulus-fading and differential-reinforcement intervention package as Shabani and Fisher (2006), which was successful at increasing cooperation with fingernail clipping. We also taught caregivers to conduct the protocol with high integrity.

Shabani and Fisher (2006), Buckley et al. (2020), and our research team have successfully treated challenging behavior during important medical or grooming routines without the use of escape-extinction interventions. Even though participants in these studies exhibited behavior that suggested a negative-reinforcement contingency (e.g., historically, problem behavior during the routine resulted in breaks from or termination of the routine by caregivers or other professionals), escape extinction may not always be an option if the implementers of the intervention cannot carry out the intervention with high integrity. Attention to safety measures becomes especially critical when the routine involves potentially dangerous equipment (e.g., hair cutter, nail clippers, syringe for blood draws). Future research should conduct component analyses to evaluate whether stimulus fading alone would suffice in reducing challenging behavior and increase cooperation during routine medical or grooming activities.

Appropriate Toileting as Self-Care

Along with tolerance of routine medical or grooming procedures, self-care activities can also encompass independence with appropriate toileting. Most children between the ages of 18 and 30 months have the necessary prerequisite skills to begin toilet training; however, not all children with autism or feeding difficulties progress according to this typical sequence (Greer et al., 2016). Teaching children with autism to engage in appropriate toileting routines can help the child achieve an important goal toward becoming more independent. It can also greatly reduce caregiver stress or the costs associated with prolonged incontinence (e.g., diapers, wipes, supervision during bathroom trips). By teaching appropriate toileting skills, researchers could help children with feeding difficulties and comorbid gastrointestinal dysfunction increase their regularity with bowel movements. Poor diet, especially diets lacking in fiber or appropriate hydration, can be one of the primary contributors to chronic gastrointestinal conditions, such as diarrhea or constipation (United States Department of Health and Human Services, 2017). Therefore, it is not surprising that children with ARFID often display challenges with independent toileting, and why it is a critical area to address.

Currently, there is a wide breadth of empirically supported interventions for teaching children appropriate toileting steps and routines, including children with autism and related disabilities (Azrin & Foxx, 1971; Cocchiola et al., 2012; Greer et al., 2016; Hanney et al., 2013; LeBlanc et al., 2005). Most often, these interventions involve: differential reinforcement for appropriate eliminations, regularly scheduled toilet sits, overcorrection procedures, wearing underwear instead of pull-ups or diapers, fluid-loading, teaching effective communication skills, and some type of urine sensor or alarm system.

Greer et al. (2016) conducted a component analysis of common toilet-training procedures with children who were identified as neurotypical. Greer et al.'s intervention procedures included having the child wear underwear, use of differential reinforcement, and a dense toilet-sit schedule that began with the researcher prompting the child to sit on the toilet in 30-min intervals. Greer et al. found that wearing underwear was the most essential component of this intervention package. Perez et al. (2020) extended the Greer et al. study by evaluating a similar progression and package for 11 children with autism. Overall, Perez et al. found that the intervention package described by Greer et al. was effective for the majority of their participants. Combined, the outcomes of these two studies suggest that the more intensive intervention components (e.g., overcorrection, urine sensors, timed sits) may only be necessary for a subset of children, but additional research is needed.

Although many studies have identified effective strategies for teaching appropriate toileting for children with autism or developmental disabilities, more research is needed to evaluate the generality of these interventions to other settings and for children with feeding difficulties specifically. It would be helpful to know whether intervening on appropriate toileting could serve as one step toward addressing gastrointestinal dysfunction for children with ARFID. Future researchers should also evaluate toilet-training procedures in relevant settings, such as at home, school, or daycare locations. Perez et al. (2020) conducted their study solely in an early intervention center in which the participants were receiving behavior-analytic treatment for other goal areas (e.g., language, pre-academic skills). This location is important and relevant for many children, but may not capture whether children could achieve similar progress or maintain success in the natural environment. In addition, researchers may wish to expand the scope of toilet-training studies to involve bowel movements and to increase children's independence with initiating bathroom trips.

Conclusion

Overall, the current literature is replete with strategies for teaching important self-care skills to children with autism or related disabilities. Previous research has identified that there are specific needs in these populations for more intensive intervention relative to children who develop according to more typical progressions. However, more research is needed to identify the prevalence of self-care skill deficits in other vulnerable populations, such as among children with ARFID. In our clinical experience, we have identified that children with feeding disorders often display marked self-care skill deficits across a variety of domains (e.g., tooth brushing, appropriate toileting, cooperation with medication taking). In addition to skill deficits, children with feeding difficulties often have oral aversions due to long histories of complex medical interventions, or they engage in change-resistant behavior during meals or other self-care tasks. These situations can be stressful and problematic for caregivers for a number of reasons.

Failure to progress through developmental milestones or acquire the skills necessary to perform self-care tasks independently could affect the child in a number of ways. For example, children who refuse to brush their teeth independently and consistently consume diets that are high in sugar could be at greater risk for poor oral health (Ma et al., 2016). This situation is further complicated if the child repeatedly engages in challenging behavior during the caregiver's attempts to brush the child's teeth. In some cases, the caregiver may give up trying the routine altogether. Over time, the child will likely develop concerning oral-health conditions, which then require potentially painful, expensive, or invasive procedures later in life (e.g., root canal, dental surgery; Rada, 2014). In other cases, children who have not acquired the necessary skills to self-feed must rely on caregivers to ensure sufficient intake or they will likely continue consuming diets that are lacking in nutrition. Over time, prolonged exposure to poor diet could lead to many serious side effects (e.g., obesity-related illnesses, learning problems; Freedman et al., 1999). Children who engage in challenging behavior during medical procedures or grooming routines could be at risk for injuring themselves or others, especially if the equipment involves sharp or dangerous objects (e.g., syringes for blood draws and scissors for haircuts).

Future researchers should focus their efforts on developing efficient and effective strategies for filling gaps in the self-care literature. These might include strategies to advance children toward all types of age-typical feeding practices, such as eating foods in their natural form or in a variety of locations and public settings. Interventions that promote or serve to teach advanced feeding skills have benefits that go far beyond supporting physical growth and development. For example, teaching children to consume meals according to a more typical routine could increase the opportunities for that child to engage with family members or friends during shared meals at home or school. As mentioned earlier, the social implications of eating include many different meaningful opportunities, such as friends and family coming together to interact around the dinner table. In these cases, effective feeding interventions could actually serve to expand a child's access or ability to contact numerous reinforcers. Massey (2004) noted that mealtimes are one major activity during which children learn and practice their social skills. Therefore, if a child has difficulties during mealtime in terms of their insistence on sameness or level of dependence on others, progress in this domain might be limited. Alternatively, in the home setting, caregivers might continue to experience high levels of stress if they must physically guide their child to complete self-care skills at an age in which the child would be expected to be independent. If a child is able to efficiently consume meals with minimal oversight and in the face of unpredictable changes, the benefits for the child and their family are countless.

Other important directions for future research include increasing independence, not just tolerance of, critical hygiene routines and grooming tasks. Teaching children to become more independent with self-care skills could greatly reduce safety risks, and increase the likelihood that children will continue to thrive independently as they progress through school-age years and into adulthood. In addition, teaching children how to engage in appropriate grooming or hygiene routines could provide increased self-esteem or confidence. When the child reaches adolescence, they may be more confident to leave the home to meet up with friends, attend social events, visit new places, or even apply for jobs.

The implications of achieving a certain level of independence with self-care skills extend well into adulthood, particularly for individuals with autism and related disorders who continue to struggle with areas like personal hygiene (Eaves & Ho, 2008). Although children with autism are often eligible for services through educational institutions and other public and private programs (Thomas et al., 2012), there are generally a fewer number of supports for adults with autism and related disorders (Schott et al., 2020). The support programs that are currently available (depending on the state or funding options) span a wide range of areas, such as employment or vocational services, educational programs, and residential housing facilities. These support systems or organizations might expect or require a specific baseline level of independent self-care skill performance for individuals to access the service. For example, generally appropriate hygiene and basic self-care skills are necessary to provide support in many different employment settings (Garff & Storey, 1998). Therefore, an individual with a greater number of independent self-care skills might have increased eligibility to enroll in vocational training or supported employment programs. Considering these factors, it becomes even more crucial for healthcare providers to focus on acquisition of self-care skills that will better prepare an adult to navigate the obstacles or meet eligibility requirements for limited adult services.

It also may be important for researchers to evaluate the long-term effects of interventions on acquisition of self-care skills during childhood. Studies have shown that intervening in these areas can decrease the likelihood of child abuse and caregiver stress (Macias et al., 2006); however, less is known about the long-term outcomes of specific interventions or whether children will sustain the progress they have made after initially acquiring self-care skills. Relatedly, more research is needed to determine whether children with feeding disorders who receive effective intervention at a young age continue to eat appropriately years after treatment ends. Researchers should also assess the factors that affect whether successful teaching strategies generalize and maintain (e.g., do caregivers continue to practice the skill, are there relapses in problem behavior). Researchers should focus their efforts on identifying optimal training environments, planning for long-term maintenance and generalization, including caregivers as trainers early in the process.

In terms of teaching environments, there is currently a growing wave of interest in telehealth-based options. Historically, telehealth alternatives became a viable solution for families of children who lived at a greater distance from clinical settings (e.g., rural or remote areas; Peterson et al., 2017; Wacker et al., 2015). Recently, the COVID-19 pandemic has required that many clinical spaces shut down due to social distancing and safety restrictions. This pandemic has placed an even greater emphasis on the provision of services to families from a distance. However, there are also many practical reasons that delivering interventions to teach self-care skills using telehealth might be relevant. First, the caregivers could practice the skills with the child in the natural setting, where the routine is most likely to occur and where there has been a history of challenging behavior (instead of a novel clinical setting). Second, conducting sessions via telehealth would allow the clinician to identify whether there are specific barriers that may hinder success during the self-care routine (e.g., meal utensils are not developmentally appropriate, seating at the dinner table is unsafe). Finally, teaching in the home or public setting could provide another avenue for promoting long-term maintenance. For example, teaching the caregiver to embed strategies into their existing routines or modifying the strategy to fit the materials or resources the caregiver has on hand might lead to greater success overall. Teaching a child to tolerate haircuts at the salon while the clinician observes and provides feedback via telehealth can offer invaluable opportunities for necessary generalization.

Boutain et al. (2020) used behavioral skills training and telehealth to teach caregiver how to develop three important self-care skills with their children (i.e., face washing, lotion application, and hand washing). Following the intervention, all three caregivers could carry out the teaching strategies with high integrity and all three children displayed high levels of cooperation and accuracy with the self-care skills. Future researchers should continue to evaluate the efficacy of telehealth as a medium for teaching self-care skills.

In summary, researchers and clinicians should continue to focus their efforts on developing important self-care skills in these vulnerable populations of children. When caregivers bring their children in for treatment of autism or feeding difficulties, self-care skill development may not be the initial or most pressing focus. However, clinicians should be mindful of these deficits as they plan goals for the child's admission. It may be important to obtain baseline measures of self-care skill performance initially, and then to regularly check in on whether skills have developed over time. For example, it is plausible that because of exposure to intervention for the feeding disorder (e.g., escape extinction to increase bite acceptance from a spoon), the child might engage in less problem behavior when caregivers attempt to present a toothbrush to the child's lips, without specific or formal programming with the toothbrush.

Ultimately, eating, grooming, toileting, and carrying out important medical or safety routines are all regular activities that occur multiple times a day and throughout our lifetimes. Therefore, the impact of these deficits on a child's health and development, and their family's wellness, and quality of life, cannot be overstated.

38 Preschool Life Skills and the Prevention of Problem Behavior

Tracie B. Mann and Einar T. Ingvarsson

This chapter is organized into two parts. In part one, we provide an overview of the Preschool Life Skills (PLS) program, including the rationale for conducting the original study in 2007, discussion of the replications and extensions, and its status today. In part two, we look to place PLS in the context of popular early childhood prevention programs. We provide a brief overview of several commonly used models and their respective salient features, and critique PLS as a preventative model. We conclude with recommendations for researchers and clinicians. To date, there have been two PLS reviews published by Fahmie and Luczynski (2018) and Luczynski and Fahmie (2017). Our aim is to update the information covered in previous reviews by including PLS studies published since 2018 and to extend the reviews by comparing PLS with popular mainstream prevention programs.

Part One: Preschool Life Skills

Original Study Description

The PLS program was born from the relatively recent (at the time) finding from the National Institute of Child Health and Human Development (2013) that children who spent a significant amount of time in non-familial child care were more likely to develop problem behavior. This relationship should not be mischaracterized; child care is a necessary part of life for many families and quality child care programs and preschools can provide many benefits for young children, particularly in the area of academic skill development (e.g., Bakken et al., 2017; Meloy et al., 2019). However, like most environments, the contingencies arranged within them, if not thoughtfully designed, can also contribute to the development of problem behavior. A thorough discussion of factors that influence the development of problem behavior in children is well beyond the scope of this chapter (see Komro et al., 2011; Luczynski & Fahmie, 2017), but they are often characterized on a spectrum from distal (poverty) to proximal (daily interactions in the home or school setting). It is the latter with which this chapter is concerned. Children in child care or preschool experience dozens, if not hundreds, of interactions with teachers and children every day. These interactions can influence the development of both prosocial behavior and

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_38

functionally equivalent problem behavior. Thus, although the link between non-familial child care and the development of problem behavior is perhaps tenuous, it suggests a practical approach to mitigate its development. Almost one quarter of children under the age of five are in some kind of organized child care arrangement (Laughlin, 2013). What a perfect opportunity to intervene and make a difference.

Greg Hanley and his graduate students recognized this opportunity and designed a curriculum to teach prosocial skills to children in a university-based preschool (Hanley et al., 2007). They identified 13 skills across 4 broad units: instruction following, functional communication, tolerance for delay, and friendship skills. These skills were derived from two sources: the functional analysis and the school readiness literature. From the former came an understanding of common situations that reliably produce problem behavior, and the knowledge that strengthening functionally equivalent replacement behaviors is the "gold standard" treatment for reducing it (Luczynski & Fahmie, 2017). The second source, the school readiness literature, strengthened the rationale for teaching skills in the first three units and informed the addition of the fourth unit. In their survey of kindergarten teachers, Lin et al. (2003) found that teachers valued self-regulation behavior over early academic skills and also rated friendship skills, including empathy and sharing, in their top five skills for incoming students. More recent survey data support the rationale behind an emphasis on skills that can be conceptualized as socio-emotional behaviors over academic skills (e.g., Hustedt et al., 2012).

When designing their instructional package, Hanley et al. (2007) departed from most mainstream early childhood prevention programs guided by developmentally appropriate practice (DAP). DAP was then, and is still the guiding force behind preschool program development. It is a practice that promotes young children's optimal learning and development, and is heavily influenced by the work of developmental psychologists. As such, DAP is underscored by philosophies of development that emphasize maturation and readiness. Experience is not ignored, but moderated by the internal state of the child (i.e., age, maturity, developmental stage, etc.). This philosophy influences how preschool directors and teachers arrange their program to promote prosocial development. For example, the National Association for the Education of Young Children published a position statement in 2009 detailing how to use DAP to teach prosocial skills (Copple & Bredekeamp, 2009). The strategies are overwhelmingly antecedent-based and include practices such as building strong teacher–child relationships, modeling prosocial behavior, and giving plenty of opportunity for collaborative play (specific programs aimed at building prosocial skills are discussed in detail later in the this chapter). Although these are crucial characteristics of quality child care, are they sufficient to impart the prosocial skills that elementary teachers value? Maybe for some children, but certainly not for all. Thus, instead of primarily focusing on antecedent manipulations, PLS incorporates explicit, repeated practice in relevant situations and immediate feedback following the presence or absence of the desired skill. The *piece de resistance*, so to speak, of PLS is the evocative situation. The evocative situation, whether contrived or naturally occurring, is the event that sets the stage for the child to engage in a PLS. If practicing instruction following, the evocative situation is the delivery of an instruction. If practicing greeting a friend, the evocative situation is the arrival of a newcomer to the child's immediate area. Although PLS incorporates proactive teaching in the form of behavioral skills training (BST) (specifically the instructions/rationale and modeling components), it is the repeated presentation of the evocative situation and delivery of differential consequences that drives the bus. As reference, see Table 38.1 for a description of the 13 skills and relevant evocative situations from the original 2007 study:

To teach these 13 skills, Hanley et al. (2007) trained preschool teachers to implement PLS with 16 children. They used a multiple-probe design across skill units to evaluate the effects of a class-wide BST approach to teach PLS. During the initial baseline, teachers arranged the evocative situations throughout the regular preschool

Table 38.1 Thirteen skills and relative evocative situations from Hanley et al. (2007)

Unit	Skill	Evocative situation
1: Instruction following	Responds appropriately to name	Name call
	Complies with a simple, single-step instruction	Delivery of an instruction
	Complies with a multi-step instruction	Delivery of a multi-step instruction
2: Functional communication	Requests assistance with, “help me, please”	Child needs help
	Requests adult attention with, “excuse me,”	Child needs attention
	Requests using a framed response, “may I…”	Child needs an item or materials (from adult)
	Requests to peers using a framed response, “may I…”	Child needs an item or materials (from peer)
3: Delay tolerance	Tolerates delays imposed by adults	Is instructed to wait by adult
	Tolerates delays imposed by peers	Is instructed to wait by peer
4: Friendship skills	Says “thank you” after receiving an item	Receives an item
	Acknowledges or compliments newcomer	Newcomer arrives in area
	Offers toys/materials to newcomer	Newcomer arrives in area
	Comforts others in distress	Someone is in distress

day and measured the presence or absence of the desired skill. Next, teachers used BST to teach children how to emit the skills in Unit 1 (one skill at a time). After children had experienced 10 trials for each of the skills in the unit, another baseline probe was administered. This was followed by instruction in the subsequent units, until the children had received instruction for all skills and completed the final baseline probe. The results from this study were compelling. Overall, researchers observed a more than four-fold increase in PLS and a 74% decrease in problem behavior.

The authors concluded the article with many suggestions for future research, including programming for and evaluating durability and generality, including less-experienced teachers, higher-risk children, and more typical teacher-to-student ratios, modifying the dose of instruction by manipulating mastery criteria and intensity of instruction, refining the evocative situations to more closely resemble those that occur naturally in preschool settings, and evaluating PLS as a preventative model. The first direct replication was conducted soon after the original study, but not published until 2014. Hanley et al. (2014) replicated the procedures in two Head Start classrooms using a consultative model with preschool staff. They extended the 2007 study by including teachers with varied backgrounds in a program with larger teacher-to-student ratios. Although they also observed improvement, gains were not as robust and considerable variability was observed between children.

Since 2007, several researchers have performed systematic replications and extensions of the 2007/2014 studies, many addressing the areas of future research suggested by the original authors. We will discuss these studies by examining how they contributed to the understanding of different PLS components and effects, including the target skills, teaching method, and learning outcomes. To date, close to 115 children have participated in published PLS research and benefited from such instruction.

Target Skills

Unit 1: Instruction Following Teaching precursors to compliance, and compliance with one- and two-step instructions seems a good place to start in a curriculum designed to teach prosocial skills. If children are not attending to the teacher before she delivers an instruction, or if they do not complete simple instructions, then teaching more complex skills might be difficult. This is, of course, an empirical question, and no study has looked at the benefits or limitations of a linear progression through PLS (i.e., the importance of mastering skills 1–13, in order). However, Beaulieu et al. (2012) conducted a form of this analysis with skills 1 and 2. They first conducted a descriptive assessment in a preschool setting and determined that, most of the time, when a teacher called a child's name, an instruction followed. They also found that a child was more likely to comply with an instruction if he either stopped his activity and/or looked at the teacher following a name call. These findings provided the rationale for teaching critical precursors to compliance: stopping, looking at the teacher, saying "yes?" and waiting for a response. In the second part of their study, they found that teaching these precursors improved compliance for all children. Moreover, they found that children in a control group did not show improvement, suggesting that the much espoused advice to wait for children to naturally develop prosocial skills through experience of high-quality early child care environments might not always bear the fruit it promises.

In two related studies, Beaulieu and colleagues found peer mediation can maintain precursor behavior once teaching discontinues (Beaulieu et al., 2013), and that teaching precursors and using peer mediation could be "scaled up" and taught class-wide using BST to improve preschoolers' compliance (Beaulieu & Hanley, 2014). The results of these follow-up studies provide tentative evidence that the PLS model can be adopted by larger classrooms, an important quality when considering its viability in mainstream early childhood settings. Further, the peer mediation component may have implications when considering long-term maintenance and generalization. Leveraging peers, who are a consistent presence in a classroom environment, to provide prompts and reinforcement for target behaviors may be another tactic to promote lasting change. This will be discussed again later in the chapter.

Units 2 and 3: Functional Communication and Delay Tolerance Units 2 and 3 comprise the six skills that might be considered the "meat" of PLS. The evocative situations arranged in these units are common events which evoke problem behavior in young children. In the original study, Hanley et al. (2007) demonstrated a 67% increase in functional communication skills and an 88% increase in delay tolerance (Luczynski & Hanley, 2013). However, not all children learned these skills and the design did not completely rule out the possibility that preschool children would simply learn these skills over time, presumably as a function of experience with the regular preschool programming.

To address these limitations, Luczynski and Hanley (2013): (1) expanded the social skills to include precursor behavior (stopping, looking, and raising hand before making a request), (2) multiple functionally equivalent response forms ("Excuse me" and "Pardon me" to get attention/"May I" and "Can you" to request items or attention), (3) taught children to tolerate delays and denials, (4) used performance-based criteria rather than time-based, (5) taught skills in a small group format, and (6) included a matched control group for comparison. All children in the experimental group learned every skill, demonstrating the skill in over 80% of opportunities. By contrast, children in the control group did not learn these skills, and in fact, the control group children's problem behavior worsened over time (more evidence to move away from a purely developmental approach to teaching prosocial skills).

No other study has looked at functional communication and delay tolerance skills independent from the other units (aside from the follow-up to this study by Luczynski et al., 2014, which will be discussed later), but there are noteworthy findings from replications. First, in several studies, researchers noted that these particular skills were rarely observed in children before teaching (Gunning et al., 2020; Hanley et al., 2014; Luczynski & Hanley, 2013; Robison et al., 2020), but responded well to intervention. There is also some tentative evidence that individual skill repertoires moderate outcome. Falligant and Pence (2017) found that participants with less advanced verbal repertoires required more extensive instruction and procedural modifications to acquire skills in these units. Gunning et al. also found that participants with autism who demonstrated limited language, play, and listener skills required more support and modifications. These findings are important if PLS is to develop into a widely adopted prevention program. Teachers of children with repertoires that might not be responsive to the "standard" PLS should have a road map of modifications to make when results are not optimal.

Unit 4: Friendship Skills The Friendship Skills are an interesting group. These skills do not fit quite as neatly within the conceptualization of "preventative" skills in the preceding units. That is, teaching to greet, offer toys, and show empathy are not likely to prevent the development of problem behavior directly because they do not serve as appropriate replacement behavior to evocative situations which reliably proceed problem behavior. They are important, however, considering studies referenced earlier related to the kinds of prosocial skills elementary teachers rate as foundational and important to success (e.g., Hustedt et al., 2012; Lin et al., 2003). Further, there can be little argument that a classroom of socially responsive children who compliment and show empathy to others creates a more pleasant environment than one whose children do not.

Compared to the other skill units, these skills have been relatively understudied (McKeown et al., 2021) and, interestingly, tend to show more modest and variable improvement following intervention. In their recent evaluation of friendship skills, McKeown et al. (2021) identify several possible reasons why friendship skills responded differently in previous studies. The first two reasons are related to the context in which friendship skills typically occur in preschool settings: during play. Children actively engaged in play may be unlikely to pay attention to others bidding for their attention or newcomers entering their area, and thus, unlikely to respond to or initiate a bid. Further, children may avoid these social skills because emitting them requires termination of a preferred activity. Third, children participating in previous studies may not have received the appropriate "dose" of instruction (i.e., not enough practice trials). Finally, previous studies may not have adequately measured friendship skills by only assessing two opportunities per skill following teaching.

To further examine and extend this unique set of skills, McKeown et al. (2021) taught four children with and without disabilities five friendship skills and evaluated generalization of skills to a same-aged peer. In contrast to the original 2007 study, they delivered the instruction in a one-to-one format, expanded the friendship skills to include empathy toward positive responses, modified the *welcoming a newcomer* skill to include complimenting, and included more stringent mastery criteria. Overall, these procedures improved friendship skills for the two neurotypical children; however, several modifications were needed for the children with ASD to learn three of the five skills. Further, one-to-one teaching with an adult experimenter did not result in satisfactory generalization to the same-aged peer. Improvement in generalization was only observed after the experimenter delivered feedback following opportunities to emit the friendship skill.

To the best of our knowledge, this is the only study that has taken a closer look at the friendship skills; however, the authors identify important considerations when designing instruction for these skills. They note that the likely reason performance with the peer was so variable was because toy play competed with attending to the relevant features of the evocative situation. They suggest solving this problem by making features of the evocative situations more salient. For example, they increased the saliency of the peer's arrival by having the peer initiate a greeting and tap the participant on the shoulder. The authors also suggest learning more about how peers typically interact in a classroom environment to inform the design of evocative situations and target responses, thus improving ecological and social validity (see Gunning & Holloway, 2021, for a recent descriptive analysis of preschool social interactions).

In summary, the target skills included in PLS have largely remained stable over several replications and extensions. Each unit of skills has also been evaluated independently from the others, but not thoroughly (i.e., three studies for Unit 1 skills, two studies for Units 2 and 3, and one study for Unit 4). Future research should aim to continue to make refinements within each skill unit. Several researchers have recently emphasized the importance of assessing the instructional context before teaching in order to identify target behaviors teachers and parents value. With the widespread use of technology as leisure items, parents in particular may be interested in modifying Units 2 and 3 skills to focus on denying or terminating access to electronic devices. On the other hand, teachers may be more interested in expanding the Unit 1 skills to include more sophisticated rule following behavior during a variety of classroom routines, or in strengthening and expanding the Unit 4 skills. Thus, future research should also identify methods to identify meaningful skills across settings. After all, at the heart of PLS is the mission to "create a nurturing classroom environment in which all teachers and young children promote and reinforce prosocial skills" (Luczynski & Fahmie, 2017, p. 10). To this end, it should be flexible, and not promote a strict adherence to the original 13 skills. Finally, it is important to evaluate the preventative validity of PLS, especially if PLS is to have a seat at the table with other early childhood prevention programs. We have little data to suggest that teaching these skills will reduce the likelihood that children will develop problem behavior over time.

Teaching Method

BST is the most common procedure used to teach PLS. There are several advantages to using BST. It is: (1) evidence-based and incorporates several components of effective instruction, (2) "low-tech" in that it is low-cost, requires no devices or internet access, is easy for teachers to learn, and can be implemented immediately (Twyman & Heward, 2016), (3) flexible in that it can be delivered in a variety of settings, with groups of children of different sizes, and can accommodate a variety of modifications, and (4) highly acceptable as reported by teachers and parents on social validity assessments (see Kirkpatrick et al., 2019 for a brief review of using BST with teachers and Gunning et al., 2018, 2020; Luczynski & Hanley, 2013; Hanley et al., 2007 for PLS-specific examples).

Moreover, BST is compatible with the primary group-instruction period in preschools and child care centers: circle time. Circle time is a ubiquitous preschool practice; it typically occurs first thing in the morning, and involves children sitting in a semi-circle around a teacher, moving through various activities related to early learning goals. In the 2007/2014 studies, and in several of the replications (e.g., Gunning et al., 2018; Robison et al., 2020), researchers used circle time to conduct the initial BST. It looks like this: the teacher presents the particular skill to the children, perhaps provides a rationale, models the evocative situation and the target skill, and then moves around the circle practicing with each child and delivering differential consequences. Following this class-wide instruction, children are directed to participate in typical center-based activities, evocative situations are contrived or occur naturally, and feedback is delivered depending on the child response. This process continues until the mastery criteria are met.

There have been both minor and more significant modifications to the standard teaching procedure since the 2007/2014 studies. Minor modifications include withholding experimenter attention following errors (extinction; Luczynski & Hanley, 2013), incorporating "booster" sessions following skill and unit probes (Gunning et al., 2018; Robison et al., 2020), introducing visual cues to prompt responding (Falligant & Pence, 2017; Luczynski & Hanley, 2013; Robison et al., 2020), accepting modified vocal responses for children with speech deficits and delays (Falligant & Pence, 2017; Robison et al., 2020), and introducing tangible and edible reinforcers (Falligant & Pence, 2017; Gunning et al., 2018; McKeown et al., 2021).

Of note, many of the modifications listed above were designed to facilitate skill acquisition in children with developmental disabilities. An emerging theme of recent PLS research is how children with disabilities respond differently to the "standard" PLS procedures compared to neurotypical children. In the 2007/2014 studies, children who attended a university-based and Head Start classroom, respectively, participated, and, with the exception of two children diagnosed with developmental delays (one in each study), all children were neurotypical. Because both studies were designed as class-wide interventions, there were no systematic measures to improve performance in either child; however, Hanley et al. (2007) noted that the child with developmental delays did experience more teaching opportunities than other participants. Both children showed modest improvement in PLS. As mentioned earlier, Hanley et al. (2007) noted that future research should evaluate the procedures with children with disabilities. Ten years later, Falligant and Pence (2017) published their study examining a tiered instruction model on eight children with developmental disabilities. This was followed by a similar study with nine children with disabilities (Robison et al., 2020), a parent training study with seven children with ASD (Gunning et al., 2020), a study with a 5-year-old girl with a symptoms consistent with attention-deficit/hyperactivity disorder (ADHD) (Víðisdóttir & Sveinbjörnsdóttir, 2021), and the friendship study mentioned above which included two children with ASD (McKeown et al., 2021). The authors of these studies all noted that modifications were needed to promote acquisition and, in those that measured them, generalization and maintenance.

A more sophisticated modification of the standard BST procedure, primarily used in studies with participants with developmental disabilities, follows a recommendation from the original authors to vary the "dose" of instruction to match individual need; or, to arrange the instruction to be delivered on a continuum of least to most intensity or intrusiveness. When considering the heterogeneity of preschool and early childhood classrooms, it is likely that not all children will learn all skills via class-wide instruction, even if they are all neurotypical. Thus, incorporating a model that provides tiers of instruction might be a good solution to maximizing outcomes. Enter the response to intervention (RTI) model—a process of modifying instruction for students not making adequate progress during regular classroom instruction by providing increasingly intensive support (National Center on Response to Intervention, 2007). RTI is an evidence-based model commonly applied in public school classrooms that provides three levels of support, ranging from least to most. Within Tier 1, all children experience the same class-wide instruction. Children who do not show adequate progress move to Tier 2, in which they will receive targeted interventions, usually in a small group. Students needing more support are moved to Tier 3, and are provided with individualized, intensive intervention.

There may be many ways to apply an RTI model to PLS, but the most common way evaluated in the literature is, as mentioned above, to vary the "dose" of instruction defined primarily by the group size within which the instruction is delivered. Luczynski and Hanley (2013) were the first to modify class-wide BST by delivering instruction to the children in a small-group context with no more than three children in an instructional group. These children did not experience the progressively "tiered" approach inherent in RTI; nonetheless, this study was the first example to show how PLS can be delivered in a smaller, more supportive setting. Falligant and Pence (2017), Gunning et al. (2018) and Robison et al. (2020) included tiered approaches to instruction to ensure that all children learned all skills. In these studies, participants had the opportunity to first learn the skills in a class-wide format (Tier 1). If any did not meet the mastery criterion, they moved into either a small-group or individualized format. The small-group, or Tier 2, intervention format varied only by the number of children participating. The individualized, or Tier 3, instruction was unique in each study. Gunning et al. replicated the teaching procedure across all tiers of instruction (thus, tiers only varied by group size). Falligant and Pence introduced a prompt delay procedure in Tier 3, in addition to individualized modifications (modified response topographies, edible reinforcers, visual prompts, and less stringent acquisition criteria). Robison et al. used a progressively increasing intertrial interval approach (PITI, Francisco & Hanley, 2012) in tier 3, during which evocative situations were presented at 3, 10, 30 s, 2, 4, and 16 min after the termination of the previous trial. These Tier 3 approaches were successful in teaching all PLS to all participants in the Gunning et al., and Robison et al. studies, and all but one participant in the Falligant and Pence study.

In a unique application of PLS, Víðisdóttir and Sveinbjörnsdóttir implemented PLS with a 5-year-old girl with symptoms consistent with ADHD. Because she was the only participant, the experimenters implemented one-to-one instruction (consistent with Tier 3) from the start. Additionally, they conducted the one-to-one teaching in a separate classroom, relatively free from distractions, and probed for mastery in her regular classroom with other children present. They found that the participant acquired eight PLS (instruction following, functional communication, and tolerance of delays and denials) using the BST procedures originally described by Hanley et al. (2007). However, the participant received a relatively larger number of teaching opportunities (578 across all skills), suggesting that some children with special needs may acquire PLS given a higher dose of the original procedures. Interestingly, both parents and teachers reported a lower number of ADHD symptoms (inattention, hyperactivity-impulsivity) following the intervention. Future research should further explore the utility of the PLS program for children with this common diagnosis.

A final noteworthy variation of the standard teaching procedure is teaching parents, rather than teachers, to use PLS at home. Gunning et al. (2018) taught parents of both neurotypical children and children with autism to use PLS to improve prosocial skills. The authors found that BST was effective in teaching parents to deliver PLS to both groups of children; however, children with autism needed more modifications. Further, the effects generalized to a classroom setting for the neurotypical children. This is a critical extension of the classroom PLS research. Parents of children with disabilities are less likely to access quality early childhood programs than parents of neurotypical children for several reasons: (1) unwillingness of caregivers to accept children with disabilities, (2) transportation and logistical barriers, (3) difficulties coordinating early intervention and child care services, (4) lack of appropriately trained providers, and (5) cost (Novoa, 2020). Teaching parents to use PLS at home gives them a tool to promote important prosocial behavior while their children are young. Further, even if children are in early childhood programs, teaching parents to use PLS is likely to facilitate generalization and maintenance of the intervention effects.

So, what do we know? BST is an effective strategy to teach class-wide PLS and it seems to be highly compatible with instructional routines in early childhood and preschool programs. Modifications to instruction will surely be needed if all children in a classroom, particularly those in inclusion and special education classrooms, are to acquire all skills. Researchers should carefully document these strategies to aid clinicians in the problem-solving process. Delivering instruction using RTI is a promising approach to maximizing acquisition for all children; plus, aligning PLS with a traditional framework might help with the dissemination of PLS to mainstream early childhood settings. Future studies might address the feasibility and efficiency of a multi-tier approach.

Generalization and Maintenance

The question as to whether class-wide BST, modified as needed, is effective in teaching children PLS has been convincingly answered. The extent to whether the effects maintain over time and generalize to novel contexts, however, has not. This is a critical area for future research, particularly because PLS is promoted as a preventative early childhood curriculum. If skills learned in preschool do not follow children through kindergarten and beyond, PLS is unlikely to prevent problem behavior. Stokes and Osnes (1989) outlined specific tactics to promote stimulus generalization across three broad categories: use of functional contingencies, training diversely, and including functional mediators. Although it was not assessed, the original study included several of these tactics to promote generalization: (1) teaching responses likely to contact naturally reinforcing consequences, (2) programming multiple exemplars by including different adults and peers and teaching across different activities at different times of the school day, and (3) incorporating common stimuli in the teaching session (Luczynski et al., 2014).

Luczynski et al. (2014) expanded these tactics to assess the extent to which the self-control skills they taught in a previous study (Luczynski & Hanley, et al., 2013) maintained over a 3-month period and generalized to new teachers and classrooms. They made modifications to train more "loosely" than researchers in the original study by adding unsignaled delays and denials (e.g., a teacher ignoring an appropriate request for attention) with vague cues (e.g., a teacher shaking her head instead of delivering a vocal cue to wait following an appropriate request) and incorporating longer delays to reinforcement. In almost all cases, generalization was initially observed, but declined after a few trials. It was not until they provided additional training to the generalization teacher on the specific skills the children were learning and how to respond to them that they observed satisfactory levels of generalization. Similarly, partial maintenance was observed after 3 months, but increased to high levels once the experimenters trained teachers using the same technique.

Similarly, McKeown et al. (2021) evaluated the extent to which friendship skills generalized to a novel same-aged peer. They also found that generalization was fleeting and it took adult feedback to participant responses following evocative situations to observe acceptable friendship skills to a peer. Subsequent studies obtained mixed results after assessing generalization and maintenance. In their pilot study replication of PLS, Gunning et al. (2018) observed some degree of maintenance and generalization to a new caregiver. In their 2020 study, Gunning et al. found that children who learned PLS from their parents at home were able to demonstrate many of them in their preschool.

Although programming tactics to promote generalization and maintenance appear helpful to improve the durability of responding (e.g., Luczynski et al., 2014), it seems that "priming" the novel instructional environment holds the most promise to facilitate long-term generalization and maintenance. This includes preparing teachers and peers to continue to deliver evocative situations and provide reinforcement and error correction. How often and for how long is unknown and future research should begin to evaluate variables that influence the extent to which teachers should continue with these practices. With respect to peers, there is tentative evidence that peer mediation may be helpful. Beaulieu et al. (2013) showed that peer prompting and feedback improved short-term maintenance. Peer mediation should continue to be studied as a tactic to promote generalization and maintenance.

PLS holds promise for building kind, caring, and nurturing classroom cultures. The studies discussed above show that children with and without disabilities can learn these skills, and with support, can demonstrate them in novel settings with new friends and teachers. Further, parents and teachers find PLS to be highly acceptable and the outcomes meaningful (e.g., Gunning et al., 2018, 2020; Hanley et al., 2007; Luczynski & Hanley, 2013). PLS is only one of many programs designed to promote prosociality and prevent the development of problem behavior. In the second part of this chapter, we will discuss some of the more common and well-established prevention programs and how PLS might be complimentary to them. We also take a closer look at the evidence to support PLS as a preventative program and end with a discussion of other considerations related to problem behavior prevention.

Part Two: Comparison to Popular Programs and Evaluation as a Prevention Program

Other Problem Behavior Prevention Programs

As noted above, the goal of PLS is to increase adaptive social and interpersonal skills and reduce the likelihood of the development of problem behavior. While PLS has a unique standing within the field of applied behavior analysis (ABA), several programs with similar goals (e.g., teaching social and emotional skills) have originated in other fields (e.g., education and psychology). Some of the more popular of these programs have been evaluated in randomized controlled trials and found to reduce behavior problems and improve social behavior and academic outcomes (Jones et al., 2017). As an example, *The Incredible Years* (Reinke et al., 2018) consists of a group of programs aimed at parents, teachers, and children, focusing both on universal prevention and risk factors associated with particular diagnoses (e.g., ASD, ODD/CD, and ADHD). The programs are based on developmental theory, and aimed jointly at promoting "…emotional, social, and academic competence and to prevent, reduce, and treat behavioral and emotional problems in young children" (The Incredible Years, 2020). The programs rely on video vignettes and trained facilitators for implementation. The parent and teacher training programs focus on aspects such as proactive strategies, relationship-building, effective use of praise and other incentives, how to react to problem behavior, how to teach and promote empathy, social skills, and problem solving. The overall goals include teaching "emotional literacy," empathy and perspective-taking, friendship skills, problem solving, anger management, and rule-following (Webster-Stratton, 2017).

I Can Problem Solve (ICPS; also known as *Interpersonal Cognitive Problem Solving*) (Boyle & Hassett-Walker, 2008) is another program with similar content and goals. Based on the conceptual systems of *Social and Emotional Learning,* the program is focused on reducing impulsivity, and improving problem solving and social skills (I can Problem Solve, 2021). A distinctive aspect of ICPS is the concept of *Dialoguing,* which describes different kinds of two-way communication strategies between an adult and child regarding a challenging situation. The lowest level of dialoguing is the "power approach" in which adults provide direct demands or directives to the child, and the highest level is the "problem solving approach", in which the adult prompts the child through a process to find potential solutions to the challenging situation. ICPS includes separate programs for preschool, kindergarten and primary grades, and intermediate elementary grades. As an example, the preschool program includes 59 brief (5–10 min) scripted lessons for teachers, to be delivered 2–3 times per week over 3–5 months, in a small group of 10 children or fewer. The lessons focus on "pre-problem solving skills" such as "feelings and preferences" and "listening and paying attention", as well as problem solving skills labeled as "alternative solutions thinking" and "consequential thinking." For each age group, ICPS offers strategies for teachers to integrate the lessons into curricular content. Finally, ICPS also offers a curriculum for parents: *Raising a Thinking Child.* Completion of 2-day training by ICPS-approved trainers is required for implementing the programs.

The above-mentioned programs, along with similar programs such as *PATHS* (Domitrovich et al., 2007), *Second Step* (Upshur et al., 2019), and *Tools of the Mind* (Barnett et al., 2008), could be viewed either as alternatives or complements to PLS. There is some overlap in the targeted skills and instructional strategies between PLS and many of these programs. For example, PLS focuses on broadly similar interpersonal skills and self-control/self-regulation skills (i.e., tolerance for delays and denials) as several other programs (e.g., ICPS, PATHS). Further, PLS incorporates instructional strategies that are common to other programs, such as a didactic component (i.e., circle-time in PLS), role-play, and visual prompts (Jones et al., 2017). However, several important features set PLS apart. First, while PLS includes a fixed set of skills drawn from the behavioral literature on functional assessment of problem behavior and functional communication training (FCT), it also incorporates teacher preference in selecting skills that are perceived as important in elementary school. Second, PLS incorporates repeated practice of objectively defined skills to a greater extent than other programs and emphasizes embedding these practice opportunities into challenging contexts in a programmatic way. As an example, the primary instructional strategy used in ICPS is discussion (used in 63% of activities), with some role-play (23% of activities), but no activities including skill practice (Jones et al., 2017). In contrast, the majority of instruction in PLS consists of direct skill teaching and practice. Finally, PLS relies more explicitly on direct observation data to evaluate mastery and assign children to tiered and individualized instruction.

PLS has unique strengths that are not found in other programs aimed at pro-actively building a pro-social repertoire and preventing problem behavior. Importantly, it involves deliberately arranging challenging contexts that are likely to evoke problem behavior, and teaching desirable alternative behavior in these contexts. It involves repeated practice with modeling and feedback, and the possibility of teaching each skill to mastery using tiered and individualized instruction as needed. Further, determination of mastery, maintenance, and the need for additional tiers and individualized teaching is based on direct observation data. PLS is, however, relatively more limited in scope in terms of the number and complexity of skills that are included (cf., the Incredible Years program). The social-emotional learning programs discussed above typically involve a greater number of relatively complex problem-solving skills, as well as skills that are more precisely tailored to particular developmental levels. Further, these programs often have a more extensive didactic and discussion-based components, which may be more appropriate for slightly older children. Instead of pitting these two approaches against each other, it seems possible to design a comprehensive curriculum for problem behavior prevention that combines the strengths inherent in both ABA and social-emotional learning.

PLS and Prevention of Problem Behavior

PLS can help reduce challenging behavior and improve socially important appropriate behavior in the short run, as shown in multiple studies (e.g., Hanley et al., 2007; Robison et al., 2020). However, one of the ultimate goals of PLS is to prevent the development of problem behavior in future environments. To the best of our knowledge, only one study on PLS has directly addressed this question (briefly mentioned in a previous section, but described in more detail here). Luczynski and Hanley (2013) conducted a study with 12 preschool children between the ages of three and five who were nominated by their teachers due to concerns with emerging problem behavior and lack of self-control and communications skills. These children were randomly assigned to a test and control group. The experimenters taught three PLS to the children in the test group: requesting attention, requesting materials and assistance, and delay and denial tolerance. Meanwhile, the children in the control group participated in free-play sessions in which adult attention and high-quality play materials were noncontingently available. Prior to and following the intervention, both groups participated in probe sessions in which the experimenters presented evocative situations (typical of other PLS studies) but did not prompt or follow through with the life skills. As an example, the experimenters would deliver an item after a delay, regardless of behavior during the delay (correct life skill, problem behavior, or error of omission). These probes were meant to simulate conditions under which problem behavior might be likely to emerge in the absence of a PLS repertoire. During baseline probes, children in neither group emitted any of the PLS, and the test group was slightly more likely to engage in problem behavior. Following the intervention, only the test group was found to reliably emit the PLS. More importantly, the mean level of problem behavior decreased to zero for the test group, while all the children in the control group engaged in problem behavior in the post-test, with a mean of over 50% of trials. These results suggest that establishing a repertoire of PLS can reduce the probability of problem behavior emerging when challenging (evocative) situations are presented. Thus, this study provides important evidence for the effectiveness of PLS to prevent the emergence of problem behavior, at least in the short term.

Additional literature on the prevention of problem behavior Independent of the PLS framework, several authors within the fields of ABA and positive behavior support have written about the importance of preventing problem behavior (Ala'i-Rosales et al., 2019; Dunlap et al., 2001, 2006; Powell et al., 2006; Williams et al., 2016). However, apart from general recommendations, little research has focused specifically on prevention. A notable exception is a study by Reeve and Carr (2000), who identified eight children (ages 3–5) with developmental disabilities who were reported to engage in minor problem behavior (e.g., whining to get someone's attention). Similar to the study by Luczynski and Hanley (2013), the authors randomly assigned the children into two groups. The treatment group received FCT, while the control group received expressive language instruction. The FCT intervention consisted of training the children's teachers to teach them to appropriately request attention, for example, by tapping the teacher on the arm and saying "Look what I'm doing!" This skill is similar to the one targeted in PLS, which is not surprising given the common influence of the FCT literature (e.g., Carr & Durand, 1985). However, Reeve and Carr's intervention lacked the structure of PLS, particularly the deliberately planned and contrived evocative situations that are characteristic of the approach. Instead, Reeve and Carr trained their teacher participants to prompt the responses during naturally occurring opportunities, to minimize attention (and continue to periodically prompt) during problem behavior, and to maximize their attention when the appropriate functional communication responses occurred. The authors found that with only one exception, the number of intervals of problem behavior, as well as the intensity of the behavior, was more likely to increase over repeated sessions for the children in the control group than the children in the FCT group. Thus, teaching simple functional communication responses, per se, may decrease the likelihood that relatively mild problem behavior escalates in frequency and intensity over time. These results are consistent with the results of Luczynski and Hanley (2013), albeit less robust, possibly due to the absence of planned evocative situations and standard instructional procedures (e.g., BST).

In recent years, Tara Fahmie and colleagues have published a series of innovative translational studies on the early emergence and potential prevention of problem behavior (Fahmie et al., 2016, 2018, 2020). The general purpose of this line of research is twofold: first, to identify evocative environmental conditions that occasion emerging problem behavior (i.e., mild problem behavior that might become more intense and frequent if reinforced over time), and second, to evaluate procedures (e.g., differential reinforcement of alternative behavior) that might prevent these emerging behaviors from becoming more severe with repeated exposure to the evocative environmental conditions. This line of research has the potential to strengthen the empirical basis of PLS by (a) providing further evidence for the validity of the evocative situations included in PLS, (b) identifying potential alternative evocative situations to include in future versions of PLS, (c) developing a process for individualizing evocative situations, and (d) evaluating the effectiveness of differential reinforcement procedures (DRA) to prevent the development of severe problem behavior.

In the first of these studies, Fahmie et al. (2016) conducted "sensitivity tests" with a 20-year-old man with autism who did not have a history of severe problem behavior, but had been identified as being at risk at developing problem behavior evoked by restricted access to preferred items. These sensitivity tests were similar to the trial-based functional analysis (Bloom et al., 2011; Sigafoos & Saggers, 1995). The sensitivity tests are similar to the evocative situations of PLS in that they involve systematically programming challenging environmental conditions that might evoke problem behavior. The authors conducted five different sensitivity tests: Restricted access to preferred items, removed access to preferred items, blocked access to preferred items, a work-task (silverware sorting), and a request-access test (i.e., the experimenter requested the item while the participant had access to it). After initial screening trials, the authors conducted repeated sessions in which both appropriate behavior (e.g., requests for preferred items) and mild problem behavior were intermittently reinforced and severe problem behavior was reinforced on an continuous schedule (in order to simulate reinforcement schedules that are likely to operate under naturalistic conditions). The authors found that problem behavior reliably occurred in the first four conditions. Further, in the restricted-access and removed-access test conditions, problem behavior seemed to get gradually worse over repeated sessions. The authors then implemented the intervention, referred to as "FCT Inoculation" (implying that the intervention should inoculate the individual against reinforcement contingencies that maintain problem behavior) in a staggered manner across the restricted-access and removed-access test conditions. The intervention consisted of teaching the individual to appropriately request the preferred items. The authors observed a post-intervention reduction in the problem behavior under both conditions, even as the reinforcement schedules for both appropriate behavior and problem behavior remained unchanged. Further, these effects generalized to the third condition (blocked access) without direct intervention. This study provides preliminary evidence that FCT, very similar to that included in PLS, can prevent the development of problem behavior under conditions in which problem behavior is likely to contact reinforcement.

To further evaluate the generality of the sensitivity tests, Fahmie et al. (2020) conducted a study with 21 typically developing children between the ages of 4 and 6. These children were included in the study due to teacher reports of moderate (but not severe) problem behavior. Similar to Fahmie et al. (2016), the sensitivity tests were based on common test conditions included in functional analyses of problem behavior (Hanley et al., 2003) and consisted of test for attention, escape, and tangible functions. In addition to problem behavior, the researchers measured appropriate requests evoked by the sensitivity tests (e.g., "Excuse me, I want my toy back"). The authors found that 86% (18/21) of the participants engaged in mild or moderate problem behavior (e.g., grabbing items, loud vocalizations, facial expressions of disgust) evoked by one or more of the test conditions. The tangible condition was most likely to engender problem behavior, which is noteworthy, because it has typically been found to be among the least common functions of problem behavior in reviews of the functional analysis literature (e.g., Beavers et al., 2013). This may be a reflection of a population difference, as most published research on functional analysis of problem behavior has been conducted with individuals with developmental disabilities. It is also noteworthy, especially when considering the purpose of the PLS program, that only 52% (11/21) of the children engaged in appropriate requests during sensitivity tests. Overall, 71% of the children engaged in problem behavior with no functionally matched appropriate requests, 14% of the children engaged in problem behavior and functionally matched appropriate request, while another 14% showed low levels of both. These findings indicate that (a) the sensitivity tests are capable of detecting functionally differentiated emerging problem behavior in typically developing children, (b) the majority of these children (71%) are likely to engage in emerging problem behavior at the exclusion of appropriate requests when evocative contexts are presented, and (c) only about half of the children engaged in functionally relevant appropriate requests at all. These results provide evidence for the validity of the sensitivity tests, as well as potential way to individualize skill instruction based on the results on these tests.

In order to more systematically evaluate DRA as a prevention strategy, Fahmie et al. (2018) conducted a translational study with 48 undergraduate college students who responded by clicking on squares presented on a computer screen. While such studies lack ecological validity, they allow researchers to more precisely control environmental conditions and program reinforcement contingencies for arbitrary responses that serve as analogs for problem behavior and appropriate alternative behavior. The participants were randomly assigned to one of three groups: Control, DRA, and NCR. In each condition, they were presented with a screen consisting of 320 squares, one of which was designated as the target square (analog for problem behavior). In baseline (all participants), clicks on the target square were reinforced on an FR1 schedule, while clicks on any other square had an overall 0.33 probability of being reinforced (reinforcers were points that could be exchanged for a gift card). This was meant to simulate conditions in which problem behavior would be unlikely to develop. The control condition, in contrast, was designed to simulate a naturalistic conditions in which problem behavior is gradually shaped by prevailing contingencies. Based on where on the screen participants had been most likely to click in the baseline, the computer program (using percentile schedules) automatically adjusted the probability of reinforcement such that clicks closer and closer to the target square were differentially reinforced. This was meant to simulate the process in which a caregiver unsuccessfully attempts to extinguish problem behavior, but ends up inadvertently shaping up the intensity, frequency, or duration of the behavior instead (e.g., an extinction burst results in escalation in behavior to the point that the caregiver has no choice but to "give in" and deliver reinforcement). The results of the control condition were compared against two conditions that simulated intervention: DRA and NCR. In the DRA condition, a percentile schedule was used in the same manner as in the control condition, except that responses closer and closer to the square representing alternative behavior were reinforced. This square was located in the opposite corner of the screen from the target square. Finally, in the NCR condition, points were delivered for clicking on any square, but point delivery for each participant was yoked to randomly selected participants in the DRA condition. This was meant to simulate conditions in which caregivers deliver frequent reinforcers independent of behavior. The experiment concluded with a test condition which was identical for all groups. In this condition, only clicks to the square were reinforced, which simulates an environmental condition in which problem behavior should be likely to develop, because it is the only way to obtain reinforcement.

The results of Fahmie et al. (2018) showed that 100% of participants in the control group developed "problem behavior" (i.e., clicking on the target square). However, only 24% of participants in the DRA group and 8% in the NCR group developed problem behavior. It is important to note that the differences between the control group and the two experimental groups were statistically significant, the difference between the two treatment groups was not. While it might be tempting to conclude that these results demonstrate that noncontingent reinforcement is an equally good prevention strategy as DRA, this would be a premature assumption, because the NCR procedure employed in this study was fundamentally different from other studies employing such procedures. Typical NCR procedures entail response-independent stimulus presentation in which stimuli are delivered either on a time-based schedule (e.g., Vollmer et al., 1993) or are continuously available, independent of responding (e.g., Hernandez et al., 2007). In contrast, the NCR schedule employed by Fahmie at all involved reinforcing *any response*. Therefore, it was perhaps functionally more akin to a DRA procedure in which multiple response topographies are reinforced. Nevertheless, the overall results are consistent with previous research (e.g., Fahmie et al., 2016; Luczynski & Hanley, 2013; Reeve & Carr, 2000), suggesting that establishing alternative responses can reduce the likelihood of the development of problem behavior, even when contingencies favor problem behavior over alternative behavior. Thus, these results provide some indirect support for the utility of the PLS approach.

Future research on the prevention of problem behavior As discussed above, a small number of studies provide direct and indirect evidence for the general preventative approach inherent in PLS (e.g., Fahmie et al., 2016, 2018; Luczynski & Hanley, 2013; Reeve & Carr, 2000). This general approach can be summarized as teaching and differentially reinforcing appropriate alternative responses under conditions in which problem behavior would otherwise be likely to emerge. The available evidence suggests that this kind of intervention can indeed reduce the likelihood of the development of problem behavior in the short run. However, more research is needed to evaluate the extent PLS prevents problem behavior under different conditions, with different populations, and over longer periods of time. For example, future research could focus on the effects of teaching tolerance to delays and denials on the probability of development of problem behavior in environments in which delays to reinforcement are frequent and unpredictable. This may be a particularly important line of research with children with developmental disabilities, for whom delays and unpredictable availability of preferred items and activities are especially challenging. The friendship-skills component of PLS also needs additional empirical work, and future research could evaluate whether learning these skills is likely to reduce bullying and social isolation in preschool and elementary school.

To evaluate the preventative effects of PLS, additional short-term research similar to the study by Luczynski and Hanley (2013) is needed, along with larger scale research that spans longer periods of time. For example, researchers could employ randomized controlled trials to compare long-term performance of groups of children who did and did not receive PLS while in preschool. To achieve this, researchers would have to follow the children through the first few grades of elementary school and employ multiple measures of academic achievement and social competence, as well as direct and indirect measures of problem behavior. Finally, longitudinal follow-up through adulthood could shed light on broader outcomes of the PLS program.

Even though these studies have yet to be conducted, available evidence can guide practitioners in the meantime. As Ala'i-Rosales et al. (2019) pointed out, the literature on the functional analysis of problem behavior and FCT is large and fairly robust, which means that as a field, we know a lot about the conditions that are likely to evoke and maintain problem behavior as well as how to teach appropriate behavior to replace it. This knowledge provides a strong base on which to build programs to prevent problem behavior, as shown by the PLS program.

Other components of comprehensive prevention programs PLS and other similar programs primarily focus on building specific skills and repertoires to ward against the development of problem behavior when contingencies may favor its occurrence. However, it is likely that attention to broader aspects of behavioral repertoires, as well as the design of healthy environments, is also important to maximize the effectiveness of such programs. While a thorough discussion of these issues is outside the scope of this chapter, we will briefly mention a few components. First, it is very likely that a strong repertoire of healthy leisure skills plays an important part in preventing the development of problem behavior, in part because these skills result in enriched lives with increased opportunities for positively reinforcing experiences (Ala'i-Rosales et al., 2019). Second, a broader array of skills that encompass self-control, delay to gratification, and problem solving is likely important for long-term success in most naturalistic environments (i.e., skills that build on the tolerance component of PLS). Third, effective instructional strategies that result in acquisition of basic life and academic skills are likely to reduce the occurrence of problem behavior maintained by escape from demands (Williams et al., 2016). Fourth, various aspects of environmental design are likely to reduce the likelihood of problem behavior, such as: (a) enriched environments that include preferred items and activities, (b) healthy contingencies, in which appropriate behavior is more likely to "pay off" than problem behavior, (c) some level of noncontingent reinforcement, such as attention that is not contingent on any particular behavior, (d) multiple opportunities for making choices, and (e) proactive, clear, and fair rules and expectations (Dunlap et al., 2001, 2006; Powell et al., 2006; Williams et al., 2016).

Conclusion

For decades, behavioral researchers have focused on treating existing problem behavior (Fahmie et al., 2018). This research has not only resulted in the discovery of efficacious function-based treatment procedures, but has also revealed the conditions which reliably produce problem behavior in individuals. PLS offers parents, teachers, and clinicians a way to arrange these conditions safely and early-on in a child's life, and a procedure to teach replacement behavior—perhaps before problem behavior is ever observed. We can imagine a world in which PLS has been adopted in every early childcare setting and children entering Kindergarten are good friends, responsible citizens, and prepared to become successful scholars. There is much to be done before we get there. Some of the most critical work includes: identifying tactics to reliably produce generalization and maintenance, packaging and manualizing PLS to promote dissemination and adoption, and in recognizing the many other evidence-based prevention programs, researching how to combine them to produce a more sophisticated, comprehensive prevention curriculum that could span through the elementary years and make a meaningful difference in the lives of children and their families.

Treating Mealtime Difficulties in Children

39

Melanie H. Bachmeyer-Lee, Caitlin A. Kirkwood, and Connor M. Sheehan

Teaching Mealtime and Feeding Behavior

Eating is not only necessary for development and survival; it also plays a major role in human behavior and social interactions. Throughout history, mealtimes have occurred as meaningful social gatherings with friends and family, and most social events include the consumption of food. While most individuals often look forward to the next meal, some individuals face challenges that make eating less pleasurable.

Eating is a complex chain of behaviors and difficulties may arise at any step in the chain, leading to the potential risk of developing a feeding disorder. Eating begins with acceptance of food or liquid into the mouth and the formation of a bolus (i.e., amount of food or liquid) using the tongue. We move the tongue from side to side inside the mouth (tongue lateralization) to manipulate food to be chewed before we again form a bolus in the center of the mouth. We then propel the food or liquid to the back of the mouth, swallow it, and retain it (Arvedson & Brodsky, 2002). One may exhibit problems at different points in this chain. For example, a child may turn his or her head or cover his or her mouth when a caregiver presents a bite, preventing food from being accepted or deposited into the mouth. A child may accept bites into his or her mouth but expel (spit out) the food or have difficulty lateralizing and chewing the food and hold the food in his or her mouth (packing or pocketing bites). Persistent difficulties at any step in the behavior chain may lead to dysfunctional patterns of eating that without intervention may result in long-term eating problems.

Diagnosis

Many children exhibit problematic mealtime behavior that resolves naturally over time, such as picky eating during the toddler years (Cermak et al., 2010). However, some children exhibit persistent feeding difficulties that warrant intervention (Mascola et al., 2010). Feeding disorders are heterogenous and encompass a wide range of dysfunctional patterns of eating. Some children exhibit selective consumption by food type, texture, brand, color, presentation format, or a combination of these factors (Bandini et al., 2010). For example, some children may eat a limited number of foods within or across food groups, refuse entire food groups (e.g., vegetables), eat only smooth foods (e.g., baby food or yogurt) or crunchy dissolvable foods (e.g., crackers and chips), or eat only a specific brand of foods (e.g., chicken nuggets only from McDonald's™).

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_39

Whereas other children may consume only limited quantities or refuse all food or liquid. Additionally, some children may lack the skills that allow them to eat or drink independently during meals. It is not uncommon for a pediatric feeding disorder to result as the manifestation of some combination of these difficulties.

Children born prematurely, with developmental or genetic disorders, or complex medical conditions are at greater risk for developing feeding difficulties (Arvedson & Brodsky, 2002; Burklow et al., 2002; Manikam & Perman, 2000). It is estimated that feeding disorders occur in 2–35% of typically developing children and up to 80% of children with developmental disabilities (Bachmeyer, 2009; Williams et al., 2005). The range in reported prevalence rates is likely due to the wide range of difficulties and clinicians and researchers using different definitions for diagnosis (Piazza, 2008). A feeding disorder is often diagnosed when these difficulties result in inadequate nutrition, failure to maintain or gain weight, and/or dependence on supplemental means of nutrition, such as enteral feeds or high calorie formulas beyond an age that is appropriate (Bachmeyer, 2009; Piazza, 2008). However, several terms have evolved to describe feeding difficulties in children including failure to thrive, infantile anorexia nervosa, and posttraumatic feeding disorder, which each encompass a different range of dysfunctional feeding. Most recently, the category of "Feeding and Eating Disorders" in the DSM-V (American Psychiatric Association, 2013) contains diagnostic criteria for Avoidant/Restrictive Food Intake Disorder (ARFID) which is diagnosed when an individual exhibits a feeding disturbance that inhibits their ability to meet their nutritional needs. A feeding disturbance may manifest as a disinterest in food or eating, avoidance of certain foods based on characteristics of the food (e.g., texture, color), or concern for aversive consequences that may be associated with eating (e.g., dysphagia). Persistent failure to meet appropriate nutritional and/or energy needs is characterized by at least one of the following: significant weight loss, significant nutritional deficiency, dependence on enteral feedings or oral nutritional supplements, and/or psychosocial functioning interference.

Etiology

Feeding disorders are as heterogeneous in the factors leading to their development as they are in their presentation. Some combination of co-occurring medical, oral-motor, and behavioral concerns often contribute to the development and maintenance of feeding disorders (Rommel et al., 2003). Medical factors that may contribute to feeding difficulties include gastrointestinal problems (e.g., gastroesophageal reflux disease [GERD], eosinophilic esophagitis (EoE), constipation, motility disorders), anatomical anomalies (e.g., cleft palate), neurological conditions (e.g., cerebral palsy), and food allergies or intolerances (Field et al., 2003; Piazza, 2008). For instance, a child with untreated GERD may experience pain following meals when the gastric contents pass from the stomach into the esophagus (Rybak et al., 2017). This painful experience may lead to the child refusing some or all foods and/or liquids in the future to avoid the painful experience he or she has after eating (classical conditioning). The child may refuse to eat or drink by exhibiting inappropriate mealtime behaviors (e.g., covering the mouth, turning away from or pushing away food or drink presentations), expelling (spitting out food or liquid), or packing (holding food or liquid in the mouth).

Oral-motor factors, such as problems with lip closure or tongue movement, delayed chewing skills, difficulty swallowing (i.e., dysphagia), or structural impairments, may also contribute to feeding difficulties (Field et al., 2003). A child with dysphagia may experience pain when swallowing certain foods or liquids or may cough and gag excessively during meals (Arvedson, 2008). Similar to a child experiencing pain from reflux after eating, a child may also begin to refuse foods and/or liquids to avoid the discomfort associated with painful swallowing (classical conditioning). Additionally, if a child has delayed skills at any point in the chain of eating, the child may refuse certain foods or liquids or refuse eating all together. For example, children with immature patterns of chewing may exhibit inappropriate mealtime behavior or expel food that is not masticated if they are unable to efficiently chew their food. Children with delayed oral motor skills often refuse to eat toward the end of meals with higher textured foods due to fatigue because the effort associated with eating becomes too high. Furthermore, children who are dependent on liquids or enteral feeds for their nutrition may miss opportunities to develop more advanced oral-motor skills, such as chewing or lateralization.

Inappropriate mealtime behavior may be maintained or worsen as a result of the consequences provided after it occurs in the natural environment (operant conditioning). That is, caregivers often deliver consequences following inappropriate mealtime behavior that may be effective for children without feeding difficulties but reinforce the inappropriate mealtime behavior exhibited by children with feeding difficulties. Caregivers may deliver attention in the form of coaxing ("Peas are so yummy"), comforting ("You're okay"), or reprimanding ("Don't push the spoon away"); provide escape by removing the food or drink or ending the meal; and/or deliver highly preferred toys or foods to try to motivate the child or ensure that they consume something. For example, a child may exhibit inappropriate mealtime behavior when the child's caregiver tries to feed him or her a nonpreferred food. If the caregiver responds by removing the nonpreferred food and providing the child with a preferred food, the child may learn that exhibiting inappropriate mealtime behavior results in removal of a nonpreferred food (negative reinforcement) and delivery of a preferred food (positive reinforcement). Relief from the child's inappropriate mealtime behavior might lead the caregiver to terminate more meals or provide preferred foods again in the future. Thus, the caregiver's behavior may become maintained by negative reinforcement (in the form of escape from the child's inappropriate mealtime behavior). These repeated interactions between the child and caregiver may ultimately contribute to the long-term maintenance of the child's feeding difficulties.

Associated Problems

Children with feeding difficulties may be at risk for associated medical conditions (Cohen et al., 2006). Dysfunctional patterns of eating can lead to medical conditions, such as lethargy, recurrent infections, constipation, compromised immune systems, high cholesterol, and obesity (Cohen et al., 2006). For example, enteral feedings or consumption of a high-calorie formula can be a good temporary solution, but children may develop infections, vomit more frequently, and undergo multiple surgeries for tube placement or re-placement if they are dependent on enteral feeds for long periods of time. Children with feeding disorders may also be at risk for delayed cognitive and social development (Piazza, 2008; Volkert & Piazza, 2012). Severe malnourishment may impair adequate brain development and lead to learning difficulties and behavior disorders. Children with feeding difficulties may not be motivated or able to participate in social events or daily activities that involve eating (e.g., school lunches or birthday parties) because the child exhibits problem behavior when food is present or requires an atypical mealtime structure. Children who receive tube-feedings may be subject to social stigma resulting in social isolation from their peers. Spending less time with peers because of these situations may lead to delayed social development.

Caregivers of children with feeding disorders are at risk for increased mental health difficulties and have often reported mental health problems associated with increased stress, depression, and anxiety (Garro et al., 2005; Greer et al., 2008). Caregivers of children who receive tube feedings may be at risk for additional stress related to tube maintenance and frequent visits with specialists (Garro et al., 2005). Feeding disorders may also create a financial burden on families if the child is dependent on tube-feedings, drinking nutritional supplements, or receiving specialized services (Franklin & Rodger, 2003; Greer et al., 2008).

Interdisciplinary Approach

Given the complex etiology, prevalence of co-occurring medical conditions, and range of feeding difficulties, an interdisciplinary approach to the assessment and treatment of feeding disorders is necessary. An interdisciplinary team should include a medical provider (physician or nurse practitioner) with expertise in pediatric gastroenterology, an oral-motor specialist (speech-language pathologist or occupational therapist) with expertise in feeding, a pediatric dietician, and a behavior analyst. All members of the interdisciplinary team play a critical role during assessment and treatment.

The medical provider's role is to rule out or identify and treat any medical conditions that might be contributing to the child's feeding difficulties. The medical provider completes a physical examination of the child and reviews the child's medical history and any test results to determine if medical treatment or additional testing/evaluation is needed. They clear the child to begin feeding therapy, monitor and treat any previously identified or new medical concerns, and coordinate care with the child's other medical providers. For example, if a child is constipated, the medical provider might order an abdominal X-ray, provide caregivers with clean out instructions, and follow-up with the child's pediatrician to provide a medication and care update. Another medical condition seen in children with feeding difficulties is eosinophilic esophagitis (EoE), which is caused by an abnormal immunologic response to specific food antigens that results in irritation of the esophagus and tissue damage (DeZoeten & Markowitz, 2008). Children with EoE often present with symptoms of GERD and dysphagia, but additional medication and dietary restrictions are needed to improve symptoms (Liacouras et al., 2005). Without ongoing medical oversight, serious conditions such as EoE can be overlooked, and when medical problems are not effectively treated, they may decrease the effectiveness of the behavioral treatments and/or worsen the feeding difficulties.

The oral-motor specialist assesses the child's oral-motor skills and safety while eating. They are trained to identify potential risks (e.g., aspiration, difficulty swallowing) and might refer for additional testing prior to treatment (e.g., modified barium swallowing study) to gather more information about the child's specific needs. They provide recommendations for appropriate food texture, liquid consistency, bolus size, and feeding apparatus based on a child's oral motor structure and skills to keep a child safe during intervention. They also identify demands of appropriate effort to ensure the effectiveness of behavioral intervention and create a plan in which oral-motor skills are developed in a systematic way. For example, if a child demonstrates aspiration, the specialist might recommend thickening foods or liquids. If a child who exhibits food selectivity has an immature pattern of chewing, the specialist may recommend an altered food texture based on the child's specific oral-motor skills. It is a common misconception that children who are selective eaters have adequate chewing skills because they consume some table texture foods. However, often, the food selective eaters consume foods that do not require mature oral motor skills, such as soft or smooth foods, starches/carbohydrates that dissolve in saliva, and even processed meats. In fact, Williams et al. (2005) showed that children with special needs had significantly more oral-motor difficulties than other children. It is important that the expertise of an oral-motor specialist also be incorporated throughout behavioral intervention to: (a) inform necessary modifications when oral motor concerns arise during intervention or current treatment plans are not effective, (b) reevaluate the child's oral motor skills when new treatment goals are developed (e.g., increasing food texture), and (c) provide guidance on teaching new oral motor skills (e.g., chewing).

The dietician assesses the child's nutritional status and growth parameters. This is often done through daily logs of the child's diet, medication, and elimination (urination and bowel movement) to help determine the child's nutritional excesses and deficits. The dietician reassesses the child's nutritional status based on their oral consumption and growth parameters throughout treatment and makes quality and quantity recommendations for food and drink items and supplements for each child's growth and health needs.

The behavior analyst conducts assessments to identify environmental variables that contribute to the child's feeding difficulties and uses empirically supported antecedent- and consequence-based treatments to increase appropriate mealtime behaviors (e.g., accepting, swallowing, chewing, self-feeding) and decrease maladaptive behaviors (e.g., inappropriate mealtime behavior, expulsion, packing).

Assessment

Indirect Assessment Methods

The interdisciplinary team gathers information regarding the child's medical, developmental, and feeding histories from the caregiver(s) via questionnaires, interviews, and the child's medical records. The medical history might include the child's medical diagnoses, current medications, growth curves, current heigh and weight, results of medical tests (e.g., swallow study, endoscopy), gastrointestinal symptoms, bowel history, allergies and intolerances, and a review of bodily systems (e.g., ear, nose, and throat; cardiovascular; endocrine; respiratory). The developmental history might include the child's birth history, developmental delays or diagnoses, developmental milestones, and general behavior concerns. The feeding history might include tube-feeding placements and schedule, oral feed schedule, typical mealtime structure (e.g., seating arrangement, average length of meals), feeding milestones (e.g., advancement through textures), current feeding skills (e.g., use of various utensils, self-feeding skills), current oral motor behaviors (e.g., biting off pieces of food, tongue control, swallowing, chewing, coughing, gagging), the variety of food types and textures and liquids consumed, the typical quantity of food and liquid consumed, and goals and results of other therapies.

Descriptive Analysis

A descriptive analysis provides an opportunity for the behavior analyst to observe a natural, unstructured meal to identify antecedent variables (e.g., food type and texture, bite size), appropriate and inappropriate child behavior, and caregiver-delivered consequences (Borrero et al., 2010; Piazza et al., 2003a). For example, Borrero et al. (2010) conducted descriptive analyses of 25 parent–child dyads with histories of feeding difficulties and calculated the conditional probability (i.e., the likelihood of one event given some other event) of the caregiver delivering escape, attention, or preferred foods or drinks and toys following inappropriate mealtime behavior. Results showed that common caregiver responses to inappropriate mealtime behavior include delivering escape from bite presentations, access to attention (in the form of coaxing, comforting, and/or reprimanding), and/or access to preferred foods or drinks and toys. A descriptive analysis also provides an opportunity for the oral-motor specialist to observe the child's oral motor skills and function.

Functional Analysis of Inappropriate Mealtime Behavior

A functional analysis of inappropriate mealtime behavior involves systematically manipulating antecedents and consequences to determine caregiver-delivered consequences that reinforce inappropriate mealtime behavior (e.g., Bachmeyer et al., 2009; Girolami & Scotti, 2001; Najdowski et al., 2008; Piazza et al., 2003a). For example, Piazza et al. (2003a) used procedures similar to those described by Iwata et al. (1982/1994) to conduct functional analyses of 15 children with feeding problems. Conditions included: escape, attention, and tangible test conditions and a control condition. The feeder delivered continuous access to preferred items and attention and did not provide differential consequences following inappropriate mealtime behavior in the control condition. The feeder removed the bite or drink following inappropriate mealtime behavior in the escape condition; provided attention following inappropriate mealtime behavior in the attention condition; and provided either preferred toys or foods following inappropriate mealtime behavior in the tangible condition. Results showed that negative reinforcement was the most common variable maintaining inappropriate mealtime behavior (i.e., 90% of the 10 children who exhibited differential responding showed a sensitivity to escape). Results also showed that the inappropriate mealtime behavior of 80% of children who exhibited differential responding was maintained by multiple functions. Not every child's behavior was maintained by the same or all functions.

The procedures described by Piazza et al. (2003a) involved prompting bites across all conditions. An alternative method involves prompting bites only in the escape condition (e.g., Najdowski et al., 2008). Bachmeyer et al. (2019) assessed the inappropriate mealtime behavior of three children with an identified feeding disorder by comparing the two procedural variations. The two methods resulted in different outcomes for two of three children. The method that prompted bites only in the escape condition identified only an escape function, and the method that prompted bites across all conditions identified multiple functions (escape from bites and attention). The researchers examined the relative effects of extinction procedures matched to both functions (individually and in combination) to determine the validity of each functional analysis method. Results suggested that the procedural variation that failed to identify an attention function for two of three children produced false negative findings. Presenting bites and prompts to eat only in the escape condition may omit the relevant discriminative stimuli or motivating operations for inappropriate mealtime behavior in the other test conditions and result in false negative findings for some children. Therefore, sources of reinforcement for inappropriate mealtime behavior are contextual. That is, an event such as attention functions as reinforcement in the presence of prompts to eat, but not in other contexts, such as when a child is left alone with a plate of food on the table or outside of the mealtime context. However, presenting bites across all conditions may result in a lack of discrimination, particularly during an alternating treatment design involving rapid alternation of more than two conditions. Therefore, functional analyses of inappropriate mealtime behavior are often conducted in a reversal design (Piazza et al., 2003a) or pairwise design (Bachmeyer et al., 2009). A pairwise design involves rapid alteration of only one test condition and the control condition and may more efficiently identify functions than a reversal design in which phases are repeated to demonstrate a functional relationship.

Researchers have shown that failure to identify all functions of inappropriate mealtime behavior could lead to an ineffective intervention (Bachmeyer et al., 2009; Kirkwood et al., 2020). For example, Bachmeyer et al. (2009) showed that a treatment that combined escape extinction and attention extinction was necessary to increase acceptance to high and stable levels and decrease inappropriate mealtime behavior maintained by escape and attention to near-zero levels for all children. Alternatively, implementing a package that addresses all potential functions could lead to a less specific intervention. For example, Kirkwood et al. (2021) observed that although caregivers of three children with feeding disorders provided escape from bites and drinks and attention following inappropriate mealtime behavior, results of functional analyses showed that inappropriate mealtime behavior was only maintained by escape from bites or drinks for all three children. They examined the effects of escape extinction when the feeder either provided or withheld attention following inappropriate mealtime behavior and found that inappropriate mealtime behavior decreased and acceptance increased when the feeder implemented escape extinction independent of whether they provided or withheld attention.

It is not uncommon for practitioners to question the utility of a functional analysis to treat pediatric feeding disorders because research has shown that escape plays a major role in the maintenance of inappropriate mealtime behavior and escape extinction is often necessary. Further, escape extinction is commonly described in the literature as being structurally similar to escape extinction combined with attention and/or tangible extinction. That is, the feeder withholds both escape and other potential reinforcers (attention or tangible items) following inappropriate mealtime behavior regardless of the procedure. In addition, practitioners often teach caregivers to implement escape and attention extinction as a treatment package. However, identifying the specific reinforcers that maintain inappropriate mealtime behavior can be important. For example, although a clinician would not typically teach a caregiver to provide attention following instances of inappropriate mealtime behavior, teaching a caregiver to withhold escape and attention for inappropriate mealtime behavior (i.e., escape and attention extinction) when only escape is identified as a reinforcer, may be unnecessary. Training a caregiver to refrain from providing reprimands for a child's problem behavior may eliminate a strategy that the caregiver has previously used to manage the child's behavior or create an additional procedure for the caregiver to follow. Clinicians might also avoid unnecessary conflict with caregivers who are adamant about not ignoring their child's behavior when their child's inappropriate mealtime behavior is not maintained by attention (Kirkwood et al., 2020). Finally, training caregivers to implement treatment packages that include unnecessary components may increase treatment complexity and could negatively impact procedural integrity (Vollmer et al., 2008).

Antecedent Assessments

Analyses of motivating operations may provide useful information about specific stimuli that can alter the efficacy of the reinforcers identified during the functional analysis, thus increasing or decreasing the likelihood of appropriate or inappropriate mealtime behavior (Michael, 1993). Within the feeding context, this may include the feeding utensil (e.g., spoon versus Nuk® brush or cup versus bottle), bolus (bite) size, food texture (e.g., puree versus wet ground), and bite placement (e.g., Munk & Repp, 1994; Patel et al., 2002; Sharp & Jaquess, 2009; Sharp et al., 2012). For example, Munk and Repp (1994) evaluated the effects of different food types at various textures (e.g., junior [50% puree and 50% wet ground], ground, and chopped texture) on bite acceptance, inappropriate mealtime behavior, and expulsion with five individuals with intellectual disabilities. Specific food types and textures were associated with different levels of appropriate or inappropriate mealtime behavior. Sharp and Jaquess (2009) compared the effects of bite size (ranging from 1 to 5 cc) and food texture (pureed, wet ground, ground, and chopped) on the inappropriate mealtime behavior, gagging, and packing exhibited by a child who presented with food selectivity. Results showed increased inappropriate mealtime behavior with larger bite sizes and increased gagging and packing with higher textures. Sharp et al. (2012) compared the effects of presentation method with a flipped versus upright spoon on expulsion and mouth clean (a product measure of swallowing). Lower levels of expulsion and higher levels of mouth clean occurred during the flipped spoon presentation for all participants.

Identification of antecedent variables (e.g., food type and texture, bite size, feeding utensils) that may influence the likelihood of appropriate and inappropriate mealtime behaviors allows the behavior analyst to individualize the child's behavioral intervention.

Intervention

Behavioral interventions have proven effective and currently have the most scientific support to decrease maladaptive mealtime behaviors and increase appropriate mealtime behaviors (e.g., Addison et al., 2012; Kerwin, 1999; Peterson et al., 2016; Volkert & Piazza, 2012). Kerwin (1999) and Volkert and Piazza (2012) conducted systematic searches of peer-reviewed studies on psychosocial or behavioral interventions for children with a feeding disorder. They identified studies with rigorous methodologies and classified the treatments as well-established, probably efficacious, or promising according to specific criteria and guidelines described by the Task Force on Promotion and Dissemination of Psychological Procedure (1995) and Society for Pediatric Psychology. Results indicated that some behavioral treatments are empirically supported and are well-established treatments for pediatric feeding disorders. Addison et al. (2012) and Peterson et al. (2016) directly compared the relative effectiveness of behavior-analytic and sensory integration therapies to treat feeding disorders. Results showed that the behavior-analytic therapy reduced inappropriate mealtime behavior and increased acceptance to stable and acceptable levels for all children, whereas inappropriate mealtime behavior remained above clinically acceptable levels and acceptance remained low or variable with the sensory integration therapy.

Consequence-Based Procedures

The most frequently researched behavioral intervention is a multi-component treatment package that combines two consequence-based procedures, escape extinction and differential reinforcement of alternative behavior (DRA) (e.g., Ahearn et al., 1996; Anderson & McMillan, 2001; Babbitt et al., 1994; Cooper et al., 1995; Hoch et al., 1994; Kerwin et al., 1995; Patel et al., 2002; Piazza et al., 2003b). In fact, Kerwin (1999) and Volkert and Piazza (2012) found that escape extinction and differential reinforcement of alternative behavior are both empirically supported and the well-established treatments for pediatric feeding disorders.

Escape Extinction

Escape extinction, which is implemented when a child's feeding behavior is presumed to be maintained by negative reinforcement (escape from food or drink), is a procedure in which escape from the demand of eating or drinking is no longer permitted. That is, the feeder no longer removes the bite or drink following inappropriate mealtime behavior. Two common escape extinction procedures are nonremoval of the spoon and physical guidance. Nonremoval of the spoon involves positioning the spoon or cup at the child's lips until he or she accepts the bite or drink, thus preventing escape from the bite presentation (e.g., Ahearn et al., 1996; Babbitt et al., 1994; Cooper et al., 1995; Piazza et al., 2003b; Reed et al., 2004). An alternative escape extinction procedure, physical guidance, consists of applying gentle pressure to the child's mandibular joint to guide the mouth open, so that the bite may then be deposited in the child's mouth (e.g., Ahearn et al., 1996). Ahearn et al. (1996) compared the relative effects of nonremoval of the spoon and physical guidance on appropriate and inappropriate mealtime behavior for three children with an identified feeding disorder. Results showed that both treatments were effective at increasing bite acceptance for all three children. Re-presentation, a procedure in which the feeder scoops up expelled food or liquid and re-deposits it in the child's mouth until it is consumed, is commonly used in combination with nonremoval and physical guidance (e.g., Piazza et al., 2003b; Reed et al., 2004).

Differential Reinforcement of Alternative Behavior

Differential reinforcement of alternative behavior (DRA) involves providing the child with access to preferred stimuli (e.g., foods/drinks, toys, activities) contingent on appropriate behaviors, such as accepting or swallowing bites of food or drinks (e.g., Brown et al., 2002; Cooper et al., 1999; Levin & Carr, 2001; Piazza et al., 2003b; Riordan et al., 1980; Riordan et al., 1984). For example, Riordan et al. (1980) treated the feeding problems of four children who exhibited limited and selective food intake. The primary treatment procedures involved delivering preferred foods contingent on acceptance of non-preferred foods, which resulted in increased food intake for all four children.

It may be possible to increase the quantity or variety of foods some children consume using DRA in the absence of escape extinction when it is possible to identify highly preferred foods or drinks (e.g., Brown et al., 2002; Cooper et al., 1999; Levin & Carr, 2001; Riordan et al., 1980; Riordan et al., 1984). However, there are factors that may influence whether preferred foods or drinks may function as positive reinforcers in the treatment of feeding difficulties, including the magnitude of the reinforcer and reinforcer deprivation. For example, Cooper et al. (1999) manipulated the quantity and/or the quality of positive reinforcement (i.e., contingent access to preferred foods or drinks) paired with acceptance of bites of nonpreferred foods in the treatment of four children who exhibited either low overall intake or highly selective food intake. Increasing the quantity of reinforcers (i.e., number of sips of Pepsi™ or bites of potato chips) provided contingent on acceptance of bites of nonpreferred foods resulted in an overall increase in food acceptance (in the absence of escape extinction) for one of four children. These results suggest that it may be necessary to increase the number of reinforcers offered for each bite of nonpreferred food consumed if treatment effects are not achieved with the initial quantity of reinforcers selected. After consumption of nonpreferred foods has been established utilizing contingent access to preferred foods, the proportion of bites of preferred and nonpreferred foods may be altered by either gradually decreasing the schedule of reinforcement or gradually increasing the demand requirement to access reinforcement. For example, Riordan et al. (1980) utilized demand fading (i.e., gradually increasing the demand requirement to access reinforcement) combined with contingent positive reinforcement to increase the proportion of nonpreferred foods to preferred foods consumed by two children who exhibited low and selective food intake.

Another factor that may influence the effectiveness of potential reinforcers, particularly preferred foods or drinks, is the relative states of deprivation associated with the preferred stimuli. For example, Levin and Carr (2001) examined the differential effects of having or not having access to preferred food items prior to meals that involved the presence versus absence of contingent positive reinforcement for acceptance of bites of nonpreferred food with four children exhibiting food selectivity by type. All four children consumed nonpreferred foods only when the positive reinforcement contingency was implemented and access to the preferred foods prior to meals was restricted.

Although DRA may not be effective without escape extinction for all children, it has been associated with beneficial effects for some children when added to escape extinction. For example, Piazza et al. (2003b) examined the effects of DRA (contingent access to preferred toys) and escape extinction, individually and in combination, to treat the feeding disorders of four children. Results showed that DRA alone did not increase food consumption, whereas escape extinction increased food consumption independent of whether DRA was present or absent. However, DRA combined with escape extinction produced lower levels of inappropriate behavior and negative vocalizations for some children.

Noncontingent Reinforcement

Noncontingent reinforcement (NCR) typically involves continuous access to preferred adult attention and/or preferred toys or leisure activities in the treatment of pediatric feeding disorders (e.g., Berth et al., 2019; Reed et al., 2004; Wilder et al., 2005). For example, Wilder et al. (2005) examined the use of NCR to decrease self-injury and increase food acceptance in a child who exhibited limited and selective food intake. Treatment involved continuous access to a video during meals without the use of escape extinction, which resulted in decreased self-injury and increased food acceptance.

Noncontingent reinforcement has also been associated with beneficial effects when added to escape extinction for some children. For example, Reed et al. (2004) examined the effects of NCR (continuous access to preferred toys) and escape extinction, individually and in combination, to treat the feeding disorders of four children. Noncontingent reinforcement alone did not increase food consumption, whereas escape extinction increased food consumption independent of whether NCR was present or absent. However, NCR combined with escape extinction produced lower levels of inappropriate behavior for some children.

Berth et al. (2019) compared the effects of DRA and NCR and the relative effects of escape extinction with and without DRA or NCR when escape extinction was necessary. Both reinforcement procedures were effective without escape extinction to treat the food refusal of one child, but only DRA was effective without escape extinction to treat the child's liquid refusal. Escape extinction was necessary for four of five children, and similar to the results of Piazza et al. (2003b) and Reed et al. (2004), the addition of positive reinforcement resulted in beneficial effects for three of four children (i.e., more stable acceptance, decreased inappropriate mealtime behavior or negative vocalizations). With escape extinction, DRA was more effective to treat food refusal for two children and NCR was more effective for one child. Thus, the results of Berth et al. suggest that the addition of positive reinforcement to escape extinction may have beneficial effects for some children, but the relative effects of DRA and NCR are idiosyncratic.

Antecedent-Based Procedures

The earliest behavioral literature on the treatment of pediatric feeding disorders focused primarily on consequence-based treatment procedures (i.e., reinforcement, extinction). A second wave of studies introduced antecedent-based treatment procedures (e.g., utensil manipulation, simultaneous presentation, stimulus fading, demand fading). Researchers have demonstrated that some of these procedures may result in desired treatment outcomes without the need for other treatment components, increase the effectiveness of other treatments, or attenuate the side effects of escape extinction for some children with feeding difficulties. It may be that these antecedent treatments enhance treatment outcomes because they decrease the aversiveness of the mealtime context and/or reduce the response effort for appropriate mealtime behavior, which may alter the value of reinforcers maintaining inappropriate mealtime behavior (motivating operations), accommodate or support oral-motor skill deficits, or a combination of both.

Utensil Manipulation

For some children, re-presenting bites does not effectively decrease expulsions and increase mouth clean. A few researchers have shown that flipping the spoon over (open bowl on the top of the tongue) when depositing the food may decrease expulsion and increase mouth clean (e.g., Dempsey et al., 2011; Rivas et al., 2011; Sharp et al., 2012; Sharp et al., 2010). For example, Sharp et al. (2012) examined the effects of bite placement with a flipped versus upright spoon on expulsion and mouth clean for three children with a feeding disorder and identified oral motor deficits. For all three children, nonremoval of the spoon resulted in decreased inappropriate mealtime behavior and increased bite acceptance; however, re-presentation did not reduce expulsion or increase mouth clean. Flipped spoon presentations and re-presentations decreased expulsions and increased mouth clean for all children. Similarly, Dempsey et al. (2011) treated the liquid refusal of a child with a feeding disorder using a flipped spoon presentation combined with a chin prompt. Mouth clean did not increase with the chin prompt alone and increased only modestly with the flipped spoon alone. The greatest increases in mouth clean resulted from the combination of two antecedent manipulations (flipped spoon and chin prompt).

Using a Nuk® brush to present bites may be an alternative option to decrease expulsion and increase mouth clean (e.g., Sharp et al., 2010; Wilkins et al., 2014). For example, Wilkins et al. (2014) compared presenting bites on a spoon or on a Nuk® brush using nonremoval and re-presentation for 12 children with feeding difficulties. Feeding behavior improved for eight children. Of those eight children, five showed lower levels of expulsions and four showed higher levels of mouth clean with presentations on the Nuk® brush than with the spoon. Similarly, Sharp et al. (2010) compared the effects of presentations on an upright spoon, flipped spoon, or Nuk® brush in the treatment of a feeding disorder for one child. The child expelled all bites presented on an upright spoon but showed decreased expulsions and increased mouth cleans with the flipped spoon and Nuk® brush presentations.

Simultaneous Presentation

Simultaneous presentation involves presenting a more preferred with a less preferred food at the same time (e.g., Ahearn, 2003; Buckley & Newchok, 2005; Piazza et al., 2002). The foods may be presented together on the same utensil in an observable format, blended together in a pureed format, or the nonpreferred food may be inside or covered by the preferred food. This strategy has been effective at increasing consumption of nonpreferred foods in the absence of escape extinction and increasing the effectiveness of escape extinction for some children. For example, Piazza et al. (2002) showed that simultaneous presentation of a more preferred food with a less preferred food may actually be a more effective method than contingent access to preferred foods to increase acceptance of less preferred foods. Piazza and colleagues compared the effects of these two methods of food presentation (simultaneous versus contingent) to increase the acceptance of less preferred foods by three children with feeding difficulties. The simultaneous presentation involved presenting preferred foods at the same time as a nonpreferred food (e.g., a piece of broccoli on a chip, salad dressing on a piece of broccoli). The contingent presentation involved presentation of a preferred food following acceptance of a nonpreferred food. Acceptance of nonpreferred foods immediately increased (without escape extinction) for two of the three children with the simultaneous presentation relative to the contingent presentation. For one child, acceptance of nonpreferred food increased with the simultaneous presentation but not the contingent presentation with the addition of escape extinction (physical guidance and re-presentation).

Results of these studies suggest that simultaneous presentation may be an effective treatment option when preferred foods can be identified. This strategy may momentarily decrease the aversive properties of the nonpreferred food and thus decrease the child's motivation to refuse the nonpreferred food. An alternative explanation is that flavor–flavor conditioning occurs (i.e., a preference for the nonpreferred is acquired as a result of pairing it with a preferred flavor; Piazza et al., 2002). However, it is possible that preference for the preferred food may be altered as a result of pairing it with nonpreferred foods; thus, this strategy may be more appropriate when a child demonstrates a strong preference for food(s) other than those that comprise the majority of the child's current nutrition.

Stimulus and Demand Fading

Food Type Researchers have shown that gradually changing the ratio or concentration of preferred and nonpreferred foods or liquids (stimulus fading) may increase acceptance of nonpreferred foods or liquids in the absence of escape extinction (e.g., Luiselli et al., 2005; Tiger & Hanley, 2006) or increase the effectiveness of escape extinction (e.g., Mueller et al., 2004; Patel & Piazza 2001). For example, Luiselli et al. (2005) gradually faded the concentration of liquid in the absence of escape extinction to establish milk consumption with a child with identified feeding difficulties. Treatment consisted of gradually increasing the concentration of milk in a beverage the child consistently consumed (Pediasure®, a supplemental nutritional beverage). After nonremoval and DRA or NCR, increased consumption of only one or two of 16 foods for two children with feeding difficulties, Mueller et al. (2004) added stimulus fading in which they blended a small portion of nonpreferred pureed foods into the pureed foods the children consistently consumed (e.g., 10% nonpreferred/90% preferred) and gradually altered the ratio until the children were consuming the nonpreferred foods alone during probes.

It may also be necessary to gradually change the ratio or concentration of paired preferred and nonpreferred foods or liquids after successfully using simultaneous presentation in order to maintain appropriate feeding behavior with nonpreferred foods or liquids alone. For example, Luiselli et al. (2005) gradually faded the concentration of liquid (without escape extinction) to establish milk consumption with a child who drank Pediasure® at full strength and at a blend of 50% Pediasure® and 50% whole milk but refused whole milk at full strength or when it was blended with Pediasure® at a concentration of less than 50% Pediasure®.

Gradually introducing the proportion of nonpreferred foods paired with preferred foods may also reduce the risk associated with pairing nonpreferred and preferred foods. Initially presenting the nonpreferred food with the preferred food at a minimal concentration or proportion may reduce the likelihood that the preferred food does not acquire the aversive properties of the nonpreferred food. A limitation to this procedure may be the length of time required for fading; however, periodic probes (of the full-strength substance) can be conducted to determine whether continuing to fade the concentration is necessary, as in the Mueller et al. (2004) study.

Food texture or liquid consistency Children with feeding disorders often display food selectivity by texture. For many of these children, consuming higher textured foods may be aversive or potentially dangerous due to delayed oral motor skills. For example, Shore et al. (1998) used texture fading in combination with nonremoval and DRA to treat the food selectivity exhibited by four children with feeding difficulties. Fading involved gradually increasing texture using various proportions of puree, junior, ground, and finely chopped food, based on results of periodic probes. Similarly, Bachmeyer et al. (2013) examined the effects of gradually altering the concentration of liquid by adding baby food to the liquid with two children who consistently consumed liquids, but not baby food, after treatment using physical guidance with re-presentation and DRA. High levels of mouth clean maintained throughout fading for both children. Mouth clean and gram intake increased and negative vocalizations decreased with 100% baby food after the fading treatment.

Utensil or feeding apparatus A few researchers have gradually altered the feeding apparatus from a utensil from which a child consistently accepts to an age-typical utensil (e.g., Babbitt et al., 2001; Groff et al., 2014; Johnson & Babbitt, 1993). For example, Babbitt et al. (2001) faded from a spoon with thickened liquids to a cup with thin liquids using nonremoval and DRA to establish cup drinking skills with two children who consistently consumed solid food but refused all liquids. Similarly, Groff et al. (2014) conducted syringe to cup and syringe to spoon fading after they established acceptance of liquids and solids with a syringe when nonremoval failed to be effective with a spoon or cup. The treatment involved using a syringe to deposit liquids and solids, increasing the volume of liquids and solids in the syringe, and conducting syringe-to-cup and syringe-to-spoon fading.

Bite size or quantity It may be beneficial to decrease the bite size and/or bite requirement at the beginning of treatment to reduce the aversive properties of the meal or response effort, and then gradually increase the bite size and/or number of bites to maintain low levels of problematic mealtime behavior and high levels of appropriate mealtime behavior (Kahng et al., 2003; Kerwin et al., 1995; Najdowski et al., 2003; Penrod et al., 2010; Sharp & Jaquess, 2009). For example, Kerwin et al. (1995) examined the role of bite amount (i.e., empty, dipped, quarter, half, and level spoon), differential reinforcement of incompatible behavior, and physical guidance or nonremoval of the spoon on feeding behaviors with three children with food refusal. Differential reinforcement of incompatible behavior and physical guidance or nonremoval of the spoon were introduced at the smallest bite amount and later introduced at the larger bite amounts with moderate to high levels of acceptance. Kahng et al. (2003) used contingent access to escape (termination of the meal) and token-based DRA to establish acceptance and consumption of food with a child with feeding difficulties, and then gradually increased the number of bites required to access reinforcement using a changing criterion design.

High-Probability Instructional Sequence

High-probability (high-*p*) instructional sequence involves presenting a series of instructions for which compliance is highly probable followed by a request for which compliance is not probable (i.e., a low-probability [low-*p*] instruction). For example, Patel et al. (2007) evaluated the effects of a high-*p* instructional sequence on food acceptance with a child who inconsistently consumed a limited variety of foods. The high-*p* sequence consisted of three presentations of an empty spoon, and the low-*p* instruction was the presentation of a spoon with food. Acceptance of food increased in the presence and not the absence of the high-*p* instructional sequence. The high-*p* instructional sequence has been effective at increasing food consumption in the absence of escape extinction (Patel et al., 2007) and associated with beneficial effects when combined with escape extinction for some children (Dawson et al., 2003; Patel et al., 2006). If a child demonstrates high levels of compliance with a request similar to eating, such as acceptance of an empty spoon, then a high-*p* instructional sequence may be effective at increasing compliance (e.g., acceptance, mouth clean) with target foods.

Advanced Skill Development

In addition to learning to consume a sufficient variety and quantity of foods and liquids to meet their nutritional needs, some children with feeding difficulties need to explicitly learn to chew because of oral motor delays or dysfunction and/or lack of opportunities to naturally develop chewing skills during critical periods. Volkert et al. (2013, 2014) described the first treatment protocols to increase chewing using least-to-most prompting combined with either a descriptive verbal prompt (of the number of times to chew) or stimulus and demand fading (i.e., the child was required to chew on an empty chew tube, a bite of food in a chew tube, a strip of food on half of a chew tube, a strip of food, a bite of food, and increased bite sizes of food). In 2013, Volkert and colleagues also developed a product measure of chewing (i.e., if the food is broken down enough to safely swallow after chewing), termed mastication, to evaluate the effects of the treatment protocols.

Even after successful intervention to increase acceptance of solids and/or liquids, children with feeding difficulties may not demonstrate the skills or motivation to begin feeding themselves (Volkert et al., 2016). Therefore, additional intervention may be necessary to teach self-feeding/drinking skills to promote independence during mealtimes. For example, Peterson et al. (2015) demonstrated that differential positive reinforcement alone (descriptive praise and preferred toys/leisure items) was effective at increasing self-drinking for two children with feeding difficulties. Collins et al. (1991) used physical guidance with a constant-time delay procedure and descriptive praise to teach self-feeding to two children with feeding difficulties. After the children mastered self-feeding with physical guidance and a 0-s time delay, a 3-s time delay was implemented, and independent self-feeding increased for both children. Alternatively, Volkert et al. (2016) examined the effects of manipulating response effort and/or food preference to increase self-feeding by three children with feeding difficulties after descriptive praise alone was not effective. That is, researchers biased the children's responding to feed themselves instead of being fed by a therapist by increasing the number of bites and/or decreasing the relative preference of the foods they had to consume if a therapist fed them.

Ethical Considerations

No behavior analyst would knowingly or intentionally harm a client. However, practicing outside of one's competency without adequate supervision (Bailey & Burch, 2016), practicing outside of an interdisciplinary approach, and failing to select and implement safe and effective treatments can result in unintentional harm.

Training and Supervision

The Professional and Ethical Compliance Code for Behavior Analysts (Behavior Analyst Certification Board, 2014), herein referred to as the "Code," specifies providing services, conducting research, and teaching only within the boundaries of one's *competence*, defined as being commensurate with education, training, and supervised experiences (Code 1.02). As Bailey and Burch (2016) discuss:

> …beyond that, practitioners will have to determine whether they are indeed competent in certain subspecialities of ABA. Examples of such subspecialties include treating feeding disorders, self-injurious behavior, aggression, and destructive behaviors. Attending a workshop or seminar on one of these specialties is not sufficient to describe oneself as competent in a subspecialty area. (p. 58)

Behavior analysts might take on a client or attempt to treat problem behaviors that are outside of their scope of competence because they want to help the child and caregiver. However, the long-term effects of behavior analysts working within the subspecialty without adequate training or supervision can be detrimental to a child's health and future success with eating and drinking.

Practitioners whose background did not involve extensive training in assessment and treatment of pediatric feeding disorders should seek comprehensive training and supervised experiences from a behavior analyst competent in this subspecialty prior to practicing or conducting research within this area. Alternatively, practitioners may be able to provide safe and effective services with ongoing consultation from a behavior analyst who is competent in this subspecialty prior to receiving additional training experiences. When behavior analysts have received some training within the subspecialty (e.g., practicum, internship, research experiences), their experience may have been limited in the number of clients and range of feeding difficulties treated, working within an interdisciplinary team, and/or the extent to which they learned to safely and effectively select, implement, and evaluate a limited variety of procedures. These behavior analysts should evaluate their competence with their supervisors or mentors to determine whether they will require additional supervision or consultation to provide safe and effective treatment. Behavior analysts practicing in this subspecialty must maintain their competence through professional development by staying current in the literature, attending conferences and workshops, and even completing additional coursework or supervised experiences (Code 1.03).

Interdisciplinary Approach

Behavior analysts protect their clients and themselves by making sure that they do not treat the behavioral manifestations of undiagnosed or unrecognized medical conditions (Copeland & Buch, 2020). Code 3.02 states that behavior analysts recommend seeking medical consultation if there is any reasonable possibility that a referred behavior is influenced by medical or biological variables. Given that approximately 86% of children diagnosed with a feeding disorder are diagnosed with a medical condition (Rommel et al., 2003), behavior analysts should assume that the child's feeding difficulties have a medical or biological component. The best way for the behavior analyst to protect his or her client and him or herself is to work within an interdisciplinary approach.

In addition, Code 2.03 states that it is always indicated and professionally appropriate to cooperate with other professionals in a manner that is consistent with the philosophical assumptions and principles of behavior analysis to effectively and appropriately serve clients. Medical providers, speech and language pathologists, and occupational therapists often have different philosophical views, but it is the behavior analyst's responsibility to collaborate with other interdisciplinary team members to ensure the best outcomes for the client.

Treatment Selection and Implementation

Code 2.09 specifies that every client has a right to an effective treatment. Many practitioners may be aware that escape extinction and reinforcement are the most commonly used evidence-based treatments for feeding difficulties, but they may not be familiar with all of the factors that should be considered to safely and effectively program and implement treatment.

For example, researchers have shown that escape extinction is highly effective to treat feeding difficulties and is often a necessary treatment component. However, extinction has been associated with numerous side effects, such as extinction bursts, emotional responding, and extinction-induced aggression (Lerman et al., 1999). Caregivers of young children with feeding disorders and often complicated medical histories may find these potential side effects unacceptable. Further, it can be discouraging for caregivers if appropriate mealtime behavior (e.g., bite acceptance) does not occur relatively quickly or if additional topographies of inappropriate mealtime behavior emerge (e.g., expulsion, packing). Consistent with Code 4.08, including a positive reinforcement component with escape extinction or other aversive procedures may attenuate the potential side effects of escape extinction for some children (e.g., Berth et al., 2019; Piazza et al., 2003b; Reed et al., 2004). Further, manipulating antecedent variables when programing escape extinction may reduce the potential side effects of extinction and increase its effectiveness, resulting in quicker acquisition of appropriate mealtime behaviors (e.g., Munk & Repp, 1994; Patel et al., 2006; Sharp & Jaquess, 2009). In addition, when developing an intervention utilizing contingent access to preferred foods or drinks, consideration needs to be given to completely restricting access to preferred foods as this could result in a decrease in overall food intake for some children. Likewise, caution should be used when simultaneously presenting preferred and nonpreferred foods because the preferred food may become aversive and result in a decrease in their overall consumption for some children. Code 4.03 requires that the behavior analyst tailor behavior-change programs to the unique behaviors, environmental variables, assessment results, and goals of each client. "One of the most difficult tasks the behavior analyst faces is extrapolating from published research methods to procedures that will work with an individual client" (Bailey & Burch, 2016). Knowing how to develop individualized antecedent assessments and interpret the results to develop the most safe and effective individualized treatment for a child with feeding difficulties requires sufficient training and experience with numerous clients with a wide range of feeding difficulties and with a variety of assessment and treatment procedures.

Considerations when implementing escape extinction should include procedural fidelity and safety of the client. Consistent with Code 4.08, escape extinction should only be implemented to treat feeding difficulties by individuals who are well-trained and receiving appropriate supervision and oversight. Forced feeding, although structurally and theoretically different than escape extinction, has been identified as a contributing factor in the development of feeding problems (Palmer et al., 1975; Riordan et al., 1980) and aspiration pneumonia (Perske et al., 1977). Escape extinction implemented by a behavior analyst without proper training and supervision can pose the same safety risks as forced feeding. Further, treatment fidelity can be greatly influenced by the child's size and strength and history with escape extinction procedures. The risks and benefits of using escape extinction with older and stronger children must be considered in terms of how likely a trained feeder can accurately and safely keep the utensil at the child's lips during high rates of intense inappropriate mealtime behavior, extinction-induced emotional responding, and aggression and/or self-injurious behavior. Further, escape extinction should only be implemented in a setting, where additional trained therapists are available to block inappropriate mealtime behavior (to ensure the feeder can keep the utensil at the child's lips to prevent escape) and where additional materials are available (e.g., appropriate adaptable seating, padding for the table and seating, protective equipment for the feeder). There are additional safety issues to consider when structuring the mealtime, particularly when implementing escape extinction, such as keeping the child in a safe, upright position; not depositing bites or drinks when the child is coughing or gagging or when the head is tilted back; appropriate bite size, food texture, and liquid consistency;

appropriate placement or deposit of the food or liquid; and appropriate pacing between bite or drink presentations. Fortunately, this knowledge and skills can be acquired with appropriate training and supervision or consultation with a behavior analyst who is competent in this specialized area of behavior analysis.

Summary

Failure to consume sufficient calories or meet nutritional needs can place a child at risk for significant delays to their growth and overall development. Children with feeding difficulties, such as ARFID, may exhibit a wide range of presenting problems, including refusal of all food or liquid, dependence on liquids, highly selective patterns of eating, and skill deficits. Behavioral interventions are effective at decreasing maladaptive behaviors (e.g., inappropriate mealtime behavior, expulsions), increasing appropriate mealtime behaviors (e.g., bite acceptance, swallowing), and teaching new skills (e.g., chewing, self-feeding). However, given the variance in presenting problems and complex etiology of feeding difficulties, an interdisciplinary approach to assessment and treatment is necessary. Further, it is important that the behavior analyst be adequately trained or receive sufficient supervision or consultation to provide an effective intervention and keep the child safe as indicated by the Professional and Ethical Compliance Code for Behavior Analysts.

Over the past two decades, behavior analysis has made great strides in the subspecialty of feeding disorders. Investigators developed new assessment methods to prescribe individualized treatments. Numerous researchers also developed a range of antecedent-based treatments that provide additional treatment options, and in some cases, may enhance existing treatments by altering motivating operations or supporting skill deficits. Further, some researchers improved our knowledge on methods to teach new skills. Although replication of some of these methods is necessary to establish additional behavioral treatments as efficacious, as we move into the next decade, there remains several other areas for investigation to further advance the effectiveness, efficiency, and specificity of our therapeutic approach. Given the complexity and heterogeneity of feeding difficulties, it is likely that multiple antecedent variables may interact to influence the value of reinforcers that maintain problem behavior in the mealtime context and/or influence feeding behavior based on response effort and acquired skills or deficits. Therefore, more comprehensive assessments evaluating potential interactions between multiple antecedent variables and research examining interactions between various antecedent manipulations and different consequence-based procedures may allow practitioners to more efficiently and specifically prescribe treatment. Further, research examining interactions between biological and behavioral variables in the treatment of feeding difficulties may also provide more effective treatments. Finally, long-term effectiveness of our treatments in the natural setting is essential to resolve feeding difficulties and achieve typical eating patterns. Therefore, future research should explore methods to program for generalization and maintenance of treatment success and prevent treatment relapse.

40 Telehealth and Applied Behavior Analysis: An Overview and Examples of Application

Joy Pollard, Shawn Quigley, Matthew O'Brien, Stephanie Peterson, and Sean Casey

Tele-, a prefix that means at a distance ("Tele-", 2011), combines with various words indicating the distal relationship. Common examples may include instruments to transmit information, such as a television (i.e., an instrument that receives transmitted images from one location and reproduces them on a screen in a different location) or a telescope (i.e., an instrument to make distant objects appear nearer). Other examples (e.g., telephone, telegram) indicate how two or more people share information across a distance. A specific form of information sharing across a distance is telehealth.

Many definitions of telehealth[1] exist and typically reflect nuances specific to a particular profession. The American Telemedicine Association (2013) defines telemedicine as the exchange of medical information from one site to another via electronic communication. Another example, from the American Psychological Association (2013), defines telepsychology "as the provision of psychological services using telecommunication technologies." The Health Resources and Services Administration (HRSA) defines telehealth more broadly as the "use of electronic information and telecommunication technologies to support and promote long-distance clinical health care, patient and professional health-related education, public health and health administration" (Health Information Technology, 2017). For this chapter, we utilize the HRSA definition as it does not utilize profession-specific language and the language is inclusive of appli-

[1] Telehealth is used throughout this chapter although other terms, such as telemedicine, might be applicable. Per the given definition, telehealth broadly recognizes technology utilized to enhance others' health. Additionally, it does not specify any one profession (e.g., telemedicine, telepsychology) responsible for enhancing others' health. Unless quoting or paraphrasing another source that specifically references a different term, telehealth is used exclusively.

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_40

cations beyond clinical care (i.e., education and health administration) and articulates telehealth as a modality, rather than a distinct service.

According to Bashshur and Shannon (2009), the simplest forms of telehealth (i.e., connecting those in need of care to those who provide care) arguably existed with ancient civilizations utilizing rudimentary strategies to remain connected. The same authors described transformations of technology to bridge distance and provided examples of written words, semaphore, telegrams, radio signals, and the internet. Advances in technology reinforce telehealth as a service modality to connect those in need of care with those who provide care. The Council for Autism Service Providers (CASP, 2020, 2021) has stated telehealth is not a separate or distinct healthcare, but rather a service delivery model that may be met synchronously or asynchronously.

Synchronous methods utilize technology to transmit information between two parties in "real-time" (i.e., at the same point in time) (CASP, 2020). A parent and child, seeking care for a cough, might visit with a healthcare professional via a video platform using "real-time" video and audio (e.g., Zoom or Doxy). Additionally, a direct support professional may seek care from a healthcare professional via a phone call to meet emerging medical needs for a congregate-care resident. Asynchronous methods are similar to synchronous but do not occur during the same point in time (CASP, 2020). A teenager struggling with social anxiety may email weekly with a therapist describing the number and quality of social interactions achieved during the week. An adult seeking better health may enter eating and exercise information into an application on a smartphone, later reviewed by a supporting professional.

Although technology is not new to behavior analysis (e.g., Rutherford, 2009), practicing behavior analysts have fairly recently implemented telehealth models to deliver treatment. Examples include telehealth for assessments (e.g., Barretto et al., 2006), to train others to conduct assessments (e.g., Frieder et al., 2009; Rios et al., 2020), and to deliver treatment (e.g., Peterson et al., 2017; Wacker et al., 2013b). The novel COVID-19 pandemic further created a context for discussion about and advancements in the implementation of behavior analytic services via telehealth models (e.g., Baumes et al., 2020; Crockett et al., 2020; Cox et al., 2020; LeBlanc et al., 2020; Sivaraman et al., 2020). Several resources provide an in-depth discussion of the considerations when using telehealth models (see Table 40.1); however, it is worth discussing a few of the considerations associated with telehealth models.

Understanding Differences Between Telehealth Service Delivery and Other Models

As discussed by the American Psychological Association (2013) and Quigley et al. (2019), telehealth service delivery models necessitate some modifications to traditional in-person models. Practitioners need to develop minimum competencies in these modifications to practice within the service delivery model, plan for known risks, and maintain good outcomes. Practitioners implementing telehealth should have enough awareness to tact several of the key points below.

Understanding Telehealth Service Delivery Models

Not only must a practitioner understand variables associated with modifying behavior analytic interventions delivered via telehealth, practitioners should also know the differences between telehealth models. CASP (2020) describes at least four different models for consideration during the COVID-19 pandemic: full telehealth, partial telehealth, caregiver-implemented, and caregiver consultations (see Table 40.2). Practitioners should be able to state the pros and

Lee et al.	2015	Autism Spectrum disorder	The researchers describe the implementation of a behavior analytic telehealth model for assessment and treatment. The article contains technical descriptions of technology and useful troubleshooting guidance	Yes
Lindgren, et al.	2016	Autism Spectrum disorder	The authors evaluated the impact of three different service delivery models on children's challenging behavior. The research demonstrated each model successfully decreased challenging behavior. The home telehealth model had the lowest overall cost	Yes
McGarry, Vernon, & Baktha	2019	Parents	The authors evaluated the effectiveness of training parents to implement a pivotal response treatment (PRT) for children with autism Spectrum disorder. The article is an example of a parent-focused behavior analytic telehealth model	Yes
Hall, Monlux, Bujanda-Rodriguez, Jo & Pollard	2020	Fragile X syndrome	Randomized control trial evaluating a telehealth service delivery model for reducing problem behavior in boys with fragile X syndrome. The article is an example of an application of a telehealth model with a non-autism population	Yes
Pollard, Karimi, & Ficcaglia	2017	Professionals	The authors discuss the ethical considerations of behavior analytic telehealth models. The authors provide recommendations for developing clinical and business infrastructure	Yes
Pollard, LeBlanc, Griffin, & Baker	2020	Autism Spectrum disorder	The authors report outcomes on a sample of 17 patients with autism Spectrum Disorder who transitioned from in-person to telehealth technician-delivered ABA treatment at the onset of the COVID-19 pandemic	Yes

Author	Years	Population	Summary	Technology specification
Quigley et al.	2019	Professionals	The authors discuss the presence/absence of ethical considerations in telehealth research specific to individuals with autism Spectrum disorder. The authors provide recommendations for ethical considerations for research and practice	No
Rios, Kazemi, & Peterson	2018	Professionals	The authors discuss best practices for implementing behavior analytic telehealth services. The article contains useful information regarding technology considerations in relation to the best practices	Yes
Tomlinson, Gore, & McGill	2018	Professionals	A literature review summarizing training of employees delivering behavior analytic telehealth services. The article contains useful information regarding training practices and barriers to implementation	Yes

Table 40.2 Summaries of telehealth service models

Full telehealth	Services are delivered and received completely through technology
Partial telehealth	Some aspects of service delivery are delivered and received through technology. For example, a technician delivers services in-person, whereas the overseeing clinician utilizes technology for oversight
Caregiver implemented	The caregivers deliver services with oversight, training, and support from a clinician via technology. The focus is approximation of a typical model (e.g., services provided by a technician and overseen by a clinician) to support acquisition and maintenance of skills
Caregiver consultation	A clinician provides training and support to caregivers via technology. The focus is prevention of crisis and regression, and in some cases teaching of a few essential skills

Note. See Council of Autism Service Provider (2020) for additional information

cons of each model. One assumption of this competency is that it will improve the practitioner's ability to improve outcomes by choosing the correct model to fit the needs of the individual's circumstances best. Another assumption of this competency is the financial implications between models (see Funding of Services Delivered via Telehealth Model). CASP (2020) provides a tool is to assess the best-fit service delivery model for a given situation.

Regulation of Practitioners in a Telehealth Model

According to Green and Johnston (Green & Johnston, 2009; see also Carr & Nosik, 2017), regulation of professionals occurs via certification and licensure. Any practitioner with a professional certification or license must understand how the credentialing body regulates professional activities, as well as the jurisdictions of professional activities rendered. For example, the behavior analyst licensure law for Arizona regulates professionals residing in Arizona and providing services to someone in Arizona; a professional residing in Arizona providing services to someone in another state; and a professional residing in a different state and providing services to someone residing in Arizona (see https://psychboard.az.gov/statutes-rules for further information). Behavior analysts practicing using telehealth must be aware of the regulations in all states in which they practice. Additionally, different states may have overarching guidance specific to telehealth service delivery (e.g., APA, 2013; Health and Human Services, 2015). It is vital that the practitioner remains updated regarding the regulation of specific service delivery models, such as telehealth, as these rules are changing rapidly in today's society.

Funding of Services Delivered via Telehealth Model

CASP (2020, 2021) is a recommended resource for discussion of different telehealth service delivery models. These resources are unique in many ways but provide a necessary discussion of funding considerations for behavior analytic services delivered via a telehealth model. For example, CASP, 2020 contains a table indicating Current Procedural Terminology (CPT) codes and how those codes might be utilized via a telehealth service delivery model. The distinction between face-to-face and in-person services as defined by the American Medical Association (AMA) is also reviewed to aid practitioners in understanding when services can be rendered via telehealth. For example, some CPT codes require services to be delivered "face-to-face," which the AMA considers this requirement to be met when the face-to-face interaction occurs via synchronous videoconferencing.

Importantly, no practitioner should assume a service delivered via telehealth will be reimbursed and should carefully review funder guidelines. For example, some funders will approve the use of synchronous videoconferencing, but asynchronous review of patient and provider interactions is not allowed. Alternatively, some funders may have distance restrictions that only allow telehealth service delivery when a patient lives a specified distance from the provider (CASP, 2021). As recommended by CASP (2021), organizations should complete a review of each patient's health insurance coverage to determine if telehealth is a covered benefit, and if so, obtain additional information on approved modalities (i.e., synchronous and asynchronous), services (e.g., caregiver coaching, adaptive behavior treatment with protocol modification), and any restrictions that may exist.

Necessary Equipment and Expertise of a Telehealth Model

Telehealth delivery of behavior analytic services requires the use of technology. Some forms of technology might be more familiar than others (e.g., cellular phone versus a video technology platform, such as Doxy) to the practitioner. Each practitioner should be competent in the use of technology in general (e.g., needed technological support for setup, maintenance, and troubleshooting), specific technologies (e.g., difference between features associated with Zoom versus Doxy), and ethical issues that can arise specifically when using digital technology (e.g., confidentiality, privacy, consent). The American Psychological Association (2013), CASP (2021), and Pollard et al. (2017) are useful resources for general considerations associated with telehealth. Rios et al. (2018) describe a useful resource for technology considerations. Quigley et al. (2019) describe a useful resource for ethical considerations. Romani and Schieltz (2017) provide an example of determining unique telehealth considerations specific to an application area (i.e., problem behavior).

Behavior Analytic Telehealth Applications

Now that the reader understands the broad definition of telehealth and some of the considerations that the practitioner should take into account when practicing telehealth, some examples of behavior analytic practice using telehealth are provided. For each application, we provide a brief description, sample publications evaluating outcomes, and a discussion of key points, barriers, and future areas of research needed. The application areas described below are not exhaustive. The breadth of the behavior analytic applications to telehealth is, frankly, astounding. Furthermore, this is a burgeoning and continually evolving modality of service delivery. Detailed discussions of all these applications are beyond the scope of this chapter. Readers are encouraged to read the numerous citations within the chapter, information provided elsewhere in this volume, review other helpful resources (e.g., Bernstein & Chase, 2013), and continue to access professional journals, as new information is published.

Telehealth Applications for Severe and Challenging Behavior

The earliest documented application of synchronous telehealth in behavior analysis dates back to the late 1990s (Barretto et al., 2006). Using a statewide fiber-optic telecommunications system, Barretto and colleagues at the University of Iowa conducted over 75 telehealth evaluations across a 4-year period for children and adolescents who exhibited challenging behavior. Parents and school personnel at community sites (e.g., schools, Department of Human Services office) with synchronous video and audio coaching from a behavior analyst at a remote site conducted the assessments, which included descriptive and/or brief functional analyses (FAs). Despite initial demonstration of the feasibility of telehealth as a service modality for addressing challenging behavior, only three additional behavioral assessment or treatment telehealth studies with four total participants were published within the following 5 years (i.e., Frieder et al., 2009; Gibson et al., 2010; Machalicek et al., 2009).

Early feasibility studies were further validated by a series of studies conducted by Wacker and colleagues at the University of Iowa beginning in 2013. Wacker et al. (2013a) reported on 20 successful functional analyses conducted with young children with autism via telehealth and Wacker et al. (2013b) provided the FCT treatment data for 17 of those same children. The treatment data showed that substantial reductions in challenging behavior—greater than 93% reduction from baseline—could be obtained using an FA plus FCT approach via telehealth. Although still employing a single case design for data collection and analysis, the Iowa researchers published two subsequent large group studies involving FA plus FCT. However, rather than a clinic-to-clinic model, these studies employed a clinic-to-home model, whereby parents conducted all assessment and treatment sessions at home with coaching from the clinician at a remote clinic site.

Unlike previous studies, which were focused on establishing the feasibility of telehealth models to assess and treat challenging behavior, the focus of Lindgren et al. (2016) was to compare telehealth models to in-person service delivery in terms of outcomes and costs. The comparison was made between clinic-to-home, clinic-to-clinic, and in-home (on-site coaching) models. The three approaches did not differ statistically in terms of treatment outcomes related to reduction in child challenging behavior, increased child communication, or parent satisfaction. However, the clinic-to-home telehealth model cost was 67% less than the in-home model and 33% less than the clinic-to-clinic model, most of which was accounted for by travel costs. Moreover, the number of weekly visits to obtain the reduction in challenging behavior was an average of nine sessions for both the clinic and home telehealth models, whereas the average number of sessions required to reach the desired behavior reduction averaged 17 sessions for the in-person home model. Thus, not only did the clinic-to-home telehealth prove just as effective as other service delivery models, it was at a substantially reduced financial and time cost.

More recently, Lindgren et al. (2020) used telehealth to conduct a randomized controlled trial of FCT. In this study, telehealth no longer served as the independent variable, but as a method to conduct a study requiring a large sample to answer a research question. Another evaluation of FCT as a treatment approach for young children with autism who exhibit challenging behavior, a clinic-to-home telehealth model was used to coach the parents of 38 young children using FA plus FCT. Coaching parents via telehealth to implement FCT had superior results compared to treatment-as-usual with all children demonstrating substantial reductions in challenging behavior and increases in communication.

Studies from other research sites have also reported effective use of telehealth to assess and treat challenging behavior for young children with autism (e.g., Benson et al., 2018; Dimian et al., 2018; Hoffman et al., 2019; Machalicek et al., 2016; Martens et al., 2019; Simacek et al., 2017; Tsami et al., 2019). Additionally, studies have extended the use of telehealth to other diagnostic categories, such as cerebral palsy (Benson et al., 2018), Rett syndrome (Martens et al., 2019), and fragile X syndrome (Monlux et al., 2019; Hall et al., 2020); adolescents with challenging behavior (Machalicek et al., 2016; Tsami et al., 2019); international originating sites and families requiring language interpreters (Tsami et al., 2019); FBA methods other than FAs, including indirect methods (e.g., caregiver interview; Benson et al., 2018; Bice-Urbach & Kratochwill, 2016; Machalicek et al., 2016; Simacek et al., 2017; Tsami et al., 2019), descriptive assessments (Benson et al., 2018; Bice-Urbach & Kratochwill, 2016) and structured descriptive assessments leading to contingency space analyses (Martens et al., 2019), and other function-based treatments not involving FCT (Machalicek et al., 2016).

Telehealth Applications for Skill Acquisition

The COVID-19 pandemic led to a rapid expansion of telehealth service delivery and research on the direct delivery of treatment to patients via synchronous videoconferencing emerged (Ferguson et al., 2020; Pellegrino & DiGennaro Reed, 2020; Pollard et al., 2020). Pellegrino and Reed taught two adults with Intellectual and Developmental Disabilities (IDD) adaptive living skills (e.g., cook and manage a budget). All instructions and prompts were delivered via videoconference and both participants not only acquired the skills, but also expressed high satisfaction with the modality. Similarly, Ferguson et al. taught six children diagnosed with ASD tact relations via synchronous videoconferencing. All instructions, prompting, and reinforcement were delivered via videoconferencing and participants acquired and maintained the tact relations.

These initial findings are promising and beg the question of whether telehealth direct treatment is as effective as in-person delivery. Pollard and colleagues conducted an archival analysis of a sample of 17 cases who transitioned from in-person to telehealth technician-delivered applied behavior analysis (ABA) when shelter-in-place orders were issued at the onset of the COVID-19 pandemic to examine client progress pre- and post-transition to telehealth. The authors reported that 76% of participants demonstrated all of the CASP-recommended prerequisite skills (CASP, 2020) and 100% of those participants were successfully transitioned to a telehealth direct delivery model in which the participants participated in treatment with limited or no caregiver assistance. The remaining participants ($n = 4$) were transitioned to a caregiver-implemented model, in which the caregivers were the primary intervention agent responsible for delivering all components of the intervention (e.g., instructions, prompts, and reinforcement). Notably, participants continued with a similar dosage of treatment (in-person $M = 12$; telehealth $M = 11$) and maintained or improved correct independent responding (in-person $M = 75\%$; telehealth $M = 80\%$).

Based on a multitude of studies, there appears to be strong support for the delivery of behavior analytic services to assess and treat challenging behavior via telehealth. The literature base would be strengthened through studies utilizing larger participant groups, diversity of participants (e.g., age, diagnosis), generalization to other care providers (e.g., grandparents versus parents), and settings (e.g., community versus home). Additionally, research is needed to determine whether there are limiting factors for therapists (e.g., a parent who responds emotionally to child behavior) or behavior coaches (e.g., poor vocal communication). Finally, the future use of telehealth is contingent on governmental and business policies that will determine who can provide such services and where, as well as whether such services will be adequately reimbursed, if at all.

Telehealth Applications for Feeding and Nutrition

In the area of pediatric feeding, the first documented telehealth approach was conducted in 2008 by a hospital-based program that deployed a multidisciplinary team primarily consisting of Behavioral Psychology and Speech and Language Pathology (i.e., Clawson et al., 2008). In this study, the use of the telemedicine permitted the initial evaluations of 12 children and families for prospective treatment. The method in which telehealth was delivered was through the purchase of specific telehealth equipment for use at their site. Since all participants were out of state, each family was required to travel to a remote site locally that had compatible equipment to meet virtually with the clinicians who were based in Virginia. Treatment recommendations were provided for six children and admissions to their 6-week day treatment program were recommended for the other six participants. Results consisted of parent satisfaction surveys. Unfortunately, no clinical results were reported in the study. Follow-up (by phone) was also reported with three families. Thus, the overall results of the study showed that telehealth was an acceptable technology via satisfaction surveys in the initial assessment of children with pediatric feeding concerns.

Six years later, three papers were published that evaluated treatment results through telehealth technologies. The first of the three studies occurred outside the field of ABA. Malandraki et al. (2014) evaluated one participant who lived in another country (England; the researchers were based in New York City). A case study design (AB) was used to evaluate a treatment that consisted of several components, including, but limited to: (1) reduce response effort—use of a simulated spoon, (2) differential reinforcement for bite acceptance, (3) swallowing practice, and (4) muscle strengthening exercises (e.g., drinking from a straw, tucking his chin). The telehealth platform that was used for all sessions freely available (i.e., VSee). This platform also allowed the use of visual stimuli (i.e., a board game) that the participant could see, but all stimuli were manipulated by the researchers (i.e., the child could not control the objects on the screen). The experimenters primarily used this feature to deliver positive reinforcement along with sticker rewards provided on-site by the parents when the participant completed specific treatment steps. A larger reward was also delivered at the end of sessions. Intensive treatment consisted of a total of eight 1-h sessions that occurred twice, weekly. Parents were also required to implement, 30+ min of the treatment strategies on a daily basis. Treatment results that were gleaned included: (1) a decrease in the latency to bite acceptance (5 s–1 s); (2) an increase in texture of items consumed (thin liquids to purees); (3) an increase overall number of items consumed (4 in baseline to 21 by the end of treatment); (4) a decrease in swallowing latency (i.e., 89% reduction; from ~27 s to ~3 s); (5) a decrease in aerophagia (i.e., 12 liters per day to <1 liter/day); (6) improved scores on a swallowing measure checklist; and (7) positive post-treatment social validity measures indicating equal or better than face-to-face consultation. It should be noted that despite these improvements, the child remained tube dependent following treatment.

The remaining two studies were the first ones that employed ABA approaches using telehealth to address pediatric feeding (Rivas et al., 2014; Wilkins et al., 2014). Wilkins and colleagues focused primarily on a comparison of utensil usage (i.e., spoon versus nuk brush) to assess their impact on expulsions for patients who were admitted to their intensive day-treatment ($n = 11$) or intensive outpatient program ($n = 1$). The impact of the two different utensils was evaluated between two phases of treatment: (1) baseline and (2) non-removal and re-presentation of food items (i.e., escape extinction) using an ABAB design. Eight of the 12 (75%) participants achieved therapeutic effects. However, the nuk brush was associated with lower amounts of expulsions for five of the eight. Additionally, four of these five participants also demonstrated higher percentages of mouth cleans (i.e., food was swallowed within 30 s following acceptance). All seven participants demonstrated additional improvements during follow-up visits ranging from 3 months to 2 years. Pertinent to the topic of telehealth was that follow-up visits with one of the responders were entirely conducted using telehealth (via a secure web-conferencing program). Of note was that for this participant, her follow-ups at 3 and 18 months demonstrated improvements similar to patients who had in-clinic follow-up visits. However, during her 6-month follow-up, her expulsions increased back to baseline levels, acceptance decreased from 100% to 41%, and mouth cleans decreased from 100% to 20%. These trends reversed at 12-month follow-up with zero expulsions, 100% acceptance, and 73% mouth cleans. Notably, this patient was the only patient with follow-up data that showed regression of gains. However, it is unclear if these results of the 6-month follow-up were due to a utensil transition, treatment integrity concerns, or specific aspects of follow-up through telehealth. It should also be noted that at the 6-month follow-up, the transition from the nuk brush to the spoon occurred (however, this effect did not occur for the other six patients with follow-up data).

In Rivas and colleagues' study (2014), three participants were treated in an outpatient clinic during weekly 60–90-min sessions. The primary purpose of the study was to increase self-feeding behaviors for three children with a history of food refusal. Notably, one of the three participants was evaluated entirely through telehealth consultation. Treatment consisted of several components; however, the primary variable was that the child could choose to independently consume a target food (i.e., self-feed) or have one or more of those bites fed to them. Thus, the target food could not be escaped only the manner of delivery (fed or self-fed). For all participants, when the choice between being fed or self-fed one bite, all children most frequently chose to be fed. Therefore, the response effort of target foods was increased by increasing the number of required fed bites (i.e., to 2, 3, 4, and 5 fed bites) across phases until the participant probably shifted towards self-feeding. Thus, by self-feeding, they could escape or avoid the presentation of additional bites of target foods (i.e., greater effort). Treatment was successful for the two in-clinic participants when the required number of fed bites increased to two and three bites, respectively. However, the participant that was exposed to the same procedures via telehealth the probability of self-feeding remained low even when five fed target food items were presented. Therefore, an additional phase was included, in which the fed bites were switched from the same bite of the target food item to bites of a food that the participant avoided or never consumed (as identified through a stimulus preference assessment). Thus, if the participant would not consume the target food item independently, instead of additional fed bites of the same food item (same quality of food), he was then be given a prescribed number of fed bites of a different, less preferred food item (lower quality of food). This procedure was successful when the ratio of fed lower quality food items reached 4:1. That is, he biased his responding towards self-feeding 1 bite of target food to avoid being fed 4 bites of a lower quality (i.e., less preferred) food item. With respect to telehealth treatment delivery, it is interesting that the participants who received the same assessment and treatment in-person at the clinic were successful in 50% or fewer sessions (i.e., 120, 60 sessions versus 275 sessions) and with less intrusive procedures as compared to the child who received treatment through telehealth. Because only one participant was exposed to a telehealth mode of delivery, it is unclear if these results were due to modality or idiosyncratic variables associated with the participant, however.

The first study that exclusively utilized telehealth during assessment and treatment of food refusal was conducted by Peterson et al. (2015). In this study, two patients presented liquid refusal and were treated through an outpatient telehealth clinic during weekly 1-h outpatient appointments. Sessions were conducted using Adobe Connect with parents serving as the therapists. However, it should be noted that both participants had been admitted previously to an 8-week feeding program. The goals of this study were an extension of treatment goals through that program and this study occurred 1 week following the patient's discharge from day treatment. Treatment consisted of evaluation of differential reinforcement of liquid acceptance (2 cc per sip). Treatment results were demonstrated through a reversal design (ABAB) with liquid fading from 2 to 4 cc and 10 cc for the two participants. This is the first published study that completed treatment, with liquid consumption increasing for both participants to 100% of offers which was executed exclusively through a telehealth platform.

In the aforementioned studies, telehealth appeared to be of a practical matter as opposed to a programmed one to evaluate its effectiveness. Peterson et al. (2020) conducted the first study comparing in-clinic and telehealth models. The authors examined the results of three children who initially were previously admitted to an intensive feeding program and then received follow-up through a combination of in-clinic and telehealth follow-up appointments. Overall, results were similar for all measures (i.e., acceptance, mouth cleans, and inappropriate behavior) across modalities. However, for one participant, there was a significant decrease in acceptance and a concomitant increase in inappropriate behavior during the second instance of telehealth consultation. Notably, the experimenters included treatment integrity data, which showed covariation between treatment integrity problems and increases in target behaviors. Thus, the problems with effectiveness did not appear to be due to telehealth treatment delivery, but rather to poor treatment integrity. In the second part of the study, 12 patients were divided into two groups and exposed to follow-up exclusively via either telehealth or in-clinic. Rather than presenting child-specific data, the percentage of goals met during follow-up was reported. These occurred in 3-month intervals, up to 21 months of follow-up. The patients in the telehealth group met 100% of their goals and those in the in-clinic group met

92% of their goals. Thus, overall, no major differences in treatment effectiveness were found across modalities during outpatient follow-up.

The application of telehealth in pediatric feeding is still in its infancy. Research in this area has somewhat lagged behind that found in the challenging behavior literature. Most pediatric feeding programs have essentially four phases of assessment and treatment: initial evaluation and screening, outpatient treatment, intensive treatment (e.g., day treatment or inpatient treatment), and follow-up. The handful of studies in pediatric feeding that employ ABA approaches via telehealth have revealed that telehealth has been primarily used in the follow-up aspects of cases. Non-behavior analytic studies of feeding disorders have utilized telehealth in the initial evaluation and outpatient treatment phases. No studies have used telehealth during intensive treatment.

A myriad of reasons may explain the limited use of telehealth in the initial evaluation and intensive treatment phases of treatment of feeding disorders. In the initial assessment and screening phase, unique information is best obtained in-person. For example, key idiosyncratic child and parent behaviors may be missed when the only view is a front facing camera (e.g., sibling behaviors, body language of the feeder, joint attention, distractions). These could be key antecedents and consequences for specific mealtime behaviors (i.e., bite acceptance, refusals, problem behavior). How food is prepared (e.g., poorly cooked, the size of bites, brand changes) is a key variable for consideration and may be missed. In addition, for some children, medical issues (e.g., aspiration, allergic reactions, aerophagia), oral-motor concerns (e.g., lateralization, packing), and other nuances (e.g., parents pushing liquids through the tube during a meal, sibling kicks the patient under the table) might be missed or may create an unsafe situation using telehealth. In an initial evaluation, it may be useful to have a wide-angle camera lens to capture variables that could be missed through the current telehealth technology formats.

Intensive treatment also presents several significant issues that could limit the usefulness of telehealth. First, for most children admitted to these programs, they have already failed outpatient treatment or the feeding issue was so severe that a multidisciplinary team was needed. Ongoing medical issues could result in the activation of emergency medical services, which would be impractical and unsafe to implement via a telehealth model, where the child and family are at home. Another factor is that most intensive programs replace the caregivers as feeders with trained feeding staff, at least initially. Some treatment procedures such as nonremoval of the spoon require specific training to implement correctly. Moreover, inappropriate application of some procedures could result in several poor outcomes (e.g., poor integrity with intermittent reinforcement, latency to respond errors, poor technique, frustration by the caregivers, and longer need for treatment). Finally, some treatment procedures result in significant increases of other behaviors that parents may not be able to address adequately or respond to appropriately when they occur (e.g., vomiting, packing). In these situations, having trained therapists may be important for the safety of the child and positive outcomes of treatment.

The challenges presented to safety and expertise needed may be why there is limited research on intensive treatment of feeding disorders using telehealth. Telehealth may be more feasible during other phases of treatment for feeding disorders (e.g., follow-up), as evinced by the studies described here. This notion of differential viability of procedures within telehealth is also present in other professions (e.g., in-person surgery versus telehealth wellness check). The differential viability should not limit the application of telehealth models to address clinical needs (e.g., funders limiting reimbursement for outpatient telehealth services because the intensive model is not viable). It appears that after an effective treatment has been established and presumably, initial treatment effects have occurred in-person, a move to telehealth for follow-up is more feasible (e.g., Peterson et al., 2015, 2020; Rivas et al., 2014). Future research should explore the limits of telehealth applications for intensive treatment, clearly indicating when in-person treatment versus telehealth treatment can begin and end across the four phases of assessment and treatment process. A randomized control-design (e.g., Lindgren et al., 2016) would appear to be a welcomed addition to the literature to further elucidate the benefits and limitations of telehealth treatment of feeding disorders. Additionally, adding cost or social validity measures would further bolster current findings.

Telehealth Applications for Clinical Behavior Analysis

Clinical behavior analysis, a subspecialty within the field of behavior analysis, broadly focused on traditional mental health issues (Dougher, 2000), has benefitted from research supporting both synchronous and asynchronous teletherapy approaches. Technological advances have given clinical behavior analysts the opportunity to deliver a broad range of therapeutic approaches traditionally offered only in-person clinic settings through real-time remote videoconferencing and/or web-based asynchronous programs and applications. For therapeutic approaches relying heavily on oral discourse, service via telephone may be an adequate alternative or simply an adjunct to in-person or video conferencing. This section provides a brief overview of research on the use of telehealth for several common behaviorally based therapeutic approaches to mental health disorders.

Cognitive–Behavioral Therapy Cognitive–behavioral therapy (CBT), a form of psychotherapy with a focus on challenging negative thought and behavior patterns, has been one of the most researched and effective approaches to various child and adult conditions (Friedberg & Paternostro, 2019). Additionally, it was one of the earliest forms of psychotherapy delivered via telehealth (Selmi et al., 1982). Studies over nearly 30 years have provided evidence of the efficacy of telehealth-delivered CBT for a variety of conditions, including post-traumatic stress disorder (e.g., Germain et al., 2009), panic disorder (e.g., Bouchard et al., 2004), insomnia (e.g., Espie et al., 2012), depression and/or anxiety (Khatri et al., 2014), and eating disorders (e.g., Abrahamsson et al., 2018).

Perhaps, due to real and perceived barriers to accessing psychotherapy (Mohr et al., 2010), including face-to-face synchronous telehealth delivery of CBT, self-guided web-based CBT has become a popular alternative (Webb et al., 2017). Self-guided programs typically involve a combination of psychoeducation, skills instruction, homework, and at least some offer occasional remote therapist involvement (e.g., Spence et al., 2011). Research has largely shown web-based self-guided CBT approaches to be superior to no treatment for several conditions, such as depression/anxiety (e.g., Karyotaki et al., 2017) and insomnia (e.g., Holmquist et al., 2014). However, models incorporating therapist support or guidance appear to have better outcomes than those without (e.g., Baumeister et al., 2014). To better approximate the therapeutic process observed in face-to-face therapy, new forms of web-based CBT have employed artificial intelligence (AI) to serve as conversational agents mirroring face-to-face encounters (e.g., Fitzpatrick et al., 2017; Fulmer et al., 2018; Schure et al., 2020), but research comparing AI versus human support is still needed.

Habit reversal therapy and exposure with response prevention Habit reversal therapy (HRT) and exposure and response prevention (ERP) are first-line behavioral treatments for tic disorders and obsessive–compulsive disorder (OCD), respectively (Franklin et al., 2012). Both approaches depend heavily on behavioral treatment models and are oftentimes categorized as forms of CBT. There are studies to support the feasibility of telehealth-delivered models for both HRT and ERP, although there is more research dedicated to evaluate the effectiveness of ERP. Varieties of telehealth models yield positive results when treating OCD via ERP. Models include computerized (non-web-based) programs with and without therapist support (e.g., Greist et al., 2002; Kenwright et al., 2005), asynchronous web-based treatment with intermittent synchronous therapist support (e.g., Andersson et al., 2012; Kobak et al., 2015), and synchronous video-based (e.g., Comer et al., 2017; Goetter et al., 2014; Vogel et al., 2014) or telephone-based (Turner et al., 2014) therapy. In general, telehealth delivered ERP appears to be as effective as in-vivo therapy for treatment of OCD (Dèttore et al., 2015).

Only two studies have evaluated the use of telehealth to deliver HRT, both of which focused on videoconferencing for youth with tic disorders. Himle et al. (2012) conducted a small-randomized trial comparing telehealth-delivered HRT to in-vivo HRT and showed that telehealth was just as effective and acceptable as in-person therapy. While Himle and colleagues utilized a clinic-to-clinic model, Ricketts et al. (2016) conducted a randomized trial of clinic-to-home telehealth. Compared to a wait-list control, clinic-to-home telehealth resulted in significant reductions in tic severity and patient satisfaction was high.

Acceptance and commitment therapy Acceptance and commitment therapy (ACT) utilizes techniques such as mindfulness and behavior-change strategies to promote psychological flexibility (Hayes et al., 2006). Like CBT, acceptance and commitment therapy (ACT) has been heavily researched and shown effective across a broad range of conditions (Gloster et al., 2020). However, few studies have evaluated telehealth-delivered ACT and those published largely focus on delivering ACT to adults. Studies evaluating the effects of web-based ACT on anxiety and depression comprise the majority of studies, including several systematic reviews and meta-analyses. Recently, Thompson et al. (2020) conducted a systematic review and meta-analysis of research on web-based ACT, with and without therapist guidance. They reported small, but significant effect sizes for web-based ACT on depression and anxiety, and they found that therapist guidance led to greater improvements in depressive symptoms than approaches, where therapist support was not included. These findings are consistent with several other systematic reviews and meta-analyses (e.g., Brown et al., 2016; Kelson et al., 2019). Feasibility and comparative studies on web-based ACT have demonstrated successful application to a variety of other conditions, including pain (e.g., Herbert et al., 2017; Scott et al., 2018), insomnia (Chapoutot et al., 2020), and smoking (Bricker et al., 2014).

Behavioral activation therapy With a primary focus on increasing engagement in activities that result in positive reinforcement, behavioral activation (BA) therapy has been shown effective in the treatment of depression (e.g., Dimidjian et al., 2006; Ekers et al., 2014). More recently, research suggests that BA may be an effective component in the treatment of post-traumatic stress disorder (PTSD; Flint et al., 2020). Given the evidence base for BA and the common view that BA is a low intensity therapy approach, it has been suggested that BA therapy is ideal for delivery through telehealth formats (Huguet et al., 2018). Indeed, BA has been a treatment component in numerous teletherapy studies, even though few have evaluated BA as a stand-alone treatment. Studies utilizing BA to treat depression have shown success with blended models of in-person and technology (e.g., smartphone application (Ly et al., 2015); text messaging (Hart et al., 2019); clinic-to-home videoconferencing (Acierno et al., 2016); clinic-to-clinic videoconferencing (Lazzari et al., 2011); computer modules with as needed therapist support (Spates et al., 2013); email-only therapy (Eisma et al., 2015)). Satisfaction of telehealth-delivered BA therapy has generally been high (Pruitt et al., 2019) and the cost comparatively lower than in vivo delivery (Egede et al., 2018). Although numerous web-based applications utilizing BA to treat depressive symptoms are available, Huguet et al. (2016) concluded very few provide therapeutic components consistent with evidence-based BA therapy.

Contingency management Contingency management (CM) is an incentive-based intervention that can be used to promote a variety of clinically relevant, adaptive behaviors. Typically, some kind of material incentive is provided contingent upon the patient meeting some criterion for displaying a target behavior, which is objectively measured and verified (Lussier et al., 2006). One area in which contingency management has been shown to be efficacious is for promoting and maintaining drug abstinence (e.g., Benishek et al., 2014). Recently, DeFulio et al. (2021b) evaluated the use of a smartphone application and smart card (i.e., reloadable debit card that protects against risky withdrawals or debits) in participants diagnosed with opioid use disorder. The smartphone intervention was delivered in addition to ongoing, typical therapy. Participants with problem alcohol use also used the smartphones, along with a Bluetooth integrated breathalyzer device that connected to the app to remotely conduct random breathalyzer tests. The smartphone app cued participants to engage in the target behaviors, notified participants of corresponding incentives, notified participants of breathalyzer tests, and provided reminders of clinic appointments. Participants completed textual CBT modules, including comprehension questions on the modules in the app. Participants earned money on their smartcards by attending appointments, providing consistent urine tests, and completing CBT modules. Financial incentives were delivered within a couple of hours after participants met the criteria for an incentive. Participants who used the app were statistically more likely to have clean urine tests than the control group (who received the business-as-usual treatment only) in the first 30 days of treatment. They were also four times more likely to have urine tests consistent with abstinence at the end of the study. Taken together, these results suggest that ongoing use of the app produced higher maintenance of treatment effects relative to treatment without the app. The smartphone app produced impressive outcomes and had the advantages of providing participants with advanced notifications, automated accounting of their incentives, prompt delivery of the incentives, and frequent contact with the treatment. This example of telehealth treatment provides promise for an effective intervention for drug abstinence. It also has the potential to decrease clinician burden, because so much of the intervention is delivered automatically. Finally, the treatment was found to be highly acceptable to participants.

Another interesting application of CM delivered by smartphones is in promoting medication adherence. DeFulio et al. (2021a) evaluated the use of a smartphone-based incentive system on the adherence to antiretroviral therapy (ART) in patients living with HIV. ART can reduce the chance of transmission of HIV to others and can increase both the quality and length of life for those infected with HIV. However, high levels of medication adherence are required to achieve the positive effects of ART. While several interventions, such as CM, reminders, and counseling, have shown positive effects on adherence, these effects are often short-lived and do not maintain after the intervention has been discontinued. DeFulio and colleagues (under review) provided HIV-infected participants with smartphones and an app called SteadyRX, which allowed participants to take time-stamped selfie videos demonstrating ART adherence, which were checked daily and asynchronously by the researchers. The app also provided feedback on incentives earned for days with medication adherence and disbursed incentives every time participants reached \$10. Finally, the app provided listings and contact information for community resources, as well as pdf training materials. While underpowered, the study showed positive effects of the CM intervention delivered by smartphones (95% adherence), suggesting feasibility of the intervention. The intervention was easy to implement and convenient for participants to use. It was also found to be acceptable by participants, who reported improvements in understanding their own care and who reportedly felt empowered to ask more questions about their care. The long-term benefits of the intervention still need to be evaluated, and the cost of intervention implementation may be a barrier to long-term use of the intervention. Thus, the cost effectiveness of SteadyRX still needs to be analyzed. In spite of these challenges and needs for further study, SteadyRX and other smartphone applications of

CM are a very creative, interesting way of providing asynchronous telehealth treatment for clinical populations.

Additional Questions and Considerations

Despite the bevy of studies that have established the efficacy of behaviorally based telehealth therapies, there continue to be challenges and unanswered questions involving their use. For example, a great deal of research has shown that the successful development of a therapeutic alliance or connection between a therapist and patient is one predictor of positive treatment outcomes (Norcross & Lambert, 2019). However, one of the primary factors contributing to this alliance is therapeutic presence, being fully engaged with the patient in the moment (Geller, 2017), which may be challenging when therapy sessions are conducted through remote technologies. Worse yet, this therapeutic presence may not exist at all when asynchronous telehealth and online therapy without therapist support is used. Indeed, several studies have found better treatment effects when in-person therapist support is provided than when it is absent (e.g., Baumeister et al., 2014). Only a few studies have evaluated the development of the therapeutic alliance in remote therapies (Flückiger et al., 2018; Wehmann et al., 2020).

Roughly 50% of all people living with a mental health disorder in the US go without treatment, often due to a combination of limited availability and high costs of therapy (NAMI, 2017). Bolstered by a growing body of literature supporting the use of telehealth in clinical behavior analysis, telehealth may be an ideal solution that provides both a low-cost approach and the ability to reach individuals in virtually any location. Unfortunately, outside of telehealth-delivered HRT, a glaring hole in the research literature is the lack of studies involving children and adolescents. Given that nearly one in six children in the US experience a mental disorder (Whitney & Peterson, 2019) and suicide is the second leading cause of death in adolescents (Shain, 2016), it will be important for future studies to establish the efficacy and satisfaction associated with delivering behaviorally based therapies to children and adolescents via telehealth.

Finally, there seems to be no end to the number of modalities that clinical behavior analysis can be provided using telehealth. It is virtually impossible to determine what model or mixture of models is most effective and for whom. Although we have tried to focus largely on telehealth approaches involving some form of therapist–patient interaction, whether synchronous or asynchronous, there are many studies providing at least some support for self-guided approaches, with and without therapist support. Comparative studies evaluating the effectiveness of telehealth-based delivery and in-person delivery are necessary, but not sufficient for understanding optimal therapeutic benefit. Although it would be impossible to evaluate every telehealth permutation possible, it would be beneficial to directly compare the effectiveness of the different delivery models. Additionally, important people variables (e.g., conditions, ages), procedural variables (e.g., timing and dosage, integration of therapist support), perceptions (e.g., patient acceptability), accessibility, and costs should be documented and evaluated for clinicians to be fully informed of the optimal treatment options.

Telehealth Applications for Education and Professional Development

Closely related to the telehealth approaches described above, there are additional behavior analytic applications of intervention that can be applied to the education of both children and adults. One might refer to these applications as "tele-education." Historically, education, both for children and adult learners, has occurred largely in an in-person context. However, as technologies have developed, more and more learners have begun to access online platforms for their learning. For example, Driscoll et al. (2012) estimated that over 30% of college students take at least one online course. Of the 592 university programs offering a Verified Course Sequence for training in behavior analysis, 289 of them offer an online option for training and an additional 62 offer a hybrid (online combined with in-person instruction) option for training (Association for Behavior Analysis, International, November 8, 2020). Furthermore, the COVID-19 pandemic brought forth a rapid change in landscape for both learners and educators, with an almost overnight requirement to shift education for children and adult learners from traditional, in-person learning models to hybrid and fully online models. A thorough review of the literature in this area or even of examples of research in this area is well beyond the scope of this chapter. Thus, the purpose of this section is to describe a few behavior analytic applications of "tele-education." We begin with an example applications of behavior analytic tele-education for children and conclude with multiple examples of tele-education for adult learners.

Tele-education for children One of the best-known examples of asynchronous education for children that was developed from a behavioral perspective is Headsprout *Early Reading*, and later Headsprout *Reading Comprehension,* were developed as online platforms for teaching reading. The platforms address each of the areas identified by the National Reading Panel (2000) as key areas of reading proficiency: phonemic awareness, phonics, fluency, vocabulary, and comprehension. In short, these programs include a number of online "episodes" designed for young children (i.e., kindergartners through second grade). These episodes contain interesting characters, such as dinosaurs and space aliens. The episodes are "gamified," and children have to help the characters solve problems or reach a goal. Students are rewarded for correct responding by the presentation of interesting visual and auditory stimuli. High levels of correct responding (90% correct) are required for children to move on to a new skill (see Layng et al., 2004 and Twyman et al., 2004 for detailed descriptions of these programs.) Rigney et al. (2020) conducted a review of published studies evaluating the effectiveness of Headsprout. This analysis showed that there is strong evidence of Headsprout's effectiveness in teaching phonics, fluency, vocabulary, and comprehension skills. However, many of the studies conducted to date do not meet the quality standards for research based on standards established by the What Works Clearinghouse (2017). Therefore, more research needs to be conducted before strong conclusions about the efficacy of Headsprout can be made. Rigney et al. (2020) suggest that Headsprout does seem to be effective in many areas, but that it is important to continue research on this curriculum to guard against the widespread adoption and use of an intervention that may not be as effective as claimed. Regardless, Headsprout exemplifies a behavior analytic approach to education.

Headsprout is but one example of effective behavior analytic education that is presented virtually. There are many more examples available—too many to adequately address here. Furthermore, there is a vast array of very creative, non-behavior analytic applications for tele-education (e.g., Tanaka et al., 2015). Moran and Malott (2004) include several chapters describing behavior analytic approaches to education (e.g., personalized systems of instruction and precision teaching) that may be implemented in a telehealth format. An additional resource is the American Psychological Association (APA) Division Two, Society for the Teaching of Psychology (see http://teachpsych.org/about for further information). In fact, the Society for the Teaching of Psychology recently supported the Online Teaching of Psychology Conference: Using Behavior Science to Improve Online Higher Education (see https://media.wcsu.edu/channel/Online%2BTeaching%2Bof%2BPsychology%2BConference%2B%2528Nov.%2B13th%2B2020%2529/189596123?fbclid=IwAR0kvOoijW28xC1jzRjF_nCZa0iz2Ul1la1kM-p69aE6kaG_nDwG-zkGEodQ) for further information).

Tele-education for professional development Technological advances have afforded the opportunity for advanced training and continuing education opportunities for behavior analysts and behavior technicians (Gerencser et al., 2020; Tomlinson et al., 2018). Similar to those seeking treatment for problem behavior, food refusal, or clinical disorders at specialized hospitals and clinics, travel to local higher education institutions or organizations that provide advanced training is often a barrier for providers, particularly those living in rural and geographical isolated areas (Arora et al., 2007). In order to meet the training needs of providers in rural and underserved communities, researchers have developed synchronous and asynchronous training options that have been employed to disseminate Applied Behavior Analysis (ABA) teaching methodology worldwide. Technologies enable direct care technicians and behavior analysis to receive training in their local communities, thereby improving access to quality care for families in those same communities.

Effective instruction often employs behavioral skills training (BST; Reid & Parsons, 1995), which consists of a slow release of responsibility from the teacher to the learner in displaying the desired skill. Typically, this consists of the instructor telling students who to perform the skill, then showing students how to perform the skill, having students practice performing the skill with close supervision for feedback, and then having students perform the skill independently and in the natural context of where the skill is needed. BST is an established teaching method that used to teach a variety of ABA methodologies to staff, caregivers, and teachers (e.g., Lavie & Sturmey, 2002; Sarokoff & Sturmey, 2004). Under traditional in-person training model, instructions are provided orally or in written format and modeling of the skill may be provided live with the instructor demonstrating the skills. Role-play opportunities are typically provided with the instructor and/or another trainee serving as role-play partner and instructor feedback is provided during role-plays or immediately following role-plays. Staff training delivered via telehealth often follows the same BST model implemented during in-person training, with some modifications to the delivery format. For example, instructions might be provided via asynchronous online modules (Gerencser et al., 2020; Higbee et al., 2016; Pollard et al., 2014) or via synchronous videoconferencing platforms (e.g., Fisher et al., 2014). Skill modeling may also be provided asynchronously using video models to demonstrate the skill or might include synchronous, real-time viewing via screen sharing features in the video conference platform. Role-play and feedback opportunities often require some modifications. For example, the trainee may be required to identify an on-site role-play partner with whom to rehearse the skills in-person. Similar to live training, the trainer might observe the trainee rehearse the skills via live videoconferencing and provide real-time coaching and feedback (e.g., Buzhardt & Heitzman-Powell, 2005). Using a combination of these procedures, individuals have been successfully trained to implement a variety of ABA teaching methods, including mand training, discrete trial teaching, preference assessments, functional communication training, and functional analysis implementation.

Rios et al. (2020) used remote BST to train practitioners to implement functional analysis conditions using a nonconcurrent multiple baseline to evaluate the effects of training. Ten behavior analytic clinicians participated in training delivered remotely using video conferencing software. Participants were provided with written descriptions for how to implement functional analysis conditions. Then, they watched video models synchronously with the researchers. Next, they were provided opportunities to practice the skills remotely with a confederate serving as a child with problem behavior. The confederate was at the site with the trainers, while the practitioners were located at their center. Practitioners practiced the skills with live feedback through video conferencing until they reached mastery. After participants had reached mastery on all functional analysis conditions, maintenance probes were conducted regularly until they needed to implement conditions with an actual client. Practitioners were observed as they implemented conditions with actual clients to determine if their skills generalized. These probes were also conducted remotely. All participants improved their skills with functional analysis implementation. Eight of ten participants' performance maintained at or above mastery during maintenance probes and with actual clients. Only two needed further training and support. In addition, training took very little time—time required for training averaged 50 min across participants (range 36–75 min). This study demonstrated that BST could be implemented efficiently and effectively through synchronous remote training.

Asynchronous training methods also have been employed to teach caregivers, providers, and teachers about the principles of behavior analysis, as well as specific teaching methodologies (e.g., discrete trial teaching, mand training) (Gerencser et al., 2020; Higbee et al., 2016; Pollard et al., 2014). Asynchronous trainings are typically delivered in a self-paced format, in which individuals may view recorded webinars. Sometimes referred to as e-learning or online learning, the instructions might be provided orally via asynchronous web-based platforms and/or written instructions may be delivered via electronic format (e.g., email, website, or smartphone application) (e.g., Granpeesheh et al., 2010; Hamad et al., 2010). Asynchronous learning often incorporates components that are similar to behavioral skills training, as described above. For example, trainees may receive access to audio and written instructions as well as video models remotely and asynchronously. Such asynchronous lessons may also include rehearsal exercises, during which the trainee practices implementing specific skills on their own. One drawback of asynchronous rehearsal exercises is that the trainee may rehearse incorrect implementation of skills with little immediate feedback due to the lack of an expert available during practice. However, despite this limitation, research has suggested asynchronous training can have a positive impact on skills development, especially when it is followed by coaching and feedback (Gerencser et al., 2020; Granpeesheh et al., 2010; Higbee et al., 2016; Pollard et al., 2014; Vismara et al., 2009).

A vital component in the delivery of quality services is continuing education. Typically delivered in a workshop or didactic format, continuing education opportunities can provide limited results, particularly for the management of complex cases. Combining in-person with synchronous and asynchronous tele-education can provide a comprehensive, effective, long-term solution to the need for ongoing mentoring and staff development. To help address the limitations of the traditional continuing education model, the Extension for Community Healthcare Outcomes (ECHO) was developed as a new model of healthcare training. Project ECHO combines brief didactic training with case mentoring that is designed to create on-going learning opportunities for participants through a virtual learning network. Using synchronous videoconferencing, experts provide shared case management and consultation on complex cases to providers. Providers are able to enhance their clinical knowledge using their own cases for training and may present their cases multiple times for on-going, case-specific mentorship.

Project ECHO is not intended to replace the continuing education system. Rather, it is a technology-supported, supplemental continuing education and mentoring program designed to increase provider competence and confidence in treating patients. Leveraging the strengths of multiple training formats, Project ECHO not only has been effective in disseminating information quickly, but also in reducing the barriers related to provider isolation and burnout, both of which are common among rural providers (Arora et al., 2007). Rural providers who participated in these programs reported increased knowledge, empathy, comfort, and self-efficacy in dealing with chronic conditions. Project ECHO has been replicated across various complex disorders, including ASD, mental health, epilepsy, dementia, palliative care, and chronic pain internationally (Zhou et al., 2016).

Pollard et al. (2021) adapted the Project ECHO model with behavior analysts to promote advanced care coordination with multidisciplinary professionals, as well as mentoring behavior analysts to implement telehealth service delivery models for ABA services. ECHO Autism for Enhancing Coordination of Care for Autism was successfully piloted with the behavior analytic community. ECHO clinics were delivered via synchronous videoconferencing twice per month for 2 h each time. A multidisciplinary panel consisting of a developmental pediatrician, a doctoral level Board Certified Behavior Analyst, a Licensed Clinical Social Worker, a masters level Healthcare Administrator, and a parent of a child with ASD led each ECHO clinic. Each clinic began with a 30-min didactic presentation from multidisciplinary team members and followed with a 90-min interactive case presentation that was designed to expand the behavior analyst's knowledge of coordination of care. All panelist and participants participated using real-time video and audio technology (i.e., Zoom). Case presenters received oral and written recommendations for their case in real-time during the ECHO clinic, and supplemental resources were emailed following each clinic to support clinical recommendations (e.g., research, tool kits, programs and other resources). Providers reported high levels of satisfaction with the mentoring model, as well as increased confidence in coordinating care. Applications of Project ECHO are widespread, and due to the benefits, we are beginning to see emerging programs and research within the field of behavior analysis.

As technology continues to advance, new technologies will continue to emerge to meet the training needs of providers, caregivers, and staff, as well as provide continuing education opportunities. For example, podcasts have emerged as another avenue to disseminate behavior analytic information, and while there is not any research to date on this avenue for providing continuing education to staff, researchers should consider exploring this modality for supplemental staff training. Virtual reality has been used in healthcare education and training, including telesurgical applications, emergency response training, and 3D environments for treating mental health disorders (Mantovani et al., 2003). Virtual reality training and training using robotics also will likely emerge in future behavior analytic research for staff training. These applications may provide additional opportunities to enhance provider training, particularly in rural areas, where limited training opportunities exist (Mantovani et al.). Often, providers acquire training experience with already existing patients; however, when ABA services are delivered in-home, this can often be obtrusive and uncomfortable for a family to have trainees in their home working with their child (e.g., Karst & Van Hecke, 2012). Advances across multiple technology platforms will continue to provide additional avenues to standardize training and better prepare the ABA workforce.

Conclusion

Telehealth is a service delivery model utilized by many different professions, including behavior analysts. As with all service delivery models, professionals should be aware of pros and cons to ensure implementation meets the needs of those served. We have provided several resources for behavior analysts to evaluate fit of a telehealth service delivery model within their practice. Additionally, we have described and discussed how telehealth has been applied in several behavior analytic service programs. The information provided here should not be considered exhaustive, as the breadth and depth of application are vast within the field. Furthermore, technology evolves extremely rapidly, and thus, applications rapidly change and improve. This is an important and ever-evolving area in the field of behavior analysis. The reader must stay current with contemporary research to stay abreast of developments in this area. This is true across the field of behavior analysis, but perhaps especially true, where computer technologies are concerned.

41 Smoking Cessation

Jesse Dallery, Lesleigh Stinson, and Andrea Villegas

Smoking Cessation

Cigarette smoking continues to take an enormous toll on society. Since the first Surgeon General's report on the health consequences of smoking in 1964, more than 20 million Americans have died prematurely from tobacco-related diseases (U.S. Department of Health and Human Services, 2014). An estimated 34.2 million people still smoke combustible cigarettes in the United States, and smoking remains the leading cause of premature death and preventable disease (Creamer et al., 2019). At least 70 chemicals in cigarette smoke are known carcinogens including arsenic, benzene, formaldehyde, lead, nitrosamines, and polonium 210 (Prochaska & Benowitz, 2019). Most adult smokers, 88%, smoked their first cigarette before the age of 18 (U.S. Department of Health and Human Services, 2012). Quitting cigarette smoking produces health benefits regardless of age (U.S. Department of Health and Human Services, 2014), and novel regulatory and treatment options continue to emerge to promote cessation (Bricker et al., 2018; Donny et al., 2014).

In this chapter, we review a behavior analytic approach to conceptualizing, assessing, and treating cigarette smoking. A behavior analytic perspective views cigarette smoking as operant behavior, or behavior that is selected and maintained by consequences (Thompson & Johanson, 1981; Silverman, 2004). Viewing cigarette smoking as operant behavior is tremendously useful in assessment and treatment (Henningfield & Higgins, 1989). The acquisition and maintenance of smoking can include social and non-social primary reinforcers, conditioned reinforcers, observational learning, the influence of advertising, social media, rules, and negative reinforcement. A behavior analytic account also entails contextual factors such as the availability of alternative sources of reinforcement and environmental stressors. It is also compatible with other biological and psychosocial theories to account for cigarette smoking. For example, genetic or acquired characteristics (e.g., family history of cigarette smoking or substance dependence, other psychiatric disorders) can affect the probability of cigarette smoking (Hatsukami et al., 2008). These characteristics may produce individual differences in sensitivity to reinforcement (to drug and/or social reinforcers), punishment, and delay to reinforcement that may contribute to cigarette smoking (Thompson, 2007). The operant view also incorporates private events such as craving and anxiety, as well as verbally mediated processes as part of a comprehensive account of the determinants and outcomes of smoking (DeGrandpre, 2000; Wilson & Hayes, 2000). Finally, a behavior analytic perspective also pro-

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_41

vides a useful framework to account for the effects of conventional treatments for smoking such as nicotine replacement, behavioral treatments focused on providing incentives contingent on abstinence, and novel regulatory and intervention efforts to prevent smoking and promote long-term cessation (Cassidy & Kurti, 2018).

Conceptual Framework: The Four-Term Operant Unit

Most of the biological and environmental variables associated with the acquisition, maintenance, and successful treatment of cigarette smoking can be captured by the four-term operant unit (Dallery et al., 2013; Thompson, 2007). The four-term operant unit consists of motivating operations, discriminative stimuli, the target behavior of cigarette smoking, and consequent stimuli. Figure 41.1 presents a schematic of these units and some of their interactions. We have included examples of each term in the operant unit, but these nominal examples are not meant to apply universally across individuals. Also, the static nature of the figure belies the dynamic nature of how these units emerge over time, and how the influence of different variables may vary over time and across individuals.

Upon inhalation, nicotine rapidly enters the lungs, undergoes dissolution in pulmonary fluid, and is transported to the heart and then to the brain (Hatsukami et al., 2008). It takes about 10 s for nicotine to enter the brain (Rupprecht et al., 2015). Daily smokers may smoke consistently throughout the day to maintain nicotine levels in a particular range (Benowitz, 1991). Cigarette smoke contains over 7000 chemicals, some of which may enhance the psychoactive effects of nicotine and some of which have independent psychoactive properties (Rupprecht et al., 2015). Evidence suggests that nicotine can serve as a positive reinforcer in non-humans and humans (Henningfield & Goldberg, 1983; Perkins et al., 2001). Laboratory research with non-human animals, however, suggests that nicotine serves as a weak primary reinforcer (Caggiula et al., 2009), and self-administration is increased by the presence of sensory stimuli such as illuminated cue lights during nicotine delivery (Palmatier et al., 2007). In humans, reinforcing consequences associated with smoking may include the physiological effects of nicotine, such as the arousal, increased energy, or appetite-suppressing effects of tobacco use (Hatsukami et al., 2008). Smoking

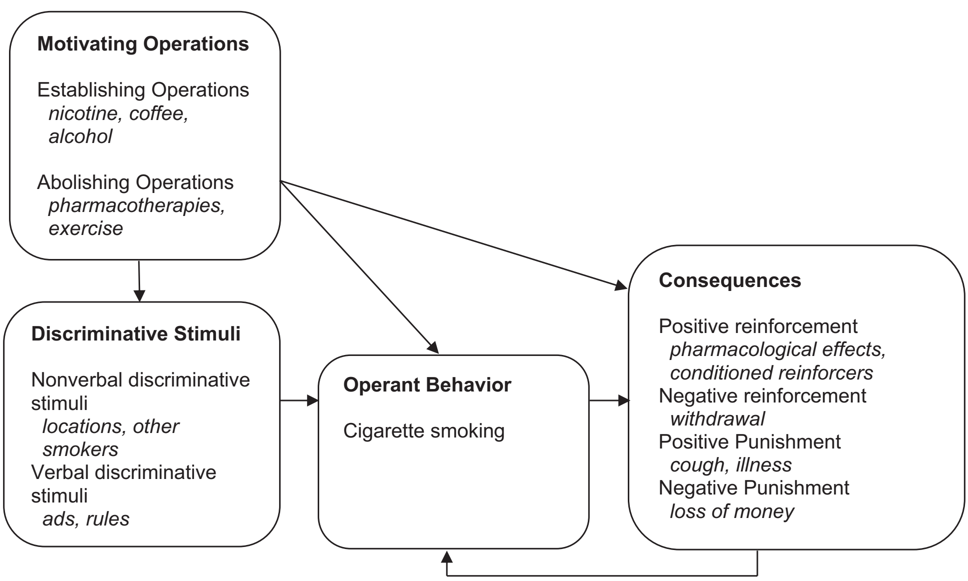

Fig. 41.1 The four-term functional unit of analysis

can be acquired and maintained through other sources of positive reinforcement, such as social interaction (Friedman et al., 1985). Although nicotine may serve as a weak primary reinforcer, it may still confer conditioned reinforcing properties to stimuli associated with smoking such as the taste, smell, airway stimulation, and other sensory stimuli (Rose, 2006; Russel et al., 1974).

Negative reinforcement can also contribute to the origin and maintenance of smoking behavior (Eissenberg, 2004). Nicotine withdrawal is characterized by negative affect such as irritability, anger, cravings, and depression, and physiological symptoms such as constipation, coughing, dizziness, and even mouth sores (American Medical Association, 1994; Hughes et al., 1990). These symptoms peak in the first week of abstinence, but several studies have reported their persistence several months into abstinence (Gilbert et al., 2002; Piasecki et al., 2002). Although alleviation of negative affect is often endorsed by smokers, human laboratory research suggests that smoking relieves negative affect under limited conditions (Lerman & Audrain-McGovern, 2010; Perkins et al., 2010). For example, in the human laboratory, Perkins et al. found that smoking only reduced negative affect induced by abstinence, but not after other procedures to induce negative affect and anxiety (e.g., preparing for a speech, viewing negative mood slides). Interestingly, such effects were independent of nicotine: smoking denicotinized cigarettes had similar negative affect-reducing effects. Following smoking cessation in clinical contexts, negative affect has been found to characterize over 50% of all smoking lapses (Shiffman et al., 1996; Robinson et al., 2017). The role of negative affect on smoking is complicated, and may depend on factors such as nicotine content, stages of smoking (e.g., maintenance versus relapse), and other factors (see Kassel et al., 2003, for a review). Negative reinforcement associated with smoking can also occur when a smoker takes a break from work to smoke (Dunbar et al., 2018).

Establishing operations momentarily increase the value of a reinforcer and increase the likelihood of the response that produces that reinforcer (Laraway et al., 2003). In addition to serving as a reinforcer, nicotine may also function as an establishing operation. In laboratory animals, systemic injections or infusions of nicotine increase responding maintained by conditioned reinforcers such as an illuminated cue light (Charntikov et al., 2020; Donny et al., 2003; Chaudhri et al., 2006; Raiff & Dallery 2006; Palmatier et al., 2007; Liu et al., 2007). These findings, along with the findings that nicotine serves as a primary reinforcer, led to the dual reinforcement model of nicotine self-administration, which posits that nicotine has reinforcing and enhancement (establishing operation) effects on behavior (Caggiula et al., 2009). In humans, administration of nicotine has been shown to increase responding (e.g., under a progressive ratio schedule) maintained by access to music and video, and their self-reported pleasantness (Perkins & Karelitz, 2014; Perkins et al., 2017). Using electronic daily diaries, Piasecki et al. (2011) found that tobacco use increases the pleasure and subjective effects (e.g., "buzzed") of alcohol use, and vice versa. In addition, a review by Martin and Sayette (2018) found that nicotine enhanced social behavior, meaning that it increased positive features of social functioning and decreased negative features. For example, participants exposed to nicotine were faster at identifying facial expressions than after abstinence and were less likely to engage in aggressive behavior after being provoked. Nicotine enhancement may be selective to certain types of reinforcing consequences such as sensory and social stimuli. Nicotine does not appear to enhance responding maintained by food reinforcers in animals (Raiff & Dallery, 2008) and monetary reinforcers in humans (Perkins et al., 2017). More work is needed to identify the generality of the establishing operation functions of nicotine across different types of reinforcers, and the extent of individual differences in these effects.

Antecedent events and stimuli are also associated with cigarette smoking (Niaura et al., 1988; Shiffman et al., 2004, 2014). For example, smoking may occur in the presence of specific people (peer smokers), places (outside, in car), and things (smoking paraphernalia). These stimuli may function as discriminative stimuli within the four-term unit, and they may also have additional Pavlovian effects (Thompson, 2007). The presence of certain peers may be associated with smoking-related reinforcement, and thus increase the probability of smoking. The presence of the same peers may also elicit physiological conditioned responses, and the same is true for other stimuli associated with smoking such as cigarettes, smoke, smoking paraphernalia, coffee, and so on (Conklin et al., 2013; Winkler et al., 2011). These physiological conditioned responses may set the occasion for the verbal responses characterized by "craving" (a full account of the origins and the multiple functions of verbal craving responses is beyond the scope of this paper). Nicotine itself can serve as a discriminative stimulus and increase responding maintained by ethanol in the animal laboratory (Ginsburg et al., 2018). Other environmental events may function as discriminative stimuli and alter the probability of smoking. For example, rules concerning the health consequences presented by parents, teachers, or the US Surgeon General may decrease smoking (Cerutti, 1989). Advertising may have discriminative stimulus effects (and establishing operation effects), as ads may signal the availability of social reinforcement for smoking. The role of advertising is particularly pernicious in light of the 26 million dollars per day spent on advertising cigarettes by tobacco companies in the United States (Centers for Disease Control, 2020).

Aversive consequences following smoking may also occur. Unless these consequences reduce the likelihood of smoking behavior, they cannot be termed "punishers." Some aversive physiological stimuli may occur immediately following smoking, such as throat irritation, mouth dryness, shortness of breath, and cough (Şanli et al., 2016). Other consequences such as the increased likelihood of cancers and cardiovascular disease may be delayed and probabilistic (U.S. Department of Health and Human Services, 2010). Delaying the presentation of aversive stimuli reduces their punishing effects, as does reducing the certainty that they will occur (Green et al., 2014). Even when increased disease risk is communicated based on genomic information tailored for the individual, it does not appear to increase cessation (Ramsey et al., 2018).

The four-term unit comprising the operant determinants of smoking is also situated in the context of other biological vulnerabilities, previous operant learning, and current circumstances. Some of these will require consideration in assessment and treatment. Gene variation may increase the risk of dependence and treatment failure. Recent research suggests that individuals with genetically slow nicotine metabolism have higher cessation success with behavioral counseling and nicotine patch treatment (Chenoweth & Tyndale, 2017). In addition, the presence of comorbidities like depression, anxiety, posttraumatic stress, and schizophrenia requires effective management to increase the probability of cessation (Prochaska & Benowitz, 2019). The same is true with respect to the presence of other smokers and non-smokers in the individual's environment, such as parents, partners, and friends (vanDellen et al., 2016). Additionally, individuals from lower socioeconomic classes and with lower educational attainment have been shown to smoke at higher rates and be less successful when they attempt to quit smoking (Garrett et al., 2019; Jarvis, 2004).

The availability of alternative sources of reinforcement may also influence smoking. Dallery and Raiff (2007) found that choice to smoke in the human laboratory decreased with the magnitude of the monetary alternative (see also Johnson & Bickel, 2003; Stoops et al., 2011), and Cassidy et al. (2015) found a similar pattern of decreasing smoking choices with increasing magnitude of an alternative monetary reinforcer in adolescents. In a non-lab, naturalistic setting, Audrain-McGovern et al. (2004) showed that school involvement, physical activity, academic performance, and sports team participation were associated with decreased risk of smoking. In a human laboratory choice arrangement, concurrent access to money and food decreased choice for cigarette puffs under some conditions (Epstein et al., 1991). In addition, Schnoll et al. (2016) found that the extent of alternative reinforcers predicted long-term abstinence following treatment. These findings suggest that enriched environments with a variety of opportunities to obtain alternative reinforcers may decrease smoking (Acuff et al., 2019; Correia et al., 2002; Vuchinich & Tucker, 1988).

Lastly, other behavioral tendencies or processes have also shown to be correlated with smoking status, such as the degree of delay discounting and distress tolerance (MacKillop & Munafò, 2017; Veilleux, 2019). For example, individual differences in delay discounting, or the rate at which a future outcome loses value with increasing delays, have been reliably associated with smoking status and severity (Bickel et al., 1999; DeHart et al., 2020). Research suggests that rapid discounting increases the later propensity to smoke compared to those who discount at lower rates (Audrain-McGovern et al., 2009; Dallery & Raiff, 2007), and nicotine and other drugs of abuse may increase impulsive and risky choice (Dallery & Locey, 2005; Locey & Dallery, 2011; Perry & Carroll, 2008).

Assessment

Assessment of smoking includes consideration of reliable and valid methods to assess cigarette smoking, the functional assessment of the variables associated with the four-term unit, and characteristics such as degree of nicotine dependence and self-reported motivation that may be used to guide treatment decisions.

Cigarette Smoking

Self-report of smoking, as operant verbal behavior, is influenced by a variety of social contingencies. The self-report may vary depending on the contingencies associated with the age of the smoker (adolescent versus adult), the reasons for quitting (pressure from spouse or personal health reasons), and whether quitting may result in a positive consequence such as a monetary incentive. As such, no unitary statement about the validity of self-report is possible. Clinicians must assess and possibly attenuate the influence of social and non-social contingencies operating on the form of the self-report (Critchfield et al., 1998). One method to increase the accuracy of self-report is to count smoking episodes within a time period (Frederiksen et al., 1979; McFall & Hammen, 1971). These self-monitoring methods can vary in precision from simply counting the number of cigarettes smoked in one day to recording the number, time, and behaviors or environments relevant to each smoking episode. These methods involve discrimination of the smoking episode and recording of that episode. As such, measurement error can occur in both of these steps. Another method involves counting the permanent product of a smoking episode, that is, the smoked cigarette (Schwartz, 1992). Similarly, Timeline Follow-Back (TLFB) procedures may be used to increase accuracy. These methods are also well-suited to collect information about smoking over longer periods (e.g., 30 days) and with non-daily smokers (Harris et al., 2009). Briefly, the TLFB procedure uses key events (such as birthdays) to prompt respondents to provide daily retrospective estimates over a specified time period (Lewis-Esquerre et al., 2005). The TLFB procedure may have limits in terms of accuracy, particularly for heavy smokers (Griffith et al., 2009; Shiffman, 2009).

More objective methods include biochemical assessments of the metabolites of nicotine in saliva or urine, or exhaled breath carbon monoxide (CO; Benowitz et al., 2020). Benowitz et al. reported that up to one in ten who self-report abstinence do not meet biochemical abstinence criteria in research settings. Not only are biochemical methods often more accurate than self-report, but also they may be useful in populations in which smoking may occur surreptitiously such as with adolescents. Cotinine is the primary result of the metabolization of nicotine in the body and is most easily measured via saliva or urine. One consideration for the use of cotinine as an objective measure for smoking is that cotinine may also be present in the body if the individual is using other nicotine-containing products, such as electronic cigarettes (ECs) or nicotine replacement. Commercially available products such as NicAlert® for salivary testing may be useful in clinical settings. NicAlert® is advantageous in that it is inexpensive, and results are available within minutes of collecting the (urine or saliva) sample. In addition, cotinine's long half-life (10–30 h) permits detection for several days after cessation (Benowitz et al., 2020).

An alternative objective method is the measurement of breath carbon monoxide (CO). Commercially available devices (e.g., Pico Smokerlyzer®; Bedfont Scientific Ltd) measure the rate of conversion of CO to carbon dioxide when the smoker exhales air over a catalytically active electrode. Breath CO measurement is highly correlated with blood nicotine levels (Jaffe et al., 1981). Optimal cutpoints for abstinence range between 4 and 6 ppm and will depend on the manufacturer of the CO meter (Perkins et al., 2013). Another consideration is the short half-life of CO, which is about 4 h, which may necessitate twice-daily measurements to provide an index of daily abstinence. Breath CO may reach a "non-smoking" cutpoint in a regular smoker in 6–24 h, and can depend on other factors such as activity level, sleep, and ambient sources of CO (Benowitz et al., 2020). Recently available CO monitors, such as the Smokerlyzer®, can be connected directly to a smoker's smartphone. For detailed consideration of biochemical confirmation procedures and cutpoints for CO and cotinine, the reader is directed to Benowitz et al. (2020).

Functional Assessment

In contrast to the ubiquity of functional assessment methods in other areas of Applied Behavior Analysis (Hanley, 2012), there are relatively few examples of functional assessment methods in the area of cigarette smoking (Cole & Bonem, 2000; Epstein & Collins, 1977; Pomerleau et al., 2003). Many treatment guidelines recommend assessment of "triggers" for smoking, but they do not assess the full range of functions as exemplified in modern assessment methods. Axelrod (1991) reported on one of the first approximations to a functional assessment that included both antecedents and consequences. It was not developed by behavior analysts but rather by physicians and published in a medically oriented encyclopedia. The questionnaire asked smokers their reasons for smoking (e.g., to relax, deal with anger, to get a lift), and then various activities were recommended based on the responses (e.g., deep breathing, going for a walk).

Burrows et al. (2020) developed the Functional Assessment for Smoking Treatment Recommendations (FASTR). The FASTR is a 30-item questionnaire designed to identify 5 potential functions of smoking derived from the four-term unit: automatic positive reinforcement, automatic negative reinforcement, social positive reinforcement, social negative reinforcement, and antecedent stimuli. The questionnaire is divided into five subscales, one for each function, and each item was rated on a 5-point Likert scale, from strongly disagree to strongly agree. Although Burrows et al. found that the measure has good psychometric properties, it has not been evaluated as a method to improve cessation treatment.

Ecological Momentary Assessment (EMA) is a common self-report method to assess smoking behavior along with its antecedents, and less commonly its consequences (Shiffman et al., 2008). EMAs involve the delivery of short questionnaires throughout the day, directly to an individual's smart phone or other mobile device. These questionnaires typically include measures of the individuals' covert behaviors and states, overt behaviors, and environmental conditions (e.g., location, social context). As such, EMAs provide a way to sample behavior over long periods of time in a way that reduces recall bias and maximizes ecological validity (Shiffman et al., 2008). They are particularly useful in identifying social and situational factors that contribute to smoking, and thus may offer a functional approach to the assessment of smoking. Lag analyses between antecedents and smoking behavior found that the presence of cigarettes significantly predicted smoking both before and after a quit date, while the presence of other smokers predicted a smoking lapse, with the likelihood increasing with days after the quit date, though non-significantly (Koslovsky et al., 2018). Using a similar analysis with recently abstinent smokers, alcohol use (within 15 min) predicted smoking lapses for low-nicotine-dependent smokers up to 25 days after quitting (Dermody & Shiffman, 2020). Although EMA represents an improvement over global retrospective self-reports, there is a dearth of work comparing EMA to direct observation (Dallery et al., 2013; Shiffman et al., 2008).

Assessing Nicotine Dependence and Motivation

Assessing nicotine dependence may suggest different kinds or levels of treatment. The most common method to assess dependence is the Fagerström Test for Nicotine Dependence (FTND) (Heatherton et al., 1991). The FTND is comprised of six yes/no items, and higher scores reflect a greater degree of dependence. Physical dependence is the result of chronic smoking, with the individual showing signs of withdrawal that are ameliorated by smoking. Two questions seem to be particularly important indicators of dependence: cigarettes per day and time to first cigarette of the day (West, 2004). The FTND has been shown to predict treatment outcomes. Results may also indicate different intensities or doses of behavior therapy or pharmacotherapy, respectively (Fiore et al., 2008; West, 2004).

Finally, assessing self-reported motivation may be used to select treatment approaches. West (2004) recommends simple direct questioning about a smoker's interest and intent to quit in clinical contexts. More structured, brief questionnaires are also available (Hall et al., 1990). For behavior analytic clinicians, assessing motivation may be a precursor to assessing the contingencies that lead to the different responses. For example, high motivation to quit smoking may be a result of threat of divorce and health problems. These factors could also be addressed or harnessed in treatment. In addition, if a smoker reports low motivation to quit smoking, strategies such as motivational interviewing may be warranted before (or in addition to) recommending other treatments. However, evidence is inconclusive about the effects of motivational interviewing on smoking (Lindson et al., 2019b). Furthermore, as West (2004) notes, the degree of nicotine dependence is a much better predictor of treatment outcome than motivation once treatment has commenced.

Treatment

Although over 70% of smokers express some desire to stop smoking and 45% actually make a quit attempt per year, only about 5% are successful (Hatsukami et al., 2008). The United States Public Health Service endorses a variety of pharmacological and counseling therapies for smoking cessation (Fiore et al., 2008). Most patients, however, relapse within six months, even when various treatments are used together (Cahill et al., 2014, 2016; Hartmann-Boyce et al., 2014; Hughes et al., 2014; Stead et al., 2015, 2016). Although smoking cessation rates are higher following these treatments compared to placebo, the high relapse rate, in absolute numbers, presents a formidable challenge for smoking reduction efforts. A review of smoking cessation interventions designed to prevent relapse found that no psychosocial interventions were effective in preventing relapse (Hajek et al., 2013). Treatment of cigarette smoking should not be viewed as a behavior problem treated acutely, but rather as a chronic, relapsing condition that is likely to require long-term behavior management. Most smokers try to quit several times, and thus repeated intervention may be necessary to support this dynamic process (Hughes, 2003; Niaura, 2008).

Accessible, effective smoking cessation programs are needed. Stitzer (1999) argued that increasing the acceptability and accessibility of behavior therapy in particular is critical: "Greater use of behavior therapy is especially important in view of the research findings that support its dose-related ability to improve cessation" (p. 186). The goal of treatment is cessation. Smoking reductions may increase the probability of later cessation, but there is no evidence that smoking reduction leads to decreases in health risks (Hughes & Carpenter, 2006). In addition, smokers who reduce their smoking engage in compensatory smoking (e.g., deeper inhalation per cigarette). A reduction in cigarette consumption of 50% or more results only in a 30% decrease in biomarkers for toxicant exposure (Hatsukami et al., 2008). In this section, we discuss briefly pharmacotherapy, behavior therapy, and technology-based platforms to deliver behavior therapy. The focus will be on contingency management (CM).

Pharmacological Therapy

The most common pharmacological therapy is nicotine replacement therapy (NRT). NRT can be administered transdermally with a patch, orally (gum, lozenge or sublingual tablets, inhaler), or nasally (Hatsukami et al., 2008). As the name implies, NRT replaces nicotine in tobacco to maintain some of its effects while also reducing its abuse liability (i.e., by reducing the amount and speed of nicotine delivery). Evidence suggests that all forms of NRT are equally effective, and approximately doubles the probability of cessation relative to placebo control conditions (Lindson et al., 2019a, b). In addition, a recent systematic review indicates that combination NRT versus single-form NRT, and 4 mg versus 2 mg nicotine gum, can increase the chances of cessation (Lindson et al., 2019a, b). A common combination is a fast-acting NRT such as gum with a nicotine patch. There is also some evidence for more success with higher-dose nicotine patches, such as 21 mg patches relative to 14 mg patches. The review also suggested that there is some evidence that using NRT prior to quitting may improve quit rates when compared to starting on the quit date.

Other common pharmacological treatments include bupropion and varenicline. Both are non-nicotine-based drugs. Bupropion is also used as an anti-depressant, but its effects appear to be similar in depressed and non-depressed smokers (Hughes et al., 2014). Varenicline targets a specific nicotinic receptor subtype (technically, varenicline is a potent α4 β2 partial agonist). Overall, bupropion produces similar rates of cessation compared to NRT (Cahill et al., 2016), while varenicline increases cessation relative to NRT and bupropion. Cahill et al. concluded that compared to those not treated with varenicline, the use varenicline produces one extra successful quitter for every 11 people treated. Some side-effects associated with varenicline may be of concern (e.g., nausea). More significant side-effects associated with all forms of pharmacotherapy (e.g., cardiovascular events) have not been supported in large, systematic studies (Benowitz et al., 2018)

Pharmacological interventions influence the effects of positive and negative reinforcement associated with smoking. For example, NRT leads to a decrease in withdrawal symptoms. Research also suggests that medicinal nicotine, particularly transdermal patches, results in reduced reinforcement from cigarette smoking, at least as measured by ad libitum cigarette smoking and self-reports of satisfaction derived from smoking (Hatsukami et al., 2008). As such, NRT may function as an abolishing operation to the extent it attenuates the reinforcing value of smoking cigarettes (Laraway et al., 2003). Interestingly, recent research also suggests that adhering to NRT may prevent the loss of the establishing operation effects of nicotine on sensory stimuli (Perkins et al., 2019). Varenicline also has effects that can be understood within the four-term unit. It provides relief from tobacco withdrawal (via its agonist action) and it also attenuates the reinforcing effects of nicotine (via its antagonist action; Hatsukami et al., 2008).

Electronic cigarettes (ECs) have also emerged as a potential pharmacological treatment for cigarette smoking (Glasser et al., 2017; Martner & Dallery, 2019). ECs are battery-operated devices that contain a liquid consisting mainly of water, propylene glycol, vegetable glycerin, nicotine, and flavorings. ECs can deliver nicotine at doses and rates that are similar to what is observed with combustible cigarettes. In addition, they both involve similar patterns of inhaling, exhaling, and hand-to-mouth gestures (Farsalinos, et al., 2013), and as such may substitute for the conditioned reinforcing stimuli associated with smoking. Several studies suggest that ECs may function as a substitute for cigarettes in laboratory settings (Grace et al., 2015; Johnson et al., 2017; Pope et al., 2019; Quisenberry et al., 2016, 2017; Snider et al., 2017; Stein et al., 2018), and a small number of randomized controlled studies suggest that vaping may promote smoking cessation (Adriaens et al., 2014; Bullen et al., 2013; Caponnetto et al., 2013). Although the use of cigarettes among youth has declined over the past decade, the use of electronic cigarettes in this population is increasing (Singh et al., 2016). EC use in youth may increase the chances of initiation of cigarette smoking and affect brain development (U.S. Department of Health and Human Services, 2016).

Behavior Therapy

A plethora of counseling and talk-therapies exist to treat cigarette smoking. These range from brief counseling such as the 5 As (Ask, Advise, Assess, Assist, Arrange) that can be used by clinicians mostly in a primary care setting (Fiore et al., 2008), to individual and group cognitive-behavioral therapy (Niaura, 2008). Cognitive-behavioral approaches include components such as learning to cope with craving and withdrawal induced by nicotine deprivation, learning and avoiding antecedent “triggers” for smoking, stress management, social support, and motivational enhancement (e.g., listing reasons for quitting) techniques. There is good evidence of a dose–response increase in efficacy, at least as measured by total minutes in contact (Fiore et al., 2008; Niaura, 2008). Overall, according to systematic reviews and expert panels, there is moderate evidence for efficacy of these treatment approaches.

Technology-based platforms also deliver cognitive-behavioral approaches along with social support and other components (Taylor et al., 2017). For example, BecomeAnEx.org focuses on teaching strategies to identify and cope with smoking cues, along with providing social support and pharmacotherapy resources. The website contains an online forum for smokers to communicate with one another, videos, interactive content, and a personalized quit plan. The social network component has been found to increase cessation, but only for those who actively participate in the forum. In a large sample (n = 2657), Graham et al. (2017) found abstinence rates of 7.7% in non-users of the forum, 10.7% in passive users, and 20.7% in active users. A theme in research on technology-based platforms is that although they provide access to evidence-based treatment components, users generally do not engage with relevant content and adherence is poor (Eysenbach, 2005). Recent research has explored how specific intervention components may increase engagement. For example, Graham et al. found that increasing engagement in the social network component of BecomeAnEx and provision of free NRT increased adherence across all three recommended components of an evidence-based smoking cessation program (skills training, social support, and pharmacotherapy use).

Bricker and colleagues developed a web-based Acceptance and Commitment Therapy (ACT) called WebQuit (Bricker et al., 2014, 2018). ACT for smoking focuses on acknowledging and accepting emotions, thoughts, and other antecedents for smoking without allowing them to control subsequent behavior. ACT uses six core processes to develop such “psychological flexibility”: acceptance, cognitive diffusion, being present, self as context, values, and committed action. Without going into detail, these processes focus on two main activities: mindfulness and acceptance of thoughts and feelings, and identifying values and behavior change procedures to commit to these values (e.g., smoking cessation). Core processes of ACT were embedded in the website by using personalized quit plans along with videos of former smokers sharing success stories and modeling acceptance. A pilot randomized controlled trial indicated that WebQuit outperformed the Department of Health and Human Services’ website, Smokefree.gov. Cessation rates were higher for the web-based ACT intervention than the Smokefree (23% versus 10%) at a 3-month follow-up (Bricker et al., 2014). However, in a larger randomized controlled trial involving 2637 smokers (Bricker et al., 2018), there were no differences in abstinence at a 12-month follow-up: 24% (278 of

1141) for WebQuit.org and 26% (305 of 1168) for Smokefree.gov. The authors point out the increase in the Smokefree.gov group relative to the previous trial, and they suggest that several new elements of the site may have bolstered efficacy (e.g., new content and front-page placement of coping with depression, an interactive feature to select pharmacotherapy). In addition, in both trials, participants in the ACT group reported increased acceptance of internal experiences (e.g., cravings), and this acceptance was also related to the impact of ACT on smoking. Despite the lack of group differences in the second study, both platforms resulted in positive outcomes. The public health impact of both sites can be estimated based on the product of reach and efficacy. As such, for every 1 million smokers reached, approximately 250,000 would stop smoking (Bricker et al., 2018).

Contingency Management

Contingency management (CM) interventions emerged from basic research on operant behavior and drug reinforcement (Silverman, 2004; Silverman et al., Chap. 65, this volume). Specifically, CM incorporated the finding that linking the absence of a problem behavior with contingent delivery of a reinforcer can lead to decreases in or elimination of problem behavior (Hunt & Azrin, 1973; Miller, 1975; Stitzer et al., 1977). Under contingency management procedures for cigarette smoking, smokers receive desirable consequences contingent on objective evidence (CO or cotinine) of smoking reductions and abstinence. Several early studies provided the initial evidence of the feasibility of using CM to reduce smoking (Tighe & Elliot, 1968; Paxton, 1980, 1981, 1983; Winett, 1973). These studies generally offered rewards, such as the return of monetary deposits, contingent upon self-reports of smoking abstinence and showed that CM could reduce levels of smoking. These studies suffered from several limitations, however, including reliance upon self-reports of abstinence (versus biochemical verification of abstinence) for implementing the contingencies or insufficient monitoring of smoking status. Subsequent studies, using more rigorous experimental methods, provided persuasive demonstrations that CM could reduce smoking (Sigmon & Patrick, 2012; Stitzer & Bigelow, 1982, 1983, 1985; Stitzer et al., 1986; Rand et al., 1989). For example, Stitzer and Bigelow (1982) delivered $5 payments to participants who submitted CO samples with at least a 50% decrease from the average baseline readings. This contingency effectively decreased CO levels, decreased number of self-reported cigarettes per day, and increased the latency to the first cigarette of the day.

A 2019 Cochrane review of CM for cigarette smoking concluded that incentives improve smoking cessation rates at long-term follow-up (i.e., at least six months from treatment onset) in mixed population studies (Notley et al., 2019). The review also highlighted that effects were sustained even after withdrawal of incentives. There was considerable diversity across studies, which included 33 studies and more than 21,600 participants. Settings included workplaces, clinics, hospitals, and community programs, and monetary consequences ranged from 0 (under deposit contract procedures, which are discussed below) to $1185. Interestingly, the review found no discernable effect of reward magnitude on outcomes. Notley et al. also examined CM targeting pregnant women who continue to smoke and found higher cessation rates compared to control groups both at the end of the pregnancy and after the birth of the baby. Smoking during pregnancy is the leading cause of infant morbidity and mortality (U.S. Department of Health and Human Services, 2001). Another major review of extant interventions revealed that incentive-based CM interventions were the most efficacious in promoting cessation among pregnant women (Chamberlain et al., 2013; see also Higgins et al., 2012; Ierfino et al., 2015; Tappin et al., 2015). Furthermore, the benefits of incentive-based interventions extend beyond smoking outcomes. Higgins et al. (2012) found incentive-based interventions improved estimated fetal growth, average birth weight, percentage of low-birth-weight deliveries, and breastfeeding duration. In several recent studies, Higgins et al. (2014) found that

CM increased estimated fetal weight and abdominal circumference, and Lopez et al. (2015) revealed a reduction in the severity of postpartum depression.

Technology-Based Contingency Management

Despite the well-established efficacy of CM to promote cessation, there remain several challenges in adopting, implementing, and ensuring the fidelity of CM interventions (Dallery & Raiff, 2011). Making weekly or daily visits to a clinic to provide evidence of smoking status may also represent a substantial burden to various patient populations. To address these challenges, Dallery and colleagues developed a smoking cessation intervention that employed remote, web-based technology to allow for frequent (twice daily) and convenient breath CO collection (Dallery et al., 2008, 2013, 2017; Dallery & Glenn, 2005; Jarvis & Dallery, 2017; Reynolds et al., 2015; Stoops et al., 2009). Individuals provided CO samples in front of a video camera connected to the Internet. The video was time stamped, sent across the Internet, and evaluated by staff. An incentive was delivered electronically if the sample was valid and if the CO level displayed on the CO meter met the criterion for incentive delivery. This intervention has been effective in promoting smoking cessation (Dallery et al., 2015a, b), including in a nationwide study of smokers (n = 94) from around the United States (Dallery et al., 2017). In the nationwide study, the treatment lasted seven weeks, and there were significant differences in negative COs between the treatment group and a group that received incentives for submitting CO samples: 54% versus 25%, respectively. Although group differences persisted at the three- and six-month follow-ups, these differences were not statistically significant.

Technology-based CM has also been used to arrange group contingencies, where small groups of smokers must collectively achieve cessation goals to receive consequences (Dallery et al., 2015a, b; Meredith et al., 2011; Meredith & Dallery, 2013). Participants also provided and/or received encouragement, feedback, and support via a discussion board. Some evidence suggests that social networks influence smoking abstinence (Christakis & Fowler, 2008; Mermelstein et al., 1986; Mermelstein & Turner, 2006). Moreover, research suggests that practitioners are more willing to adopt treatments that use social components relative to those that use only tangible reinforcers (Kirby et al., 2006). Overall, group-based and individual CM appear to generate similar rates of abstinence, but there are individual differences in preferences for individual or group arrangements. One advantage of technology is that one size need not fit all: a variety of group or individual contingency arrangements could be delivered in a single platform.

To facilitate dissemination, basic cell phones and smartphones have been used to implement similar incentive-based interventions in adults (Alessi et al., 2017; Carpenter et al., 2015; Dallery et al., in press; Dan et al., 2016; Hertzberg et al., 2013; Kendzor et al., 2020; Kurti et al., 2020) and adolescents (Kong et al., 2017). For example, Alessi et al. used a CM procedure and basic cell phones to obtain visual evidence of the CO sampling procedure. CM plus usual care (n = 45) was compared to usual care alone (n = 45), which consisted of pharmacotherapy (i.e., nicotine patch) and twice-weekly counseling sessions conducted remotely via telephone. Results indicated that 82% of mobile CM versus 41% of usual care participants were abstinent at 4 weeks, and 21% versus 16% at 24 weeks. Smartphones have even greater reach relative to Internet-based methods. Compared to white Americans in the United States, black and Hispanic groups report equivalent rates of smartphone ownerships: 77% for whites, 72% for blacks, and 75% for Hispanics (Perrin, 2017). African Americans and Hispanics use their smartphones more often for health-related activities like searching for health information compared to whites (Perrin, 2017). As such, mobile technology could further reduce the "access gap" to the receipt of evidence-based interventions to promote cessation.

Monetary consequences may limit the application of CM interventions. To address this limitation, Dallery et al. (2008) used a deposit contract method that we introduced in the early CM studies noted above. Smoking status was verified via CO and Internet-based procedures. The procedure required an up-front deposit of $50 by the participant, which could be recouped based on evidence of abstinence. The deposit contract procedure produced equivalent rates of abstinence relative to a no-deposit group, and it resulted in cost savings. Jarvis and Dallery (2017) also investigated self-selected deposits rather than a fixed deposit. In Experiment 1 of their study, 47% of the CO samples met the criterion for abstinence, compared to 1% during baseline. Experiment 2 evaluated the impact of an additional clinic "match" of the participant's deposit. No samples met the criterion during baseline but 41.5% met it during treatment. The average deposit was $82 in Experiment 1 and $49 in Experiment 2. Participants rated the intervention favorably, and sample submission rates were high. The deposit arrangements completely eliminated voucher costs, even when incorporating a clinic-match. After payments to 19 participants, $332.66 was left in surplus and donated to charity.

Halpern et al. (2015) evaluated incentive treatments for smoking cessation, including deposit contracting, in a large (N = 2538) randomized six-month intervention. Sustained abstinence for those who accepted the programs (i.e., participants could refuse the group assignment) was 52.3% in the deposit groups compared to 17.1% in the reward groups. However, the rate at which participants selected the deposit was low: only 13.7% accepted the deposit. The acceptability of a deposit—or the number of individuals who actually make a deposit—will depend on a host of factors (Halpern et al., 2012; Stedman-Falls et al., 2018). More research is needed to assess variables that influence acceptability. A technology-based method to enable a deposit (e.g., via PayPal) may lower the response effort associated with making deposits and therefore increase acceptability for some individuals (Stedman-Falls & Dallery, 2020). Deposit contracts may not only offset voucher costs, but also they may mitigate a public policy concern with paying people to change behavior (Madison et al., 2011). A deposit contract method may be acceptable and efficacious for a sizeable enough portion of smokers and stakeholders to deliver a public health impact, and it could be used in individual treatment in clinical settings.

There is certainly more work to be done to further promote cessation. Qualitative data from a recent mobile phone CM study revealed that participants wanted help learning personally relevant new skills or information about smoking cessation, and several reported significant life stressors (Dallery et al., in press). Multi-component technology-based interventions hold promise. Several mobile phone CM interventions have included skills building, stress management, and/or motivational enhancement treatment components (Carpenter et al., 2015; Hertzberg et al., 2013). For example, Carpenter et al. (2015) included weekly cognitive-behavioral therapy and pharmacotherapy, and they found smoking abstinence rates of 65% and 60% at 3 and 6 months after the mobile CM intervention, respectively. Mobile interventions have also been designed to provide intervention components such as stress management on demand based on participant input (Heron & Smyth, 2010). Such "ecological momentary interventions" may be useful adjuncts to CM (Businelle et al., 2016). In addition, methods to assess the functions of cigarette smoking should be explored to tailor intervention components to promote cessation (Burrows et al., 2020).

Considerations in the Delivery of CM in Clinical Settings

CM interventions are comprised of several components that can be implemented in a variety of ways (Meredith et al., 2014; Petry, 2000). Once a reliable and valid monitoring system is selected, either CO or cotinine in saliva or urine, the clinician must select a CM intervention (e.g., voucher or prize-based in which reinforcers are available intermittently). In addition, several specific parameters of the CM intervention must be selected to maximize cost-effectiveness and access to treatment. For example, the clinician must select parameters of reinforcement (e.g., delay, magnitude) to maximize the probability of successful outcomes (Lussier et al., 2006; Stitzer & Bigelow, 1983). As noted above, however, a major Cochrane review found little evidence of magnitude effects across smoking cessation studies. It may have been the case that the magnitudes were all sufficiently high, which means that care should be taken to ensure that the magnitude selected is above an empirically informed threshold. In clinical practice, the parameters of a specific CM program may need to be modified iteratively, using experimental methods, to reveal the optimal program for a specific individual (Dallery & Raiff, 2014).

Another consideration in designing a CM intervention in a clinical setting is the schedule of reinforcement. The most common schedule of reinforcement used in CM interventions is the ascending schedule of reinforcer delivery with resets of the voucher value for evidence of lapses or missed samples (Roll & Higgins, 2000; McPherson et al., 2018). One study found that a schedule that included ascending values plus resets resulted in greater rates of smoking abstinence than an ascending schedule without resets, and greater rates of abstinence compared to a fixed schedule in which the same amount was available for each negative sample (Roll & Higgins, 2000). Prize-based procedures also involve escalation (Petry, 2000), but because rewards are available intermittently, they may represent a lower-cost method to deliver incentives.

One potential problem with an ascending schedule of reinforcement is the low initial value of the consequence for abstinence. Several researchers have noted that some participants never contact the monetary reinforcers for abstinence (Correia et al., 2005). One reason some participants do not achieve abstinence is that most CM interventions require an abrupt transition to complete abstinence. Gradual reductions in drug use may permit greater contact with monetary reinforcers for changing drug use behavior. Several studies suggest that gradual reductions, or shaping procedures, can generate high initial rates of abstinence in nicotine-dependent individuals (Lamb et al., 2004, 2010). Shaping procedures are only possible if some quantitative or semi-quantitative monitoring of drug status is available, which is the case for CO- and several cotinine-based measures.

Conclusions

Cigarette smoking remains a vexing problem, or what some have called a wicked problem (Wallace et al., 2015). Although smoking rates overall have declined, there remain substantial disparities in smoking prevalence. Smoking remains high among people who have less education, American Indians/Alaska Natives, those who experience serious psychological distress, those experiencing socioeconomic disadvantage, people with a disability, and those who are lesbian, gay, or bisexual, to name a few examples. Population-level interventions are responsible for most of the reductions in smoking such as increased taxes, smoking bans, and mass media campaigns, especially those interventions targeting youth initiation. Nevertheless, a role still exists for treatments focused on individuals, and as such behavior analytically derived interventions are justified and require further development. This development will need to be sensitive to the changing landscape of tobacco control policies. For example, in 2017, the U.S. Food and Drug Administration announced a focus on reducing nicotine in cigarettes to levels low enough that cigarettes would be minimally or non-addictive (Gottlieb & Zeller, 2017). If new policy is implemented, it would mean that only very low nicotine content (VLNC) cigarettes would be sold in the United States. Research has found that VLNC cigarettes lead to lower dependence, fewer cigarettes smoked per day, and increased quit attempts compared to standard nicotine level cigarettes (Donny et al., 2015; Hatsukami et al., 2010), and that VLNC reduced abuse liability compared to higher nicotine content cigarettes in adolescent smokers (Cassidy et al., 2018).

As we have reviewed in this chapter, a behavior analytic framework of the etiology, maintenance, and treatment of smoking has proven to be robust and pragmatic. Many researchers and clinicians have lamented the limited scope of behavioral interventions, despite their potential to address a wide range of socially relevant behavior (e.g., Friman, 2010; Normand & Kohn, 2013). Cigarette smoking is a case example of how behavior analysis has been broadened to inform understanding and treatment of the leading preventable cause of death in the developed world. Indeed, Henningfield and Higgins (1989) noted the important contributions of behavior analysis to the 1988 Annual Report of the Surgeon General on the Health Consequences of Smoking (U.S. Department of Health and Human Services, 1988). Specifically, the contributions included research on the cross-species similarities in drug taking behavior, research showing drug taking follows the same general laws as other operant behavior, and research on behavioral treatments for cigarette smoking. We hope that the current chapter provides further evidence for the continued vitality and social relevance of behavior analytic research on cigarette smoking.

Acknowledgment We thank Lindsey Ives and Alexandra Knerr for comments on a previous draft of this chapter.

Safety Training

42

Antonia R. Giannakakos-Ferman
and Jason C. Vladescu

Worldwide 4.9 million people died in 2016 from injuries that could have been prevented. Of those deaths 644,855 were children under the age of 15 (World Health Organization, 2018). Deaths from unintentional injuries disproportionately occur in developing nations and affect children in disadvantaged socioeconomic areas (Laflamme et al., 2010). In the United States unintentional injuries are the leading cause of death for children, and 9.2 million children under the age of 19 are treated in the emergency room (ER) for non-fatal injuries (Borse et al., 2008). These deaths could be prevented if children and caregivers were provided with evidence-based comprehensive safety instruction.

Chapter Overview

The purpose of this chapter is to provide an overview of behavior analytic evidence-based methods for assessing, designing, and implementing safety instruction. The chapter will focus on child and adolescent safety. The procedures that will be discussed are applicable to both children and adolescents who are neurotypical and those with developmental disabilities. This chapter is divided into three main sections. Section one introduces safety instruction and discusses limitations of education-based methods and the contributions of a behavior-analytic approach. Section two describes the process of assessing safety behaviors and designing instruction. Section three discusses evidence-based interventions, design considerations, and suggestions for generalization and maintenance. For ease of reading, the term *learner* is used in lieu of *children and adolescents*.

An Overview of Safety Instruction: The Need for a Behavior Analytic Approach

Safety instruction addresses safety on two fronts: prevention strategies and safety responses. These two fronts are each an essential part of safety instruction. Prevention seeks to eliminate potential dangers from the environment and teaching safety responses seeks to provide learners with behaviors they can engage in when they encounter a danger. Current mainstream safety instruction attempts to address prevention and teaching safety responses through education-based instruction. Education-based instruction is a passive learning methodology that targets the

acquisition of safety knowledge to promote safety behaviors (Miltenberger et al., 2020).

Education-Based Prevention Instruction

Mainstream safety instruction, focused on prevention, targets caregivers as their behaviors can directly affect the safety of the children in their charge (Krenzelok, 1995). The typical method of intervention is to provide caregivers with a set of rules on how to remove dangers from the environment. The rules are usually disseminated through pamphlets, commercials, ad campaigns, and online recourses (Krenzelok, 1995). A characteristic example of prevention-based safety instruction is the State of Texas's *Keep 'Em Safe Texas* safe gun storage program. *Keep 'Em Safe Texas* is a program launched in 2020 in response to Centers for Disease Control and Prevention (CDC) data that indicated annually Texas is among the top three states in the United States for unintentional shootings by children (Centers for Disease Control and Prevention, 2020). The program targets safe storage of firearms and its message comprises three rules: "Safely store fire-arms, safely store ammunition, and restrict access." Like many of its predecessors this program attempts to change behavior through education. However, research suggests that the effectiveness of education-based prevention programs is limited. Despite the existence of education-based safe gun storage programs in the United States, only about 55% of gun owners with children under the age of 18 report storing all their guns safely (Crifasi et al., 2018).

These data are not presented to suggest prevention initiatives are completely ineffective. Preventative environmental manipulations, such as mandated four-sided pool fencing, smoke alarms, firearm storage programs, and bike helmets, have reduced the number of injuries and deaths, but the reduction is not substantial enough (Centers for Disease Control and Prevention, 2012). Even if caregivers employ preventative measures, learners may still encounter dangers. A learner may encounter a dangerous item or situation at school, in the community, or when at the home of a peer. Therefore, safety instruction also seeks to teach a variety of responses that learners can use to stay safe.

Education-Based Safety Instruction

Concerningly, most mainstream safety programs approach safety instruction by using the same education-based methodology just discussed. Education-based safety instruction uses a variety of age-appropriate activities, such as games, reciting slogans, illustrative anecdotes, and art activities to disseminate safety information (Kennedy & Mason, 2015; Mondozzi & Harper, 2001). For instance, Kennedy and Mason (2015) evaluated the effectiveness of a fire safety program on increasing student knowledge and awareness of the risks of fires and false calls to emergency services. The participants in the study were 226 10- and 11-year-olds at four public middle schools in the United Kingdom. The *Facing up to Fire* program used was implemented by staff at each school and used a series of CDs, DVDs, VHS tapes, and worksheets that described fire-related situations. The participant's knowledge was assessed through a survey that was administered before training, after training, and three months after the end of the program. A comparison of pre-program and post-program data indicated a statistically significant increase in fire safety knowledge and the results of the three-month follow-up survey indicated participants could still recall the information taught. Although Kennedy and Mason (2015) demonstrated the effectiveness of the *Facing up to Fire* program at increasing safety knowledge, the authors acknowledge that it is unknown if there was a subsequent increase in safe behavior.

A potential flaw of education-based safety instruction is that it operates on the assumption that acquisition of verbal-safety behavior will lead to non-verbal safety behaviors. Research evaluating if education-based instruction is effective at increasing safe behaviors has found that this verbal behavior to non-verbal behavior transfer does not consistently occur (Beck &

Miltenberger, 2009; Carroll et al., 1992; Gatheridge et al., 2004; Schwebel & McClure, 2014).

Schwebel and McClure (2014) evaluated correspondence between gains in verbal statements of safety behavior and the related non-verbal safety behaviors. Safe street crossing behavior was taught to 240 participants ages 7 to 8. Participants were assigned to one of four conditions: An education-based instruction condition, a virtual reality (VR) instruction condition, an individualized street side instruction condition, or a no-treatment control condition. Following intervention participants in the education-based instruction group engaged in verbal behaviors regarding safe street crossing, but not the non-verbal safe street crossing behaviors. Participants in the virtual reality condition engaged in the non-verbal safety behaviors, but not the corresponding verbal behaviors and participants in the individualized street side instruction condition acquired both verbal and non-verbal behaviors.

Himle et al. (2004) evaluated the effectiveness of the National Rifle Associations' *Eddie Eagle GunSafe Program*, an education-based instructional program used in the United States to teach learners about gun safety. The *Eddie Eagle GunSafe Program* uses a series of activities to teach participants that when they encounter a firearm they should "Stop. Don't touch. Leave the area. Tell an adult." The activities include reviewing the safety message, responding to "what would you do if…" anecdotes, and art activities such as slogan coloring sheets. After the participants in the study completed the *Eddie Eagle Gun Safe Program*, they were exposed to a simulated situation in which they came across an unattended firearm. The participants were naive to the assessment and were not aware they were being observed. The results of the assessment indicated that although all the participants demonstrated acquisition of the safety message, they did not subsequently engage in the safety response.

Beck and Miltenberger (2009) evaluated the effectiveness of *The Safe Side* program, a training program that purportedly teaches learners 5-to-10-years-old abduction prevention responses. The program comprised a training DVD entitled "Stranger Safety" and its goal is to teach learners through instructions and modeling to respond to various abduction situations. The authors showed the training DVD to six participants, 6-to-8-years-old. After exposure to the training DVD, the participants were exposed to a series of simulated situations such as a stranger knocking on the door and a stranger approaching and violating the participants' space. Beck and Miltenberger found that despite having watched *The Safe Side* DVD none of the participants engaged in the safety responses explained and demonstrated in the video.

The results of these studies identify an expected flaw with education-based instruction. Learners receiving education-based safety instruction fail to demonstrate the safety responses taught because instruction alone is insufficient to establish stimulus control over the safety behavior.

A Behavior-Analytic Approach to Safety Instruction

Although a behavior-analytic approach to safety instruction is similar in focus on prevention and teaching safety responses to an education-based approach, several features distinguish these approaches. First is the addition of an active learning component. The term active learning refers to the addition of components that require the learner to practice the steps of the safety response while receiving feedback on and correction of their performance (Miltenberger et al., 2020). As demonstrated above, numerous behavior analytic studies have demonstrated that skill acquisition is better achieved when an active learning component is included in intervention as opposed to instruction alone.

A second key component of behavior analytic safety instruction is the incorporation of procedures to increase the likelihood that an established safety response will generalize to the natural environment and be emitted under appropriate stimulus conditions. Behavior analytic safety instruction incorporates methods such as programming common stimuli, teaching mediating responses, and multiple exemplar training to facilitate transfer of safety behaviors to the natural environment (Stokes & Baer, 1977).

Behavior analytic researchers have recognized the limitations of an education-based approach and have evaluated interventions to teach safety responses across an impressive array of areas over a span of almost 45 years (Giannakakos et al. 2020a; Mechling, 2008). The safety literature in behavior analytic research has particularly focused on abduction and sexual abuse prevention (Dixon et al., 2010; Doughty & Kane, 2010; Lumley & Miltenberger, 1997), fire safety (Bertsch et al., 1984), and firearm safety (Jostad & Miltenberger, 2004; Miltenberger, 2008).

The remainder of this section briefly discusses each safety category and the types of behaviors that have been taught. Table 42.1 contains a breakdown of each safety area, the safety responses taught within that area, and references for several representative studies in each area.

Transportation Safety Transportation safety involves teaching responses that keep adults, children, and infants safe when using bicycles and motor vehicles. Research on bicycle safety has focused exclusively on increasing helmet wearing behavior (e.g., Ludwig et al., 2005; Van Houten et al., 2007). Research on motor vehicle safety has focused on increased seat belt use (e.g., Geller et al., 1982, 1989), correct installation of child passenger safety restraints (e.g., Giannakakos et al., 2018; Himle & Wright, 2014), and reducing cell phone use while driving (Clayton et al., 2006).

Personal Safety Personal safety is focused on three main areas: responding to emergency situations, abduction prevention, and sexual abuse prevention. Safety training on emergency situations has focused on determining emergency situations and dialing 911 (e.g., Jones & Kazdin, 1980; Spooner et al., 1989). Abduction prevention targets teach learners to resist lures from strangers (e.g., Beck & Miltenberger, 2009;

Table 42.1 Overview of responses addressed in the behavior analytic literature

Safety area	Response taught	Select references
Transportation safety

Safety area	Response taught	Select references
Sharp object safety	Disposing broken items	Winterling et al. (1992)
Suffocation prevention	Identification and removal of household hazards	Barone et al. (1986), Metchikian et al. (1999)
Poison prevention	Responding to household poisons	Dancho et al. (2008), Collins and Griffen (1996)
	Responding to medications	Giannakakos et al. (2018), King and Miltenberger (2017)
Infant safety	Arranging a safe sleep environment	Austin et al. (2018), Carrow et al. (2020)
Community safety		
Social safety	Refusing requests for money and personal information	Spivey and Mechling (2016)
Pedestrian safety	Crossing the street	Harriage et al. (2016), Wright & Wolery (2014)
Seeking help when lost	Making and answering calls from parents	Carlile et al. (2018)
	Exchanging an ID card	Taylor et al. (2004)
	Making a vocal request for help	
Water safety		
	Basic swimming and flotation skills	Alaniz et al. (2017)
	Holing on to the pool side to reach the stairs and throwing and catching a lifeline	Turgut et al. (2015)

Note: The references provided in this table are illustrative of the research in each area. Additional studies have been published that are not listed on the table

Ledbetter-Cho et al., 2019) use a safe word (Rodriguez & Jackson, 2020), and respond to a stranger at their door (Summers et al., 2011). Sexual abuse prevention teaches individuals to identify private body parts (Boyle & Lutzker, 2005; Miltenberger & Thiesse-Duffy, 1988), and discriminating and responding to abuse situations (e.g., Egemo-Helm et al., 2007; Miltenberger et al. 1999).

Home Safety Home safety is one of the largest areas of focus within the behavior analytic literature and includes the widest range of safety responses. Interventions have targeted both preventative methods and safety responses. Researchers have evaluated procedures for teaching children and young adults fire-related safety (e.g., Haney & Jones, 1982; Houvouras & Harvey, 2014), responding to an unattended firearm (e.g., Himle et al., 2004; Rossi et al., 2017), cleaning up sharp and broken objects (Winterling et al., 1992), and poison prevention responses (e.g., Collins & Griffen, 1996; Dancho et al., 2008). Studies targeting caregiver prevention strategies have trained safe arrangements of infant sleep environments (Austin et al., 2018; Carrow et al., 2020; Vladescu et al., 2020) and removing potential hazards from the home environments (e.g., Barone et al., 1986).

Community Safety Community safety covers skills related to safely navigating community locations such as public transportation, stores, and streets. Research has been conducted evaluating procedures for teaching safe street crossing (e.g., Harriage et al., 2016; Wright & Wolery, 2014), seeking help when lost in public (e.g., Carlile et al., 2018; Taylor et al., 2004), and refusing inquiries from strangers for money and personal information (Spivey & Mechling, 2016).

Water Safety Water safety is an area of research that has garnered limited attention within the behavior analytic literature. The responses taught in this area comprise basic swimming, flotation, and water awareness skills (Alaniz et al., 2017), water recovery and deck behavior, and throwing and catching of a lifeline (Turgut et al., 2015).

Assessment and Design

Assessment

The first step to comprehensive safety instruction is assessment. Safety assessments can be separated into two categories: assessing the environment and assessing behavior. There are two types of assessments indirect and direct. Indirect assessment can provide useful information on a learner's safety repertoire or lack thereof. Direct assessment allows direct observation of the learner's behavior and can identify if a learner will engage in a safety response under the appropriate conditions. Research supports the use of indirect assessment methods if they are followed up with direct assessment of the behavior (e.g., Lutzker et al., 1998; Mandel et al., 1998). Comprehensive assessment is essential to identifying deficits in prevention and responsive behaviors and should inform subsequent intervention.

Assessing the Environment The purpose of assessing the environment is to identify potential hazards that may interfere with safe behavior. To date, the behavior analytic literature has paid little attention to methods of environmental assessment as they pertain to safety. The recommendations provided in this section are behavior analytic in nature; however, the supporting literature is largely derived from safety research in other fields.

One environmental assessment commonly used in research on child neglect and family services, that may be of use to behavior analysts, is the Home Accident Prevention Inventory-Revised (HAPI-R; Mandel et al., 1998). The HAPI-R is a validated checklist that assesses safety hazards across 10 categories (i.e., poison, choke, suffocation, drowning, fire/electrical, fall, sharp object, firearm, crush, and allergen/organic). The HAPI-R is administered using an assessment form (available in Lutzker & Bigelow, 2002). The person assessing the environment uses the form to collect information on the learners in the home, including their eye level and how far and high they can reach. This information is subsequently used to determine if dangerous items are placed safely out of reach. The assessor then goes through each room of the home and indicates the number of hazards present across each category. One assessment form is filled out per room. The total number of hazards within and across the 10 categories is calculated and used as a measure of safety.

Jabaley et al. (2011) provided a characteristic example for how the HAPI-R is used as an assessment tool. The authors used the HAPI-R to assess the existence of safety hazards in the homes of three families living in a large metropolitan area in the United States. During the initial assessment, the experimenters first established the eye level and reach of the oldest child in the home (up to age 5). These data were used to determine at what height hazards would need to be placed to be considered inaccessible. The experimenters then went through each of the three rooms and collected data on the number of hazards in each room. The number of hazards recorded provided a baseline measure of safety within the home.

The existing research using the HAPI-R assessment has emphasized in-person consultation. However, in-person assessment of the home environment may not always be possible. One solution may be to incorporate videoconferencing software, wherein a researcher or practitioner could score the HAPI-R, as a caregiver virtually navigates their home.

The HAPI-R provides a comprehensive assessment of household dangers; however, there are some home safety areas not included in the assessment. One such absent area is home pool safety. CDC (2012) data indicate 74% of fatal pool accidents occur at residential locations and the highest drowning rates are in children 1-to-4-years-old. Drowning prevention research has identified several environmental manipulations that are effective in decreasing pool-related drownings, including four-sided pool fencing, pool alarms, automated covers, and restricting access by keeping the pool area locked when appropriate supervision is not available (Coffman, 1991). Researchers might consider developing a checklist that could be used to identify potential safety risks and subsequently inform safety instruction targeting responsible caregivers.

Finally, for individuals with disabilities an additional prevention assessment may be needed. It is estimated that 49% of learners with autism spectrum disorder (ASD) engage in elopement behavior (Anderson et al., 2012). Elopement can be potentially life threatening as learners may encounter dangers outside the home (e.g., traffic, drowning, suffocation). To date, no experimentally validated elopement prevention checklist for individuals with ASD or developmental disabilities exists. The National Autism Association developed an elopement prevention checklist that caregivers can use to evaluate their home (https://nationalautismassociation.org/docs/BigRedSafetyToolkit.pdf). Used in a research or clinical context this checklist may present an assessment option to identify preventative measures already in place and guide caregivers through implementing the remaining safety precautions.

Indirect Safety Response Assessment Indirect assessments can be a useful tool for identifying deficits in a learner's safety repertoire. To our knowledge, there is only one commercially available standardized assessment that evaluates safety responses, the Assessment of Functional Living Skills (AFLS; Partington & Mueller, 2012). The AFLS assesses several areas including safety responses related to independent living, basic health safety and first aid, and workplace safety.

There are also several checklists specific to a variety of common safety areas available from national and international organizations such as Safe Kids Worldwide. Researchers and practitioners might consider using these checklists to collect information from caregivers or guide interviews about safety. Checklists on a variety of areas including fire safety, water safety, and pedestrian safety are available of the Safe Kids Worldwide website (https://www.safekids.org/).

Direct Safety Response Assessment The most reliable method of determining a learner's safety repertoire is to directly observe whether the learner engages in safety responses when they are required. Two methods of assessment have been well researched in the behavior analytic safety literature, in situ, and role-play assessments (Giannakakos et al. 2020a; Miltenberger et al., 2020). These assessments simulate a dangerous situation the learner might encounter without placing them at risk.

In Situ Assessment In situ assessment has been used to assess safety behavior across numerous areas including firearm safety (e.g., Hanratty et al., 2016; Jostad et al., 2008), abduction prevention (e.g., Beck & Miltenberger, 2009), fire safety (e.g., Houvouras & Harvey, 2014; Vanslow & Hanley, 2014), help-seeking behavior (Pan-Skadden et al., 2009), and poison prevention (Dancho et al., 2008). In situ assessment involves arranging a simulated situation in which the safety response can occur without exposing the learner to actual danger. In situ assessment is often conducted in the natural environment with precautions in place to ensure the learner's safety (Carlile et al., 2018; Summers et al., 2011). During in situ assessment, the learner is observed remotely or covertly and is unaware they are being assessed. Covert observation during in situ assessment is essential so that the observer's perceived presence does not exert control over the safety response (Miltenberger et al., 2005). There are several ways to arrange covert observation during in situ assessment. For instance, Dancho et al. (2008) observed participants during in situ assessment through a one-way mirror in an observation area attached to the assessment area. Giannakakos et al. (2020b) used video streaming software installed on a tablet device placed in the assessment room and streamed to the instructors' smart phone and Hanratty et al. (2016) placed a baby monitor with video capability in the assessment area.

Another consideration during in situ assessment is the inclusion of a termination criterion to ensure the learner does not practice, or inadvertently contact reinforcement, by engaging in a dangerous behavior. For example, Ledbetter-Cho et al. (2016) taught four learners with ASD an abduction prevention response. During the in situ assessment, the participant was brought to the assessment area by a known adult who then gave an excuse to leave the participant unattended. A confederate unknown to the participant approached and presented a lure such as "Come play with my iPad." If the participant began to leave with the confederate, the confederate made an excuse such as "I forgot I have to meet a friend" and disengages from the interaction. Thereby eliminating the possibility that the participant's behavior might contact reinforcement by leaving with the confederate. Although in situ assessment provides the closest indication of how a learner might respond to an actual danger, the covert and simulated aspects of the procedure may not be appropriate to all safety responses.

Role-Play Assessment In the case of some safety responses such as exiting a house fire (Rosenbaum et al., 1981) or sexual abuse prevention (e.g., Egemo-Helm et al., 2007; Katz & Singh, 1986; Miltenberger et al., 1999), it may be unethical or infeasible to conduct an in situ assessment. Unlike in situ assessments, during role-play assessments the learner is aware that their behavior is being assessed. During role-play assessments, the learner is presented with a scenario and asked to demonstrate how they should respond.

Egemo-Helm et al. (2007) used a role-play assessment to evaluate the sexual abuse prevention skills of four women with developmental disabilities. During the role-play assessment, the participants were aware of the assessment condition. Abuse lures were presented by the experimenter and the participant was asked what they would do if it were a real situation.

Rosenbaum et al. (1981) used a role-play assessment to evaluate 27 preschoolers' ability to differentially respond to emergencies and dial 911 when required. During the role-play assessment, participants were shown videotaped scenes. For each scene, the participant was told to pretend they were at home and then asked if the situation required them to call someone and why. The participant was then asked to act out the response they described.

Designing Safety Instruction

After deficits in a learner's safety repertoire has been identified, it is necessary to select target safety responses, instructional settings, and instructional materials.

Expert Consultation Expert consultation can be an integral tool when designing safety instruction (Jones et al., 1981; Katz & Singh, 1986). Experts such as firefighters, police officers, and physicians can provide useful information on how a certain safety response will keep a learner out of danger. Because safety recommendations may change over time as further research is conducted, recommendations should not be taken directly from the published literature without verifying their current accuracy from experts. Researchers and practitioners are encouraged to collaborate with local agencies and consult official websites such as the Centers for Disease Control and Prevention, the American Medical Association, and the National Fire Protection Association for up-to-date information that can assist in the selection of the most effective safety recommendations. One example of changes in safety recommendations is exemplified by a study that taught participants to extinguish cooking fires (Mechling et al., 2009). One of the extinguishing materials used in the study was flour. Although flour was a recommended extinguishing method at the time of publication, the National Fire Protection Associations has since recommended against the use of flour to extinguish cooking fires, as flour is flammable and particles suspended in the air may catch fire and can cause an explosion (Ahrens, 2017). Therefore, it is imperative to include qualified experts into the process of designing safe and effective safety interventions.

Selecting the Safety Response

General Safety Response Learners may come across a variety of dangers: comply with a lure from a stranger, play with an unattended lighter, mistake a bottle of pills left out on the counter for candy, or gain access to an unsupervised pool area. With such a wide variety of possible situations, numerous studies have targeted a safety response that is applicable to most dangerous situations. In a systematic review of the literature, Giannakakos et al. (2020a) reported that nearly half of the studies taught a general three component safety response. The general safety response comprises three components and is appropriate to a wide range of potential dangers, including abduction prevention, abuse prevention, and dangerous object safety (e.g., Giannakakos et al., 2020b; Houvouras & Harvey, 2014; Johnson et al., 2005; Rossi et al., 2017; Summers et al., 2011; Vanslow & Hanley, 2014). First, the learner is taught to identify that a danger is present in their environment. As part of this component intervention should include teaching the learner to identify the names of any stimuli that will be involved in safety training. For learners with appropriate skill sets, tact training (i.e., expressive identification; Sundberg et al., 2000) and listener training (i.e., receptive identification; Grow & LeBlanc, 2013) can be used to ensure learners can identify dangers and other stimuli associated with safety training.

Second, the learner is taught that after identifying a danger they should immediately avoid interaction with the danger. Depending on the nature of the danger being addressed, avoidance may be leaving the area or not entering an unsafe one (e.g., unattended pool) or it may comprise refraining from handling an item (e.g., lighter or prescription medication). Any level of interaction with a dangerous item could lead to injury or death; therefore, learners should be taught that no level of interaction with a dangerous item is acceptable. For instance, a learner putting their foot in an unattended pool may fall in, or a learner who verifies if a firearm is real by picking it up may accidentally discharge the weapon.

Finally, the learner must locate and notify a responsible adult of the danger. This final component is essential as it allows a caregiver to remove the danger and establish a safe environment.

Specific Safety Responses The general safety responses discussed above are applicable across multiple dangers, but situation-specific safety responses are sometimes required.

Several studies on fire prevention responses have taught participants to exit their home or school in response to a fire alarm (e.g., Bigelow et al., 1993; Garcia et al., 2016; Jones et al., 1981). The complexity of the exiting response varies greatly across studies as is dictated by the skill repertoire of the learners targeted for intervention. Some studies have taught learners to stop what they are doing and walk out the nearest exit in response to a fire alarm (Bigelow et al., 1993). Others have taught learners to exit their homes via multiple routes and to make decisions when pathways are blocked by fire or smoke (Jones et al., 1984).

In the area of pedestrian safety learners are taught safe street crossing behaviors. These behaviors are similar across studies and include stopping at the edge of the roadway, checking for oncoming vehicles, and crossing when the way is clear. Some studies have taught learners to cross only simple one- or two-lane road ways (e.g., Steinborn & Knapp, 1982), while other have taught learners to navigate more complex environments such as four-way roadways with a center island (e.g., Wright & Wolery, 2014).

While most of the abduction prevention literature has taught learners to engage in the general safety response described above, one study is a notable exception. Rodriquez and Jackson (2020) taught learners a safe word response applicable to abduction attempts by familiar adults. When approached by a familiar adult, the learner was required to ask for the safe word and provide an appropriate response to the adult's knowledge of the word. If the adult said the safe word, the participant would say "ok" and comply with the adults' request. If the adult did not know the safe work, the participant would say "no" and run away (Dowshen, 2018).

Modifications for Individuals with Developmental Disabilities Individuals with developmental disabilities may have skill deficits that necessitate modifications to safety responses described above.

First, safety responses with vocal components may present a barrier for learners with limited vocal verbal behavior repertoires. Modifications to common safety responses are required to ensure the topography of the safety response is appropriate to the vocal repertoire of the learner. One example of this type of modification is demonstrated in Taylor et al. (2004). The study taught three teenagers with ASD who had limited vocal repertoire to seek help when lost. As a complex vocal request for help was not possible, the participants were taught that if separated from a caregiver, they should approach an adult, say "excuse me" and produce a communication card. The communication card contained the participant name, a statement that they were lost, and instructions to call their parent or caregiver. Although this study was conducted with teenagers, the response topography is appropriate to younger learners as well.

Second, some learners may not have the skills necessary to respond differentially to safe and unsafe stimuli and situations that share common features. When an undeveloped discriminative repertoire poses a barrier to safety-skills acquisition, stimulus prompts can be used to facilitate differential responding (Maglieri et al., 2000). For example, a learner could be taught that if a certain sticker, such as the Mr. Yuk sticker (Fergusson et al., 1982; i.e., green stickers emblazoned with a disgusted face and the national poison control number) appears on an item, they should not touch it and, when skill sets allow, should report the item to a caregiver. Then stickers are placed on all dangerous items or access points (e.g., pool gate). Reinforcement in the form of praise is provided for avoiding and reporting stickered items left unattended in the environment. The primary advantage of this discrimination method is that it does not require the learner to respond differentially based on physical features, which vary widely across different types of dangers. The stimulus control exerted by the stickers serves to control the safety response and can be extended to novel dangers as needed. In the context of generalization, the stickers may be conceptualized as common stimuli (Stokes & Baer, 1977). A response trained in their presence is likely to generalize to untrained stimuli that are labeled with that same sticker.

Selecting the Instructional Setting(s) Research recommends teaching in the natural environment to promote generalization and increase the likelihood the safety response will occur when needed (Miltenberger, 2008; Miltenberger et al., 2020). For instance, Johnson et al. (2005) taught thirteen 4-and-5-year-olds to engage in an abduction prevention response. Behavioral skills training sessions occurred at each participant's day-care program, in a classroom, various hallways, and outside on the playground. Following behavioral skills training (BST), in situ assessments were conducted on the playground, in the school building, and at each participant's home. The results of this study indicated that the inclusion of BST and in situ training (IST) components was effective at establishing the abduction prevention response for all participants.

However, if teaching in the natural environment is not possible or not feasible, practitioners should attempt to create an analog instructional setting that contains stimuli common to the natural environment (i.e., program common stimuli; Stokes & Baer, 1977). The inclusion of common stimuli promotes generalization by pairing the targeted safety response with stimuli which may be present in the natural environment or may share a sufficient number of stimulus features (e.g., signs, store employee regalia, locations of customer service markings) Several studies have incorporated stimuli common to the natural environment into controlled teaching settings. Page et al. (1976) arranged a simulated street model complete with houses, cars, trees, and people to teach individuals with disabilities to discriminate safe conditions for crossing the street. Carlile et al. (2018) taught participants in a public school setting how to respond when lost in public through simulated commercial stores using large color photos of store interiors and instructors dressed in employee uniforms. Jones et al. (1984) taught four individuals with congenital blindness to exit their school dormitories during a night-time fire. The experimenters simulated the features of an actual fire using a taped recording of the school's fire alarm, a recording of the sound of flames, and a hair dryer to provide the sensation of nearby flames.

Selecting Instructional Materials When selecting instructional materials, the practitioner should ensure training exemplars are physically representative of actual dangers the learner might encounter. One method that has been used to identify representational stimuli is a psychometric sort (Giannakakos et al., 2020b; Lee et al., 2019, Rosch, 1975), in which the instructor identifies a pool of exemplars of a danger and has relevant stakeholders (e.g., caregivers, individuals in the local community) order the exemplars from most representative to least representative by assigning each exemplar a number from one (most representative) to 10 (least representative). An average score is calculated for each exemplar and these averages can be used to establish a representation gradient from which exemplars can be chosen. An example of a representation gradient is displayed in Fig. 42.1. A psychometric sort could also be used to select non-dangerous exemplars. Non-dangerous exemplars could be selected based on having non-relevant shared characteristics with the dangerous exemplars, then a psychometric sort could be conducted to establish a gradient of most representative to the least representative exemplars (i.e., boundary stimuli).

For ethical and safety purposes, actual dangerous materials are never used in safety instruction unless they have been rendered inoperable (e.g., lighters emptied of fluid and refilled with water, firearm with cemented barrel). The literature provides several innovative methods for the creation of realistic instructional materials, including lighters (e.g., Houvouras & Harvey, 2014; Rossi et al., 2017), firearms (Jostad et al., 2008; Lee et al., 2019), medications (Dancho et al., 2008; Giannakakos et al., 2020b), and cleaning products (Rossi et al., 2017; Summers et al., 2011). There are several ways to simulate dangerous items. Table 42.2 provides suggestions for safe alternatives for use in research and instruction.

Safety Response Interventions

Antecedent Interventions

Antecedent interventions as they pertain to safety are focused on manipulating a dangerous environment to eliminate or reduce learner exposure to danger. The section on assessment discussed using the HAPI-R and publicly available checklists to assess the home environment and identify potential dangers. This section describes how to use the results of these checklists might be used provide instruction on preventative safety measures to caregivers.

The results of the HAPI-R provide information on the locations and number of hazards in the home and are used to identify specific training targets for caregivers (Barone et al., 1986). For example, Metchikian et al. (1999) used the HAPI-R to assess the homes of three families referred from their county's child protective services. The HAPI-R was used to identify the presence of hazards in at least four rooms including the living room, kitchen, bathroom, and the child's bedroom. The rooms were target for treatment based on the number of hazards recorded during baseline, whereas the room with the highest number of hazards was targeted first. During training, the instructor informed the caregivers of the types of hazards that could posed a threat and provided three suggestions on how to eliminate such hazards, such as, placing it out of reach, locking it up, or fastening drawers with child locks. Then the instructor asked the parents to identify other hazards and demonstrate how they could be made inaccessible. Positive and corrective feedback were delivered and parents were

Exemplar	Average rating	Exemplar	Average rating
	1.4		2.2
	3.6		4.4
	4.5		6.6
	7.4		7.6
	8.4		8.9

asked to make the target room safe before the next session. The intervention was successful at training parents to reduce the number of hazards in all target rooms.

After completing the elopement checklist like the one described intervention might focus on training caregivers putting missing preventative measures in place. Here we describe some useful prevention strategies that can be targeted for intervention. First, installation of secondary locks should be considered if a learner is able to independently exit their home (e.g., unlock doors, reach door handles). Secondary locks are installed out of the learner's reach or require a key to

Table 42.2 Recommendations for simulations of dangerous objects

Dangerous object	Safe preparations	Average cost
Firearm	Movie prop replicas can be obtained from online movie prop warehouse	$100–$200 per replica
	Real firearm disabled by pouring cement down the barrel	Sometimes available through police departments
Lighter	Empty one time use lighter of fluid, refilled with water, and remove flint. Lighting mechanism should be tested to ensure it no longer produces a flame	$2–$4 per lighter
	Reusable lighters can be purchased online and filled with water. Flint should be removed	$15–$30 per lighter
Prescription medications	Pharmacies may donate empty l prescription bottles. Simulated prescription labels can be printed online. Lids should be sealed with super glue	Free
	Empty prescription bottles can be obtained from online sellers. Simulated prescription labels can be printed online. Lids should be sealed with super glue	$0.20–$0.50 per bottle
Cleaning chemicals	Bottles can be obtained online and filled with water. Food coloring can be used to replicate color as needed. Lids and spouts should be rendered inoperable by sealing them with glue	$1.50–$30 per bottle
Broken objects	Breakaway glass also known as sugar glass, is a transparent form of sugar. It is available from theater production companies. It breaks similar to glass, and although it can still cause a cut is generally less dangerous	$20–$50 per item

which the learner does not have access. Second, contact sensors on exterior doorways can act as an alert if a door is opened unexpectedly. A contact sensor is a small two-piece device that attaches to the door and door frame. When a door is opened, the contact between the sensors is broken and an alarm is triggered.

Direct Intervention Procedures

Behavioral Skills Training A recent review of the literature found that the majority of studies used behavioral skills training (BST) in isolation or in combination with other methods to teach a wide range of safety responses (Giannakakos et al., 2020a). BST is a treatment package comprising instructions, modeling, role-play, and feedback. In the context of safety training, the instructor first provides the learner with information on the nature of the danger and the safety response. The type and complexity of this information are appropriate to the learner's age and skill level can be written, vocal, or both. Next, the safety behaviors are modeled. The model is presented so that the learner can observe every component of the response. Then the instructor gives the learner the opportunity to practice the response and provides feedback, both positive and corrective on their performance. The cycle of modeling, role-play, and feedback is repeated until the learner completes the target behavior correctly and independently. The termination criteria for BST vary across studies. One commonality is the requirement that learners emit all steps of the target safety responses independently and without error; however, the number of times a learner emits the response before BST is considered complete varies. Some studies required only one instance of criterion responding (e.g., Ledbetter-Cho et al., 2016) and others required as many as five instances (e.g., Carrow et al., 2020; Sanchez & Miltenberger, 2015).

One example of how BST may be used to teach an appropriate safety response is exemplified by Summers et al. (2011) who used BST to teach six young children with ASD how to respond to the ringing of the doorbell in their home. First, the instructor provided the participant with a clear rule, "when the doorbell rings, do not open the door, you need to go tell mom." Next, the instructor gave the participant the opportunity to engage in the safety response. The instructor observed the participant as they completed the response and provided praise contingent on a correct response. If the participant did not engage in the safety response a series of partial physical prompts were provided to complete the response and another opportunity to engage in the response was presented. Rehearsal and feedback were repeated until the participant independently engaged in the safety response for three consecutive opportunities across three separate days.

Another example of how BST has been used to teach safety responses is a study conducted by Vladescu et al. (2020) who used BST to teach 31 new or expectant caregivers to arrange a safe infant sleep environment. During BST, the instruction and modeling portion was conducted in a group format. The instructor reviewed an educational brochure called Safe Sleep for Babies (Consumer Product Survey Commission, n.d.) with the participants and reviewed the importance and rationale for arranging a safe sleep environment. Next, the instructor modeled the steps of setting up the safe sleep environment. Participants questions were answered throughout this group training. Rehearsal and feedback were conducted with participants individuals. The participant was given an opportunity to arrange the sleep environment independently. If the participant completed a response correctly, they received behavior-specific praise. If the participant engaged in an error, corrective feedback was immediately provided. BST continued until the participant demonstrated 100% correct responding for two consecutive role-play opportunities.

Variations on Behavioral Skills Training Several effective variations of the standard BST format have been evaluated in the literature. One variation of BST that can be useful in settings with low trainer-to-client ratios, such as public schools is to replace the in-person instruction and modeling portion of the treatment with a video model (e.g., Giannakakos et al., 2018; Gunby et al., 2010). There are several important factors to consider when using video modeling. Video lengths vary within the literature, but research supports that the video should be long enough to demonstrate the skill (Karsten et al., 2015). Video models can be shot from the point-of-view of the person engaging in the behavior (i.e., first-person perspective) or that of an observer (i.e., third-person perspective). Studies comparing first-person and third-person perspective suggest both perspectives are equally effective as models for target behaviors (Ayers & Langone, 2007). Although video models can be time intensive to create and require some technical knowledge (e.g., using video editing software, using a device with a sufficient camera quality), they have the advantage of providing a standardized model and set of instructions that can be used across multiple learners (Karsten et al., 2015). For instance, Giannakakos et al. (2018) taught three adults to correctly install and use child passenger safety restraints (CPSR; i.e., car seats). The instruction and modeling portion of BST was provided via video. During the first session of BST, participants watched a short video which provided information on motor vehicle-related infant and child mortality rates and the role correctly installed and used CPSRs serve in reducing deaths and injuries. Next, the participants were brought out to a vehicle and given a tablet containing the video model of correct installation and use of the CPSR. Participants watched the video and followed a checklist as they completed the steps of the installation. Following completion of the installation they were provided with behavior specific positive and corrective feedback on their performance. This was repeated until the participants installed the CPSR 100% correct for three consecutive sessions.

A second variation of BST is computer-based BST. Vanslow and Hanley (2014) evaluated computerized BST and in-person IST to teach abduction prevention and responses to dangerous items. Computer-based BST consisted of a computer game approximately 20 min in length. In the first part of the game a narrator described the dangers and steps of the safety response. Video models of children responding to the dangers were shown. Then the participants completed a series of mini games that required them to practice the order of the steps of the safety response, discriminate safe and unsafe objects, and act out the steps of the response with a cardboard cutout that was placed in the room. In study one computerized BST was used to teach an abduction prevention response. However, in a subsequent in situ assessments only one participant demonstrated the entire safety response. IST was added to establish the abduction prevention response.

A third variation is parent implemented BST. Parent implemented BST has the advantage of reducing the need for a behavior analyst to be present for sessions and may be an attractive option in remote areas or areas with few behavior analysts. In a recent study, Novotny et al. (2020) used a web-based manual to guide parents through the steps of using BST to teach their children to respond to the presence of an unattended firearm. The website created for the study provided parents with all the materials needed to conduct BST, instructions and checklists on how to conduct each component, and video models of the rehearsal and feedback components of the safety response. Experimenters conducted in situ assessments before and after the parent training to measure its effectiveness. Results indicated parent implemented BST was effective for three of the six child participants. For the other three participants experimenter implemented IST was required before they mastered the safety response. The findings of this study are preliminary support for parent implemented web-based BST.

In Situ Training Giannakakos et al. (2020a) reviewed the safety literature and found that in almost half of the studies, BST alone was insufficient to establish the target safety response for all learners. The subsequent inclusion of in situ training (IST) was effective at increasing responding to mastery levels (Giannakakos et al., 2020a). Once a safety response has been established it is then necessary to ensure that response will occur under the control of the danger rather than irrelevant aspects of the environmental arrangement present during training. Including IST as a component of safety instruction serves to assess and facilitate the establishment of appropriate stimulus control (e.g., Beck & Miltenberger, 2009; Giannakakos et al., 2020b; Lee et al., 2019; Miltenberger et al., 2005.) During IST, the practitioner sets up a simulated situation in which the learner will have an opportunity to demonstrate the safety response. The learner is then introduced to the situation while the instructor observes covertly. If the learner completes a step of the safety response incorrectly the instructor interrupts the situation in a natural way and provides corrective feedback, models the correct response, and has the learner practice.

Sanchez and Miltenberger (2015) taught four young adults with intellectual disabilities the general abduction prevention response described earlier in the chapter using BST. Then participants were exposed to an IST condition. The participants were placed in a simulated situation like the one described above. If the participant failed to engage in the abduction prevention response the instructor interrupted the session and demonstrated the correct behaviors. The participant was then required to rehearse the behaviors until they completed the response correctly. Training was considered complete once the participant engaged in the abduction prevention response independently and correctly during an IST probe.

Virtual Reality Virtual reality is an intervention tool that has been garnering increased attention in the safety literature recently. Virtual reality technology is used to create a realistic simulated learning in which the learner can practice the target safety skills. Virtual reality technology has been incorporated into safety instruction to teach fire safety (Çakiroğlu & Gökoğlu, 2019; Padgett et al., 2006) and safe street crossing (e.g., Josman et al., 2008; McComas et al., 2002). One consideration when seeking to use virtual reality as a training mode is to ensure that sufficient hardware is available to run the simulations. As with any relatively new technology, the advancements in this area are constant and become more affordable over time. A recommendation is therefore made to thoroughly research the hardware capability needed to run the targeted simulations and determine if the investment is financially reasonable. Another consideration is that some VR immersive simulations carry the risk that some individuals might experience simulator sickness. In a study evaluating VR software to teach pedestrian safety 11% of participants dropped out due to simulator sickness. A final consideration for using virtual reality is that simulations may not be available for all intended safety responses and finding qualified programmers may be challenging.

Çakiroğlu and Gökoğlu (2019) used VR-based BST to teach 10 adolescents fire safety responses. Participants were taught a variation of the general safety response, if they see a fire they should not interact with it, get away, and tell an adult. During VR training participants wore a virtual reality headset that created a 360 view of a simulated home. The instruction, modeling, rehearsal, and feedback components of BST were provided using avatars in the VR environment. Three participants mastered the safety response following VR BST, for the other seven participants one to four subsequent IST sessions were required to reach mastery. As we discussed earlier in the chapter, research recommends teaching in the natural environment whenever possible; however, it may not always be possible to do so. Virtual reality technology may provide an alternative method in which a realistic instructional setting can be simulated. The simulated environmental stimuli created would have the potential to produce strong stimulus control over the safety response and increase the likelihood of generalization to the natural environment.

Important Intervention Elements

Establishing a Mastery Criterion Mastery criterion is an important consideration when teaching safety responses. In all cases a safety response should be taught to a mastery criterion of 100% or all components completed correctly. Incorrect completion of even a single step of a safety response could result injury or death.

Discrimination Training Just as it is important to establish an appropriate safety response, it is equally important that learners be taught the conditions under which the safety response is not required (Lee et al., 2019; Giannakakos et al., 2020b). Research suggests that safety instruction without discrimination training may lead to overgeneralization of the safety response (Ledbetter-Cho et al., 2019). We therefore recommend that discrimination training be incorporated into all safety instruction. In the context of safety training an individual is taught to emit one response in the presence of a dangerous stimulus and an alternative response in similar situations that do not contain the dangerous component.

Procedures used by Giannakakos et al. (2020b) provide an illustrative example. Two typically developing preschoolers were taught to engage in a safety response when they encountered a variety of dangerous items (i.e., firearm, medications, lighters). Discriminated responding was obtained by also teaching the participants to stay and play when physically similar non-dangerous items (i.e., hair dryer, containers, flash drives) were present in the same environment.

Rossi et al. (2017) also evaluated responding in the presence and absence of the dangerous items in their study to demonstrate appropriate stimulus control. Rossi et al. taught three 5- and 6-year-olds diagnosed with ASD to engage in the general safety response in the presence of an unattended firearm, lighter, or cleaning product and to continue to play if those items were absent in the environment.

Ledbetter-Cho et al. (2019) also used discrimination training to establish correct stimulus control over a safety response. The instructors used BST to teach four learners with ASD to engage in an abduction prevention response following lures from strangers. All participants acquired the abduction prevention response, but when an overgeneralization probe was conducted in which participants were approached by a police officer all participant engaged in some portion of the safety response. Discrimination training was provided in the form of BST and participants were taught to differentially respond to civilian strangers and police officers, and to go with the police officer if asked. Following discrimination training participants successfully engaged in differentiated responding.

Instructional Context The conditions under which a learner encounters a danger may be multifaceted. Most of the studies that have established a safety response in the presence of dangerous stimuli such as poisons, firearms, and fire-starting devices have used only one instructional context. The instructional context typically is a simplistic one, a learner is left in, or told to go to a room that is baited with a dangerous stimulus. Although this is a realistic context a learner may come across a dangerous stimulus in other more complex situations. For example, a learner may see prescription medications left on a table after viewing their parent consume them. A learner may be enticed to touch a firearm by a friend or sibling or a learner who sees birthday candles left out and knows the location of matches may attempt to access them. One study to date has evaluated procedures for teaching a response to a dangerous item under more varied contexts. Lee et al. (2019) evaluated the extent to which a safety response taught in the presence of a firearm under one context would generalize to a representative sample of additional contexts. BST and IST with discrimination training were used to teach participants to engage in the three-step safety response in the presence of an unattended firearm or to stay and play in the presence of a hair dryer. Participants were taught that in the context of finding a firearm placed on a piece of furniture among their toys they should engage in the three-step response—don't touch, leave the area, and tell an adult. Generalization was then assessed to four other contexts. In general, the contexts varied by who was present in the setting, the placement of the gun, and in what way it was left unattended. More specifically, these contexts included, the participant's parent being present in the room, the firearm placed on a piece of furniture, the experimenter asking the participant to retrieve an item from a location where the firearm is placed, a firearm left unattended after a parent finishes interacting with it in view of the participant, and a peer or sibling holding the firearm and attempting to induce the participant to play with it. Following BST and IST in the first context all participants demonstrated generalization of the safety response to the remaining untrained contexts. The results of this study provide preliminary evidence that BST and IST may be effective in establishing a safety response with generality to a variety of related contexts. Additional replications of Lee et al.'s (2019) procedures are needed to establish the generality of this outcome.

Modified Reinforcement Contingencies It is sometimes necessary to modify the reinforcement contingencies surrounding the safety response (Hanratty et al., 2016; Miltenberger et al., 2004). If the natural reinforcing contingency for the safety response (i.e., caregiver praise) is not sufficient to establish and maintain responding additional reinforcement contingencies may be required. In their study evaluating the effects of BST and IST on teaching a firearm safety response to 5 preschool children, Hanratty et al. (2016) found that following BST and IST participants failed to acquire the safety response. To address this issue the experimenter added both a positive and negative reinforcement contingency to the IST procedure. If during an IST session the participant did not engage in the correct response within one minute or if they touched the firearm the experimenter interrupted the session, reviewed the safety response and had the participant practice the skills for 10 min instead of attending their class playtime. If the participant correctly engaged in the safety response during the IST session, they were given the option to go outside and play or complete an activity of their choice. These modifications were effective in increasing correct responding for four of the five participants.

Generalization and Maintenance Establishing a safety response is only a fraction of comprehensive safety instruction. It is unknown when, if ever, a learner will need to demonstrate a safety response. Therefore, it is imperative that established responses generalize to novel stimulus conditions and maintain over time (Miltenberger, 2008). Careful consideration should be given to programming for generalization and maintenance. This section breaks down the procedures described above and identifies those elements that promote generalization and long-term maintenance.

First, several of the studies discussed used realistic simulations of dangerous stimuli during training. This procedural element serves to establish a common stimulus (dangerous item) that is shared by both the training setting and any future dangerous situation. Subsequently, the common stimulus serves to control the safety response regardless of how other stimulus conditions might vary. If appropriate stimulus control of the response is established during training it will increase the likelihood the learner will engage in the safety response if they encounter that dangerous stimulus.

Second, because we cannot predict the exact stimulus conditions surrounding a dangerous situation, the practitioner should incorporate multiple exemplar training into their safety instruction (e.g., Lee et al., 2019; Rossi et al., 2017). Depending on the safety response being taught this may include multiple exemplars of dangerous stimuli, discrimination stimuli, or teaching the response in a variety of different scenarios. For example, a learner being taught not to touch fire starting devices might be exposed to multiple exemplars of fire-starting devices (e.g., matches, butane lighter, Bic lighter) and variations in appearance for each one (e.g., different colors and sizes). If designing an intervention to teach a learner not to approach an unattended pool, multiple scenarios could be used such as, being outside when the pool gate is left open, or a sibling suggests jumping in the pool when caregivers are inside. Including varied materials and scenarios in training increases the likelihood that generalization of the response will occur to similar untrained conditions and therefore be more likely to maintain over time.

The unpredictable nature of dangerous situations makes it imperative that behavior analysts conduct regular maintenance checks. Whenever possible maintenance probes should be conducted using an IST format (Miltenberger, 2008). Regular assessments to evaluate in the target safety response are still present in a learner's repertoire can in themselves be a type of preventative measure as they allow parents and practitioners to identify if a response needs to be retrained. Few studies in the safety literature have evaluated the long-term maintenance of the responses they established (Giannakakos et al., 2020a). It is essential therefore that established responses maintain long term. There is a need in the field of behavior analysis for follow-up studies that evaluate if safety responses have maintained at mastery levels. It is concerning that it remains largely unknown how safety responses established using behavior-analytic methodology maintain over time.

Giannakakos et al. (2020b) evaluated the effectiveness of a treatment package consisting of BST, IST, and equivalence-based instruction (EBI) at establishing a concept of danger that was not limited by the physical features of the dangerous stimuli and a collateral safety response. The authors first determined their exemplars of dangerous stimuli through a psychometric sort. Ten individuals were asked to sort 10 pictures each of handguns, medication, and lighters. The results of the psychometric sort generated a gradient of stimuli for each dangerous item. The most representative and least representative exemplars were used during training, while the exemplar with the median score in each gradient was reserved for generalization. Non-dangerous items were then selected for use in discrimination training based on shared physical features with the non-dangerous items (i.e., hair dryers, flash drives, and containers filled with small objects or liquid). BST and IST were used to teach participants a safety response—don't touch, leave the area, tell an adult—in the presence of one type of dangerous stimulus, and to stay and play in the presence of the corresponding non-dangerous stimulus. Then participants were exposed to EBI to establish classes of dangerous (i.e., handguns, lighters, and medications) and non-dangerous (i.e., hair dryers, flash drives, and containers) stimuli. After participants demonstrated acquisition of the classes, their response in the presence of the two remaining types of dangerous and non-dangerous stimuli was probed. Both participants demonstrated transfer of the safety response taught during BST to untrained types of dangers and novel exemplars following EBI and engaged in discriminated responding in the presence of the related non-dangerous stimuli. Several aspects of this study provide examples of generalization strategies. First, generalization of the safety and play responses to untrained exemplars was likely facilitated by the responses having been trained in the presence of the most and least representative exemplars during BST and IST. The most and least representative exemplars of each stimulus served as boundary stimuli for each of their respective classes, making generalization to examples with physical characteristics between these boundaries highly likely. Second, the authors demonstrated that EBI could be used to establish classes of stimuli that were related to each other not by their physical characteristics, but by a conceptual property (i.e., dangerous of non-dangerous). The inclusion of the dangerous and non-dangerous stimuli used during BST and IST in the class formation during EBI facilitated transfer of the safety and play responses to the untrained stimuli without the need for BST and IST.

Future Directions

There are several areas of the safety literature that could be strengthened. One such area is environmental assessment. The HAPI-R assessment discussed in this chapter is a useful tool but does not cover all the areas that might need to be evaluated. To date no assessment of environmental manipulations related to safety exists that reflects the unique needs of individuals with developmental disabilities. Environmental assessment plays an important role in subsequent antecedent interventions targeting creating a safe environment. Researchers should consider developing and evaluating assessments that could assist practitioners in identifying safety response deficits.

A second area for future research is discrimination training. Several studies have found that safety training is enhanced by the inclusion of discrimination training. Ledbetter-Cho et al. (2019) demonstrated the risk for overgeneralization that occurs when a safety response is not established under appropriate stimulus control. Future studies should seek to incorporate discrimination training into different areas of safety instruction. For instance, the area of emergency responses seems a prime candidate for teaching discriminated responses. Information provided by Arizona State University Center for Problem-Oriented Policing (Sampson, 2004) suggests that in some United States counties close to 50% of monthly calls are non-emergencies. These findings suggest a vast majority of people fail to discriminate the conditions under which they should *not* call emergency services. Discrimination training could be employed to teach learners at a young age to respond differentially to emergency and serious, but non-emergency situations.

A final area of safety instruction that has received limited attention within the behavioral literature is water safety, particularly regarding preventative methods and responses that could help a learner should they begin to drown. Researchers and practitioners should look to the prominent water-safety courses by organizations such as the American Red Cross and seek expert consultation from credentialed Water-Safety Instructors (https://www.redcross.org/take-a-class/swimming/water-safety) when designing safety responses around water safety. A general safety repertoire for water-safety instruction should minimally address treading water, identifying life guards, walking while on the pool deck, identifying prominent pool signs (e.g., no diving) as well as gauging the depth of water by referencing the numbers marked around the pool deck. Other behaviors which may help a learner in a pool setting may also include recognizing the signs of active drowning so that they can alert a lifeguard or adult if they witness an individual in distress

Chapter Summary: Key Points

- Education-based instruction is insufficient to establish safety behaviors due to the lack of an active learning component. To effectively establish a safety response instruction must include a rehearsal and feedback component.
- The first step in comprehensive safety instruction is to use identify potential dangers in a learner's environment and deficits in safety responses. Subsequent instruction should be comprised of both antecedent and direct intervention procedures.
- Expert consultation is an important component of safety research and instruction. Researchers and practitioners should collaborate with local agencies and consult official websites such as the Centers for Disease Control and Prevention, the American Medical Association, and the National Fire Protection Association for up-to-date information during the intervention planning process.
- BST in isolation and in combination with IST are the most evidence-based methods for establishing safety responses.
- All learners regardless of skill level should have a repertoire of safety responses. Research has identified procedures that are effective for both neurotypical learners and learners with developmental disabilities.
- Programming for generalization of the safety response to the natural environment should be incorporated into safety instruction. Evidence-based methods of programming for generalization may include programming common stimuli, multiple exemplar training, and discrimination training.
- The most important area for future research in behavior analytic safety instruction is response maintenance. It is unknown when, if ever, a learner will need to demonstrate a safety response. Therefore, it is imperative that established responses maintain over time.

Part VII

Leisure and Social Behavior

43 Mobile Devices in the Context of Applied Behavior Analysis: A Multipurpose Tool

R. Allan Allday, Amy D. Spriggs, Megan E. Jones, and Christina Noel

History of Mobile Device Usage

Mobile devices, specifically cellular phones, have rapidly revolutionized society's use of technology over the last century and significantly shaped how we communicate with each other. Beginning in the early 1900s, the first mobile devices possessed limited radio capabilities and were mainly utilized for ship-to-shore and police communication (Satia, 2010). By 1964, a limited number of non-cellular car phones were installed, which utilized ineffective radio bandwidth. The first cell phone tower was installed in 1969, and the first cellular call devices were prototyped 4 years later. Popularized car phone usage did not occur until the late 1980s with the use of large, bulky devices that consumed great amounts of energy (Smith, 2010). It was not until the mid-1990s that the Blackberry® and Nokia® "Communicator" devices were popularized for sending and receiving emails and fax messages. Despite these technological advances, the devices were still ineffective for the use of voice calls. In 2004, Cingular® became the first carrier of the mobile phone. The first iPhone or "smartphone" was released in 2007 (Pothios, 2016) marking a significant step in mobile cellular technology. These "smartphones" increased the usage abilities of the phone beyond calling, texting, and email to a variety of uses (e.g., Internet access, maps, music, games).

Over the past three decades, mobile device usage radically increased in the United States and has become integrated into everyday life. By 2008, the number of individuals who owned a mobile device rose to 262 million (Shelton et al., 2009) and continued to escalate to 318 million users by 2019 (Pew Research Center, 2019). This growth has resulted in 75% of Americans accessing the Internet from their smartphone an average of 5 hours per day (Mendoza et al., 2018).

Social media usage on platforms such as Facebook, YouTube, Instagram, Twitter, Pinterest, and LinkedIn have also expanded in a diminutive timeframe (Mendoza et al., 2018; Pew Research Center, 2019). Pew Research Center (2019) noted that the number of Americans using one of these social media sites increased from 5% in 2005 to 72% in 2019. This has resulted in social media being integrated into the daily routine as 75% of Facebook users and 60% of Instagram users claimed to access the site at least once per day (Pew Research Mobile, 2019).

Among this substantive growth in mobile device use have been users who are teens and young adults, who are considered "digital natives" in today's society (O'Bannon & Thomas, 2014), meaning they have not known a

world without mobile cellular technology or smartphones. Teen users have disclosed that they access the Internet at least daily (Sibley et al., 2017). It has been reported that young people receive or send an average of nearly 109 texts per day (Mendoza et al., 2018), as teens and youth oftentimes associate mobile usage with social connection. According to Tulane et al. (2017), the devices provide (a) connection with friends and family, (b) peer attention and acceptance, and (c) levels of regulation and autonomy. These devices have led many to create and maintain relationships through interaction of social media platforms, texting, sending pictures, and scheduling events (Carels, 2019; Nesi et al., 2018; Thomas & McGee, 2012; Tulane et al., 2017).

Within the past few years, mobile technology has morphed into portable tablets and wearable smartwatches that synch with another mobile device. These smartwatches have increased in their usability as there have been increases in app development (BusinessWire.com, 2020). As these technologies have once again broadened the communicative abilities of mobile devices, the smartwatch has also bridged into a tool to assist with documentation of health conditions (e.g., heart attack detection; Tison et al., 2018).

A thorough history of mobile technology is outside the purview of this chapter; however, the previous paragraphs provide a brief overview of the rapid spread of these technologies and how they have become intertwined in the social and health-related facets of modern society. Throughout this chapter, we will discuss mobile devices as a general term that encompasses cellular phones, smartphones, smartwatches, and tablets (e.g., iPad®, Kindle, Amazon Fire®). If needed, we will specify which type of device has been referenced in the literature. The remaining sections of this chapter will address these technologies in relation to the human behavior change, specifically applied behavior analysis (ABA). Understanding some basic tenets of how these technologies have and can be used for ABA practitioners can assist in furthering the quality of services provided in the field.

Mobile Devices as Agents of Behavior Change

There are numerous studies that have shown the effects of mobile devices on human behavior. These studies have varied across the spectrum of academic research and have shown both the benefits and detriments of these technological advancements. Hypotheses related to mobile device effects on human behavior have been posited related to medical sciences (Thomas et al., 2019), business (Thusi & Maduku, 2020), education (Clemons et al., 2016), and the arts (Tyak et al., 2017). This breadth of research has encompassed a wide swath of human behaviors ranging from taking medication as prescribed (Armitage et al., 2020) to encouraging social interaction among children with autism spectrum disorder (ASD; Grosberg & Charlop, 2017). A cursory search of the literature reveals a multitude of studies aimed at utilizing mobile devices to assist in behavior change.

Each of these studies suggests that technology has the power to reinforce and shape human behavior in manners that have previously been unavailable. Throughout most of human existence, there needed to be an actual person present to develop social interaction skills, and there needed to be additional people present to encourage the generalization of these skills. With mobile devices, the need for a person to be physically present to teach, reinforce, and generalize a social interaction behavior is not required. The device provides multiple platforms that involve voice and video with live or recorded interactions that can shape the social interaction behaviors. Additionally, throughout the Coronavirus Disease-2019 (COVID-19) pandemic, mobile devices became an important way for individuals to stay socially connected to one another. While many were quarantined, many individuals were only able to connect with family through voice calls, text messaging, and video-based communication (Banskota et al., 2020).

Additionally, even niche behaviors that require specialized skill and information have become simpler as a result of the mobile device utility. For example, if a person is trying to engage in a specific behavior (e.g., rebuild an engine from an antique car), they have access to a device that can provide them with multiple means to assist in engaging in the behavior accurately: (1) vocal communication through a call to an expert on the subject; (2) using a live, video-based communication (e.g., FaceTime, Zoom, or Skype) to be shown what to do in real time; (3) using mobile data to download an owner's manual for the specific model of automobile; (4) using a video-based platform (e.g., YouTube) to watch the specific skill multiple times via a video model of how to specifically perform the task; and so on. Prior to the invention of the mobile device, a person would have to either have experience with engine repair or have a person physically present with them to show them how to perform the tasks needed.

Although there have been many positive aspects to the behavior change associated with mobile devices, we would be remiss to not address some of the detrimental side effects. Mobile devices have caused people to engage in distracted behaviors that have led to accidents, injury, and death (National Safety Council, 2012). For example, distracted driving causes thousands of deaths each year (National Center for Statistics and Analysis, 2021). This is when the driver of the automobile is focused on talking or texting on their mobile device, as opposed to observing the road for warning signs (e.g., brake lights) or hazards. Distracted pedestrians using their mobile device are also a growing problem. This problem has required a behavioral intervention to cue the pedestrians that they are about to enter a dangerous area (e.g., intersection; Larue & Watling, 2021). A common sign when at many crosswalks now is "Phone Down and Head Up" to remind pedestrians to look before crossing the road (Barin et al., 2018).

Perhaps one of the most challenging aspects of behavior changes has been the problematic nature in which people have engaged with these devices. Nomophobia is a term that has been used to describe the fear that a person has when they are unable to access their phone or mobile device (Tams et al., 2018). Addictive mobile phone behaviors have been associated with more stress (Khalili-Mahani et al., 2019). Stressors surrounding mobile devices have sparked a growing call for additional research regarding "screen addiction" (World Health Organization, 2015) and development of tools to evaluate this phenomenon (Domoff et al., 2019). Any addiction suggests that the mechanism (i.e., chemical substances, gambling, Internet browsing) the individual is addicted to is providing some form of reinforcement that maintains the behavior (Alavi et al., 2012; Dixon et al., 2015). In the case of "screen addiction," the reinforcer maintaining the behavior(s) is a device that has a screen (e.g., mobile device). The emergence of this industry shows the reinforcing power of the mobile device to catch and hold a person's attention to the point that they are unable to function within their daily lives.

Contingency Analyses of Mobile Devices

As technology continues to improve, the use of mobile devices in our everyday lives does not seem to be slowing. It is for this reason we should consider how mobile devices function within a basic ABA framework. As noted above, addressing "screen addiction" is an emerging field that suggests that there are many reinforcing qualities surrounding mobile devices. When considering these qualities, it is important to note that mobile devices may serve several potential behavioral functions.

Considering that mobile devices are by definition tangible, handheld tools, it is clear that they may serve as a positive reinforcer (S^{R+}) in the form of a tangible reinforcer. In addition to being tangible, the mobile device offers a variety of activities in which the user can engage. According to estimates in late 2020, there were almost one million gaming apps available on Apple® App Store, while Google Play® had almost 500,000 available gaming apps (Statista, 2021b). It was reported in the same timeframe that there were over 3.4 million non-gaming apps on Apple® App Store and almost 2.5 million non-gaming apps on Google Play® (Statista, 2021a). With apps being created that serve a myriad of purposes, it is clear that the one tangible device provides access to almost endless activities. Although there are always idiosyncratic variables that may affect tangible or activity reinforcer effectiveness (Cooper et al., 2020; Schlichenmeyer et al., 2013), an individual's particular fixation to one type of activity may be able to be met in a variety of ways through the available apps. Having access to all of these apps that may contain a reinforcing activity further emphasizes the premise that mobile devices can serve as a tangible reinforcer. Refer to Tables 43.1 and 43.2 for example contingencies for mobile devices.

A second way in which mobile devices can serve as S^{R+} is in the form of social attention. Many of these devices provide direct access to other people through text, voice, video communication, or through social media platforms. Historically, phone calls have served to provide social attention for the caller and receiver of the call. As telecommunications have improved, phone calls have been used as social attention reinforcers that aimed to help with follow-through on interventions (Laforest et al., 2012), counseling (Lash et al., 2001), as well as reinforcing parents for their child's school attendance (Copeland et al., 1972). Some mobile devices do not have a phone function; however, through various apps (e.g., WhatsApp®), a phone call can still be made using mobile or Internet data. Additionally, mobile devices allow individuals to have conversations with multiple people simultaneously, thus increasing the potential potency of the reinforcement. Social media is designed to provide social attention to users in such a manner that users will increase the amount of time spent on the app (Guedes et al., 2016). In addition, gaming apps provide access to social attention through online gaming (Thomas & Martin, 2010). Based on this limited discussion, it is evident that reinforcement in the form of social attention is built into the fabric of mobile devices.

Negative reinforcement (S^{R-}) is the removal of an aversive stimulus following a behavior that increases the likelihood the behavior will recur (Cooper et al., 2020). When considering functioning, behaviors that are reinforced using S^{R-} are often considered "escape-maintained behaviors" (Allday, 2019). Mobile devices have the potential to provide escape in a few different ways. First, users can "escape" from social interactions (i.e., attention). This is accomplished by focusing on the device screen as opposed to

Table 43.1 Example attention contingencies related to mobile device use

	Motivating Operation	Antecedent	Behavior	Consequence	Potential reinforcement
Phone call 1	Desire to avoid contact with individual	See individual	Look at caller ID	ID shows a known caller	S^{R-} Attention
		ID shows a known caller	Silence ringing and ignore	Avoid conversation with unknown caller	
Phone call 2	No contact	Device rings	Look at caller ID (known caller)	ID shows a known caller	S^{R+} Attention
		ID shows a known caller	Touch green button and say "hello"	Person on other end says, "hi"	
Text message	No contact	Device "dings"	Look at phone	Notification shows "message from mom"	S^{R+} Attention
		Notification shows "message from mom"	Unlock phone to read message	Read message from mom	
		Read message from mom	Type a message to mom	Phone "dings" with heart emoji	

Table 43.2 Example activity contingencies related to mobile device use

	Motivating Operation	Antecedent	Behavior	Consequence	Potential reinforcement
Map app	Desire to meet friends	Voice prompts that church St. is the next left	Initiate turn signal to go left onto church St.	Arrive at destination	S^{R+} Attention/ activity
Reading app	Desire to read	Find the "book" icon on the screen	Touch the "book" icon	Book opens on screen to allow reading	S^{R+} Activity
Gaming app	Tired of working	Find the "game" icon on the screen	Touch the "game" icon	Game begins	S^{R-} Activity

looking or talking to the person that is being avoided. Second, users can escape from non-preferred tasks. When tiring from non-preferred tasks (i.e., activity), the user can engage the mobile device to play a preferred app. This type of escape is moving from a non-mobile device activity to an activity that can be completed on the device. Another means of escape can be achieved with the device, when the user stops working in one application to engage in a more preferred application. Please refer to Tables 43.1 and 43.2 for example contingencies related to mobile device use.

We have considered S^{R+} in the form of gaining access to attention and a tangible/activity reinforcer as well as S^{R-} in the form of escape. The only other primary behavioral function is related to automatic reinforcement. When considering how a mobile device can be used within a contingency that results in automatic reinforcement, it is not as clearly identifiable. Definitions of automatic reinforcement posit that a behavior must occur when there is not another person mediating the behavior (Vaughan & Michael, 1982). Furthermore, automatic reinforcement suggests the potential for non-social interactions or an environment without socialization (Falcomata et al., 2004; Patel et al., 2000) where the behavior continues without another person being involved (Cooper et al., 2020). The mobile device is a tangible tool that can be manipulated in isolation without socialization or another person mediating the behavior. The reason it would be difficult to identify an automatic reinforcement contingency for mobile devices is the fact that it always provides access to activities through its tangible existence; however, it is possible through these devices that an individual could engage in a variety of behaviors with the device without other socially mediated contingencies.

Mobile devices can also serve as a discriminative stimulus (S^D). An S^D is the antecedent stimulus that signals that reinforcement is available for engaging in a specific behavior (Cooper et al., 2020). With mobile devices, there may be several discriminative stimuli based on the specific audible sound that emits from the device. For example, a text message may make one sound ("beep"), while the phone ringing may make another sound ("rrrrring"), while a game notification may make another sound ("bim bam"). The user engages in a non-systematic form of stimulus discrimination training to determine which sound is associated with each function of the device. In this regard, the audible sound serves as a discriminative stimulus for engaging in specific behaviors associated with the device. For example, when a "beep" is heard, the user learns to read activate the screen to read the text versus if a "rrrring" is heard the user knows to press the "green button" to answer the phone. The user quickly learns which sound represents which information is being delivered. Research is emerging in how to better use these devices within the context of discriminative stimulus training (Lorah et al., 2014; Mitteer et al., 2020).

A unique observation of mobile device users is that there are many times that they will pick up the device and activate it without a clear audible sound to prompt them. This may be observed as a user pressing a button to check the time, then placing the device back on the table. As noted earlier, the ever-expanding utility of the mobile device makes it difficult to know how motivating operations impact device use.

As shown in this section, the mobile device has been a powerful agent of behavior change among people from a variety of demographic and social backgrounds. Although these examples are not directly related to the field of ABA, it is vital to reflect on how the wider professional and social communities have studied and focused on these technologies. Understanding how they can be an agent of behavior change requires us to focus on the potential reinforcing properties of the devices, as well as how they can serve as antecedent stimuli to engage in certain behaviors.

Mobile Devices in the Field of ABA Research

As mobile device use in the larger society has grown so has their use within research studies in ABA. As noted in the previous sections, it is clear how these devices can function to prompt and reinforce specific behaviors. It is in this utility that ABA researchers have considered the value of the mobile device in relation to their ability to be used within various components of single case designs. A cursory scan of behavior analytic literature reinforces the breadth of how mobile technology has been used to change human behavior systematically. It is outside the purview of this chapter to provide an in-depth analysis of research in ABA using mobile devices; however, we will address some of the studies that have used these devices.

Utilizing the full range of innovations that mobile devices may provide has shown how they can help to improve a variety of skills. Carlile et al. (2018) taught individuals with autism spectrum disorder (ASD), within a multiple probe design, to use a communication app (i.e., FaceTime®) on a device to seek help when lost. The researchers were able to produce generalized responses to novel situations among the participants. Bicard et al. (2012) utilized text messaging to improve the class attendance and reduce tardiness among college-aged student athletes. This was evaluated within a multiple baseline with embedded reversal design and found that the text messaging helped the student athletes regarding their classes. Also, there have been multiple studies that have utilized single case designs to evaluate mobile devices' ability to improve geometry skills of students with learning disabilities (Cihak, 2009), transition behaviors in school for students with ASD (Cihak et al., 2010), and self-monitoring skills for students with emotional and behavioral disorders (Gulchak, 2008). These studies show how mobile devices can help with a variety of behaviors across ages and settings.

Driving while distracted on a mobile device is one example that has a practical application to an issue addressed earlier, and has the potential to result in an accident, injury, or death (National Center for Statistics and Analysis, 2021). With this in mind, Clayton et al. (2006) used a sign at the exit of a parking lot to prompt motorists to put their phone down while driving, as well as put on their seat belt. Using a multiple baseline with reversal design, the authors found that the sign prompting motorists to put their phone down prompted many drivers to comply. Unfortunately, the authors noted that approximately 33% of drivers were on their phone again within one block.

Another example from the literature shows how an interdependent group contingency was used to reduce cell phone usage in schools (Jones et al., 2019). Within the context of a reversal design, students at an alternative high school had an interdependent group contingency (i.e., all students can access the reinforcer if all students meet a specific, predetermined criterion (Litow & Pumroy, 1975)) implemented to decrease mobile device use. Results showed a functional relation between the interdependent group contingency and reduced use of mobile devices for a specific student and for the entire class. In these two examples, mobile device use was considered unacceptable at the moment. These two studies showed ways in which to reduce mobile device usage.

There are numerous studies that focus on the use of mobile devices in changing health-related behaviors. The most common use of mobile devices to change health behaviors is when using some form of a contingency management (CM) intervention. CM interventions focus on providing access to reinforcers following exhibition of a targeted, desired behavior (Petry, 2011). There are many examples of using CM including a mobile device to change a specific health-related behavior. For example, Raiff et al. (2016) used a multiple baseline design to implement a package intervention (i.e., text-message reminder and monetary incentive) to increase the adherence to taking medication for participants with diabetes. Results showed that the intervention improved participant adherence to their medication regimen. Dallery et al. (2021) used a mobile app that included CM to decrease smoking behaviors among adults. Results suggested that this type of app was user friendly and encouraged participants to complete the required activities. Stedman-Falls and Dallery (2020) examined a mobile device-based and in-person deposit contract to increase physical activity (i.e., steps taken per day). The authors noted that both interventions were successful, yet participants preferred to use the mobile device-based system over the in-person.

It is evident that there are many uses of mobile devices within the research protocols of single case designs. The preceding citations reflect a small portion of the literature that has been produced showing how mobile devices can be used to promote behaviors as well as reduce behaviors. As a field, ABA researchers should continue to pursue the use of mobile devices within their research and discover the most efficient manners in which they can assist in improving socially significant behaviors.

Mobile Devices in ABA Practice

The field of ABA has grown exponentially over the past two decades with the advent of the Board Certified Behavior Analyst® (BCBA®) credentialing. The BCBA has helped the field to grow and organize in a manner that has greatly expanded practice opportunities (Behavior Analyst Certification Board, 2019). Behavior analysts have been able to incorporate mobile devices to streamline the manner in which the science is being delivered to consumers. The range of applications of the mobile devices has the potential to impact every facet of ABA practice including, but not limited to, assessment, intervention, data collection, and communication.

Assessment Using Mobile Devices

Prior to beginning any behavioral intervention, there are assessments that must be conducted to determine which skills need to be taught and reinforced or behavior to be changed. There are several popular forms of pen and paper assessments that have been used over the past decade that have been digitized and made available on mobile platforms.

The *Assessment of Basic Language and Learning Skills—Revised* (ABLLS-R; Partington, 2010) is a commonly used assessment that informs curricular decisions related to language instruction. The digitized version (i.e., WebABLLS-R) provides digital tools to collect and analyze data related to ABLLS-R programming, as well as serve as a communication tool to share the data with other practitioners.

Another common tool used by practitioners in ABA is the *Verbal Behavior Milestones Assessment and Placement Program* (VB-MAPP; Sundberg, 2008). The VB-MAPP is another tool that is used to evaluate verbal behavior. The program also provides a guide to instruction based on identified deficits. The mobile platform version of the VB-MAPP allows for practitioners to enter and analyze data via visual analysis. In addition, the mobile VB-MAPP provides a communication tool that allows immediate sharing of progress data.

Within the realm of functional living skills, the *Assessment of Functional Living Skills* (AFLS; Partington & Mueller, 2012) has also created an online system that is compatible with mobile devices that allow practitioners to organize and communicate results quickly and easily. Each of the AFLS® domains (i.e., Basic, Home, School, Community, Vocational, and Independent Living) is available to complete the evaluation of these skills for an individual. As with the other apps, the AFLSonline™ allows for quick scoring and tracking of skills, as well as a mechanism to create and share reports with stakeholders quickly.

Assessments designed to evaluate challenging behaviors are perhaps one of the most difficult assessments to fully digitize. One reason for this challenge is that there are numerous variations of data needed for these evaluations. For example, to complete a functional behavioral assessment (FBA), the practitioner may need to assess using interview, record review, behavior rating scales, and direct observation (Sugai et al., 2000). The process a practitioner would follow may depend on the individual and the severity/topography of the problem behavior. Therefore, there are a number of apps that can capture different pieces of the FBA process. For instance, mobile devices can record and digitize the interview. Hopper and associates (2021) have suggested that such interviews can be recorded and transcribed utilizing mobile devices and cloud-based tools. This would allow the practitioner to easily refer back to information from the interview after the direct observation. Additionally, programs such as the multi-option observation system for experimental studies (MOOSES; Tapp et al., 1995) or Countee (Peić & Hernández, 2016) can be used to collect and analyze direct observational data. ABA clinicians can use these applications on mobile devices to collect an array of assessment data in either full or partial capacities depending on the functionality of the app and the needs of the clinician.

Data Collection Applications in ABA

One of the primary tenets of behavior analysis as a field is the collection of direct observation data to drive intervention and to evaluate outcomes to determine if changes need to be made. There are many dimensions of behavior (e.g., frequency, rate, duration, latency, topography, force, locus) that can be collected by the behavior analyst (Alberto & Troutman, 2017). Additionally, some behaviors lend themselves to being collected using time-based interval systems such as whole- or partial-interval recording or momentary time sampling (Alberto & Troutman, 2017). Apps developed on mobile devices have increased the ease with which practitioners and researchers can reliably collect these data. Apps such as MOOSES and Countee have been designed to collect almost all of these types of data. Furthermore, other apps such as Intervals ABA (Mays, 2019), Behavior Tracker Pro (Marz Consulting, 2019), and Nulite Behavior Tracker for Special Education® (Moy, 2015) are also designed to collect a variety of types of data. See Figs. 43.1, 43.2, 43.3, and 43.4 for example screenshots from these apps. As with other general use apps, the number of data collection and integration apps, as well as ABA specific apps, continues to grow and be developed.

Some dimensions of behavior may be best measured using permanent product. Mobile device cameras allow practitioners to take pictures to produce a permanent product. This may be used by practitioners working with clients who engage in property destruction. Prior to the easy use of photographs, the level of the property destruction was typically recorded through notes, or some sample of the property destruction was kept (e.g., a torn worksheet). Now, practitioners can photograph the classroom or clinic via a mobile device and use it as a point of comparison when determining whether an intervention is working.

Mobile devices can also make the measurement of descriptive data easier. For example, Antecedent–Behavior–Consequence (ABC) data are often collected as a way to evaluate the environmental variables that maintain a behavior (Tarbox et al., 2009). Given the importance of ABC data to practitioners of ABA, there are a number of structured (i.e., predetermined choices) data collection forms and narrative (i.e., open response) data collection forms meant to prompt and aid the practitioner to record the important environmental variables. The use of mobile technology allows practitioners to record this information easily. As noted in Fig. 43.2, this app allows users to collect ABC data as one of the option of data collection. This feature allows for both structured and narrative forms of data collection. There are apps that will then graph these data to help the practitioner identify trends

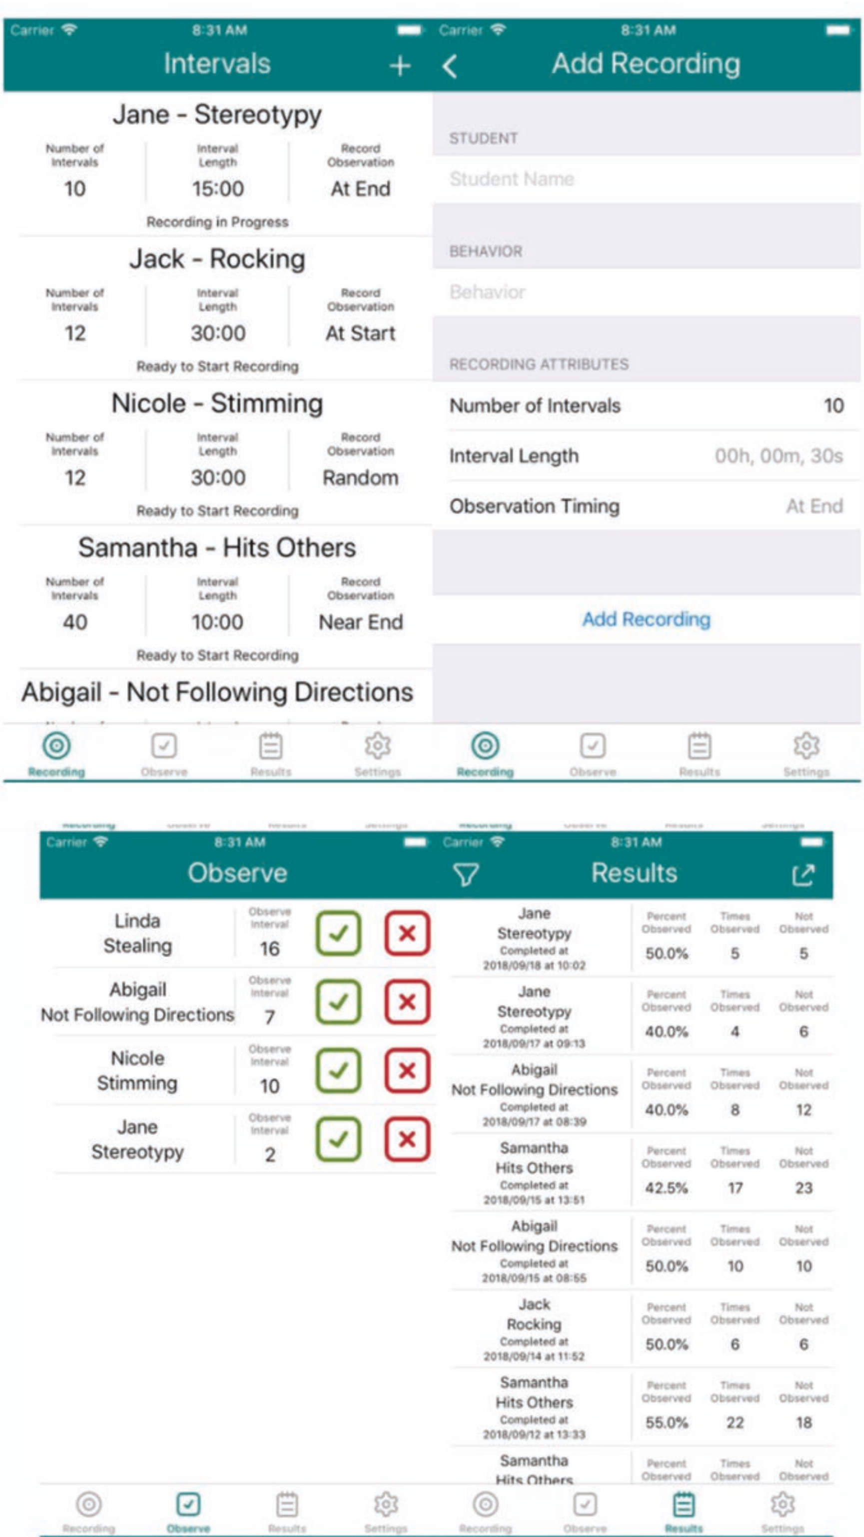

Fig. 43.1 Screenshots from Intervals ABA (Mays, 2019)

Fig. 43.2 Screenshot from Behavior Tracker Pro® (Marz Consulting, 2019)

in the data, thereby pinpointing the most salient environmental variables. As noted in Fig. 43.3, many of the apps will allow for phase lines to be drawn to help the user see the effects of changes to intervention. Further, many apps have a function by which the practitioner can share the results with the clients, family members, teachers, or other people for whom that information may be useful. Figure 43.4 shows how data can be exported (note the export arrow on top right) to share results with stakeholders.

Historically, data collection was completed using paper forms. These paper forms were often stored and organized into files and hand graphed or graphed within a computer software system. This was generally cumbersome and time consuming. Since the advent of mobile devices that have Internet or mobile connectivity, the profusion of data collection apps has allowed practitioners to assess, graph, and communicate outcomes more efficiently with caregivers and clients.

One interesting outcome of the advance of mobile device technology is that it provides a way to engage in real-time data collection in the individual's natural environment. Real-time data collection reduces the need for retrospective self-report or for information to be collected in a contrived setting. The mobility of these technologies has also increased the ability to conduct ambulatory assessments (AA) that provide experience sampling or ecological momentary assessment (EMA; Trull & Ebner-Priemer, 2014). AA allows the individual to collect data on themselves and encompasses a wide range of methods used to study individuals in their natural environment. It also encompasses EMA (Stone & Shiffman, 1994) and experience sampling (Csikszentmihalyi & Reed, 1987) to provide a real-time self-report (i.e., EMA), as well as a random sampling of data using alerts sent to phones (experience sampling). Through AA, practitioners and researchers are provided with a way to assess self-collected data in their natural environment throughout the day within a particular context, as opposed to relying on recall (de Vries, 1987).

Ebner-Priemer and Trull (2009) identified the benefits of AA that would be of particular importance to the field of behavior analysis. First, the use of real-time data collection circumvents inaccuracy or bias in recollection of experiences. AA

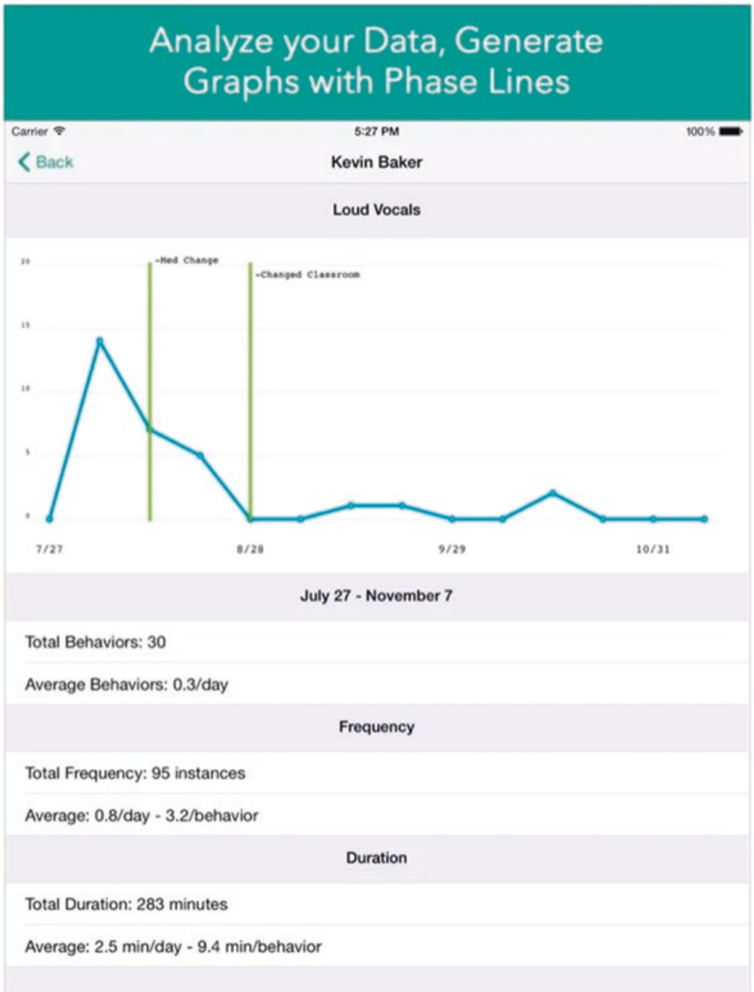

Fig. 43.3 Screenshot from Nulite Behavior Tracker for Special Education® (Moy, 2015)

does not require trained or skilled data collectors to be sent to the field to collect data. Rather, the individual records their own behavior using cell phone technology and the researcher and practitioner can analyze those data. Additionally, the ease of data collection allows for continuous and repeated assessment. For behavior analysts working with limited resources, this could be especially beneficial.

Second, collecting data in the natural environment allows practitioners to improve generalizability. Measuring components of behavior as they are occurring in the individual's environment, a practitioner may be able to design an intervention that can address an individual's natural contingencies. Behavior analysts can use this information to structure environments, so the individual is more likely to be successful. Finally, AA allows for the opportunity to investigate context-specific contingencies. Behavior analysis has long desired the ability to assess naturally occurring contingencies, and AA offers a promising way to do this.

Research on AA suggests that the approach appears to be a cost-effective and easy-to-use method of data collection. Haedt-Matt and Keel (2011) used AA to determine that individuals who engage in binge eating record negative affect before and after an episode, which had not been the predicted result. AA has also been used to

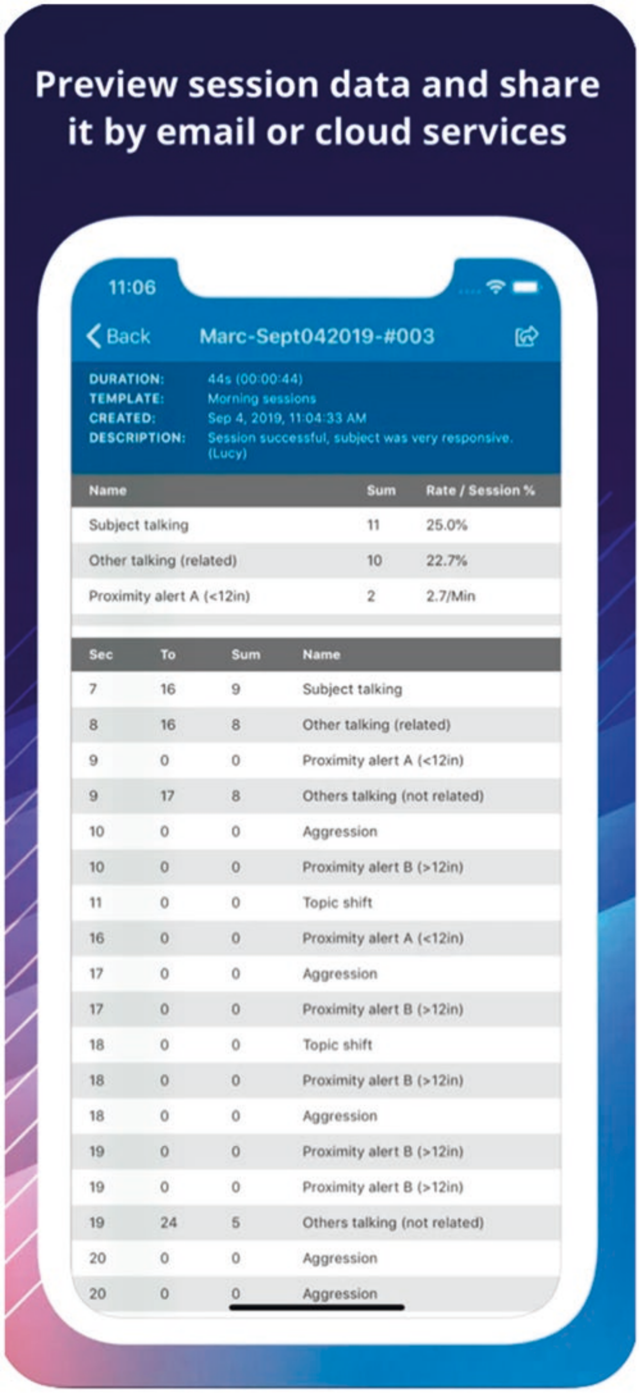

Fig. 43.4 Screenshot from Countee (Piec-Gavran & Hernández, 2019)

study self-reports for other addictive behaviors, such as tobacco or alcohol use (Hofmann et al., 2012). Individuals using AA have high levels of compliance with the study protocols, even those with serious and chronic mental health conditions (Trull & Ebner-Priemer, 2014).

Communication Applications of Mobile Devices Within ABA

Providing caregivers with feedback on client progress toward meeting specific skills is important for practitioners of ABA. This helps to achieve the core tenet of ABA by focusing on interventions that are *effective* (Baer et al., 1968). Delivering effective interventions is important; integral to that is the ability to communicate to other stakeholders regarding the successes or failures of the intervention as it provides a sense of accountability to the consumer. Mobile technology has become a common vehicle for providing this accountability related to intervention effectiveness. As noted above, many of the apps used by ABA practitioners allow for instantaneous communication of assessment results and progress monitoring to interested stakeholders.

One aspect of increased communication using mobile devices is the delivery of telehealth services. Telehealth is “the delivery of healthcare services, where patients and health care providers are separated by distance” (World Health Organization, 2021). The use of telehealth to deliver ABA is an increasing practice that saw great growth throughout the COVID-19 pandemic; many states passed emergency resolutions to allow for the delivery of telehealth provision of ABA (Pollard et al., 2021). This use of technology assisted practitioners in continuing to be able to communicate and serve their clients without having to be physically present. Telehealth has also been shown to be effective at delivering interventions and more cost effective than in-home, in-person treatment (Lindgren et al., 2016). This suggests that the trend of increased telehealth services may not decrease following the end of the pandemic.

Telehealth has been used on mobile devices to deliver services on several topics including brief functional analysis (Gerow et al., 2021), functional living skills (Craig et al., 2021), and tacting (Ferguson et al., 2020). In addition, the utilization of telehealth with mobile devices has been provided for adults (Shawler et al., 2021), children (Sivaraman et al., 2020), parents (Boutain et al., 2020), and in rural communities (Hamrick & Lock, 2020). Utilizing telehealth to reach those who may not have direct access to ABA services allows for practitioners to meet the needs of those who may not otherwise receive services. Mobile devices that improve access to communication between practitioner and client may be able to increase the impact that ABA can have in the community. See Tomlinson et al. (2018) and Ferguson et al. (2019) for recent reviews of literature regarding training and coaching of individuals to provide ABA using telehealth.

Mobile Devices as Teaching Tools

Teaching new skills that are socially significant is a defining feature of our field (Baer et al., 1968). Mobile devices have proven to be an effective tool for behavior analysts to improve skill development for their clients. Mobile devices have been used to help prompt specific behaviors (Shepley et al., 2018), organize the day (Spriggs et al., 2015), and serve as a system to assist in reinforcement (Getty et al., 2019). The benefit to using mobile devices for these teaching techniques is that they are ubiquitous in the population, so the client will not need to carry around extra reinforcement schedules or prompting cards or calendars. In this way, mobile devices as mobile technology have improved and expanded in utility, so has the use of the device to teach skills.

The types of skills that are available for teaching on mobile devices encompass a spectrum of academic (Tingir et al., 2017), functional (Smith et al., 2015), vocational (Hayes et al., 2015), and social (Tetreault & Lerman, 2010) behaviors. Researchers have shown that skills taught to individuals using mobile devices also encompass the spectrum of ages from early childhood (Lorah et al., 2014) through adolescents (Shepley et al., 2018) and into adulthood (Bicard et al., 2012). As these technologies have been further incorporated into daily practice, there is still work to be done to examine the effects of mobile devices on how they work to provide instruction. Cumming and Rodriguez (2017) conducted a meta-analysis of the utilization of mobile technology for students with disabilities. The authors noted that the evidence is emerging to support this practice when teaching academic skills, daily living skills, vocational skills, and communication. There is also evidence to support using mobile devices to improve transition behaviors between activities and settings (Cihak et al., 2010), increase task engagement and completion, and decrease challenging behaviors.

Video-based instruction (VBI) is one of the more common strategies utilized within the context of mobile devices to teach new skills (Cumming & Rodriguez, 2017). Video-based instruction utilizes video modeling or video prompting, interventions that have been employed for decades across multiple environments and individual functioning levels. Video modeling involves the learner watching a skill in its entirety and then performing that skill (Bellini & Akullian, 2007). Video prompting involves the learner watching part of a skill, completing that step (or steps), and then watching another part of that skill and completing that step (or steps) until the entire skill has been completed (Banda et al., 2011). VBI is based on Bandura's (1977, 1997) social learning theory that individuals learn a myriad of skills through observing others perform the skill then imitating what was observed. This theory of learning new skills was perfectly suited for mobile devices since VBI allows the observer (i.e., the learner) to watch the skill needed to be performed in the environment in which it needs to be performed. The video serves as the S^D for the behavior that needs to be performed and is particularly useful as a video is consistent each time it is accessed.

VBI on a mobile device can lead to increased quality of life as the learner can rely on it as a self-instructional tool. Self-instruction is a critical skill to consider when teaching new skills since the goal is for learners to gain skills independent of another person's direction. Mobile devices can serve as self-instructional tools, allowing them to serve as the mechanism for instruction delivery. Devices can be set up to include a video library of common tasks to be performed, learners can be taught to search the Internet for videos, and learners can be taught to activate the virtual assistant within their device (e.g., Siri, Alexa) to locate videos. There are applications that can be downloaded to store videos. One application, *ChoiceWorks*, encourages self-instruction by embedding video models into visual activity schedules. The application displays a daily schedule using thumbnail pictures. Each picture (or select pictures) can be linked to a video of the task to be completed. The idea is that as an individual progresses through their daily routine, if they come to a task that they do not know how to complete, they can touch the picture and a video model of the task will appear. These video activity schedules can lead to greater independence as the learner begins to rely on the prompts within their mobile device, as opposed to relying on another adult to provide the prompts (e.g., Shepley et al., 2018; Spriggs et al., 2015).

Mobile Devices in K-12 Classrooms

Due to the increase in mobile device use within broader society, it is of little surprise that mobile phones have also increased in school settings. Mobile device use is pervasive in middle and high school settings given the large percentage of youth and teens who own a device (Hernan et al., 2019). It has been reported that school-aged students interact with their device an average of 8 hours a day, in both personal and classroom environments (Schreiner, 2018), with many students communicating with other users during class (Burns & Lohenry, 2010). Unfortunately, schools have not been prepared for the academic and social impact created by the rapid adoption and technological dependence of such devices (Tulane et al., 2017). School administrators and teachers currently face a multitude of advantages and disadvantages surrounding the topic of mobile device usage in the classroom.

Educators and researchers have begun to explore how mobile devices can be used for academic gain. As has been noted, mobile devices have been widely accepted among school-aged children; therefore, it makes sense to leverage their popularity in an attempt to improve academic skills. School-aged children can use devices to conduct independent research, access educational apps and tools, collaborate through texting and cloud-based programs such as Google Drive, and improve writing through auto-correct or text to speech options (Hernan et al., 2018; O'Bannon & Thomas, 2014; Vaterlaus et al., 2012). As noted in preceding sections, mobile devices have been used to provide instruction on a wide array of academic, social, and functional behaviors. It is through this medium (i.e., mobile device) that educators must continue to determine evidence-based practices on how to utilize these tools to maximize student performance. As the technology is changing faster than the research can be conducted, educators will have to remain cognizant of the most recent approaches to using these devices.

Despite the potential of numerous benefits, many researchers have debated whether the negative outcomes of school-aged children mobile device usage in the classroom overshadow the benefits (Hernan et al., 2018; Mendoza et al., 2018). One reason is that mobile devices can prove detrimental to a student's social development. Principals and teachers have conveyed concerns regarding cases of cyberbullying (National Center for Education Statistics, 2019), cheating (Hernan et al., 2018), sexting (Hachiya, 2017), and increased interpersonal conflicts (Tulane et al., 2017). Virtually engaging with peers, regardless of the detrimental outcomes, is a highly reinforcing act for students (Tulane et al., 2017). Students check devices regularly in a way considered analogous with individuals with compulsive or addictive behaviors (Lee et al., 2017). As aforementioned, researchers have coined the term "nomophobia" to describe the heightened anxiety, distress, and discomfort experienced in the absence of one's mobile device (Carels, 2019; Lee et al., 2017; Mendoza et al., 2018; Tams et al., 2018).

Along with the social concerns of mobile devices in schools, numerous reports show that significant loss in academic performance occurs when youth simultaneously interact with a device during lecture (Carels, 2019; Diamantes, 2010; Hachiya, 2017; Hayashi & Blessington, 2018; Hernan et al., 2018; Hernan et al., 2019; O'Bannon & Thomas, 2014; Tams et al., 2018; Thomas & Muñoz, 2016; Tulane et al., 2017). For example, studies have suggested that engaging with a device during a lecture results in losing course-related information and ultimately performing more poorly on exams (Froese, 2012; Lee et al., 2017; Shelton et al., 2009).

Given the benefits and drawbacks of mobile device use in schools, it is not surprising that students and teachers/administrators have vastly different perspectives about device use in the classroom. Students believe that they should be allowed to text during class (Tulane et al., 2017) and teachers should integrate mobile device use in the classroom (Thomas & Muñoz, 2016). They believe that the devices do not present interference with their academic performance, despite the research that states otherwise (Carels, 2019). Conversely, teachers overwhelmingly conveyed that mobile devices were an unnecessary distraction in the classroom and were largely utilized for non-academic purposes, and allowed for cheating, cyberbullying, viewing inappropriate content, and a general class disruption (Thomas & O'Bannon, 2014; Hernan et al., 2019). School administrators viewed student mobile device usage analogously with teachers and staff, with most supporting some implementation of mobile device restrictions in middle and high school settings (Tandon et al., 2020). It is clear that mobile device use within the K-12 classroom is an issue that has the potential to both support a student's education and hinder their social or academic performance. It is unknown as to how these devices will be used in future classrooms; however, it is unlikely that they will decrease in prevalence within the K-12 settings.

Summary and Future Impacts of Mobile Devices in ABA

Fifty years ago, it would be difficult to imagine our current world with the mobile technology that exists today. Throughout this chapter, we have attempted to show how mobile devices have rapidly impacted most facets of life. Mobile device usage has shown an accelerated trend in over the last 10 years, and the devices will most likely remain prevalent for the foreseeable future. As we look to the future, it is difficult to imagine a world without mobile devices. Given how these tools have become so intertwined in social and professional lives, further studying the best practices for utilization will continue to be important. Mobile devices have afforded practitioners (ABA clinicians, educators, and researchers) the opportunity to widen the horizons of practice and research through the use of apps, academic and behavioral monitoring, reinforcement, and video-based instruction. As noted in the chapter, mobile usage can have negative social, behavioral, and academic outcomes, which further heightens the importance of researchers finding methods that can reduce the potential harmful effects and accentuate the promise that mobile devices can produce. Mobile technology has the ability to change human behavior; therefore, we must continue to understand the behavioral mechanisms responsible for behavior change and the best utilization of this technology in the field of ABA.

44 Teaching Musical Skills and Developing Music Therapy Interventions

Hayoung A. Lim

A behavioral view of the management of behavior in teaching musical skills has been and continues to be a dominant and influential paradigm in both music education and music performance. Despite a rich history and extensive empirical underpinnings, the behavioral perspective on teaching and management is not highly regarded in the music education and performance community. Moreover, behavioral research in music seems to be misunderstood and behavioral strategies have been implemented incorrectly or inconsistently in teaching music. Despite the discordance of the practice of behavioral management in teaching music, the behavioral view remains a frequent theme in the literature on music education, preparedness of musicians, pedagogical approaches in music lessons, and music therapy. This chapter will provide some examples of solid applications of behavioral management strategies and modification techniques directed from Applied Behavior Analysis (ABA) methods used in teaching musical skills and therapeutic application of music.

Numerous studies have been contributed to augment the level of understanding for the application of the principles of behavioral psychology in music education (Sink, 2002). Most of these studies provide evidence of the efficacy in direct music instruction including systematic observation and teaching behavior techniques for the music student's attentiveness, attitude, and achievements (Sink, 2002). One of the compelling behavioral approaches in teaching music is direct music instruction with the three-step instructional sequence: the teacher presents a task, students respond to the task, and the teacher provides feedback to students in a manner that stresses positive learning experiences (Madsen & Madsen, 1981; Sink, 2002; Yarbrough & Price, 1981). These three sequences in direct music instruction can be understood and demonstrated within ABA functional analysis. In teaching musical skills, task presentation is the antecedent; learning musical skills is the behavior; and the teacher's feedback is the consequence. Therefore, this chapter focuses on musical task presentation using behavioral development techniques including imitation, shaping, and chaining. Teacher feedback while teaching musical skills based on four basic behavioral operations such as positive reinforcement, negative reinforcement, extinction, and punishment with an aversive will be discussed.

Developing Musical Skills

Teaching musical skills is directly involved in developing new behaviors in learners. Developing new musical behaviors by learning musical skills can be achieved by imitation, modeling, behavioral shaping, and behavioral chains.

Imitation

The process of acquiring new musical skills through imitation is evident in any music lesson since imitation is the essential process for demonstration and explanation of the necessary skills.

Imitative musical behaviors are acquired and maintained like other operant behaviors within the following three environmental arrangements: (1) a model is presented as the most optimal antecedent stimulus that is topographically identical to the behavior the student wants imitated; (2) the imitated behavior is promptly emitted after the model within a designated response interval; and (3) the imitative behavior produced by the student is reinforced (Cooper et al., 2020). In teaching music, the teacher naturally provides imitative models and demonstrates the target behaviors. These models can include the actual demonstrations such as the teacher's movements (e.g., playing the instrument with a certain fingering or changing a posture) or desirable sounds. Models can be planned or unplanned; however, an imitative behavior by the student should immediately follow a model's demonstrating behavior.

The purpose of using imitation in teaching music is for the student to obtain similarity between the teacher providing a model and the individual emitting imitation. The instructor should reinforce the imitative behavior that is similar to the model. Once the student has perceived the similarity between his/her imitative behavior and that of the instructor, the student's self-efficacy might reinforce further imitations. A model with prestige, confidence, and instruction will increase the imitative behaviors in the learner (Cooper et al., 2020).

Modeling

Modeling is a behavior change strategy in which learners acquire new skills by imitating skill demonstrations of live or symbolic models (Cooper et al., 2020). Since online teaching and virtual music lessons have become inevitable, video modeling has captured a high level of attention from music instructors and teachers. In online music lessons, video modeling is a major teaching technique that involves the teacher's demonstration of desired behaviors (e.g., correct finger numbers, handling instrument, posture, movements, facial expression, musical pattern production, and sound production) through video presentation (on screen) of the behavior.

Through online music lessons, not only is video modeling possible but so is video self-modeling given common virtual platforms (e.g., Zoom, FaceTime, Skype). Video self-modeling is a specific application of video modeling that allows the student to analyze the multistep procedures embedded within complex target behaviors by observing themselves successfully performing a behavior (Cooper et al., 2020). Video modeling can be used to introduce new musical skills, correct a problematic behavior or habit, and provide feedback. Video self-modeling can be used to acquire the desired musical skills by practicing and rehearsing the newly learned behaviors to perform music. Recording and replaying performances is useful to master the respective musical skill sets because it allows for modeling and self-modeling of a particular musical skill or a set of behavioral sequences.

Behavioral Shaping

Shaping, or behavior shaping, is a variant of the operant conditioning paradigm used primarily in the experimental analysis of behavior. This method uses differential reinforcement of successive approximations—a gradual, behavior modification technique in which successive approximations to the desired behavior are rewarded. Instead of waiting for a student to exhibit a desired behavior, any behavior leading to the target behavior is rewarded. The process of establishing a behavior that is not learned or performed by an individual at present is referred to as *shaping*. Shaping can also be defined as the procedure that involves reinforcing behaviors that are closer to the target behavior, otherwise known as successive approximations (Cooper et al., 2020). Figure 44.1 provides an example of behavioral shaping in teaching music illustrated by multiple steps that differentially reinforce the performance of a new piece of music on the piano.

Musical behavior shaping is defined as the differential reinforcement of successive approximation toward a terminal behavior such as mastering/performing an entire piece of music. If the final behavior is performing "*Fur Elise*" by Beethoven, the necessary prerequisites include reading every note, playing keys (on the piano) with the assigned finger numbers for both hands, following every dynamic and incidental marking/sign, and musical expression.

Each of these behaviors would be differentially reinforced to achieve a successful performance of the piece. Performing music is a higher-order member of a response in which the form of the behavior is the same. However, the intensity (amount or duration of the behavior) is not equal and multiple layers of responses occur simultaneously. Behavior shaping is considered to be a positive approach when teaching new musical skills. Reinforcement is delivered consistently upon the occurrence of successive approximations to the desired musical behaviors including producing the correct pitch/intonation and rhythm, keeping a consistent tempo, and

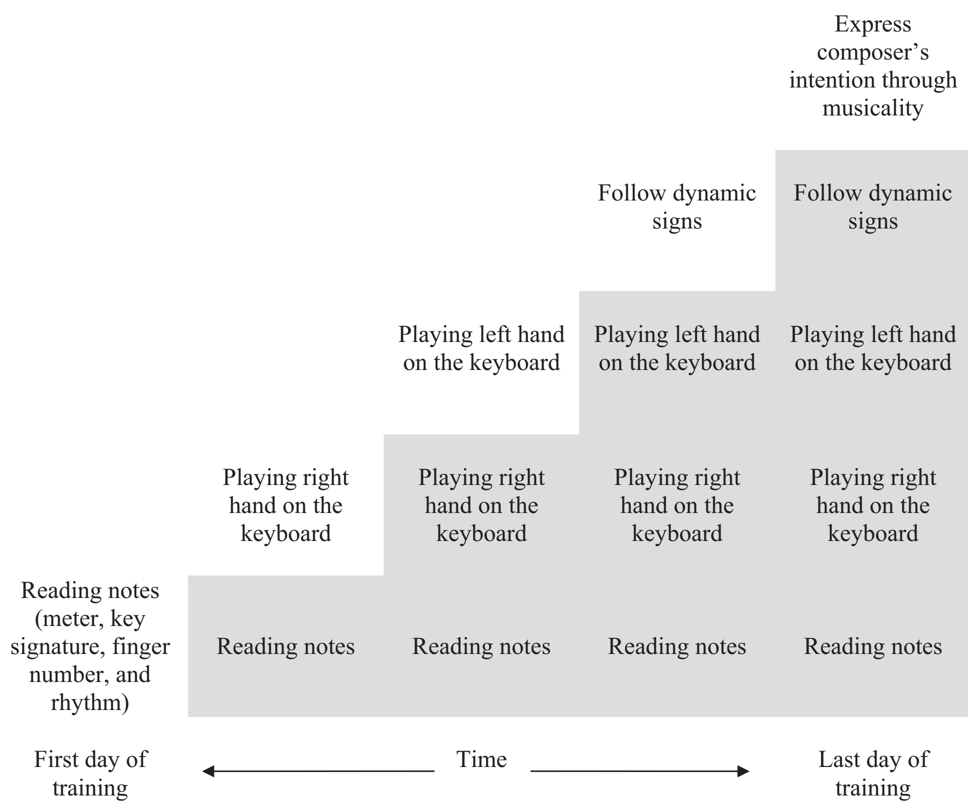

Fig. 44.1 Behavioral shaping with differential reinforcement in a piano lesson

expressing every assigned dynamic. Punishment or other aversive procedures are not involved in teaching musical skills by shaping. Behavioral shaping in musical skill development should be systematically and gradually implemented, and the end goal should always be fully anticipated and achieved.

Teaching how to perform a musical instrument with behavioral shaping is time consuming. Both teacher and learner must be prepared for the possibility of an extended training duration before the final goal is achieved. In addition, the teacher should consistently monitor the student's progress because the student does not always proceed from one skill to the next in a continuous, uninterrupted flow for a linear progress (Cooper et al., 2020). As the student masters each step, the teacher should inform the student that he/she must now advance to the next objective to receive a positive reinforcement. If the jump between two steps is too difficult, then the teacher must break down the steps even further into smaller increments. It is recommended that the teacher clearly indicates and demonstrates the expectations. Furthermore, the teacher should check if the student has acknowledged and agreed to the level of expectation for every behavior, including the terminal behavior. The criterion for a successful performance should be specified. The teacher must determine the concrete and specific expectation for the terminal behavior (i.e., performing the musical piece) before it can be considered learned. A rubric for the end goal will be helpful.

When the student performs the entire piece, it is necessary to continue to reinforce the performance until the criterion for success is achieved and a maintenance schedule of reinforcement is established. Performing for a recital or concert will be the further reinforcement when the final goal is for the student to demonstrate the piece. Continuous reinforcement will improve the performance quality and the individual's musicality as generalization of a new musical skill. An example of rubric and procedure for behavioral shaping in teaching music is presented in Table 44.1.

Table 44.1 Behavioral shaping in teaching music rubric and procedure

Example of rubric for terminal behavior	How to use shaping in teaching music
1. Identify the key signature and meter of the piece 2. Read the notes correctly by playing the accurate intonations (pitches) and rhythmic figures 3. Keep the indicated tempo from the beginning of the piece to the end 4. Follow every dynamic marking/sign (i.e., *crescendo*, *decrescendo*, *ff*, *mp*), incidental signs (sharps, flats, etc.), and tempo change marks (i.e., *retardando*, *rubato*, *molto*) 5. Express the composer's indicated intention with personal musicality 6. Play the entire piece by memory 7. Perform the piece for any audience	1. Identify a desired behavior for the student 2. Determine the final goal 3. Identify the student's current level of performance in displaying the desired behavior 4. List the steps that will eventually take the student from his/her current level of performance to the final desired behavior.*These levels of skill should be progressively more demanding, and the complexity of step should be increased 5. Tell the student that s/he must accomplish step 1 to receive the positive reinforcement 6. Once the student has mastered a specified musical skill, require that s/he demonstrate the next level of skill to receive a positive reinforcement

Behavioral Chains

Acquiring musical skills, such as playing a musical instrument, performing songs from a Broadway musical, and composing a song, consists of multiple tasks and requires sequential responses. A particular behavior modification method called *behavior chains* might be beneficial when teaching these musical skills.

A behavior chain involves the performance of a specific series of discrete responses. The performance of each behavior in the sequence changes the environment to produce a conditioned reinforcement for the preceding response while also serving as a stimulus for the next response. In addition, the behaviors must be performed in the correct order, preferably in close temporal succession to one another (Cooper et al., 2020). These parameters indicate that a musical behavior can be categorized as a behavior chain. Furthermore, in music, these behaviors are linked together beginning with the first behavior in the sequence; it fits for *forward chaining*. In forward chaining, the behaviors identified in the task analysis are taught in their naturally occurring order (Cooper et al., 2020).

A behavior chain in music can be defined as a specific sequence of musical responses, each associated with perceiving and producing a musical pattern (e.g., rhythm, tempo, meter, pitch, interval, key, scale, harmony, chord progression, dynamic, timbre, form, instrumentation). Each discrete response and its associated musical pattern (stimulus condition) serve as an individual component of the chain. When individual components are linked together, the result is a behavior chain, which is the complete production of musical patterns. In a chain, the stimulus conditions (i.e., the discriminative musical patterns and the musical sound as conditioned reinforcers) operate so that each musical response (i.e., sound or musical notation) produces a conditioned reinforcer that simultaneously serves as a discriminative stimulus for the next response (i.e., next notes, rhythm figures, chord progression). The complete chain will be a musical product and/or performance of a piece of music.

Furthermore, this chaining technique is commonly used when the teacher breaks down a sequence of events into smaller parts. Chaining can provide both perceptual and behavioral tools by which a series of discrete behaviors can be combined to form a more complex series of responses that occasion the delivery of positive reinforcement (Cooper et al., 2020). Chaining is a procedure that can be used to add behaviors to an existing behavior repertoire. When teaching music, this element of the chaining technique is fully utilized. For instance, a music teacher may begin his/her lesson by teaching a student how to hold an instrument (e.g., violin, clarinet) through a series of simplified sequential steps. In this way, the chaining procedure enables simple behaviors such as holding a violin to be combined into a longer/multiple series of complex responses such as playing a G major scale on the violin. The music teacher could also use a chaining procedure to increase the number of measures or lines on a music sheet that must be performed before reinforcement is delivered. The completion of a musical piece can be the ultimate positive reinforcement.

When practicing the chaining procedure in teaching various musical skills, it is recommended that the teacher analyzes and organizes the multiple components of the targeted musical and behavioral sequence in the lesson plan. Behavior chains can be established by task analysis. Task analysis involves the breaking of a complex skill or series of behaviors into smaller, teachable units (Cooper et al., 2020). Task analysis can be used to correct and/or modify a specific musical behavior during the lesson. For example, when the student repeats the same mistakes in specific bowings for a very challenging section of a violin sonata, the teacher can implement a task analysis in which (1) the student moves the right arm without the violin in upward and downward bowing strokes; (2) the student speaks or sings the rhythmic and melodic pattern (i.e., solfège) while moving his/her arm in bowing strokes; (3) the student picks up the bow and plays each bow stroke in a very slow tempo on the open strings; (4) the student plays the same part with a slightly increased tempo on the open strings; and (5) the student plays the musical phrase by combining the corrected bowings and the melodic intonations with the left hand. The teacher should determine the sequence of critical behaviors that the student must perform to complete each assigned task efficiently and successfully.

Behavioral Modification in Teaching Musical Skills

Teacher Feedback Using Behavioral Modification Techniques

The teacher's feedback can greatly improve the student's musical skills. High approval reinforcement from the teacher improves student attention and achievement in learning music. Half a century ago, Madsen and Madsen (1972) reported that students achieved significantly more accurate intonation in choir performance when contingent reinforcement was used rather than when the teacher refrained from providing reinforcement. Since then, a large body of literature pertaining to the behavioral approach in teaching music has supported the theory that teacher feedback characterized as high approval reinforcement improves the student's attention, learning attitude, direction following, endurance, on-task behaviors, and performance (Sink, 2002). However, several music educators who researched and practiced the behavioral approach reported that most music teachers do not effectively deliver contingent reinforcements as feedback nor properly practice the behavioral modification techniques (Madsen & Duke, 1985; Sink, 2002). Given the prevalence of behavioral topics in professional literature and courses of music education and music therapy, it is imperative that teachers, practitioners, and researchers take a logical and empirical approach to understand the behavioral view of teaching music and utilizing musical experiences for behavioral modification. It would seem important to fully understand what behavioral modification methods should be implemented for teaching musical skills.

Behavior modification in teaching music relies on the concept of operant conditioning, which is a form of learning, and involves using a system of rewards and/or punishments. In behavior modification, certain musical behaviors can be learned and unlearned. Many different techniques can be implemented to either elicit a behavior or stop it. The purpose of using behavior modification in teaching musical skills is to improve target behaviors of performance or production of music by changing the behavior. This can be accomplished through various methods including positive reinforcement, negative reinforcement, extinction, and punishment.

Positive Reinforcement

Positive reinforcement is pairing a positive stimulus to a behavior. A good example of this is when a cello teacher rewards the student for using the correct fingering shift from the first position to the fourth position. The reward can be a positive stimulus like praise, a sticker, or moving to the next page/piece. Positive reinforcements will increase the hours of practice, level of attention during lessons, and quality of musical performance.

Negative Reinforcement

Negative reinforcement is the opposite of positive reinforcement and it is the increase in a behavior due to the removal of a stimulus. In a piano lesson, if the student plays the entire musical piece without any error, he/she will not have the weekly music theory homework. Removing a less-preferred musical task might increase the hours of practice, level of concentration when playing the piece, and quality of musical performance.

Extinction

Extinction is the removal of all reinforcements that might be associated with a behavior. This is a powerful management tool for teachers and works especially well with young children (Landrum & Kauffman, 2006). There are many different styles of music and techniques in playing instruments. After a piano student practiced for many weeks and successfully performed a piece composed in a slow ballad form with *legato* style of expression (i.e., notes in each phrase are connected), the teacher gave the student well-deserved verbal praise and the student's favorite CD as a reward (i.e., positive reinforcement). In the next piano lesson, the teacher introduced a different style of music in a fast *scherzo* (a vigorous, light, or playful composition) form with *staccato* technique (i.e., performed with each note sharply detached or separated from the others). However, the student played the piece with *legato* style in a slower tempo. The teacher needs to use the extinction method as the proper form of feedback in this situation and they should not reinforce the student's legato style of playing.

Extinction is often referred to as *planned ignoring* and is used to decrease negative or undesirable behaviors that have been previously maintained by a reinforcer (Landrum & Kauffman, 2006). If the student played the new piece with a *staccato* technique in a correct tempo and expression, the teacher should reinforce this new behavior. This process involves providing a reinforcer contingent upon a desired response (i.e., playing *staccato* in a fast tempo) and withholding the reinforcer when the response is not occurring or when an undesired response is displayed (i.e., playing *legato* in slow tempo). In the preceding example, the piano teacher would respond positively to the student playing the appropriate style for the new piece and give feedback such as “your staccato has improved and I can hear the strong beat of every note in this page,” while ignoring any legato style of playing the student learned from the previous piece.

Punishment

Punishment is a basic principle of learning and is particularly designed to diminish behaviors by pairing an unpleasant stimulus to a behavior. Learning from consequences that produce pain, discomfort, or the loss of reinforcers has constructive value for the students (Cooper et al., 2020). Punishment can be used in teaching necessary musical skills. For example, the teacher observes significant errors in intonation when their voice student sings his/her favorite song during the lesson. The teacher discovered that the student incorrectly read the score, skipped the sight-reading exercise, and did not use solfege while practicing on their own. The consequences of poor performance during the lesson might be eliminating the student’s favorite song until he/she corrects errors in intonation (i.e., negative punishment) and singing extra scales or vocal exercises with only solfège for the rest of the lessons (i.e., positive punishment). Punishment used in teaching music can eventually increase/improve the terminal target behaviors. The vocal student’s intensive training with vocal exercises that include solfège will improve his/her performance of the favorite song with less error in intonation.

Use of Music in Reinforcement

Reinforcement in Teaching Music

Positive reinforcement functions as a way to increase or maintain a desirable behavior. However, teachers must use an appropriate reinforcer, one that is truly reinforcing and motivating for the student and reinforces the student immediately after the student exhibits the target behavior (Adamek & Darrow, 2018). In teaching music, reinforcers might be social (e.g., praise, a pat on the back), tangible (e.g., a star on their paper, a sticker, a prize), or activity-related (e.g., extra music time, free time). Reinforcement in a music classroom and/or music lesson must be immediate, continuous, and consistent when the appropriate musical skills (behaviors) are being produced (Adamek & Darrow, 2018). Praise is frequently used as a positive reinforcement to improve the student’s musical skills. Praise from a teacher’s detailed or intense response to a student’s behavior consists of high approval and feedback for a particular response or behavior. Therefore, praise in teaching musical skills should have the qualities of contingency, specificity, sincerity, variety, and credibility (Adamek & Darrow, 2018). After the positive reinforcement has been implemented, teachers should evaluate the efficacy of their task presentation and instruction for the target behavior pertaining to the reinforcement.

Use of Music for Reinforcement

Music is highly effective as a contingent factor for either increasing desirable behavior or reducing undesirable behavior. Early educators found music to be a reinforcing, valuable tool to facilitate learning and strengthen the student’s achievement (McDowell, 2010). Standley (1996) conducted a meta-analysis on the effects of music as reinforcement for educational/therapeutic objectives. The study reported that the contingent music was more effective than contingent nonmusical stimuli used in these studies and more effective than continuous music. Pairing other stimuli (e.g., food, approval, or visual stimulation) with the music decreased its effectiveness as a reinforcer. Music interruption is more effective than music initiation as the procedure for establishing the contingency and immediate initiation of the music is more effective than delayed initiation. Uniquely, music functioned simultaneously as a reinforcer and the subject matter. There was also evidence of generalized benefit to other academic and social behaviors that were measured but were not contingently reinforced with music (Standley, 1996).

The most frequent use of contingent music has occurred in the field of education (Adamek & Darrow, 2018; Byo & Sims, 2015; Standley, 1996). In regular school classrooms, music in various forms of delivery has reinforced other academic achievements, particularly reading and math skills. Forms of music deliver may include listening to preferred pieces, individual music lessons, group ensembles/choir, and/or musical games (Lim et al., 2014). Piro and Ortiz (2009) reported that students who received piano lessons had significantly higher vocabulary and verbal sequencing scores than students who did not receive piano lessons. Several meta-analyses of music education have shown that carefully designed music instructions can have a positive impact on cognitive development and academic performance of children (Lim et al., 2014; Portowitz et al., 2009).

Jellison and her colleagues (1984) indicated that the frequent positive social interactions among children with and without disabilities in the inclusive music classroom are dependent upon the degree to which the teaching method structures antecedents and reinforcement for these instructions. The research findings suggest that music lessons also serve as a reward for successful completion of academic tasks; contingent music functions as a "social agent" for interactions in a small group of music class (Jellison et al., 1984). Thirty-two at-risk elementary school students were randomly assigned to 10 weeks of 30-minute one-to-one training conditions (piano lesson, music therapy, and no-training). No significant difference between the training conditions was found on the pre-post comparisons of academic achievement (Lim et al., 2014). However, behavioral observations of both piano lessons and music therapy instructors indicated the positive impact of training conditions on social and emotional variables: increased assertiveness when singing and playing self-composed songs, increased smiling and verbalizations pertaining to musical tasks as lessons progressed, decreased resistance and increased initiative in learning more songs than were required, increased positive self-statements and desire to perform for others, pride taken in songs learned, improved walking and sitting posture, and increased volume of speech (Lim et al., 2014).

Classroom teachers might use music-related reinforcement to motivate students to complete academic works and improve the learning environment. A primary criticism of reinforcement for education endeavors has been the contentions that reinforcement reduces intrinsic motivation including self-engagement, self-efficacy, and enjoyment of the activity itself (Cooper et al., 2020; Maehr et al., 2002; Standley, 1996). Since student motivation is a critical factor in academic and social-emotional learning, establishing a positive contingent reinforcement that might improve intrinsic motivation is essential. Music enhances a student's motivation to learn and improves self-esteem by making their learning experience more positive (Costa-Giomo, 2004; Lim et al., 2014).

Motivation in Music Reinforcement

The understanding of motivation is concerned with observable behaviors that reflect engagement in a particular activity (Maehr et al., 2002). Teaching children any desirable skill begins with the teacher encouraging cooperation with the child's current level of motivation. For example, if the child wants to watch a video, the instructor might use that motivation along with the reinforcement of turning on the video to establish target behaviors. The desired training relationship is established when the instructor is consistently associated (paired) with the delivery of reinforcing items and events to the child (Lim, 2010;

Sundberg & Partington, 1998). Musical activities such as playing the preferred instrument or listening to a favorite piece of music might be optimally paired with reinforcements for establishing the desired musical skill.

The most fundamental principle of the ABA approach is to select and use the effective reinforcer for every trial in the training with high-preference stimuli being the most effective (Lim, 2010). Music stimuli can be the most effective reinforcement for desired musical behaviors. Music can function as an establishing operation (EO) in the ABA-incorporated music classes. Various musical experiences can provide students with effective motivational variables (i.e., EO) for many musical skills. Musical stimuli within the musical instrument(s) including sounds, movements, notations, and instruction can motivate students to produce better musical responses such as creating desirable musical sounds, practicing target musical skills, and performing pieces. Furthermore, the motivational variables established in such musical experiences result in improved self-efficacy, attributions, goals, values, and interest when facilitating learning and achievement (Byo & Sims, 2015; Lim, 2010; Maehr et al., 2002).

Maehr and his colleagues (2002) demonstrated four behavioral indicators (action patterns) of motivation in student learning that might address why music students want to achieve greater musical skills: choice and preference, intensity, persistence, and quality of engagement. Music functions as an EO, which is the motivational variable, in each behavioral indicator. Some examples include: a student who chooses to practice the piano instead of playing video games (choice and preference), or focuses all of their attention on practicing a difficult passage in his/her favorite piece (intensity), or continues to practice the cello solo after the orchestra rehearsal ends (persistence), or analyzes a piece that is difficult to play, and works on those passages until he/she can play up to the tempo (quality of engagement).

Music can also function as an automatic reinforcement. Skinner (1957) used the term *automatic reinforcement* to indicate that the reinforcement occurred without manipulating or demeaning the learner. Automatic reinforcement involves a strengthening effect that occurs due to an antecedent pairing of a neutral stimulus with the established form of reinforcement. Such reinforcement is a result of pairing what the student needs to learn with what he/she wants as reinforcement. The behavior that is paired with reinforcement becomes a target behavior for further training. An example of the application of music as an automatic reinforcement procedure is pairing singing with playing a drum. This pairing might increase vocal behavior in a child who particularly likes the drum. Since playing instruments can become a strong reinforcer for the child, singing (vocal/verbal behavior) then becomes reinforcing (Lim, 2010). Musical training should be enjoyable for the student and paired with musical automatic reinforcement for further development of musical skills.

Musical automatic reinforcement is also used to develop non-musical behaviors in therapeutic settings. If the target behavior is sitting on a chair for a certain duration and the therapeutic goal is to increase attention span, playing the individual's preferred instrument can function as the automatic reinforcement. Playing the instrument can be established as contingent reinforcement for further target behaviors such as completion of a task. If the target behavior is upper body movement exercise for a patient who had a stroke (cerebrovascular accident [CVA]) and the therapeutic goal is to increase endurance and range of motion in the upper body, playing a drum with a mallet in a physical rehabilitation setting will function as the automatic reinforcement. The musical experience can be inherently enjoyable for individuals and, therefore, can automatically reinforce further musical and non-musical behaviors.

Behavioral Modification in Music Therapy

Music has been used to change an individual's behavior throughout history; music therapy is defined as the systematic use of music or musical experiences to make positive changes in particular non-musical human behavior. The music therapy profession has adopted behavioral modification techniques since the infancy of the therapeutic application of behavioral principles (Standley et al., 2004). The effective application of the behavioral approach in music therapy identifies the functions of music as a cue, time and body movement structure, focus of attention, and reward. The correct adaptation and utilization of the behavioral approach in music therapy requires a solid understanding of the behavioral principles, ability to analyze the treatment procedures, and extensive training of clinical implications (Standley et al., 2004).

ABA is often used in music therapy because ABA approaches and procedures have been validated through scientific research and clinical practice in educational and clinical settings (Standley et al., 2004). The common behavior modification techniques pertaining to ABA methods including positive/negative reinforcement of target behaviors, punishment and extinction of undesirable behaviors, token economies to strengthen socially adaptive behaviors, and shaping are frequently used in music therapy (Davis et al., 2008). Behavior modification techniques such as reinforcement and shaping can be particularly easy to integrate into music therapy sessions by music therapists to help clients engage and participate successfully in the therapy sessions (Davis et al., 2008). Other behavioral operant techniques include task analysis, prompting, errorless learning and chaining, The Premack Principle, modeling, generalized conditioned reinforcer, group contingencies, time out, overcorrection, and negative practices. These techniques establish an environmental antecedent event that will teach new behaviors and encourage appropriate behavioral responses (Standley et al., 2004).

The behavioral approach to music therapy is defined as the use of music in association with the therapist to change undesirable patterns of non-musical behavior into more desirable behavior. For instance, music can be used to help a child who frequently screams in the classroom to find more constructive ways of interacting and communicating with others. Standley's meta-analysis on the effects of music as reinforcement for educational and therapeutic objectives indicated that contingent music reinforced overt non-musical behaviors of patients with comatose, decreased crying of infants with colic syndrome, improved neck strength and head posture of individuals with neurologic impairments, and reduced headache pain through biofeedback (Standley, 1996). Procedures derived from behavioral therapy, such as ABA, have been used to assess and treat a wide range of clinical populations (Davis et al., 2008). The final section of this chapter will demonstrate how ABA can be incorporated within music therapy for major clinical entities including children with developmental disorders, individuals with psychiatric disorders, and patients with physical disabilities and neurologic disorders.

Music Therapy for Developmental Disorders: Special Education

During the early history of music education in the United States, music was an important part of the school curriculum for students with disabilities (McDowell, 2010). Music educators today find themselves teaching special learners with far greater needs and more severe disabilities than in years past. Music teachers make adaptations in curriculum, classroom activities, and materials for students with special needs; music therapists become actively involved in education and therapy for students with special needs. The music therapist may work individually with a student who has music therapy listed as a related service on their individualized education program (IEP) to help that student make progress toward various therapeutic goals and objectives.

In special education, contingent music has been used to increase self-feeding skills for children with cerebral palsy; decrease habitual regurgitation or disruptive behaviors for children with autism spectrum disorder (ASD); decrease off-task behaviors for children with learning disabilities; and increase appropriate social behaviors in the classroom such as eye contact, following directions, and imitation in children with attention deficit hyperactivity disorder (ADHD) (Standley, 1996; Standley & Jones, 2007). Music can be used to teach spelling for children with specific learning disabilities. For example, a melody (pitch and rhythm) is attached to "teacher, teacher, T, E, A, C, H, E, R," which the children are prompted to sing before the spelling test. The student gets to play the ukulele if they memorize the correct spelling by singing. Other behavioral modification techniques including approving/disapproving, prompting, task analysis, evaluating, chaining, fading, ignoring, and modeling have been used along with the positive reinforcement of music to change the children's behaviors in music therapy sessions (Standley & Jones, 2007). Table 44.2 indicates examples of musical activities and corresponding ABA techniques for target behaviors of common developmental disabilities.

Lim and Draper (2011) compared a common form of Applied Behavior Analysis–Verbal Behavior (ABA-VB) approach and music incorporated with ABA-VB method as part of developmental speech-language training in the speech production of children with autism spectrum disorder (ASD). This study explored how the perception of musical patterns incorporated in ABA-VB operants (mand, tact, echoic, and intraverbal) impacted the production of speech in children with ASD. Participants included 22 children with ASD between the age of 3 and 5 years who were verbal or pre-verbal with presence of immediate echolalia. Every child was randomly assigned a set of target words for each of the three training conditions: (1) music- incorporated ABA-VB, (2) speech (ABA-VB), and (3) no-training. Results showed how both music and speech trainings were effective for production of the four ABA verbal operants. However, the

Table 44.2 ABA techniques incorporated in music therapy for children with developmental disabilities

Disability	Target behavior	Use of music	ABA techniques
ASD	Verbalize vocabulary	Singing	Mand; tact; modeling; imitation; intra-verbal
	Increase joint attention	Listening to preferred music	Contingent reinforcement
	Decrease inappropriate, stereotypical mannerisms	Playing instruments in an ensemble	Prompting; ignoring
ID	Follow specific directions	Movement to music	Chaining; modeling; prompting; task analysis
	Increase socially appropriate manners	Choral performance	Modeling; prompting; fading
	Recall-procedural memory	Playing color-coded chords on the guitar	Automatic reinforcement; modeling; prompting
Hearing impaired	Use signs	Signing to recorded song with repeated words	Chaining; modeling; prompting
	Read musical notes/rhythms	Written measures of rhythm patterns	Chaining; modeling; prompting
Visually impaired	Indicate body parts	Actions songs with body parts	Chaining; prompting
	Practice grooming skills	Newly composed song with instructions	Prompting
SLD	Improve spelling	Newly composed songs with spelling	Task analysis; prompting Automatic reinforcement
	Improve reading	Melody adapted from familiar song	Chaining; prompting Automatic reinforcement
Behavior disorders	Follow rules	Complex rhythm production	Automatic reinforcement Chaining
	Reduce inappropriate behavior	Client selected music	Contingent reinforcement Prompting

ASD autism spectrum disorder; *ID* intellectual disability; *SLD* specific learning disability difference between music and speech training was not statistically significant. Results also indicated that music-incorporated ABA-VB training was most effective in echoic production, and speech training was most effective in tact production. Music can be incorporated into the ABA-VB training method, and musical stimuli can be used as successfully as ABA-VB speech training to enhance the functional verbal production in children with ASD (Lim & Draper, 2011).

Music Therapy for Psychiatric Disorders: Mental Health

Applied Behavior Analysis is one of the main approaches in contemporary behavior therapy for individuals with mental illness and it has been responsive to advances in experimental psychology and innovations in clinical practice. Since music functions as both a stimuli and response and musical behavior, music can provide essential therapeutic elements in ABA therapy. Therefore, the application of music in behavioral therapy can be justified because the perception of musical stimulus properties is not an end in itself but leads to transferable responses that can be meaningful determinants of musical behavior (Unkefer & Thaut, 2002).

The fundamental aim of behavioral music therapy for an individual with mental illness might be to create an environment in which positive, desirable behaviors are rewarded and negative/disruptive behaviors are reduced by eliminating reinforcement of those negative actions. Consequently, the music therapist should not only analyze and evaluate the client's present behaviors but also manipulate music (the essential form of communication) because music functions as an engaging and rewarding sensory stimulation and is used as a contingent reinforcement to encourage the desired target behaviors or to eliminate the negative behaviors.

Problem behaviors are identified and documented during the music therapy assessment based on the antecedent and the extent to which they occur. During the music therapy assessment, the client's musical preference and positive musical responses should be noted because they will be used as a primary reinforcement. Finding a reinforcement that is truly meaningful to the individual client with a psychiatric disorder is an essential procedure of music therapy. One of the special tools that music therapists use for reinforcement is music, because well-designed music interventions that include the client-preferred music experiences (e.g., music listening, playing musical instruments, singing, song writing) can be gratifying and used as a reward to help change behavior in the desired direction (Davis et al., 2008). Unkefer and Thaut (2002) classified the taxonomy of programs and techniques in music therapy for mental disorders and the application of music in treatments for individuals with mental disorders. Table 44.3 exhibits the taxonomy, which includes music performing, music psychotherapy, music and movement, music combined with other expressive arts, recreational music, and music and relaxation.

In music therapy, music, often referred to as the "language of emotions," becomes a significant tool for emotional experience and expression (Davis et al., 2008; Unkefer & Thaut, 2002). Music enhances non-verbal expression; therefore, it facilitates communication between therapists and clients. Through the music-making experience, the individual with emotional problems can increase their sense of mastery, sense of reality, sense of control over his/her own reactions, and sense of self-esteem. Standley (1996) indicated that individuals with mental disabilities demonstrated greater benefits from music contingencies than individuals with medical/physical impairments. If the music therapist has been successful in establishing a positive therapeutic relationship with the client with mental illness, the interventions designed with pleasant musical experiences and operated with positive musical reinforcements will result in beneficial therapeutic outcomes. Behavioral music therapy can be used to improve a wide variety of behaviors including interpersonal skills, anger manage-

Table 44.3 Taxonomy of programs and techniques in music therapy for behavior–emotional disorders

Programs	Music therapy techniques
Music performing	*Instrumental group improvisation*: A technique using musical instruments to provide experiences for socialization, communication, and expression of feelings and emotions among group participants *Instrumental performance ensemble*: A technique using the client's existing musical skills, as well as newly acquired skills, to form teaching and rehearsing performance groups on various musical instruments *Group singing therapy*: A technique using singing activities to provide experiences for socialization, communication, and expression of feelings and emotions among group participants *Vocal performance ensemble*: A technique using existing and newly acquired vocal music skills to provide experiences in cooperation among group participants through teaching and rehearsing *Individual instrumental instruction*: A technique focused on the acquisition of musical skills by an individual client on any one of a variety of musical instruments *Individual vocal instruction*: A technique using the private voice lesson to provide the client with an opportunity to develop and improve singing skills through a series of formalized appointments for instruction and planned periods of individual practice *Individual music improvisation/interaction*: A technique using musical instruments in individual therapy settings to provide a structured non-verbal mode for communication and expression of thoughts and feelings as well as reality- and sensory-ordered behavior patterns between clients and therapist

(continued)

Table 44.3 (continued)

Programs	Music therapy techniques
Music psychotherapy	*Supportive music group/individual therapy*: A technique using music activities as a starting point and catalysis for individual and group therapy processes *Interactive music group/individual therapy*: A technique using music and/or music activities as stimuli for initiating individual and group therapy processes *Catalytic music group/individual therapy*: A technique using music activities as the starting point and catalyst for individual and group therapy processes
Music and movement	*Movement awareness*: A technique using music and movement activities to encourage clients to interact and express themselves on an introductory level through body movement in a group setting *Movement exploration*: A technique using music stimuli and the elements of movement to explore and improve the client's body image and feelings of competence in moving effectively and comfortably *Movement interaction*: A technique using music and movement activities to provide the opportunity to experience social and emotional concepts in an affective, essentially non-verbal modality *Expressive movement*: A technique using music and movement activities to assist clients in becoming aware of feelings and emotions that are relevant to their personal functioning and coping abilities in daily life *Dance*: A technique using established and pre-structured dance forms, steps, and styles with music to encourage social interaction, self-confidence, and recreational skills *Music and exercise*: A technique using music to provide the temporal framework for adaptive physical exercise

(continued)

Table 44.3 (continued)

Programs	Music therapy techniques
Recreational music	*Music games*: A technique using music games to provide experiences in which human behavior can be acted out in play form, providing participants with an opportunity for emotional and social learning in a safe and predictable environment *Music appreciation awareness*: A technique using a variety of music stimuli to provide the experience of listening to, and at times creating and performing, music in group or on a one-to-one basis *Recreational music performance groups*: A technique providing diversional and success-oriented music experiences using instrumental and/or vocal media *Leisure time skill development*: A technique to emphasize music's role in a client's discharge planning and community follow-up
Music and relaxation	*Music with progressive muscle relaxation training*: A technique using music in conjunction with progressive muscle relaxation training in individual or group settings. *Music for surface relaxation*: A technique using music as a medium for temporary respite from anxiety/stress conditions in individual or group settings *Music imagery*: A technique that involves listening to music in a relaxed state to facilitate increased self-awareness, which in turn may facilitate psychological and physical relaxation *Music-centered relaxation*: A technique using music as a perceptual focus and stimulus for relaxation training
Music combined with other expressive arts	*Music and fine arts* (drawing, Drama, sculpting): A technique focused on combining music and fine arts to provide for expression of feelings and emotions among group participants or on a one-to-one basis *Music and writing* (poetry, prose): A technique focused on combining music and writing to provide experiences for expressions of feelings and cognitive responses among group participants on a one-to-one basis

Note: The author reorganized "Taxonomy of Programs and Techniques in Music Therapy for Mental Disorders" from *Music Therapy in the Treatment of Adults with Mental Disorders* by Unkefer and Thaut (2002)

ment, appropriate expression of emotion, communication skills, concentration, executive functioning skills, coping skills, and one's physical condition/relaxation. Other behavioral therapeutic techniques including approving/disapproving, ignoring, role playing, modeling, and teaching action steps have been used with the positive reinforcement of music to change the behaviors of individuals with mental illness in music therapy sessions (Standley & Jones, 2007).

Music Therapy for Neurologic Disorders: Rehabilitation

As interest and research in music's influence on brain function increase, a reciprocal relationship in musical behavior has been recognized. This relationship demonstrates that the brain that engages in music is also changed by engaging in music through reorganization of musical stimuli and production of new behaviors (i.e., neuroplasticity) (Thaut, 2005). The effect of music on brain structure and function as the non-musical therapeutic response has been studied for the fundamental mechanism of music therapy for individuals with neurologic disorders including strokes, Parkinson's disease, traumatic brain injuries (TBIs), and dementia. The therapeutic application of music necessitates a rational translation of a musical experience into a non-musical therapeutic experience including production of target behaviors. A scientific-empirical and theoretical understanding of music perception and production validates the application of music in treating individuals with neurologic disorders. This understanding determines music's physiological and psychological foundation as well as its influence on human behavior in producing non-musical target behaviors (Thaut, 2005).

In neurological rehabilitation, therapy should help prevent complications such as illness, muscle weakness, or contractures that can constrict the natural recovery process. Therapy also involves teaching adaptive strategies so that the patients can learn to use the unaffected parts of the body in place of the affected ones; it is directed at retraining the affected parts of the nervous system through specific exercise techniques (i.e., motor performance, speech, attention, and memory). Principles for the development of treatment techniques emphasize functional, task, and goal-oriented activities and exercises through the training of functional movements and behaviors in a highly repetitive, patterned, and rhythmic manner (Davis et al., 2008).

Neurologic music therapy might not directly utilize ABA methods and techniques in treating individuals with neurologic disorders. However, the rationale and logic for the use of music to enhance non-musical functions incorporates the concept of music as a mediating stimulus for the desired therapeutic response (Thaut, 2005). Music can engage behavior and mediate changes in behavior. The music response mediates between current behavior or brain function, the goals of therapy, and the desired therapeutic response. The mediating response in music is caused by the individual's perception of the intrinsic pattern in the music (i.e., tempo, rhythm, pitch, melody, chord progression, dynamics, instrumentation, and form) that has become linked to the music through some associative learning process (Thaut, 2005). Production of musical responses (i.e., emitting musical responses) evidenced by intact perception of those musical patterns (through musical experience) would be transformed into desirable non-musical behaviors as a therapeutic outcome.

According to a transformational design model (TDM), music therapy and music medicine require systematic procedures, such as treatment planning, implementation, and evaluation, for them to be functional for individual with neurologic disorders (Thaut, 2000). Treatment planning is the first step of practicing neurologic music therapy. Transformational design model (TDM) provides a system for music therapists to follow for planning music therapy interventions in their music therapy practice. TDM is designed for the systematic application of the knowledge of music therapy on clinical practice, which is based on the scientifically examined rationale for the use of music to enhance non-musical functions/behaviors. TDM suggests five steps of the planning processes: (1) Diagnostic and functional assessment of patients; (2) Development of therapeutic goals/objectives; (3) Design of functional, non-musical therapeutic exercises and stimuli; (4) Translation of step 3 into functional, therapeutic music experiences; and (5) Transfer of therapeutic learning to real-world applications. TDM for functional music therapy is presented in Table 44.4.

TDM provides a clear direction for each procedure in treatment planning. Each step in the model aims at one therapeutic purpose, which is enhancing a non-musical function that the client needs to improve. It is a goal-directed and client-

Table 44.4 Transformational design model (TDM) for functional music therapy

1. Diagnostic and functional assessment of patients
The first step is to gain information about the client. In the assessment, music therapists analyze the client's ability including current functions, needs, and problems. The result of the assessment should address the dysfunctions or deficits of the clients and guide the nature and scope of following treatment procedures. The most important part of the assessment is to know the client's current functioning levels and to determine the client's needs in detail *Assessment example*: The client is a 76-year-old Caucasian female who resides in a nursing home. She has been diagnosed with hand osteoarthritis. The music therapist observed stiffness and weakness of the client's wrist and finger movements. The client has also displayed insufficient wrist/finger movements and inefficient fine motor skills. She has complained about arthritic discomfort, but voluntarily participated in music therapy sessions focused on movement enhancement. Moreover, she has intact cognitive function and is able to follow simple motor tasks
2. Development of therapeutic goals/objectives
The second step is to determine therapeutic goals and objectives based on information from the assessment. A goal may be defined as a broad statement of the desired outcome of treatment. Objectives are more specific and short-term. Each objective should describe a small step in the process of achieving a final goal. A certain behavior that the client needs to enhance (the target behavior) must be stated in the objective. In addition, criteria (i.e., range, intensity, quality, and quantity) of the target behavior, a target date of achievement, and the termination date should be indicated to evaluate the achievement of the goal/objectives *Example goal*: To increase strength, stability, and pliability of the joints in the wrist and fingers *Example objective*: The client will complete 15 repetitions for each of the 5 different functional upper extremity (wrist and fingers) movements during one music therapy session by May 1, 2021
3. Design of functional, non-musical therapeutic exercises and stimuli

(continued)

Table 44.4 (continued)

The third step is to design therapeutic exercises and activities to implement, based on the established goals and objectives. The purpose of the step is to develop a therapeutic experience for enhancing the target behavior. Since the target behavior is non-musical, the initial treatment plan should be directly focused on the non-musical therapeutic experience rather than the musical experience. A benefit of planning non-musical therapeutic experiences lies in sharing the client's treatment procedures with other therapeutic disciplines. Facilitating common therapeutic experiences by aiming at the same clinical goal is critical for treating the client. Additionally, it justifies the music therapy treatment procedure as a clinical therapy discipline *Example of non-musical therapeutic exercise*: To improve strength, stability, and pliability of the joints in the wrist and fingers, the client needs to engage in the repetitive practice of using the muscles in movements. This practice needs to be completed at an appropriate pace and for an adequate duration of time
4. Translation of step 3 into functional, therapeutic music experiences
The fourth step is to translate functional and therapeutic exercises into music experiences. The functional exercises in music experiences should contain the common mechanisms of the non-musical therapeutic exercise developed in the previous step. The TDM defines these functional therapeutic music exercises as "isomorphic" to the non-musical therapeutic exercises. In this step, music therapists should determine precise musical elements to use in the functional exercises and choose effective music therapy protocols for the therapeutic experiences. The therapeutic application of music on non-musical functions is completed throughout this step. Music therapists should design the musical experiences based on the scientific logic that researchers have examined. Creativity, advanced musical analysis, and thoughtful consideration of the client's musical preference will facilitate the process of planning music therapy interventions *Example of music therapy protocols*: Wrist flexion and extension (raise and lower) with a song in a ¾ meter (30 measures) at a moderato tempo. The tempo of this sing will determine the pace and number of the wrist movements. The meter will provide the temporal cuing (timing) for the movements. The rhythmic cuing by a specific accompanying pattern will indicate the initiating point of each movement and enhance the patterned/efficient muscle control
5. Transfer of therapeutic learning to real-world applications
The fifth step is to finalize music therapy treatment procedures. In this step, the client completes the target behavior in the therapeutic/clinical situations and starts to apply the practiced function in the real-life situations. In this step, the effect of the music therapy treatment should be evaluated by the client and the therapist and certain processes should be modified for further treatments *Example of transferring of therapeutic learning to real-world applications*: The client tries to push a large button on the table

Note: The author reorganized the five steps of TDM from *A Scientific Model of Music in Therapy and Medicine* by Thaut (2000)

centered model for the application of music in rehabilitation. TDM assists music therapists to adapt common therapeutic mechanisms, including ABA, that are frequently used by other therapeutic disciplines. The third step of TDM is to design functional, non-musical therapeutic exercises and stimuli. It is an excellent approach to demonstrate that music therapy treatment can share common therapeutic goals and mechanisms with other science-based, non-musical therapeutic modalities (Thaut, 2000).

Conclusion

There has been dynamic growth in behavioral music therapy and development of diverse techniques over the past 60 years. An examination of contemporary literature serves to indicate the continued prominence of behaviorism in music therapy practice and reveals the beneficial application of music in treatments for various clinical populations. The theoretical underpinnings and empirical evidences of the behavior music therapy approach conclude that music can be used as an antecedent, temporal stimuli for brain function (movement, speech, cognitive and affective domains), behavioral momentum, establishing operation, and reinforcement. The effective application of music in ABA requires a solid understanding of the principles of behavior, refined training for behavior observation and analysis, and extensive creativity in designing intervention procedures. However, because of the promising outcomes and benefits of ABA incorporated in music therapy, it is worthwhile to explore and examine the application of music in treatments for individuals in need due to developmental disorders (ASD, ID, speech-language impairment, etc.), physical disabilities, emotional and behavior disorders (mental illness), and neurologic disorders (CVA, Parkinson's disease, TBI, Alzheimer's disease, and dementia). Further research will allow music therapists and music educators to investigate and determine the extended range of the application of music in the field of ABA for various behavior functions. Teaching musical skills and using musical stimuli for non-musical therapeutic responses indicate the efforts to expand the field of ABA.

45 Behavior Analysis and Sports Performance

Raymond G. Miltenberger and Merritt J. Schenk

Behavior Analysis and Sports Performance

One of the most important features of applied behavior analysis (ABA) is that the science targets behavior deemed important by society (Baer et al., 1968). This is a slightly different aim than a pure scientific approach as it allows us to take the established science of behavior and demonstrate its significance to everyone. ABA researchers have focused on numerous target behaviors deemed important to society and sports is one of those behaviors.

Engaging in and viewing sports is a ubiquitous activity that has been a celebrated part of society for nearly all of written history. Not only will nearly all people participate in sporting activities during their life (even as simple as throwing a Frisbee), but also the impact of sports transcends its immediate reinforcing properties. As stated by Jones (2015), "sports are a major part of U.S. culture, … are a big driver of economic activity, and the market for commerce related to sports is enormous." In fact, the global sporting industry is estimated to be worth more than 500 billion dollars annually ("Why the Sports Industry is Booming,", 2020). Thus, it is our responsibility to determine how behavior analysis can contribute to the development of sports. Fortunately, everything one does when participating in sports is behavior and, thus, relevant subject matter for ABA.

In our view, approaching sports from a behavioral perspective provides three substantial benefits to the athlete. First, behavioral interventions can promote skill development when specific athletic skills are not in the participant's repertoire (e.g., Luyben et al., 1986). Second, behavioral interventions can enhance performance when a skill is present but not demonstrated to a desired level (e.g., Kelley & Miltenberger, 2016). Third, behavioral procedures can change potentially harmful behaviors to minimize the likelihood of injury (e.g., Tai & Miltenberger, 2017).

Studying sports can also contribute to our understanding of behavioral science as sports environments provide analogue settings for the study of behavior. In sports, one can study basic principles, such as manipulating schedules of reinforcement, to better understand how basic principles and procedures derived from them affect behavior in the natural environment (see Schenk & Reed, 2020). Therefore, it is conceivable that by studying behavior in a sporting environment, we might better understand factors that influence behavior more broadly. Thus, combining ABA and sports is beneficial to both the behavior analysts and the athletes involved.

The purpose of this chapter is to discuss research findings on the application of ABA to

enhance sports performance. The chapter discusses the different types of sports and target behaviors, the ages and populations of research participants, the different types of interventions evaluated in research, and some issues for future research directions.

Sports and Target Behaviors Addressed in ABA Research

This section focuses on each of the sports and target behaviors addressed in the literature (see review by Schenk & Miltenberger, 2019). Some of the sports are recreational and some are competitive with a range of age groups. Most of the target behaviors focus on improving the athlete's performance directly. However, some of the research focuses on improving the coach's performance to in turn enhance the athletes' performance. The section is ordered by the most to least studied sports.

There have been 15 studies to enhance the performance of skills in tennis or table tennis. Seven studies improved the execution of the service swing (e.g., Rikli & Smith, 1980) and four studies enhanced the performance of forehand or backhand swings (e.g., Buzas & Ayllon, 1981). Two studies improved the performance of service returns (e.g., Scott et al., 1998). Two studies decreased inappropriate outbursts during play to improve performance (e.g., Allen, 1998). Two studies improved hitting trajectory or ball placement (e.g., Todorov et al., 1997), and one study improved the execution of a paddle swing (Carroll & Bandura, 1982).

We found 11 studies on enhancing basketball skills. Eight evaluated behavioral interventions for improving shooting form (e.g., Hall & Erffmeyer, 1983). One study attempted to decrease fouls and increase assertiveness (Connelly, 1988). One study focused on improving defensive performance (Kendall et al., 1990), and one study taught an individual with autism nine essential basketball skills using a combination of interventions (Lambert et al., 2016).

We identified 11 studies on enhancing football performance. Four studies focused on improving tackling form (e.g., Harrison & Pyles, 2013) and two focused on improving offensive blocking (Allison & Ayllon, 1980; Stokes et al., 2010). Some studies focused on improving multiple behaviors including route running, initial release, and play execution (e.g., Smith & Ward, 2006). Two studies focused on improving defensive responses accuracy and speed to an offensive play (e.g., Ward & Carnes, 2002).

We identified 11 studies that enhanced the performance of swimmers. Three studies increased the number of lengths swam during practice (e.g., Schonwetter et al., 2014) and two decreased the number of stroke errors and improved stroke execution (e.g., Koop & Martin, 1983). One study each taught three new swimming skills (Rogers et al., 2010), decreased the strokes needed to swim a set distance (Polaha et al., 2004), improved attendance and work output (McKenzie & Rushall, 1974), decreased nonproductive behavior and increased productive behavior (Hume & Crossman, 1992), improved the coach's correct use of reinforcement and feedback to improve athlete performance (Rushall & Smith, 1979), and improved the performance of swimmers with spina bifida (Dowrick & Dove, 1980).

Nine studies focused on enhancing golf performance. Five studies increased the form accuracy of a golf swing (e.g., Fogel et al., 2010), three increased shot making and decreased the number of strokes to complete a round (e.g., O'Brien & Simek, 1983), and one focused on improving power and distance control when putting (Fery & Ponserre, 2001).

Six studies evaluated behavioral interventions for improving dance performance. All of these studies focused on improving different dance moves and typically focused on increasing the percentage of steps correct in a task analysis of the movement (e.g., Fitterling & Ayllon, 1983; Quinn et al., 2015, 2020).

Six studies focused on improving gymnastic performance. The target behaviors included rope climbing/dancing skills (Magill & Schoenfelder-Zohdi, 1996), three basic entry-level gymnastic skills (Allison & Ayllon, 1980), pommel horse skills (Baudry et al., 2006), three skills on the uneven bars (Boyer et al., 2009), and overall behavioral output during practice (Wolko et al., 1993).

We identified five studies to enhance the performance of ice skaters. Two studies improved the performance-specific "figures" (e.g., Ming & Martin, 1996), two increased the overall output of athletes during practice (e.g., Wanlin et al., 1997), and one improved the correct execution of relay tagging (Anderson & Kirkpatrick, 2002).

We identified five studies to enhance soccer performance. Two studies focused on improving passing (e.g., Ziegler, 1994), one improved the performance of headers, throw-ins, and goal kicks (Rush & Ayllon, 1984), one improved the athlete's on-field positioning during game-play (Brobst & Ward, 2002), and one improved the number of effective coaching strategies used to improve player performance (Partington et al., 2015).

Four studies have been published on behavioral approaches in baseball. Simek and O'Brien (1988) used a combination of interventions to help hitters discriminate the difference between strikes and balls, as the more quickly a batter recognizes the pitch, the easier the pitch is to hit. Osborne et al. (1990) also used behavioral interventions to improve curveball hitting. Heward (1978) used reinforcement to increase the overall offensive efficiency average, a combination of successful performance indicators. Additionally, Little and Simpson (2000) focused on decreasing negative thoughts to improve baseball performance.

We identified four studies enhancing the performance of track and field athletes or runners. Two studies decreased the time taken to complete a race (e.g., Shapiro & Shapiro, 1985). One study improved the performance of throwing the discus and hammer (Maryam et al., 2009), and one study increased the height of a pole extension in pole vault (Scott et al., 1997). Another study increased weekly distance of runs for recreational runners (Wack et al., 2014).

We identified three studies enhancing the performance of volleyball skills. One study improved the ability to receive the ball (Barzouka et al., 2007), one taught the overhand pass and serve (Zetou et al., 1999), and one improved the execution of ball setting and serving (Zetou et al., 2002).

Three studies evaluated behavioral procedures to enhance cycling performance. Two studies focused on improving pressure distribution (e.g., Sanderson & Cavanagh, 1990) and one focused on improving the standing start (Jennings et al., 2013).

Three studies improved the performance of rowing athletes. Two decreased the amount of time it took to complete a race (e.g., Thelwell & Greenlees, 2001) and one increased the amount of distance covered over a 40-min period (Scott et al., 1999).

We identified two studies to improve hockey skills. One focused on increasing the number of goalie saves (Rogerson & Hrycaiko, 2002) and the other decreased the number of penalties incurred while increasing goals and assists (Silva III, 1982).

Two studies focused on kickball players. One improved sportsmanship (Hupp et al., 2002) and the other increased attentive behavior while decreasing disruptive behavior (Reitman et al., 2001).

We identified two studies that enhanced martial art performance. One study improved the athletes' performance of three different techniques (BenitezSantiago & Miltenberger, 2016), and the other increased the athlete's use of varied techniques so as to not become predictable (Harding et al., 2004).

We identified one study to enhance the performance of rock climbers; this study improved the performance of the drop knee, heel hook, and rear flag techniques (Walker et al., 2020).

One study evaluated behavioral procedures to enhance the performance of three different horseback riding skills (Kelley & Miltenberger, 2016).

We identified four studies enhancing the performance of weight lifters, and all studies improved the correct execution of one or more lifts Sewal et al., 1988).

One study enhanced the performance of rugby players. This study increased the number of ball carries, tackles made, successful kicks, and takeaways won (Mellalieu et al., 2006).

One study evaluated behavioral procedures to enhance field hockey skills. O'Neill and Miltenberger (2020) focused on improving three types of shots players use to shoot on goal or pass the ball.

One study focused on performance in lacrosse. DePaolo et al. (2019) evaluated behavioral procedures to increase the percentage of times players called the name of the player to whom they were passing the ball.

Research has shown that numerous behaviors have been targeted for improvement across sports. The target behaviors have included (1) skill acquisition or skill improvement, typically measured as the number of steps completed correctly in a task analysis of the skill (e.g., Boyer et al., 2009; Quinn et al., 2015; Stokes et al., 2010) or (2) behavioral output during practice or performance of mastered skills during practice (e.g., DePaolo et al., 2019; Wolko et al., 1993). Thus far, behavior analytic techniques have been used to enhance athletic performance in at least 23 different sports. Because there are hundreds of different sports across the world, there is much room to expand research on ABA interventions across sports. Each sport has its own set of complex behaviors, rules, and strategies, which would allow for multiple aspects of each sport to be targeted for improvement. Because all sports performance is behavior, every measurable aspect of the performance could become a target behavior in future research.

Ages and Populations in ABA Sports Research

The participants in research on ABA procedures to enhance sports performance range from 4-year-olds to over 60-year-olds. Study populations have also ranged in competition levels, including recreational, beginner, high school, collegiate, and professional athletes, although the fewest studies have been conducted with professional athletes (Schenk & Miltenberger, 2019).

The number of participants in research on ABA and sports performance up to this point is surprisingly small, with just over 1500 total participants (Schenk & Miltenberger, 2019). According to a recent review of participant characteristics in behavior analytic sports studies, 52% of participants are female and 48% are male (Rotta et al., 2020). About one-third of the participants have been children, and well over 90% of the participants have been considered typically developing (Schenk & Miltenberger, 2019). The limited number of studies with participants who have been diagnosed with a developmental disability are often focused on team sports, not only to improve skills but also to lead to greater inclusion of individuals with disabilities (e.g., Lambert et al., 2016; Luyben et al., 1986). Because sports performance is relevant to all ages or populations, the scope of research should continue to be extended to all individuals who participate in sporting activities. Furthermore, participant demographics should only be a limiting factor as it relates to the purpose of a given study or availability of athletes as research participants. Systematic research on different ages, populations, and ability levels will tell us more about interventions that are most successful for each individual participant.

Types of ABA Interventions for Sports Performance

This section focuses on the numerous different behavioral interventions used in sports performance research. Because most of the research on enhancing athletic performance involves skill acquisition or improvement, and a skill that cannot be unlearned or untaught, multiple baseline designs are the most common form of experimental design used for sports performance research and reversal designs are relatively rare (Schenk & Miltenberger, 2019). The important aspect of each study is that it focuses on an observable and measurable behavior and implements procedures to change that behavior. Some of the interventions use basic behavioral principles (e.g., positive reinforcement; Buzas & Ayllon, 1981), whereas others use techniques that may be based on several behavioral principles (e.g., video feedback; Kelley & Miltenberger, 2016), and many use combinations of procedures (e.g., behavioral skills training [BST]; Tai & Miltenberger, 2017). Across these varied interventions, researchers described procedures to facilitate replication and demonstrated beneficial changes in the targeted athletic skills.

Antecedent Procedures

Antecedent interventions, often consisting of some form of instructional procedure, are implemented in advance of performance and are designed to evoke the correct performance. Antecedent procedures most often are used as part of a package intervention (Schenk & Miltenberger, 2019).

Expert Modeling Expert modeling involves having someone demonstrate the behavior for the participant so the participant can imitate it. We identified 20 studies using expert modeling. For example, Koop and Martin (1983) used expert modeling to show coaches how to deliver prompts and different consequences to decrease problem behaviors and increase appropriate behaviors of competitive swimmers. This study is also an example of teaching coaching strategies that in turn enhance competitor performance.

Instruction Instruction involves the clear and concise explanation of each aspect of a target behavior. Also, depending on the research aims, the instructions might include an explanation of the appropriate context for the target behavior. Over 30 studies used instruction as part of an intervention to improve athletic performance (Schenk & Miltenberger, 2019). For example, Komaki and Barnett (1977) used instruction along with other intervention components to teach proper play execution to youth-level football players. Instructions for this behavior included describing to the participant the stimulus to be observed (e.g., which direction a quarterback moved) and then explaining to the participant the proper response to the stimulus.

Goal Setting Goal setting involves setting attainable and measurable performance targets and documenting behavioral achievements related to the targeted goals. With goal setting, reinforcement might occur in the form of achieving the set goal, but additional reinforcement can also be programmed for reaching specific goals. We identified 12 studies using goal setting to improve athletic performance. For example, Mellalieu et al. (2006) used goal setting to increase several specific on-task behaviors of rugby players, and they demonstrated desirable effects of goal setting on individual performance. Additionally, they found that team performance concurrently improved as a result of individual performance enhancement.

Physical Prompting Physical prompting in sports is used to help an athlete move their body in a specific way to produce the desired effect. For example, when coaching young or beginner athletes (young tee-ball players) the coach may have to physically adjust a child's hands or feet for the child to learn correct form when throwing or hitting a baseball. We identified five studies using physical prompting to improve athletic performance. Luyben et al. (1986) used physical prompting to teach participants with developmental disabilities how to pass a soccer ball using the side of their foot. This allowed the individuals to play soccer together and engage in sporting activity that had previously been unavailable to them.

Video Modeling Video modeling involves the athlete viewing a video recording of an individual correctly engaging in the target behavior. Often, each step in a task analysis of the behavior is observed and identified in the model while the video is played. We identified 20 studies using video modeling to enhance athletic performance. For example, Maryam et al. (2009) used video modeling to demonstrate an improvement of track and field athletes' ability to throw the discus and hammer. However, recent research indicates that video modeling does not substantially improve athletic performance without other intervention components such as video feedback (Quinn et al., 2020).

Discrimination Training Discrimination training involves reinforcing correct responding in the presence of discriminative stimuli, and then fading the stimuli to get the behavior to occur in a competitive setting. In the one study using discrimination training, Osborne et al. (1990) used marked baseballs to help hitters discriminate between a curveball and other pitches, as correct identification of a pitch promotes successful hitting. The experimenters demonstrated that participants hit a greater percentage of marked balls than unmarked balls; however, the degree to which this generalized to in-game performance was not established.

Contingency Management

In contingency management, reinforcing consequences are delivered contingent on some measures of successful performance.

Reinforcement Procedures Reinforcement procedures program the delivery of a reinforcer contingent on athletic performance to improve that performance. Although reinforcing consequences occur following the correct behavior in each study to some degree, we identified 20 studies that specifically programmed reinforcement contingencies. Tangible reinforcers are occasionally used, but the most common form of reinforcement used in sports research is praise from the experimenter or the coach (Schenk & Miltenberger, 2019). Rushall and Pettinger (1969) increased the work output of swimmers during practice by providing a reinforcer for each lap completed. Furthermore, they compared the use of candy, money, and coaches' attention as reinforcers and found that reinforcement in any form improved behavior compared to no reinforcement. However, candy and money improved performance more than a coach's attention.

Token Economies Token economies involve delivering tokens for correct performance and exchanging tokens later for different types of reinforcers. Two studies used token economies to improve athletic performance. For example, Hupp et al. (2002) used a token economy to improve sportsman-like behavior of five kids diagnosed with attention deficit hyperactivity disorder (ADHD). They demonstrated that the delivery of immediate tokens for sportsman-like behavior helped improve the behavior while playing kickball.

Feedback Procedures

In feedback procedures the researcher or coach gives information about correct and/or incorrect aspects of performance immediately after the target behavior occurs. Feedback might function as reinforcement to increase correct responses or as punishment to decrease incorrect responses. Furthermore, feedback may serve as instructions to guide future performance. Because feedback could have both punishing and reinforcing properties as well as instructional properties, these procedures are categorized as feedback instead of contingency management or antecedent interventions.

Graphical Feedback Graphical feedback involves providing participants with information on their performance in graphical form. We identified six studies using graphical feedback to enhance athletic performance. For example, Wack et al. (2014) used graphical feedback along with goal setting to increase the distance run each week by five runners. The participants and experimenters set running goals and the experimenters provided weekly verbal and graphical feedback to the participants. This intervention increased the distance for all participants.

Public Posting Public posting involves providing information on the participant's performance in a setting that is available to the participant and others. We identified nine studies using public posting to enhance sports performance. Brobst and Ward (2002) used public posting along with goal setting and feedback to improve three behaviors of three competitive soccer players. The researchers measured the three behaviors during scrimmages or games, and provided performance feedback orally and in graphical form prior to each practice. All participants met the goals for each behavior.

Self-Monitoring Self-monitoring involves participants recording their own behavior during practice or as they perform their athletic skill. Critchfield and Vargas (1991) used self-recording along with instructions and public posting to increase the number of lengths swum by competitive swimmers. At the end of every four lengths swam, swimmers recorded their behavior on a board poolside. They found that self-recording improved the performance of all swimmers, but sustained and substantial improvement occurred after the public posting component was added to the intervention for four of the seven swimmers.

Verbal Feedback Verbal feedback is often provided by coaches in a sport setting, but verbal feedback in research only refers to verbal feedback that was a programmed part of an intervention. In research, verbal feedback is the delivery of spoken information about performance immediately following performance. It may involve descriptive praise and/or instructions for improvement. We identified 28 studies using verbal feedback to enhance sports performance. For example, Schonwetter et al. (2014) used verbal feedback with self-monitoring to improve the number of laps swum by six competitive swimmers. Participants recorded the number of laps they swam during practice, and then the experimenter provided positive feedback regarding number of laps swum or correct recording of behavior. Although behavior improved for all participants with self-recording, performance improved further with the addition of the verbal feedback component.

Video Feedback Video feedback involves video recording a participant performing the target behavior and then reviewing the video with the participant while identifying correct aspects of performance and providing further instruction to correct incorrect aspects of performance. Over 20 studies used video feedback to enhance sports performance. For example, BenitezSantiago and Miltenberger (2016) used video feedback to improve three martial arts behaviors for five participants. Each participant was filmed engaging in the target behavior. The experimenter and the participants then reviewed the recording, and the experimenter provided praise for correct execution of each step with the task analysis (TA) and corrective feedback for incorrect execution of each step. As a result, all participants improved all target behaviors.

Auditory Feedback Auditory feedback is provided in the form of a sound such as a clicker directly following a correct behavior and is intended to function as a conditioned reinforcer to increase correct responding. Seven studies used auditory feedback to enhance athletic performance. Quinn et al. (2017) used auditory feedback to improve complicated dance moves of six competitive dancers. They created a TA for the target behavior and trained peers to provide auditory feedback following correct responses of each step of the TA. Their results show that auditory feedback was an effective intervention. Additionally, they demonstrated that peers could provide auditory feedback successfully, increasing the efficiency of the intervention.

Skills-Training Procedures

Skills-training procedures refer to procedures that teach athletes a specific skill that is not the target behavior but that facilitates improvement of the target behavior.

Relaxation Training Relaxation training involves teaching different strategies to help a participant become calmer, in turn improving performance. Eight studies used relaxation training to enhance sports performance. For example, Kearns and Crossman (1992) used relaxation training along with self-imagery to help increase the free-throw percentage of college basketball players. Participants were trained to engage in a relaxation exercise during which the participants engaged in covert behavior related to decreasing anxiety and focusing on correct musculoskeletal movements. During practice and at home, all participants engaged in these relaxation and self-imagery behaviors each day. All participants' free-throw percentage improved during practice following the implementation of the intervention.

Self-Imagery Self-imagery involves teaching a participant how to engage in the covert behavior of imagining correct overt execution of the target behavior. We identified ten studies using self-imagery to enhance sports performance. For example, Thelwell and Greenlees (2003) used self-imagery along with relaxation training to help recreational athletes decrease the amount of time needed to complete a triathlon. Each participant was trained to use self-imagery and relaxation to minimize the effects of pain and fatigue and help them maintain desirable levels of relaxation. Following implementation of the intervention, all participants substantially decreased the amount of time needed to complete the race.

Self-Talk Self-talk involves a participant engaging in covert verbal behavior to promote correct execution of the target behavior. We found 12 studies using self-talk to enhance sports performance. For example, Landin and Hebert (1999) developed a self-talk procedure to improve the volleying skills of five collegiate tennis players. Participants were taught to engage in two self-talk steps to promote correct movement after each ball strike. A ball strike prompted self-talk, which prompted movement to improve volleying and overall scoring performance. All participants improved their performance following the self-talk intervention.

Acceptance Commitment Therapy Acceptance and Commitment Therapy (ACT) is becoming a widely used psychological intervention in which psychological flexibility is promoted so that covert behavior does not adversely impact overt behavior (see Hayes et al., 2006). Little and Simpson (2000) used ACT to improve the performance of collegiate softball players. Participants engaged in a 30-min ACT session 2–3 days before certain game days. During these sessions a therapist reviewed performance with each athlete and different strategies to deal with covert behavior during athletic performance, and four of five players improved their performance over the course of the study.

Rehearsal Procedures

In rehearsal procedures, the athlete is instructed to engage in the skill a set number of times as a stand-alone procedure or combined with other interventions.

Additional Rehearsal Additional rehearsal involves the participant practicing the target behavior outside the context of coaching; thus, no feedback or critique is provided. Often, an individual can improve their performance via repetition of the target behavior, especially when the outcome of the behavior can function as a reinforcer (Larry Bird famously shot at least 500 free throws every day). Six studies used additional rehearsal to enhance sports performance. For example, Kirschenbaum et al. (1998) used additional rehearsal and self-monitoring to improve the performance of five experienced golfers. They had all participants focus their attention on good shots as opposed to problematic shots, and then had the golfers practice doing this while playing rounds of golf. As a result, they found that all golfers improved their average golf scores.

Simulated Practice Simulated practice involves a participant engaging in the target response while interacting with a visual-electronic device often using a device similar to a video game console. We identified five studies using simulated practice to enhance sports performance. For example, Christina et al. (1990) used a joystick and a video recording to improve response accuracy of a linebacker for a college football team. The researchers video recorded offensive plays, had the participant watch the plays, and asked the participant to respond by moving the joystick in the appropriate direction according to the play being shown. Correct responding was dependent on the offensive player movements. Over the course of the intervention, not only did the participant's responding become more accurate, but his response time slightly decreased as well. A limitation of this study was that it did not examine generalization to on-field performance. However, Scott et al. (1998) demonstrated that simulated practice of tennis skills could generalize to actual performance.

Behavioral Skills Training BST involves the systematic use of instruction, modeling, rehearsal, and feedback to enhance performance. Two studies evaluated behavioral skills training (BST) to enhance athletic performance. For example, Tai and Miltenberger (2017) used BST to teach safe-tackling techniques to six pop-warner football players. They instructed the participants how to properly engage in each step in a ten-step TA and then modeled each step. Following instructions and modeling they had the participants rehearse the steps while making a tackle and provided immediate feedback to the participants on which steps were done correctly or incorrectly. All participants improved responding following the introduction of BST.

Habit Reversal Habit reversal involves awareness training to help an individual recognize an undesirable response and teaching that person a competing response to replace the undesirable response. Allen (1998) used a habit reversal procedure to decrease anger outbursts of a competitive teenage tennis player. An auditory device was used to help the participant identify when the inappropriate behaviors were about to occur, and the participant engaged in a competing response that was similar to a deep-breathing exercise. The participant's parents then reinforced the use of this competing response. Over time, the intervention eliminated the anger outbursts during tennis matches.

Research has demonstrated that multiple forms of behavioral interventions can be used to enhance sports performance (Schenk & Miltenberger, 2019). These interventions include antecedent approaches to evoke correct performance, reinforcement approaches to strengthen correct performance, feedback approaches that may serve multiple functions, and skills training approaches. Antecedent procedures are most often used in conjunction with other procedures such as reinforcement or feedback. Although reinforcement procedures are effective in strengthening correct forms of behavior that may be evoked by instructions or modeling, providing immediate reinforcement (or punishment) within a sports setting is often difficult because the game flow cannot be interrupted. Therefore, reinforcement procedures are often used in practice in the hopes that behavioral improvement will also occur in games. Because correctly engaging in the target behaviors related to sports performance usually produces naturally occurring reinforcement (e.g., correct performance of the skill or its outcome [making a goal, making a tackle] functions as a reinforcer for most competitive athletes), interventions involving different forms of feedback are often effective. Although the behavioral mechanism involved in feedback interventions is not clear, research shows they are effective for enhancing athletic performance.

Research Considerations

Since the late 1960s (Rushall & Pettinger, 1969), there has been a growth in research evaluating ABA procedures to enhance sports performance using single-subject research designs to demonstrate intervention effects. Although this research has demonstrated the effectiveness of numerus interventions across numerous sports skills, there are still multiple considerations to be addressed. First, the majority of studies to this point have used multi-component interventions to improve performance (Schenk & Miltenberger, 2019). These package interventions are often useful because of the small amount of time that can be allotted to research in a sports setting. In most studies, there is a limited number of sessions because of the time-frame of a sports season and the need for the athlete (and sometimes the coach) to dedicate time in or outside of practice to participate in research. Therefore, research often focuses on results-driven package interventions. This approach has not allowed researchers to identify the effectiveness of individual intervention components. It would be beneficial to know which intervention components are most effective so coaches can provide the most efficient interventions for each target sport, behavior, and age group. Thus, there is a need for further research analyzing the individual components of package interventions.

Second, most sports research is divided into training sessions and assessment sessions. In training sessions, the behavioral procedure is implemented and in assessment sessions, the performance is evaluated under natural (extinction) conditions. Often, multiple training trials are conducted before completing assessment trials, and this process is repeated until a mastery criterion has been reached in assessment trials. Although it is during the training phase that behavior is modified, data from the training trials are usually not reported. However, it would be useful to see the degree of behavior change over each implementation of the intervention. Without data from training sessions the change in behavior that occurs on a trial-to-trial basis is unknown, and if efficiency is an important factor in choosing which intervention to use, these data would be important to monitor and report.

Third, there is an important distinction between skills acquisition and performance management in sports. New or amateur athletes have yet to correctly engage in many of the target responses required of the sport. Therefore, behavioral interventions will focus on teaching a new skill and consist of antecedent strategies such as instruction and modeling or prompting to evoke the skill and reinforcement or feedback strategies to strengthen the skill. Thus, initial acquisition of skills most often requires teaching packages. However, when the goal is performance enhancement of an already learned behavior, teaching approaches might be less important than a reinforcement, feedback, or goal-setting intervention. In such cases, the goal is to manage the athlete's use of the skill in the correct circumstances—to promote the execution of the skills when needed. Researchers should focus on evaluating behavioral strategies for these two purposes in sports research.

A fourth issue for future research is promoting generalization of performance to games or competition. In the current literature, most studies do not measure the effects of the behavioral intervention during in-game performance. This may occur because the researcher has control over creating opportunities for the skills during practices but not during games or competition. In competition, the researcher has to wait for naturally occurring opportunities for the performance of the skill. In some sports the target behavior might be difficult to assess because it does not occur often. For example, in a football game, a player might have few opportunities to make a tackle for an entire game. Furthermore, attending competitions and games can be difficult for the researcher because of time and travel or because access is restricted, so finding a way to observe and record behavior can be difficult. Video recording may be a good alternative for researchers, but one must be aware of ethical considerations and who or what might be video recorded. Despite these difficulties, researchers should evaluate performance during games or competition whenever possible and implement behavioral strategies to promote generalization. Some methods to promote generalization could include training coaches to implement behavioral interventions, providing reinforcement for in-game performance, or increasing practice in competition-like settings.

In summary, numerous behavioral approaches have proven effective for teaching sports skills and improving athletic performance. Because of the importance of sports across the world, this line of research should continue to grow and mature. One benefit of further research in ABA and sports is to identify which interventions are most effective for different sports, different skills, different age groups, and different levels of expertise. The research tells us generally that behavioral interventions work to enhance sports performance, but it does not yet tell us how to choose specific interventions for specific athletes. Our hope is that refinements in this research will begin to answer that question.

46 Physical Activity, Exercise, and Fitness

Paul Oh, Lisa Cotie, and Lais M. Vanzella

Guidelines for Physical Activity and Exercise

Regular physical activity is one of the most important things people can do to improve their health. Physical inactivity puts people at a very high risk for adverse short-term and long-term health outcomes including heart disease, diabetes, some types of cancer, and mental health issues. These chronic health problems place an enormous clinical and financial strain on the healthcare system and society as a whole. In 2020, about half of all American adults, about 117 million people, were living with one or more preventable chronic diseases related to physical inactivity (U.S. Department of Health and Human Services, 2018). There is a plethora of information from large clinical studies to demonstrate that physical activity has a dramatic impact on reducing the incidence and improving the management of these chronic conditions.

Unfortunately, the majority of population is physically inactive. Nearly 80% of North American adults are not meeting the key guidelines for both aerobic and muscle-strengthening activity, while only about half meet the key guidelines for aerobic physical activity (U.S. Department of Health and Human Services, 2018; A common vision for increasing physical activity and reducing sedentary living in Canada, 2018).

The recent *Physical Activity Guidelines for Americans*[1] (U.S. Department of Health and Human Services) provides detailed recommendations for cohorts across the life span. Preschool-aged children (aged 3 through 5 years) should be physically active throughout the day to enhance growth and development. Active play that includes a variety of activity types should be encouraged throughout the day. Older children and adolescents aged 6 through 17 years should do 60 minutes or more of moderate to vigorous-physical activity (MVPA) daily including a mix of aerobic, muscle, and bone strengthening activities on at least 3 days a week. These physical activities should be age appropriate as well as fun and engaging.

Adults should move more and sit less throughout the day. Excessive sedentary time has independently been linked with marked increases in the risk of developing chronic conditions such as diabetes and heart disease, as well as total mortality (Biswas et al., 2015). Getting any level of physical activity, including sitting less, is a great start for people who are largely sedentary.

To achieve optimal health benefits, adults should do at least 150–300 minutes a week of moderate-intensity or 75–150 minutes a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and

J. L. Matson (ed.), *Handbook of Applied Behavior Analysis*, Autism and Child Psychopathology Series, https://doi.org/10.1007/978-3-031-19964-6_46

vigorous-intensity aerobic activity. Preferably, aerobic activity should be spread throughout the week. Adults should also do muscle-strengthening activities of moderate or greater intensity and that involve all major muscle groups on 2 or more days a week, as these activities provide additional health benefits (U.S. Department of Health and Human Services). In addition to the above guidance, as part of their weekly routines, older adults should do mixed physical activity that includes balance, aerobic, and muscle-strengthening activities. Older adults should be mindful of their level of effort during any given activity, as well as the impact of underlying medical conditions (U.S. Department of Health and Human Services, 2018).

The Canadian Society of Exercise Physiology (CSEP) recently produced the *Canadian 24-Hour Movement Guidelines* (Ross et al., 2020). This document also provides advice specific to age categories, and emphasizes engaging in activity throughout the day, reducing sedentary behavior (such as limiting screen time to less than 3 hours per day for children, or breaking up extended sitting time for adults), and an additional recommendation around practicing healthy sleep hygiene for all age groups (i.e., developing routines, behaviors, and environments conducive to sleeping well) (Ross et al., 2020). The 2020 World Health Organization (WHO) guidelines on physical activity and sedentary behavior are very consistent with the North American guidelines (WHO guidelines on physical activity and sedentary behaviour, 2020).

For adults who are living with chronic conditions or disabilities, the *Physical Activity Guidelines for Americans* recommend that for those who are able, performance of at least 150–300 minutes a week of moderate-intensity, or 75–150 minutes a week of vigorous-intensity aerobic physical activity, spread throughout the week. Those who are able to should also do muscle-strengthening activities of moderate or greater intensity that involve all major muscle groups on 2 or more days a week (U.S. Department of Health and Human Services, 2018). These recommendations are very consistent with the guidelines from disease-specific groups including those affiliated with diabetes, cardiovascular, and cancer organizations. The American Diabetes Association statement highlights that physical activity and exercise improves blood glucose control in type 2 diabetes, reduces cardiovascular risk factors, contributes to weight loss, and improves well-being (Colberg et al., 2016). Regular exercise also has considerable health benefits for people with type 1 diabetes (e.g., improved cardiovascular fitness, muscle strength, insulin sensitivity, etc.) (Colberg et al., 2016). Physical activity and exercise recommendations should be individualized since glucose control may vary by diabetes type, activity type, and presence of diabetes-related complications (Colberg et al., 2016). Current guidelines published by the American Heart Association and the American College of Cardiology broadly recommend lifestyle approaches to prevent and treat important and common cardiovascular risk factors such as elevated blood pressure and cholesterol. For patients with mildly or moderately elevated blood pressure and blood cholesterol, lifestyle-only approaches are actually endorsed as the first line of therapy rather than initiating medications (Gibbs et al., 2021). A recent consensus statement and guideline in oncology indicated that exercise training and testing were generally safe, that every survivor should avoid inactivity, and that specific doses of aerobic, combined aerobic plus resistance training, and/or resistance training could improve common cancer-related health outcomes, including anxiety, depressive symptoms, fatigue, physical functioning, and health-related quality of life (Campbell et al., 2019). People with chronic conditions should consult with their healthcare professional or physical activity specialist about the types and amounts of activity appropriate for their abilities, symptoms, health status, and medications (U.S. Department of Health and Human Services, 2018).

Importance of Behavior Change in Fitness

An abundance of strong evidence exists, outlining the benefits of physical activity and fitness. A relatively small increase in oxygen uptake (VO_2)

of one metabolic equivalent (MET; 3.5 mL O_2/kg/min) is associated with large (10–25%) improvements in survival (Kaminsky et al., 2013). A 1000 kcal/week increase in physical activity (approximately 1-MET increase in fitness) leads to a 20% mortality benefit (Myers et al., 2004). Health benefits from physical activity and fitness occur in healthy people and those with established disease or disability and the literature consistently reports the benefits of good fitness and regular physical activity in all age categories and in every racial and ethnic group studied to date (Bull et al., 2020).

A large prospective study from 1989 studied physical fitness and risk of all-cause and cause-specific mortality in 10,224 men and 3120 women. Risk estimates for all-cause mortality suggest that low physical fitness is an important risk factor in both men and women and that higher physical fitness appears to delay all-cause mortality (Blair et al., 1989). This is primarily due to lowered rates of cardiovascular disease (CVD) and cancer (Blair et al., 1989). Another study including 122,007 patients from a tertiary care academic medical center between 1991 and 2014 (mean age 53.4 years, 59% male) found that cardiorespiratory fitness was inversely associated with long-term mortality and that there was no upper limit to this observed association (Mandsager et al., 2018). Extremely high aerobic fitness was associated with the greatest survival and was associated with benefits in older patients and those with hypertension (Mandsager et al., 2018). In summary, higher physical fitness from regular physical activity has a positive effect on reducing all-cause mortality.

In addition to decreasing mortality rates, improved fitness also has a positive effect on many other variables. Undeniable evidence exists in the literature highlighting the effectiveness of physical activity in the primary and secondary prevention of many chronic diseases (Bull et al., 2020; Booth et al., 2012; Warburton et al., 2006; Pronk et al., 1998; Reddigan et al., 2011; Taylor et al., 2004). These include cardiovascular disease (Reddigan et al., 2011; Alves et al., 2016), cancer (Thune & Furberg, 2001; Paffenbarger Jr. et al., 1992; Kampert et al., 1996), stroke, (Hu et al., 2000; Kurl et al., 2003), diabetes (Helmrich et al., 1994; Helmrich et al., 1991; Lynch et al., 1996), hypertension, (Diaz & Shimbo, 2013) and obesity (Blair & Brodney, 1999), among others (Bull et al., 2020). An adequate level of aerobic endurance is required to perform activities of daily living. It has been estimated that a minimum VO_{2max} of 15 mL/kg/min is necessary to maintain independence (Paterson et al., 2007). Good physical fitness from regular physical activity leads to longer independence, such that as people age, they do not need to rely on others for their activities of daily living as early nor as frequently. Healthcare costs have steadily increased in the United States for over 50 years. The longer one can stay independent and not have to rely on the healthcare system, the less money they need to spend.

Regular physical activity contributes to improved sleep (Kredlow et al., 2015), cardiovascular health (Nystoriak & Bhatnagar, 2018), promotes strong bones and muscles (Janssen & LeBlanc, 2010), and can help to maintain a healthy body weight and reduce fat stores (Swift et al., 2014). Good physical fitness does not only have physical benefits but also mental health advantages. For instance, regular physical activity improves cognition, depression, and anxiety and reduces stress (Rebar et al., 2015; Salmon, 2001; Saunders et al., 2020). We also know that both aerobic and muscle-strengthening fitness are beneficial.

The WHO has recently released guidelines which highlight that some physical activity is better than none (Bull et al., 2020); however, evidence suggests that as people reach 150–300 minutes per week of moderate-intensity physical activity, we see even more substantial health gains (WHO | Physical activity. World Health Organization, 2017). Furthermore, additional benefits occur as the amount of PA increases, such that the higher the intensity, greater the frequency, and longer the duration, the greater the health outcomes. In most cases, the risks of adverse outcomes or injury from regular physical activity are far outweighed by the benefits incurred.

Factors Influencing Physical Activity and Fitness

Despite well-consolidated benefits, most recent data published by *The Lancet Global Health* indicate that worldwide around 32% of women and 23% of men are not reaching the recommended 150 minutes per week of moderate–vigorous physical activity to stay healthy (Guthold et al., 2018). In 2016, more than a quarter of the worlds' adult population were considered insufficiently active, putting them at a greater risk of CVD, type 2 diabetes, dementia, and cancer (Guthold et al., 2018). While having a chronic disease, individuals seem to be more likely to adhere to physical activity and fitness recommendations. A systematic review including 3721 individuals with CVD, diabetes, or cancer reported an adherence rate of 74% and 80% to clinic-based and home-based programs, respectively (Bullard et al., 2019). The included studies focused on aerobic exercise interventions designed to meet the PA guidelines at a minimum of 150 minutes of moderate–vigorous aerobic activity per week. No differences between the three chronic diseases were reported for both adherence and dropout rates (Bullard et al., 2019).

Adherence to physical activity and fitness recommendations might be influenced by several factors, usually described as individual-, provider-, and system/environmental-level barriers and motivators (Tsujimura et al., 2018; Seefeldt et al., 2002). Figure 46.1 shows the most described barriers and motivators to physical activity and fitness highlighted in the literature.

Knowledge

Knowledge is considered as both a motivator and a barrier to physical activity and fitness (Baert et al., 2011; Costello et al., 2011). Knowing about the importance and benefits of being physically active may guide an individual's decision toward behavior change. Benefits that might motivate individuals to improve their physical activity and fitness level include those experienced in either a short- or a long-term perspective. The release of endorphins and serotonin experienced right after a physical fitness performance addresses important psychological issues, as it improves an individual's mood (Wegner et al., 2014), motivation (Bethancourt et al., 2014; Yi et al., 2016), self-confidence, and sleep and relieves stress (Simmonds et al., 2016; Bird et al., 2010). From a long-term perspective, knowing about benefits like improvements on an individual's balance, walking ability, sleep, and muscle strength, and reduction in muscle pain, morbidity, mortality, and hospitalization rates may motivate people to improve their physical activity and fitness level (Welmer et al., 2012; de Groot & Fagerström, 2011; Miller & Brown, 2017). Counseling on the perception of barriers including strategies to improve physical activity and fitness knowledge is recommended to achieving long-term behavior changes (Herazo-Beltrán et al., 2017; Bouma et al., 2015).

Conversely, a lack of knowledge may decrease physical activity and fitness levels. Not being aware about benefits of being physically active may lead individuals with health impairments and limitations to fearing physical activity and being dependent while exercising. Most commonly these feelings occur when there are difficulties in walking, physical weakness, and symptoms associated with chronic diseases (Simmonds et al., 2016; Bird et al., 2010; Eronen et al., 2014; Rowiński et al., 2017; Macniven et al., 2014; Gillette et al., 2015; Shiraly et al., 2017). Additionally, not knowing the most important physical activity (PA) recommendations to stay healthy contributes to the individual's misperceived belief that they already have good physical activity habits, and thus there is a lack of motivation to change behavior further (O'Neill & Reid, 1991; Hoare et al., 2017).

Time Constraints

Time is a system-level barrier to physical activity and fitness. In many countries and cultures, the responsibilities of taking care of children and managing the home environment occupy many

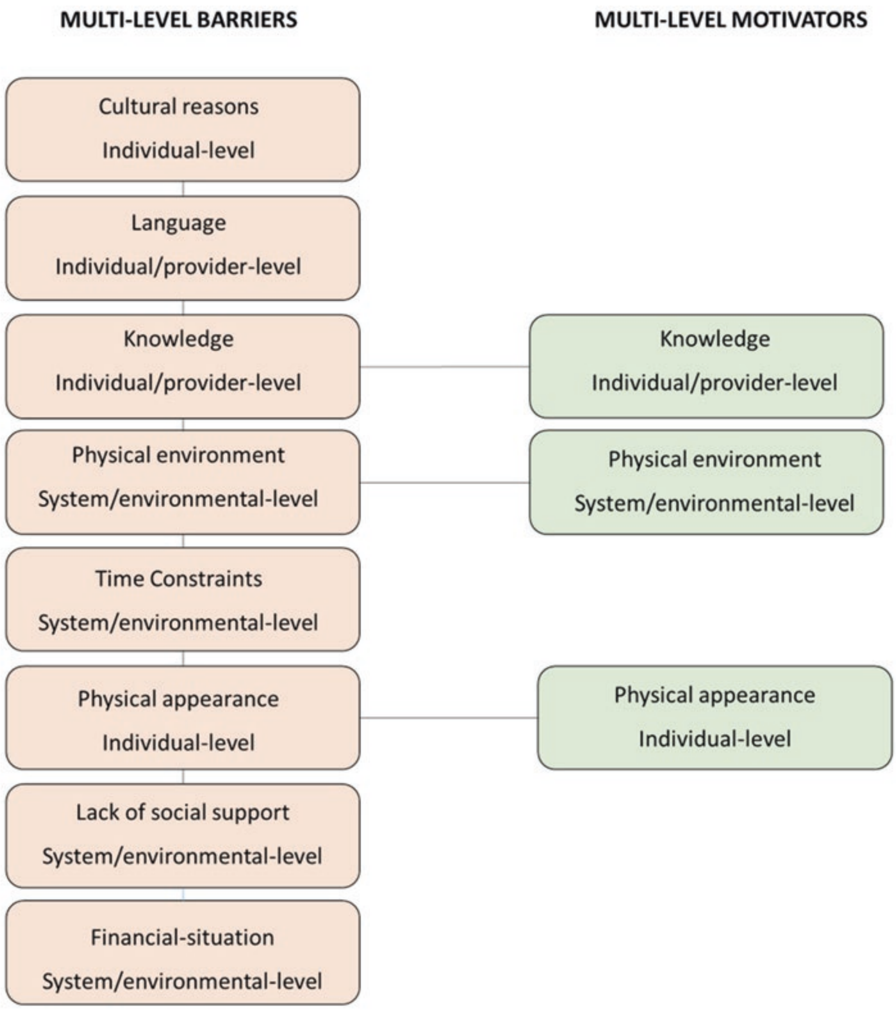

Fig. 46.1 Multi-level barriers and motivators to physical activity and fitness

hours in the day of adult caregivers, which negatively impacts the health behaviors of this population (Macniven et al., 2014). In adults and teenagers, the ability to perform physical activity is mainly influenced by social and family responsibilities, work hours, and putting academic success as a priority in life (Arzu et al., 2006).

Physical Appearance

Physical appearance is consistently reported as a motivator to physical activity and fitness, especially because of the association between weight loss/muscle gain and physical activity practice (Gavin et al., 2014). The perception and desires regarding the ideal body guide women to have higher body dissatisfaction compared to men. The internalization of the ideal body also differs between genders, as typically weight loss and being thin are desired by women and muscular bodies are desired by men (Fredrickson & Roberts, 1997). This indicates that there might be an interaction between an individual's self-perception and the extent to which an individual engages in health behaviors such as increases in physical activity (Hoare et al., 2017).

Physical Environment

Physical environment is considered as both a barrier and a motivator to physical activity and fitness. Many problems related to the environment have been reported in studies examining certain urban settings. Cited barriers include high crime rates, parked vehicles that impede access, obstacles along walking routes (e.g., potted plants, food retailers, broken sidewalks, scaffolds, snow accumulation along the street in winter), and lack of facilities such as benches for resting (Eronen et al., 2014; Shiraly et al., 2017; Chen et al., 2015; Chippendale & Boltz, 2015; Van Holle et al., 2015; Rantakokko et al., 2010). Alternatively, safe routes, pleasant landscapes, streetlights, sidewalks, bike riding routes, established walking paths, the neighborhood suitability for walking, interconnections between streets, environment free from threatening social activities (e.g., smoking, drinking alcohol, gambling), green space, benches for resting, a smooth surface for hiking, and good weather conditions seem to motivate the overall population for improving physical activity and fitness levels (Yi et al., 2016; Macniven et al., 2014; Chippendale & Boltz, 2015; Van Holle et al., 2015; Yoo & Kim, 2017).

Social Support

Social support is an important motivator to physical activity and fitness. Usually, more social support is needed for older than for younger cohorts because of waning independence (Baert et al., 2011; Miller & Brown, 2017). Close physical activity supervision and encouragement by fitness professionals has an important impact on adherence to physical activity reported by this older group. It has been suggested that by providing information and raising awareness about physical activity and fitness, providers augment the self-confidence of elderly individuals to begin their exercise regimens (de Groot & Fagerström, 2011). Social support provided by government and private institutions to improve access to adequate spaces or equipment that facilitate active lifestyles, as well as safe physical and social environments are recommended (Herazo-Beltrán et al., 2017).

Financial

Financial barriers to physical activity and fitness are reported by low-income populations as the number one cause of low PA levels (Steenhuis et al., 2009). The financial problems involve costs for membership of fitness clubs, and costs for clothing and equipment. Although some individuals identify they found a cheaper alternative to exercise (e.g., walking in a mall instead of exercising at a health club), this option might not be their preferred activity, which might also contribute to a low adherence to physical fitness observed in this population.

Language

Language is among the most important barriers that ethnic minorities face while engaging in physical activity and fitness programs. Insufficient communication might create misunderstandings and pose challenges to gain in-depth knowledge about the importance of physical fitness and the current guidelines and recommendations (Jacobs et al., 2004). It might also pose challenges to other medical treatments and negatively impact on the health of ethnic minorities in the long term (Al-Sharifi et al., 2019; Trinh et al., 2019). A language barrier is not only considered an individual-level barrier but also a provider-level barrier (Jacobs et al., 2004). The use of interpreters in physical activity and fitness programs and development of multi-language documents with a cultural repertoire to provide fitness education might help to engage with diverse groups and improve adherence in following overall health recommendations.

Designing Physical Activity and Fitness Interventions

Physical activity and fitness interventions aim to change a specific behavior pattern, such as being sedentary. An effective "behavior change intervention" should be designed based on factors influencing behavior change as well as the components and concepts involving the behavior system. Designing and planning the behavior change intervention is as important as the application of the intervention per se as it might directly influence motivation and adherence to behavior change.

Well-established behavioral researchers suggest that understanding factors influencing a specific behavior before designing the intervention is crucial to the development of strategies to improve motivation and overcome barriers (Michie et al., 2011). Next steps involve determining the broad approach that will be adopted and working on the specifics of the intervention design (Michie et al., 2011). In the behavior change model proposed by Michie and colleagues (Michie et al., 2011), the main components of the behavior system include capability, motivation, and opportunity. Those are key factors that interact with each other to guide a specific behavior, like exercising. Capability is *the individual's psychological and physical capacity to engage in the activity concerned*, including having the necessary knowledge and skills. Motivation is *all brain process that energize and direct a behavior*, including not only goals and conscious decision-making but also habitual processes, emotional responding, and analytical decision-making (Michie et al., 2011). Opportunity is a group of *factors that lie outside the individual to make the behavior possible* (Michie et al., 2011). When designing an intervention, it is important to keep in mind what components of the behavior system need to be changed in the individual. A full range of theory-based behavior change models exist and help the development and implementation of effective interventions to improve physical activity and fitness level.

Theory-Based Behavior Change Models

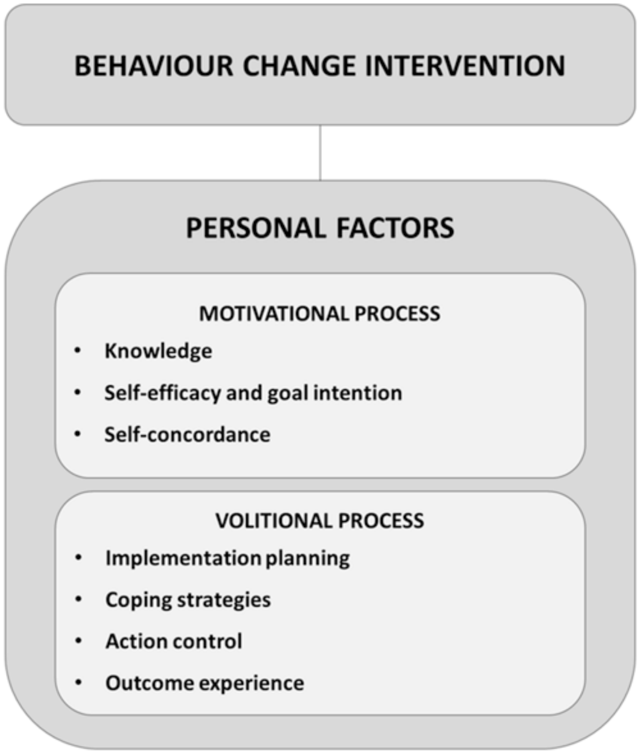
About 75 different theories have been described in the literature as effective options to promote health behavior change (Michie et al., 2011). It is important to highlight that having a broad number of theory-based behavior change models do not necessarily guarantee effectiveness of the intervention. The choice of a theory-based model that best fits with the program's main goals is key for a successful intervention. In clinical practice, most interventions seem to be designed based on a common-sense behavior change model (Michie et al., 2009). This opens a huge gap, as some theory-based models may not cover the full range of possible factors that influence behavior change, compromising the effectiveness of the intervention. Thus, systematic methods aimed to understand the nature of the behavior and identify components that can be used for its understanding are important (Michie et al., 2011).

In the literature, psychological theory-based models are well accepted to define personal determinants that might influence the initiation and maintenance of health behaviors, such as changing from a sedentary lifestyle to regular physical activity (Nieuwenhuijsen et al., 2006). Theory-based models such as the Health Action Process Approach (Schwarzer et al., 2011), the Integrative Model of Motivation and Volition for the Initiation of Regular Health-enhancing Physical Activity (Sudeck & Höner, 2011), and the Motivation-Volition (MoVo) Process model (Fuchs et al., 2011) are described as *neighboring psychological health behavioral change models* (Geidl et al., 2014), used to explain and predict physical activity behavior, integrate important findings from both social cognitive models and action control theories, and explain cognitive mechanisms of behavior change and exercise adherence. These theory-based models have as a consensus that a two-stage process to behavioral change should be taken into consideration while designing a behavior changing intervention. These stages are the motivational and volitional processes. Figure 46.2 illustrates components of the behavior change design process based on psychological theory-based behavior change.

Motivational Process

The motivational process involves knowledge, risk perception, outcome expectations, self-efficacy, goal intention, and self-concordance. These are factors associated with an individual's capability and motivation. Strong motivation is key for the development of the intention, which is essential for an effective behavioral change (Rhodes & de Bruijn, 2013). These modifiable

Fig. 46.2 Components of the designing behavior change process based on psychological theory-based behavior change



personal determinants and main related program goals for improving adherence to physical activity recommendations were summarized by Geidl et al. (2014). Those are described below.

Knowledge

In this stage, individuals should understand about the main exercise concepts (i.e., physical activity, exercise, fitness, types of exercise, intensity, duration, frequency, and progression), and outcome expectations like important health benefits associated with regular physical activity and exercise practice (i.e., feeling of well-being and reduced stress, improved health and fitness). It is also important to have an individual assess their physical activity behaviors in a realistic way and to understand the negative impact of being insufficiently active or sedentary (Geidl et al., 2012, 2014).

Self-Efficacy and Goal Intention

Individuals should be certain they need to be physically active on a regular basis and organize their routine to do it. Their life should be adapted for them to be overall physically active, and to plan effectively to respond to some relapses. Also, the pattern of the physical activity program should comply with and be assessed against the established guideline recommendations (Geidl et al., 2012, 2014).

Self-Concordance

The intention of being physically active should be guided by personal and internal reasons that are important and self-reinforcing. For example, physical activity practice is routine in their life, it is fun, and offers good experiences they tend to not want to miss it, and thus for them the benefits of being physically active are worth the effort (Geidl et al., 2012, 2014).

Volitional Process

The volitional process is a pre-action phase in which an individual decides and commits to a particular behavior change. In this preparatory phase, the individual considers and identifies the best method to meet their behavioral goal (Geidl et al., 2012; Caudwell et al., 2016). This process involves multiple stages including implementation planning, coping strategies, action control, and outcome experience (Geidl et al., 2012). These stages are described further below.

Implementation Planning

This stage includes the planning to incorporate physical activities into an individual's daily routine. Individuals will specifically identify the type and intensity of physical activities, and the frequency, duration, location, and other enablers for success in the activity to be carried out (Geidl et al., 2012, 2014).

Coping Strategies

In this stage, individuals will identify and recognize internal and external barriers to physical activity and create strategies to overcome barriers and improve motivation. They should also identify barriers that may lead to relapses, such as holidays or vacations, and develop a plan to keep their physical activity routine over these periods (Geidl et al., 2012, 2014).

Action Control

Action control refers to self-monitoring. Individuals must be able to continuously evaluate their physical activity behavior with regard to their goal intentions and physical activity recommendations and be aware of potential changes to their exercise programs or physical activity plan (Geidl et al., 2012, 2014).

Outcome Experience

In this stage, individuals identify potential positive effects of regular physical activity behavior and fulfilled former outcome expectations, and recognize the need to reach personal goals by being physically active on a regular basis (Geidl et al., 2012, 2014).

Measuring Fitness and Behavior Change Success

In order to evaluate the success of fitness behavior change interventions, a validated fitness assessment is invaluable. There are several ways to measure fitness and increased physical activity levels, including both objective and subjective tools and tests. Objective fitness tests often provide a more accurate value (Prince et al., 2008); however, they are sometimes more logistically challenging and expensive. A cardiopulmonary exercise test (CPET) is the gold standard for measuring maximal oxygen uptake (VO_{2max}), an indicator of cardiopulmonary fitness and exercise capacity (Cardiopulmonary & Testing, 2018). CPET involves the pulmonary, cardiovascular, hematopoietic, neuropsychological, and skeletal muscle systems and their combined overall responses to exercise (ATS/ACCP Statement on cardiopulmonary exercise testing, 2003). These tests are typically done using either a treadmill or cycle ergometer (ATS/ACCP Statement on cardiopulmonary exercise testing, 2003). A gold standard CPET can provide many output variables, the most important of which is VO_{2max}, for measuring fitness changes. For individuals who are not physically active at all, improvements in VO_{2max} can be seen in as little as 4–6 weeks. The fitter that an individual is at baseline, the longer it takes to see improvements in VO_{2max}.

When a CPET is not available, there are other objective methods of measuring fitness change. Many submaximal tests have been used in research and clinical settings; these estimate VO_{2max} values and are less costly, shorter in duration, and may be more accessible. The premise of estimating a VO_{2max} from a submaximal test is built from several assumptions. Primarily it is assumed that a linear relationship exists between VO_2 and heart rate (HR) within the range of 110–150 bpm (Heyward & Gibson, 2014). Therefore, the HR and work rate from two submaximal work outputs can be plotted against each other to extrapolate the HR_{max} and estimate VO_{2max} from submaximal data. However, we know that this relationship turns curvilinear at higher workloads decreasing the accuracy of submaximal tests to estimate maximal values (Heyward & Gibson, 2014). Submaximal exercise tests can be conducted on a variety of equipment including, treadmills, steps, cycle ergometers, and arm ergometers. Like the maximal tests, many of the exercise protocols involve a multi-stage ramped approach, where each subsequent stage becomes progressively more difficult using either speed or resistance/grade to increase intensity.

Other methods of measuring exercise capacity and physical fitness exist, that do not provide a VO_2 value. The Senior Fitness Test (SFT) was designed to assess physical fitness in older populations across a range of age groups and ability levels (Rikli & Jones, 2013). The SFT is a comprehensive battery of tests that provide information related to upper and lower body strength, aerobic endurance, upper and lower body flexibility, agility, and dynamic balance (Rikli & Jones, 2013). There is typically no overall score related to SFT but instead individual values can be compared to population norms for each of the different test components. Changes in the SFT over time provide a good indication of overall fitness changes that can be related to changes in physical activity behaviors. For older adults, this can translate to more independence for a longer time.

The 6-minute walk test (6MWT) is a commonly used assessment to measure functional exercise capacity (*American Journal of Respiratory and Critical Care Medicine*, 2002). The 6MWT evaluates the integrated responses of the pulmonary and cardiovascular systems (*American Journal of Respiratory and Critical Care Medicine*, 2002), and is commonly used in individuals with lower aerobic capacity. Typically, individuals do not achieve maximal exercise capacity and therefore it reflects the functional exercise level achieved during daily activities more than a CPET.

When objective testing is unavailable, self-report options are available to measure change related to fitness and physical activity. The validated Duke Activity Status Index (DASI) is a questionnaire that asks the user to determine whether they can perform a variety of everyday physical activities (Hlatky et al., 1989). Each question is weighted and scored based on the known metabolic cost of each activity in metabolic equivalent of task units (Hlatky et al., 1989). The responses are added together and used to estimate the individuals' VO_{2max} (Hlatky et al., 1989). The DASI is an effective tool to measure fitness. There are a number of other validated questionnaires to measure physical activity levels. The Godin Leisure Time Physical Activity (Amireault & Godin, 2015; Godin & Shephard, 1985) and the International Physical Activity Questionnaires (Craig et al., 2003) are among the most commonly used self-report tools used to measure physical activity levels. Tracking physical activity levels would allow one to measure the success of behavior change related to fitness.

Use of Technology/Wearable Devices to Improve and Motivate Behavior Changes

Each year technology access and use increases. As of July 2020, 4.57 billion people worldwide were active Internet users, equating to approximately 59% of the world population (Clement, 2020). Technology offers an accessible, cost-effective, and time-efficient approach for the promotion and assessment of exercise behavior change (WHO | eHealth. World Health Organization, 2017). As technology develops, options to monitor fitness and physical activity levels have become more widely available. There are a variety of ways technology can be used to improve and motivate behavior change. Among these options are websites, activity tracking wearable devices, smartphone applications, and text messages. A recent systematic review ($n = 60$ studies) and meta-analysis ($n = 20$ studies) summarized the effectiveness of eHealth technologies to improve moderate-to-vigorous physical activity in the short term in working-aged women (Cotie et al., 2018). The meta-analysis demonstrated eHealth interventions improved moderate-to-vigorous physical activity on average by 25 minutes/week (Cotie et al., 2018). The American physical activity guidelines suggest individuals should complete a minimum of 30 minutes/day of MVPA (Piercy & Troiano, 2018), suggesting that eHealth interventions could act as a stepping stone to achieve these behaviors. In the last decade, wearable fitness tracking devices have become more popular.

Wearables are technology or devices incorporated into items that can be comfortably worn on the body. These devices are used for tracking information in real time and include fitness trackers, smartwatches, heart rate monitors, and Global Positioning System (GPS) tracking devices. Many of them have various sensors built in to track health parameters (steps, calories, heart rate, etc.). The idea is that by recording and reporting information about behaviors, the device can then motivate and educate people toward behavior change. Fitness behavior changes could lead to meaningful improvements in overall health, but likely only if they are long term and sustained. Despite the short-term success many people experience using wearable technologies, there is very little evidence to suggest the sustainability of their benefits. There is a large gap in knowledge between recording behavior and making the necessary changes. Wearable devices tend to be targeting individuals who are already motivated to change, suggesting they are tools that can be used to facilitate but are likely not drivers of behavior change (Patel et al., 2015). Research is ongoing when it comes to the use of technology to promote fitness and physical activity behavior change.

Summary

Physical inactivity is a very common issue around the world and is associated with the development of many frequently occurring and costly chronic physical and mental health conditions. There are many national and international guidelines around physical activity and exercise that all support the recommendation that our entire population across the age spectrum needs to move more each and every day. Physical activity and exercise plans should include being less sedentary along with a mix of aerobic, resistance, and balance activities throughout the day and week. Recommendations can be adjusted to meet the needs and preferences of each person according to age, ability and comorbidity. The evidence for adoption of regular physical activity is very compelling including reductions in the incidence and improved management of chronic diseases like diabetes, heart disease, certain cancers, mental health issues, and overall improved survival. Successful behavior change can be complex. Addressing knowledge gaps about the importance of physical activity and understanding of individual circumstances, motivators, and barriers is key. Designing physical activity interventions requires thoughtful planning and application of behavior change models appropriate to the setting and population. Once implemented, the effects of the intervention should be evaluated through quantification of fitness measures and physical activity patterns. There are many validated measures of fitness ranging from laboratory based cardiopulmonary stress testing, functional assessments, to questionnaires. New technologies, such as wearable devices, can be very helpful in these assessments and may also aid in the adoption of regular physical activity.

47 The Good Behavior Game

P. Raymond Joslyn and Emily A. Groves

Introduction

The Good Behavior Game (GBG) was first described by Barrish et al. (1969) as a classroom management procedure for fourth-grade students. In this intervention, researchers divided the class into two teams and asked students to follow specific classroom rules (e.g., receive permission before leaving their seats or talking). Whenever a student broke one of the rules, their team received a mark on the board and teams with less than six marks at the end of the 30-minute period won the game. If both teams had more than five marks at the end of the period, the team with the lowest score won. Winning teams received extra privileges such as lining up early for lunch, wearing "victory tags," and free time at the end of the day. The GBG produced substantial reductions in inappropriate talking out and out-of-seat behavior (see Fig. 47.1).

Since this initial evaluation, the GBG has been replicated and extended in a range of education settings, showing consistent effects on student behavior (Bowman-Perrott et al., 2016; Flower et al., 2014a; Tingstrom et al., 2006). Behavioral research has repeatedly demonstrated that the GBG produces immediate and substantial effects on student behavior such as disruptive talking out, out-of-seat behavior, and off-task behavior. As we will discuss below, researchers have also demonstrated increases in other behaviors such as class participation and physical exercise. The considerable empirical support for the GBG has established it as a best-practice intervention in education, and it may be implemented in schools as a Tier 1 (preventive) or Tier 2 (targeted) intervention in the Positive Behavior Supports framework (Horner et al., 2005; Wright & McCurdy, 2011). It has also been shown to be a robust procedure, remaining effective under challenging conditions, low levels of treatment integrity, and given procedural modification.

In addition to the immediate short-term effects on student behavior, longitudinal research has demonstrated that the GBG may benefit students later in life. When implemented with young students (i.e., in first or second grade), the GBG has been demonstrated to reduce rates of substance abuse disorders, incarceration for violent crimes, risky sexual behavior, and other undesirable outcomes in adulthood (Kellam et al., 2008, 2011, 2014). Although the findings are promising, it should be noted that the exact mechanisms for these changes are not known. Later in this chapter, we will discuss possible underlying mecha-

nisms that may be responsible for the short- and long-term effects of the GBG.

Despite its substantial literature base, there are still important unanswered questions about the GBG, and it remains underutilized in education (Joslyn et al., 2019b; Stormont et al., 2011). Understudied areas related to the GBG include applications in novel settings outside of education, determining its underlying behavioral mechanisms, methods for streamlining and optimizing the procedure, and ways to improve contextual fit. As researchers address these questions, the task of effectively disseminating the GBG to educators will become more feasible. Currently, however, the extensive literature base and large number of variations and applications may make it difficult to provide clear treatment directions in clinical scenarios. In this chapter, we will discuss the specific procedures and common variations of the GBG, scenarios in which the GBG has been demonstrated effective, key considerations for implementation, and the potential mechanisms responsible for behavior change. We will conclude with a discussion of the current limits to our knowledge and understanding of the GBG, including areas in which more research is needed.

Good Behavior Game Procedures and Variations

The original GBG article (Barrish et al., 1969) established the framework for the GBG that is implemented today. Although published demonstrations vary in terms of procedures and behavior goals, implementation of the GBG typically includes establishing rules, delivering marks or points to teams whose members break the established rules throughout the game, and rewarding teams who remain below some point threshold at the end of the game. Because students typically "work together" to win the game, accessing rewards is contingent on team members' behavior as well as their own, making the GBG an interdependent group contingency (Litow & Pumroy, 1975).

It is recommended that behavior analysts collaborate with teachers or other stakeholders when designing a GBG intervention. This will improve social validity outcomes and facilitate data collection. Typical design of the GBG for a specific classroom consists of:

1. Selecting and establishing the rules of the game targeting the most problematic student behavior (e.g., vocal disruption).
2. Determining when the GBG will be implemented (e.g., math class) and for how long (e.g., 30 minutes).
3. Selecting the rewards students will receive for winning the game (e.g., small snacks, extra free time, and classroom privileges).
4. Baseline data collection to determine the point threshold and monitor effectiveness. Point thresholds may be based on rates of problem behavior in baseline or selected arbitrarily.

Once the above parameters have been set, implementation consists of:

1. Dividing a class into teams. Ideal team selection involves equally distributing students likely to engage in high rates of problem behavior and likely to serve as models for appropriate behavior to other students equally across the teams.
2. Writing the rules and teams on the board or otherwise displaying them where they are visible to all students. In some cases, teachers may prefer to use a computer- or web-based implementation platform where points can be delivered remotely. See Fig. 47.2 for an example of a GBG board display.
3. Introducing the game to students. This consists of explaining the rules of the game, who is on which team, and describing or showing students what rewards are available to winning teams.
4. Announcing the beginning of the game.
5. Throughout the game, the implementer should deliver a mark and feedback to a team whenever a team member breaks a rule. This consists of saying something like, "Team 1, remember to raise your hand and receive permission before you leave your seat," and placing a hatch mark under their team on the game display.
6. At the end of the game, the implementer announces that the game is over, counts the points, and announces the winners. Then, rewards are delivered to the winning team(s) immediately.

   *See Joslyn et al. (2020) for a more detailed guide to planning and implementing the GBG for practitioners.

GBG Variations

A large proportion of recent GBG research has followed similar procedures to those listed above. However, there are also several ways in which these components may be varied in an effort to improve effectiveness, address specific classroom needs, and improve contextual fit for teachers. Variations of the GBG with empirical support include contingency modifications such as awarding points for appropriate behavior, response cost, and independent group contingencies. Researchers have also conducted component analyses and explored using point thresholds and rewards that are not revealed to students until the game is over. Below, we will describe each of these variations and their empirical support.

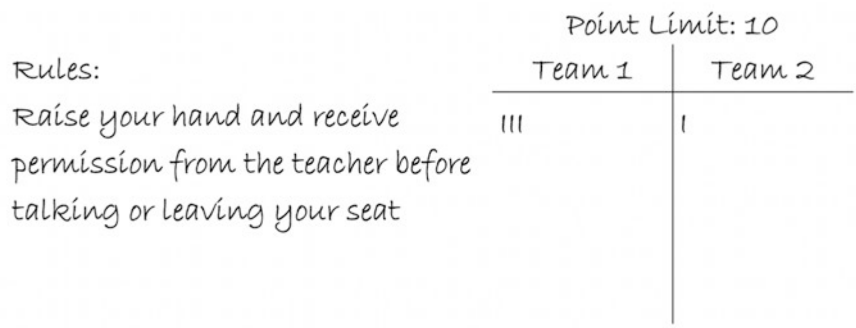

Fig. 47.2 An example board display for the GBG

The "Caught Being Good Game"

In one of the most common GBG variations, the group contingency is placed on rule following rather than rule breaking. That is, students are awarded desirable points for being in compliance with the rules and win the game by exceeding the point threshold. On a time-based schedule, the implementer scans the rooms and awards points to teams whose members are all following the rules. This variation, sometimes referred to as the Caught Being Good Game (CBGG), has been demonstrated to be similarly effective to the GBG although there have been relatively few comparison studies (Tanol et al., 2010; Wahl et al., 2016; Wright & McCurdy, 2011).

Although the CBGG produces similar effects to the standard GBG arrangement, it has advantages and limitations. There are at least three contexts in which the CBGG can be advantageous. First, because the contingency is placed on appropriate behavior rather than inappropriate behavior, it may be preferred by some teachers or school administrators (Tanol et al., 2010). Although the GBG and its variations are reinforcement based and social validity data indicate that most students enjoy playing the game (Joslyn et al., 2019b), stakeholders may view the marks delivered in the traditional GBG as punitive or disciplinary (we will discuss mechanisms of behavior changer later in this chapter). A second potential advantage of the CBGG is in its interval-based implementation, which may make it more suitable for targeting continuous (non-discrete) behaviors such as on-task behavior. Targeting continuous behaviors may be more challenging with the traditional GBG arrangement due to the continuous schedule of point delivery; whenever a rule is broken, a mark should be delivered. It is not generally feasible for a teacher to deliver a point whenever any student stops being on task for a few moments. However, for discrete behaviors like calling out, the CBGG may be less suitable due to the delay in feedback inherent in the procedure. For example, if the CBGG is being implemented on a 3-minute schedule, a student who calls out early in the interval may not receive feedback on their behavior for up to 3 minutes. This could make the GBG more appropriate for younger students who have difficulty with delayed consequences. Third, some teachers may prefer the time-based schedule of the CBGG over the continuous schedule of the GBG. Comparison studies have indicated that some teachers prefer the less frequent but more effortful scoring of the CBGG, while others prefer the more frequent but less effortful scoring of the GBG (Wahl et al., 2016). Point delivery can be disruptive to instruction, so it is important to consider teacher preference when arranging the GBG in their classrooms. The class activity during which the game will be played may also be relevant during the design of the intervention. For example, a teacher may find the continuous schedule of the GBG more feasible when students are working independently or prefer the CBGG when they are delivering instruction.

Response Cost

Another variation of GBG procedures involves the use of a response cost component in the intervention (Leflot et al., 2010; Silva & Wiskow, 2020; Tanol et al., 2010). In this variation, students are given a certain number of points at the start of the game and points are removed contingent upon rule violations. In the response cost variation, teams win by having a certain number of points left at the end of the game. Tanol et al. (2010) compared the GBG variation in which points were awarded for rule following (i.e., the CBGG) to a response cost variation of GBG and found that while both versions of the game were effective at reducing rule violations, the teacher preferred awarding points for rule following. Silva and Wiskow (2020) compared the original GBG to a response cost GBG and also found that both interventions were effective; however, the teacher appeared to prefer the response cost GBG and chose to implement this version when given a choice. The teacher reported that she found it easier to play the response cost GBG than the original GBG. The response cost adaptation is uncommon in the GBG literature relative to other variations. However, the response cost GBG may be a viable option for teachers who do not prefer the traditional GBG or CBGG variation.

Independent Group Contingency

Implementers may also choose to implement an independent group contingency rather than an interdependent group contingency during the GBG. In an independent group contingency, common rules and criteria are applied to the group and each individual's access to rewards is based solely on their own performance (Litow & Pumroy, 1975). That is, each student is effectively "on their own team." There have not been many direct comparisons of the traditional arrangement and the independent arrangement. However, Groves and Austin (2017) conducted a comparison of the two contingencies and found them to be similarly effective, although social validity data indicated that the teacher and a majority of students preferred the interdependent contingency. This variation may be advantageous with students who struggle with working collaboratively on a team, such as some students with emotional and behavioral disorders. However, the independent arrangement of the GBG is unlikely to support these students in improving peer interactions and relationships. Working together on a team may help these students gain social skills.

"Mystery" Win Criteria

Researchers have also explored the utility of an "unknown" or "mystery" win criterion in the GBG, meaning that the criterion to win the game varied across sessions and was not revealed to students until the end of the game. Studies using a "mystery" win criterion indicated characteristic GBG effects; immediate and substantial improvements in student behavior (Flower et al., 2014b; Lannie & McCurdy, 2007; Wahl et al., 2016; Wright & McCurdy, 2011), but there have been few studies that have directly compared known and unknown win criteria. Groves and Austin (2020) compared GBG implementation with known and unknown win criteria and found that both variations were equally effective, but teachers preferred the unknown criteria and student preferences were mixed. The utility of this variation will be discussed further in the implementation considerations section later in this chapter.

Component Analyses

One of the most effective ways to examine the limits of procedural variations could be to conduct component analyses. However, there have been few component analyses with the GBG. In a notable exception, Foley et al. (2019) conducted a component analysis of the GBG with preschool students. Beginning with classroom rules only, they incrementally added feedback for rule violations, a win criteria, and noncontingent reinforcement. However, they found that all components of the GBG were required to decrease disruptive behavior. Other researchers have opted to examine variations of specific components such as feedback for rule violations. Wiskow et al. (2019) compared different types of feedback for rule violations (i.e., no feedback, visual, vocal, and both) with preschool students, and found that vocal feedback was required to produce notable decreases in disruption. It is important to note that both of these studies were conducted with general education preschool students and their findings may not extend to other student populations. For example, middle- or high-school students may not require as salient feedback or the implementation of all traditional GBG components for behavior change.

Teacher Preferences

It is worth noting in this section that teacher preferences across studies and variations are inconsistent and likely idiosyncratic. Although most GBG research indicated teacher preference for the GBG over no intervention (cf., Joslyn et al., 2019a), preferences between variations of the GBG vary across studies and participants. For example, teachers in Wahl et al. (2016) indicated mixed preferences for traditional GBG and the CBGG variation, citing the point delivery schedules as a factor in their preference. In addition, although a teacher may indicate preference for the GBG, there can be components of the procedure that they find aversive or effortful which may be detrimental to sustainability over time (Joslyn et al., 2019a). Therefore, researchers and practitioners working with teachers should be aware of the established variations, their empirical support, and how they are implemented. Presenting teachers with choices and alternatives can improve contextual fit, resulting in faster adoption of procedures, higher treatment integrity and quality, and intervention sustainability (Johnson et al., 2014).

Applications

Given the versatility of the GBG, it may not be surprising that it has been implemented in a wide array of contexts. Behavioral researchers have extended the GBG beyond the fourth-grade classroom to a range of student ages, in different settings, and to address various forms of behavior beyond classroom disruption.

Student Population Characteristics and Settings

The GBG is most commonly implemented in elementary schools (Bowman-Perrott et al., 2016; Flower et al., 2014a) to reduce student disruption and increase on-task behavior (e.g., Lannie & McCurdy, 2007; Lynne et al., 2017; Wright & McCurdy, 2011). Bowman-Perrott et al. (2016) conducted a quantitative analysis of GBG studies and found that the majority were conducted with students in kindergarten through to fifth grade. Although the majority of published research has been conducted with this student age group, recent research has shown that the GBG can be equally effective with a range of student ages.

The GBG has also been evaluated in preschools with students as young as 4 years old (e.g., Foley et al., 2019; Swiezy et al., 1993; Wiskow et al., 2019). Swiezy and colleagues implemented the GBG in a preschool with children who were reported to be particularly disruptive and noncompliant. During the GBG, children worked in pairs and a “Buddy Bear” puppet provided regular instructions to the children (e.g., “Get a book from the bookcase”). When both children complied, they were given a smiley face or dinosaur token and each pair could win the game by meeting a specific point criterion that was individualized for each pair. Winning pairs received a small animal-shaped snack. The GBG was effective at increasing compliance with instructions in all pairings of children. More recently, Wiskow et al. (2019) demonstrated that variations of the GBG were effective at reducing disruption in preschoolers, with the strongest effects demonstrated when students were provided vocal feedback (alone or in combination with visual feedback).

Applications of the GBG with older students are more limited. However, researchers have demonstrated that the GBG can be effective with students up to high school and college age. Kleinman and Saigh (2011) extended the GBG to a ninth-grade classroom in a high school. The GBG was played daily and winners received a bite-sized piece of candy (identified as preferred via a student preference assessment questionnaire). The team with the lowest number of points at the end of the week was declared the "weekly winners" and received a special pizza party. The GBG was effective at reducing verbal disruption, seat leaving, and aggression, and a social validity assessment revealed that students and teachers responded favorably to the GBG. Other researchers have also successfully implemented the GBG in secondary school settings (e.g., Flower et al., 2014b; Joslyn et al., 2019a; Mitchell et al., 2015); however, the GBG should continue to be studied with this population to further understand potential age and population differences.

In a unique application, Cheatham et al. (2017) used a modified version of the GBG in three introductory psychology courses to increase class participation (i.e., hand raising) in college classrooms (see Fig. 47.3). In this application,

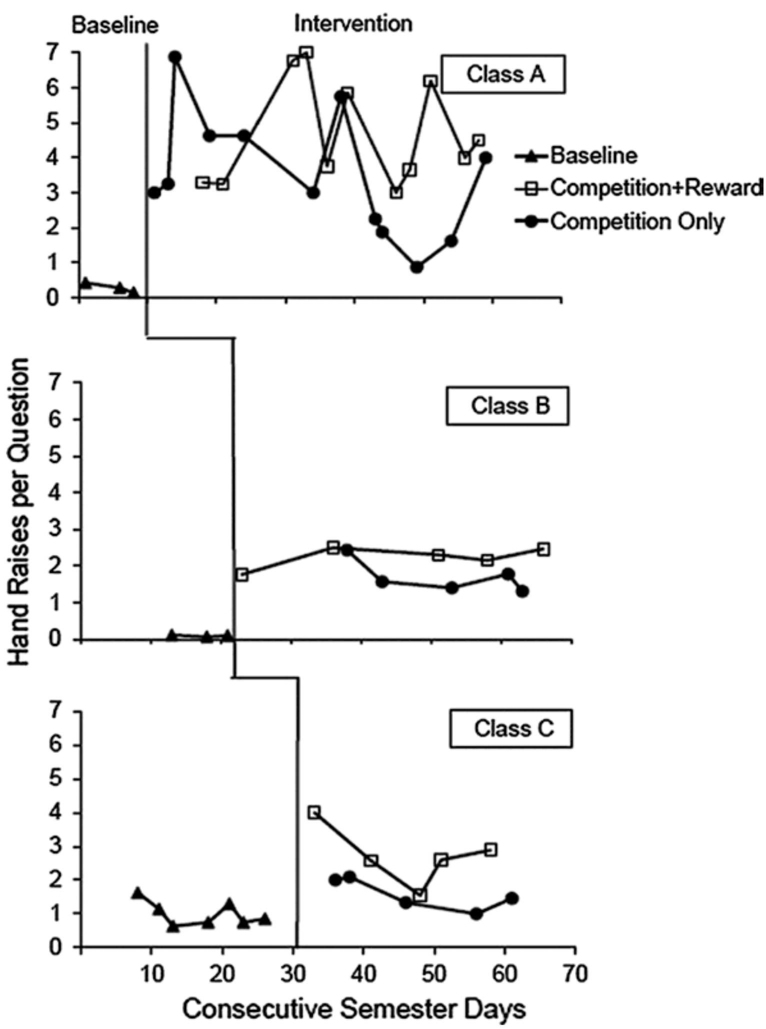

Fig. 47.3 Class participation data from Cheatham et al., 2017

each class was divided into two teams and a tally mark was awarded to a team if a member of the team raised their hand and answered a question correctly during a lecture. A team won the game by having more tally marks at the end of the lecture than the other team. This is a slight departure from typical GBG procedures, as traditionally teams compete against a fixed criterion, rather than each other (Barrish et al., 1969). Two versions of the GBG were compared in this study; in one condition (competition plus reward) the winning team received a reward (one activity point) upon winning and in another condition (competition only) the winning team did not receive a reward. Cheatham et al. found that both versions of the GBG were effective at increasing hand raising in all classes, with the competition plus reward condition producing slightly greater increases in hand raising.

The majority of GBG evaluations have been conducted with students of typical development in general education classrooms (Bowman-Perrott et al., 2016; Flower et al., 2014a). However, the GBG has also been extended to students with autism and intellectual disabilities (e.g., Breeman et al., 2016; Vargo & Brown, 2020; Wiskow et al., 2018). Vargo and Brown (2020) implemented the GBG in a special education structured learning classroom, with six high school students with autism. The researchers compared the effectiveness of the traditional GBG with technology enhanced GBG variations (GBG with ClassDojo and ClassBadges). All GBG variations were found to be effective at reducing disruptive behavior displayed by students. In another evaluation with children with disabilities, Wiskow et al. (2018) implemented the GBG in a small-group setting to successfully reduce the disruptive behavior of a 4-year-old boy with fetal alcohol syndrome. As previous research indicates, the GBG might provide a simple and effective strategy to reduce problematic behavior with students with disabilities. Although the recent GBG research in special education is encouraging, further research should be conducted to enhance our understanding of the effects of the GBG when used with students of varying degrees of intellectual disability and to evaluate the extent to which adaptations may be necessary.

Alternative education (i.e., schools for students with emotional and behavioral disorders who engage in severe problem behavior) is another setting with a strong and growing GBG literature base (e.g., Groves & Austin, 2017, 2019; Joslyn et al., 2014, 2020; Joslyn et al., 2019a; Rubow et al., 2018; Sy et al., 2016). Group-oriented contingencies like the GBG might prove particularly useful in these settings due to the likelihood that many students in the classroom will engage in high levels of problem behavior. Joslyn et al. (2019a) implemented the GBG in three high school classrooms with students with EBD and histories of delinquency. The GBG targeted disruptive behavior (talking out and out-of-seat behavior) in these classrooms, due to the high frequency at which these behaviors occurred. The authors used a modified GBG, whereby students in each class were placed on one team (as opposed to multiple, smaller teams as is typical in the GBG; Barrish et al., 1969). This modification was made due to the smaller class sizes in this setting and to prevent students from “sabotaging” the game for other students by taunting students on opposing teams into breaking the rules. The GBG was successful at reducing disruptive behavior in all classrooms.

Rubow et al. (2018) also implemented the GBG in two classrooms with students with EBD and/or severe problem behavior in an alternative school. The GBG effectively reduced disruptive behavior in both classrooms, increased teacher praise delivery relative to reprimands, and social validity assessments found that students and staff rated the GBG positively. Both of the aforementioned studies conducted in alternative education settings targeted high-frequency, low-intensity behaviors. Future research should address the potential of targeting these behaviors to prevent high-intensity problem behavior (e.g., aggression toward others, property destruction) from occurring in alternative education classrooms, as in some cases they can be precursor behaviors.

Target Behavior

Targeting low-intensity disruption is common in GBG studies. Previous reviews have found that the GBG typically targets behaviors such as calling out without permission, inappropriate sitting, seat leaving, verbal disruption, and physical disruption (Bowman-Perrott et al., 2016; Flower et al., 2014a). These disruptive behaviors are often combined into one "disruption" or "inappropriate behavior" measure in GBG studies. For example, Donaldson et al. (2011) used the GBG to reduce out-of-seat behavior, talking out of turn, and touching other students in five elementary school classrooms. The GBG is also commonly used to reduce off-task behavior (Flower et al., 2014b; Groves & Austin, 2017; Groves & Austin, 2020) and increase on-task behavior (Pennington & McComas, 2017; Lannie & McCurdy, 2007). Researchers have targeted other behaviors including aggression and property destruction (Kleinman & Saigh, 2011), swearing (Groves & Austin, 2019; Salend et al., 1989), and cell phone use in class (Groves & Austin, 2019).

Although typically used as a reductive behavior change strategy, the GBG has also been used to increase students' academic behaviors. Lynne et al. (2017) and Wahl et al. (2016) used the GBG to successfully increase students' academic engagement. Darveaux (1984) used the GBG to increase assignment completion and active participation in class, in addition to reducing problem behavior. Weis et al. (2015) evaluated the effects of the GBG on reading and mathematics in a large-scale study that included students from six school districts in the United States. The GBG was implemented in elementary classrooms across one academic year to measure the effects on academic behaviors. The study found that the GBG resulted in a statistically significant increase in basic academic skills in students who received the GBG, when compared to students in the control group who did not receive the GBG.

The GBG has also been applied to increase students' prosocial behavior. Patrick et al. (1998) evaluated the GBG in the context of volleyball games in physical education classes in an elementary school. Teams were awarded points during the GBG for appropriate social behaviors, including physical contact that was supportive in nature (e.g., pat on the back), supportive verbal statements between teammates (e.g., "good job"), and supportive gestures (e.g., thumbs up). Points were deducted from teams who displayed inappropriate social behaviors, including offensive physical, verbal, or gestural acts. The GBG was found to be effective at increasing appropriate social behaviors and decreasing inappropriate social behaviors during volleyball games.

In the classroom, Salend et al. (1989) measured students' negative comments directed toward peers (e.g., name calling), complaining about assignments, and complaining about the teaching, among other behaviors. The study was conducted in a residential school with "emotionally disturbed" students. The GBG was found to be effective at reducing all target behaviors, including negative comments and complaining about assignments or teachers. Groves and Austin (2019) further extended the GBG literature by directly measuring positive peer interactions (as well as negative peer interactions) in a primary and secondary school classroom (see Fig. 47.4). They reported that students in these classrooms had social skill deficits and poor relationships with one another and found that the GBG resulted in an increase in positive peer interactions and a decrease in negative peer interactions in both classrooms. Interestingly, the peer interactions measured in this GBG were not targeted in the GBG rules. That is, there were no contingencies in place to increase positive peer interactions or decrease negative peer interactions. This suggests that the changes in positive and negative peer interactions are welcome side effects of the GBG, rather than direct effects.

As well as evaluating the effect of the GBG on student behaviors, some researchers have measured teacher behaviors, including use of praise statements and feedback to students. Wahl et al. (2016) investigated the effect of the GBG on teacher's positive and negative statements. Positive statements included acknowledgement of rule following (e.g., "I like how everyone is focused on our work") and negative statements included disapproval of student behavior or lack

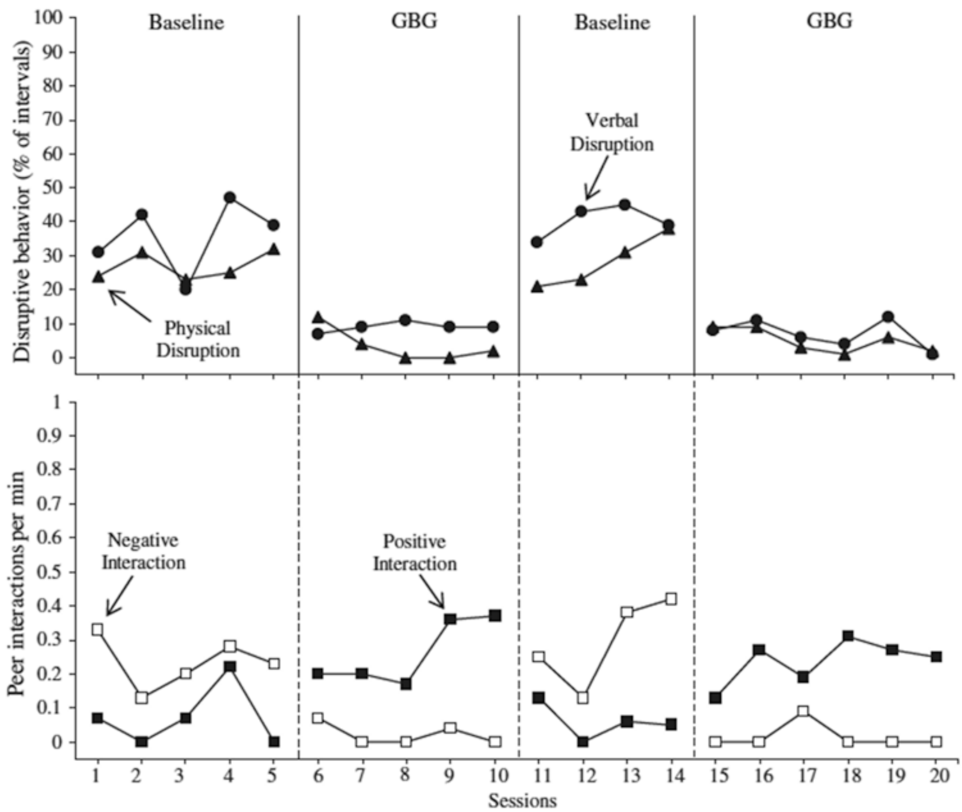

Fig. 47.4 Problem behavior and peer interaction data from Groves and Austin (2019)

of rule following and redirection (e.g., "Stop tapping your pencil on the desk, please"). The GBG did not result in an increase in positive teacher statements, nor did it decrease negative teacher statements. Conversely, Tanol et al. (2010) found that the GBG did result in a modest increase in teachers' use of praise statements. More recently, Rubow et al. (2018) found that the GBG resulted in an increase in teachers' use of praise statements relative to reprimands. Interestingly, the authors in this study did not specifically train teachers to provide praise statements and no contingencies were in effect for doing so. Rather, teacher praise statements seemed to be affected indirectly by the GBG.

The GBG has also been applied in contexts outside of the classroom, for example, in the library (Fishbein & Wasik, 1981), the cafeteria (McCurdy et al., 2009), and during school recess (Galbraith & Normand, 2017; Normand & Burji, 2020; Patrick et al., 1998). Fishbein and Wasik (1981) measured task-relevant behaviors, off-task behavior, and disruptive behavior in fourth graders during weekly library periods. The GBG was implemented by the librarian and the rules were centered around appropriate library etiquette (e.g., "if you talk, talk quietly" and "choose a library book or look at library materials"). The GBG was effective at increasing task-relevant behaviors and reducing off-task and disruptive behaviors. McCurdy et al. (2009) implemented the GBG in the cafeteria, which they referred to as the Lunchroom Behavior Game (LBG). The LBG was effective at reducing seat leaving, play fighting, physical contact between peers, throwing objects, and screaming during school lunch periods. In another novel application, Galbraith and Normand (2017) extended the GBG to school recess in order to increase physical activity in elementary school students. They measured the number of steps taken by students during recess via a pedometer. Students were divided into teams at the start of recess and the team who took the most steps was rewarded. The results showed that students took more steps during recess while playing the GBG than they did when the GBG was not played. These unique applications highlight the generalizability and flexibility of GBG procedures.

Previous reviews of the GBG literature suggest that the vast majority of applications have been conducted in the United States (Bowman-Perrott et al., 2016). However, there have been many noteworthy contributions to the GBG literature from outside of the United States (Nolan et al., 2014), including demonstrations from Belgium (Leflot et al., 2010), Belize (Nolan et al., 2013), Canada (Dion et al., 2011; Kosiec et al., 1986), Chile (Perez et al., 2005), the Netherlands (van Lier et al., 2004; Dijkman et al., 2015), Spain (Ruiz-Olivares et al., 2010), Sudan (Saigh & Umar, 1983), and the United Kingdom (e.g., Coombes et al., 2016; Groves & Austin, 2017; Phillips & Christie, 1986). However, in some of the above cases, the GBG was implemented in conjunction with other interventions (e.g., peer tutoring), limiting the extent to which we can draw conclusions about the effects of the GBG as a standalone intervention across cultures.

It is important to note that, although the GBG has been indicated effective in all of the above applications, there are key considerations for maximizing the likelihood of success. In addition, procedural variations have frequently been utilized in an attempt to optimize the intervention for a given setting, improve contextual fit, or explore specific variables in research. In the next section, we will discuss several key implementation considerations that can increase the likelihood of success across applications.

Implementation Considerations

The literature provides important considerations for implementing the GBG. However, not all aspects of GBG implementation have been experimentally manipulated. In this section, we discuss key aspects of GBG implementation and training that are supported by the empirical literature. We have supplemented this section with anecdotal information from the literature (e.g., Joslyn et al., 2020) and our collective experience for topics not yet addressed by researchers.

Designing the Good Behavior Game

An important first step in implementing the GBG is choosing the rules of the game. As mentioned previously, the GBG is typically used to reduce low-intensity disruptive behavior such as calling out, out of seat, and physical disruption, and to increase appropriate behaviors such as participation in class and assignment completion. The target behaviors (i.e., the behaviors targeted for decrease/increase) should be addressed by the rules of the game. For example, if you would like to reduce calling out in class, then a rule of the game may be, “Raise your hand and receive permission before talking.” There are typically between two to four rules in the GBG that cover the most problematic behaviors in the classrooms, as most problem behavior in the classroom can be addressed with just a few rules as long as they are carefully designed. The rules of the game should be developed with the teacher to ensure they cover the most pressing issues and also align with current behavior management practices in the classroom.

In the GBG, a class is typically divided in half to create two teams. However, the exact number of teams and how many students are in each team generally depends on the size of a class. Some studies have successfully implemented the game with three or more teams (e.g., Groves & Austin, 2020; Lynne et al., 2017), whereas some studies with smaller numbers of students per class have chosen to use the whole class as one team (e.g., Groves & Austin, 2019; Joslyn et al., 2019a). Donaldson et al. (2018) compared the GBG with one, two, and five teams in preschool classrooms and found that all were equally effective but that most teachers preferred the two-team arrangement. In games where one team is used, if any student in the class violates a rule the whole class gets a point (in the traditional GBG). When using two or more teams, it is useful to evenly distribute students who typically engage in higher levels of problem behavior across the teams. It is also useful to place students who are most likely to model appropriate behavior near the students(s) who are most likely to engage in problematic behavior.

Another important consideration when designing a GBG intervention is the selection of rewards that will be provided to the winning team(s). Each team that remains below the established point threshold will receive a reward at the end of the game. Rewards may include access to activities (e.g., games, extra recess, or time on computer) or tangible items (e.g., snacks, tokens, winner's badges). To ensure that the delivery of rewards doesn't interfere or disrupt ongoing class activities, rewards that can be delivered immediately and don't last very long are useful. Effective rewards may be idiosyncratic and tailored to the specific population or setting. For example, Cheatham et al. (2017) used activity points as a reinforcer in their application of the GBG in college classrooms. Activity points were typically earned by attending class and completing assignments and they made up 12% of the students' final course grade. Interestingly, Cheatham et al. identified the most preferred reward by conducting a preference assessment before the start of intervention and thus this was used as a reinforcer in the GBG. Other researchers have polled the class to obtain a list of students' most preferred reinforcers and offered a choice from an array to winning teams (e.g., Joslyn et al., 2019a).

Teacher Training and Consultation

In most applications of the GBG, the classroom teacher or a paraprofessional is trained to implement the procedures (Flower et al., 2014b). Ideally, all staff that work in the classroom will be trained to implement the GBG. Research has indicated that various training formats and durations can be effective. Groves and Austin (2017) trained teachers by providing a step-by-step description of the GBG, modeling of the procedures, the opportunity to roleplay, and via video observation. Wright and McCurdy (2011) also trained teachers via modeling and role-play opportunities and set a criterion of 100% procedural integrity in a role-play test before training was terminated. Alternately, some researchers have explored minimizing training duration and effort. Joslyn and Vollmer (2020) found that teachers can be trained to effectively implement the GBG effectively in as little as 20 minutes. In addition to employing evidence-based training strategies to train teachers, clinicians should consider providing follow-up support to teachers and other staff during implementation to avoid gradual decreases in treatment integrity and address problems should they arise.

It is important that the views and best interests of the teacher are considered when designing the GBG for each classroom. Teachers and other school staff should be consulted at each stage of the process when designing the exact procedures that will be implemented in their classrooms. This includes consulting with teachers regarding the specific rules of the GBG (i.e., the target behaviors), the variation of the game that will be employed (e.g., responding to rule following or rule violations), the duration of the game and how often it will be implemented, by whom it will be implemented, and the rewards that will provided to winning teams. Students can also be included in the design of the game in their classrooms. In particular, students can help choose target behaviors and rewards that they will receive if they win. As previously mentioned, preference assessments can be useful to help identify preferred rewards (e.g., Cheatham et al., 2017; Lannie & McCurdy, 2007). Preference assessments have also been used to identify preferred variations of the GBG. Groves and Austin (2017) conducted a group preference assessment with students to identify if students preferred an individual GBG (i.e., an independent group contingency) or a team-based GBG (i.e., an interdependent group contingency). Including teachers, school staff, and students in the design and implementation of the GBG can help to improve buy-in from these individuals and optimize social validity.

Data Collection and Analysis

Researchers and clinicians have used a variety of procedures to evaluate behavior change during the GBG. The specific data collection procedures used typically depend on the needs of each individual classroom, but it is common to use continuous measures (e.g., frequency, duration) or discontinuous measures (e.g., time sampling) to measure the effectiveness of the GBG. Data should be collected on behavior targeted by the rules of the game. Typically, GBG studies report on the behavior of students at the group level (Joslyn et al., 2019b). That is, data are recorded on the whole class, rather than on individual students. Collecting data at the group level may be suitable if you are interested in evaluating the effects of the GBG on the entire class (i.e., decreasing problem behavior in general). However, some researchers have chosen to collect data on individual student behavior (e.g., Donaldson et al., 2017; Groves & Austin, 2017; Tanol et al., 2010). Collecting data on individual students may be appropriate if you have a small number of students who display high levels of problematic behavior or you are primarily interested in improving the behavior of particular students without individualized interventions (e.g., when there are a few students in the class who engage in most of the disruptive behavior). This approach also allows for more efficient identifications of students who are not sensitive to the contingencies of the GBG and may require more individualized interventions (Donaldson et al., 2017).

Most behavioral GBG research has employed single-case designs to demonstrate the effects of the intervention on target behavior, including reversal, multiple baselines, and alternating treatments designs (Tingstrom et al., 2006). Before implementing the GBG, baseline data are typically collected to provide a measure of the target behavior prior to the intervention. Data collectors should work with the class teacher to identify the most appropriate times to collect data (e.g., when problem behavior is most likely to occur, during the times the teacher plans to implement the GBG). During baseline, teachers are typically asked to respond to problem behaviors as they typically would. However, it may be necessary to make slight modifications to facilitate data collection such as having the teacher signal times when calling out answers is allowed, when students may talk to each other without receiving permission (e.g., during a group activity), or when it might be acceptable for a student to leave their seat without permission (e.g., to turn in a paper or sharpen their pencil). Baseline data should be collected until a stable pattern of responding is observed. Once baseline is complete, the GBG can be implemented and ongoing data collection should continue to closely monitor the effectiveness of the intervention. In some cases, when stakeholders want the GBG implemented as quickly as possible, an alternating treatments design in which GBG and baseline sessions are rapidly alternated can be useful (e.g., Joslyn & Kronfli, 2021). This avoids prolonged baselines and can demonstrate treatment effects quickly.

It is worth noting that previous research has demonstrated that the effects of the GBG do not appear to maintain when the intervention is withdrawn and baseline is reinstated. Although this is desirable from an experimental control perspective, it is less practical for teachers who are seeking a long-term solution to behavior problems in their classrooms. Previous research has also demonstrated that the effects of the GBG do not appear to generalize outside of times in which the GBG is played. Donaldson et al. (2015) measured immediate and distal effects of the GBG by recording levels of disruption before, during, and after GBG implementation. The researchers found that while disruption did decrease during GBG sessions, it did not decrease during sessions preceding or following GBG implementation. Pennington and McComas (2017) measured individual student behavior during the GBG and in the subsequent period (in which the GBG was not implemented) and also found no generalization effects.

In addition to collecting data on student behavior, clinicians should also monitor the degree to which the GBG is implemented as planned. Treatment integrity is primarily monitored during the GBG in two ways: a) via procedural checklist, or b) scoring accuracy. Steps on procedural checklists may include the rules being visible to all students, the teacher delivering points for rule violations, and delivering the reward to winning teams (see Fig. 47.5

Appendix A

Basic Steps for Implementing the Good Behavior Game

Note: The following task analysis describes how to implement the traditional GBG. If you plan to implement the CBGG arrangement, you will be awarding points for following the rules on a time-based schedule (e.g., every 4 minutes) and students win by exceeding the point threshold.

1. Establish the rules of the game (e.g., you must receive permission to talk or leave your seat).
2. Select specific activities, class periods, or times of day to play. Choose activities and times in which the behavior you would like to improve is most problematic.
3. Choose rewards for winning the game that the students will like (e.g., snacks or free time). You can ask the students what they would like to win and let them choose from a variety of options or change the reward from day to day.
4. Divide the class into teams, distributing students likely to engage in problem behavior evenly across them. Ensure that the students know what team they are on before beginning.
5. Write the rules and teams where they will be visible to the class (e.g., on the whiteboard at the front of the room) or use a computer scoring system. This is where you will record marks.
6. Choose a mark threshold (i.e., how many marks can the students receive and still win the game). A common recommendation is to try for an 80% reduction in problem behavior from baseline. However, when first implementing the GBG, try to ensure that the students win the first game by either ending it early or using a high mark threshold.
7. During the game, consistently deliver marks to teams when students break the rules. When delivering a mark, be sure to notify the student why their team is receiving a mark.
8. At the end of the game, deliver rewards to students on winning teams and remind students who lose that they will have another opportunity next time. If both teams are under the mark threshold at the end of the game, both teams win. If both teams have exceeded the threshold, the team with the lowest score wins.

General Tips

1. Avoid delivering marks to students for engaging in behaviors that are not violations of the GBG rules. Other consequences may be delivered for these, but if they have not broken a rule specific to the GBG, do not give them a mark on the board.
2. Try to be as consistent as possible when delivering marks for disruptive behavior.
3. If a student disputes a mark for a rule violation, try not to attend to or engage with them. When a rule is broken, deliver a mark as you normally would and continue with your lesson. If the student is violating the rules to dispute their mark, this can result in additional marks.
4. If a student refuses to play the game or tries sabotages it (e.g., they are deliberately the breaking rules), they can be placed on their own team. Notify the student that they are now on their own team and allow them a proportional mark threshold. They can be returned to a team with other students after winning individually.
5. Always be sure to deliver rewards to winning students immediately following the end of the game. If you do not give them the reward they have earned or deliver the reward later than you originally stated you would, it may reduce the effectiveness of the procedure.
6. Review these steps frequently to ensure that you are not leaving anything out of the game.

Fig. 47.5 Basic guidelines for GBG implementation from Joslyn and Vollmer (2020) for an example of items that may be included in a treatment integrity checklist). Scoring accuracy compares the number of points delivered to the number of observed rule violations (Donaldson et al., 2011; Joslyn and Vollmer 2020; Sy et al., 2016). Previous researchers have found that the GBG was effective even when treatment integrity was low (Joslyn & Vollmer, 2020; see Figs. 47.6 and 47.7). Sy et al. (2016), who measured scoring accuracy during the GBG, found that the intervention was still effective at reducing target responses even when scoring accuracy was as low as 8.5%. However, further research is needed to examine the extent to which treatment integrity may be reduced while maintaining effectiveness in suppressing problem behavior. In addition, scoring accuracy only takes into consideration only one component of the GBG procedures (accuracy of point delivery); it is unknown what impact errors of omission in other GBG features may have on levels of effectiveness. For example, withholding the reward may have a more detrimental effect than low scoring accuracy on the effectiveness of the intervention.

Mechanisms of Behavior Change

Because the GBG is a multicomponent intervention, it is likely that there are several mechanisms responsible for student behavior change.

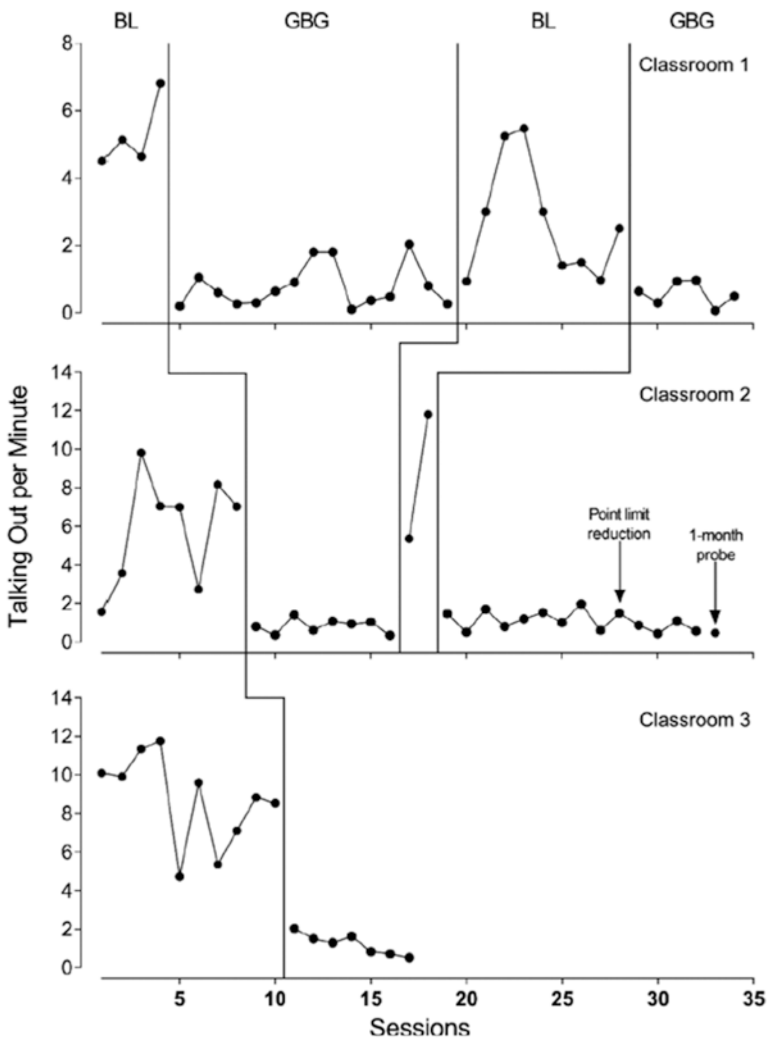

Fig. 47.6 Student behavior from Joslyn et al. (2020)

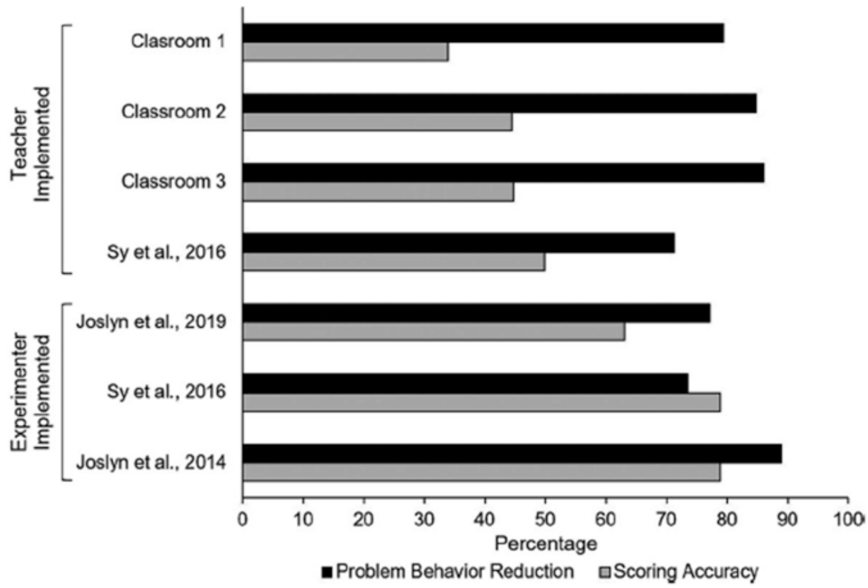

Fig. 47.7 A comparison of mean problem behavior reduction and GBG scoring accuracy values when implemented by experimenters and teachers from Joslyn and Vollmer (2020)

Although research specifically examining the mechanisms of the GBG is limited, examining the findings of specific GBG studies and applying the conceptual systems of applied behavior analysis (ABA) to the GBG allows us to consider its primary means of behavior change. First, we will address potential mechanisms for the short-term effects, followed by the long-term effects.

Short-Term Mechanisms

The GBG likely affects behavior through multiple mechanisms. One key component of the GBG is the clear and specific rules that are provided to students before and throughout each session. Providing students with these rules and explaining the consequences for breaking them likely leverages rule-governed behavior, which may contribute to the immediacy of effects. This is evidenced by the fact that student behavior often reduces immediately upon implementation of the GBG (i.e., on the first day), before students receive points for rule violations or rewards for winning. As students experience the game and contact contingencies for rule breaking, their behavior becomes contingency shaped.

Differential reinforcement is another mechanism potentially responsible for short-term improvements in student behavior. The GBG is a full-session differential reinforcement of low rates of behavior (DRL) procedure, and the CBGG variation utilizes differential reinforcement of alternative or other behavior (DRO or DRA). In DRL, students gain access to rewards contingent on engaging in fewer than a prespecified number of certain instances of behavior (e.g., calling out) throughout some specified time interval (e.g., 30 minutes). In the CBGG variation, students earn points for engaging in specific behaviors (i.e., DRA) or refraining from rule violations (i.e., DRO), depending on how the procedure is designed. Points delivered throughout the game may serve as a signal to students indicating the availability or unavailability of putative reinforcement depending on the number of points they have accumulated relative to the established point threshold.

Through repeated exposure to the GBG, points may also become conditioned as mild punishers or reinforcers (depending on the variation being implemented) due to their correlation with access to rewards. For example, Wiskow et al. (2018) found that vocal feedback (i.e., point delivery) was required to maximize GBG effectiveness with preschool students. However, research has also shown that points may not function as punishers in some cases. For example, Joslyn et al. (2019a) reported that in one high-school classroom, students' behavior was insensitive to point delivery but sensitive to the number of points they had accumulated relative to the point threshold. Students freely violated the rules until they were near the point threshold, then collectively stopped engaging in problem behavior, remained below the threshold, and were able to consistently win the game and access rewards. The experimenters then lowered the point threshold and the students' rule breaking matched the new threshold. Either or both of these mechanisms (i.e., stimulus control and conditioned punishment or reinforcement) could affect student behavior, which may contribute to the robustness of the GBG. Behavior analysts concerned about the use of punishment in this context should consider the "big picture" of the GBG; it is a reinforcement-based procedure that students enjoy playing. Consistent findings of strong student preference for the GBG indicate that the procedure is not typically aversive to students in either the traditional or CBGG arrangement (Joslyn et al., 2019b).

In addition to the programmed contingencies that shape student behavior, peers may also influence their behavior as an indirect effect of the game. Because of the interdependent group contingency, students earn rewards if both they and their peers follow the rules. Therefore, students may encourage one another to follow classroom rules and provide social consequences for doing so. This may also explain why the GBG is so generally effective, as students who are not motivated by teacher praise or the rewards available for winning the game may be motivated by peer-mediated contingencies. For example, a student who is unmotivated by 5 minutes of free time may be more likely to participate in the game if their friends want to win the game. Although one might assume that the GBG has the potential to cause bullying or harassment between students, particularly when implemented with students who engage in severe problem behavior or struggle with prosocial interactions (e.g., students with emotional and behavioral disorders), research has indicated that students engage in more positive peer interactions and fewer negative interactions while the game is being played when compared to the standard classroom contingencies (Groves & Austin, 2019).

The conceptually systematic nature of ABA allows us to hypothesize that the above mechanisms are primarily responsible for changes in student behavior during the GBG. However, it is worth noting again that there are few studies that have explicitly examined mechanisms of the GBG. It seems likely that there are multiple, layered mechanisms that synergize to produce such robust and consistent effects. If this is the case, contextual factors (e.g., student age, setting) can influence which components of the GBG are most salient in changing behavior. For example, older students with longer histories of rule following and stimulus control in the classroom may be more sensitive to their score than to the delivery of points, while younger students with less experience in classrooms and less proficiency in math and counting may be more sensitive to the delivery of points than to their score. Additional research on the mechanisms responsible for short-term effects will elucidate which of the above mechanisms are the most important given certain scenarios (e.g., implementation with younger vs. older students). This, in turn, will allow school practitioners to emphasize these components when appropriate and remove or de-emphasize them when they are not needed and may reduce implementation effort for teachers.

Long-Term Mechanisms

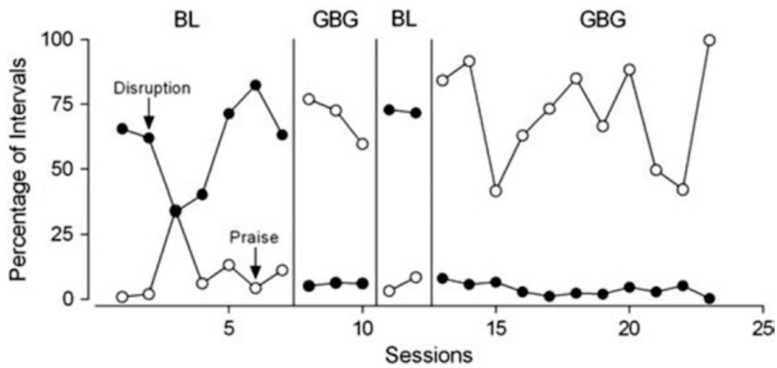
As mentioned earlier, longitudinal research has indicated that there may be long-term benefits to students who are exposed to the GBG at a young age, such as decreased rates of substance abuse disorders and incarceration for violent crimes (Kellam et al., 2008, 2011, 2014). One can hypothesize the primary mechanisms of short-term change by examining the arranged contingencies during the GBG, but the processes involved in these long-term effects are less clear. The matter is further complicated by the fact that empirical research indicates that the immediate effects of the GBG do not generalize to other times and settings in school (Donaldson et al., 2015; Pennington & McComas, 2017); student behavior only improves during the period in which the game is in effect. However, from a behavioral perspective, there are at least two potential mechanisms for these long-term effects that are supported by the literature and ABA conceptual systems: a) the benefits provided by intervening when students are young, and b) exposing students to delays to reinforcement.

In the frequently cited longitudinal research indicating long-term effects, students are usually fairly young (i.e., in first or second grade; Kellam et al., 2011). Given that many consider these ages to be critical periods for academic and social development, the GBG may foster the successful acquisition of key skills during this time. Utilizing an intervention that promotes classroom rule following, enriches the classroom environment, promotes prosocial interactions, and increases academic engagement could affect an array of student behavior important for long-term success in school and life. In terms of academics, students who remain at grade level for a longer period of time or do not fall behind at all as a result of the GBG may be exposed to fewer aversive events throughout their academic career (e.g., struggling with academics, receiving poor grades, disciplinary issues related to escape-maintained behavior). These same students may also be more likely to contact natural reinforcers in school (e.g., teacher praise, good grades, parent approval). Delaying or reducing the number of students falling behind academically can have a strong effect on their academic trajectory, which is correlated with various quality of life outcomes later in life (Prince et al., 2018; Reid et al., 2004).

In terms of social effects, the GBG has been indicated to increase prosocial student interactions and increase the extent to which teachers deliver praise relative to reprimands (Groves & Austin, 2019; Rubow et al., 2018). See Fig. 47.4 for data from Groves and Austin (2019) showing changes in peer interactions during the GBG and Fig. 47.8 for data from Rubow et al. (2018) demonstrating changes in teacher praise relative to reprimands during the GBG. These immediate effects on peer and teacher interactions enrich the school environment for students and may lead to long-term changes in the relationships between students and their peers and teachers. However, the long-term effects of the GBG on student-peer and student-teacher relationships have not been fully addressed by the literature.

A consistent finding in the longitudinal GBG research is that many of the long-term behavioral outcomes relate to impulsivity (i.e., choosing smaller, sooner reinforcers over larger, later reinforcers; Rung et al., 2019). Substance abuse and violent crime, for example, are correlated with steep delay discounting (a measure of impulsive behavior indicating how much value reinforcers lose as they become more delayed; Rung et al., 2019). These behaviors may result in immediate reinforcement (e.g., effects of alcohol, gaining access to money) at the cost of access to more potent and higher quality reinforcers later (e.g., good health, freedom from incarceration). Behavioral research with laboratory animals has indicated that rats engage in fewer impulsive behaviors after delay exposure training (i.e., being repeatedly exposed to increasing delays to reinforcement over time; e.g., Stein et al., 2013). Conceptually, the GBG could be viewed as a variation of delay exposure training in which students are presented with opportunities to obtain larger later reinforcement by abstaining from impulsive behavior. For example, students may avoid engaging in talking out or off-task behavior that results in low quality, immediate reinforcement (e.g., brief interaction with a peer, momentary escape from academic demands) if they can access larger reinforcers later (e.g., 10 minutes of free time in which they can access high quality social reinforcers and escape academic demands for a longer period of time) by doing so. Over repeated exposures to the GBG,

Fig. 47.8 Student disruption and teacher praise data from Rubow et al. (2018)



students may become less likely to make impulsive choices.

All of the above hypotheses of behavioral mechanisms come with a caveat; they have not been explicitly examined by empirical research. As we will discuss later in this chapter, mechanisms of behavior change are in need of more research. By learning more about the primary mechanisms responsible for change in the GBG (both short- and long-term), we may be able to develop more interventions that are as robust and generalizable as the GBG. Although longitudinal studies are uncommon in behavioral research, they may be necessary to examine the outcomes of our interventions with more detail.

Future Directions for the Good Behavior Game

Although the GBG has a substantial literature base, there are still areas in need of additional research. Addressing unanswered questions about the GBG will allow for more precise clinical direction, clarify the utility of different variations, and contribute to the development of more effective classroom management interventions. Below, we will discuss key areas in which more research is needed and describe the implications of expanding our understanding in each area.

The GBG has been repeatedly demonstrated to be effective in improving student behavior in a range of school settings and activities (Bowman-Perrott et al., 2016; Flower et al., 2014a; Joslyn et al., 2019b; Tingstrom et al., 2006). However, there have been few applications of the GBG or its variations in non-school settings. Given the consistency of effects and hardiness of the GBG, it is likely that it would be effective in other settings familiar to behavior analysts. For example, the GBG could be adapted for implementation in autism treatment clinics to address a variety of client behavior. Practitioners may see success in targeting problem behavior for reduction, increasing appropriate social interactions between clients, or even in increasing the variety or quality of food consumed during lunch. Other settings in which the GBG would be well-suited for adapted implementation could include the workplace, the home setting (e.g., improving behavior among a group of siblings), or other areas in which the behavior of multiple individuals could be improved. Although individual, function-based interventions are a key component of effective behavioral treatment, group contingencies like the GBG are currently underutilized in ABA.

Improving the dissemination of the GBG (and behavior analysis in general) is another important area for future research. The GBG is a "success story" of ABA and behavior analysts are becoming increasingly common in schools, but the GBG remains a largely untapped resource for teachers. Research on the rates of GBG implementation is rare, but what information we have indicates that many teachers have never heard of the GBG. In a survey of 239 teachers across five school districts, 91% of teachers reported never having heard of the GBG (Stormont et al., 2011). Although the GBG's popularity has only increased since this study was published, researchers should examine ways in which we can increase the visibility and implementation rates of the GBG. There are multiple potential approaches to this task. First, despite the GBG being most frequently implemented to reduce problem behavior in the classroom, it is also effective in increasing desirable behaviors in the classroom. Research exploring the upper limits of what GBG implementation can produce in terms of class participation, positive peer interactions, academic engagement, and other desirable or prosocial behaviors could further establish the GBG as a powerful and versatile procedure. This would likely hasten its dissemination particularly for teachers who may not struggle with problem behavior per se, but would embrace a procedure that increases specific, desirable student behavior. Second, research that streamlines the implementation of the GBG by reducing implementation effort or removing aversive procedural components to improve contextual fit without sacrificing effects would make dissemination easier. Researchers have reported that teachers find aspects of the procedure to be problematic, likely decreasing the likelihood that they will sustain the intervention or adopt it in the first place (e.g., Joslyn et al., 2019a). For example, teachers have reported that the delivery of points in both the GBG and CBGG variation can be disruptive or distracting when they are delivering instruction (Wahl et al., 2016). Existing component analyses of the GBG have indicated that most or all components are necessary for effectiveness, but these analyses have only been conducted with preschool students (Foley et al., 2019; Wiskow et al., 2019). Given the various mechanisms responsible for behavior change, it is likely that certain components are more or less relevant given certain factors, but there is insufficient available research to draw conclusions or provide treatment recommendations.

The GBG is a notable intervention for its versatility and robustness, but it is not a panacea. Researchers should further explore the limits of the GBG. Treatment failures are rare in GBG research, but that could be a function of non-effects being difficult to publish rather than the invulnerability of the GBG. As practitioners, both authors of this chapter have seen scenarios in which the GBG does not produce its characteristic effects and required procedural variation and troubleshooting. It is likely that there are prerequisite conditions that must be met for the GBG to be effective. For example, teachers must exhibit some degree of instructional control in order for the GBG to even be presented to students. In addition, it must be possible for teachers to be able to present rewards for winning the GBG that compete with reinforcers available for problem behavior (e.g., peer attention, escape from academic demands). Qualitative features of the teacher or classroom that may be predictive of intervention success or failure should be further explored in behavioral education research generally, as well as in relation to the GBG.

Finally, the hardiness of the GBG makes it a useful model for studying classroom management and other aspects of school-based interventions such as teacher training, treatment integrity, and behavior measurement. Exploring these aspects of education can be challenging due to difficulties conducting research and demonstrating experimental control in unpredictable applied settings like schools. However, using the GBG as an intervention to explore areas like teacher training methods can reduce the challenge of demonstrating intervention effects when focusing on dependent variables other than student behavior. Class-wide procedures like the GBG may also prove to be valuable both as prevention approaches and as indicators of a need for more targeted interventions. When interventions like the GBG fail to address the behavior of particular students in a class, it could be indicative of the need for individualized behavioral interventions (i.e., a screening tool; Donaldson et al., 2017).

Chapter Summary

The GBG is an effective classroom management procedure with over 50 years of empirical support in various settings and contexts. Typically implemented with elementary-aged students in general education, researchers have effectively extended and adapted the GBG to a wide range of education settings and populations (e.g., pre-school students, alternative education, college classrooms, students with intellectual disabilities; Joslyn et al., 2019b). Further, the GBG is effective outside of the context of problem behavior in the classroom; it has been demonstrated effective in increasing physical exercise and academic engagement, improving behavior in the cafeteria, and increasing class participation (Joslyn et al., 2019b). The GBG has also improved long-term outcomes for students (Kellam et al., 2008, 2011, 2014).

The versatility and robustness of the GBG are made possible by the numerous procedural variations and underlying behavioral mechanisms. In addition to versatility across environment and population, the GBG remains effective when implemented with poor treatment integrity and with substantial modifications to its procedures (Joslyn et al., 2019b). The GBG likely leverages some combination of rule-governed behavior, differential reinforcement, conditioned reinforcement and/or punishment, stimulus control, and peer-mediated contingencies. The synergy of these mechanisms may maintain effects when procedural variation, poor treatment integrity, or setting or population characteristics render one or more of these mechanisms ineffective or irrelevant. Long-term effects of the GBG may be due to the crucial age at which students were exposed in longitudinal research and its potential function as a delay exposure training variation, decreasing the likelihood of impulsive behavior in students.

Although it is a robust and relatively simple procedure, care should be taken when implementing the GBG to maximize the likelihood of immediate and strong effects, teacher motivation to implement it, and its sustainability over time. Researchers have not yet examined every potential variation or implementation consideration but have established general recommendations for practice. Consistent findings in the behavioral literature have elucidated ways to optimize aspects of the GBG such as rule selection, team size, data collection methods, clinical decision-making, and teacher training methods. Researchers continue to explore ways to optimize and disseminate the GBG.

Important areas for future research on the GBG include extension and adaptation to non-school settings (e.g., the workplace, autism clinics), improving dissemination and sustainability, and exploring the boundary conditions of GBG effectiveness. The GBG can also be conceptualized as a model for studying classroom management and other school-based interventions due to its consistency in producing effects. Researchers interested in exploring research methodology in schools (e.g., behavior measurement), teacher training approaches, or other topics sometimes challenging to study in schools may benefit from using the GBG as a model intervention due to its apparent low likelihood of treatment failure.

Compliance Training

Generally, compliance is understood as the extent to which an individual behaves in accordance with a proposed request, demand, or expectation of the social environment. On the surface, some practitioners and researchers may view the concept of compliance pejoratively as it suggests the removal of autonomy and control by another individual. However, both children and adults encounter a plethora of situations where compliance behaviors are commonplace. For children, opportunities to engage in compliant behaviors with parent and teacher instructions occur on a daily basis. In many cases, these requests or demands are intended to increase academic and social skills and to ensure the safety of the child. Likewise, adults enrolled in higher education, those who are employed, and law-abiding citizens are also required to follow the rules and requests of other individuals and institutions. For individuals diagnosed with autism and other developmental disabilities, compliance is a basic skill required for both the assessment and treatment of other behavior. Failure to comply with requests in these circumstances may produce delays in learning, development, integration, and health. Continued compliance issues may result in diagnoses such as oppositional defiant disorder, conduct disorders, or attention deficit hyperactivity disorder and may be associated with social and legal issues into adulthood (American Psychiatric Association, 2013).

In this light, the need to formally address compliant behavior often occurs as a result of noncompliance, which is paraphrased by Lipschultz

and Wilder (2017) as "doing anything other than what has been requested by a parent or other adult authority figure within a specific time frame" (p. 263). Noncompliant behavior can be a common challenge for caregivers of individuals with and without disabilities. Oftentimes, behavior that occurs in place of compliance is undesirable and problematic, and typically consists of challenging behavior that occurs after the instruction has been delivered (Cook et al., 2019). As such, professionals in the field of applied behavior analysis have been at the forefront of developing effective methods to enhance compliance skills.

Within this research area, compliance is designated as either active or passive. That is, the compliant behavior of interest may involve the occurrence of a specific behavior or the absence of a specific behavior. With respect to active compliance, common examples include following instructions and completing tasks, without engaging in other problematic behaviors. More specifically, if a parent asks a child to make their bed, the child engaging in the behaviors required to make the bed would be considered active compliance. Noncompliance often occurs together with many forms of challenging behavior, such as physical aggression or self-injury. Frequently, the behavior exhibited is part of the same functional response class (i.e., maintained by the same outcome). For example, aggression and self-injury may be negatively reinforced by removing or delaying demands after those behaviors occur, thus leading to noncompliance. Therefore, one strategy to increase compliance is implementing procedures that target the undesirable behavior that is associated with noncompliance (Cook et al., 2019).

Concerning passive compliance, a parent may ask a child to keep their knit cap on outside in the winter. In this example of passive compliance, the child is expected to passively keep their knit cap on their head. Some common examples of passive compliance include participating in a dental examination (e.g., Cuvo et al., 2010a), receiving haircuts (e.g., Schumacher & Rapp, 2011), and wearing a heart monitor (e.g., Dufour & Lanovaz, 2020). Given the potentially detrimental effects of noncompliance, compliance is often central for practitioners of behavior analysis. The purpose of this chapter is to review behavior analytic practices in the assessment and treatment of compliance. Specifically, this chapter will first review preliminary assessments to conduct before treatment and then examine both antecedent-based and consequence-based interventions. This chapter ends with practical considerations to ensure a rigorous approach to compliance training with different populations.

Assessment

To begin, practitioners and researchers should identify the contingencies preventing the emergence of compliance. The first step in this process is to identify whether the lack of compliance is the result of a skill deficit. This issue may be addressed by way of a skill assessment. If noncompliance is not the results of a skill deficit, a functional behavior assessment should then be conducted to determine the contingencies maintaining the undesirable behavior, as well as preference assessments to evaluate effective reinforcers to target compliance (Lipschultz & Wilder, 2017).

Skills Assessment

Prior to selecting a treatment to increase active compliance, practitioners should first determine whether this lack of compliance is due to a skill deficit. In layperson's terms, the question is whether the person *can't* or *won't* engage in the behavior. The former would lead to straightforward skills training as the issue is not noncompliance, but rather a limited behavioral repertoire. In this case, we recommend that the reader consult the subsequent chapters on teaching (see Chaps. 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, and 62). In contrast, this chapter focuses on those individuals who have the behavior or skill in their repertoire, but that fail to engage in it when required. Therefore, the emphasis is on increasing the frequency or duration of compliance rather than teaching.

Assessing whether the lack of compliance is due to a skill deficit remains a challenge because noncompliance may lead to the individual failing to engage in the skill during the assessment even when the skill is in their repertoire. To increase the probability of responding, the practitioner may provide choice during the assessment, deliver high-density and high-quality reinforcement, and alternate the skill being evaluated with skills that the child already complies with regularly (Lerman et al., 2004). For example, a task analysis may divide the skill into smaller units and reinforcement provided for each unit rather than the task as a whole (e.g., Lalli et al., 1995). This procedure may increase responding and facilitate differentiation between skill deficit and noncompliance. Furthermore, the trainer may provide reinforcement for any attempts at responding to the discriminative stimulus (rather than following correct responses only) to evoke responding in the individual during the assessment. Finally, the assessment may embed the skill at the end of a high-probability request sequence (see section "Antecedent-Based Interventions" for details on procedures) to increase the likelihood that the individual will respond (Mace et al., 1988).

Functional Assessment

Because individuals avoid or escape something when they engage in noncompliant behavior, the most common behavioral function for noncompliance is escape (Hong et al., 2018). However, attention in the form of guided compliance may also maintain engagement in challenging behavior (Kern et al., 2002; Rodriguez et al., 2010). Given that both functions may lead to different treatment selections, we recommend that practitioners conduct a functional assessment before the onset of compliance training (see Chaps. 26, 27, 28, 29, 30, and 31 for details).

Beyond identifying the behavioral function of noncompliance (e.g., attention and escape), practitioners may also use functional analyses to identify idiosyncratic variables that may affect responding to demands or tasks (Carey & Halle, 2002; Cooper et al., 1992; McComas et al., 2000). The trainer may manipulate variables such as task duration, task difficulty, number of tasks, type of task or demand, or the presence or absence of other stimuli (e.g., music). This type of assessment involves comparing at least two conditions: one condition involves the presence of the potentially evocative stimulus and the other condition is its absence while the trainer provides escape contingent on noncompliance or other challenging behaviors.

As an example, assume that a child refuses to follow parental demands. Some demands may be more effortful than others. The practitioner could set up two conditions: one with less effortful demands (e.g., bring me the phone) and one with more effortful demands (e.g., emptying the dishwasher). In each condition, the parent could make 10 demands of each type and then examine whether the different types of demands evoke differential responding. This functional analysis would not only lead to the identification of motivating operations, but may also support the practitioners when setting treatment parameters (e.g., high-probability request sequence, demand fading).

Preference Assessments

Trainers should always conduct a preference assessment prior to the implementation of interventions that involve the delivery of preferred stimuli or reinforcers. Conducting a preference assessment may increase the effectiveness of the intervention being implemented (Kang et al., 2013; Simonian et al., 2020). Apart from reminding the reader of the importance of preference assessment prior to compliance training, we will not review detailed procedures here. For those readers unfamiliar with preference assessment, we refer them to Chap. 21 on this topic. In sum, skill, functional, and preference assessments remain essential preliminary steps preceding the selection and implementation of treatment for noncompliance. These assessments should increase the probability that the treatment will produce the expected outcomes with the individual targeted by the practitioner.

Treatment

Antecedent-Based Interventions

Antecedent-based interventions involve the manipulation of stimuli that precede the behavior. In other words, the trainer manipulates the antecedents (i.e., what occurs before the behavior) independent of engagement in a specific behavior. Examples of antecedent-based interventions for compliance include manipulating demand and task parameters, the high-probability request sequence, graduated exposure, noncontingent reinforcement, and self-monitoring.

Manipulating Demand and Task Parameters

When demands and tasks fail to evoke compliance, the first step is often to examine the demand or task itself. For example, ambiguous demands are difficult to follow for anyone regardless of the presence of any noncompliance issues. Researchers have found that delivering clear, concise, and feasible demands increases the probability of compliance (e.g., Bouxsein et al., 2008; Browning, 1974; Matheson & Shriver, 2005). In an observational study, Christenson et al. (2011) found that elderly patients receiving long-term care were more likely to comply with demands that were clear, concise and feasible than with demands that were ambiguous, interrupted or unfeasible. These results suggest that nursing staff should be trained to modify their demands to increase compliance rate. The advantage of modifying the demands or tasks to make them clearer is that this type of intervention requires low response effort. That said, the intervention may produce insufficient changes, especially in those individuals who show persistent noncompliance under diverse environmental conditions.

A second intervention that involves manipulating demand and task parameters is demand fading. In demand fading, the trainer reduces the number of demands presented to the individual and then gradually increases them (Pace et al., 1993). For example, Pace et al. (1994) reduced verbal obscenities in an adult with brain injury by initially reducing the number of demands below baseline levels. Then, the authors reintroduced demands gradually until the person complied with the same number of demands as were presented during the initial baseline while engaging in zero rates of challenging behavior. Although the intervention may function as a standalone treatment, researchers have repeatedly used demand fading in combination with other interventions to increase their effectiveness or reduce their side-effects (e.g., Gerow et al., 2020; Ringdahl et al., 2002; Shillingsburg et al., 2019; Zarcone et al., 1993a). That is, implementing demand fading along with other interventions may reduce engagement in challenging behaviors associated with demands. Similar to modifying demands, reducing the number of demands or tasks is simple to implement for practitioners. The main drawback being that the demands must be initially faded, which may be unrealistic in certain contexts or when the staff-to-client-ratio is too low.

Choice

Another low effort intervention to improve compliance is the use of choice. Researchers have shown that different types of choice may increase responding following demands (e.g., DeLeon et al., 2001; Dunlap et al., 1994, Harding et al., 2002; Kern et al., 2001; Lory et al., 2020; Peck et al., 1996). For example, Kern et al. (2001) examined the effects of choosing the sequence in which multiple tasks could be completed in three children with attention-deficit hyperactivity disorder, intellectual disability, or both. Their results indicated that having the child choose the sequence of tasks not only increased engagement with the tasks (i.e., compliance), but it also reduced engagement in challenging behavior. In a more recent example, Lory et al. (2020) provided instructional choices to children with autism and found that it increased compliance with tasks. Another type of choice involves selecting the reinforcer that will be provided contingent on compliance. In such an implementation, Peck et al. (1996) reported that choice-making may improve compliance while reducing engagement in challenging behavior in young children. Providing choices has the advantage of promoting self-determination with individuals who may experience limited opportunities for making decisions on their own.

High-Probability Request Sequence

The high-probability request sequence is an intervention derived from behavioral momentum theory (see Mace et al., 1988). During the high-probability request sequence, the trainer delivers a rapid succession of high-probability requests followed by a low-probability request (Bross et al., 2018). The high-probability requests are requests with which the individual is highly likely to comply (i.e., 80% or more of the time) whereas the low-probability requests are those with which the individual is unlikely to comply (i.e., less than 50% of the time). The trainer should provide praise contingent on compliance with each type of request and consider providing tangible reinforcement for compliance with the high-probability request (Cooper et al., 2020). Whenever possible, the intervention should involve varying the high-probability requests as much as possible because invariant requests (i.e., always the same) may reduce the persistence of the observed effects (Davis & Reichle, 1996).

Researchers widely consider the high-probability request sequence as an empirically supported intervention for improving compliance (Banda et al., 2003; Brosh et al., 2018; Maag, 2019). Humm et al. (2005) have shown that parents may effectively implement the high-probability request sequence with minimal training, which is an advantage of the approach. In a recent application, Planer et al. (2018) compared the effects of high-probability requests that were relevant or irrelevant to the low-probability requests in children diagnosed with autism spectrum disorder. Their findings indicated that more relevant high-probability requests typically led to better compliance. One benefit of using the high-probability request sequence is that the intervention does not require the implementation of extinction. On the other hand, practitioners may struggle in identifying high-probability requests with individuals who engage in challenging behavior or fail to comply following many types of requests.

Graduated Exposure

Graduated exposure involves gradually and systematically subjecting individuals to stimuli that they are attempting to avoid (Jones, 1924). Although mainly used for the treatment of phobias, researchers have also applied graduated exposure to both improve passive and active compliance (Carter et al., 2019; Cromartie et al., 2014; Ellis et al., 2006; Rapp et al., 2005; Schmidt et al., 2013; Szalwinski et al., 2019). In an example of active compliance, Schmidt et al. (2013) trained a 16-year-old adolescent with autism and intellectual disability to comply with requests to participate in activities in different rooms in a school. The researchers gradually increased the duration of time spent in these rooms as well as the duration spent engaging in activities. This gradual exposure led to the adolescent complying with the requests despite low levels of reinforcement. In an example of passive compliance, Cromartie et al. (2014) taught a woman with intellectual disability and schizoaffective disorder to comply with blood draws by gradually exposing to different steps involved in the procedure. The previous examples show how practitioners may use graduated exposure in situations where the individual exhibits avoidant behavior related to the stimuli they must be engaged with for compliance. The systematic nature of graduated exposure is also its main weakness: the gradual transition from one step to another may make progress slow and take a lot of time.

Noncontingent Reinforcement

Noncontingent reinforcement (NCR) is a procedure that delivers preferred stimuli on a time-based schedule that is independent of the behavior. Put differently, a trainer provides the individual with a preferred stimulus on a regular or continuous basis regardless of the occurrence of behavior. This method alters engagement in the behavior by reducing the motivation to access the reinforcer (Cipani, 2018). Behavior analysts widely accept NCR as an empirically supported intervention to reduce undesirable behavior in individuals with developmental disabilities (Carr et al., 2009). In this population, noncompliance often occurs concurrently with the undesirable behavior; hence, NCR shows promise as a compliance training treatment procedure.

Researchers have shown that NCR interventions are effective at increasing compliance with wearing medical devices in children with developmental disabilities (DeLeon et al., 2008; Nipe et al., 2018; Richling et al., 2011). For example, Richling et al. (2011) have increased passive compliance with wearing prostheses by providing noncontingent access to preferred stimulation (e.g., music, tangibles, attention) to two children with multiple disabilities. In an example of active compliance, Ingvarsson et al. (2008) reported that NCR (e.g., noncontingent delivery of an edible item) alone was sufficient to increase compliance and reduce the rate of challenging behavior in a demand context. In situations where the target behavior is maintained by negative reinforcement (e.g., escape from tasks), a break from tasks can be delivered independent of behavior, which is termed noncontingent escape. Kodak et al. (2003) examined the effects of noncontingent escape in reducing challenging behaviors and increasing compliance in children with disabilities and showed that providing a brief break from tasks reduced challenging behavior and increased active compliance. Interventions based on NCR are relatively simple to implement and changes in the target behavior can occur quickly. A drawback with the intervention is that specific replacement behavior (i.e., compliance) is not taught using NCR; therefore, this procedure is often used in combination with other interventions designed to teach specific functionally matched replacement behavior (Cook et al., 2019).

Self-Monitoring

In behavior analysis, one common form of compliance is treatment adherence (Allen & Warzak, 2000; Dunbar-Jacob & Mortimer-Stephens, 2001). Treatment adherence generally refers to a patient or caregiver correctly following and implementing the recommendations of a professional (i.e., compliance with treatment). One method to improve adherence is the use of self-monitoring, which involves measuring or recording one's own behavior (Kanfer, 1970). Researchers have shown that self-monitoring may improve compliance with treatment in a population with a variety of problems such as asthma, acquired immunodeficiency syndrome (AIDS), and cardiac illness (e.g., Burke et al., 2011; Janson et al., 2009; Oldridge & Jones, 1983; Safren et al., 2001). In a behavior analytic example, Wadsworth et al. (2015) showed that students diagnosed with developmental disabilities could learn to self-monitor their compliance with requests. The results of the study suggested that self-monitoring may have facilitated the maintenance of compliance over time. As with choice, one of the strengths of self-monitoring is that the intervention encourages self-determination. That said, some researchers have suggested that self-monitoring alone is insufficient to maintain changes in behavior in some populations (Fritz et al., 2012).

Consequence-Based Interventions

Consequence-based interventions typically involve increasing the future occurrence of compliant behavior by manipulating stimuli that follow its occurrence. That is, the behavior change agent manipulates events or stimuli contingent on engagement in a specific behavior. Examples of consequence-based interventions include differential reinforcement of alternative behavior, differential reinforcement of other behavior, functional communication training, guided compliance, escape extinction, and public posting.

Differential Reinforcement of Alternative Behavior

Differential reinforcement of alternative behavior (DRA) involves "Providing greater reinforcement, along at least one dimension, contingent on the occurrence of one form or type of behavior, while minimizing reinforcement for another form or type of behavior" (Vollmer et al., 2020, p. 2). During DRA for compliance, the trainer typically provides a reinforcer to an individual contingent on the occurrence of a compliant behavior and minimizes reinforcement for noncompliance. Although often combined with escape extinction (see section on the same topic below), a recent review by Trump et al. (2020) concluded that DRA without the use of extinction is an effective treatment option.

Researchers have recognized DRA as a well-established treatment to increase compliance during mealtimes (food acceptance) in individuals with developmental disabilities who exhibit challenging behavior (Petscher et al., 2009), and have shown that DRA procedures continue to be effective without an extinction component (Athens & Vollmer, 2010; MacNaul & Neely, 2018). Recently, Briggs et al. (2019) indicated that robust treatment effects can be developed using DRA without the use of extinction by manipulating a combination of magnitude and quality of reinforcement for active compliance, and these effects can be maintained with reasonably lean schedules of reinforcement. Thus, DRA procedures may be easily implemented by caregivers because durable effects can be achieved even when destructive behaviors continue to occasionally result in a functional reinforcer and reinforcement for compliance is thinned (Briggs et al., 2019; Dowdy et al., 2018).

Functional Communication Training

A common variation of DRA is functional communication training (FCT). In FCT, the trainer teaches and reinforces an alternative communication response. If a student does not respond to instructions delivered by the teacher in order to escape from demands, an example of FCT could involve teaching the student to ask for a break instead of running away when they are asked to complete their work. FCT was initially defined by Carr and Durand (1985) and continues to be a valuable, well-established treatment for problem behavior (Kurtz et al., 2011; Petscher et al., 2009). The emphasis in many research studies is to increase appropriate communication without extinction (Johnson et al., 2004; Schindler & Horner, 2005). Although FCT has been shown to produce immediate effects, less research has examined the generalization and maintenance of this intervention over time (Neely et al., 2018).

Differential Reinforcement of Other Behavior

Differential reinforcement of other behavior (DRO), also referred to as differential reinforcement of zero occurrences or omission training, involves delivering a reinforcer in the absence of the specified target behavior within a predetermined interval (i.e., whole-interval DRO) or at a specific moment (i.e., momentary DRO). If an undesirable behavior occurs, the interval restarts and reinforcement is withheld. The duration of intervals continues to increase as long as the individual refrains from engaging in the target behavior until the terminal time interval is reached.

Researchers have used DRO interventions as part of medical treatment packages (Cuvo et al., 2010a, b; Shabani & Fisher, 2006) and alone (Carton & Schweitzer, 1996; Dufour & Lanovaz, 2020) to increase passive compliance with medical procedures (e.g., dental examination, blood draws, wearing heart rate monitors, and physical examinations). A DRO procedure may be useful for instances where noncompliance evokes challenging behavior (e.g., self-injury, aggression), when response blocking or escape extinction is unrealistic, or when NCR alone is unsuccessful (Dufour & Lanovaz, 2020; Hagopian & Toole, 2009). As with NCR, one of the main disadvantages of DRO is that the procedure does not specifically teach an alternative behavior (especially in the case of active compliance). Moreover, individuals untrained in behavior analysis may find DRO under dense schedules challenging to implement.

A variation of DRO that uses a functional reinforcer rather than an arbitrary reinforcer is differential negative reinforcement of other behavior (DNRO). When using DNRO procedures, the aversive stimulus is removed (i.e., negative reinforcement) contingent on the absence of the target behavior for a specified time period. A DNRO procedure allows the individual to avoid an unpleasant event by engaging in a range of behaviors if the target behavior does not occur. Researchers have shown that DNRO interventions are effective at increasing passive compliance with wearing medical devices (e.g., medical alert bracelet) in children with developmental disabilities, reducing challenging behavior in the presence of aversive music, and improving behavior during haircuts (Buckley & Newchok, 2006; Cook et al., 2015; Schumacher & Rapp, 2011; Wheatley et al., 2020). The DNRO intervention provides regular access to escape throughout the intervention; however, the procedure requires constant monitoring for occurrences of challenging behavior, and expertise in schedule thinning (Geiger et al., 2010). Since access to escape is unlikely to be under the individual's control, DNRO is most appropriate for increasing passive compliance to an aversive event (e.g., an invasive medical procedure).

Guided Compliance

Guided compliance involves systematically providing more intrusive prompts in response to noncompliance (Lipschultz & Wilder, 2017). Typically, the trainer implements a least-to-most prompting procedure, which has been evaluated as effective for children with and without developmental delays (e.g., Tarbox et al., 2007; Wilder & Atwell, 2006). The traditional three-step prompt hierarchy (i.e., vocal, model, and physical) is often used in guided compliance interventions to increase active compliance. The procedure begins with the delivery of a verbal prompt (e.g., an instruction) and more intrusive prompts are methodically introduced if noncompliance persists. Next, the trainer provides a gestural or model prompt, culminating with a physical prompt when necessary in which the individual is physically guided through the task.

Teachers, caregivers, and researchers have successfully implemented this intervention (Reisener et al., 2014; Smith & Lerman, 1999; Wilder et al., 2012b). While the three-step guided compliance procedure is effective, Wilder and Atwell (2006) also found that the effectiveness of the procedures may largely depend on individual characteristics. Wilder et al. (2012a) found that modifications to the procedure may be required to reach acceptable levels of compliance for some children. These modifications included omitting the model prompt and decreasing the inter-prompt interval, and the use of differential reinforcement in the form of delivering a highly preferred item contingent upon compliance with the first vocal prompt (Wilder et al., 2020). Guided compliance, like other compliance training procedures, can be an effective intervention, but the function of noncompliance must be first identified. If the function of noncompliant behavior is to gain access to social attention, guided compliance may cause an increase in undesirable behaviors (Kern et al., 2002; Wilder et al., 2008) and may be more difficult to implement because the procedure may require the use of prompt fading to lessen the dependence on prompts from others (MacDuff et al., 2001).

Escape Extinction

Extinction generally involves withholding a reinforcer contingent on engagement in a target behavior that was previously reinforced by this same reinforcer (Cooper et al., 2020). If the behavior is maintained by escape (which is often the case with compliance issues), the procedures are referred to as escape extinction. For example, the implementation of escape extinction to increase compliance may involve preventing an individual from escaping an activity, task, or demand. The trainer maintains the activity, task, or demand until the individual complies. Escape extinction has been successfully applied as part of a multi-component treatment package to treat selective and inadequate food intake in children (Bachmeyer, 2009) and is often an addition to compliance training for individuals with developmental delays who exhibit challenging behavior (Cook et al., 2015; DeLeon et al., 2008; Iwata et al., 1990; Piazza et al., 1997; Zarcone et al., 1994). For example, Zarcone et al. (1993b) observed no improvement in compliance or challenging behavior maintained by escape from tasks until extinction was implemented.

A benefit of escape extinction is that it can be combined with other procedures (e.g., demand fading, DNRO) used during compliance training to improve outcomes (Geiger et al., 2010; Lipschultz & Wilder, 2017). The use of extinction may lead to a temporary increase in challenging behavior (i.e., extinction burst) or evoke aggressive behavior (Lerman et al., 1999). The implementation of escape extinction often requires high effort, which may result in lower treatment integrity. Thus, appropriately trained professionals are needed to confirm the maintaining variables, carry out the treatment, and ensure the safety of the individuals involved (Cook et al., 2019; Geiger et al., 2010; McConnachie & Carr, 1997).

Group Contingencies

In all previous interventions, the trainer delivered (or withheld) the consequence contingent on engagement in individual behavior. An alternative to this approach is the implementation of group contingencies, which involve the delivery of reinforcing stimuli for the behavior of the group (Hayes, 1976). Three types of group contingencies exist: independent, dependent, and interdependent (Cooper et al., 2020; Theodore et al., 2004). In independent group contingencies, the trainer implements the same contingency for all members of the group, but only those members who contact the contingency receive reinforcement. In dependent group contingency, the whole group receives reinforcement contingent on the performance of an individual or of a subgroup. In interdependent group contingencies, all members of the group must achieve the criteria set out in the contingency for the group to access reinforcement.

Researchers have repeatedly shown that group contingencies may be an effective method to improve compliance with rules within a group setting (Joslyn et al., 2019; Pokorski et al., 2017). In an example of interdependent contingencies, Swiezy et al. (1992) required that preschool children cooperate in pairs; each child in the pair had to meet a different criterion and reinforcement was contingent on both children achieving their criterion. The intervention increased instruction-following in all participants. In a more recent example of group contingencies, Deshais et al. (2019) compared the effects of independent and randomized dependent contingencies on compliance with academic tasks. The randomized dependent contingency involved randomly and anonymously selecting the subgroup of participants whose behavior controlled the contingency. Although both group contingencies were generally effective, the researchers found that independent contingencies were typically equally or more effective than randomized dependent contingencies to increase compliance. Group contingencies have the advantage of being more easily applicable to a larger number of students. In contrast, practitioners must remain wary of potentially stigmatizing effects when a single individual systematically prevents others from accessing the reinforcer.

Public Posting

Public posting is a consequence-based strategy used to increase compliance or performance of a skill. During public posting, the trainer provides a consequence in the form of feedback about a behavior (e.g., score, graph, and chart) that is posted in a public area where others may see (Nordstrom et al., 1991). Researchers have demonstrated the efficacy of public posting to treat compliance or adherence issues in multiple settings, such as improving student and teacher behavior in school settings (Gross & Ekstrand, 1983; Holland & McLaughlin, 1982), improving employee behavior (Hutchison et al., 1980), increasing compliance (e.g., hygiene) in individuals with developmental disabilities (Blount & Stokes, 1984), and increasing citizen compliance with laws (e.g., obeying speed limits; Ragnarsson & Bjorgvinsson, 1991; Van Houten et al., 1980). The benefits and drawbacks of public posting are similar to those described for group contingencies: this type of intervention is easy to implement with groups of individuals but carries the risk of stigmatization. To address this issue, public posting should be used for participants of a similar level or the goal should be adapted so that it is based on the individual rather than the group.

Practical Considerations

For clarity, the treatment section of this paper presented each antecedent-based intervention and each consequence-based intervention separately. Researchers in behavior analysis often test interventions individually so that they can isolate their specific effects (Cooper et al., 2020). In practice, behavior analysts often combine interventions in a treatment package to increase the likelihood the treatment will produce the desired change in behavior. For example, Lalli et al. (1995) showed that a treatment package involving the manipulation of the antecedents, functional communication training, and extinction increased compliance with tasks in children and adolescents diagnosed with developmental disabilities. When choosing which components to include in a treatment package, practitioners should carefully consider the advantages and disadvantages of each.

A second practical consideration is the effort and resources required for training individuals who will be implementing compliance training. Simply explaining the procedures to the trainee is often insufficient to teach others (e.g., caregivers, teachers) to implement behavioral interventions to increase compliance (Miles & Wilder, 2009; Reisener et al., 2014). Behavior analysts must implement systematic procedures to teach others to implement behavioral interventions with high integrity (Brock et al., 2017). Compliance is no exception and we refer the reader to Chap. 24 to monitor treatment integrity as well as Chaps. 35 and 36 to learn more about how to conduct effective training with both caregivers and staff.

Finally, the practice of behavior analysis involves continuous monitoring of the intervention to examine whether the individual is making progress (Cooper et al., 2020). Behavior analysts should bear in mind that they can never perfectly predict whether an intervention will be effective to improve compliance for a given individual prior to its implementation. Rigorously monitoring the effects of the intervention using valid measures of behavior (Chap. 19) and the use of single-case designs (Chap. 20) appears essential when adopting an evidence-based practice. The implementation of the assessments and interventions should systematically rely on the previous approach to determine whether compliance training was effective in producing socially significant changes for the individual receiving treatment.

Conclusion

Researchers have validated the effects of multiple antecedent-based and consequence-based interventions to support practitioners in conducting compliance training. These studies have applied compliance training in a variety of populations including children with and without disability, adolescents in residential juvenile facilities, workers in employment, elderly patients, and citizens in general. These applications show the breadth and contribution of applied behavior analysis to solving issues related to compliance. Behavior analysts have numerous options at their disposal to treat compliance. Although the advantages and disadvantages of each intervention should guide selection, the main criterion to judge the effectiveness of a treatment for a given individual remains the direct implementation and assessment of its effects within a single-case design. By using a systematic approach to compliance training, behavior analysts may not only improve their practice and research, but also promote the learning, health, social inclusion, and well-being of those who benefit from their services.

49 On-Task Behavior

Amarie Carnett and Christopher Tullis

> We may have taught many social skills without examining whether they actually furthered the subject's social life…many on-task skills without measuring the actual value of those tasks; and, in general, many survival skills without examining the subject's actual subsequent survival.—Baer et al., 1987

Developmentally, the beginnings of on-task behavior begin around 6 months of age with initial eye-contact (Novak & Pelaez, 2004). This step, in a relatively complex chain of responses, has been indicated as an initial marker of potential future developmental delays or disabilities (e.g., Fragile X syndrome, autism spectrum disorder (ASD); Hall et al., 2006; Clifford & Dissanayake, 2008). Although a relatively simple operant response, eye contact has been a key dependent variable in early behavior analytic research focusing on attending skills and compliance with instructional cues (Foxx, 1977; Hamlet et al., 1984). Additionally, this early skill may be conceptualized as the basis or early emergence of more complex on-task responding or sustained attention that is typically developed in increasing complexity during the first 4 years of life (Grazino et al., 2011). These types of sustained interactions with stimuli have been positively correlated with problem solving, intelligence quotient (IQ), and communication skills (Choudhury & Gorman, 2000; NICHD, 2003).

On-task behavior, or the extent to which a person engages in sustained attention and allocates the majority of their responding toward specific stimuli, is a key determinate of success in a number of educational and social environments (Greenwood et al., 2002). Although the definition of on-task behavior may be further refined to specific, environmentally relevant responses (e.g., math problem completion, scanning an array of materials to complete a task) for the purpose of this chapter we will broadly define it as responding that requires sustained behavior specifically allocated to one stimulus or a set of stimuli. Overall, students in classroom contexts are on task between 77% and 89% of the instructional day (McConaughy et al., 1988; Weisz et al., 1995). Additionally, evidence from the literature supports the assertion that sustained on-task behavior is required for academic success regardless of educational environment or diagnosis (Greenwood, 1991).

Defining and Measuring On-Task Behavior

On-task behavior is a commonly targeted response across typical and atypical development, and the definition of this specific response varies from engaging with stimuli visually to complex reading comprehension tasks. For general analysis, it may be useful to view "on-task" behavior as a class of responses versus one specific response topography. In doing so, defining individual instances of on-task behavior requires an evaluation of contextual variables within specific environments, such as discriminative stimuli, and specific chains of responses that are classified as "on-task." As stated previously these may vary widely depending on current environmental expectations, specific participant/learner skill level, and task complexity (see Table 49.1 for definition variations). For example, Slattery et al. (2016) operationally defined on task responding for participants without an intellectual or developmental disability diagnosis in terms of engagement with environmental stimuli either passively (e.g., reading a book) or actively (e.g., asking questions) when specified routines were presented. In comparison, Li et al. (2019) defined on task responding in terms of task completion and use of a self-monitoring strategy.

As a response or response class, on-task behavior may be classified as a continuous responding. Stated differently on-task behavior is not a class of responses that necessarily has a discrete beginning and end. Given the somewhat fluid nature of what is termed "on-task" behavior in the literature, it seems that measurement systems based in temporal extent (Cooper et al., 2019). These types of measurement systems are focused on the duration or length of time a response or response class occurs during a set period of time/session, or the amount of time a response or response class occurs during one episode. See Table 49.1 for examples of various measurements that correspond to various on-task behaviors.

A number of introductory texts in applied behavior analysis (ABA) outline various measurement systems appropriate for responses that

Table 49.1 Example definitions of on-task behavior defined in the literature

Study	Operational Definition	Measurement	Activity/Task
MacDuff et al. (1993)	(a) Visually attending to any appropriate play or work materials, (b) looking at their photographic schedules, (c) manipulating play or work materials appropriately (i.e., as they were designed to be used), or (d) in transition from one scheduled activity to another.	60 s momentary time sampling	6-item activity schedules across academic work and leisure tasks (e.g., handwriting worksheet, blocks, snack, TV).
Warren et al. (2019)	Eyes oriented toward instructor, task materials, reinforcers, or AAC device, and complying with task demands	10 s momentary time sampling	Visual activity schedules across low preferred and high-preferred tasks
Axelrod et al. (2009)	Actively (e.g., writing notes) or passively (e.g., reading homework materials) attending to martials, and asking relevant questions about homework materials	10 s partial interval recording	Homework tasks
Xu et al. (2019)	Engaging in an academic task, looking at the instructor or instructional materials, and refraining from engaging in challenging behavior	1 min whole interval recording	Academic tasks
Kim et al. (2018)	Meaningfully participating in reading activities (e.g., asking/answering questions, reading aloud, writing)		
Hume and Odom (2007)	Visually attending to materials, manipulation of materials, or moving from one task to another		
Carnett et al. (2014)	Sitting with buttocks on ground, head oriented towards teacher, and absence of challenging behavior		

are continuous in nature, and a full explanation of each is beyond the scope of this chapter. From the literature, it seems that duration per session or time-sampling may be appropriate if a leaner is engaged in on-task responding during a set instructional period and the purpose of the intervention is to increase the percentage of time during instruction the learner is on-task (e.g., Warren et al., 2021). When the environment is not as controlled or easily observed as a classroom or clinic context, duration per occurrence or time sampling may be more appropriate as well as feasible (Boden et al., 2018).

Pre-requisite Skills

In populations of people that deficits in skills related to on-task responding, the behavior analytic literature contains a number of teaching demonstrations that target specific and related behaviors. For example, Legge et al. (2010) demonstrated the impact of a self-management intervention with three children diagnosed with autism spectrum disorder. The self-management intervention consisted of a MotivAider that vibrated at preset intervals, which prompted participants to engage in self-evaluation of whether or not they were on-task. Increases in on-task responding were observed across all participants that maintained after the self-monitoring procedure was withdrawn.

Although the literature is rich with suggestions for interventions to teach on-task behavior, the prerequisite skills necessary to engage in or effectively learn responding related to on-task behavior is absent. In behavior analytic assessments (VB-MAPP, Sundberg, 2008; ABLLS-R, Partington, 2006), some of the components or prerequisites are reflected in specific skill areas that may be assessed and targeted for intervention. For example, in the VB-MAPP (Sundberg, 2008) contains assessment elements for attending to stimuli, attending to an instructor, responding to instruction, and visual attention.

It would seem that on-task behavior would require developed skill in three specific areas. First, learners would need a strong repertoire of attending skills that would include but are not limited to sustained attention, as well as the ability to switch briefly from on element of a task to another in the case of more complex types of tasks (e.g., taking notes in a lecture). In a recent review, Markelz and Taylor (2016) provide some support for attending as a prerequisite skill, reporting that praise for attending responses was correlated with increases in on-task responding for people with emotional and behavioral disabilities. For more impacted populations of learners, several investigations have supported the implementation of pairing procedures to increase visual attending and manipulation of educational materials (Singer-Dudek et al., 2011; Longano & Greer, 2006), and attending to voices during group instructional periods (Greer et al., 2011). Although these studies did not specifically assess the extent to which the presence or absence of attending skills impacted "on-task" behavior, the targeted dependent variables (e.g., object manipulation, attending to voices) may be conceptualized as responses that define whether or not a learner is on-task, lending further support to the assertion that basic attending skills may be a prerequisite skill.

Second, for more complex responses, learners may need a repertoire of self-monitoring or self-evaluation to determine how close or far away they are from the terminal goal or termination of present activities. One type of academic of self-evaluation that is often employed within some special education classrooms is strategy instruction (Whitby et al., 2009). Strategy instruction may be used in a number of curricular areas, and generally includes teaching flexible skills, as well as specific rules, that may be utilized somewhat uniformly within a curricular area. These strategies include self-evaluation of responding against established strategies as well as learned rules to determine if the response matches.

Last, in the event that tasks themselves are not fully in the learner's repertoire (i.e., are unmastered or novel), repertoires related to asking for assistance, recruiting reinforcement, or delivering self-reinforcement for related responses may be necessary. Stated differently, when novel tasks are present, learners may require repertoires that allow others in the environment to mediate their on-task responding. For example, for a learner that has not fully mastered a math or reading task, a repertoire of asking for assistance may need to be taught. For example, Germer et al. (2011) demonstrated the utility of a function-based treatment package that included a component acquire teacher assistance during independent seatwork. Results of this investigation reflected an increase in on-task responding when the antecedent intervention targeted at requesting assistance was implemented.

The prerequisites for on-task behavior are not as well established, but results from a number of investigations (e.g., Greer et al., 2011) in combination with descriptive information from developmental literature (e.g., Grazino et al., 2011) may help provide some possible examples for further empirical study. It should be noted that specific prerequisites may vary across populations of people. For example, a person with autism spectrum disorder (ASD) may require more intensive intervention related to intervening behavior (e.g., stereotyped hand movements) before intervention for a prerequisite for on-task responding may be targeted (Morrison & Rosales-Ruiz, 1997). Similarly, someone with a social aversion may require supports to lessen the aversiveness of social approach before teaching to ask for assistance with a novel task (Spain et al., 2017).

Contexts, Populations, and Relevance

On-task behavior is a class of responses that may be observed and required across a number of environmental contexts that include academic, vocational, and social situations where sustained interaction with environmental variables may be necessary for success (Gettinger & Stoiber, 1999). For example, a student in a general education setting would need to engage in some level of on-task responding to access educational materials and learning opportunities (Christle & Schuster, 2003). Similarly, a student in a college classroom or lecture hall would need to engage in a level of on task responding to fully engage with presented materials. Given the range of contexts in which on-task behavior is relevant for an individual's repertoire, it is often targeted within individualized interventions to help increase the number of learning opportunities. Further, for most children, the amount of time spent engaging in academic tasks are predictive of overall academic achievement (Gettinger & Stoiber, 1999). Thus, further highlighting the importance of on-task behaviors within an individual's repertoire.

Strategies for Teaching On-Task Behavior

A variety of intervention strategies related to increasing on-task behaviors have been cited in the literature across a variety of disability populations. Some commonly utilized intervention components include the use of reinforcement procedures (e.g., Tarbox et al., 2006), prompts/visual cues, and the use of technology. The following sections of this chapter review several of the commonly reported strategies and treatment packages used to teach on-task behaviors. An overview is provided in Table 49.2.

Reinforcement

One of the most frequently used intervention components to promote on-task behavior involves the use of reinforcement procedures. Although for most interventions that target increasing on-task behaviors include reinforcement procedures, consideration of reinforcer type, and delivery schedules play a critical role in an intervention's effectiveness. (For review of concepts related to reinforcement see Cooper et al., 2019; Hackenberg, 2018).

Conditioned reinforcement, such as the use of token reinforcement or specific praise statements, has been evaluated in the context of teaching on-task behavior. For example, Tarbox et al. (2006) evaluated the use of token reinforcement on attending (i.e., making eye contact with the instructor) during discrete trail training sessions.

Table 49.2 Review of intervention strategies

Intervention strategy	Description	Literature examples
Reinforcement	Consequence variable (within the response/consequence functional relation) use to reinforce the future likelihood of on-task behavior(s) under similar conditions. Reinforcers are idiosyncratic and include both conditioned (e.g., token economies) and unconditioned (e.g., food).	Carnett et al. (2014)
		Diaz de Villegas et al. (2020)
Choice and preference	Antecedent-based strategies used to account for motivational effects (establishing operations) to increase the behavioral evocative effects for increasing on-task behavior(s).	Morrison and Rosales-Ruiz (1997)
		Watanabe and Sturmey (2003)
Self-management	A range of activities (i.e., both cover and overt behaviors) that an individual engages in to increase appropriate (targeted) behavior(s).	
Prompting and visuals schedules	A supplementary stimulus used (e.g., visual cue) for evoking behavior or a series of behaviors related to preforming an on-task behavior(s). Visual schedules are often used within the context of self-management plans.	Hume and Odom (2007)
		Bryan and Gast (2000)
Technology	Equipment used as an intervention component, ranging from touch screen devices, computers, and watches, to help increase on-task behavior(s). Technology is often utilized within self-management interventions.	Mechling et al. (2006)
		Romans et al. (2020)
Self-management interventions	A general term related to a range of behaviors both overt and covert, that increase the probability of on-task related behavior(s).	Axelrod et al. (2009)
		Harris et al. (2005)

Findings of this study indicate that the use of token reinforcement was successful for increasing attending behavior. Additionally, Carnett et al. (2014) evaluated the effects of two types of token economy systems (i.e., traditional vs. perseverative interest-based) for on-task behavior for a child with ASD. During both conditions, on-task behavior (i.e., sitting, orienting toward the teacher, absence of disruptive behavior) was reinforced in the context of a read-a-loud literacy activity (group instruction). Although results showed both token systems were effective at increasing on-task behavior. Higher rates of on-task behavior during the perseverative interest-based token economy sessions were observed, compared to lower rates in the traditional token economy sessions. Further, these results also generalized to an inclusion classroom, indicating the quality of secondary reinforcers may have an effect on rates and generalization of on-task behavior for some children.

More recently, research has compared reinforcement schedules to evaluate the effects on on-task behavior. Specifically, Diaz de Villegas et al. (2020) compared the use of a synchronous-reinforcement and accumulated reinforcement conditions and the effects for on-task behavior for preschool aged children. During the synchronous reinforcement condition the child was provided access to reinforcement (i.e., preferred song and social attention from the experimenter) while they engaged in the targeted on-task behaviors. However, if the child stopped engaging in on-task behaviors for 2 s the experimenter stopped providing reinforcement (i.e., the song was paused, and social attention was discontinued). Comparatively, during the accumulated reinforcement condition, the delivery of reinforcement was yoked to the duration of on-task behavior during the session, meaning the total duration of time on-task was equivalent to the duration of reinforcement provided at the end of the session. One unique aspect of this study was the evaluation of participant preference for the two types of reinforcement delivery. Results indicated that participants on-task behavior increased during both reinforcement conditions, compared to baseline levels of responding. However, the synchronous reinforcement condition was more effective for increasing on-task behavior. And further, when assessed for preference of the two types of conditions, participants indicated this condition was also the most preferred condition.

Although reinforcement of behavior is a critical component of any intervention that aims to increase or teach a new behavior, each of the studies mentioned above also point out the importance schedules and delivery of reinforcement. For example, for complex behaviors it may be disruptive to use synchronous schedules, and within many environments, a dense delivery schedule may be impractical, thus consideration should be made with regard to schedule thinning and would typically occur within the natural environment (Trump et al., 2018). Thus, careful assessment and consideration of reinforcement type, delivery, and schedules should be planned within any intervention to promote acquisition or increases in on-task behavior.

Choice and Preference

In addition to consequence-based strategies, such as reinforcement, research has also evaluated antecedent-based strategies, such as evaluating the effects of preferred materials and activities when targeting on-task behaviors. In some populations, such as individuals with ASD, interfering behaviors (e.g., stereotypy) may cause a barrier to engagement and correct responding during academic tasks, which can limit the amount of learning opportunities of a child (Cook & Rapp, 2020). One general method to increase a variety of responses, including on-task behavior, is the inclusion of assessments of preference for environmental stimuli, and the provision of choice based upon results from such assessments (Tullis et al., 2011). Research has evaluated procedures to identify the effects of differential preferred objects on rates of stereotypy and correct responding academic-related tasks. Specifically, Morrison and Rosales-Ruiz (1997) evaluated choice and preference of object sets used in the context of a counting activity. Object sets were evaluated in a preference assessment and ranked as low, medium, and high preference. Results of this study indicated that correct responding and low rates of stereotypy were observed when using low- and medium-preferred items, as compared to high-preferred items. Thus, evaluation of materials used may be especially important when incompatible behaviors, such as stereotypy, are observed and are likely to be evoked by certain materials.

Further, effects of preference (via choice) have also been evaluated within the literature for increasing on-task behavior. For example, Watanabe and Sturmey (2003) evaluated the effects of increasing choice-making embedded within activity schedules for adults with ASD working in a community vocational setting. Specifically, during the choice phase, participants wrote down their choice of task order for their schedules, from a list of tasks assigned by their supervisor. Results indicated higher rates of on-task behavior during the choice condition indicating the potential value of choice to help contriving a learner's motivation to engage in on-task behaviors.

Similarly, research has also evaluated preference and choice of activities and materials used for increasing on-task behavior in children with ASD (Keen & Pennell, 2015; Ulke-Kurkcuoglu & Kircaali-Iftar, 2010; Warren et al., 2019). For example, Ulke-Kurkcuoglu and Kircaali-Iftar (2010) compared the effects of choice of activities and materials on the on-task behavior for four boys with ASD. During the activity choice condition, the children were provided with two activity options (via clear plastic boxes) and able to select which activity they would complete. And during the material choice condition, the teacher would select an activity (e.g., matching colors activity or matching shapes activity) for completion, but the participants were provided two different sets of materials and instructed to select one (e.g., colored pencils or crayons). Each participant had higher levels of on-task engagement during the choice conditions compared to baseline (no choice) condition. However, there was little differentiation across types of choice provided (activity versus materials) in respect to rates of on-task behavior. Thus, indicating that providing choices in general may help to increase on-task behavior, which can provide more flexibility for the types of choices that are conducive and feasible for specific learning environments.

The studies reviewed in this section highlight the utility of providing choice to help decrease interfering behaviors while increasing on-task behaviors. In other words, when an individual finds a task unappealing, there may be a higher likelihood that lower rates of on-task behavior occur (low-probability), compared to situations in which an individual finds the task, materials, or choices provided appealing (high-probability). Thus, the reinforcing function of items, tasks, or choice may play in important role for interventions aimed at increasing on-task behavior.

Prompting and Visual Schedules

When individuals struggle to attend to the natural discriminative stimuli within an environment that should signal behavior, prompts are often used to evoke the targeted behavior. However, some individuals may come to rely on their therapists, teachers, or caregivers to initiate or complete a task, rather than the natural cues in the environment (Oppenheimer et al., 1993). One type of visual prompting strategy (cues) used to prevent dependency on verbal prompts or instructions is known as activity schedules. This specific type of visual support involves the sequential representations of task steps or of individual tasks, where each visual representation serves as a discriminative stimulus for specific behavior (Koyama & Wang, 2011). The use of a sequenced discriminative stimulus can help enable participants to complete the steps in a complex task or to change tasks independently (Miguel et al., 2009). Thus, to teach a range of related on-task behaviors, prompts and visual cues, such as activity schedules, are often used as a part of intervention programs (Koyama & Wang, 2011).

Several studies have focused on the use of activity schedules to provide a visual cue to help promote independence and increase occurrences of on-task behaviors (e.g., Bryan & Gast, 2000; Koyama & Wang, 2011; MacDuff et al., 1993; Mattson & Pinkelman, 2020). A varieties of activity schedule formats (e.g., pictures, symbols, written word) across various populations have been cited in the literature, and correspond with age, complexity (i.e., number of steps/behaviors needed to complete the task), developmental functioning, and targeted tasks/activities. Generally, this type of system consists of a binder or posted schedule, where an individual is taught to look at the picture symbol (in a set order) and respond with the corresponding behavior(s) associated to the task (MacDuff et al., 1993; Miguel et al., 2009).

Over time, the derived control of the behaviors associated to each visual within the activity schedule can develop a complex behavior chain needed to complete a task or activity. As such, activity schedules are often selected as an intervention component to help improve on-task behavior targets. For example, MacDuff et al. (1993) used graduated guidance prompting procedures to teach four boys (ages 9–14 years old) with ASD, who had dependence on verbal prompts, to follow a six-item picture-based activity schedule to increase on-task and on-schedule behaviors. Results of this study indicated an increase for all participants for on-task behaviors (e.g., visually attending to any appropriate materials, looking at their activity schedule, using materials as designed). Replication of these results were reported by Bryan and Gast (2000), who also utilized graduated guidance to teach four children with ASD to use of an activity schedule to develop independence in the context of a literacy activity within a resource-based special education class. Further, data were also collected on generalization of skills to a novel activity where assessments were made indicating high rates of on-task behavior in the context of the untrained activity.

Recently, research has continued to evaluate the use of visual schedules to promote on-task behavior within the general education environment. Specifically, Macdonald et al. (2018) evaluated the use of visual schedules within the context of a structured work systems for four children within an inclusive school setting. Results showed increases in on-task behaviors (e.g., writing or typing using a workbook or computer) after visual schedule implementation. Most recently, consistent findings were reported by Mattson and Pinkelman (2020) for the use of activity schedules to increase on-task academic behaviors (e.g., orientating toward work materials, manipulating work materials as designed) and on-task schedule behavior for middle school students with specific learning disabilities and attention deficit hyperactivity disorder (ADHD), showing increase rates of on-task behavior for each participant, with similar increases reported in the generalization setting (i.e., language arts classroom).

Although the studies reviewed in this section highlight the utility and ease of visual picture schedules within educational settings, prerequisite skills should also be evaluated prior to use. Specifically, attending to visual stimuli, the correspondence of picture/object to the related task skill represented by the visual image should be assessed prior to implantation of a visual cue or schedule system to ensure the participant has the needed prerequisite skills to maximize the effectiveness of this type of intervention (MacDuff et al., 1993).

Technology

As mentioned in the previous sections outlining interventions to support a child's on-task behaviors, the use of technology as an intervention component is often utilized. A variety of technology can be used to help promote on-task behavior, ranging from touch screen devices and computers (Carlile et al., 2013; Soares et al., 2009; Xin et al., 2017) videos (Schatz et al., 2016; Mechling et al., 2006) and watches (Legge et al., 2010). For example, Carlile et al. (2013) used a digital activity schedule to promote increased on-task behavior by programming an iPod Touch with pictures of activities (each embedded with a small image of the clock application) within the photo album. Upon seeing the picture related to the activity with the schedule, the participant would exit the photo app and set the timer application (preset) to indicate when to progress to the next activity. Following the timer, the participant would navigate back into the relevant schedule (photo album) and use the arrows or swipe the screen with their finger to advance to the next activity within the schedule.

Further, research has also investigated the use of technology to reinforce on-task behavior. For example, Mechling et al. (2006) evaluated choice of high-preference video stimuli compared to tangible reinforcement (as a reinforcer for on-task behaviors and task completion for two middle school students with ASD who received instruction in a self-contained classroom. Results highlighted the effects of reinforcer quality for improving rates of task completion for the participants.

Technology has also been utilized to help individuals self-monitor to improve rates of on-task behavior (e.g., Soares et al., 2009; Romans et al., 2020; Rosenbloom et al., 2019). For example, Romans et al. (2020) used a web-based self-monitoring system to increase on-task behavior in the context of an academic tasks (i.e., essay writing and pre-algebra) for high school students with ASD. Specifically, this study utilized I-Connect self-monitoring, which is a web-based application that can be installed on smart devices (i.e., phones and tablets) to help monitor on-task behaviors. Results of this study indicate an immediate increase in on-task behaviors for both participants, although a functional relation, with regard to academic accuracy, was not observed for the participant engaging in an essay writing task. This study highlights the utility of increasing on-task behavior with digital self-monitoring systems; however, perhaps levels of fluency and acquisition of skills should be a considered prior to use. Another example of the use of app-related technology is provided by Xin et al. (2017). Researchers in this study utilized iPads installed with the application "Choiceworks," which is an app that allows for images, photos, and video to be used to customize a child's daily schedule and routines. In the context of the present study, it was used to help provide support for self-monitoring. Specifically, video models of on-task behaviors with vocal descriptions of the behaviors were programed into 30s clips and saved into the app. Each participant watched the video clips at the beginning of their class. At the end of each class the participants were required to self-assess if they had engaged in that behavior. On instances where one of three target on-task behaviors (e.g., paying attention, sitting in their seat, working on their assignment) did not occur, the participant would discuss it with their teacher and watch the relevant video clip for review. If all the targeted behaviors occurred, then access to a preferred activity was provided. As such, all participants were reported to have shown increases in on-task behaviors.

Although one might argue the availability and ease of many forms of technology exist within our daily lives, considerations of use specific promote on-task behavior should be made prior to the inclusion within an intervention. Similar to previously discussed prerequisite skills for the use of visual systems (e.g., correspondence, attending to the stimuli) should also be considered for technology-based systems. And although many children have previously developed technology repertoires, such as the ability to activate touch screens and navigate within the device, some children may require explicit instruction on these behaviors (Carlile et al., 2013). Further, clear instructional parameters of use would need to be established prior to the inclusion of technology, otherwise the potential for unrelated and possibly interfering behaviors (e.g., using an app to play games rather than engage in the self-management app) may occur. In summary, assessment of the skills needed to properly engage with the technology should be completed prior to the selection and inclusion of technology within a treatment program.

Self-Management Interventions

Self-management, or as described by Skinner (1965) as self-control, involves controlling one's response(s), and generally includes range of behaviors that increase or decrease the probability that desired behavior occurs (Mace et al., 1987; Thoresen et al., 1974). Stated in another way, self-management is the personal application of behavior change components that produce desired improvement of targeted behavior(s). Research has evaluated the use of self-management components with a variety of populations, both typically developing (Bodenheimer et al., 2002; Donaldson & Normand, 2009) and with diagnoses of intellectual disability and/or ASD (Axelrod et al., 2009). Self-management interventions are often utilized within high-incidence disability populations and people with low-incidence disabilities with lower support needs, such as individuals with learning disabilities (LD), attention deficit hyperactive disorder (ADHD), conduct disorder (CD), emotional and/or behavioral disorder (EBD), and ASD often are taught as part of an individualized program to promote autonomy and independence (Briesch & Briesch, 2016).

Further, self-management includes several components, including self-monitoring and self-evaluation. Self-monitoring (also termed self-recording or self-observation) can be defined as a procedure in which an individual observes and reports (e.g., occurrences vs. nonoccurrences) their own behavior (Harris, 1986). Self-monitoring is often associated to on-task-related behaviors. Several studies have evaluated procedures to teach self-monitoring related to on-task behavior (e.g., Holifield et al., 2010; Stasolla et al., 2014; Wolfe et al., 2000). For example, Wolfe et al. (2000) evaluated the use of self-monitoring to promote on-task behavior for children with ASD with lesser support needs, finding an increase in on-task behavior and reduction of stereotyped behaviors. Further, similar results were reported when using self-monitoring for a writing task with elementary students with LDs.

Result of this intervention indicated both an increase in on-task behaviors and some moderate increases in written performances. A greater increase in writing progress occurred with the introduction of a change in criterion with a public posting condition. Additionally, research has also evaluated self-monitoring in the context of on-task behavior and academic accuracy (see Reid, 1996 for a review). Harris et al. (2005) noted the potential for differential effects on on-task and academic (i.e., spelling task) behavior, and thus highlight need to monitor both related types of on-behavior (i.e., attention to task and task performance). Along those lines, accurate reporting is a critical feature of an effective management program. Research has evaluated interventions targeted to develop accurate self-monitoring to help decrease problem behavior (e.g., Cavalier et al., 1997; Wills et al., 2019) increase academic performance (e.g., Hudson, 2019; Scheithauer & Kelley, 2017) and general task completion (e.g., Lee et al., 2018; Li et al., 2019).

In sum, self-management interventions can be utilized across a wide variety of skills and populations. As an intervention, self-management interventions have been successful in encouraging on-task responding, with durable effects. Additionally, the nature of self-monitoring programming may be unique in that the effects may be easily generalized across settings because of the portability of the intervention components (e.g., reminders, data collection). Although the ultimate goal of self-management interventions is independence, some populations of people may not easily learn this relatively expansive system, which may then require more intensive teaching procedures. Regardless of learner skill, practitioners should implement systematic teaching procedures for each component with careful planning and evaluation of each intervention component.

Treatment Packages

In some cases, multiple intervention components may be useful for addressing on-task behavior. As such, several studies related to increasing on-task behavior utilize treatment packages that include intervention components previously discussed in this chapter (e.g., reinforcement, prompting, visuals schedules, technology). For example, King et al. (2017) use a treatment package called "On-Task in a Box," which is a manualized intervention that incorporates self-monitoring and video modeling for school settings. Participants were trained using the manualize procedures and the use of a MotivAider watch to self-monitor their behavior. Results of this treatment package indicated increased levels in on-task behavior (similar levels to classroom peers) for the participants.

Further, research has also evaluated the use of structured teaching to promote on-task behaviors. For example, Park and Kim (2018) evaluated the effects of the TEACCH structured teaching program on on-task independent works skills for individual with severe disabilities. Specifically, this treatment package utilized the guidelines of structured teaching (see Mesibov et al., 2005) visual schedules, work systems, and task organization. Results of this study indicate increases in on-task behavior, thus supporting the utility of treatment packages, such as structed teaching to help promote on-task behavior. Further, treatment packages, such as "The Good Behavior Game" (GBG), have also been cited in the literature to have positive effects for increasing on-task behaviors. For example, Pennington and McComas (2017) evaluated the effects of the GBG across classroom context for three children with EBD. Results showed that when the GBG was implemented in one context (e.g., morning meeting, math class) on-task behavior increases were not observed in the other contexts until the GBG was implemented. These findings highlight the need to program for generalization of behavior across various contexts (environments).

General Recommendations for Practice

Specific considerations for various treatment procedures have been mentioned throughout this chapter. Although this chapter does not provide an exhaustive review of the literature, there are several overarching considerations that have been identified to help guide the development of interventions that target on-task behaviors and warrant further discussion.

First, when evaluating an intervention to promote behavior change, an initial starting place is to first assess the learner's current repertoire. As mentioned in previous sections, utilizing an assessment that clearly evaluates the parameters and abilities of the learner will help to ensure the learner's identified target behavior is appropriate in terms of their current abilities. Next, it is important that a precise definition of the behavior of interest is developed, and considers made for how it would most accurately be measured (see Cooper et al., 2019 for defining and measurement behavior). As such, the actual value of the targeted on-task behavior should be of equal weight when making intervention plans. These variables are subjective and individualistic, and when evaluated within assessment and treatment development, can help to ensure the intervention provided ascribe to the values of concept of social significance within the field of ABA (Wolf, 1978; Snodgrass et al., 2018).

Next, given the variety of behavioral definitions within the literature for on-task behaviors (see Table 49.1), consideration of the context and learner abilities should be reflected when defining the targeted on-task behavior(s). A clearly developed definition of the targeted behavior will help to ensure accurate measurement procedures are implemented, and that data-based decisions can occur to guide future program decisions. Along these lines, considerations should also be made related to the accuracy and fluency of other responses, or those where a desired increase is anticipated. When defined in a general sense of the concept, being on-task might be mutually exclusive to accurate responding. For example, if on-task behavior is defined as paying attention to an academic task, this may not mean that accuracy of the task was observed. Thus, consideration should also be given to the accuracy, fluency, and/or amount of the task that was completed. Specifically, if the targeted on-task behavior is aligned with a general goal for promoting independence, it would be important that the task selected for the intervention was a previously mastered skill, perhaps selected from a maintenance program.

Lastly, any behavior change intervention should actively program for generalization of a targeted skill (Carnett, Sigafoos, & Neely, in press; Osnes & Lieblein, 2003; Stokes & Baer, 1977). However, this often does not occur within intervention planning or in the context of research. Thus, we encourage both practitioners and researchers to program and evaluate generalization of on-task behavior and considered critical elements, such as appropriate environments, contexts (e.g., skills, activities, tasks), and the use of maintenance program to help ensure relevant and lasting behavior changes. When generalization is actively programmed for within a behavior change intervention, we can ensure the lasting effects of the intervention occur (Carnett, Sigfoos, & Neely, in press; Osnes & Lieblein, 2003; Stokes & Baer, 1977). As discussed by Osnes and Lieblein (2003) it is critical when considering generalization of behavior change that we continue to raise the bar with our efforts as part progression within research and practice.

Summary and Conclusion

The ultimate goal for acquisition of on-task-related behaviors seems to be functionality, autonomy, and independence. On-task behaviors can range in complexity, topography, and are subjective to the contextual variables within the environment. The current research reviewed in this chapter supports this conceptualization and indicates the potential need for refinement in our behavioral definitions for "on-task," as evaluation of collateral effects of these various interventions. Regardless, research on this topic indicates this category of behaviors can be pivotal for providing learning opportunities and the development of fluent repertoires. Thus, consideration should be made of contextual variables that help generalize behaviors to gain autonomy and independence across the life span.

50 Teaching Play Skills

Angela Persicke, Elizabeth Meshes, Adel C. Najdowski, and Emma I. Moon

Teaching Play Skills

Play skills are an integral part of child development in facilitating repertoires, such as exploration of functions of objects (Bruner, 1973), motor skills (Ozaydin, 2015), leisure interests (Barton, 2010), language, problem-solving (Boutot et al., 2005), sharing (Ginsburg, 2007), initiation (Zanolli et al., 1996), making choices, following rules (Vidoni & Ward, 2009), compromise (Francis et al., 2019), cooperation, negotiation (Gibson et al., 2017), creativity, flexibility (Bateson, 2005), coping skills (Hess & Bundy, 2003), awareness of others' thoughts and emotions (Barton & Pavilanis, 2012), entering others' play activities, managing conflicts (Ladd, 2005), building relationships (Hirsh-Pasek et al., 2009), school readiness, and literacy (Roskos & Christie, 2001).

In children of typical development, play skills tend to develop through natural reinforcers and require little teaching from adults (Lovaas, 2003), whereas children diagnosed with autism spectrum disorder (ASD) present with deficits in play skills and do not receive the natural benefits from play in the same ways that their typically developing peers do (Boutot et al., 2005). In addition to the benefits of play outlined above, children with ASD and other developmental disabilities (DD) are more likely to successfully integrate with typically developing preschoolers when they demonstrate proximity to peers, engage in social interactions, and play (Nelson et al., 2007). Moreover, positive behaviors related to play are correlated with social engagement (Hobson et al., 2013) and improvement in a child's social standing as it relates to their peers, which might be particularly helpful for children who suffer from peer exclusion (Rubin et al., 2007).

Research has demonstrated that interventions based in applied behavior analysis (ABA) can improve play skills (Lang et al., 2009). This chapter aims to provide practitioners with evidence-based behavioral strategies for teaching play skills.

Developmental Age and Types of Play

To lay the foundation and context for teaching this repertoire, the types of play and when they emerge in typical child development are described in Table 50.1 with approximate developmental age and available literature. Because the domain of play consists of a wide variety of behaviors and involves a wide range of complexity, the majority of studies teaching play skills identify

Table 50.1 Approximate developmental age and types of play

Age of emergence	Type of play	Definition	References
0–10 months	Sensorimotor	Consists of indiscriminate and simple actions with objects, including physical manipulation, looking, picking up, dropping, banging, grasping, mouthing, etc., sometimes in a repetitive fashion; appears to serve a sensory function—No functional relationship between manipulation of the object and the object itself	Casby (1992), Lifter et al. (2011), Lydon et al. (2011), Nelson et al. (2017)
Occurs at all ages	Solitary	Consists of independent play, with and without toys	Salkind (2002), Nelson et al. (2017)
10–12 months	Relational	Emerges as non-functional manipulation involving the association of objects that are not functionally related (e.g., hitting two blocks together); develops into manipulation of objects that are functionally related (e.g., stacking blocks, pretending to comb hair, bouncing/rolling a ball, etc.)	Casby (1992), Lydon et al. (2011), Nelson et al. (2017), Patry and Horn (2020)
9–12 months	Functional pretend	Consists of manipulation of objects in a conventional manner (e.g., pushing a toy car, feeding a baby with a bottle, pretending to drink tea from a teacup, etc.); early pretend play is typically self-directed	Lifter et al. (2011), Lillard (2015), Lydon et al. (2011), Lee et al. (2017)
18–24 months	Symbolic pretend	Involves the manipulation of objects that represents some other action, often in the context of a play scheme and usually reality oriented; play sequences become more complex with chains of events and increased levels of planning (e.g., hosting a pretend tea party, playing house, etc.); object substitution emerges (i.e., using arbitrary objects as items related to the play sequence)	Boutot et al. (2005), Casby (1992), Lifter et al. (2011) Lillard (2015), Patry and Horn (2020)
24–36 months	Parallel	Consists of independent play in close proximity to peers that are playing in a similar fashion; includes referencing or acknowledging others and peers' actions	Francis et al. (2019), Nelson et al. (2020)
24–48 months	Associative	Children begin to interact during play more frequently while engaging in common activity, though there is a segregation of duties and a lack of organization (e.g., playing dress-up, doing crafts, building adjacent Lego structures, etc.)	Nelson et al. (2017)
30–48 months	Sociodramatic pretend	Play sequences with greater complexity including fantasy and dramatic play—Children pretend to be things outside of reality; imaginary objects are used and reliance on language to narrate play schemes; several play schemes are often linked together with multiple participants	Lillard (2015), Nelson et al. (2017), Patry and Horn (2020)
36–48 months+	Cooperative	Consists of more organized group play involving communication to achieve a common goal (e.g., building a fort, acting out a prolonged play sequence, creating a dance, etc.)	Nelson et al. (2017)
36–48 months	Constructive	Involves the assembly of objects to create something else (e.g., playing with blocks, building sandcastles, shaping clay, etc.)	Lillard (2015), Nelson et al. (2017), Salkind (2002)

(continued)

Table 50.1 (continued)

Age of emergence	Type of play	Definition	References
May emerge around 12 months, most prominent between 48 and 60 months	Physical/Rough & Tumble	Includes activities such as climbing, swinging, jumping, chasing, pretend fighting/wrestling accompanied with smiles and laughter	Lillard (2015) Nelson et al. (2017)
60 months	Games with rules	Characterized by commonly known procedures and rules that are either predetermined or spontaneously derived within the group	Lillard (2015), Nelson et al. (2017), Salkind (2002)

the broader category of play and provide operational definitions relevant to the skills targeted for each intervention. Although this is a good strategy when researching these topics, conceptual accounts may assist in the future direction and research of play. A behavioral conceptual account of all forms of play is not available as far as we are aware, outside of one article that proposes a behavioral perspective specific to symbolic play (see Lee, Qu, et al., 2020b). Conceptual accounts of the types of play listed in Table 50.1 may be beneficial for a more comprehensive account of these behaviors and the identification of effective teaching strategies to promote the full range of play skills.

Research on Effective Play Strategies

The following sections review the empirical basis for behavior analytic intervention strategies related to teaching play skills. An overview of each approach is provided, along with the current state of the research and considerations for implementation.

Structured Versus Naturalistic Instructional Approaches

There are several prominent instructional approaches to teaching play skills that are supported by behavior analytic research. These range from structured approaches (e.g., discrete trial teaching, video modeling) to less structured, naturalist approaches (e.g., pivotal response training, peer-mediated interventions). The various approaches and teaching strategies supported by research are outlined below for teaching skills categorized as play.

Discrete Trial Teaching (DTT)

Discrete Trial Teaching (DTT) is a structured approach with materials selected by an adult implementer, clear directions, prompting, shaping, and contrived reinforcement (Tarbox & Najdowski, 2008). It has effectively taught early play responses, including extended play sequences using task analyses (Oppenheim-Leaf et al., 2012a) and teaching from simple object manipulation to complex play themes (Lifter et al., 2011). DTT is effective in conditioning toys and play as reinforcers and correlates with decreases in stereotypical behavior among learners with ASD (Eason et al., 1982). Procedures have been embedded in DTT programs to enhance the efficacy of instruction, such as embedded instructive feedback and modeling (Grow et al., 2017). Additionally, research has shown that DTT is an efficacious approach to maintain and generalize established play skills (Eason et al., 1982).

Promoting Creativity, Variability, and Generative Responding. A concern of structured intervention strategies such as DTT is that some interventions do not always establish responses that look natural, or the interventions result in limited novel or creative responding. However, research indicates that increasing variety in play can reduce stereotypy and improve indices of happiness (Lang et al., 2014). Procedures to enhance variability and generalization of skills are often incorporated into DTT play interventions. These include self-management of token delivery for variable responding (Newman et al., 2000), lag schedules of reinforcement to enhance creativity (Galizio et al., 2020), and extinction of previously reinforced play behavior to promote novel responding (Lalli et al., 1994).

Another approach to teaching a generalized repertoire of play skills, as opposed to teaching specific isolated play behaviors, involves matrix training, which refers to a generative instructional approach wherein skills with overlapping components are arranged in a matrix allowing various recombination of each of the component skills (Goldstein, 1983). This approach focuses on teaching a small subset of component play skills, followed by tests for generalization to other scenarios and skill sets to determine if the learner responds to novel combinations of the trained skills (see Curiel et al., 2020 for a review). For example, Hatzenbuhler et al. (2019) used matrix training to teach one of four character–action–vocalization combinations and demonstrated generalization to novel character–action pairs. Responding to untrained pairs in this manner is referred to as *recombinative generalization* (Goldstein, 1983). Several studies have shown that matrix training is an effective and efficient approach to training independent and interactive pretend play skills (Dauphin et al., 2004; Hatzenbuhler et al., 2019; MacManus et al., 2015) and can be combined with other evidence-based teaching strategies.

Matrix training may be useful when intervention time or access is limited and a generalized behavioral repertoire is ideal, such as during pretend play activities that require a broader and more flexible repertoire. In contrast, this approach may not be appropriate for play activities in which specific rules should be followed, such as card and board games, sports, or other structured activities. Although only a few studies have specifically evaluated matrix training for teaching play skills, the results are encouraging for the use of this approach.

Pivotal Response Training (PRT)

Pivotal response training (PRT) is an instructional approach that enhances motivation and generalization of skills, especially when implemented with learners with ASD (Pierce & Schreibman, 1995). PRT focuses on teaching behaviors considered critical to the development of other complex behavioral repertoires, referred to as *pivotal behaviors,* including responsivity to multiple cues, motivation, self-management, and child initiations (Carrero et al., 2014). A play intervention based on PRT would enhance motivation for a play activity by using a child-directed approach and allowing the learner to choose the toy or activity of interest. For example, reciprocal imitation training based on PRT has been effective in spontaneous object imitation, and learners with ASD have demonstrated collateral improvements in language, pretend play, and joint attention (Ingersoll & Schreibman, 2006). Additionally, natural forms of reinforcement are provided for any correct attempt related to the target play behaviors; therefore, the child accesses reinforcement at a higher rate compared to other intervention strategies (Stahmer, 1999). Research shows that PRT-based interventions are effective for teaching manipulative play (Malone & Langone, 1999), pretend play (Lydon et al., 2011), symbolic play (Stahmer, 1995), and sociodramatic play (Thorp et al., 1995), with generalization demonstrated across toys/activities and people.

PRT may be beneficial, especially early in treatment, when levels of motivation are low and high levels of maladaptive behaviors may disrupt treatment gains related to play skills (e.g., Hart et al., 1968). Additionally, this approach may be beneficial when access to opportunities to generalize skills is limited, for example, with learners who are not in inclusive settings and may not have access to peers or siblings outside of treatment. For learners who are somewhat isolated from social interaction, enhancing opportunities for generalization of these skills is critical to future success in general education settings or other inclusive environments. Additionally, PRT strategies may help supplement other structured approaches to enhance the acquisition of play skills.

Comparing DTT and PRT

Comparisons between DTT and PRT have mixed results on their efficacy of teaching play skills. For example, Strauss et al. (2014) showed that a flexible, as opposed to a structured, approach resulted in higher play and more appropriate engagement with peers. Lee et al. (2020a) showed the emergence of symbolic play in only one of three participants in free play observation (i.e., a naturalistic setting) following teaching specific symbolic play actions (i.e., structured trials). Jobin (2020) directly compared PRT and DTT in skill acquisition for early learners with ASD and found that both intervention approaches led to improvement of various skills. Results showed that the same participant might respond differently based on skill and dimension, which supports the idiosyncratic nature of ASD. A more structured teaching strategy may be necessary to teach initial play skills before expanding to more stimuli, expanded trials, or more naturalistic settings (Wong et al., 2007).

Peer- and Sibling-Mediated Play Interventions

Peer-Mediated Interventions. Peer-mediated intervention (PMI) refers to the inclusion of typically developing, similar-age peers trained in intervention strategies. PMI is effective for teaching play to individuals with ASD (Dueñas et al., 2019), DD (Garfinkle & Schwartz, 2002), visual impairment (Ozaydin, 2015), and socially isolated peers in educational settings (Milam et al., 2020). Several recent studies have investigated PMI combined with other evidence-based interventions, such as the system of least prompts (SLP; Barton et al., 2018), progressive time delay (PTD; Francis et al., 2019), video modeling (Dueñas et al., 2019), self-monitoring (Shearer et al., 1996), PRT (Pierce & Schreibman, 1995), and matrix training (Hatzenbuhler et al., 2019). These studies resulted in gains in target play skills and generalization to untrained play scenarios. In addition, two PMI treatment packages, *Stay, Play, Talk* (van Rhijn et al., 2019) and *Keys to Play* (Nelson et al., 2007), are effective interventions to teach play to early learners.

Many successful interventions can be embedded in a PMI format while maintaining or increasing efficacy. For guidance on PMI, several resources are available within the literature. Terpstra et al. (2002) provided recommendations for utilizing various effective strategies, including PMI, into specialized and inclusive classrooms. Further, it is important to consider the type of play and materials required as the availability of toys may promote or deter isolated versus collaborative play (Watkins et al., 2017). Patry and Horn (2020) provided guidance on considerations for selecting toys, identifying and preparing appropriate peers, and determining the appropriate level of adult guidance when using PMI (Wolfberg, 2003 as cited in Patry & Horn, 2020). Furthermore, recommendations for effectively training typically developing children to promote play skills can be found in Oppenheim-Leaf, Leaf, Dozier et al. (2012b).

The general conclusions are that PMI is not only effective but can also: be used in inclusive educational settings, promote generalization and maintenance of target skills, and result in positive social validity ratings from stakeholders (see Chan et al., 2009 or Watkins et al., 2015 for reviews). Additionally, several studies have utilized larger-scale implementation and evaluations of these interventions through group-comparison research designs providing additional evidence that PMI is effective even when scaled (see Chang & Locke, 2016 for a review).

Sibling-Mediated Interventions. Due to the positive effects of PMI to teach social and play skills, several studies have investigated the benefits of using typically developing siblings as trainers to prompt and reinforce appropriate behaviors with promising results (Akers et al., 2018; Oppenheim-Leaf et al., 2012b).

There are several benefits to including siblings in play interventions, especially in early childhood and with siblings close in age. First, siblings may be more available to participate within the home setting than attempting to schedule play dates with typically developing peers. This is pertinent if the learner is in a specialized education setting or private placement having little contact with peer models. Second, siblings may be more willing to participate in these interventions because they are motivated to learn how to better interact with their siblings. Third, these interventions may maintain skills because the siblings will have more access to the learner than a peer would due to living in the same house and likely having similar schedules. Fourth, when a sibling or peer is paired with a high magnitude of reinforcement, it may increase the likelihood of the child with ASD to engage rather than play alone (Hoch et al., 2002).

Interventions Utilizing Visual Strategies and Supports

Video Modeling

Video modeling (VM) refers to an intervention strategy that utilizes pre-recorded videos of individuals (e.g., adults, peers, learner) engaging in the target behavior. VM has been used across a variety of behaviors and settings and is one of the more prominent methods for teaching play skills, especially with learners with ASD because they often require visual modifications and visual supports to facilitate learning outcomes (Fragale, 2014). Additionally, it removes the social interaction requirement often involved with in vivo modeling, which some researchers attribute to its success at enhancing motivation to attend to and engage in the behaviors modeled through this medium (Cardon & Wilcox, 2011; Charlop-Christy et al., 2000). VM has a reasonably large evidence base in the behavior analytic literature and has been used across a variety of skills (see Park et al., 2019; Shukla-Mehta et al., 2010 for reviews).

Specific to teaching play skills, VM has been used to increase independent toy play (Paterson & Arco, 2007), game play (Charlop-Christy et al., 2000), and play-based language, including initiations and responses (Ezzeddine et al., 2020); however, the majority of VM studies focus on teaching pretend play (Akmanoglu et al., 2014; Dueñas et al., 2019; Hine & Wolery, 2006; Lee, Qu, et al., 2020b; Lydon et al., 2011; MacManus et al., 2015). VM also enhances learning outcomes related to play skills when combined with other intervention strategies, including PMI (Dueñas et al., 2019), activity schedules (Blum-Dimaya et al., 2010), matrix training (Dauphin et al., 2004; MacManus et al., 2015), and errorless learning strategies, such as graduated guidance (Akmanoglu et al., 2014).

VM interventions may have several benefits over in vivo intervention strategies with research supporting that VM may be more efficient and efficacious for some learners (Charlop-Christy et al., 2000; Cardon & Wilcox, 2011). Although research on VM has faced some criticism related to inconsistent results for promoting maintenance and generalization of acquired play skills (Lee, Qu, et al., 2020b), recent studies have demonstrated that VM interventions are effective, cost efficient, can be implemented with a variety of learners across a variety of settings, promote generalization, and can be easily combined with other intervention strategies to promote play skills (Hine & Wolery, 2006; Lee, Qu, et al., 2020b). For example, incorporating multiple exemplar training into VM interventions enhances generalization (Dupere et al., 2013). Furthermore, generative learning instructional strategies, such as matrix training combined with VM, have demonstrated that generalization is possible with this approach (Dauphin et al., 2004; MacManus et al., 2015).

Activity Schedules

Activity schedules involve pictures that provide steps needed to complete a behavioral chain related to tasks. They have been prepared using photographs/pictures, symbols, and text (McClannahan & Krantz, 1999) presented in either a notebook, checklist format (Bryan & Gast, 2000; Cuhadar & Diken, 2011; MacDuff et al., 1993; See Rehfeldt et al., 2004 for how to make activity schedules), or electronically (e.g., Brodhead et al., 2018; Kurkcuoglu et al., 2015). Common prompts to use activity schedules include graduated guidance (Bryan & Gast, 2000), least-to-most prompts (Pierce et al., 2013), and progressive time delay (e.g., Carlile et al., 2013), with the goal to fade prompts when possible (e.g., Akers et al., 2016). Reinforcement is usually provided for completing the activity schedule (Kimball et al., 2004). Often, activity schedules can teach learners to combine previously mastered play skills into lengthier play sequences (e.g., coloring, building with blocks, and putting together a puzzle) when given one discriminative stimulus such as, "Check your schedule" (McCollow et al., 2016). Activity schedules can also teach play skills that learners do not have in their repertoire by including each step of the play activity (Cuhadar & Diken, 2011). Systematic reviews of studies conducted with individuals with ASD (Knight et al., 2015) and intellectual disability (ID; Spriggs et al., 2016) have found activity schedules to effectively teach leisure or play skills. Additionally, a meta-analysis has found activity schedules to be effective for improving leisure skills of individuals with ID (van Dijk & Gage, 2019).

Low-tech photographic activity schedules have been used to: (a) increase playground activities (Akers et al., 2016; Machalicek et al., 2009); (b) teach the steps necessary to play with toys (e.g., blocks, Mr. Potato Head, bowling; Cuhadar & Diken, 2011); (c) get learners to engage in a sequence of activities (e.g., memory game, blocks, art, dollhouse, kitchen (MacDuff et al., 1993; Morrison et al., 2002); (d) play hide-and-seek with peers (Brodhead et al., 2014); and (e) teach peers with ASD who could already follow activity schedules independently to use a joint activity schedule to play previously mastered games (e.g., Don't Break the Ice®) together in a classroom (Betz et al., 2008).

High-tech activity schedules are useful for teaching various play skills to individuals with ASD. Computer-mediated activity schedules, combined with video modeling, have been used to increase play bids (Kimball et al., 2004). The iPod Touch® has been used to increase play skills (e.g., basketball, frisbee golf) in a classroom (Carlile et al., 2013). Video-based matrix training has been combined with an activity schedule notebook to teach sociodramatic play (Dauphin et al., 2004). Computer-assisted activity schedules with photographs on PowerPoint® have increased functional pretend play (e.g., dolls, cars, setting a table; Kurkcuoglu et al., 2015). And, activity schedules on an iPad® have increased the varied game play of the iPad's applications (Brodhead et al., 2018). One advantage of presenting activity schedules through electronics is that children with ASD may prefer instruction delivered by a computer over a human (Romanczyk et al., 1999). Since computers are difficult to carry around, activity schedules implemented on computers should be transferred eventually to a folder (see Kimball et al., 2004 for an example) or a smaller device.

Prerequisites for teaching learners to follow activity schedules include object and picture matching/sorting, discrimination of an object when placed on a background (McClannahan & Krantz, 1999), and picture-location identification (Brodhead et al., 2014). A beneficial feature of activity schedules is that choice-making can be embedded into creating them (Stromer et al., 2006). Unfortunately, in some cases, when the activity schedule was removed, responding did not maintain (e.g., Betz et al., 2008; Brodhead et al., 2014).

Script Training

Script training involves the use of written (visual) or audio-recorded scripts of various lengths that include phrases that the learner should say during a social interaction (Barnett, 2018). This intervention has been deemed evidence-based by a recent systematic review (Akers et al., 2016). Script training is sometimes embedded into activity schedules (Akers et al., 2018) and is often used in classrooms (Barnett, 2018). It has been used with children with ASD to increase social interactions during toy play (Akers et al., 2018; Groskreutz et al., 2015; Wichnick et al., 2010), art activities (Krantz & McClannahan, 1993), board games (Hundert et al., 2014), and sociodramatic play (Hundert et al., 2014). Script training has mostly been used to teach initiations; however, it is also used to teach responding to others' initiations (Wichnick et al., 2010). Although, overall effective, the research shows inconsistent results in generalization and maintenance of play skills acquired using script training; therefore, it is necessary to incorporate strategies to promote generalization and maintenance when utilizing this intervention strategy.

Script training alone has improved the variability of responding in social communication (Betz et al., 2011). Likewise, when script training has been combined with lag reinforcement schedules, it has improved the variability of conversational language (Lee & Sturmey, 2014). With advances in technology, some researchers are investigating methods to mainstream visual interventions, such as script training, to digital formats (Murdock et al., 2013) with generally positive outcomes. As technological applications of these interventions become more widely available, further research should evaluate and compare these methods to determine best practices.

Social Stories

A Social Story™ typically includes a combination of written and visual information depicting a social situation, scenario, or problem, along with a description of appropriate behaviors that the learner engages in given the situation in context (Gray & Garand, 1993). Numerous studies have investigated the extent to which interventions incorporating social stories play a role in establishing new behavior and reducing challenging behavior. Some researchers report benefits or moderate efficacy, and others recommend that more research is necessary to consider this an efficacious intervention strategy (Karkhaneh et al., 2010; Test et al., 2011; Wahman et al., 2019). The current state of the research on social stories shows variable results (Zimmerman & Ledford, 2017); however, social stories continue to be widely utilized to promote appropriate social behavior, especially in special education settings.

In regard to promoting play skills, several studies have incorporated this strategy in the acquisition of skills-related game play (Quirmbach et al., 2009) and independent and interactive play (Barry & Burlew, 2004). The results of studies using social stories to teach play, although reporting positive outcomes, should be interpreted with caution. With any study, it is necessary to evaluate the intervention strategies based on the level of rigor, demonstration of experimental control, and if inclusion of other treatment strategies confounds the results without analyzing the individual treatment components.

Due to the overall inconsistent results within the literature on the efficacy of social stories, practitioners and educators should utilize other evidence-based approaches for teaching play, as described in this chapter, as primary intervention strategies. If social stories are included, it is recommended to use them as an additional component to well-established interventions until more research emerges on the use of social stories to teach play behavior.

Treatment Packages

Treatment packages are common behavioral interventions that involve multiple components such as prompting, task analyses, reinforcement procedures, and so on. Treatment packages have been utilized to teach various types of play, such as pretend play (Barton & Wolery, 2010), symbolic play (Lee et al., 2017), parallel and dramatic play (Nelson et al., 2017), as well as diversity in play (Frey & Kaiser, 2011). Treatment packages have been effective in increasing components in peer play such as identifying peers' play preferences during cooperative play (Najdowski et al., 2018), sharing (Bryant & Budd, 1984), and generalization of pretend play skills (Barton, 2015).

Formally developed and manualized treatment packages to teach play are available. Three such treatment packages are *Joint Attention Symbolic Play Engagement and Regulation* (JASPER; Kasari et al., 2014), *Advancing Social-Communication and Play* (ASAP; available digitally, Watson et al., 2011), and *Play20* (Sipila-Thomas et al., 2020). All of the interventions focus on play and the social aspects associated with play. ASAP is developed from JASPER with some key differences: ASAP is targeted across a year while JASPER spans 3 months (Boyd et al., 2018). ASAP has a stronger emphasis on what to teach rather than how to teach it.

This allows for more independence for interventionists. However, it does not include the interventionist coaching embedded in JASPER (Boyd et al., 2018). JASPER has been effective within-participant (Lawton & Kasari, 2012), and both ASAP and JASPER are supported by randomized control trials (Boyd et al., 2018; Chang et al., 2016). Research on Play20 shows that it was effective with three participants, but research is still emerging (Sipila-Thomas et al., 2020).

Several studies have conducted component analyses to determine which elements of a treatment package increase efficacy. Adding an abolishing operation to a treatment package can increase functional play and decrease stereotypy (Lang et al., 2010). A verbal description before modeling an action can increase play imitation (Jahr et al., 2000). Santarcangelo et al. (1987) found that differential reinforcement of alternative behavior (DRA) alone was insufficient for increasing appropriate toy play and required a task analysis and prompting. A multi-component intervention that included the concurrent presentation of modeling and prompting was more effective for teaching independent play of block constructions than modeling or prompting alone (Quigley et al., 2018). There are no findings that any sole intervention or component is most effective for teaching play. Further, findings on maintenance and generalization for treatment packages are mixed, with some studies reporting maintenance and generalization (Barton & Wolery, 2010; Stahmer & Schreibman, 1992) and others showing low maintenance levels and mixed results with novel responses for symbolic play targets at a 10-month follow-up (e.g., Lee et al., 2017).

Conclusion

In summary, play skills are critical to many areas of development. There is a plethora of research on the use of various applied behavior analytic intervention strategies to enhance play skills as described throughout this chapter ranging from naturalistic interventions in inclusive settings incorporating peer models to structured interventions and manualized treatment packages. Although there is a fairly strong evidence base for a variety of intervention strategies for increasing play skills, the broad range of skills within this repertoire requires continued attention from researchers and practitioners alike to identify the most effective strategies for various populations based on the type and complexity of play targeted for intervention.

51 Teaching Social Skills

Alison M. Gillis, Susan M. Vener, and Claire L. Poulson

Social skills are a complex class of responses that relate to one's communication and interactions with other people in a common environment (Little et al., 2017; Ulrich et al., 1966). Although there is no explicit definition, many responses may be categorized as social. This class of behavior may be best conceived of as those responses that increase the likelihood of producing positive consequences with other people, while minimizing negative consequences (Gresham & Elliott, 1984). For example, eye contact, prosody of speech, gestures, affect, language and interactions, joint attention, and play behavior are all important responses that can affect environmental outcomes. The extent to which one displays each, or a combination of these responses can contribute to the likelihood with which that person will function competently in society (Vener et al., 2017). Social skills are vital to one's development and correspond with the likelihood of success in various avenues of life including academics, vocations, and peer relationships (Mayer et al., 2012). Many individuals with developmental disabilities demonstrate deficits in one or more areas of social behavior.

When a person displays a deficit in one or more of these responses, the probability of a positive outcome may be compromised. Nevertheless, evidence-based practices in the field of applied behavior analysis have demonstrated success in teaching social skills and increasing the likelihood of social reinforcement. Effective teaching strategies have included differential reinforcement, modeling, incidental teaching, discrete-trial teaching, script fading, and self-management, among many others. Although not an exhaustive review of the literature, this chapter does address the different components of social behavior and training procedures used in behavior-analytic research.

Research on Social Skills

As outlined by Baer et al. (1968), one of the core dimensions of applied behavior analysis is that the research is *applied* and relates to behavior that is important and socially significant to the person and consumers of the behavior. By definition, social skills satisfy these criteria. Applied behavior analysts have dedicated a vast amount of research to determining effective interventions to teach these skills.

Some of the earliest research on social skills analyzed the relationship between the broad concept of social competence and treatment outcomes of patients with various diagnoses including schizophrenia, manic depression, and personality disorders. These studies concluded that patients with lower social competency were associated with a "poorer prognosis," or less desirable outcomes, than those with higher social competency skills. Patients of the latter were associated with more favorable psychiatric outcomes, such as shorter hospitalization times or a lesser number of hospital readmissions (Zigler & Phillips, 1961; Zigler et al., 1979).

As researchers continued to focus on the study of social skills, the components of social behavior were operationalized, quantified, and measured in a more discrete manner. For example, Bornstein et al. (1977) conducted a study that taught social skills to four unassertive children. The children were between the ages of 8 and 11 years, and displayed deficits in eye contact, speech duration, speech volume, and requests. The authors presented role-play scenarios to the participants that were similar to their typical encounters in school. For example, a scenario may have been that a classmate cut the participant in the lunch line, or that a classmate broke the participant's pencil after borrowing it. The authors used instructions, modeling, feedback, and rehearsals to teach the four participants to engage in social skills appropriate for each scenario. The results indicated a systematic change in overall assertiveness across the four participants. Moreover, the findings demonstrated generalization across untrained scenarios.

Subsequent behavior-analytic studies have targeted social behavior such as eye contact, prosody of speech, gestures, affect, joint attention, language and interactions, and play behavior. Moreover, studies have included analyses of the effectiveness of specific independent variables on such social behavior, such as discrete-trial teaching, in vivo and video modeling, incidental teaching, script-fading procedures, and self-management, among many others. The results of such research have provided important information that can be used to improve social competency.

Eye Contact

One of the most fundamental responses crucial to social behavior is eye contact with other people. Eye contact is a pivotal response that is an important component in conversational behavior, direction-following skills, and in responding to social cues (Jeffries et al., 2016). One of the earlier studies on eye contact was conducted by Foxx (1977) to increase the extent to which three children with autism displayed eye contact with an instructor. The authors used an overcorrection avoidance procedure to teach participants to engage in eye contact when provided the instruction, "Look at me." When the participant emitted eye contact within 5 seconds of the instruction, an edible reinforcer and praise were delivered. If the participant did not engage in eye contact within 5 seconds, then the overcorrection procedure was implemented, during which instructors would manually prompt the participant to engage in repeated head orientations. The authors found a systematic increase in the percentage of trials with eye contact. Essentially, participants increased eye-contact responses to avoid the aversive alternative. The authors did indicate that this strategy should be considered as a last-resort option when other positive-reinforcement procedures prove ineffective.

Eye contact also may be taught by using differential reinforcement. Differential reinforcement consists of the reinforcement of responses that adhere to a specified property, while withholding reinforcement for those responses that do not (Catania, 1998). To differentially reinforce eye contact, instructors would deliver reinforcers contingent upon the occurrence of appropriate eye contact, and withhold reinforcer delivery when the learner is looking away from the instructor. Several researchers have demonstrated the effectiveness of differential reinforcement in modifying eye-contact behavior. For example, Carbone et al. (2013) conducted a study in which differential reinforcement was used to teach eye contact to a 3-year-old boy with autism. Access to preferred stimuli was granted when the participant emitted appropriate mands in conjunction with eye contact to the instructor, whereas access was denied when mands were emitted without eye contact. This use of differential reinforcement produced an increase in the percentage of mands accompanied by eye contact.

Jeffries et al. (2016) conducted a similar study and found the use of differential reinforcement to be a more effective strategy to teach eye contact to three children with autism than the use of a tablet application. By withholding reinforcers until eye contact was established during manding opportunities, the authors observed a systematic increase across all three participants.

Similarly, shaping can be used to effectively modify eye-contact behavior. Shaping consists of the modification of behavior by differentially reinforcing successive approximations to a target response (Catania, 1998). With successive shifts in reinforcement contingencies, responding gradually transforms until it resembles the desired terminal response (Cooper et al., 2020). With eye contact as the targeted terminal response, the instructor may initially reinforce a learner's orientation to the general direction of the instructor. As this behavior is reliably emitted, the instructor may then decide to withhold reinforcer delivery for these responses, and only deliver for learner orientation to the instructor's face. Finally, as this form of responding is steadily emitted, only eye contact to the instructor's eyes may occasion reinforcer delivery. This procedure, of course, may involve many more detailed steps in the shaping process, as well as careful and systematic measures. For example, Fonger and Malott (2019) used a shaping procedure to teach three young children with autism to emit eye contact with an instructor for a duration of 3 seconds. The researchers presented and removed preferred stimuli within the participants' environment. Initially, reinforcers were delivered contingent upon the orientation of the participants' eyes to the instructor's body. Once this response occurred reliably, reinforcers were only delivered contingent upon eye orientation to the instructor's face. Subsequently, any occurrence of eye-to-eye contact occasioned reinforcer delivery, regardless of duration. Thereafter, the criterion for reinforcement shifted such that eye contact was required to occur for a duration of 1 second, then 2 seconds, and finally 3 seconds. The data demonstrated a functional relation between the shaping procedure and the occurrence of eye contact across the three participants. Moreover, the authors found that initial occurrence of eye contact and the use of prompting were not required to produce this behavior.

Prosody

Prosody consists of various characteristics of speech, including volume, intonation, and rhythm. People with developmental disabilities may display speech that is monotonic, lacks volume control, and presents inappropriate quality or stress patterns (Brown & Poulson, 2009; Paul et al., 2005). All of these aspects of speech play an important role in one's interactions with other people, and a deficit in any single one can impact the outcome of a given interaction. Fortunately, behavior-analytic strategies have proven effective in modifying prosodic responses.

Voice volume is one important characteristic of prosody that can clearly impact social behavior. Researchers have successfully modified voice volume by employing various behavior-analytic procedures. Schwartz and Hawkins (1970) used a delayed reinforcement procedure to increase the voice volume of a 12-year-old "maladjusted" girl. The participant was videotaped during her regularly occurring math and spelling classes at school. At the end of the school day, she reviewed this video with the experimenter. If her voice volume had satisfied a specified criterion for volume, the participant would earn poker chips to be exchanged for preferred items. The authors found that this delayed-reinforcement strategy caused an increase in her voice volume and generalized to an untrained class in school.

Fleece et al. (1981) used a shaping procedure to increase the voice volume of two 4-to-5-year-old children with developmental delays. The participants recited nursery rhymes with the experimenter in a sound-proof room. A voice-activated relay with adjustable sensitivity was used to activate a display of red and green lights contingent upon the occurrence of a predetermined voice volume. During intervention, the sensitivity of the voice-activated relay was modified to shape increases in volume. During baseline, participant voice volumes ranged from inaudible to below-normal levels. With the introduction of the shaping procedure, participant voice volume increased systematically to levels which would be considered "normal." Furthermore, the authors observed a maintenance of increased voice volume at one- and four-month follow-up sessions.

Another important component of prosody is intonation, or pitch. Intonation refers to the rise and fall of one's speech and has been systemically modified using behavior-analytic strategies. For example, Daou et al. (2014) used a discrete-trial teaching package to teach children with autism to emit the appropriate affective behavior, one component of which consisted of vocal intonation. When presented with scenarios from various affective categories, including absurdities, empathy, excitement, and gratitude, the participants were taught to emit appropriate verbal responses in conjunction with appropriate vocal intonation. Through the use of in vivo modeling, instructions, and reinforcement, the authors observed a systematic increase in the percentage of correctly emitted vocal intonation for all three participants. Responses also generalized across untrained scenarios presented by the experimenter.

Similarly, Charlop et al. (2010) used video modeling to modify intonation among three boys with autism as one of four components targeted in teaching socially expressive behavior. The participants were presented with video scenarios which occasioned forms of intonation such as loud/authoritative or exclamatory. During baseline, none of the participants displayed appropriate intonation. With the introduction of the video-modeling procedure, however, the percentage of correct intonation responses increased systematically across participants, and demonstrated generalization across untrained settings, stimuli, and people.

Although incidental teaching (Hart & Risley, 1975, 1980) and script-fading procedures (Krantz & McClannahan, 1993, 1998) are primarily used to teach language and conversational skills, these strategies also may embed the modeling of prosodic characteristics of speech. Reinforcement contingencies may be modified such that appropriate voice volume, intonation, and/or rhythm are required to occasion the delivery of reinforcers.

Gestural Behavior

Gestures are an important aspect of social and communicative behavior. They are hand movements that add meaning to speech and convey information that otherwise would not be present during speech alone (de Marchena et al., 2019; McNeill, 1992). For example, a person who is describing a toy might hold up two hands with palms facing each other, two feet apart. The conversation partner would understand that the toy was quite large without the speaker having to say it. Similarly, gestures can link the physical environment to spoken language, such as when a parent says, "it's almost time for dessert," while pointing to the empty dinner dishes on the table.

In addition to supporting and enhancing information conveyed by speech, greater comprehension is found when speech is accompanied by gestures than when speech is not accompanied by gestures (Hostetter, 2011). Gestures can signal emphasis, uncertainty, and convey meaning. A friend who says, "the movie is still on," while placing her index finger to her lips is clearly stating that one should stop talking. Gestures are also beneficial in situations in which the quality of spoken language is weakened and/or the listener is less verbally proficient. For example, if the environment is noisy, a listener has less verbal skills than the speaker, and/or speech is unclear, gestures can perhaps clarify spoken meaning.

Evidence suggests that gestures are important in the initial stages of the development of communication (Volterra et al., 2006). Gestures develop prior to the development of speech and are later used in conjunction with spoken language (Morford & Goldin-Meadow, 1992). Between the ages of nine and 13 months, gestures such as give, show me, and point emerge and begin to express communicative intent. For example, a baby might reach toward an object or point to a desired toy. Pointing is the most frequently used gesture and is later correlated with the onset of one's first word (Volterra et al., 2006).

McNeill (1992) described gestures as iconic, metaphorical, deictic, beat, and/or emblem. Iconic gestures are gestures that describe physical characteristics, such as size or shape or size. Metaphorical gestures illustrate information in a more abstract manner, such as moving a hand outward and upward to describe a skill. Deictic gestures are pointing gestures that identify a specific object in the environment. Beat gestures are rhythmic hand movements presented in close temporal synchrony with targeted words or phrases. Emblem gestures are gestures that are culturally defined. For example, one's palm facing away from speaker's body, pointer and thumb in a circle, with the other three fingers pointing up to indicate, "OK." Other culturally defined gestures include clapping hands to show approval, bringing hand to mouth to express hunger, or bringing the hand to the ear to represent a telephone. These gestures represent reliably consistent meaning and can be interpreted without contextual reference (Volterra et al., 2006).

Bavelas et al. (1992) included interactive gestures to the list of gestures presented by McNeill (1992). An interactive gesture makes reference to the conversational partner or the conversation. For example, a speaker might point to an individual when referencing something that he or she said earlier, or gesture along with specific word or phrase to signal importance.

Individuals with autism rarely use gestures as a means of communication (Ingersoll et al., 2007; Loveland et al., 1988). Nevertheless, if they do use gestures, they use iconic more than other gesture types (Medeiros & Winsler, 2014). This finding suggests that individuals with autism predominantly use gestures for concrete as opposed to abstract function. In addition to an insufficient use of co-speech gestures, individuals with autism speak at a rate slower that typically developing peers, are slower to respond than typically developing peers, and use more unusual vocalizations during pauses more often than typically developing peers (Parish-Morris et al., 2016).

Because individuals with autism are less likely to use gestures during social interactions, they have difficulty participating in social situations. Buffington et al. (1998) conducted a study with four children with autism who used little or no gestural communication prior to intervention. Following the introduction of a modeling, prompting, and reinforcement treatment package, all four children emitted verbal and gestural responses during social interaction opportunities. These findings suggest that by learning to use gestures in combination with vocal behavior, children with autism can begin to develop a repertoire needed to engage in social interactions. The authors assessed generalization in the presence of novel stimuli and novel settings. The results showed an increase in the use of gestural communication during probe assessments. Social validity data suggested that the children's communication was rated as more expressive during treatment than baseline, suggesting that teaching children with autism to use gestures leads to improvements in the quality of their social communication.

Similarly, Duker and Van Lent (1991) stated that individuals with developmental disabilities may engage in a low variation in gestures. Five individuals with severe to profound mental retardation between the ages of 13 and 30 participated in the study. During baseline, each gesture emitted was reinforced with access to the requested object. Gestures were ranked according to frequency of use. During treatment, access was withheld from 2 to 3 of the high-frequency gestures. Low-frequency gestures were differentially reinforced. Results showed an increase in previously used gesture requests. By increasing the variation in gestures used, the ability to engage in meaningful social communication increases.

In an attempt to increase gestures in five young boys with autism, ages 3–4, Ingersoll et al. (2007) used a reciprocal imitation training strategy to increase spontaneous use of descriptive gestures during play. During free play during baseline, the experimenter modeled a descriptive gesture accompanied by a corresponding verbal statement. For example, while placing a doll in a bed, the experimenter placed her finger over her lips and said, "Sh, baby sleeping." During intervention, the experimenter followed the child's lead, imitated child actions and vocalizations, and commented on the actions that the child performed. In addition, the experimenter modeled gestures and verbal statements corresponding to the child's actions. Rather than targeting specific gestures to criterion, multiple gestures were taught that were relevant to the play actions initiated by the child. If the child imitated the gesture, praise and access to play materials were provided. If the child did not imitate the gesture, manual prompts were provided and praise delivered. The authors found that all children increased their imitation of descriptive gestures in the training setting and in an untrained setting.

Overall, co-speech gestures assist the speaker in conveying meaning. People with developmental disabilities may display considerable impairment in their spontaneous use of meaningful gestures. Across the studies reviewed, imitation training, modeling, contingent reinforcement, and prompting are promising procedures to address these deficiencies.

Affective Behavior

Affective behavior consists of various categories of responding such as facial, verbal, gestural, and postural responses (Gena et al., 1996). From as early as infancy, affective behavior serves as an important social behavior and form of communication with others. For example, the reciprocation of smiles with parents (Dawson et al., 1990) and demonstration of empathic responding to others' distress (McDonald & Messinger, 2012) are notable differences between children with developmental delays and their typically developing peers. The display of appropriate affect, however, has a large impact on the development of relationships with others across a person's lifespan.

Several studies have demonstrated that components of affective behavior can be successfully modified using operant conditioning procedures. For example, DeQuinzio et al. (2007) used a treatment package consisting of modeling, manual prompts, reinforcement, and error correction to teach three children with autism to imitate various facial models. Facial models included responses such as smiling, frowning, and a surprised face. Prior to teaching, the participants did display some imitative responding, although performance was variable and inconsistent. The introduction of the treatment package, however, produced a systematic increase in the imitation of facial models, and responding generalized across an untrained angry facial model.

Gena et al. (1996) used modeling, verbal prompting, and reinforcement to teach four youths with autism to emit appropriate affective behavior across various categories. The authors taught the participants to emit contextually appropriate verbal and facial responses to scenarios concerning sympathy, appreciation, dislike, preferred items, and absurdities. For example, the experimenter may have stated, "I have a headache," to which an appropriate affective response would include a serious facial expression and a statement of sympathy, such as, "I'm sorry to hear that." The data demonstrated that the intervention produced a systematic change in affective behavior across the participants for three or four of the targeted categories. Moreover, responding generalized across untrained scenarios within a given affective category.

In a study by Schrandt et al. (2009), a treatment package consisting of pretend play with manual prompts, auditory prompts, behavior rehearsals, and reinforcement was used to teach four children with autism to emit vocal and motor responses of empathy in the presence of a verbal stimulus. During a given session, the experimenter presented a vignette by using a doll or puppet. For example, the experimenter may have had the doll bump its leg on a table and exclaim, "Ouch!" Empathic responding was taught across three affective categories including sadness/pain, happiness/excitement, and frustration. The experimenters used manual prompts to teach the participants to emit empathic motor responses, such as patting the doll's arm. An auditory prompt, consisting of a recorded script on a Language Master © card, was used to teach participants to emit empathic verbal responses, such as, "Are you okay?" During the baseline condition, participants emitted few or none of the appropriate empathic responses. With the introduction of the treatment package, however, empathic responding increased systematically across the affective categories for all participants. Moreover, responding generalized for two of the participants from the pretend-play stimuli to untrained people in an untrained setting.

Gena et al. (2005) used in vivo modeling, video modeling, verbal prompts, and gestural prompts to teach three children with autism to emit appropriate affective behavior during pretend play. Affective categories included sympathy, appreciation, and disapproval. Affective behavior was scored as correct if the participant emitted verbal responses, vocal intonation, and facial expressions that were appropriate for the given category. The authors observed a systematic increase in the percentage of appropriate affective responding emitted by the three participants with the introduction of the treatment package. Furthermore, responding generalized to untrained stimuli and people.

Similarly, Charlop et al. (2010) taught three children with autism to emit affective behavior across scenarios during a play session, such as denying access to tickling, being shown a preferred toy, making a basket, and being shown a large toy. For each scenario, the researchers used video modeling to teach the children to emit the appropriate verbal statement, intonation, gesture, and facial expression. For example, when shown a preferred toy, the children may have been taught to say, "That's cool!" while using an exclamatory voice with positive valence, raising their eyebrows at least ¼" from resting position, and pointing with their index finger or full hand toward the object. The results demonstrated that the video-modeling procedure led to a systematic increase in the percentage of correctly emitted affective components. Moreover, results generalized across people, settings, and stimuli.

A study by Daou et al. (2014) used a discrete-trial teaching package to teach children with autism to emit the appropriate verbal responses, vocal intonation, and facial expressions when presented with scenarios from various affective categories including absurdities, empathy, excitement, and gratitude or appreciation. Through the use of in vivo modeling, instructions, verbal prompts, script fading, and reinforcement, the authors observed a systematic increase in the percentage of correctly emitted affective components for all three participants. Responses also generalized across untrained scenarios presented by the experimenter.

Finally, Argott et al. (2017) taught four children with autism to display empathetic responding across the affective categories of joy, frustration, and pain. The authors used a prompting sequence that progressed from video modeling, to in vivo modeling, to manual prompts, and then to verbal prompts. During sessions, the instructor presented an affective stimulus from the given category. For example, within the category of joy, the instructor might have held up a puzzle and exclaimed, "I finished my puzzle!" A correct empathetic response consisted of a statement of empathy emitted with appropriate intonation, an appropriate gesture, and a corresponding facial expression. In this example, a correct response included a statement such as, "That's great!" emitted in a high pitch while also smiling and offering a high five to the instructor. During baseline, the participants displayed none, or inconsistent levels, of the targeted empathetic responses. Correct empathetic responding increased systematically across participants for the three affective categories when treatment was introduced. In addition, responding generalized across untrained people and across untrained affective stimuli within each of the categories.

Joint Attention

Joint attention is a significant developmental milestone and an underlying component in language acquisition and social skills development. Joint attention refers to the mutual attention between two people toward an object in the environment (Bakeman & Adamson, 1984). It is a skill that typically develops during infancy and is a pivotal response that can lead to the acquisition of other important behavior (Jones & Carr, 2004). A deficit in joint attention is one of the core criteria in the diagnosis of autism (American Psychiatric Association, 2013). Given the impact of joint attention on various other social skills, intervention aims at teaching this skill as early as possible and has been successful through the use of behavior-analytic methods.

Whalen and Schreibman (2003) used shaping and prompt-fading procedures to teach five children with autism to initiate and to respond to bids for joint attention. To teach responding to joint-attention bids, the experimenters conducted six levels of training. During all levels, the participant was playing with a toy, but the response requirement successively shifted. At the first level, the experimenter manually prompted one of the participant's hands onto a different toy. If the participant looked at or played with this different toy, then the response was scored as correct. During the second level of training, the experimenter tapped on a different toy, and responding to joint attention was scored as correct if the participant looked at or engaged with that toy. During the third level, the experimenter showed a toy to the participant, and responding was correct if the participant looked at or engaged with the toy being shown. At the fourth level of training, the participant was now required to engage in eye contact with the experimenter. During the fifth level, the participant was required to first engage in eye contact with the experimenter and to orient their head toward an object at which the experimenter pointed. Finally, at the sixth level of training, the participant was required to orient to an object toward which the experimenter shifted their gaze, without the presentation of a pointing response. To teach initiations for joint attention, Whalen and Schreibman (2003) using a prompt-fading procedure while the participant was playing with a toy. Initially, the experimenters provided manual prompts to teach the participant to hold the toy with which they were playing and to orient their head until eye contact was established. The experimenters delivered the verbal prompt, "Show" in conjunction with gestural prompts to their eyes to teach a gaze shift between the toy and the experimenter. Experimenters faded prompts from full physical with verbal, to partial physical with verbal, to gestural with verbal, to verbal prompts only, and finally by removing all prompts. The results demonstrated that their shaping and prompt-fading procedures systematically increased the percentage of correct responses to joint attention for all five participants and increased the percentage of correct initiations for joint attention for four of the five participants.

Taylor and Hoch (2008) used a least-to-most prompting procedure to teach three children with autism to initiate and respond to bids for joint attention. The researchers targeted three components of joint attention including a shift in eye gaze between an object in the environment and an adult's eyes, a vocal response to a bid for joint attention, and a vocal initiation as a bid for joint attention. Sessions were conducted in a room containing novel or unusually placed toys. To teach responding to bids for joint attention, the instructor presented a bid for joint attention, such as pointing to a toy and exclaiming, "Wow!" Initially, if the participant did not orient to the item, the instructor provided a gestural prompt from the participant's orientation to the toy. If the participant still did not gaze with the delivery of this prompt, then the instructor used physical prompts to turn the participant's head toward the toy. The instructor then modeled a comment for the participant to emit about the toy. Gestural and verbal prompts were then used to teach the participant to shift their orientation from the toy to the instructor. A similar prompting procedure in conjunction with verbal prompts was used to teach the participants to initiate bids for joint attention. The results demonstrated that their least-to-most prompting procedure was effective in teaching the participants to engage in the three targeted components of joint attention.

Kryzak et al. (2013) taught three children with autism to respond to bids for joint attention by using the participants' intense interests in specific topics in conjunction with a most-to-least verbal-prompt-fading procedure. While the participants were engaged with their object of interest, the experimenter gazed and pointed at the object while emitting an exclamatory statement (e.g., "That's cool!"). The experimenter used verbal prompts to teach the participant to shift their eye gaze to the object by stating the participant's name or the direction, "Look." After a specified criterion of responding was achieved, the verbal prompt was faded to the initial sound of either the participant's name of the direction to look. Subsequently, a constant 4-second prompt delay was used to teach responding. Experimenters reinforced correct responses to joint attention with verbal praise statements. The findings demonstrated a systematic relation between the prompt-fading procedure and the percentage of correct responses to bids for joint attention. Moreover, data suggested generalization across untrained stimuli. Kryzak et al. (2013) suggested that the use of the participants' intense interests with their prompt-fading procedure may be a successful starting point for teaching joint-attention skills.

MacDuff et al. (2007) used a script-fading procedure and manual prompts to teach three young children to emit bids for joint attention. The experimenter walked the participant through a hallway containing various different pictures and toys. Voice-over-recording devices with the recorded script, "See" were placed upon the stimuli. Instructors used manual prompts to teach the participants to press the recorders and to orient to the experimenter while emitting the scripted statement. Correct responding was reinforced with a token motivational system and edible snacks. The recorded script and voice-over-recording device were faded systematically as the participants reliably emitted independent bids for joint attention. The data demonstrated a systematic increase in number of correct bids for joint attention emitted across the three participants. In addition, as the scripts were faded, participants began to emit unscripted initiations, such as object labeling. The findings also demonstrated generalization across untrained settings and stimuli.

Language and Interactions

There is an expansive breadth research on behavioral interventions that have demonstrated effective changes in language and interaction skills. The review that follows consists of some of the fundamental studies in this area in the field of applied behavior analysis.

One of the earliest studies on language and behavior-analytic methodologies was that conducted by Rheingold et al. (1959). The experimenters analyzed the effects of reinforcement on the vocal behavior of 3-month-old infants. Prior to intervention, the experimenter displayed a neutral affect while orienting to the infant over the crib. During intervention, the experimenter delivered social praise in the form of smiling and tickles to the infant when the infant had vocalized. The experimenters then withdrew intervention and returned to a baseline condition. They found that the infants vocalized at a higher rate during the experimental condition than in the baseline conditions. Nevertheless, it was possible that the delivery of social praise served to elicit, rather than evoke, the observed vocal behavior.

Todd and Palmer (1968) compared the effects of auditory social reinforcers (e.g., a human voice) with the adult present versus the adult being absent from the environment on the frequency of infant babbling behavior. Although the authors observed an increase in babbling under both conditions, they noted a markedly higher frequency of babbling by infants for whom an adult was present when delivering auditory reinforcers.

Other research on language and reinforcement by Ramey and Ourth (1971) found that the rate of infant vocalization behavior increased only with the presentation of immediate reinforcer delivery, rather than reinforcer delays of 3 or 6 seconds. A later study by Reeve et al. (1992) found a systematic relation between infant vocalizations and delayed social reinforcement. These studies helped to establish that language, as early as in the infant stages of life, can be modified using operant conditioning procedures.

Incidental Teaching Evidence-based research continued to demonstrate the operant nature of language and effectiveness of behavior-analytic methods on language acquisition. Incidental teaching is the process by which language is acquired in a naturalistic setting. A child initiates a verbal or nonverbal interaction with an adult that indicates a want or need for a given stimulus. For example, a child may reach for an item that is too high, or may emit a request for a desired item, activity, or information. The child's want or need is then used as an opportunity to teach language. The adult interrupts access to the desired stimulus and waits for the child to emit appropriate language, or provides a verbal prompt to emit appropriate language in the given context. Access to the desired stimulus is then granted contingent upon the occurrence of the targeted language (Hart & Risley, 1975). Hart and Risley (1975) demonstrated the effectiveness of incidental teaching in their seminal study that increased the use of compound sentences by preschool age children to their teachers.

McGee et al. (1985) conducted a study that compared the effectiveness of traditional and incidental teaching procedures to teach the use of prepositions by three children with autism. During the traditional procedure, an instructor used items at a desk to demonstrate the targeted preposition and asked, "Where is the (item)?" The instructor used verbal prompts to teach correct preposition responses. During the incidental teaching procedure, items used to teach prepositions were placed upon shelves in a manner to demonstrate targeted prepositions. When the participant emitted a request for a given item on the shelf, the instructor presented the question, "Where is the (item)?" Access to the requested item was granted contingent upon responses that contained the correct preposition (e.g., "The car is under the box"). The authors found that the incidental-teaching procedure produced a greater extent of generalization across settings and stimuli, and promoted a greater likelihood of spontaneous speech.

McGee et al. (1992) also used incidental teaching to promote reciprocal peer interactions to three children with autism. In this study, the authors trained three typically developing children to serve as peer tutors for incidental teaching to the participants in a socially integrated classroom. The peer tutor was seated with a given participant in the classroom as well as a bucket containing items identified as highly preferred by the participant. The child peer tutor was taught to wait for the participant to initiate to the bucket, to provide a verbal prompt for language (e.g., "Say duck"), to provide access to the toy contingent on the occurrence of the language, and to deliver behavior-specific praise for the language response. Data were collected on the percentage of 10-s intervals within a 5-min observation period that each participant emitted a reciprocal peer interaction. During the baseline condition, the mean percentage of intervals during which the participants emitted the targeted interactions ranged from 0% to 7%. With the introduction of the incidental-teaching procedure, data increased systematically across the three participants, with the percentage of intervals during which reciprocal peer interactions occurred ranging from 13% to 35%.

Similarly, Farmer-Dougan (1994) used incidental teaching delivered by peers to increase the requesting behavior of adults with developmental disabilities. The experimenter used incidental teaching during the typically occurring lunch-making routine in the participants' group home. When a participant attempted to gain access to one of the necessary lunch-making items, the item was placed out of reach, and the participant was prompted to emit a request for the item. Participants were granted access to the items contingent upon the appropriate request. The results demonstrated a functional relation between the number of appropriate requests and the use of the incidental-teaching procedure.

Video Modeling Researchers have also used video-modeling procedures to teach language and social interaction skills. Video modeling is a strategy by which desirable responses are displayed through video presentation. The participant views the modeled behavior and it is anticipated that observational learning and an imitative repertoire contribute to the successful performance of the desired behavior (Bellini & Akullian, 2007). Video modeling can include peers, family members, and adults, and the medium of this technique allows for it to be practiced in virtually any context.

Charlop and Milstein (1989) used a video-modeling procedure to teach conversational skills to three children with autism. Each participant viewed a videotaped conversation three times. The conversation consisted of a series of questions and statements between two familiar adults about a given topic, such as school, toys, or sports. Subsequently, the participant was presented with the opportunity to engage in the same conversation with an instructor. Correct conversational targets included the three lines presented in the video and were reinforced with praise and edibles. If the participant did not emit the three targeted lines from the video, then the video was again presented for a single viewing, and the conversation was again attempted. This sequence repeated until the participant emitted the three targeted lines for a specified topic. The findings of the study indicated a functional relation between the video-modeling procedure and the display of the targeted conversational behavior. Moreover, performance demonstrated generalization across untrained topics, conversation recipients, and settings.

In a study by Maione and Mirenda (2006), the authors used a video-modeling procedure to teach a young boy with autism to emit peer interactions during three play activities. Three exemplars of 1-minute vignettes were recorded for each of the play activities, and depicted two adults talking to one another while playing. The participant viewed the three vignettes for a given activity 30–60 minutes prior to a play session with a peer. The authors analyzed the effect of their video-modeling procedure on the total number of verbalizations emitted by the participant, on the content of his verbalizations, including whether the verbalizations matched or varied from the model, and on the frequency of initiations and responses. During baseline, there was considerable variability in the verbalizations emitted by the participant. With the introduction of the video-modeling procedure, the authors observed an increase in social language across two of the three activities. For the third activity, the authors introduced feedback on the participant's recorded sessions as well as verbal prompts to increase the targeted language responses.

Finally, Scattone (2008) used Social Stories ™ in conjunction with video modeling to modify the conversational skills of a boy with Asperger's Disorder. In addition to other dependent measures such as eye contact and smiling, the authors analyzed the effectiveness of their video-modeling procedure on the percentage of 10-second intervals during which the participant emitted initiations to a conversation partner in a 5-minute session. The video-modeling intervention consisted of three different narrated Social Stories ™ that targeted eye contact, smiling, and initiations, as well as the modeling of an appropriate conversation by two adults. The authors found that the video-modeling intervention effectively increased the percentage of 10-second intervals with initiations from about 0.8% during the baseline condition to about 33% after intervention. Moreover, the authors observed generalized behavior change across untrained peers in school.

Scripts and Script Fading Script fading is another behavior-analytic procedure that can be used to teach language and interaction skills through the process of stimulus fading. A script is a written or recorded word, phrase, or sentence that serves as a model to teach conversation. The core dependent measures when using this procedure include both scripted and unscripted interactions. Scripted interactions are defined as verbal productions that match the original scripts provided in teaching, whereas unscripted interactions are those that differ from the original scripts by more than verb tense, conjunctions, articles, prepositions, or pronouns (Krantz & McClannahan, 1993). As the participant reliably emits the scripted interactions, the scripts are systematically faded, and the number of unscripted interactions should increase correspondingly as scripted interactions decrease (McClannahan & Krantz, 2005). This procedure has proven effective in many studies aimed at teaching language and interaction skills.

In their preliminary study on the script-fading procedure, Krantz and McClannahan (1993) used written scripts to teach four children with autism to emit peer initiations during art activities. The authors provided each participant with a sheet of paper that contained a cue to talk and a list of ten different scripts pertaining to the stimuli present in the environment. The authors faded scripts by deleting words one at a time from the end of each script, until all scripts were blank. At the final fading step, only the blank sheet of paper with the cue to talk was present. The number of unscripted initiations emitted by the participants increased systematically as scripts were faded out. Moreover, responding generalized across an untrained setting and stimuli.

Krantz and McClannahan (1998) embedded Language Master© cards into activity schedules to teach three children with autism to emit initiations to adults. The authors attached written scripts, such as “Look” and “Watch me,” to photographs of objects in the activity schedules. The children were taught to obtain the object and to initiate a response to an adult by emitting the script that was attached to the pertinent photograph. Scripts were faded out by removing words one at a time from the end of each script. The authors observed a systematic increase in the number of unscripted social initiations as the scripts were faded. In addition, the authors indicated the behavior change generalized across untrained activities and in the presence of an untrained conversation recipient.

Similarly, Betz et al. (2008) also used script-fading procedures within activity schedules to teach social interactions among children with autism. The researchers presented an activity schedule to be shared between two children. The activity schedule consisted of various games for the children to play together. On each page of the schedule, a textual script was superimposed upon the game to be played. Scripts consisted of statements that would initiate the game-playing behavior, such as “Let’s play ____.” As scripts were faded, the authors observed a systematic increase in the number of unscripted social interactions emitted by the children.

Sarokoff et al. (2001) used script fading with stimuli that naturally contained textual print to teach two children with autism to engage in conversation with peers. For example, the authors used the script, “Gummi Savers© are my favorite” with a package of Gummi Savers©. The text that naturally appeared on the package was incorporated into the script. As scripts were systematically faded, the text that naturally appeared on the package remained at the final fading step. As a result, the package acquired discriminative control for engaging in conversation. The authors observed a systematic increase in the number of unscripted initiations to peers with the introduction of their script-fading procedure.

Brown et al. (2008) used a similar stimulus-fading strategy to transfer the discriminative control of social interactions from scripts to naturally occurring stimuli in the environment. The authors used a textual script-fading procedure to increase the number of social interactions among three children with autism. The authors attached textual scripts directly onto stimuli in the participants’ environment. Stimuli included items commonly found in a convenience store, such as candy bars, in a sporting-goods store, such as a football, and in a video store, such as videotapes. These stimuli were presented in a mock store display, as they might typically appear in the community. During script fading, scripts were deleted one word at a time, and were removed progressively from the training stimuli. The authors also changed the location of the scripts on the stimuli with each fading step. As scripts were removed, the environmental stimuli evoked the social interactions. This script-fading procedure produced a systematic increase in unscripted interactions.

Moreover, the effects of the script-fading procedure generalized to untrained stimuli.

Finally, Wichnick-Gillis et al. (2019) used a script-fading package to teach three adolescents with autism to engage in conversation with one another during leisure activities. The activities selected including computer games, model building, and a lunch period. These activities were deemed as appropriate situations during which conversation might naturally occur for their typically developing peers. The authors superimposed five different textual scripts onto various stimuli such as a laptop computer, Lego© model building sets, and items used during lunch (e.g., utensils, cups). Scripts were pertinent to the given activity, and included statements such as, "Check out what I'm building," or "I love this game." The authors observed a systematic increase in the number of unscripted initiations emitted across participants as the scripts were faded. Moreover, generalization was demonstrated across all three participants while engaging in the targeted activities with their siblings.

Play Behavior

Play can enhance mutual communication with others. The American Academy of Pediatrics (2013) acknowledged the importance of play in establishing relationships with others. Play provides opportunity for children to attend to directions, resolve disputes with others, behave appropriately in the presence of others, focus on activities without consistent supervision, and collaborate (Yogman et al., 2018).

There are four types of play: object play, physical play, outdoor play, and social or pretend play. Object play occurs when a child explores an object. An infant may place an object in his mouth. An older child may use a stick as a microphone. Physical play may begin with wheels-of-the-bus, and move to playing catch. Outdoor play provides opportunity for physical exercise. Social or pretend play encourages cooperation, turn taking, and negotiations of guidelines. Imaginary play, dressing up, and make believe are included as social play (Yogman et al., 2018).

Walsh et al. (2006) reviewed "the quality of learning" in 70 classes for children ages 4–5, comparing traditional classroom curriculum with play-based enhanced curriculum. Thirty-eight of the classrooms experienced traditional curriculum that involved structured play, writing, painting, listening to stories, watching television, and song. The curriculum was subject oriented, and emphasized reading, writing, and arithmetic. Thirty-two of the classrooms experienced play-based enriched activities that allowed children the opportunity to choose from a range of play stations such as the sand corner, water station, construction area, and house corner. Activities were structured by the teacher and of shorter duration. Reading activities were conducted using big books, math using puppets and games, and writing focused on creative content as opposed to writing technique. Overall, the authors found that the enriched play-based curriculum led to more opportunities for making choices and engaging in more challenging activities, and an increase in motivation, independence, and social interaction.

Stahmer et al. (2003) identified numerous behavioral approaches used to promote play with children with autism. The following is a sampling of the research-based techniques reviewed, and is by no means an exhaustive review.

Discrete-Trial Teaching Discrete-trial teaching is a highly structured behavioral strategy that focuses on the presentation of clear discriminative stimuli by the instructor. In play-based discrete-trial teaching, play materials are selected by the instructor, and a direction is presented. Reinforcement is delivered contingent upon the production of a correct response. Incorrect responses are followed by specified consequences. Rate of responding is controlled by the given opportunity to emit the response (Cooper et al., 2020).

Discrete-trial instruction is often presented with repetitive, one-step actions (e.g., rolling a ball; pushing a car). In two experiments conducted by Nuzzolo-Gomez et al. (2002), discrete-trial teaching was used to teach play behavior. In the first experiment, a three-year-old boy with autism was presented with a book and given the instruction to look at the book. If the child oriented toward the book, verbal praise and an edible reinforcer were provided. If the child did not orient toward the book, the instructor modeled the desired behavior and/or provided manual guidance. The results showed a functional relationship between the discrete-trial teaching procedure and an increase in orientation toward a book.

In the second experiment by Nuzzolo-Gomez et al. (2002), discrete-trial teaching was used to teach three children with autism to play with toys. Toys were presented and the instruction to play was provided. Correct play responses were following by reinforcer delivery. Incorrect responses were following by modeling and/or physical prompts. The results of the second experiment showed an increase in appropriate toy-play behavior and a decrease in dysfunctional, stereotypical hand movements.

Similarly, when a more complex play sequence is targeted, the discrete-trial procedure can focus on smaller component parts of the play behavior. For example, feeding a baby might involve holding a baby, getting a bottle, placing the bottle in the baby's mouth, and saying "Drink milk." Discrete-trial teaching can target the different components of the sequence in succession using verbal instruction, modeling, and/or manual guidance.

Despite the success of discrete-trial teaching, it does present several limitations. Teachings in highly structured environments: (a) do not necessarily generalize to the natural environment (Lovaas, 1977 as cited in Ingersoll & Schreibman, 2006), (b) are often dependent upon the use of continued reinforcement to maintain newly acquired play responses, and (c) are taught as isolated skills, rather than as part of a social context (Schreibman et al., 1991).

Reciprocal Imitation Training Reciprocal imitation training is another strategy used to promote play. In a study conducted by Ingersoll and Schreibman (2006), five children with autism participated. Prior to intervention, all of the participants displayed deficits in spontaneous imitation of object use by others during play. During intervention, the instructor (a) modeled actions with familiar and novel toys, (b) imitated child vocalization and actions with toys, and (c) commented on child actions. The authors found that imitation training resulted in imitative pretend play. Play responses were also found to generalized across stimuli, locations, and adults.

Stereotyped Behavior to Increase Play It is not uncommon for children with autism to engage in perseverative behavior. In a study conducted by Baker et al. (1998), three children with autism were selected to participate due to their engagement in perseverative behavior with particular items. For example, one child perseverated on Disney© characters. As a result, Disney© characters were incorporated into a playground game. Another child perseverated on maps. As a result, a game of tag was played on a giant outline of a map of the United States. A third child perseverated on movies and movie characters. Laminated photographs of movie characters were placed around a play area and used as "bases" in a game of tag. The authors found that the inclusion of perseverative themes into play activities resulted in an increase in social interactions during the targeted activities and generalized across novel activities.

Similarly, in a study conducted by Koegel, Fredeen, Kim, Danial, Rubinstein, and Koegel et al. (2012), social clubs were based on the perseverative interests of young adolescents with autism. For one participant, the perseverative interest in movies was transformed into a Movie Trivia Club. For the second participant, the perseverative interest in comic books and cartooning was turned into a Comic Book and Gaming Club. For the third participant, the perseverative interest in card games was turned into a Card Game Club. Prior to baseline, all participants remained socially isolated. Following the introduction of themed social clubs, social initiations and appropriate engagement with peers increased.

Pivotal Response Training Pivotal response training (PRT) is a behavioral strategy that has been used to increase motivation to engage in play behavior. In PRT, (a) the child selects materials from a set presented by the instructor (e.g., blocks), (b) discriminative stimuli are presented by the instructor (e.g., instructor gives block to instructor and says, "What do you want to build?"), (c) maintenance tasks are interspersed among tasks targeted for acquisition, (d) modeling is used to encourage turn taking and appropriate pace of interaction (e.g., instructor begins to stack blocks), (e) natural consequences are used to reinforce correct responses (e.g., instructor gives the child the remaining blocks in an effort to reinforce correct responding), and (f) reinforcers are delivered contingent upon attempts to respond (Stahmer, 1999).

Stahmer (1995) conducted a PRT study with seven children with autism to increase play behavior. The children were presented with toys identified as desirable (e.g., the child reached for or oriented toward the toy). If the child did not engage in play, the experimenter played with the toys and modeled symbolic actions. Simplified play responses with the toys were also interspersed and modeled to increase the likelihood of variation in responding. The author found PRT effective in increasing positive responding during play. Moreover, the findings generalized across novel toys and sustained over time.
